The Niigata-ken Chuetsu, Japan, earthquake (M_w=6.6) occurred in the Niigata Prefecture on October 23, 2004 and induced a tremendous amount of landslides in the surrounding mountainous areas. A detailed landslide inventory for the earthquake was generated by the Geospatial Information Authority of Japan (GSI 2004), and these data allow for a detailed investigation of the landslide distribution with respect to geologic, topographic, and ground shaking conditions. Additionally, the data allow for the testing of regional-scale approaches for earthquake-induced landslide prediction, which are based on the rigid sliding block approach and form the basis for seismic landslide hazard maps. Evaluations of regional-scale approaches for landslide prediction have focused predominantly on the 1994 Northridge, California (M_w=6.7) earthquake (e.g., Jibson et al. 2000), but the Niigata-ken Chuetsu earthquake provides an opportunity to test an additional landslide inventory to gain further insight into the accuracy of these procedures.

This paper describes the geologic, topographic, and ground shaking conditions across the area affected by the Niigata-ken Chuetsu earthquake. The distribution of landslides with respect to these conditions is presented and compared with the distribution of landslides from the 1994 Northridge earthquake. Using the available information, comparisons are made between regional-scale predictions of the landslides and the observed landslides.

2. NIIGATA-KEN CHUETSU EARTHQUAKE

2.1 Study Area and Landslides

The 2004 Niigata-ken Chuetsu earthquake occurred within the Niigata prefecture, approximately 200 km northwest of Tokyo. Over 5,000 landslides occurred in the Yamakoshi area (GSI 2004) situated northeast of the epicenter and above the fault rupture plane (Figure 1a). The landslide failure mechanisms include shallow translational soil failure, deep-seated failure, large rock block slides, slump-flow complexes and rapid debris flows (Kieffer et al. 2006). Heavy rainfall from Typhoon Tokage contributed significantly to the large number of landslides, with over 100 mm of rain falling in the area just a few days before the earthquake. Moreover, 10 typhoons struck Japan in the months before the earthquake. As a result, large numbers of debris flows were triggered by the earthquake, a landslide type which had previously occurred much less often than other landslide types in previous earthquakes. Slump-flow complexes, which had very long runout distances and occurred on moderately steep slopes, were probably caused by the high moisture conditions (Kieffer et al. 2006).

The GSI developed disaster condition maps which

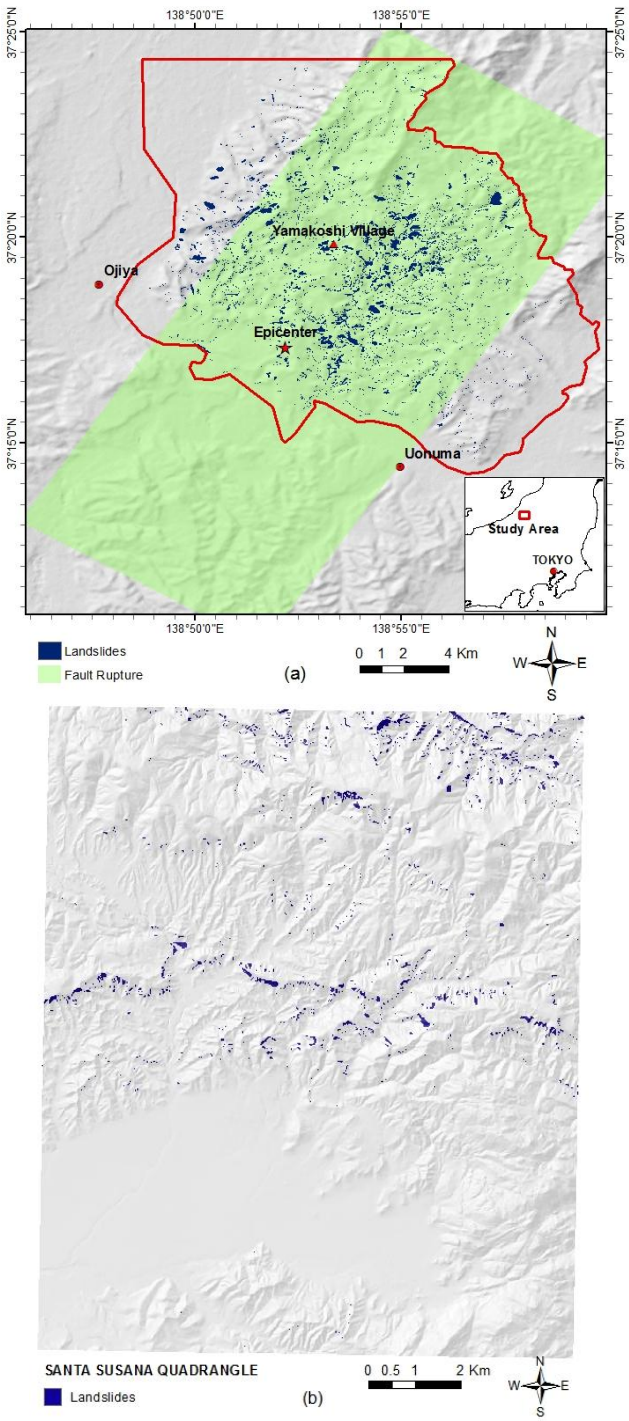

Figure 1 Landslide Distributions in a) Niigata-ken Chuetsu Earthquake b) Santa Susana Quadrangle for the Northridge Earthquake (Dreyfus 2011)

identified landslides for the Niigata-ken Chuetsu earthquake (GSI 2004). Figure 1a shows the identified landslides within the Yamakoshi area along with the surface projection of the fault rupture from the earthquake, as defined by Mori and Somerville (2006). The area around Yamakoshi village (~217 km^2) is selected for study because it experienced the largest concentration of landslides. The western and southern boundaries of the study area represent the Shinano River; the eastern boundary is an administrative boundary beyond which no landslide was recorded on the map; and the northern boundary is the upper boundary of the GSI landslide map. For comparison, the landslides induced by the Northridge earthquake in the Santa Susana Quadrangle (~159 km^2 study area) are shown in Figure 1b.

All landslides within the Yamakoshi study area were manually digitized into a vector format. The vector format maintains each individual landslide as a polygon, which is useful in counting the total number of landslides. The vector format was converted to a raster format at a 10-m grid spacing for use in comparisons with landslide predictions. Therefore, a landslide may consist of several to hundreds of 10m x 10m grid cells, depending on the size of the landslide. Furthermore, source areas, instead of entire landslide areas, were used in the following numerical analyses. Jibson et al. (2000) defined landslide source areas as those landslide areas having elevations above the median elevation for each landslide, so the upper half of each landslide was considered as a source area.

The topography and slope angles across the Yamakoshi study region are investigated using a 30-m resolution digital elevation model (DEM) from ASTER Global Elevation Model (GDEM). The Ministry of Economy, Trade, and Industry (METI) of Japan and the United States National Aeronautics and Space Administration (NASA) co-developed the ASTER GDEM product from data collected by the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), which is a spaceborne earth observing optical instrument (METI and NASA 2011). Because the resolution of the DEM is relatively coarse for the purpose of this study, the 30-m DEM was resampled to 10-m DEM by applying the spline interpolation algorithm available in ArcGIS© 10.0 developed by the Environmental Systems Research Institute (ESRI).

Most of the Yamakoshi study area is rolling hills, except for the flat northwestern corner which is the alluvial plain associated with the Shinano River. The maximum elevation difference between the alluvial plain and the hilltops in the study area is 743m (from 10m to 753m). A slope angle map was derived from the DEM using the Slope function in ArcGIS©. The statistical distribution of slope angles in the Yamakoshi study area is plotted in Figure 2. Slopes in the study area are moderately steep with about

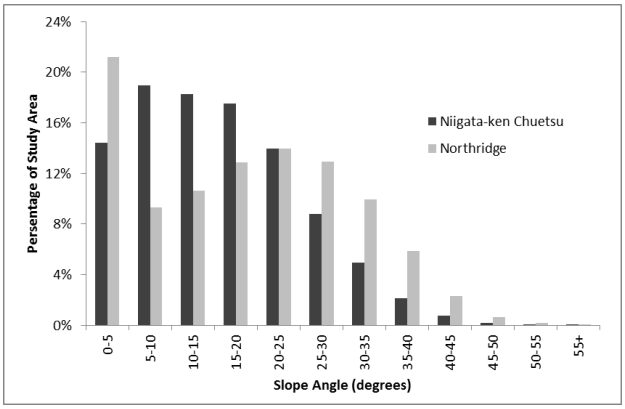

Figure 2 Distributions of Slope Angles by Area Percentage

33% of the area flatter than 10° and 59% with slope angles between 10 and 30°. Only 8% of the area has slope angles greater than 30°. For comparison, the slope angle distribution for the Santa Susana Quadrangle is also shown in Figure 2. The Santa Susana Quadrangle has relatively steeper terrain, with 19% of the quadrangle steeper than 30°.

2.2 Geological Conditions

Bedrock in the study area consists of Middle Miocene to Early Pleistocene sedimentary units. These units range from weak shale and mudstone, to slightly stronger sandstones and conglomerates, to strong volcanics (Kieffer et al. 2006). The bedrock is overlain in places by a layer of colluvium, while Pleistocene to Holocene alluvium are found within river channels and valleys (Kieffer et al. 2006).

A digital geologic map from the Geological Survey of Japan (Takeuchi et al. 2004) was used to define the geology across the study area. The map includes 33 geologic units across the Yamakoshi study area. Quaternary deposits consist of loosely consolidated debris, gravel, sand and silt, having relatively low shear strength properties. Tertiary rock units are composed of cemented shale, mudstone, sandstone, conglomerate and various volcanics with relatively high shear strength properties. The geologic units are combined into five main groups based on geologic ages and compositions (Table 1). The five geologic groups are: Alluvium (22% of the study area), Pleistocene Landslide Deposits (2.5%), Shale/Mudstone (45.5%), Sandstone/Conglomerate (19%) and Volcanics (11%). All Quaternary deposits except Pleistocene Landslide deposits are classified as Alluvium, while various volcanics, such as andesite, breccia and pyroclastic rocks, are classified as Volcanics. The other geologic units are grouped into either Shale/Mudstone or Sandstone/Conglomerate based on their major compositions. The distribution of the geologic units across the Yamakoshi study area is shown in Figure 3.

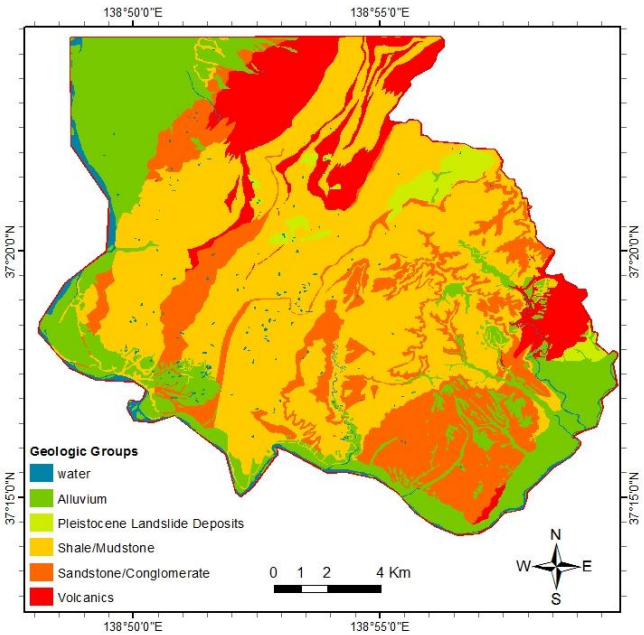

Figure 3 Geological Map of the Study Area

Shear strength properties for regional landslide assessment are commonly assigned based on geologic units and shear strength data obtained within each unit. There is no publically available testing data to directly determine the shear strengths for each geologic unit within the Yamakoshi study area. Therefore, shear strengths are assigned to the five main geologic units based on similar geologic units found in California (e.g., Jibson et al, 2000). The assignment of shear strengths to the geologic groups is presented in Table 1. The alluvial units have relatively low shear strengths and the volcanic units have relatively high shear strengths. Shale/mudstone and sandstone/conglomerate have moderate shear strengths, and the latter group is considered slightly stronger than the former group due to their coarse-grained nature. Pleistocene landslide deposits are not assigned very low shear strengths because there is no evidence that they fail preferentially during earthquakes (personal communication with Dr. Jibson).

Table 1 Geologic Groups and Shear Strength Properties

Geologic Group	Geologic Unit	c' (kPa)	φ' (deg)
Alluvium	a, al, d, f, tk, tl2, tl1, tm2, th2, th1, Oy	15	34
Pleistocene Landslide Deposits	c	20	30
Shale/Mudstone	Ue, Ud, S, Um, Ku, Am, Ts, Sm	25	30
Sandstone/ Conglomerate	Uc, W, Ks, Kl, As	25	35
Volcanics	Sv, Ka, Sy, Uv, Av, Tv, Nd, N	40	42

2.3 Ground Motions

Ground shaking estimates for the Niigata-ken Chuetsu earthquake are obtained from ShakeMap®, a product developed by the United States Geological Survey (USGS) to provide estimates of ground shaking after earthquakes. A ShakeMap® provides point estimates of ground shaking at a 30-arc second spacing, with the ground shaking estimates based on recorded motions (where records are available) supplemented by ground motion prediction equations. The latest ShakeMap® data (ShakeMap® Atlas V2.0) for Peak Ground Acceleration (PGA) and Peak Ground Velocity (PGV) for the Niigata-ken Chuestu earthquake were downloaded and converted into 10-m raster grids in ArcGIS© by applying a simple spline interpolation algorithm.

The PGA ShakeMap is shown in Figure 4. The PGA ranges from 0.52 to 1.93 g across the study site, while the PGV ranges from 22 to 182 cm/s. These high levels of ground shaking are consistent with recorded ground motions. The National Research Institute for Earth Science and Disaster Prevention (NIED) operates numerous strong-motion K-NET stations, which are uniformly

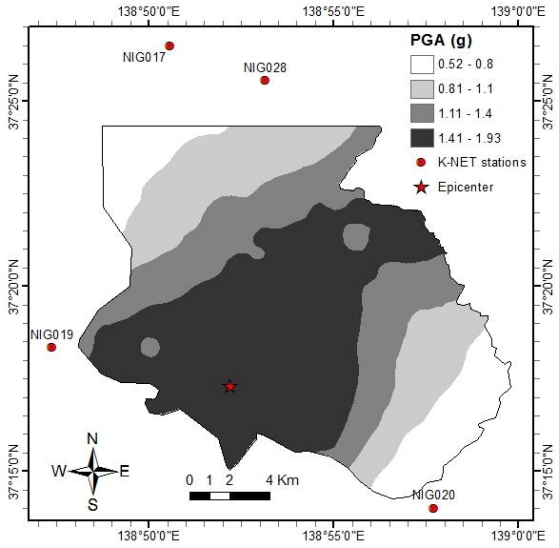

Figure 4 PGA ShakeMap®

distributed every 20 km over Japan. Immediately above of the fault rupture of this reverse event, strong hanging-wall effects led to extreme ground shaking (Kieffer et al. 2006). The largest PGA was 1.73g (with PGV = 72.8 cm/s) at Tohkamachi (NIG021 station), which is about 20 km southwest of the epicenter. Another high PGA value was 1.55g (with PGV = 123.7 cm/s) at Ojiya (NIG019), which is 4 km west of the epicenter (Figure 4). PGV values were largest at Nagaoka-Shisho (NIG028, 124.0 cm/s, 16 km north of the epicenter) and Ojiya (NIG019, 123.7 cm/s).

3. LANDSLIDE DISTRIBUTIONS FROM NIIGATA AND NORTHRIDGE EARTHQUAKES

Using the vector and raster forms of the observed landslides, the characteristics of the landslides induced by the Niigata-ken Chuetsu earthquake within the Yamakoshi study area are investigated. A total of 5,094 individual landslides occurred in the Yamakoshi study area and cover an area of 10.45 km^2, which is 4.8% of the 217 km^2 study area. The landslide source areas, which represent the landslide areas at elevations equal to or above the median elevation for each landslide, cover an area of 5.66 km^2 (~ 2.6% of the study area). For the 1994 Northridge earthquake, the Santa Susana Quadrangle (Figure 1b) had 1,562 seismically triggered landslides (3.4 km^2) covering a total of 2.1% of the quadrangle (Parise and Jibson 2000, Dreyfus 2011). Thus, the landslide area percentage for the Yamakoshi study area was more than twice that for the Santa Susana Quadrangle.

The largest landslide in the Yamakoshi study area is a deep-seated, rotational landslide with an area of about 314,000 m^2. This landslide is excluded from the assessment of empirical prediction models because the rigid sliding block approach is not applicable to this type of failure. The mean size of the remaining landslides is 1,991 m^2 and about 85% of the landslides are smaller than 2,000 m^2 (~ 45 m by

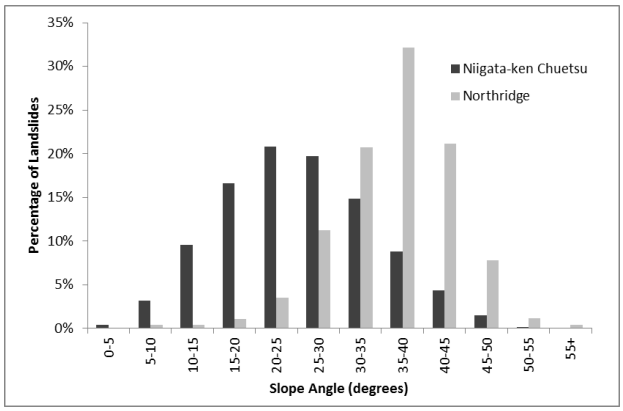

Figure 5 Distribution of Landslides as a Function of Slope Angle

45 m). Figure 5 shows the distribution of landslides with respect to the average slope angle within the landslide for the Niigata-ken Chuetsu and Northridge earthquakes. For Niigata-ken Chuetsu, the population is evenly distributed around a center value of 25^o, and most landslides are on slopes in the 15-35^o range. For Northridge, the landslides are more concentrated on slopes in the 30–45^o range. Parise and Jibson (2000) concluded that the distribution of landslides is significantly tilted toward steeper slopes relative to the distribution of slopes in general. A similar observation can be made regarding Niigata-ken Chuetsu by comparing Figures 2 and 5.

Figure 6 shows the distribution of area percentage, defined as the landslide source area divided by the total area, as a function of slope angle. For Niigata-ken Chuetsu, the area percentage moderately increases with slope angle, reaching a maximum of about 8% for slopes steeper than 45^o. One may expect the area percentage to continue to increase with increasing slope angle. However, steeper slopes are often steep because they consist of stronger materials, making them more resistant to earthquake shaking. For Northridge, a sharp increase in the area percentage occurs for slopes steeper than 40^o with a maximum of 35% observed for slopes steeper than 55^o. However, this sharp increase was not observed in adjacent quadrangles, indicating it may not be representative for the Northridge earthquake.

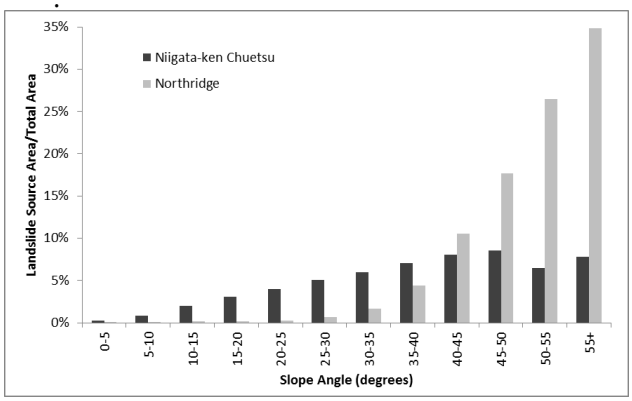

Figure 6 Landslide Source Area over Total Area as a Function of Slope Angle

The overall landslide densities for the Niigata-ken Chuetsu and Northridge earthquakes are 23.5 landslides per km^2 and 10 landslides per km^2, respectively. Despite their similar magnitudes, the 2004 Niigata-ken Chuetsu earthquake induced more landslides (in terms of either landslide density or landslide area percentage) in a relatively flatter area (Figure 2). This larger occurrence of landslides during the Niigata-ken Chuetsu earthquake is mostly likely due to the heavy rainfall before the earthquake, which caused highly unfavorable soil moisture conditions and pore water pressures at the time of the earthquake. In contrast, the Santa Susana Quadrangle had no rainfall for several months before the Northridge earthquake and the surficial slope materials were very dry (Parise and Jibson 2000).

The distribution of landslides across geologic units for the Niigata-ken Chuetsu earthquake is summarized in Table 2. Over 70% of the landslide source cells occurred in the Shale/Mudstone units, while 22.1% occurred in the Sandstone/Conglomerate units. One may also consider the area percentage within each geologic unit (% Geo Unit) such that the observed total landslide source areas are normalized by the available area within each geologic unit. Table 2 shows that the %Geo Unit was largest in the Shale/Mudstone units (4.1%) and Sandstone/Conglomerate units (3.1%). For comparison, the largest %Geo Unit values for the Santa Susana Quadrangle were 4 to 7.5%. These larger values may have been influenced by the more numerous and detailed geologic units identified in the Santa Susana Quadrangle (i.e., 13 units).

Table 2 Landslides within each Geologic Group

Geologic Groups	% of LS cells	% Geo Unit
Alluvium	1.5%	0.2%
Pleistocene Landslide Deposits	1.3%	1.4%
Shale/Mudstone	70.4%	4.1%
Sandstone/Conglomerate	22.1%	3.1%
Volcanics	4.7%	1.2%

4. LANDSLIDE PREDICTIONS

4.1 Approach

A common failure mode for landslides triggered by earthquakes in natural slopes is a thin, veneer slope failure (Keefer 2002). Therefore, regional-scale seismic landslide predictions are based on computing rigid sliding block displacements (Newmark 1965) for an infinite slope model. Many predictive models for sliding displacement have been proposed in the past decades that compute displacement based on the level of ground shaking and the resistance of the slope to sliding under seismic conditions. Ground motion parameters, such as PGA, PGV, mean period (T_m) and Arias Intensity (I_a), have been used individually or in combination for these predictive models. Using a combination of ground motion parameters can reduce the uncertainty in the displacement prediction, compared with using a single ground motion parameter. PGA and PGV are the most easily obtainable ground motion parameters across a region because USGS provides ShakeMap® data for PGA and PGV for major earthquakes across the world. Saygili and Rathje (2008) developed a model for predicting rigid sliding displacements (D in units of cm) using PGA (in units of g) and PGV (in units of cm/s). The median value of lnD can be expressed as:

$$\ln D = -1.56 - 4.58\left(\frac{k_y}{PGA}\right) - 20.84\left(\frac{k_y}{PGA}\right)^2 + 44.75\left(\frac{k_y}{PGA}\right)^3 - 30.50\left(\frac{k_y}{PGA}\right)^4 - 0.64\ln PGA + 1.55\ln PGV \quad (1)$$

The resistance of the slope to sliding under seismic conditions is characterized by the critical, or yield, acceleration (k_y). k_y is derived from limit equilibrium analysis of an infinite slope model. Considering earthquake shaking parallel to a slope, the yield acceleration (in units of g) can be expressed as:

$$k_y = (FS - 1)g \cdot \sin\alpha \quad (2)$$

where FS is the static factor of safety, g is the acceleration of gravity and α is the slope angle. The yield acceleration can be calculated by assuming the ground shaking is horizontal, but in most cases the differences are small (Saygili, 2008). Based on the slope geometry and the soil properties, the static factor of safety for an infinite slope model is computed as (Jibson et al. 2000):

$$FS = \frac{c'}{\gamma t \sin\alpha} + \frac{\tan\phi'}{\tan\alpha}\left(1 - m\frac{\gamma_w}{\gamma}\right) \quad (3)$$

where c' is the effective cohesion, φ' is the effective friction angle, γ is the material unit weight, γ_w is the unit weight of water, α is the slope angle, t is the slope-normal thickness of the rigid block, and m is the proportion of the block thickness that is saturated and thus represents pore water pressure. The slope angle is derived from the 10-m DEM in ArcGIS©. In this analysis, the other parameters in equation (3) are assigned typical values for shallow slopes: γ = 15.7 kN/m^3 and t = 2.4 m (Jibson et al. 2000). The c' and φ' values are presented in Table 1.

The selection of an appropriate saturation thickness proportion (m) requires some discussion. Considering that Typhoon Tokage occurred 3 days before the earthquake, the soils in the study area are assumed to be highly saturated. For fine-grained shales and mudstones, the extreme moisture conditions would further soften and reduce the shear strength. Based on sensitivity analyses, the most representative values of m for the Yamakoshi study area at the time of the Niigata-ken Chuetsu earthquake is set as 0.8.

ArcGIS© 10.0 is used for the development of digital maps of sliding displacement and landslide prediction at

10-m resolution. With a slope map from the DEM and shear strength assigned from the geological map, maps of FS (eq. 3) and k_y (eq. 2) are developed. The k_y values are coupled with ground motions from ShakeMap® to compute the median sliding displacement (eq. 1) cell by cell in the study area. The study area contains 2,445,263 cells in total and the number of observed landslide source area cells (LS cells) is 63,507, not including the one larger, deep-seated landslide.

Both the accuracy and the efficiency of the landslide predictions are evaluated. A predicted landslide cell (PLS cell) is defined as a cell with a predicted sliding displacement greater than a displacement threshold. The LS cells accurately identified by the PLS cells are considered landslide captured (LSC) cells. %LSC represents the percentage of the total LS cells that are accurately identified. The PLS/LS ratio is an efficiency parameter, showing the relative quantity between predicted landslide cells and observed landslide cells.

4.2 Results

Two displacement thresholds (5 cm and 15 cm) are applied to evaluate the prediction accuracy and efficiency. The 5 cm displacement threshold generally represents the boundary between very low and low hazard, while the 15 cm threshold represents the transition from low to moderate hazard (California Geological Survey 2008). Figure 7 shows the predicted landslide cells for the Yamakoshi study area using the 5 and 15 cm thresholds and m = 0.8. Almost all of the predicted landslides concentrate in the middle part of the study area, which is underlain by the fault rupture (Figure 1a) and on the hanging-wall. In this region, the intensive ground motions (Figure 4) and the steep terrain result in large predicted displacements. A threshold of 5 cm obviously predicts significantly more landslide cells than the 15 cm threshold, and thus will capture more landslides. However, this smaller displacement threshold largely over-predicts the landslide area. The 5 cm threshold captures over 75% of the landslides (%LSC = 75.3%), but the trade-off is that over 40% of the study area fails and the PLS/LS ratio is 16.1. On the contrary, the 15 cm threshold results in a smaller %LSC (40.4%) but a more acceptable PLS/LS ratio of about 5.

Table 3 Landslide Prediction Assessments for Different Displacement Thresholds and m-values

m value	5 cm threshold		15 cm threshold	
	%LSC	PLS/LS	%LSC	PLS/LS
0.0	34.0%	4.1	6.4%	0.5
0.5	62.0%	11.2	22.6%	2.4
0.7	71.4%	14.5	33.9%	4.2
0.8	75.3%	16.1	40.4%	5.4
0.9	79.0%	17.7	47.3%	7.0
1.0	82.7%	19.1	54.1%	8.8

The influence of m-value on the results was investigated by performing analyses for a range of m-values between 0.0 and 1.0. The values of %LSC and PLS/LS for these analyses are summarized in Table 3. The prediction accuracy (%LSC) definitely increases with increasing m value, due to the associated reduction in shear strength. For m = 0, both the small %LSC and the known moisture condition at the time of the earthquake suggest that such a small m-value cannot be justified. A larger m-value brings a better prediction accuracy but significantly increases the PLS/LS ratio. However, even with m = 1.0, the prediction accuracy still does not approach 100% and in these cases the PLS/LS ratio becomes excessively large.

Dreyfus (2011) performed a similar analysis of displacement for the Santa Susana Quadrangle. Considering the dry moisture condition prior to the Northridge earthquake, m = 0 was assigned. The %LSC and PLS/LS ratio were 41% and 7.1, respectively, for the 5 cm threshold, and 28.8% and 4.3 for the 15 cm threshold. These results are consistent with the results of this study and suggest that obtaining a higher accuracy by lowering the displacement

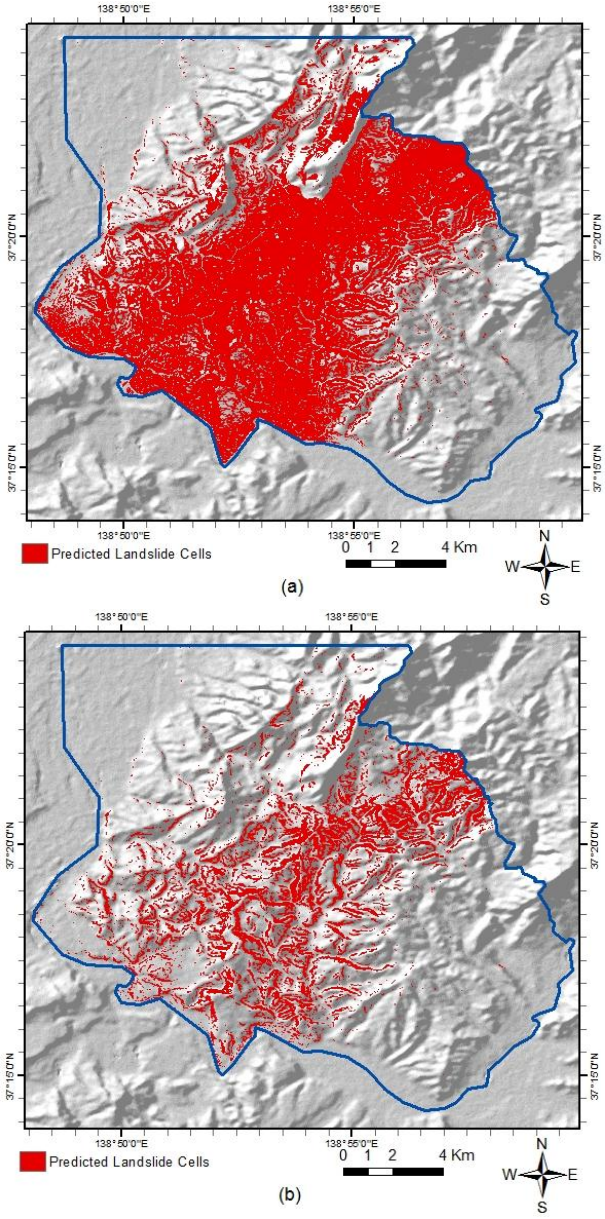

Figure 7 Predicted landslide areas for m = 0.8 with (a) 5cm threshold (b) 15cm threshold

Table 4 Summary of Prediction Accuracy and Efficiency within each Geologic Group

Geologic Group	Observed Landslides		Predicted Landslides		Captured Landslides		
	LS cells	% of Geo Unit	PLS cells	% of Geo Unit	LSC cells	%LSC in Geo Unit	PLS/LS in Geo Unit
Alluvium	950	0.2%	20,823	3.9%	365	38.4%	21.9
Pleistocene Landslide Deposits	823	1.4%	19,145	32.4%	597	72.5%	23.3
Shale/Mudstone	44,714	4.1%	259,874	23.7%	20,845	46.6%	5.8
Sandstone/Conglomerate	14,011	3.1%	46,168	10.1%	3,970	28.3%	3.3
Volcanics	3,009	1.2%	215	0.1%	5	0.2%	0.07

threshold sacrifices the efficiency of the prediction.

The accuracy and efficiency of the landslide predictions across the geologic units are summarized in Table 4. Alluvium, Pleistocene Landslide Deposits and Volcanics make up only about 7.5% of the total landslides (Table 2), such that their prediction accuracies do not contribute much to the overall accuracy. Nonetheless, their individual %LSC vary significantly: 0.2% for Volcanics, 38.4% for Alluvium, and 72.5% for Pleistocene Landslide Deposits. The corresponding PLS/LS ratios for Volcanics, Alluvium, and Pleistocene Landslide Deposits are 23.3, 21.9, and 0.07, respectively. The large PLS/LS ratios for the Alluvium and Pleistocene Landslide Deposits suggest that the assigned strengths for these units are too small such that there is a significant over-prediction in landslide area. Alternatively, the very small PLS/LS ratio for the Volcanics indicates that the assigned strength is too large. Because the observed landslides within the Volcanics group are mainly rock block slides on a weak layer or discontinuity within the bedrock (Kieffer et al. 2006), assigning shear strengths based on the rock mass results in strengths that are too large.

As previously noted, 92.5% of the landslides occurred in the Sandstone/Conglomerate and Shale/Mudstone units. The %LSC and PLS/LS ratio are relatively small for the Sandstone/Conglomerate unit (28% and 3.3, respectively), while these values are larger for the Shale/Mudstone unit (%LSC ~ 47%, PLS/LS ~ 6). While smaller strengths for the Shale/Mudstone unit would generate a larger %LSC, the over-prediction in total landslide area would greatly increase.

Similar results were obtained by Dreyfus (2011) when analyzing the six quadrangles that experienced significant landslides during the Northridge earthquake. In studying Northridge, only 30 to 40% of the landslides were accurately captured despite the use of the best geologic maps, best shear strength information, and best ground motion data. Coupled with these relatively small values of %LSC were large over-predictions in the total landslide area (PLS/LS ~ 4 to 7).

4.3 Discussion

The results from this study and others (e.g., Dreyfus 2011) indicate that only about 30 to 40% of landslide can be expected to be captured by current techniques for regional seismic landslide prediction, and the total landslide area will most likely be over-predicted by a factor greater than 5. Thus it is clear that the techniques used to map seismic landslide hazards are lacking and require improvement.

One critical component of the seismic landslide prediction methodology is the assignment of shear strengths. Currently, these strengths are assigned based on geologic unit and a single set of (c', φ') are used for each geologic unit. A constant set of shear strength parameters within a geologic unit effectively assumes 100% of slopes steeper than a critical slope angle (defined via eqs 2 and 3 for a given PGA and PGV) will fail. Failure of all steep slopes is not realistic and illustrates the need to identify spatial variability in shear strength across a geologic unit. As noted earlier, steeper slopes are often steep because they consist of stronger materials, making them more resistant to earthquake shaking. Additionally, different parts of the same geologic unit may exhibit different shear strengths due to differences in cementation, grain-size, etc. One potential approach to quantifying these variations is remote sensing, but remote sensing may be hindered by soil cover that obscures the characteristics of underlying materials. Mapping of strength in the field would be extremely time-consuming and would require collecting and testing a significant number of material samples.

Related to the issue of shear strength parameters is the assumed saturation thickness proportion (m), which affects the pore water pressures, effective stress, and strength. This assumption had a profound effect on the study of the Niigata-ken Chuetsu earthquake because of the significant rainfall before the event. Rather than assuming a value of m, a more rational approach would take into account rainfall rates, slope angle, and relative hydraulic conductivities to predict spatially variable m-values.

Finally, an additional factor that limits our ability to capture a high percentage of seismic landslides is local variability of ground shaking. Because landslides occur primarily on relatively steep slopes, most of this local variability is likely the result of topographic amplification. The regional estimates of ground shaking from ShakeMap are the best seismology has to offer, but they potentially ignore important localized topographic effects that influence the seismic loading of slopes, particularly near the crests of ridges. However, systematically predicting the location and amount of topographic amplification is a complex problem that currently has no simple, consistent solution.

5. CONCLUSIONS

The 2004 Niigata-ken Chuetsu earthquake induced a significant number of landslides across the Yamakoshi region. The landslide inventory from this earthquake provides an excellent opportunity to study the landslide distribution, to compare this distribution with the distribution of landslides in the Santa Susana Quadrangle from the 1994 Northridge earthquake, and to evaluate the procedures used in regional seismic landslide prediction.

The topography of the Yamakoshi study area is not as steep as for the Santa Susana Quadrangle; yet a larger number of landslides occurred in Yamakoshi. Additionally, the landslides in Yamakoshi were concentrated on slopes between 20 and 30 degrees, while the landslides in the Santa Susana Quadrangle occurred mostly on slopes between 30 and 45 degrees. The larger number of landslides in Yamakoshi most likely was influenced by the adverse soil moisture conditions and pore water pressures at the time of the earthquake.

More than 90% of the landslides in the Yamakoshi study area occurred in Shale/Mudstone or Sandstone/ Conglomerate geologic units. Very few landslides occurred in the Alluvium, Pleistocene Landslide deposits, or Volcanic units. Even in the Shale/Mudstone or Sandstone/ Conglomerate geologic units, however, the percentage of area covered by landslides was only 3 to 4%.

Regional-scale landslide predictions for the Niigata-ken Chuetsu earthquake were made using the rigid sliding block approach. This approach used a regional DEM and shear strengths assigned to each geologic unit to generate yield acceleration estimates on a 10-m grid spacing. Coupling the yield accelerations with ground motion estimates from ShakeMap and the displacement prediction model of Saygili and Rathje (2008), displacements were predicted across the study area. Predicted landslides were identified using a 5 cm and 15 cm displacement threshold.

Comparing the predicted and observed landslides provided several insights. The 15 cm threshold captured only about 40% of the landslides, although the total predicted landslide area was more than 5 times as large as what was observed. The 5 cm threshold increased the prediction accuracy to 75% but at the expense of over-predicting the total landslide area by a factor of 16. The saturation thickness proportion (i.e., m-value) has a significant influence on the prediction accuracy and the level of over-prediction. Selecting an appropriate m-value is essential for region-scale landslide prediction, especially for the Niigata-ken Chuetsu earthquake with heavy rainfall.

The accuracy in predicting landslides on a regional scale may be improved by refining various parts of the modeling approach. The component of the analysis that has the most likelihood of improving the predictions is the shear strength, in particular considering spatial variations in shear strengths across each geologic unit. A constant set of shear strength parameters within a geologic unit effectively assumes a 100% failure rate for slopes steeper than a critical slope angle. This result is not realistic and illustrates the need to identify spatial variability in shear strength across a geologic unit. Field test and lab test data can be helpful for determining the variability in strengths, and remote sensing may play a role in the future.

Abstract: In United States design practice, three system performance factors (R, C_d, and Ω_o) characterize the inelastic behavior of structures and are a crucial component of common elastic design methodologies. However, for steel-concrete composite frame systems these factors have been selected based on comparisons to more traditional and well-studied reinforced concrete and structural steel frame systems, without significant quantitative justification. In this study, the seismic behavior of steel-concrete composite moment and braced frames is investigated and rational system performance factors are developed. A set of archetype frames, selected to be representative of the range of frames seen in practice, were designed according to current design specifications. Using a suite of new finite element formulations for composite systems, nonlinear static pushover and transient dynamic analyses were performed on the frames. The results of the analyses served as statistical data on the seismic response from which the performance factors were quantified. The results from this investigation enable a better understanding of the variability in collapse performance of composite frame systems and will facilitate more effective designs of these systems.

1. INTRODUCTION

A key component of seismic design in the United States is the allowance for inelasticity in structural elements subjected to severe earthquake ground motions. However, static elastic analysis is prevalent for seismic design in current practice. Because of this, seismic performance factors have been developed. The factors are: the response modification factor, R, used in reducing seismic forces determined through elastic methods; the displacement amplification factor, C_d, used in amplifying displacements determined through elastic methods; and the system overstrength factor, Ω_o, used to estimate the actual strength as compared the to the design strength.

These three factors are tabulated for a variety of seismic force resisting systems in national codes (ASCE 2010), however, they have been somewhat arbitrarily assigned. Many R factors were based largely on judgment and qualitative comparisons to the relatively few seismic force resisting systems that had known response capabilities (FEMA 2009). This is particularly true for composite moment and braced frames where the seismic performance factors were assigned based on comparisons to similar structural steel and reinforced concrete systems.

A methodology has been developed to provide a rational basis for determining seismic performance factors which provide equivalent safety against collapse for buildings with different seismic force resisting systems (FEMA 2009). Equivalent safety is provided through an acceptably low probability of structural collapse common to all systems. Structural collapse in the methodology is defined in the context of incremental dynamic analysis, in which nonlinear time history analyses are performed at increasing magnitudes of seismic loading until the structure achieves its peak strength or predefined displacement limits. In this approach, no explicit modeling of collapse is included. Statistical data is generated from the analyses for a set of archetype models and uncertainty is approximated based on the level of knowledge of the particular system and accuracy of the analysis.

This paper presents a study to investigate the behavior of composite frames under seismic loading and to develop rational seismic performance factors following the methodology given in FEMA P-695 Quantification of Building Seismic Performance Factors (FEMA 2009).

2. SEISMIC FORCE RESISTING SYSTEMS

Two separate seismic force resisting systems are analyzed in this study: composite special moment frames (C-SMF) and composite special concentrically braced frames (C-SCBF). The current seismic performance factors

for these two systems are given in Table 1 (ASCE 2010).

Table 1. Current Seismic Performance Factors

System	Ω_o	R	C_d
C-SMF	3.0	8.0	5.5
C-SCBF	2.0	5.0	4.5

The requirements for composite special moment frames are described in the AISC *Seismic Specification* (AISC 2010). C-SMFs utilize fully restrained connections and consist of either composite or reinforced concrete columns and either structural steel, concrete-encased composite, or composite beams. They are expected to provide significant inelastic deformation capacity through flexural yielding of the beams and limited yielding of the column panel zones. Columns are designed to be stronger than the fully yielded and strain-hardened beams, although flexural yielding in columns at the base is permitted.

The requirements for composite special concentrically braced frames are described in the AISC *Seismic Specification* (AISC 2010). C-SCBFs consist of CFT or SRC composite columns, structural steel or composite beams, and structural steel or CFT braces. They are expected to provide significant inelastic deformation capacity primarily through brace buckling and yielding of the brace in tension.

3. ARCHETYPE FRAMES

To perform the methodology, it is necessary to have a suite of frames (termed index archetypes) for which the analyses can be performed. Ideally that suite of frames is representative of the entire range of frames seen in practice. However, it is generally recognized within the methodology that a practical number of frames cannot fully represent the permissible range, thus simplifications must be made. The selected frames are described below; complete details including the design process are presented in Denavit (2012).

The building layout is the same for each of the index archetype configurations: 3 bays by 5 bays with a bay width of either 20 ft or 30 ft (Figure 1). The buildings are 3 or 9 stories tall with a story height of 13 ft. For the moment frames the columns were either RCFTs or SRCs. For the braced frames the columns were CCFTs and the braces were either rectangular HSS or wide flange in a two-story X configuration. A composite floor system was assumed for all configurations, although the beams in the seismic force resisting systems were designed and analyzed assuming bare steel.

Two levels of gravity load were selected: "high" which corresponded to warehouse live loading (250 psf) and the interior frame and "low" which corresponded to office live loading (65 psf) and the exterior frame. Two levels of seismic load were selected corresponding to the levels design earthquake associated with the maximum (D_{max}) and minimum (D_{min}) of seismic design category D (ASCE 2010).

The methodology prescribes that $C_d = R$ (FEMA 2009), which is contrary to current practice (ASCE 2010) where C_d is typically less than R (Table 1). For deformation-controlled structures, such as moment frames, this change results in larger member sizes. In this study, most frames were designed assuming $C_d = R$, however, a subset of the moment frames were duplicated and designed with the current value (C_d = 5.5) so as to compare to the current state of design practice.

In total, 60 frames were selected and designed for this study. The frames varied in building height, column type, concrete strength, level of seismic load, level of gravity load, and bay width. Details of the frames are given in Table 2 for the C-SMFs and Table 3 for the C-SCBFs.

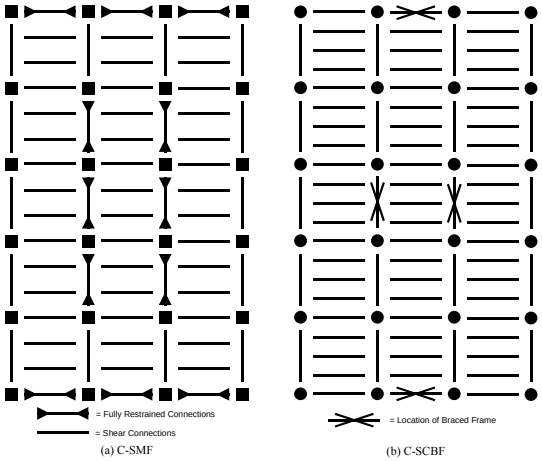

Figure 1. Building Layout

3.1 Material Strengths

Two sets of material strengths are used in this study as summarized in Table 4. The first is the nominal strength which is used in the design of the archetypes. The second is the expected strengths which are used in the analyses of the archetypes. The nominal strengths are selected as typical material properties. The expected strengths for the steel materials are defined as described in Section A3.2 of the AISC *Seismic Specification* (AISC 2010). For lack of a more appropriate definition, the expected strengths for the concrete materials are defined as the required average compressive strength from field strength tests when data are not available to establish a sample standard deviation as described in Section 5.3.2.2 of the ACI *Code* (ACI 2011).

3.2 Seismic Design

The equivalent lateral force method (ASCE 2010) was used for the seismic design. The level of seismic loading is defined in terms of the seismic design category. The frames in this study were designed for seismic design category D at either the maximum (D_{max}) or minimum (D_{min}).

The seismic base shear, V, is defined as the product of the effective seismic weight, W, and the seismic coefficient, C_s, determined based on the fundamental period, T, in accordance with Section 12.8 of ASCE 7 (ASCE 2010). The effective seismic weight of the building is determined in accordance with Section 12.7.2 of ASCE 7 (ASCE 2010).

The effective seismic weight, W, is the sum of the following:

- 100% of the dead load
- 25% of the warehouse floor live load (which is deemed storage)
- 15.4% of the office floor live load (equivalent to 10 psf for partitions)

Table 4. Nominal and Expected Material Strengths

Material	Nominal Strength (Used for Design)	Expected Strength (Used for Analysis)
Circular HSS (ASTM A500 Gr. B)	F_y = 42 ksi F_u = 58 ksi	F_y = 58.8 ksi F_u = 75.4 ksi
Rectangular HSS (ASTM A500 Gr. B)	F_y = 46 ksi F_u = 58 ksi	F_y = 64.4 ksi F_u = 75.4 ksi
Wide Flange (ASTM A992)	F_y = 50 ksi F_u = 65 ksi	F_y = 55.0 ksi F_u = 71.5 ksi
Reinforcement (ASTM A615)	F_{yr} = 60 ksi F_u = 90 ksi	F_{yr} = 75.0 ksi F_u = 112.5 ksi
Plate (ASTM A572 Gr. 50)	F_y = 50 ksi F_u = 65 ksi	F_y = 55.0 ksi F_u = 78.0 ksi
4 ksi Concrete	f'_c = 4 ksi	f'_c = 5.2 ksi

4. NONLINEAR ANALYSIS MODEL

The nonlinear analysis models consist of beam and zero length elements representing the seismic force resisting frame and nonlinear truss elements representing the destabilizing effect of the remainder of the building that is tributary to the frame. Key details of the model are presented here; full details are presented elsewhere (Denavit 2012).

The beam element used in the model is a distributed plasticity formulation developed specifically for steel-concrete composite frames. The element uses a mixed basis (i.e., using both displacements and forces as primary variables) to allow for accurate modeling of both material and geometric nonlinearities. Fiber sections and uniaxial cyclic constitutive relations are used to model cross section behavior. The concrete and steel material models account for the salient features of each material, as well as the interaction between the two, including concrete confinement and local buckling.

The connection region of special moment frames is modeled as shown in Figure 2. Key components are a rigid link parallelogram model with a rotational spring representing the nonlinear panel zone behavior and elastic beam elements which serve to move the beam plastic hinges to specified locations. Nonlinear beam elements for the columns and beams frame into this connection model. The connecting elements (e.g., split tees as shown in Figure 2) are not explicitly modeled since they are designed to not experience significant deformations, even under large frame deformations.

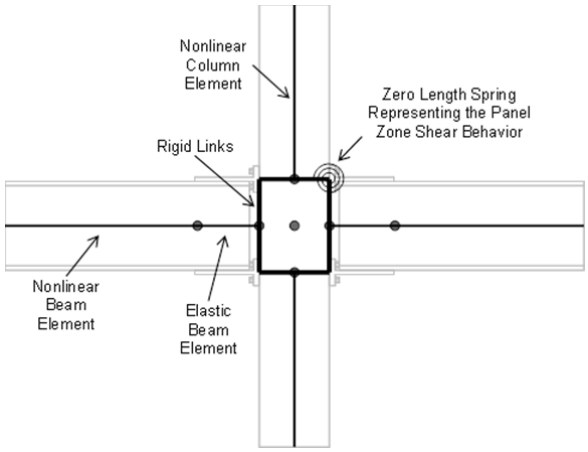

Figure 2. Schematic of the Connection Region of Special Moment Frames

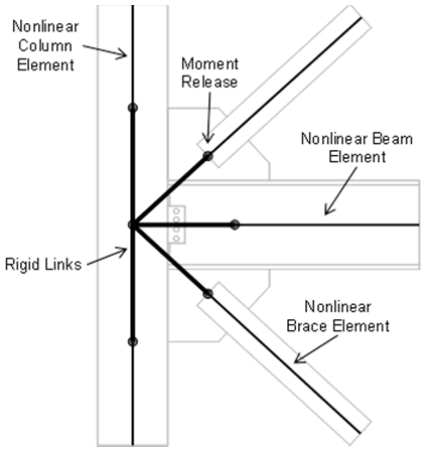

Figure 3. Schematic of the Beam-To-Column Connection Region of Special Concentrically Braced Frames

Connection regions in special concentrically braced frames have large gusset plates that serve to stiffen the connections. Hsiao et al. (2012) developed recommendations for modeling the connection region of steel special concentrically braced frames. A simplified version of the model by Hsiao et al. (2012) is used in this work. The beam-to-column connection region is modeled as shown in Figure 3. Rigid links are used to model the region where the gusset plate stiffens the beam, brace, and column. The length of the rigid link along the column is equal to the distance from the work point to the top of the gusset plate. The length of the rigid link along the brace is equal to the distance from the work point to the physical brace. The length of the rigid link along the beam is equal to the

distance from the work point to column face plus 75% of the distance from the column face to the edge of the gusset plate. The column and beam frame directly into the rigid link whereas a moment release is used between the rigid link and the brace.

The analyses were performed in two-dimensions. The mesh density was selected such that the model was refined enough to obtain accurate results, but not so dense as to introduce the ill-effects of localization. The nominal length of the column elements was one-third of the story height. The nominal length of the girder elements was one-third of the bay width for the C-SMFs and one-fourth of the bay width for the C-SCBFs corresponding to the beam spacing (Figure 1). Three integration points were used for all beam elements. Nominal size of the strips in the fiber discretization was 1/20th of the section depth, with the number of fibers in each component defined based on this fixed ratio and rounded up to the nearest integer.

The braces in the C-SCBFs are assumed to be physically oriented such that weak axis buckling is out-of-plane of the frame. However, in the model the brace is oriented such that weak axis buckling is in-plane to allow for the use of a two-dimensional model. Correspondingly, the moment releases at the brace ends represent the relatively weak out-of-plane rotational strength of the gusset plate.

As prescribed in the methodology (FEMA 2009), prior to application of the lateral load (either static or dynamic), gravity load equal to 105% of the dead load plus 25% of the live load and roof live load was applied and held constant for the remainder of the analysis. All gravity loads were applied as nodal loads based on tributary areas.

The methodology (FEMA 2009) does not explicitly define the mass to be used in the analyses. Thus, mass was assigned to the structure based on the effective seismic weight computed for design. For nodes with gravity load, the two translational DOFs were assigned equal masses equivalent to the dead load plus a percentage of the live load. Additionally, for numerical stability, a minimum nominal mass was assigned to all degrees-of-freedom. The value of the minimum nominal mass was 1×10^{-6} kip-s^2/in for the translational DOFs and 1×10^{-6} kip-in-s^2 for the rotational DOFs. Also for numerical stability, an additional elastic stiffness of EA = 300 and EI = 3000 was added to each brace section (e.g., in the event of significant yielding along the full length of the member). Rayleigh damping was used, defined as 2.5% in the 1st and 3rd modes based on recommendations from the methodology (FEMA 2009).

A summary of the gravity load cases and mass used in both the design and the analysis of the archetype frames is presented in Table 5.

The model accurately captures member plasticity, local buckling, global buckling, and panel zone behavior as demonstrated through validation studies presented elsewhere (Denavit 2012). However, some aspects of behavior and failure modes have not been modeled.

- Fracture is not included in the model. While fracture is expected during structural collapse, this study is not explicitly modeling collapse. Fracture is not anticipated o control the behavior of well-designed C-SMF, where ductile yielding of the beams in flexure is expected to dominate the response, or C-SCBF, where ductile yielding of the braces and buckling of the braces is expected to dominate the response.
- Connection regions are modeled, however, failure or degradation of the connecting elements is not included in these models. Experimental testing has shown that with proper design and detailing the connecting elements inelasticity can be confined to the member.
- In the design of the frames it was assumed that the beams were provided with lateral bracing sufficient to ensure the full plastic moment capacity could be achieved. Correspondingly, lateral torsional buckling was not included in the model

Table 5. Gravity Load and Mass in Design and Analysis

	Design	**Analysis**
Gravity Load	1.4 D 1.2 D + 1.6 L + 0.5L_r 1.2 D + 0.5 L + 1.6L_r etc., including live load reduction Section 2.3 (ASCE 2010)	1.05 D + 0.25 L + 0.25 L_r (FEMA 2009)
Mass	D + 25% storage live load + 10 psf for partitions Section 12.7.2 (ASCE 2010)	Same as for design

5. STATIC PUSHOVER ANALYSES

Static pushover analyses were performed on each frame. Lateral loads were applied at each story in fixed ratios based on the story mass and the mode shape of the structure (FEMA 2009). Thus, an eigenvalue analysis was performed prior to the application of lateral load (but after gravity load was applied). The loading was conducted in displacement control until at least a 20% drop in strength after the peak (V_{80}) was observed. Key results from these analyses include:

- The fundamental period from the model, T_1
- The maximum base shear capacity, V_{max}
- The overstrength factor, $\Omega = V_{max}/V$
- The ultimate roof displacement (i.e., at V_{80}), δ_u
- The effective yield roof drift displacement, $\delta_{y,\text{eff}}$, [Equation 1 (FEMA 2009)]
- The period-based ductility, $\mu_T = \delta_u / \delta_{u,\text{eff}}$

$$\delta_{y,eff} = C_o \frac{V_{max}}{W}\left(\frac{g}{4\pi^2}\right)\left(\max(T, T_1)\right)^2 \qquad (1)$$

where,

C_o = A coefficient based on the fundamental mode shape (FEMA 2009)

5.1 Analysis Results

An example of the results for a three-story C-SMF (RCFT columns, high gravity load, f'_c = 4 ksi, SDC = D_{max}) is shown in Figure 4. Full results are presented elsewhere (Denavit 2012).

For the C-SMFs, an initially linear response is observed followed by gradual stiffness reduction up to the peak lateral capacity of the frame then near linear post peak degradation until the analysis was stopped after at least a 20% drop in capacity was observed. For the 3 story frames an even distribution of deformation is seen among the stories with the exception of the roof story of some frames where lower deformations were observed at the V_{80} level. For the 9 story frames, the distribution of deformation was even among the stories at the design base shear level, however, at the maximum base shear and after a 20% drop in capacity, the deformation was concentrated in ranges of 4 to 6 stories forming a multi-story mechanism (Krishnan and Muto 2012). The story groups where the inelasticity was concentrated were either located at the top, middle, or bottom of the structure. No fundamental behavioral differences were observed between the frames with RCFT columns and those with SRC columns owing to the fact that flexural yielding of the beams controlled the response.

For the C-SCBFs, the response was initially linear, however, in contrast to the C-SMFs, sharp changes in stiffness including drops in capacity were observed in the response corresponding to yielding and buckling of the individual braces. These jumps are exacerbated by the fact that only one bay of bracing was modeled; had multiple bays been included with slightly different loading or material properties, the response would likely have been smoother. Also in contrast to the C-SMFs, for the 3 story frames the deformation was often concentrated into one story. The 9 story frames showed a similar response to the C-SMFs in that multi-story mechanisms were developed where the deformation was concentrated in 4 to 6 consecutive stories.

Conclusions from the results are given in Section 7.1 in the context of evaluating the system overstrength factor.

6. DYNAMIC RESPONSE HISTORY ANALYSES

In the methodology, collapse is assessed in the context of incremental dynamic analyses (IDA) (Vamvatsikos and Cornell 2002). Dynamic response history analyses are performed, subjecting each frame to a suite of ground motions scaled at different intensities. The 44 earthquake ground motions described in the methodology (FEMA 2009) were used for this study.

Explicit modeling of the collapse of structures is a challenging task and the subject of current research (Bažant and Verdure 2007; Khandelwal et al. 2009; McAllister et al. 2012; Szyniszewski and Krauthammer 2012). The FEMA (2009) methodology has avoided the need to explicitly model collapse by defining collapse in the context of incremental dynamic analyses. In incremental dynamic analyses, a frame is analyzed under different ground motions and at different intensities. The resulting curve shows a response value (typically peak story drift) versus an intensity measure. Typical results would show an initially high slope, gradually transitioning to a low slope; however, in practice a wide variety of behavior is seen.

Determination of "collapse" is necessary for the methodology and thus approximate definitions are adopted. In this work, collapse is defined when a prescribed maximum story drift of 10% is observed in the incremental dynamic analysis results. This is an approximate method since collapse is not associated with any particular drift limit (Krawinkler et al. 2003); however, some justification of the 10% limit exists. Generally, little hardening response is seen incremental dynamic analysis results beyond 10% drift. Also, the nonlinear models were not validated for deformations beyond this range and nonlinear effects that are not being modeled directly in this work, such as fracture, lateral torsional buckling, or connection degradation may

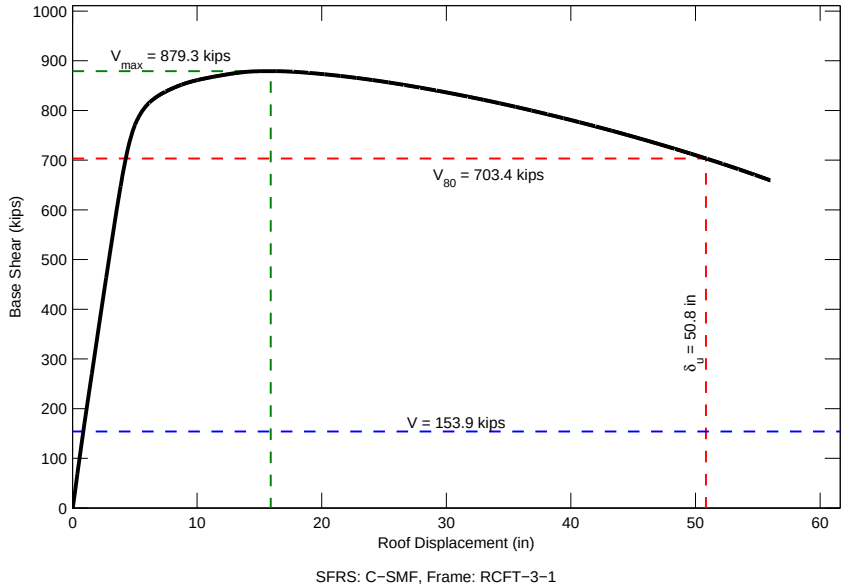

Figure 4. Sample Results of the Static Pushover Analyses

occur at these higher drift levels.

Key results from the dynamic response history analyses include:

- The median collapse intensity, $\hat{S}_{CT}$, determined as the intensity, ST, at which half of the ground motions cause maximum story drifts of greater than 5%
- The collapse margin ratio, CMR = $\hat{S}_{CT}/S_{MT}$ (where S_{MT} is the maximum considered earthquake intensity).

6.1 Analysis Results

An example of the results for the same three-story C-SMF highlighted before is shown in Figure 5. Full results are presented elsewhere (Denavit 2012).

For both the C-SMFs and C-SCBFs, the majority of incremental dynamic analysis curves exhibit the typical response with an initial relatively high slope followed by a relatively low slope at higher intensities. The initial slope of the curves for each frame varies, owing to inherent differences between the 44 ground motions. In general, at the maximum considered earthquake intensity (i.e., $S_T = S_{MT}$), the distribution of story drifts is relatively uniform along the height of the building. An exception is the 9 story C-SCBFs where often the top story exhibits deformations several times greater than that of the other stories.

7. EVALUATION OF SEISMIC PERFORMANCE FACTORS

For the purposes of evaluation, the methodology requires the archetype frames be categorized into performance groups based on the design gravity load level (high or low), design seismic load level (D_{max} or D_{min}), and fundamental period (long or short). Eight performance groups are defined for seismic force resisting system and are used as described below to evaluate each of the seismic performance factors.

7.1 System Overstrength Factor, Ω_o

According to the methodology, the system overstrength factor, Ω_o, should not be taken as less than the largest average value of overstrength, Ω, from any performance group, however, upper limits of 1.5R and 3.0 are applied (FEMA 2009).

For the C-SMFs, the average overstrength for the performance groups ranges from 5.3 (for the performance group with high gravity load, SDC = D_{max}, and long period) to 9.9 (for the performance group with high gravity load, SDC = D_{min}, and long period). These values are quite high and reflect the displacement controlled design of these structures. Other studies on steel special moment frames (NIST 2010) have also shown high overstrength. Several factors have led to the particularly high overstrength values seen in this study. The use of $C_d = R$ in the design of the frames reduced the allowable story drifts thus increasing member sizes. In the model, the plastic hinges were forced to a location 2d/3 away from the column face (where d is the bean section depth). This distance was the assumed length of the connection. Selection of this distance resulted in higher frame strengths as compared to shorter connections. Additionally, reduced beam section connections were not used for these structures; if they had been used, lower overstrength would have been observed. For the results shown, all of the performance groups exceed the practical upper limit of 3.0, so it is recommended that the system overstrength factor remain unchanged from its current value ($\Omega_o = 3.0$).

For the C-SCBFs, the average overstrength for the performance groups ranges from 1.7 (for the performance group with high gravity load, SDC = D_{min}, and short period) to 2.8 (for the performance group with low gravity load, SDC = D_{max}, and short period). These results are in contrast to the C-SMFs where high overstrength was observed and

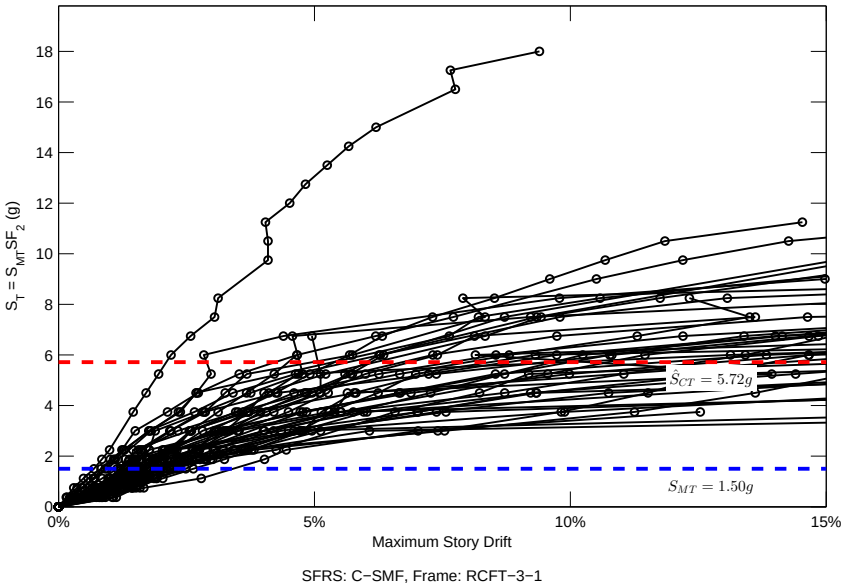

Figure 5. Sample Results of the Dynamic Response History Analyses

reflect the strength controlled design of these structures. Other studies on steel special concentrically frames (NIST 2010) have shown similar overstrength results. In light of these results (some performance groups with overstrength greater than 2.0), an increase the system overstrength factor for C-SCBFs could be warranted, although the current value ($\Omega_o = 2.0$) is likely sufficient.

7.2 Response Modification Factor, *R*

According to the methodology, the response modification factor that was used to design the archetype frames is acceptable if the probability of collapse for maximum considered earthquake ground motions is approximately 20% or less for each index archetype and 10% or less on average for each performance group (FEMA 2009). To evaluate these conditions, adjusted collapse margin ratios are computed and compared against reference values (Equations 2 and 3).

$$ACMR_i \geq ACMR_{20\%} \tag{2}$$

$$\text{mean}\left(ACMR_i\right) \geq ACMR_{10\%} \tag{3}$$

where,

$ACMR_i$ = adjusted collapse margin ratio for each index archetype, *i*

$ACMR_{20\%}$ = acceptable value of the adjusted collapse margin ratio for 20% collapse probability

$ACMR_{10\%}$ = acceptable value of the adjusted collapse margin ratio for 10% collapse probability

The adjusted collapse margin ratio is the product of the collapse margin ratio, *CMR*, as determined from the response history analyses and a spectral shape factor, *SSF*, given in FEMA P695 (2009). The spectral shape factor depends on the fundamental period, *T*, and period based ductility, μ_T, and accounts for the frequency content of the selected ground motion record set.

$$ACMR_i = SSF_i \; CMR_i \tag{4}$$

The acceptable values of the adjusted collapse margin ratio are derived from the lognormal distribution and depend on the desired collapse probability (10% or 20%) and a measure of the total system collapse uncertainty (expressed as β_{total}). Uncertainty in the system collapse assessment comes from a number of sources. Uncertainty due to the variability between ground motions records is characterized by β_{RTR} [Equation 5 (FEMA 2009)]

$$\beta_{RTR} = 0.1 + 0.1\mu_T \leq 0.4 \tag{5}$$

Uncertainty in the design requirements, test data, and nonlinear modeling are characterized by qualitative quality ratings as will be described.

For both of systems, the design requirements have been well-vetted and provide extensive safeguards against unanticipated failure modes. The hierarchy of yielding and failure of components is well established. However, construction practices are comparatively less mature than for either structural steel or reinforced concrete structures. For these reasons, a quality rating of good (B) is given to the design requirements for both C-SMFs and C-SCBFs.

Numerous tests on composite members, connections, and frames have been conducted and reported in the literature. The tests span most of the important parameters which affect design requirements and the behavior is generally well understood. For these reasons, a quality rating of good (B) is given to the test data for both C-SMFs and C-SCBFs.

The nonlinear models directly simulate all predominate inelastic effects and have been extensively validated against experimental results. The sets of archetype frames provide a reasonably broad representation of the design space. However, fracture is not included in the modeling and the frames were assumed to be properly designed to preclude connection deterioration and lateral torsional buckling. For these reasons, a quality rating of good (B) is given to the nonlinear modeling for both C-SMFs and C-SCBFs.

The quality ratings are assigned lognormal standard deviation parameters [Table 6, (FEMA 2009)] and the total system collapse uncertainty is computed with Equation 6 then rounded to the nearest 0.025. The value depends on the period based ductility but is constant for $\mu_T \geq 3$. For both systems the value of β_{total} for $\mu_T \geq 3$ is 0.525.

$$\beta_{total} = \sqrt{\beta_{RTR}^2 + \beta_{DR}^2 + \beta_{TD}^2 + \beta_{MDL}^2} \tag{6}$$

Table 6. Quality Ratings

System	Quality of Design Requirements	Quality of Test Data	Quality of Nonlinear Modeling
C-SMF	B (Good) $\beta_{DR} = 0.2$	B (Good) $\beta_{TD} = 0.2$	B (Good) $\beta_{MDL} = 0.2$
C-SCBF	B (Good) $\beta_{DR} = 0.2$	B (Good) $\beta_{TD} = 0.2$	B (Good) $\beta_{MDL} = 0.2$

For the C-SMFs, all of the evaluations pass and thus the current response modification factor is deemed acceptable. In fact, all frames pass by a significant margin. Many of the IDA curves retain a significant positive slope even at the high levels of earthquake ground motion used in this study (up to 5-7 times maximum considered earthquake intensity). This is indicative of the excellent performance of C-SMFs subjected to earthquake ground motions. For the C-SCBFs, all of the evaluations pass and thus the current response modification factor is deemed acceptable. The margin of passing is not as great as for the C-SMFs, nonetheless, the C-SCBFs exhibit excellent performance. It should be noted that these results are only strictly applicable to well designed and detailed frames where connection deterioration will not occur and sufficient lateral bracing is provided.

7.3 Deflection Amplification Factor, C_d

According to the methodology, for systems with typical levels of damping, including the systems studied here, the deflection amplification factor, C_d, is equal to the response modification factor (FEMA 2009). For C-SCBFs this represents a minor change as the current difference between R and C_d is small and there structures are typically not displacement controlled. For C-SMFs this represents a significant change. Setting $C_d = R$ results in a 45% increase in C_d from the current value. Additionally, C_d plays a central role in the design of moment frames since they are often displacement controlled.

In this study, four frames were designed with the current C_d value. These frames had smaller members than their counterparts designed with $C_d = R = 8.0$. Some differences in performance were noted. The average overstrength of the frames designed with the current C_d was 4.9 while it was 6.4 for their counterparts. The average adjusted collapse margin ratio of the frames designed with the current C_d was 5.5 while it was 6.2 for their counterparts. These results indicate that the frames designed with the current C_d value have acceptable performance and that setting $C_d = R$ for this system is unnecessary from a safety perspective.

All in all, further study is needed to determine the ramifications of setting $C_d = R$ and whether such a change is necessary. Further study should include the possibility of a corresponding increase in the deformation limits should the C_d factor increase,

8. CONCLUSIONS

A study was conducted following recommendations in FEMA P695 (2009) to determine the seismic performance factors (i.e., R, C_d, and Ω_o) for composite special moment frames (C-SMF) and composite special concentrically braced frames (C-SCBF). A suite of 60 archetype frames was selected and designed according to current design specifications. Nonlinear static pushover analyses and dynamic response history analyses were performed on the frames to characterize the behavior and generate statistical data to be used in evaluation of the seismic performance factors. Both systems exhibited excellent seismic behavior and current seismic performance factors were found to be acceptable. In particular, it was noted that frames designed with the current deflection amplification factor, C_d, were found to be acceptable and thus a potential change to set $C_d = R$ should be studied further and perhaps accompanied by a corresponding change to the drift limits such that future seismic drift requirements are equivalent to the current seismic drift requirements.

Abstract: Within the project Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru, one of the objectives is to know the most vulnerable areas in the event of a big earthquake. In Lima, the capital city of the Peru, for many years has become the destination of inhabitants of the interior of the country, which has led to use unsuitable terrain areas as for example the slopes of the hills. This disorderly development has caused that the cadastral maps are not updated and therefore the extension occupied by these populations cannot be quantified. This article presents the use and integration of two sources of satellite information for the determination of vulnerable areas in the city of Lima, high resolution optical satellite images and images from PRISM sensor, which allows getting the digital elevation model. With this integration, it is possible to delineate and evaluate the likely areas of urban concentration in areas of threat. Also it is carried out the integration with social information obtained from national census in order to determine the homes of people with low economic resources that occupy this type of land.

1. INTRODUCTION

It is well known that seismic activity in Peru is very high, due to its location in the circum-Pacific seismic belt, therefore, the evaluation of the building vulnerability it very important issue to prevent and mitigate the effects of an eventual occurrence of an earthquake. In Peru the development of cities is carry out, in many cases, without development planning projects, people from the countryside that comes to the capital city, looking for better live conditions, settles where they can, and this situation generates two big problems: first, they occupy land that are inadequate for construction of buildings, like soils with incompetent conditions as soils with low load capacity or they occupy the hillside surrounding the city. On the other hand, those peoples build their houses as they can, using low quality materials and without any technical direction. Therefore, these non-engineered buildings located in non-suitable locations, makes them very vulnerable structures in the case of an earthquake, thus their identification is very important for local authorities to make preparedness and mitigation plans.

Other problem to be faced is the lack of cadastral and topographic information that do not allow to make a building inventory and thus to evaluate the building seismic vulnerability (Estrada et. al., 2012). Therefore, it is necessary to use a technology that allows the identification of populated areas, especially those that are occupied on the hillside.

Additionally to the physical information, another type of data is the social one. The social information allows to know the economic situation of the building owner and thus to infer the quality and condition of the building.

In this paper it is proposed the use of PRISM sensor imagery to determine the location of those populated placed on hillsides and with the census data added to complement the study of the vulnerability.

2. PRESENT SITUATION

2.1 Study area

The study area is located in Lima, the capital city of Peru. Lima city is politically divided in 43 districts; one of them is Comas district. This district has a growing population of more of less half a million people, and the flat area of the district is already densely occupied, this is the reason that the hillsides are being populated rapidly, therefore the evaluation of these areas are necessary. Figure 1 shows the location of the study area. There it can be seen that the flat area is already populated and the growth of the city is towards the hills.

Figure 2, shows the conditions of the buildings built on the hillsides. It can be appreciated the informality of buildings and poor building practices, like building their houses on land fill, to accommodate to the topography of the land. This situation generates a highly risky area in case of

the occurrence of a severe earthquake.

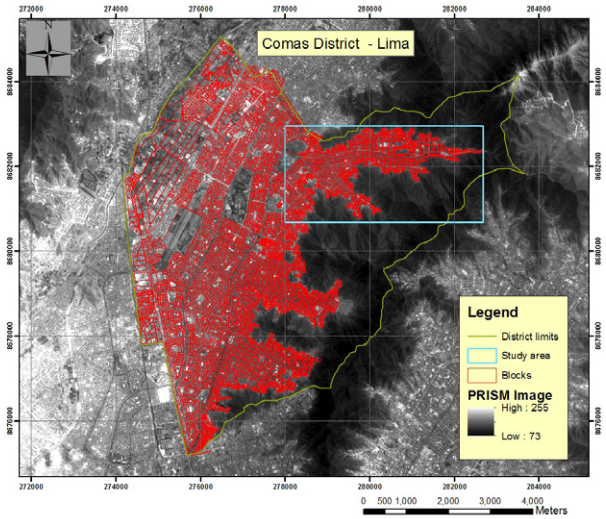

Figure 1 Map of the Comas District and selected study area.

Figure 2 Photograph of the condition of the buildings on the hillsides.

2.1 Cadastral Information

In 2007 the National Institute of Statistics and Informatics (INEI) carried out the National Census 2007: XI of population and VI of Housing (INEI, 2007). The information is aggregated in each block from where it is extracted the following information, within the study area, shown in Table 1:

Table 1. Census data of the study area.

Description	Value
Number of blocks	1016
Average number of houses per block	22
Total number of houses	14374
Total number of habitants	77900
Average Number of habitants per house	5.42

As it can be seen in Table 1, the density of habitants in each house is relativity high, this situation makes this area a highly risk one in case of a severe earthquake.

Besides of the population density, another important factor if the social class of the people. The social class is a good indicator of the quality of the building where the people live. It is obvious that well accommodated people lives in houses well constructed, while low income people construct their houses as they can and as they want, making these non-engineered buildings very vulnerable against seismic forces.

Information about social classes is shown in Table 2. As it can be seen mainly the population in this area is represented for low and middle low social class people, being almost 90% of the total number of blocks with information.

Table 2. Type of social class from census data.

Socioeconomic level	Number of blocks
Low	289
Middle low	474
Middle	82
Middle high	4
High	0
No Data	167

Another important parameter to evaluate the vulnerability of buildings is the material used in the construction. Table 3 shows the number of houses built with the different material used in this area:

Table 3. Type of social class from census data.

Material	Number of houses
Masonry	11200
Adobe	101
Wood	1979
Quincha (bamboo with wood frame)	17
Bamboo	446
Other/No Data	631

As it can be seen in this table, the main material used for construction is masonry, but even the masonry is a good material for construction the quality of the construction process is the problem, since the people built their houses by themselves, without any technical direction, these houses do not accomplish the requirements of national code, therefore their vulnerability is very high.

The presented tables show statistical values of the social condition of the people that live in this area. This is a high density populated area that is under developing with problems that make this area very vulnerable in case of an occurrence of an earthquake. Mainly there are two big problems the self-construction of the houses and the bad soil condition, as it can be seen in Figure 2. The topography of the area is very rugged and the uneven soil forces people to build their houses on landfill. Therefore, it is necessary to evaluate the topography of the area to determine the occupied land with important value of slope.

3. UMBRELLA PROJECT

This research is under the project "Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru". Generally speaking, the purpose of this project is to developed technologies and measures for prediction and mitigation of earthquake/tsunami disasters caused by large-magnitude inter-plate earthquakes occurring off the coast of Peru (Yamazaki et. al., 2012)

This project is divided into five active groups. Group 1, researches on seismology and geotechnical issues, and give the final response of the soils, like probable peak ground acceleration. Group 2, studies the source, effects and countermeasures of tsunamis produced by an earthquake, mainly the output is the travel time and high of the tsunami waves to evaluate the possible damage in the affected area. Group 3, identifies the most typical building problems and will propose retrofitting methods or will give some advises to improve the actual building code. Group 4, will develop methodologies to identify the land use, by using the satellite imagery and integrating all the information in a GIS platform to assess the risk of the building as well as to develop a methodology for fast assessment of the damaged area by an earthquake or tsunami. Finally, Group 5 will take the entire group's output and will disseminate this knowledge and propose policies for a sustainable development of the population. This project is under the support of Japan International Cooperation Agency (JICA), Japan Science and Technology Agency (JST) and Peruvian International Cooperation Agency (APCI). The institutions directly involved in this project are Chiba University, Tohoku University, Building Research Institute, Yokohama University, Tokyo Institute of Technology, Tsukuba University and Kyoto University, from the Japanese side and the Japan Peru Center for Earthquake Engineering Research and Disaster Mitigation (CISMID), Hydrograph National Direction (DHN), Geophysics Institute of Peruvian (IGP), Ministry of Construction, Housing and Sanitation, National Commission of Aerospace Research and Development (CONIDA), National Institution of Civil Defense and National Center of Assessment, Prevention and Mitigation of risk Disasters (CENEPRED).

Within this project is Group 4 who is in charge of developing methodologies to assess the vulnerability in Lima by using geo-informatics technologies.

4. SATELLITE IMAGERY INFORMATION

The original images come from the Panchromatic Remote Sensing Instrument for Stereo Mapping (PRISM) sensor that is one of the three sensors that are on board of the Advanced Land Observing Satellite (ALOS). The capability of this sensor to generate three dimensional models, comes from the simultaneous acquisition from three optical systems, as shown in Figure 3 (Pasco Corp. 2013). The general characteristics of this sensor are shown in Table **4**.

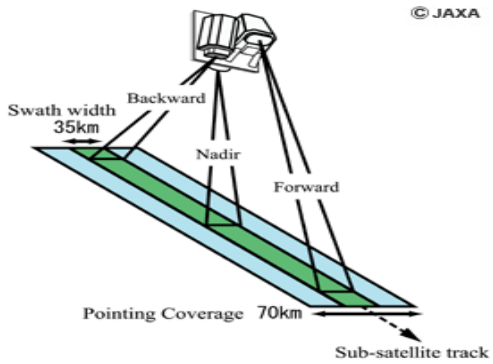

Figure 3 Schematic view of PRISM sensor, with three optical systems: nadir, forward and backward. Source: http://en.alos-pasco.com/common/images/prism2.gif

Table 4. Main characteristics of PRISM sensor.

Description	Value
Number of bans	1
Wavelength	0.52 – 0.77 µm
Number of optics	3: nadir, forward, backward
Ground resolution	2.5 m (nadir view)
Swath	70 km

Source: http://en.alos-pasco.com/alos/prism/index.html

The raw PRISM satellite images are processed to obtain two kinds of images: First the digital Surface Model (DSM) and the panchromatic image, as shown in Figure 4.

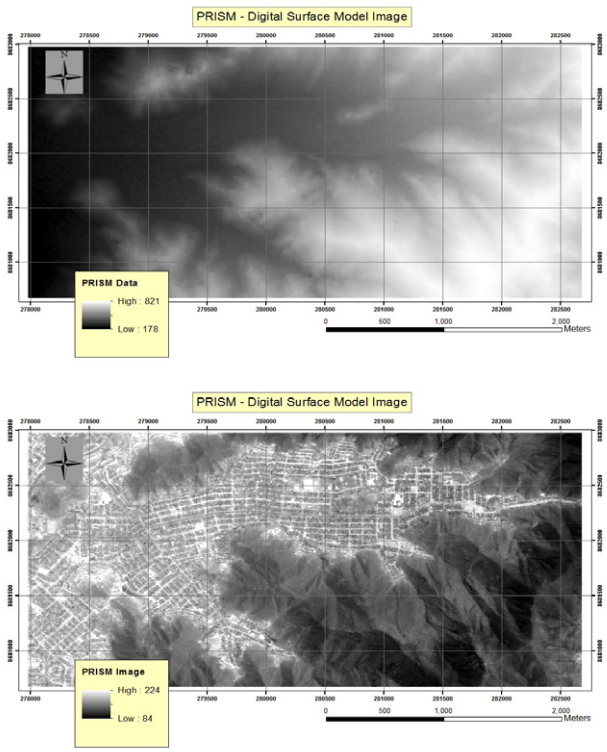

Figure 4 PRISM digital Surface Model and panchromatic image.

Since the cadastral information is not updated and since

the idea is to generate actual risk map it is used another type of optical satellite image, the WorldView-2. The characteristics of this image are shown in Table 5.

Table 5. Main characteristics of WorldView-2 sensor.

Description	Value
Number of bans (MS – P)	8 - 1
Wavelength	0.427 – 0.908µm MS, 0.632 µm P
Spatial resolution	2.0 m MS/0.5 m PAN
Swath	70 km
Acquisition date	10 April 2010

Source: https://www.digitalglobe.com/

The raw WorldView-2 image is pansharpened by using Gram-Schmidt Spectral Sharpening (ENVI program) to take advantage of the spectral information of the bands. Then this image is georeferenced to geographically match the block layer. The WorldView-2 image is shown in Figure 5.

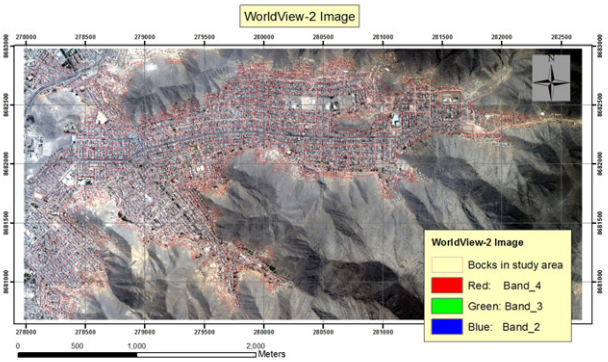

Figure 5 WorldView-2 pansharpened image integrated with blocks layer.

5. EVALUATION OF VULNERABLE AREAS

Once the images have been georeferenced with the block layer the next step is the integration of three sources of information: digital surface model, the high resolution image and the census data. Figure 6 shows the integration of these three sources:

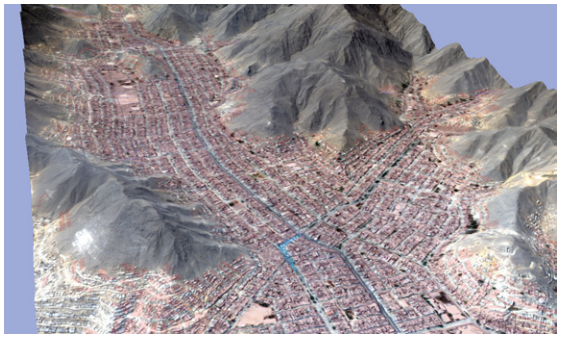

Figure 6 Integration of cadastral information, high resolution satellite image and digital surface model.

Next step is to calculate the percent of slope or gradient of the terrain in the study area. This is carried out by comparing the rate change of pixel values of the DSM image in the horizontal and vertical directions (ArcGIS Slope tool).

The result of the slope analysis is shown in Figure 7.

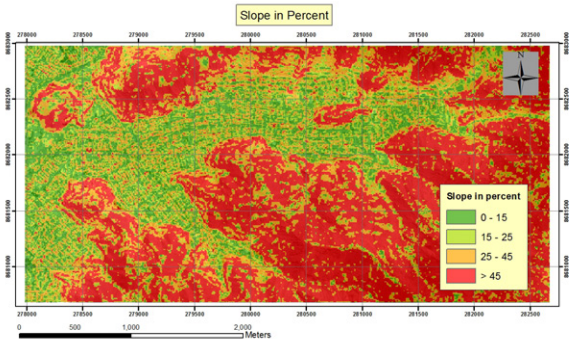

Figure 7 Slope map obtained from the DSM raster image.

Finally, this raster image that represents the slope is converted into point data, where the point value is the slope in percent. Then this point layer is aggregated into the block layer, given to each block an average of the slope. The map showing the slope in the block is shown in Figure 8.

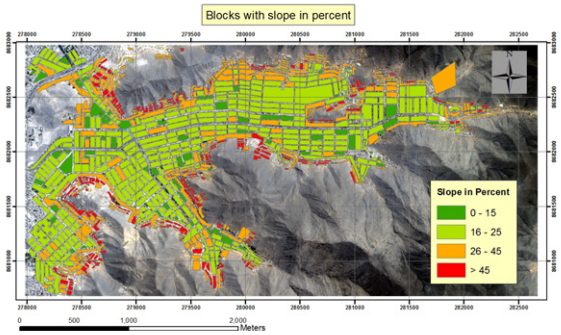

Figure 8 Percent slope integrated in the block layer.

As it can be seen those blocks that are on the hillside have been identify in red and orange color. Those blocks are settled in a land with an important slope that may produce slides in case of an earthquake and therefore people may be affected by this disaster.

6. CONCLUSIONS

The social vulnerability is very related with the social condition of the people.

It has been identified the location of low income people in the hillside that may produce a big loss in case of occurrence of an earthquake.

This proposed methodology may be used to make prevention plans to mitigate the effects of an earthquake.

Abstract: For the past decade, several efforts were made by different government and private institutions to develop vulnerability curves of key building types in the Philippines using empirical, heuristic, and/or computational methods. This paper presents the recent development of seismic vulnerability curves of buildings based on experts' opinion. A building typological system in terms of structural type and materials used in construction was proposed and a paper survey was conducted where experts input for different levels of earthquake intensity the damage ratio of each building type. Analyses revealed that there is a very low correlation between number of years of experience and the confidence level of the respondents. Results also show that the heuristic vulnerability curves of low- and mid-rise buildings are similar for both concrete and steel types. Moreover, seismic vulnerability of buildings, according to specialists, is dictated by the material used in construction rather than the number of floors of a building.

1. INTRODUCTION

The Philippines, because of its geographic location, has been the onslaught of natural hazards including earthquakes. According to the Philippine Institute of Volcanology and Seismology (PHIVOLCS), 90 destructive earthquakes have occurred in the Philippines from 1608 to 2002. The most recent destructive earthquake, the 1990 Luzon earthquake (M7.8), killed 1,283 people and caused an estimate of PhP 12.2 Billion on losses to human lives and properties (PHIVOLCS 2002). If a destructive earthquake is to happen again in the future, buildings and other structures are at risk and damage of these structures will definitely cause human lives, businesses and livelihood. According to the Metropolitan Manila Earthquake Impact Reduction Study (MMEIRS) by JICA, PHIVOLCS and MMDA, a magnitude 7.2 earthquake may hit the Marikina Valley Fault and this will affect Metro Manila (JICA 2004).

Part of the preparation of an earthquake disaster mitigation plan is the quantification of building vulnerability. A component of which is the development of seismic vulnerability curves that are used to predict the damage ratio of a particular building type for a given level of peak ground motion.

PHIVOLCS developed a software called Rapid Earthquake Damage Assessment System (REDAS) that aims to produce seismic hazard maps and seismic loss estimate maps minutes after the occurrence of a potentially damaging earthquake. PHIVOLCS-DOST is currently implementing a collaborative project with the Geoscience Australia (GA) and the University of the Philippines Diliman through the Institute of Civil Engineering (UPD-ICE) that aims to enhance the risk assessment capability of REDAS software. Building vulnerability functions and exposure data will be built in the software allowing users to assess the level of damage to building structures due to the occurrence of a potentially damaging earthquake.

Seismic vulnerability curves are used to describe the performance of a building type subjected to earthquake excitations in probabilistic terms. The main approaches in developing these curves are empirical, computational, and heuristic method. Post-earthquake data are the main source of empirical approach while computational approach utilizes computer simulations and analysis. Heuristic approach is conducted through collection of experts' opinion on structural response of buildings subjected to earthquake. Any combination of the aforementioned approaches is referred to as hybrid.

The vulnerability curve is a standard lognormal cumulative probability distribution function (Giovinazzi et.al. 2002, Saidi et.al., 2009, Pacheco et.al., 2012) of the form

$$DR[MMI] = \Phi\left[\frac{1}{\beta}\ln\left(\frac{MMI}{\mu}\right)\right] \quad (1)$$

Table 1. Key Building Types According to Structural Type, Material, Number of Floors and Year of Construction

Material	Type	Sub-type	Structural Type or Description	Year of Construction		
				Pre-1972	1972-1992	Post-1992
WOOD	W1*	W1-L	Wood frame with area ≤ 500 sq.m. (1-2		√	
	W3	W3-L	Bamboo (1-2 storeys)		√	
	N	N-L	Makeshift (1-2 storeys)		√	
MASONRY	CHB	CHB-L	Concrete hollow blocks (1-2 storeys)		√	
	URM*	URM-L	Unreinforced masonry (1-2 storeys)		√	
CONCRETE	C1*	C1-L	Concrete moment frame (1-2 storeys)		√	
		C1-M	Concrete moment frame (3-7 storeys)	√	√	√
STEEL	S1*	S1-L	Steel moment frame (1-2 storeys)	√	√	√
		S1-M	Steel moment frame (3-7 storeys)	√	√	√

* with similar counterpart model building archetypes in HAZUS-MH and FEMA-178.

where

$DR[MMI]$ is the damage ratio of a building type for the given MMI

Φ is the standard normal cumulative distribution function

β is the standard deviation of the natural logarithm of MMI which will be referred in this text as *uncertainty* or simply beta

μ as the *median* value of MMI

This paper presents vulnerability curves derived using the heuristic approach of low- to mid-rise buildings in the Philippines. A survey is conducted where participating engineers, herein referred to as *specialists*, decide on damage distributions of different structural types. The proposed heuristic approach is not susceptible to scarcity of data, as long as the specialists' experience could provide reasonable damage estimates.

1.1 Building Typology

Prior to developing vulnerability curves, a typological system for classifying/grouping existing buildings in terms of structural type, building materials used for construction, number of floors and year of construction must first be adopted. Table 1 lists the key buildings types considered in this paper with their respective descriptions. These types are the most common building types found in the country.

The codes attached to each sub-type in Table 1 denotes the height of the structure whether it is low-rise (L, 1-2 storeys), mid-rise (M, 3-7 storeys). Also included in the naming convention shown in the table are the vintages of the structures with respect to the year of publication of the different editions of the National Structural Code of the Philippines (NSCP). This classification is currently being used by UPD-ICE in the development of vulnerability functions (UPD-ICE, 2011).

2. METHODOLOGY

2.1 Survey of specialists' opinion

Paper surveys were conducted in two separate venues where a total of thirty-eight (38) specialists gather during a summit and a seminar. A survey form was distributed to gather information such as designation, specialization, and years of experience in addition to the damage ratios corresponding to five points in the vulnerability curve of a particular building type and their associated confidence level. In this paper, damage ratio is defined as the ratio of the cost of damage to the replacement cost of the building and finishes, on a scale of 0 to 1 (or 0 to 100%).

Survey forms revealed that the participating engineers specialize in design of low-rise reinforced concrete (RC) and steel structures with some indicating experience in high-rise buildings and few are affiliated with academic institutions. Number of years of experience varied from 1-2 years to 35 years.

2.2 Analysis and Filtering of Data

The first step was done to examine the responses of the specialist for purposes of filtering the available data. Sample responses are plotted (as damage ratio versus MMI) in Fig. 1. This figure implies that the respondents indicated the following relative vulnerability:

masonry < wood < concrete < steel

with buildings made of masonry being the most vulnerable, and steel types being most resilient to earthquakes. The figure also demonstrate the need to filer data such that a particular set of damage ratios for a building type should not be used when they are either incomplete or indicating a trend inconsistent with observed damage to past earthquakes (e.g., decreasing damage ratio as intensity increases).

2.2 Controlling Parameters

Specialization, numbers of years of experience, and confidence level are important fields that need to be specified in the survey. While most respondents indicated specialization in concrete and steel building types, their responses are considered for non-engineered types such as wood and masonry. The declared number of years of experience is assumed to be the same as the duration of the actual experience in the specified specialization even though some specialists may have indicated total number of years in the civil engineering profession. The confidence level (in percent) specified for each set of damage ratios of a given building type is a self-assessment which is influenced by

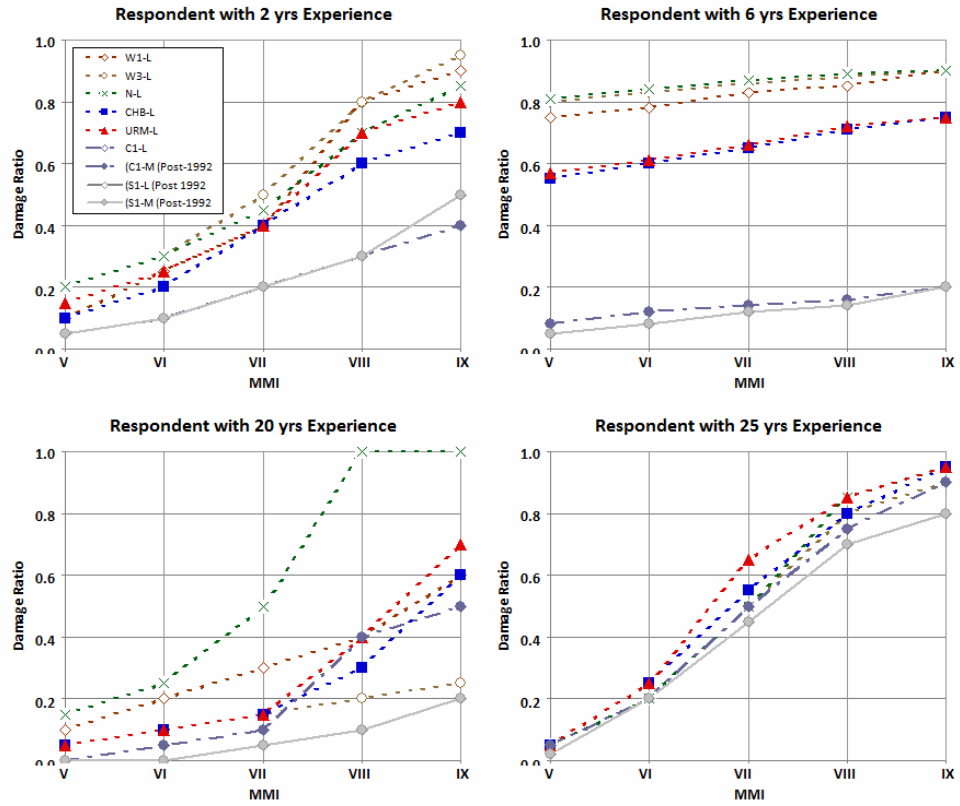

Figure 1. Assigned damage ratios of key building types to different earthquake intensities by specialists of varying number of years of experience

experience, expertise and many other personal factors. It is instructive, therefore, to see any correlation between number of years of experience and confidence level. The responses of 15 (out of 38) respondents in one survey showed that there is no apparent correlation between confidence level and number of years of experience. This is depicted in Fig. 2.

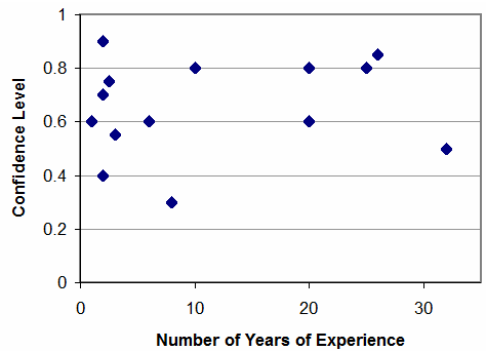

Figure 2. Confidence Level Versus Number of Years of Experience for C1-L.

Because of the subjectivity of the confidence level specified by specialists, the number of years of experience will be used as weights to the assigned damage ratios in developing the vulnerability curve of a specific building type. Table 2 lists the assigned weights for the indicated ranges of years of experience.

Table 2. Assigned Weights Associated with Number of Years of Experience

Years Experience	Weight
1-4	1
5-10	2
11-20	3
>20	4

2.3 Vulnerability Curve Development

For a given building type, the vulnerability curve is developed by first computing the weighted mean of responses for damage ratio using the number of years of experience and weights listed in Table 2 at the given ground motion intensities. The two parameters defining the lognormal vulnerability curve, median and uncertainty in Eq. (1), are then determined using curve fitting methods or choosing the parameters such that the coefficient of determination approach the value of 1, e.g., using Solver add-in in Microsoft Excel.

3. RESULTS AND DISCUSSIONS

Using the method discussed above, the vulnerability curve of W1-L is derived and shown in Fig. 3. The raw responses from the survey are plotted in this figure using gray circular markers and the corresponding median for

intensities IV to IX are shown as red diamond markers. The vulnerability curve fitted to these median points, shown as dotted black line, is a good representative curve for this type considering the large scatter of responses for each of the given intensity. The scatter such as damage ratio ranging from 10% to 100% at intensity VII, may be due to either i.) respondents specialize in concrete and/or steel building types or ii.) the performance of non-engineered houses to earthquakes are not known well by the specialist.

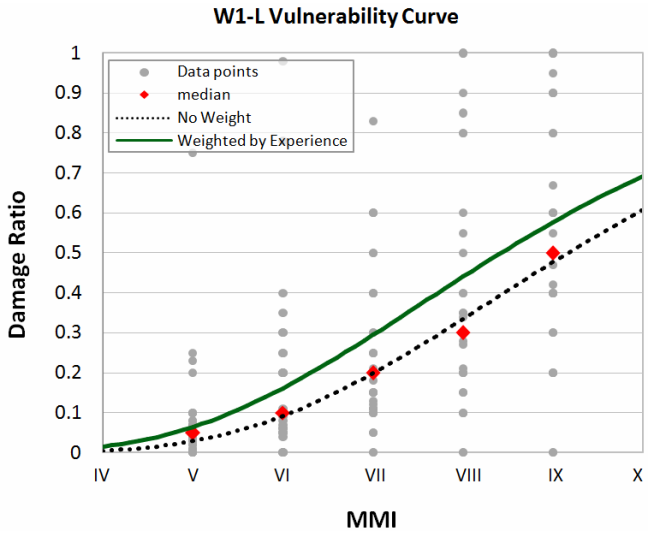

Figure 3. Sample Derivation of Vulnerability Curve of W1-L

The heuristic vulnerability curve of W1-L building type is shown in Fig. 3 as the solid green lognormal curve. With the responses weighted by number of years of experience, the curve shifted to the left (or above) of the curve fitted to the median responses. This implies that experienced engineers tend to classify buildings as being more vulnerable to earthquakes than young engineers. Similar trend was also observed in the other building types.

3.1 Vulnerability Curve of Non-engineered Types

The heuristic vulnerability curves of non-engineered building types made of wood (including W1-L) and masonry are shown with the lognormal parameters in Fig. 4. These curves were derived using survey responses weighted by number of years of experience even though similar trends were observed on the scatter of responses and the effect of taking into account experience.

As expected from the responses, the participating specialists appear to have difficulty differentiating earthquake vulnerability of different building types made of the same material resulting into almost similar curves for W1-L and W3-L as well as CHB and URM. As suggested by Fig. 4, makeshift buildings are as vulnerable as masonry building types. This may be due the fact that these buildings are either light or do not follow some kind of building code.

3.2 Vulnerability Curves of Key Concrete and Steel Building Types

The heuristic vulnerability curves of concrete and steel building types are shown in Fig. 5 with the lognormal parameters listed and derived from the responses weighted by number of years of experience. The responses were observed to have less scatter (although not shown in the figure) and the consistency may be due to the fact that the respondents specialize in these types. Moreover, similar to the case of wood and masonry buildings, the resulting vulnerability curves of low- and mid-rise buildings of the same material are similar, e.g., curves for C1-L and C1-M (high-code). This similarity implies that the specialists generally think that seismic vulnerability is dictated by the material used in construction rather than the number of floors of a building.

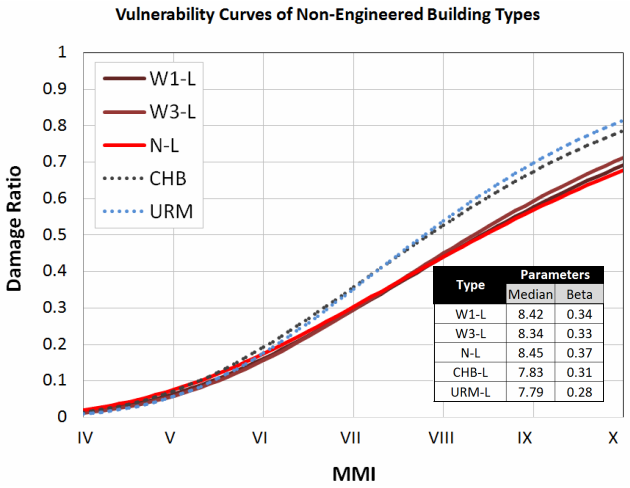

Figure 4. Heuristic Vulnerability Curves of W1-L, W3-L, N-L, CHB-L, and URM-L Building Types in the Philippines.

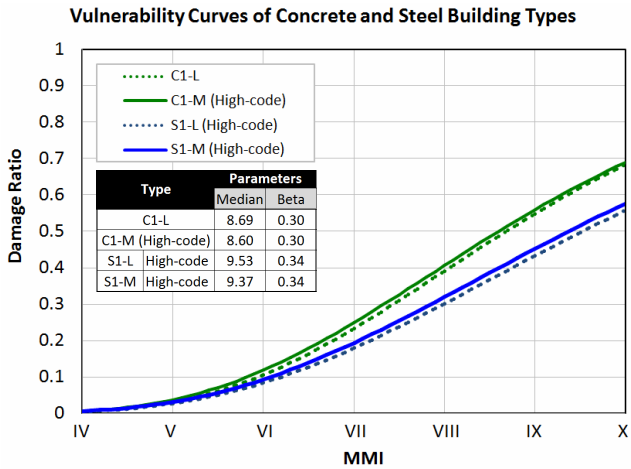

Figure 5. Heuristic Vulnerability Curves of C1-L, C1-M (High-code), S1-L (High-code), and C1-M (High-code) Building Types in the Philippines.

3.3 Comparison with Available Empirical and Computational Vulnerability Curves

In a parallel development, vulnerability curves of concrete and steel buildings types were developed using the

computational approach utilizing the Capacity Spectrum Method (UPD-ICE, 2011 and Pacheco, et.al., 2011). For non-engineered buildings, specifically CHB, empirical vulnerability curves was also developed (UPD-ICE, 2012). Fig. 6 and 7 show the comparison of the proposed heuristic vulnerability curves with the curves derived using the computational and empirical approaches. The trends discussed in the preceding sections suggest that we consider only one heuristic vulnerability curve for each of the material used, e.g., one curve for C1 concrete buildings and another curve for S1 steel buildings irregardless of number of floors as shown in Fig. 6. Similarly, three sets of heuristic vulnerability curves should be used for non-engineered types - one for each wood (W1-L and W3-L), masonry (CHB and URM), and makeshift (N) buildings.

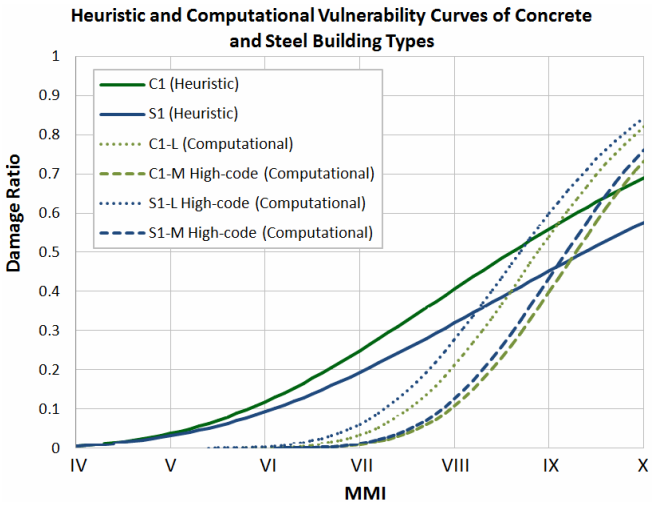

Figure 6. Comparison of Heuristic and Computational Vulnerability Curves of Concrete and Steel Building Types in the Philippines.

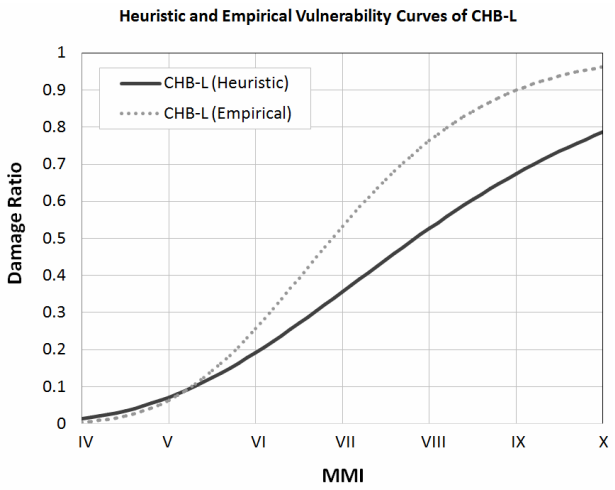

Figure 7. Comparison of Heuristic and Empirical Vulnerability Curves of CHB Building Type in the Philippines.

We acknowledge the need to review the three approaches and the resulting vulnerability curves, we factually present and compare the curves as in Fig. 6 and 7. And since the curves shown vary significantly and are considered to have equal confidence, we therefore suspend recommendation of the best set of curves and suggest that risk analysis be performed using all available curves. Furthermore, we recognize that these functions require an iterative approach so that the vulnerability functions derived using the three methods are similar or cross-validate one another.

4. CONCLUDING REMARKS

Seismic vulnerability curves of key building types in the Philippines were derived in this paper using heuristic method. Prior to the development, a typological system for classifying/grouping existing buildings was adopted. Then a survey of practicing engineers, with varying expertise and experience, was conducted in order to estimate the amount of damage in the event of a destructive earthquake.

Analyses revealed that there is a very low correlation between number of years of experience and the confidence level of the respondents. Results also showed that experienced engineers tend to classify buildings as being more vulnerable to earthquakes than young engineers. The heuristic vulnerability curves of low- and mid-rise buildings are found to be similar for both concrete and steel types. Similarly, the vulnerability curves of wood building types (W1-L and W3-L) are similar as well as masonry building types (CHB and URM). Makeshift buildings, according to experts, are as vulnerable to earthquakes as masonry buildings.

The vulnerability curves presented in this paper are the first generation of building heuristic vulnerability curves developed for the Philippines by Philippine engineers. Consequently, it is acknowledged that these functions will continue to evolve as the knowledge of the behaviour of Philippine buildings in response to ground shaking is better understood.

TRANSPARENT GLOBAL EARTHQUAKE RISK AND LOSS ESTIMATION

Kit Miyamoto[1)] and Nicole Keller[2)]

1) Founder and CEO, Miyamoto International, Sacramento, CA USA
2) Head of Communications and International Relations, GEM Foundation, Pavia, Italy

Abstract: Global Earthquake Model (GEM) is a unique collaborative effort that will provide organizations and engineers with tools and resources for transparent assessment of earthquake risk anywhere in the world. By pooling data, knowledge and people, GEM acts as an international forum for collaboration and exchange, and leverages the knowledge of leading experts for the benefit of society. When GEM's OpenQuake platform and tools are released, the engineering community will be able to calculate earthquake risk to a common standard worldwide. By participating in GEM development, the community can contribute to making the tools ever-more valuable for loss assessment of their (local) projects.

1. INTRODUCTION

This paper presents an overview of the Global Earthquake Model (GEM) with particular emphasis on how GEM will integrate with the earthquake engineering community worldwide.

2. MOTIVATION

Vulnerability to earthquakes is increasing, yet advanced, reliable risk assessment tools and data, a critical basis for managing that risk, are inaccessible to most. Even where earthquake risk information is available, it often lacks clear communication for practical applicability. Also, there is a lack of global standards to compare risk between locations. Sharing of data and risk information, best practices, and approaches across the globe is key to assessing risk more effectively.

3. STRUCTURED FOR COLLABORATION

GEM combines the strengths of the public and private sector in a continuously expanding partnership, deliberately structured to promote collaboration across sectors.

GEM is organized loosely in five main categories of participants:

The *GEM Secretariat*, located in Pavia, Italy, coordinates across GEM activities worldwide. The Model Facility within the Secretariat implements GEM tools and software, including GEM's main software platform, OpenQuake (described further below).

The *Scientific Community* engages by means of global projects, carried out by international consortia featuring renowned experts and organisations that develop global datasets and methodologies in the domains of hazard, exposure, physical (building) vulnerability, and socio-economic resilience.

Regional Initiatives work on data collection, create regional input models, provide feedback on global projects and connect GEM data and output for implementation and capacity-building in regional and local contexts.

- GEM's open-source modeling software - OpenQuake Engine - is being used in the nearly completed SHARE[1] project aimed to produce harmonized hazard maps for Europe
- GEM recently hosted a workshop to share best practices in calculating and communicating seismic hazard in sub-saharan African nations.

Sponsors, further comprised of public/national agencies and private organizations, provide guidance by way of seats on the GEM Governing Board.

The *Broader Community*, including the engineering community and other potential users of GEM products, currently participate in GEM by:

- sharing knowledge and best practices,
- contributing data such as building typology and inventory,
- test tools as they become available
- provide feedback, and
- follow GEM progress

From 2014 onwards, all these groups and many more stakeholders will additionally become users of

[1] Seismic Hazard Harmonization in Europe (http://www.share-eu.org/)

the OpenQuake Platform and GEM products, working together toward collaborative enhancement.

4. WORKING TOGETHER TO ASSESS RISK

GEM's first working programme (2009-2014) focuses on building a global framework; a basis that can then drive further development from global to local. This is envisaged as follows:

Global: GEM groups are developing tools and standardised methods for obtaining and analysing data, and these are being used to begin the process of assembling the needed (global, uniform) datasets. The result is advanced data coverage for the world which is much more uniform and complete than before.

Regional: At the same time, through regional, national and local collaboration, the global datasets are scrutinized, data, models and knowledge are being integrated to make the platform and tools ever more useful for application at local scales.

Organisations/Individuals: From the end of 2014, stakeholders across the globe will be able to access state-of-the-art, widely accepted datasets, models and (open-source) software tools through GEM's risk assessment platform (OpenQuake), allowing them not only to perform hazard and risk analyses, but also to make decisions on retrofitting and insurance and collaborate and exchange data, results and opinions amongst each other.

OpenQuake is being built in a dynamic and flexible way, so that it can capture the world's best understanding of data, the earth and earthquake behaviour, and the built environment at any given moment in the future. The user community that will hence grow around the platform will enrich and continuously enhance the datasets, tools and methodologies, for transparent and more effective hazard and risk assessment, from global to local.

GEM will actively support that community through training, dedicated resources and outreach, facilitating true global collaboration as basis for transparent and effective risk management.

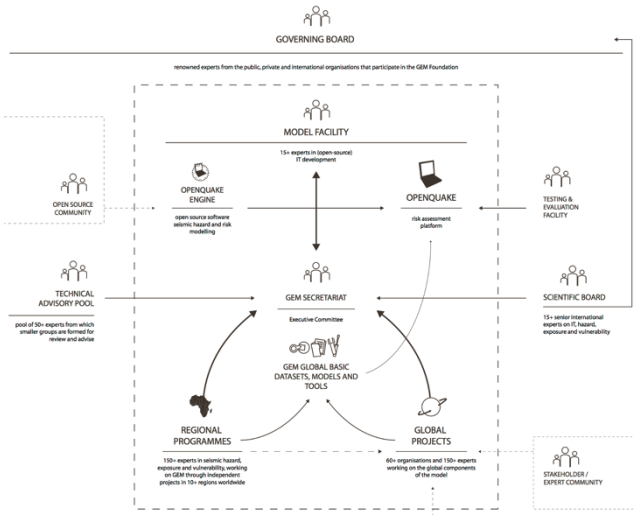

Figure 1: Collaboration among GEM Participants

5. LIMITATIONS.

GEM's first programme will not incorporate all possible data available, nor cover all countries in the world in a uniform way. Limitations include secondary hazards such as tsunamis and landslides, as well as integration of infrastructure as part of exposure modeling. These exclusions are envisaged for future versions.

6. GEM PRODUCTS

Building on collective efforts and knowledge of scientists worldwide, GEM will hence for the first time integrate state-of-the-art data, models, results and open-source tools into a single platform that is to serve as a clearing house for earthquake risk information.

6.1 Global Components

The global data, models and methodologies that serve as input to GEM risk assessment derives from contracted projects in the domains of hazard, exposure, physical (building) vulnerability, and social resilience:

Models:

- Seismic Source Models
- Ground Motion (Attenuation) Models
- Physical Exposure Models
- Physical Vulnerability Models
- Composite Index Models (social vulnerability, resilience, indirect loss)

Datasets:

- Global Earthquake History Catalogue
- Global Instrumental Catalogue
- Global Geodetic Strain Rates
- Global Active Fault Database
- Tectonic Regionalisation
- Buildings and Population Databases
- Earthquake Consequences Databases
- Physical Vulnerability Databases
- Socio-Economic Vulnerability and Resilience Indicators

6.2 OpenQuake

An integrated and holistic approach to risk is key to GEM's platform, OpenQuake, which has three main functions:

Calculate The OpenQuake platform integrates open-source applications with homogenized data and models, allowing users to model seismic hazard and risk transparently and according to the latest science. From ground motion fields to hazard spectra to maps of estimated human loss and mean economic loss; users will be able to produce a great variety of custom outputs by combining own data and (local) knowledge with GEM products. A simulation engine (the OpenQuake Engine) is the core of calculating risk metrics.

Explore and Decide The platform leverages upon open-source geospatial technologies to allow users to work in an intuitive GIS-environment. Users can explore earthquake hazard and risk by interacting with dynamic maps, indicators and graphs, develop their own maps, but also capture and integrate new data. To help users understand risk better and to facilitate risk management, decision support tools are integral to the platform.

Share Sharing of data and risk information, best practice and approaches is key to assessing risk better. The platform is to serve as a clearinghouse for all those critical in- and outputs. It will link users from around the globe so they can work together to assess risk.

With OpenQuake, homogenized information on hazard can be combined with data on exposure (buildings, population) and their vulnerability, for loss assessment around the globe. For a true integrated view on the probability of loss and the costs and benefits of different risk management measures, users can add socio-economic information to maps and estimates of 'physical' risk.

6.3 Built for Decisions

Functionality being built into the OpenQuake platform is designed specifically for direct applicability to risk-reducing decisions. Pre-computed results will include:

- *Hazard Maps*: For example, GEM has already been used to produce a hazard map for the nation of Ecuador, for which no prior nationwide hazard map had existed.
- *Hazard Curves*: probabilistic hazard for a specific site, used to estimate probabilities of shaking
- *Stochastic Event Sets*: Full suites of hypothetical earthquakes that could affect a given region
- *Risk Maps*: Both probabilistic and scenario-based. For example, distribution of damage severity; distribution of monetary losses; distribution of deaths;
- *Event Losses*: Scenario estimates of damage, monetary loss, or social factors, whether for single sites or groups of sites, or entire regions
- *Loss Metrics*: Including average annual losses, and losses related to a specific probabilities of exceedance, both total and insured, whether for a single site or correlated for a portfolio
- *Retrofit Cost-Benefit Calculator*: Based on losses with and without improved seismic resistance
- *Uniform Hazard Spectra*: For engineering design of buildings to a consistent basis.

7. REAL-WORLD APPLICATION

The design of GEM functionality is based on several primary anticipated users with associated use cases.

As an example, as an associate partner of GEM, the California Seismic Safety Commission (CSSC) is investigating potential opportunities to collaborate with GEM and use OpenQuake tools to generate transparent risk information and economic loss estimation for California.

GEM tools will have applicability related to science and engineering, insurance and risk transfer, and particularly policy making, such as urban (land use) planning and building code enforcement. They can be used at the global, national and local scale.

Various city scenarios are part of GEM's development phase, to develop best practice at urban level for risk assessment. In the Middle East there are 6 cities being assessed according to GEM methodology and tools, and city indices will be

developed in the Asia-Pacific region for socio-economic vulnerability and resilience of communities to earthquakes.

8. INTEGRATION OF GEM WITH THE ENGINEERING COMMUNITY

When the GEM platform and tools are released (late 2014), the engineering community will have open access to GEM tools for calculating earthquake risk to a common standard worldwide. Use of GEM for commercial purposes will be subject to license fees, on a sliding scale based on annual revenues of the organization.

By participating now in GEM development, the community can contribute to making the tools ever-more valuable for loss assessment of their (local) projects. Participation consists of sharing knowledge and best practices, contributing data such as building typology and inventory, testing tools as they become available and providing feedback, and following GEM progress.

Figure 3: Various typical outputs of the OpenQuake engine (a) a stochastic event set, (b) a ground-motion field with spatial correlation of ground-motion residuals, (c) a seismic hazard map with 10% probability of exceedance in 50 years, (d) a loss map in terms of fatalities with 10% probability of exceedance in 50 years

9. SUMMARY

Building on many ongoing efforts and the knowledge of scientists worldwide, GEM will for the first time integrate state-of-the-art data, models, results and open-source tools into a single platform that is to serve as a clearing house.

By participating in the effort, the engineering community, and in particular private sector representatives, can leverage the platform and its tools and contribute to making them ever-more valuable for loss assessment of their (local) projects.

METHODOLOGY FOR LIFE CYCLE COST ASSESSMENT OF SELF-CENTERING CONCENTRICALLY BRACED FRAME SYSTEMS

David A. Roke[1], Akhilesh Chandra[2], Qindan Huang[1], and Kallol Sett[1]

1) Assistant Professor, Department of Civil Engineering, The University of Akron, USA
2) Professor, G.W. Daverio School of Accountancy, The University of Akron, USA
roke@uakron.edu, ac10@uakron.edu, qhuang@uakron.edu, sett@uakron.edu

Abstract: Conventional concentrically braced frame (CBF) systems are designed to achieve life safety (LS) performance under the design basis earthquake (DBE). However, the damage state at LS performance often results in residual drift and non-structural damage, causing high post-earthquake repair costs. Recently developed self-centering concentrically braced frame (SC-CBF) systems can achieve damage-free performance under the DBE, eliminating residual drift and thus significantly reducing post-earthquake costs. A four-stage performance assessment framework will be used to probabilistically determine the life cycle costs of structural systems. The four stages of the performance assessment framework are: (1) hazard analysis, (2) seismic fragility assessment, (3) damage analysis, and (4) loss assessment. These stages address different sources of uncertainty, including uncertainties in the ground motion, the structural response under a ground motion of a given intensity, the degree of damage given a certain structural performance defined by seismic fragility, and the direct and indirect costs associated with specific damage states. This paper discusses the interdisciplinary methodology being used to apply this performance assessment framework to estimate and compare the life cycle costs of SC-CBF systems and conventional CBF systems. Ultimately, this research will lead to recommendations regarding the implementation and benefit of advanced structural systems.

1. INTRODUCTION

Conventional concentrically braced frame (CBF) systems are commonly used in seismic areas due to their strength, stiffness, and economy. However, conventional design methodology allows for significant structural (and nonstructural) damage under the design basis earthquake (DBE), provided the structure performs adequately to protect the lives of its occupants. This damage may lead to significant residual drift, necessitating costly repairs or demolition.

To address this shortcoming of conventional CBF systems, self-centering CBFs (SC-CBFs) have been developed that are intended to achieve damage-free performance under the DBE (Roke et al. 2006). SC-CBFs are expected to have greater construction costs than conventional CBFs. The premise is that the post-earthquake damage to SC-CBF systems should be less than that to conventional CBF systems, leading to a tradeoff between construction costs and maintenance and repair costs. Ultimately, this tradeoff must be evaluated to determine whether SC-CBF systems are worth the extra up-front cost.

To that end, a performance-based assessment will be used to probabilistically determine the life cycle cost (LCC) of conventional CBF systems and SC-CBF systems. A comparison of the LCCs of the two systems will determine if the benefits of SC-CBF systems outweigh the costs.

This paper presents the methodology that will be used to assess and compare LCCs of CBF and SC-CBF systems. The ultimate goal of this research is to develop recommendations for the implementation of SC-CBF systems, based on the expected reduction in LCC with respect to conventional CBF systems.

2. ASSESSMENT FRAMEWORK

A framework for probabilistically assessing the seismic performance of a structural system was developed by Moehle and Deierlein (2004). This framework consists of four analysis steps, as indicated in Figure 1: (1) hazard analysis, (2) seismic fragility assessment, (3) damage analysis, and (4) loss analysis. This research will address each of the four analysis steps in a comprehensive approach to determine the life cycle cost of SC-CBF systems.

2.1 Hazard Analysis

The hazard analysis step is used to obtain probabilistic ground motion time histories for seismic fragility assessment of the system under evaluation. This research will analyze the ground motion hazard at a site in the Los Angeles basin, considering modeling uncertainty and uncertainties associated with source (fault), path (rock) and site (soil) parameters. A set of

scenario bedrock motion time histories will be generated through probabilistic seismic hazard analysis, followed by probabilistic site response analysis to obtain representative site-specific ground motion time histories. The hazard analysis step is schematically depicted in Figure 2.We will start by identifying a set of future scenario earthquakes, originating from nearby faults, that may cause damage to the SC-CBF system under evaluation. The next step will be to probabilistically estimate the severity of bedrock shaking (e.g., response spectrum, peak bedrock acceleration, and duration of shaking) using appropriate attenuation models for each scenario earthquake. We will use the regression equations proposed by Abrahamson and Silva (2008) to compute the response spectrum and peak bedrock acceleration and the empirical model proposed by Kempton and Stewart (2006) to compute the duration of shaking. Note that the above models implicitly account for the modeling and source and path parameter uncertainties, and provide estimates of the severity of shaking parameters in terms of their respective mean and standard deviation.

Thus estimated probabilistic response spectrum, peak bedrock acceleration, and duration of shaking will be used to generate a suite of synthetic bedrock motion time histories. A FORTRAN program, SIMQKE, developed by Gasparini and Vanmarcke (1976) will be employed to this end. SIMQKE first uses a pre-defined envelope function in conjunction with the user-defined peak bedrock acceleration to simulate transient characteristics of real earthquakes, which are then used to smooth a spectral density function computed using the user-defined duration of shaking and response spectrum information. However, note that in our case, the SIMQKE input parameters are probabilistic in nature. Hence, they will first be randomized using their respective means and standard deviations; the SIMQKE code will then be run in a Monte Carlo (Metropolis and Ulam 1949) fashion.

To account for hazards associated with the uncertainty and nonlinearity of the soil properties at the site, probabilistic site response analysis will be performed with the above generated suite of (probabilistic) bedrock motions and site-specific soil data. To this end, following DeGroot and Baecher (1993), the site-specific soil data will be statistically analyzed to quantify the uncertain spatial variability and testing uncertainty associated with the soil properties and to model the soil properties as one-dimensional random fields. The random field parameters (mean, variance and correlation structure) of the soil properties will be used to generate realizations of the soil properties in the deposit. Using the OpenSees software (Mazzoni et al. 2009), the suite of bedrock motions will be numerically propagated through the deposit within a Monte Carlo (Metropolis and Ulam 1949) framework to obtain a suite of surface motion time histories. An appropriate elastic-plastic soil constitutive model will be used to capture the soil nonlinearities as the soils plastify.

2.2 Seismic Fragility Assessment

The seismic fragility assessment step is used to quantify the probabilistic structural response. For this research, the structural response will be generated analytically using numerical models developed using OpenSees (Mazzoni et al. 2009).

The SC-CBF numerical models are intended to capture the rocking behavior of the SC-CBF systems, which softens the lateral force-lateral drift response without damaging the structural members (Roke et al. 2006). The numerical models used in this study will capture three types of nonlinearity: (1) column base gap opening, which permits the rocking behavior of the SC-CBF system; (2) yielding of the vertically oriented post-tensioning bars, which determines the maximum overturning moment resistance of the SC-CBF system; and (3) member yielding, which should have a low probability of occurrence due to the design of the SC-CBF systems (Roke et al. 2010).

Seismic fragility is defined as the conditional probability that a demand quantity of interest attains or exceeds a specified capacity level for given values of earthquake intensity measures. The data obtained from the numerical models will be used to develop probabilistic capacity and demand models and to develop seismic fragility curves. Seismic fragility, expressed via a fragility curve, is a critical component in performance-based assessment, providing valuable information for evaluating probabilistic structural damage states and assessing regional risk related to seismic hazards.

Following the conventional notation in structural reliability (Ditlevsen and Madsen 1996), seismic fragility can be expressed as:

$$F\left(\mathbf{x},\boldsymbol{\Theta}\middle|\mathbf{IM}\right)=P\left\{\bigcup_{k}\left[g_k\left(\mathbf{x},\boldsymbol{\Theta}_k\right)\right]\middle|\mathbf{IM}\right\} \quad (1)$$

where $\boldsymbol{\Theta} = \{\boldsymbol{\Theta}_k\}$, $[g_k(\mathbf{x}|\boldsymbol{\Theta}_k) \le 0]$ is a failure event of the structure in the kth failure mode, $g_k(\mathbf{x},\boldsymbol{\Theta}_k) = C_k(\mathbf{x},\boldsymbol{\Theta}_{C,k}) - D_k(\mathbf{x},\boldsymbol{\Theta}_{D,k})$ is the limit state function for the kth failure mode, $\mathbf{x}$ is a vector of basic variables (e.g., structural properties and boundary conditions), C_k is the probabilistic capacity, D_k is the probabilistic demand, and $\boldsymbol{\Theta}_k = \{\boldsymbol{\Theta}_{C,k}, \boldsymbol{\Theta}_{D,k}\}$ are the model parameters in the capacity and demand models, respectively. In this research, we will consider failure (defined as demand exceeding capacity) with respect to the limit states of PT bar yielding, member yielding, and member failure.

The proposed capacity and demand models will be developed based on the probabilistic capacity models proposed by Gardoni et al. (2002) and the probabilistic demand models proposed by Huang et al. (2010). The models will account for the prevailing uncertainties, including model error arising from potential inaccuracies in the model form and potentially missing variables, as well as measurement errors and statistical uncertainties. The capacity and demand models are developed by adding correction terms to currently-used deterministic capacity and demand models for SC-CBF systems, respectively, to account for the inherent bias and uncertainty in the models.

2.3 Damage Analysis

Damage analysis relates structural fragility to damage states, which are used to quantify the damage to the structural elements, nonstructural elements, and

building contents; this quantification is necessary for assessing losses. Damage states of structures can be characterized by damage measures, including but not limited to permanent displacement, maximum inter-story drift ratio, energy dissipation capacity, and ductility demand (Gunturi and Shah 1992, Park and Ang 1985).

The performance levels that will be considered in this study for developing fragility curves are immediate occupancy (IO), life safety (LS), and collapse prevention (CP). In order to relate damage states to the structural performance levels, we will adopt the damage states defined by Bai et al. (2009), where the damage state classification is defined by the IO, LS, and CP performance levels. Bai et al. (2009) define four damage states: insignificant (I), moderate (M), heavy (H), and complete (C). Figure 3 can be used to define a possible relationship between the performance levels and damage states (Yang et al. 2009, Bai et al. 2009). In Figure 3, PI|IM, PM|IM, PH|IM, and PC|IM refer to the conditional probability of the structure achieving each damage state (I, M, H, and C, respectively). P_{IO}, P_{LS}, and P_{CP} represent the conditional probability of reaching each performance level (IO, LS, and CP, respectively), and can be determined based on the fragility curves. The differences between the conditional probabilities (PM|IM, PH|IM, and PC|IM) define the probabilities of achieving specific damage states.

The losses associated with nonstructural components may outweigh the losses associated with structural components; therefore, the performance of nonstructural components must be considered. Fragility curves for the nonstructural components can be obtained from previous research (e.g., Krawinkler (2005) and ATC (2007) developed fragility curves for specific non-structural elements).

2.4 Loss Analysis

A useful metric to assess relative performance of structural systems is the life cycle cost (LCC) of the competing systems. Broadly, LCC includes construction costs, maintenance costs, and post-earthquake induced costs. Of these three cost types, post-earthquake induced costs are the most difficult to estimate and have consistently challenged economic analysts. The challenge stems from the probabilistic and uncertain nature of these costs, most of which are intangible and are therefore not directly measurable.

Using the total probability theorem, we will use the following formulation to derive the LCC for CBF and SC-CBF systems:

$$E\left(LCC_{\phi}\right) = \sum_{i=1,4} E\left(\kappa_{\phi,t}\right) \tag{2}$$

where ϕ is a vector of variables that impact the robustness of buildings (e.g., material properties and maintenance schedules). Cost-type is indicated by κ and is linked with subscript i that takes values from 1 to 4 to denote (1) initial construction cost, (2) maintenance costs, (3) inspection cost, and (4) post-earthquake induced cost. Estimation time is denoted by t ($0 \le t \le 4$) to reflect a four period analysis; $t = 0$ indicates current cost and pertains primarily to initial construction cost; all other costs are incurred probabilistically and conditionally in future. Future costs ($t \ge 0$) are converted into their present values using the net present value (NPV) approach that considers an appropriate discount rate.

The post-earthquake induced costs ($\kappa = 4$ in Eq. (2)) include both direct and indirect losses. Direct loss is immediate and easier to measure. Indirect losses extend into the future and are difficult to measure; therefore, they must be approximated. The degree of precision of such approximations usually declines as a function of estimation period. Since each entity can have varying economic post-earthquake loss, we will utilize Eq. (3) to derive entity-specific indirect costs:

$$K = \sum_{f} \left(1 - \alpha_{f,t}\right) \cdot d_{f,t} \cdot \theta_{f,t} \tag{3}$$

where K indicates indirect costs for entity f for period t that ranges from 1 to 4 for a four period impact analysis. Each entity's shock absorbing capacity at time t is denoted by α so that a value of 0.6 reflects a 40% loss in the entity's operating capacity and revenues (on the assumption of a direct correlation between revenues and operating capacity). The extent of post-earthquake damage is indicated by d and is computed in the damage analysis step described earlier in the paper. The relative economic value of entity f is approximated by θ and is derived as a product of the percentage of the economic value shared by the entity with respect to the total economic value provided by all entities in the building; in this sense, θ approximates the maximum post-earthquake loss the entity can suffer.

The shock absorbing capacity is a function of each entity's contingency plans for addressing and mitigating damage from post-earthquake shocks. The expression $(1-\alpha_{f,t})\cdot d_{f,t}$ in Eq. (3) approximates the loss function corresponding to the indirect cost for entity f. Aside from the structural uncertainties, uncertainties associated with entity-specific variables (e.g., risk management policies and human resources management) moderate the nature of the loss function. For the set of entities in the building, the loss function is a density function with an expected mean and standard deviation.

The indirect loss K in post-earthquake shock is aggregated with the direct loss of each entity to estimate the total loss for that entity. The total loss of all entities in the building is aggregated to estimate the post-earthquake induced cost for the building.

The estimation of indirect losses as specified above necessitates several assumptions in view of the uncertainties. By changing the values of those assumptions, we can assess the impact of each on indirect costs and the LCC.

3. SUMMARY

This research will provide a comprehensive probabilistic evaluation of the life cycle cost (LCC) of SC-CBF systems by following the four phases of an earthquake performance assessment framework: (1)

hazard analysis, (2) seismic fragility assessment, (3) damage analysis, and (4) loss analysis.

This paper presents the methodology that will be used to incorporate various uncertainties into each step of the assessment framework. Addressing the uncertainties in each step of the framework will create a very complete picture of the LCCs of both CBF and SC-CBF systems.

The ultimate goal of this research is to assess if the superior performance of SC-CBF systems is worth the increased cost over conventional CBF systems. Comparing the probabilistic LCC of the two competing systems will provide evidence for the effectiveness of SC-CBF systems and lead to recommendations regarding their use.

FRAGILITY CURVES FOR REINFORCED CONCRETE BUILDINGS TO EARTHQUAKE-INDUCED SLOPE DISPLACEMENTS

Stavroula D. Fotopoulou[1)], Kyriazis D. Pitilakis[2)]

1) Post-Doctorate Researcher, Dept. of Civil Engineering, Aristotle University of Thessaloniki, Greece
2) Professor, Dept. of Civil Engineering, Aristotle University of Thessaloniki, Greece

Abstract: An abacus of probabilistic fragility functions has been developed for low-rise, reinforced concrete (RC) buildings subjected to earthquake triggered slow-moving slides, applying a recently published methodology by the same authors (Fotopoulou and Pitilakis 2012). In particular, the method is based a two-step numerical approach, namely a slope-foundation dynamic and a structure's quasi-static analysis, to assess the expected building's distress and damage to earthquake-induced landslide displacements. We perform an extensive numerical parametric study considering different idealized slope configurations, soil and geological settings, as well as distances of the structure to the slope's crest. The effect of the various analyzed features on the structural performance is investigated, highlighting trends on the building's behavior to the permanent co-seismic slope deformations. Generalized fragility curves as a function of outcrop peak ground acceleration or the induced permanent slope ground displacements are then suggested based on the most influential parameters to the structure's vulnerability. The proposed curves, which are adequately validated with existing data, can be efficiently applied within a probabilistic risk assessment framework to evaluate the vulnerability of RC buildings subjected to earthquake-induced slope displacements.

1. INTRODUCTION

The destructive impact of earthquakes can be strongly enhanced by the induced triggering of landslides during or after the shaking (Bommer and Rodrıguez 2002). Earthquakes can potentially trigger landslides that can induce catastrophic losses in terms of human lives and infrastructure damage. Therefore, there is an urgent need for efficient landslide risk assessment and management at different scales. An efficient Quantitative Risk Assessment (QRA) tool that allows for establishing risk management strategies and emergency planning in a cost-effective manner requires the quantification of both hazard and vulnerability of the exposed structures. However, most of the existing risk assessment studies do not focus on the comprehensive evaluation of the vulnerability component. Instead, they often provide empirical or expect judgment-based vulnerability values depending on the landslide type and the element at risk (e.g. Dai et al. 2002). This is principally due to its complex and multidimensional nature and to the difficulty in acquiring reliable damage data from previous landslide events. A better understanding on the parameters affecting the building damage due to the different landslide mechanisms is therefore essential to reduce the great deal of uncertainty associated with the landslide vulnerability modeling. The probabilistic treatment of these uncertainties may be achieved through the use of the co-called fragility (or vulnerability) curves, which provide relationships between the landslide intensity and the probability of exceeding predefined damage limit states.

In this paper several portfolios of probabilistic fragility curves for low-rise, RC building subjected to earthquake induced slow- moving slides are proposed based on the recently published by the authors vulnerability assessment methodology (Fotopoulou and Pitilakis 2012). To achieve this goal, an extensive numerical parametric investigation is conducted considering a variety of idealized slope configurations, soil and geological settings, as well as distances of the structure to the slope's crest. The derived fragility curves are compared with corresponding literature ones to strengthen their effective implementation within a QRA framework.

2. VULNERABILITY ASSESSMENT METHODOLOGY

According to the proposed method (Fotopoulou and Pitilakis 2012), a single RC building is subjected to forced differential displacement due to the earthquake-triggered landslide and subsequently to structural distress and damage. A low-rise RC frame building located next to the crown of a potentially unstable finite soil slope is considered. Figure 1 illustrates the key parameters of the investigated problem. The method is principally based on a two-step numerical approach and adequate statistical analysis that are shortly outlined hereafter.

The total and differential permanent displacements are first estimated using a plane strain FLAC2D (Itasca 2008) finite difference, non-linear dynamic slope-foundation model. The model consists of four-node quadrilateral

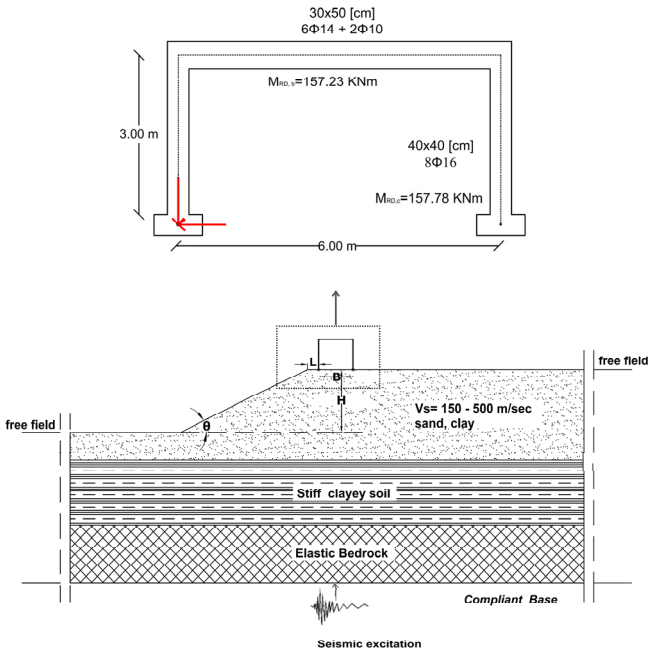

Figure 1 The main parameters of the problem under study

elements of various sizes determined by the shear wave velocities of the medium and the frequency content of the incident motions. A finer discretization is adopted in the slope area, whereas towards the lateral boundaries of the model the mesh is coarser. The width and the height of the model are selected in a way that the effects of artificial wave reflections from the boundaries near the slope are sufficiently reduced. For the same purpose, free field (Cundall et al. 1980) and quiet boundaries (Lysmer and Kuhlemeyer, 1969) are applied along the lateral boundaries and the bottom of the dynamic model respectively.

The soil materials (sandy or clayey) are modeled using a simple elastoplastic constitutive model with Mohr-Coulomb failure criterion, assuming a non-associated flow rule for shear failure. Soil strength properties are properly selected to account for the dynamic ground response. The bedrock is idealized considering a linear elastic soil material.

A low-rise RC frame building is assumed to be located next to the slope's crest. Shallow foundation systems of different stiffness characteristics are considered: isolated footings and/or a uniform loaded continuous slab foundation. In the first case, the foundation is simulated with concentrated loads at the footings' links assuming no relative slip and/or separation between foundation and subsoil. In the second case, the foundation system is modeled as a deformable elastic beam connected to the soil elements' grid through appropriate interface elements.

The seismic input applied along the base of the model consists of SV waves vertically propagating upwards from the base. Different gradually increasing acceleration time histories recorded on rock outcrop are applied to cover a wide range of seismic motions in terms of amplitude, frequency content and significant duration in order to provide the necessary response quantity statistics.

Then, non-linear static time history analyses of the building are performed to assess the building's response to the differential ground deformation induced by the earthquake induced landslide. The analyses are conducted using the finite element code SeismoStruct (Seismosoft 2011) for progressively increasing levels of differential displacements extracted from the non-linear dynamic analysis. In particular, the derived differential displacements at the foundation level are imposed quasi-statically at one of the RC building supports.

The studied building (see Fig. 1) is a typical RC bare frame structure with flexible or stiff foundation system designed with "low" or "high" seismic code prescriptions. The "fibre approach" is used to represent the cross-section behaviour, where each fibre is associated with a uniaxial stress-strain relationship. Both local (beam-column effect) and global (large displacements/rotations effects) sources of geometric nonlinearity are automatically taken into account. Nonlinear constitutive models are used to simulate the behavior of RC materials since cracking and irreversible deformations are normally expected to govern the building's response. More specifically, a uni-axial nonlinear constant confinement model is used for the concrete material (Mander et al. 1988) whereas a uni-axial bilinear stress-strain model with kinematic strain hardening is utilized for the reinforcement.

Structural response data in terms of maximum material strain are then statistically correlated to the corresponding limit damage states and the landslide intensity parameters to estimate structure's performance and fragility. Four damage limit states (LS1, LS2, LS3, LS4) are defined in terms of threshold values of building's material strain based on previous literature work (Crowley et al. 2004, Bird et al. 2005; 2006, Negulescu and Foerster 2010) and proper engineering judgment. They describe the exceedance of minor, moderate, extensive and complete structural damage of the RC building.

Vulnerability is finally assessed through probabilistic fragility (or vulnerability) curves, which describe the probability of exceeding a certain limit state of the building exposed to the landslide hazard given the measure of the landslide intensity. A two-parameter lognormal distribution function is adopted to represent the fragility curves. The corresponding analytical form reads:

$$F(IM) = \Phi\left[\frac{1}{\beta} In\left(\frac{IM}{\overline{IM}}\right)\right] \quad (1)$$

where

IM is the intensity measure; $\Phi[\cdot]$ is the standard normal cumulative distribution function; $\overline{IM}$ is the median value of the specified intensity parameter at which the building reaches the specified limit state; β is the standard deviation of the natural logarithm of the specified intensity parameter.

The landslide intensity is expressed both in terms of peak horizontal ground acceleration (PGA) at the seismic bedrock and permanent ground/foundation displacement (PGD) at the slope area (i.e. a product of PGA). The latter is generally better correlated to structural deformation and

damage (Fotopoulou 2012).

Different procedures can be applied to estimate the log-normally distributed fragility parameters (median and log-standard deviation) given the simulated damage data. A purely statistical approach, i.e. the Maximum Likelihood Method (Shinozuka, 2000; 2003), is implemented in this study considering a common log-standard deviation for all limit states (Shinozuka, 2003).

The likelihood function is introduced as:

$$L\left(IM_1, IM_2, IM_3, IM_4, \beta\right) = \prod_{i=1}^{N}\prod_{j=0}^{4} P_j\left(IM_i; E_j\right)^{y_{ij}} \quad (2)$$

where

Ej the specified damage state for no damage (j=0), at least slight damage (j=1), at least moderate damage (j=2), at least extensive damage (j=3) and complete damage (j=4).

yij=1 if the damage state Ej occurs for the i simulation of the structure subject to the landslide intensity and 0 otherwise.

Then the maximum likelihood estimates for $\overline{IM_i}$ and β are obtained by solving the following equations:

$$\frac{d\ \mathrm{lnL}}{d\,\overline{IM}} = \frac{d\ \mathrm{lnL}}{d\,\beta} = 0 \quad (3)$$

The computation is performed numerically using a standard optimization algorithm.

Three primary sources of uncertainty, associated with the variability on the capacity properties of the structure, the demand and damage state thresholds, contribute to the total variability. Uncertainty on the demand is taken into account from the dispersion of the recorded maximum strain as a function on the selected IM. Damage state definition uncertainty is accounted for by performing a Monte Carlo simulation for the simulated damage data. A lognormal distribution, in accordance to the pertinent literature (Crowley et al. 2004), is considered for the specified limit states with median the already defined limit state values and coefficient of variation equal to 0.4. Finally, capacity uncertainty is taken equal to 0.25 or 0.30 depending on the code design level of the structures (NIBS, 2004). The total variability is estimated through the following expression:

$$\beta = \sqrt{\beta'^2 + \beta_C^{\ 2}} \quad (4)$$

where β' is the combined variability associated with the demand and the limit damage states and β_c is the capacity properties of the structure respectively.

The reliability of the proposed method was assessed through its application to two real case histories (Fotopoulou et al. 2011; Fotopoulou 2012), verifying its effective implementation in several vulnerability assessment studies.

3. PARAMETRIC STUDY

In order to construct generalized fragility curves applicable to low-rise RC frames for various soil conditions and slope configurations, we perform an extensive parametric investigation based on the briefly described vulnerability assessment method. The main parameters selected to vary are associated to (Fig. 1):

- The slope height (H=20, 40 m)
- The slope inclination (θ = 15°, 30°, 45°)
- The soil properties of the slope material (soft to stiff clayey and sand soils corresponding to soil categories B, C and D according to EC8 (CEN-European Committee for Standardization 2003))
- The relative position of the building with respect to the slope crest (L=3, 5 m).

Six simplified –yet realistic– finite slope configurations are considered for the present study based on the varying slope geometry (see Fig. 1). For each geometry, 4 different models are constructed that vary on the soil conditions (sand, clay) and the relative location of the building to the slope crest (L=3, 5 m). It is noticed that the soil properties of the slope materials are taken to be consistent with the considered inclination angles to ensure static slope stability. Thus, we do not analyze steep slopes with soft soil, as the slope would be already unstable in static conditions. It is also important to note that only the cases that represent the highest potential to landsliding are modeled. For instance, we do not investigate slopes with small inclination (i.e. θ=15°) on stiff soil as the resulting permanent slope displacements and consequently the building expected damage would be negligible and thus out of the scope of this study. Table 1 presents the properties for the soil materials and the elastic bedrock assumed for the analyses.

Table 1 Soil properties of the analyzed slope configurations

	Bedrock	Stiff soil		Relatively stiff soil		Soft soil	
		sand	clay	sand	clay	sand	clay
Density (kg/m3)	2300	2000	2000	1800	1800	1700	1700
Poisson's ratio	0.3	0.3	0.3	0.3	0.3	0.3	0.3
Shear wave velocity Vs(m/sec)	850	500	500	250	250	150	150
Cohesion c (KPa)	-	10	50	0	10	0	5
Friction angle φ (degrees)	-	44	27	36	25	25	15

Table 2 Records used for the dynamic analyses

Earthquake	Record station	Mw	R (km)	PGA (g)
Valnerina, Italy 1979	Cascia	5.9	5.0	0.15
Parnitha, Athens 1999	Kypseli	6.0	10.0	0.12
Montenegro 1979	Hercegnovi Novi	6.9	60.0	0.26
Northridge, California 1994	Pacoima Dam	6.7	19.3	0.41
Campano Lucano, Italy 1980	Sturno	7.2	32.0	0.32
Duzce, Turkey 1999	Mudurno_000	7.2	33.8	0.12
Loma Prieta, California 1989	Gilroy1	6.9	28.6	0.44

The seismic excitation applied along the base of the dynamic model consists of a suite of 7 real acceleration time histories from different earthquakes worldwide recorded on

rock outcropping conditions (Tab. 2) and scaled at different level of PGA i.e. 0.3 g, 0.5g, 0.7g and 0.9g. Some additional analyses for lower levels of PGA (e.g. 0.1 g) were deemed necessary for certain models in order to obtain reliable results for all damage states.

The herein studied building is a single bay-single storey RC bare frame structure with flexible foundation system (see Fig. 1), which was found to be adequately representative of the performance of real low-rise RC frame buildings (Bird et al. 2005, Negulescu and Foerster 2010). The structure has been designed according to the provisions of the modern Seismic Code of Greece (EAK 2000). The specified yield stress of reinforcing steel and the compressive strength of concrete are 400 MPa and 20 MPa respectively. The adopted dead and live loads (g = 1.3 kN/m^2 and q = 2 kN/m^2) represent typical values for residential buildings.

As described in the previous section, four local damage limit states are defined in terms of threshold values of steel and concrete material strain. The first limit state is specified as steel bar yielding whereas for the rest, mean values of post-yield limit strains for steel reinforcement and concrete material are suggested, as shown in Table 3.

Table 3 Definition of limit states for "high" code design RC buildings

Limit state	Limit strains	
	Steel strain (εs)	Concrete strain (εc)
Limit State 1	Steel bar yielding	-
Limit State 2	0.0125	0.005
Limit State 3	0.04	0.010
Limit State 4	0.06	-

The parametric analysis results to the construction of fragility curves as a function of PGA at the outcrop and PGD at the slope area for the different investigated models with the aid of the Maximum Likelihood Method. In the following, we perform a sensitivity analysis for the derived fragility curves, which allows gaining a better view on the relative influence of each analyzed feature to the expected damage level of the building and finally proposing generalized fragility curves.

3.1 Effect of slope inclination

First, the influence of the slope inclination to the fragility curves is shown. Figure 2 presents representative fragility curves in terms of PGD for varying slope inclinations (15^o, 30^o, 45^o) considering both sand and clayey slopes. In particular, the fragility curves for extensive and slight damage are presented for the sand and clayey slope respectively. Soft, relatively stiff and stiff soil materials are considered for the 15^o, 30^o and 45^o slope configurations respectively that distinguish different mechanical parameters for the sand and clay slopes. The height of the slope for the herein examined models is 20 m.

It is shown that, as it was expected, the slope inclination plays a crucial role in the fragility analysis of the building standing next to the slope's edge. However, it should be regarded in conjunction to the slope soil properties to obtain meaningful conclusions. Thus, for the sand slope, the building would suffer more damage as the slope inclination increases. On the contrary, for the clayey slope case, the building is expected to sustain less structural damage when standing on the 45^o inclined slope compared to the gentler ones, due to the stiff cohesive soil conditions assumed for the steep slope configuration. These trends seem to hold when considering both PGA and PGD as intensity measures.

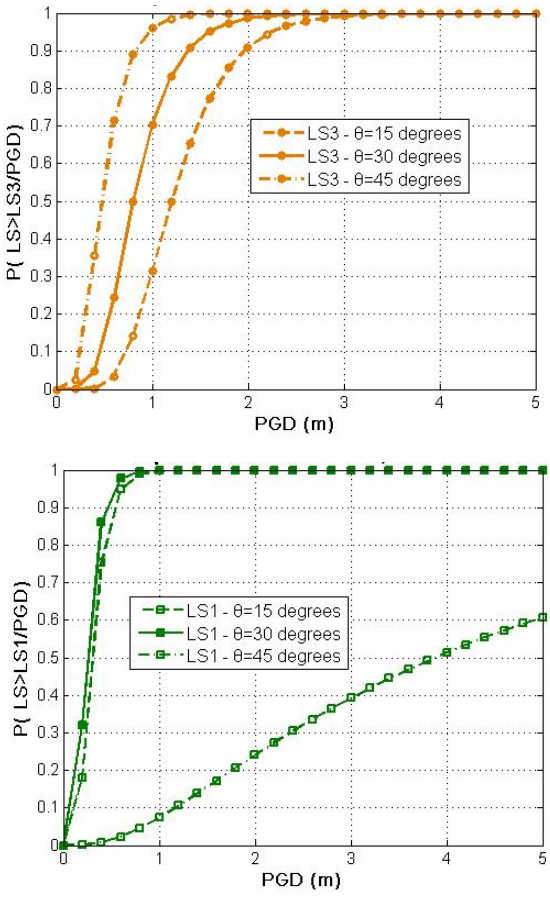

Figure 2 Fragility curves as a function of PGD when varying slope inclination [β=f (soil properties) = 15^o, 30^o, 45^o] for a 20 m high sand (up) and clay (bottom) slope respectively

3.2 Effect of slope height

The relative influence of the slope height on the vulnerability of the building to the permanent landslide differential displacement is also investigated in this study. Representative comparative plots of fragility curves as a function of PGA and PGD respectively are presented in Figure 3. Overall the slope height can moderately affect the structure's fragility. Different trends are revealed depending on the selected intensity measure (PGA or PGD) and the inclination angle of the analyzed slopes (15^o, 30^o, 45^o). Similar trends are evident for the clayey soil as well.

We see that, when using PGA as an intensity parameter, the vulnerability of the building increases with the slope height. As it would be normally expected, this increase is more pronounced for the 45^o steep slope configurations, whereas it is less important for the 15^o inclined slopes. In

contrast, the use of PGD as intensity measure, apart from some exceptions, is associated to lower vulnerability values of the building with increased slope heights. A plausible explanation of the latter is that in the case of higher slopes the mobilized sliding mass is larger and thus it affects more the building located close to the crest in terms of total displacements, which are larger, while the differential displacement demand on the building is reduced.

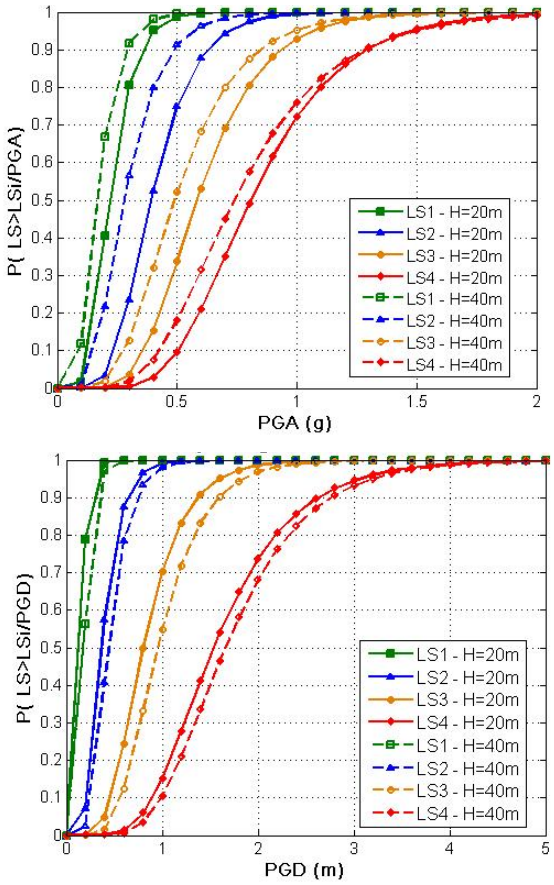

Figure 3 Fragility curves as a function of PGA (up) and PGD (bottom) respectively when varying slope height (H= 20, 40 m) for a 30° sand slope

3.3 Effect of soil material

The soil material is certainly a significant parameter in assessing building's vulnerability standing near the crest of a potentially precarious slope. Figure 4 presents the derived sets of fragility curves as a function of PGD, when varying slope soil properties (sand, clay) for the 15° and 45° slope configurations respectively. Soft and stiff (sand or clay) soil conditions are considered for the 15° and 45° inclined slopes respectively**.** It is observed that slopes consisting of clay material generally demonstrate better performance compared to sands when subjected to differential permanent ground displacements, resulting to lower vulnerability levels for the building. This is largely due to the inherent cohesive behavior of clay soil material that is associated to the formation of larger and deeper sliding surfaces. Thus, the considered one-bay building located at a close distance (i.e. 3m) from the slope's crest would be practically within the sliding mass and therefore it is primarily expected to move uniformly with the landslide mass rather than to distort differentially. The above observation is more noticeable as the slope inclination increases, i.e. for the stiffer clayey soil materials.

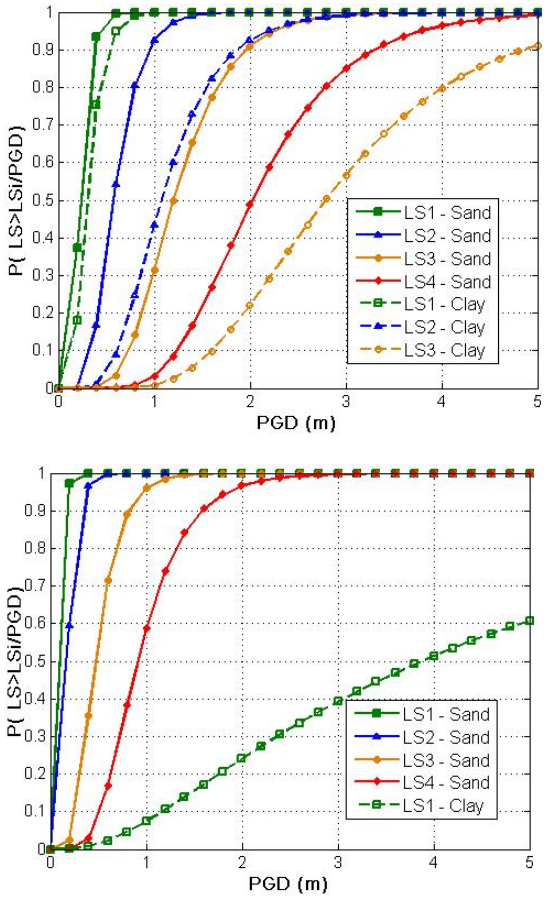

Figure 4 Fragility curves as a function of PGD when varying soil material for 15° (up) and 45° (bottom) slope configurations respectively

3.3 Effect of relative position of the building to the slope's crest

The distance of the assumed building from the crest of the slope may also considerably influence its vulnerability to the permanent landslide displacement. Figure 5 displays representative derived sets of fragility curves, when varying the distance from the crest (L= 3, 5m), for a 30° inclined sand and clayey slope respectively. Different observations can be made depending on the type of the considered slope soil materials. For sand slopes, the building is expected to suffer less damage as the distance from the crest increases. On the contrary, for the clayey slopes, the more distant building from the crest would be more vulnerable. This differentiation lies again on the nature of the slope soil materials involved, which are associated to the formation of sliding surfaces that may vary for very small and shallow for sands brittle slopes to large and deep for clayey deformable slopes. Thus, the assumed one-bay building standing at 3m

from the crest of the clayey slope is basically within the landslide mass and moves rather uniformly as a rigid body whereas for increasing distances from the crest (5m) the building shifts (partially) outside the landslide mass and therefore it exhibits higher differential (rather than uniform) ground displacements and hence more structural damage. On the other hand, the building located at the closest distance from the crest (i.e. 3m) of the sand slope is outside the landslide mass and consequently it is subjected to extensive differential deformation demand that is gradually decayed as the distance from the crest increases.

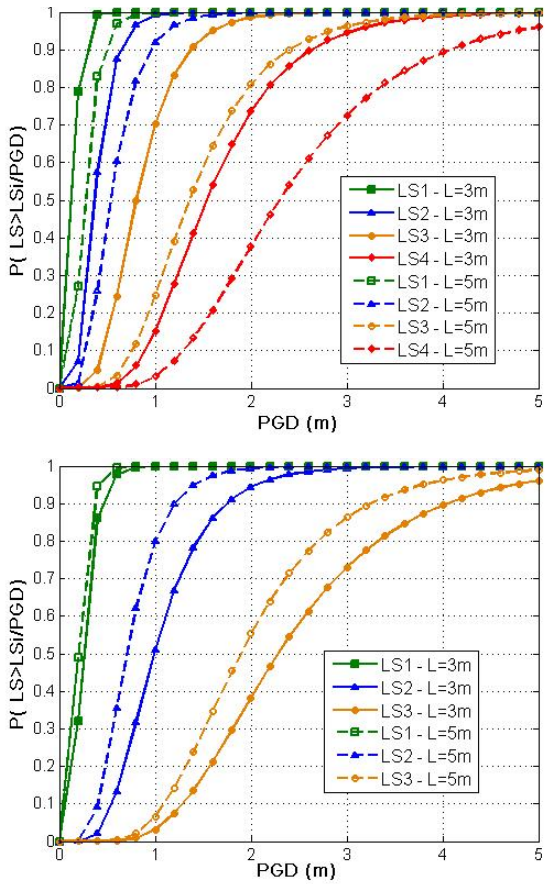

Figure 5 Fragility curves as a function of PGD when varying the distance from the crest (L= 3, 5m) for a 30° sand (up) and clay (bottom) slope respectively

3.3 Generalized fragility curves

Seven sets of fragility curves both in terms of PGA and PGD are proposed herein that could be used for several engineering applications. They are based on the main features that proved to most significantly influence the vulnerability of the building to the differential permanent landslide displacement. These are principally the slope inclination and the soil material of the slope, which are highly correlated. The slope height is also proved to be an important contributor to the building's fragility for the steep sand slope configurations. Thus, for the 45° inclined sand slopes fragility curves are also differentiated with respect to the considered slope height (H=20, 40 m). The latter curves are probably less accurate than the others as they are based on a smaller simulated dataset. It is noted that the proposed curves have been constructed considering the most adverse position of the building with respect to the landslide that was found to be different for sand and clay slopes. It is also important to note that the curves presented herein refer to "high-code", adequately confined RC frame structures. Tables 4 and 5 present the derived median and dispersions of the suggested curves when using PGA and PGD as intensity measure respectively.

As already shown, the building founded upon sand slopes is expected to demonstrate a greater damaging potential than the respective clayey ones. Thus, the corresponding curves referring to sand slopes are generally shifted to the left compared to clays (yielding to lower medians for the same limit states) and they are associated with a more rapid transition from slight to complete damage limits. These differences are becoming much more pronounced as the slope inclination increases. As it can be readily seen from the tables, the sand steep, high-rise slope and clay steep slope configurations are producing the most and the least damage respectively on the building. The dispersion of the suggested curves is found to vary from 0.39 to 0.66 and from 0.40 to 0.50 when considering PGA and PGD respectively as an intensity parameter.

Table 4 Parameters of fragility functions when using PGA as intensity parameter

Parametric models	Median PGA (g)				Dispersion β
	LS1	LS2	LS3	LS4	
sand_θ30	0.20	0.34	0.54	0.76	0.40
clay_θ30	0.27	0.53	0.93	1.37	0.46
sand_θ15	0.28	0.50	0.83	1.17	0.44
clay_θ15	0.23	0.54	1.01	1.51	0.50
sand_θ45_h20	0.23	0.35	0.55	0.81	0.39
sand_θ45_h40	0.12	0.19	0.25	0.30	0.44
clay_θ45	1.04	1.77	-	-	0.66

Table 5 Parameters of fragility functions when using PGD as intensity parameter

Parametric models	Median PGD (m)				Dispersion β
	LS1	LS2	LS3	LS4	
sand_θ30	0.15	0.39	0.87	1.64	0.43
clay_θ30	0.22	0.67	1.70	3.43	0.43
sand_θ15	0.24	0.60	1.29	2.19	0.40
clay_θ15	0.28	0.94	2.32	-	0.43

clay_θ45	0.77	1.72	-	-	0.47

4. COMPARISON OF THE PROPOSED FRAGILITY CURVES WITH LITERATURE ONES

The validity of the developed curves is assessed through their comparison with respective literature curves derived by different approaches. In particular, fragility

curves based on empirical damage data (Zhang and Ng 2005), engineering judgement (NIBS 2004) and on numerical simulations (Negulescu and Foerster 2010) are used for that comparison. Among the developed curves, the ones that are selected for the comparison refer to the RC frame building located next to the crest of the 30° inclined sand slope. These curves generally represent a somewhat moderate case in terms of the expected vulnerability of the building to the permanent landslide displacement (see Tables 4 and 5 for the corresponding fragility parameters).

4.1 Comparison with empirical curves

Zhang and Ng (2005), based on statistical analysis of the actual observed displacement on over 300 buildings, proposed empirical fragility curves in function of the limiting tolerable settlement (maximum vertical foundation displacement) and angular distortion (the average slope of the associated differential settlement of the building). The authors used the term "intolerable" to describe the displacements (settlements and angular distortions) that affect the safety, function and appearance of the structure. The buildings were classified into two main categories according to their foundation type (shallow or deep foundation). Among the studied buildings, they found that 95 experienced certain settlement and 205 certain angular distortion. The authors did not mention the origin of these displacements (e.g. due to landslide hazard). Table 6 provides the mean and standard deviations of the limiting tolerable and intolerable displacements of these buildings (shallow foundation and all foundations cases are shown herein) in terms of settlements and angular distortions respectively.

To allow for direct comparisons of the fragility curves developed in this study to the corresponding curves provided by Zhang and Ng (2005), the proposed curves were properly modified as a function of the induced settlement and angular distortion respectively. The Maximum Likelihood method, as described previously, is used to estimate the log-normal distributed fragility parameters. Comparative plots of the proposed curves for the studied building to the empirical ones as a function of settlement and angular distortion are given in Figure 6.

Overall, the comparison between the curves is judged satisfactory considering the large uncertainty and variability involved and the fact that the empirically derived curves are dealing with foundation movements irrespective of their origin (e.g. earthquake induced landslide hazard) and the superstructure typology. A good correlation is observed between the empirical curves and the proposed fragility curves for the building when using Settlement as a metric of the landslide displacement. It is seen that the proposed fragility curve for Limit state 2 (moderate structural damage) almost coincides with the empirical curve for limiting tolerable settlement. In addition, the proposed curve for Limit state 3 (extensive structural damage) is in good agreement with the curve proposed by Zhang and Ng for intolerable settlements. The correlation is not so good when using Angular distortion as an intensity parameter. In particular, the empirical curves are generally shifted to the left predicting quite low median values of limiting tolerable angular distortion and consequently increased expected building damage. These low values are probably associated to loss of functionality (e.g. due to tilting), which is not accounted for in the proposed numerically derived curves, and not to structural damage to the building members.

Table 6 Statistics of intolerable and limiting tolerable settlement and angular distortion of buildings (adapted from Zhang and Ng, 2005)

Statistics	All foundations		Shallow foundations	
	Mean	Standard deviation	Mean	Standard deviation
Observed intolerable settlement (cm)	40.3	33.4	39.9	32.3
Limiting tolerable settlement (cm)	12.3	7.3	12.9	7.2
Observed intolerable angular distortion	0.0116	0.0143	0.0119	0.0138
Limiting tolerable angular distortion	0.0028	0.0024	0.003	0.0015

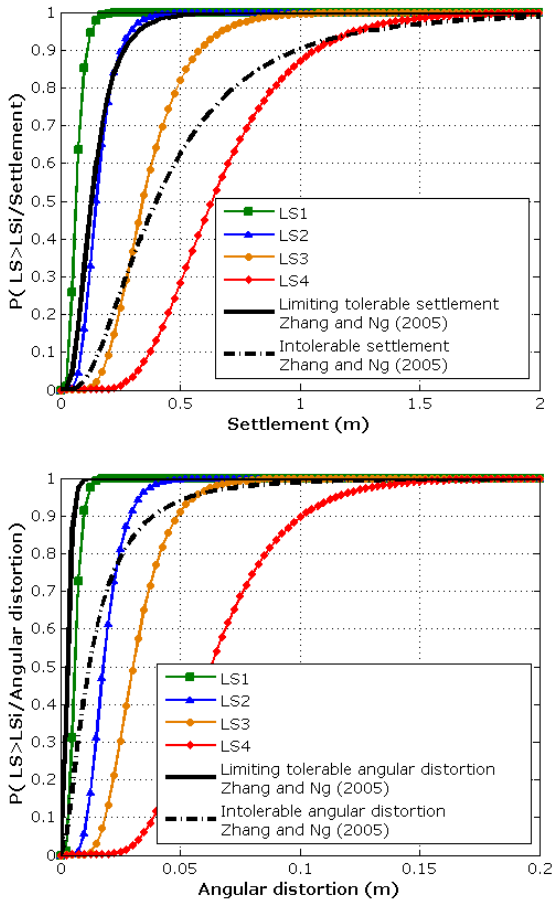

Figure 6 Comparison of the proposed fragility curves as a function of settlement (up) and angular distortion (bottom) for the studied building with the corresponding empirical curves provided by Zhang and Ng (2005)

4.2 Comparison with expert-judgment curves

HAZUS loss estimation methodology (NIBS 2004) provided fragility curves for structures subjected to earthquake-induced ground failure taking into account the expected mode of failure and the foundation type. Separate fragility curves distinguishing between ground failure due to lateral spreading and ground failure due to ground settlement, and between shallow and deep foundations were proposed. Only one combined Extensive/Complete damage state was considered. In essence, according to HAZUS, buildings were assumed to be either undamaged or severely damaged due to ground failure. Fragility curves were derived as a function of permanent ground displacement (PGD) using a form similar to those used to estimate shaking damage. Engineering judgment was used to develop a set of assumptions, which define building fragility. The expert judgemental curves provided by HAZUS are compared with the numerically derived curves for extensive and complete damage for the building on flexible and stiff foundations (Fig. 7). The herein proposed curves are given as a function of the maximum permanent ground displacement (PGD) the slope area.

A generally good agreement between the proposed curves for the building on flexible foundation and the respective HAZUS curves is observed. In particular, the later curves predict larger vulnerability values when damage due to settlements (principally vertical movement) is more imminent and lower vulnerability values when the damage occurs as a result of extensive lateral spreading (principally horizontal movement).

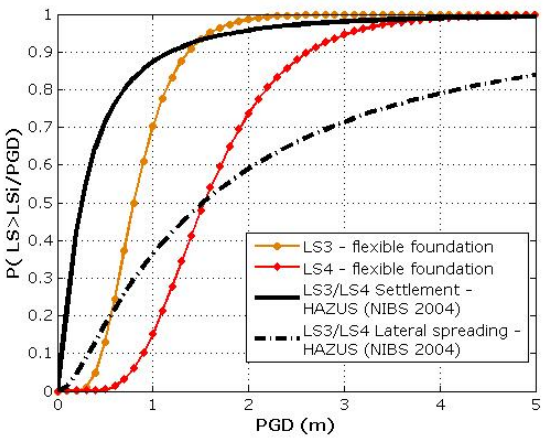

Figure 7 Comparison of the proposed fragility curves for extensive and complete damage as a function of permanent ground displacement (PGD) for the studied building with the corresponding expert judgment curves provided by HAZUS (NIBS, 2004)

4.3 Comparison with analytical curves

Negulescu and Foerster (2010) proposed a simplified analytical methodology to assess the vulnerability of simple RC frame structures subjected to free-field differential ground displacement based on 2-D nonlinear static time-history analyses. They examined different parameters that could influence structural behavior: foundation type (i.e. different combinations of links), cross-section geometry, section reinforcement degree, displacement magnitudes and displacement inclination angles. Structural damage levels were considered, as in the present study, based on the local strain limits of steel and concrete constitutive materials. A set of preliminary fragility curves was derived considering encasing links for the foundation to represent a continuous surface foundation or a building with a basement. To assess the validity of the curves proposed in this research, they are also compared with the curves given in Negulescu and Foerster (2010). For the purpose of this comparison, the herein proposed curves are modified in terms of differential ground displacement at the foundation level.

Figure 8 shows comparative graphs of the proposed fragility curves as a function of differential ground displacement for the building with the corresponding analytical curves given in Negulescu and Foerster (2010). It is observed that the suggested curves in this research for the building are in good correlation with the Negulescu and Foerster‘s curves, especially for lower levels of damage (e.g. LS1 and LS2), taking also into account the different assumptions and uncertainties associated with them.

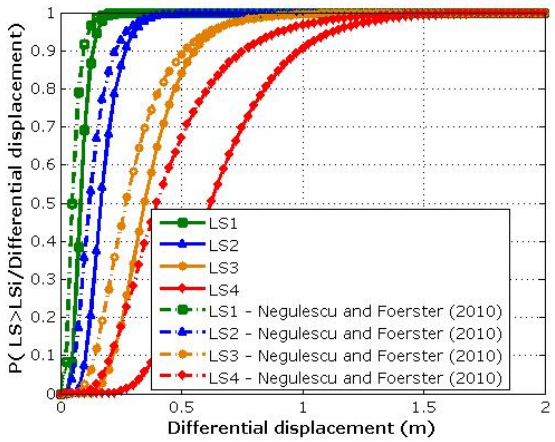

Figure 8 Comparison of the proposed fragility curves as a function of differential ground displacement for the studied building with the corresponding analytical curves provided by Negulescu and Foerster (2010)

5. CONCLUSIONS

Several sets of fragility curves for low-rise RC frame structures both in terms of PGA and PGD have been proposed based on an extensive numerical parametric investigation of various step-like slope configurations, soil properties and distances of the building with respect to the slope’s crown. Sensitivity results have shown that, among the analyzed features, the ones that have proved to affect more drastically the vulnerability of the building to the differential permanent deformation due to the seismically

induced landslide hazard are the slope inclination in conjunction with the slope soil material. The slope height has also turned out to be an important contributor to the building's fragility for the 45° inclined sand slopes. Based on the above observations, seven sets of fragility curves have been suggested depending on most influential parameters and considering the most unfavorable position of the building with respect to the landslide. The latter was found to largely depend on the type of the slope soil materials involved (sand or clay).

The reliability of the proposed fragility curves has been assessed through the comparison of representative developed fragility curves with corresponding literature ones derived by different approaches (e.g. empirical, expert-judgment, analytical). Relatively good correlations have been shown in all cases enhancing the validity of the curves. Thus, the suggested curves can be efficiently employed within a QRA study to assess the vulnerability of RC buildings subjected to earthquake induced slope displacements.

Abstract: In this paper, the fragility curves of mid-rise reinforced concrete moment-resisting frame structures in the Greater Metro Manila Area, Philippines are derived. Aside from typical structural parameters known to strongly influence fragility curves, soil type and fault proximity are also considered. The methodology implemented involves the use of a database of building models and the Capacity Spectrum Method for generating the probability distribution of the structural response for a given peak ground motion. In this study, two sets of fragility curves were developed considering two different vintages: pre-1992 and post-1992. For buildings constructed after 1992, 50% of the building population will experience slight damage at 0.13g, moderate damage at 0.15g, extensive damage at 0.26g, and complete damage at 0.52g. On the other hand, for buildings constructed before 1992, 50% of the building population will experience slight damage at 0.16g, moderate damage at 0.18g, extensive damage at 0.26g, and complete damage at 0.52g.

1. INTRODUCTION

The Philippines, being part of the Pacific Ring of Fire, is prone to earthquakes. If a destructive earthquake is to happen again in the future, buildings and other structures are at risk. Damage and loss of these structures will definitely cause human lives, businesses and livelihood to be lost as well. This is why risk management is important and in order to manage risk, it should be assessed. Part of the preparation of an earthquake disaster mitigation plan is the quantification of building vulnerability. A component of which is the development of seismic fragility curves that are used to predict the probability of reaching or exceeding specific damage states for a given level of peak ground motion. It is developed using a building database for a region of interest analyzed using the Nonlinear Static Pushover Method to estimate the peak response of the structures and to generate the frequency distribution of the structural responses for a given ground motion (Longalong et. al., 2012).

One major area of improvement is in the development of fragility curves for common building types in the region of interest. A fragility curve expresses the probability of being in or exceeding a certain damage state as a function of the hazard (Giovinazzi et. al., 2002). This paper discusses the generation of fragility curves of one of the common building types in the Philippines which is a mid-rise reinforced concrete moment-resisting frame structure (C1-M). The building height considered in this study ranges from three to eight storeys, and the lateral force-resisting system assumed is a moment-resisting frame system. The pilot area or the region of interest is identified as the Greater Metro Manila Area which consists of the National Capital Region and several nearby provinces in the country.

2. METHODOLOGY

Several approaches exist for developing fragility curves, as shown in Figure 1. The heuristic approach relies heavily on expert's opinion, whereas the empirical approach requires actual damage data. The computational approach, on the other hand, can be static or dynamic and linear or nonlinear. In this research, the different approaches were used in deriving fragility curves.

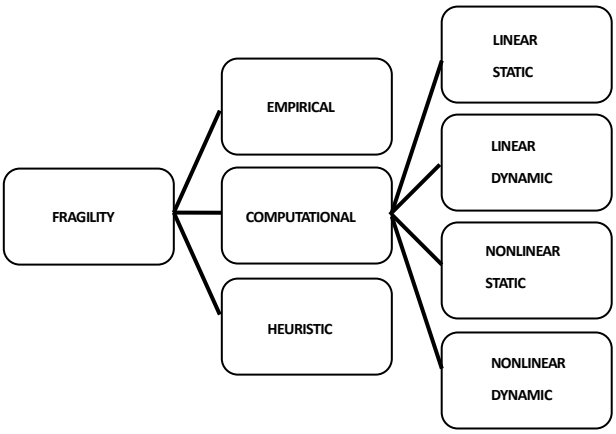

Figure 1 Conceptual Framework

Due to the absence of strong-motion earthquake records in the country, a nonlinear dynamic analysis cannot be conducted. Thus, a nonlinear static analysis called the nonlinear pushover method is used in this research. The flowchart in Figure 2 shows the computational procedure used in developing fragility curves.

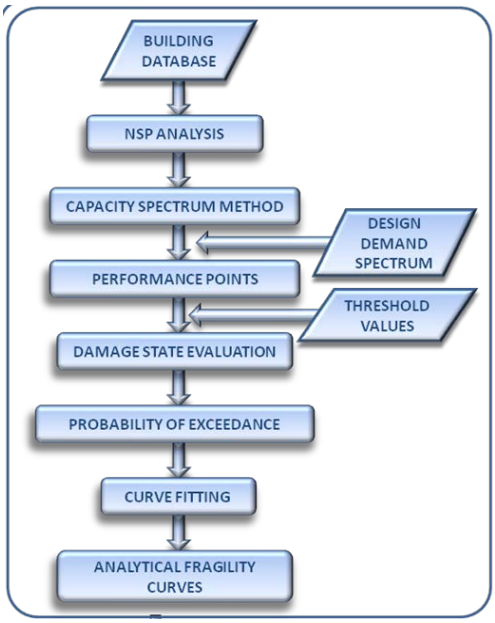

Figure 2 Fragility Curve Development Procedure (UPD-ICE Technical Report, 2011)

2.1 Development of Building Database, Structural Properties, and Sensitivity Analyses

The building database consists of mid-rise reinforced concrete structures with varying structural configurations, dimensions, and material properties. To limit the number of structures in the database, sensitivity analyses were performed. Sensitivity, measured by the ratio of the range of spectral displacement to the mean of the spectral displacements considering changes in the parameter, greater than five percent is assumed to have significant effect on the spectral displacement (Longalong et. al., 2012).

After performing the sensitivity analyses, parameters considered to have an effect on the spectral displacement in C1-M structures are bay length, number of storeys, storey height, column dimension, and beam dimension. Bay length ranged from three to six meters. The number of storeys ranged from three to eight. Storey heights considered were 2.5 m and 3 m. Columns were limited to square dimensions with sizes varying from 0.4 to 0.7 m. Beam widths considered were from 0.2 to 0.5 m while beam depth considered were from 0.4 to 0.75 m. Steel reinforcement yield strength considered was 40 ksi. Columns were modeled to have pin connections at the base. Table 1 illustrates a sample list of models used in this research.

Table 1 Sample C1-M Model List

Model ID	Bays	Bay Length (m)	No. of Storeys	Col Width (m)	Beam (m)
C1M-01	3	4	3	0.4	0.20x0.40
C1M-02	3	5	3	0.5	0.20x0.40
C1M-03	3	6	3	0.6	0.25x0.40
C1M-13	3	4	4	0.4	0.35x0.55
C1M-17	4	5	4	0.5	0.35x0.60
C1M-18	4	6	4	0.6	0.40x0.60
C1M-20	3	5	5	0.5	0.35x0.55
C1M-21	3	6	5	0.6	0.40x0.60
C1M-27	3	6	6	0.6	0.40x0.60
C1M-33	4	6	7	0.6	0.40x0.60

To account the vintage or the age of the structure, the local structural code of the country was used as the basis. The structures were identified among three vintages: Pre-Code, structures that were constructed before 1972; Low Code, structures that were constructed between 1972 and 1992; and High Code, structures that were constructed after 1992. Table 2 shows some identified differences in construction practice during the three periods.

Table 2 Vintage Parameters (Pacheco et. al., 2011)

Parameter	Pre-Code (Pre-1972)	Low Code (1972-1992)	High Code (Post-1992)
Ductility Requirements	no conventional requirements	minimal requirements	stricter requirements
Compressive Strength, f'_c	3,000 ksi	3,000 ksi	4,000 ksi
V/W	0.0731	0.0938	0.1171

2.2 Determination of Structure Capacity Using Nonlinear Static Pushover Analysis

Nonlinear Static Pushover (NSP) Analysis is performed to come up with the pushover curve (representing the capacity) of the structure. Nonlinear pushover procedure involves the application of horizontal forces incrementally applied in a prescribed loading pattern along the building height. Every structural member that fails is effectively removed by reducing its stiffness. The process of applying

horizontal forces then removing structural members is continued until the structure is no longer stable. Plotting the base shear force (V) against the deformation (D) experienced by the structure will give the pushover curve or the capacity curve. The software ETABS is used as an aid in performing the NSP Analysis which follows the guidelines presented in ATC-40. Figure 3 shows an example of a capacity spectrum of an RC model.

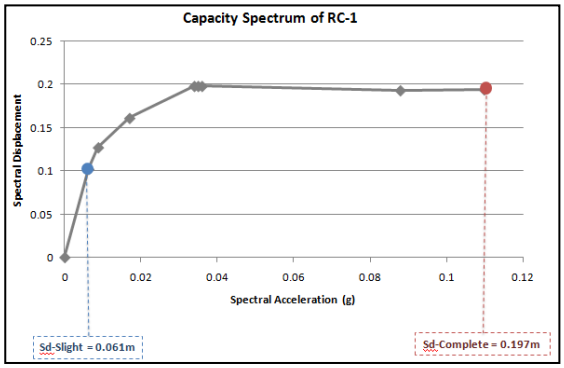

Figure 3 Sample Capacity Spectrum

2.3 Earthquake Demand

To characterize the earthquake demand, standardized code response spectrum was used due to limitations on available earthquake records. The response spectrum is defined in three parts, a constant spectral acceleration, constant spectral velocity and a constant spectral displacement. It is based on magnitude, peak ground acceleration (PGA), and amplification factors which are reflective of the soil profile. The soil site for the Greater Metro Manila Area is of soil types C, D, and E which give several values for the seismic coefficients C_a and C_v. These values will define the standardized code spectrum as shown in Figure 4. The GMI parameter is taken to be the spectral acceleration intercept which is also regarded as the peak ground acceleration.

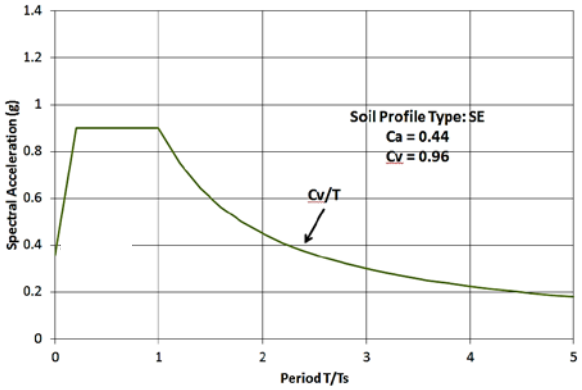

Figure 4 Earthquake Demand Spectrum (NSCP 2010)

2.4 Capacity Spectrum Method

The Capacity Spectrum Method (CSM) from ATC-40 is used to determine the performance points of each building model when subjected to a particular earthquake demand. These performance points will serve as the basis for computing the fragility curves by determining how many of them fall within the set damage thresholds.

Graphically, the performance point is the intersection of the capacity spectrum and the demand spectrum (ATC 40). Essentially these performance points describe the peak spectral response of a structure at a given demand level. Capacity Spectrum Method (CSM) is employed to generate performance points. Capacity curves derived from nonlinear pushover analysis are converted into spectral values. Similarly, demand curves are also converted to spectral values to be able to superimpose with the capacity spectrum in the same coordinate system.

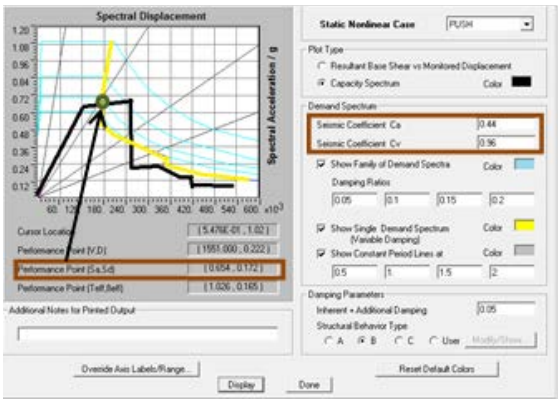

Figure 5 Sample Computation of Performance Points

2.5 Definition of Threshold Values for Different Damage States

In order to identify whether a building is in the slight, moderate, extensive or complete collapse damage state, it will require a certain criterion. This is in the form of drift ratio at the threshold of structural damage. HAZUS has developed threshold values using inter-storey drift for different building types and for different seismic design levels. These values determine whether a structure is in the slight, moderate, extensive or complete damage state.

Threshold values can be established from the pushover curves. According to Bazzurro (2006), *DS1* [Slight], or onset of damage, is defined where nonlinear behavior starts on the curve, whereas the Complete Damage State according to Gencturk et.al. (2007) is taken as the post-peak displacement when the load carrying capacity has undergone a small reduction. Moreover, instead of defining the threshold values in terms of inter-storey drifts derived from the pushover curve, the threshold values were defined in terms of spectral displacements derived from the equivalent capacity spectrum since these threshold values will be compared with the performance points which are in spectral values. The moderate and extensive damage state threshold values are calculated based on the ratios of the threshold values provided in HAZUS. These coefficients have different values for different building types. Figure 6 illustrates a sample calculation of damage thresholds for one C1-M model.

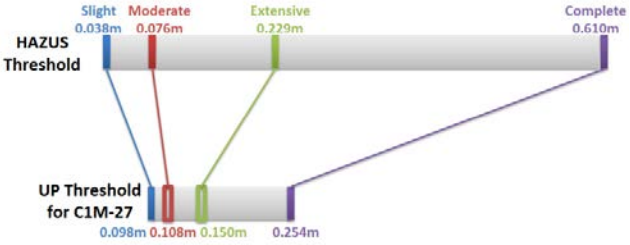

Figure 6 Sample Calculation of Damage Thresholds

2.6 Development of Initial Fragility Curves

For each structure, the threshold values in terms of spectral displacements were determined. To develop the fragility curves, the earthquake level was varied by changing the parameters that define the code response spectrum. In each earthquake level, the number of structures that have their performance point exceeding the set damage thresholds was recorded to come up with the probability of exceeding the damage state. Table 3 gives an example of a damage probability matrix.

Table 3 Sample Damage Probability Matrix

PGA(g)	Probability of Exceeding a Damage State			
	Slight	Moderate	Extensive	Complete
0.066	0.0000	0.0000	0.0000	0.0000
0.132	0.0000	0.0000	0.0000	0.0000
0.176	0.0571	0.0000	0.0000	0.0000
0.220	0.4286	0.1714	0.0000	0.0000
0.330	1.0000	0.8857	0.1714	0.0000
0.440	1.0000	1.0000	0.4571	0.0000
0.550	1.0000	1.0000	0.9714	0.1429
0.660	1.0000	1.0000	1.0000	0.6857
0.770	1.0000	1.0000	1.0000	0.8857

The probability function of seismic fragility curves is approximated by the lognormal cumulative distribution function given by Equation 1.

$$P[ds \mid GMI] = \Phi\left[\frac{1}{\beta_{ds}} \ln\left(\frac{GMI}{\overline{GMI}_{ds}}\right)\right] \qquad (1)$$

There are only two parameters defining this curve which is the median $\overline{GMI}_{ds}$ and the uncertainty β_{ds}. The aim is to determine these values such that the resulting curve represents the data points obtained. Figure 8 shows the curve-fitting of the fragility curves (broken lines) corresponding to Slight (S), Moderate (M), Extensive (E) and Complete (C) damage states.

2.7 Adjustments in the Uncertainty Parameter: Epistemic Uncertainty

Uncertainty in the assessment of structures is made up of aleatory, uncertainty that is inherently random, and epistemic uncertainties, uncertainty that is due to lack of knowledge as a result of incomplete data, ignorance or assumptions in modeling. Following the work of Tan (2011), the aleatory uncertainty is estimated when a lognormal cumulative probability distribution is fitted to the computed data points. The epistemic uncertainty, on the other hand, is computed using quality ratings from a survey of experts on the following sources of variability: design requirements, test data and modeling. Following the FEMA P695 method, the quality ratings are translated into quantitative values of uncertainty based on the following scale: (A) superior, $\beta = 0.10$; (B) Good, $\beta = 0.20$;(C) Fair, $\beta = 0.35$; (D) Poor, $\beta = 0.50$. These sources of uncertainties are statistically independent of each other, so that the total uncertainty β is computed by taking the square root of the sum of the squares of the uncertainties from the different sources. Using SRSS method to combine the different sources of epistemic uncertainties gives a value of 0.7036.

2.8 Development of Final Fragility Curves

Using the fragility curves initially derived from the Capacity Spectrum Method, the value for the epistemic uncertainty is then incorporated. With this, three sets of curves are generated representing the three vintages identified earlier in this paper.

3. RESULTS AND DISCUSSIONS

3.1 Fragility Curves

Fragility curves were then fitted and epistemic uncertainties were included. This is regarded as the computational fragility curves. Figures 7 and 8 illustrate the three sets of fragility curves according to vintage. It can be observed that the Pre-Code and Low Code curves are very close that they may be merged as one set of curves.

For example, referring to the second set of curves, at a peak ground acceleration of 0.5g, the probabilities of exceeding the slight, moderate, extensive, and complete damage states are around 96%, 94%, 81%, and 48% respectively. This means that the probability of no damage is 4%. On the other hand, the probabilities of slight, moderate, extensive, and complete damages are 2%, 13%, 33%, and 48% respectively.

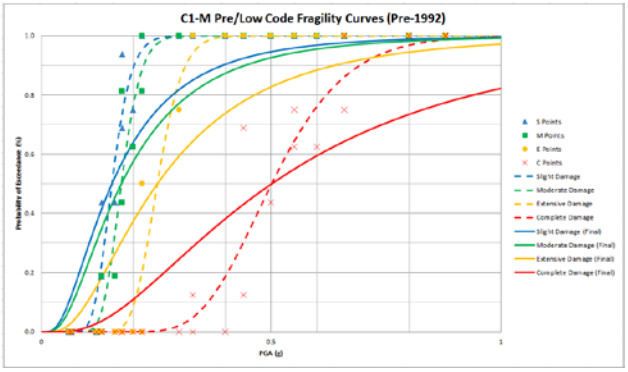

Figure 7 C1-M Fragility Curves (Pre-1992)

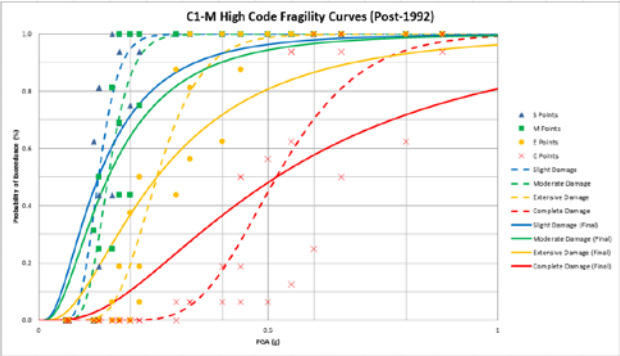

Figure 8 C1-M Fragility Curves (Post-1992)

3.2 Fragility Curve Comparison

The two sets of curves are then plotted using the same graph for comparison. It is observed that the fragility curves for Pre and Low Code and for High Code are very close to one another as shown in Figure 9. The curve parameters (i.e. median and standard deviation) are shown in Table 4.

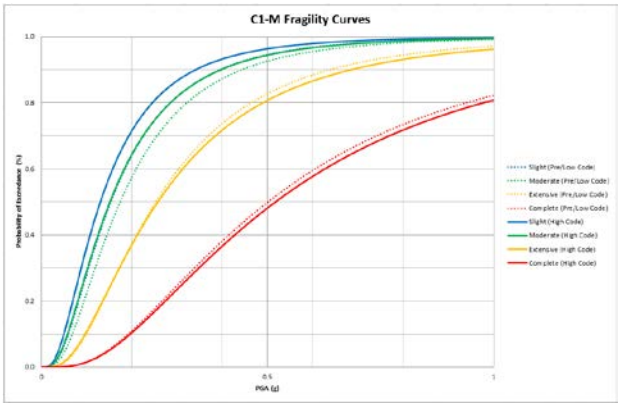

Figure 9 C1-M Fragility Curves

Table 4 C1-M Fragility Curve Parameters

Damage State	Pre/Low Code		High Code	
	Median (g)	Beta	Median (g)	Beta
S	0.1537	0.7352	0.1304	0.7510
M	0.1742	0.7293	0.1516	0.7516
E	0.2525	0.7238	0.2577	0.7638
C	0.5012	0.7476	0.5179	0.7556

4. CONCLUSIONS

Seismic fragility of mid-rise reinforced concrete frame structures in the Greater Metro Manila Area, Philippines were derived using the capacity spectrum method. From a model database of C1-M structures created by varying parameters sensitive to spectral displacement, nonlinear static pushover curves were generated. Damage thresholds were then established from each pushover curve. After varying the demand spectra by changing seismic coefficients, the number of structures which have their performance points exceed the damage threshold were counted. This number corresponds to the probability of exceeding the damage state. Lognormal cumulative distribution functions were fitted for each damage state.

In order to include the non-ductile behaviour of reinforced concrete members designed using pre and low code, a frame hinge reduction factor for shear and bending moment capacity was applied to the models before the nonlinear pushover analysis is conducted to determine the capacity curve. Thus, another step is added to the existing procedure in order to analyze buildings of a different vintage. The results show that a single set of fragility curves and vulnerability curve can be adopted for the pre and low code vintage buildings. Also, it was observed that the fragility curves for all codes were very close to one another.

Abstract: Determining the earthquake risk of buildings in a town or settlement has lately become a more prominent issue. The process can provide important data for governments, authorities, disaster management and insurance companies to better understand risks to many buildings and engineering systems rather than a single building. By this assessment process they can make better decisions about remedial actions, insurance underwriting, and evacuation and rescue. This paper addresses the rapid evaluation of a large number of similar buildings in the area of Győr. The steps involve determination of the hazard, assessing building stock, and computing vulnerability. The method for determination of vulnerability functions is a non-linear static analysis using a simple model with the bilinear approximation of the capacity curve, assuming first mode force distribution and linear first mode shape thus linear strength distribution. From the curve of the seismic demand and the shear capacity of the building the vulnerability function of the building can be obtained. These vulnerability functions should be derived for typical layouts, offering a family of curves allowing the experts to decide the vulnerability category of a specific building on-site based on visual screening.

1. INTRODUCTION

Recent earthquakes with high number of casualties and enormous devastation proved that the hazard of natural disasters should not be neglected. Preventive approaches have received greater attention recently. Research in earthquake hazard mitigation has focused on evaluating possible damage scenarios for different magnitude events (Luco et al 2007; Committee on National Earthquake Resilience 2011). Two widely different approaches exist; one considers the effect of previous earthquakes, listing the damaged buildings and casualties. The other offers a method to evaluate possible damages prior to an event. The latter method facilitates prevention by gathering information about the state of the building stock and the expected damages, so the authorities can strengthen the most vulnerable buildings in order to mitigate risk.

The challenge with this method is that many uncertainties must be taken into consideration. In order to determine earthquake risk within towns a fast and simple method should be developed. Otherwise it would be very time-consuming and require too much expert participation. The steps are the following:

- determin the hazard and the expectance of an earthquake,
- assess building stock with the help of previously derived vulnerability functions.

With given input parameters of subsoil and PGA (peak ground acceleration) and the examined vulnerability, the damage based on building classes can be obtained, and earthquake scenarios can be derived.

This concept is suitable even in Hungary. Here there are about 100-120 smaller earthquakes per year; which are below the perceptible level, and 4-5 perceptible earthquakes per year (Földrengés Információs Rendszer / Earthquake Information System / www.foldrenges.hu). Earthquakes with a greater effect, causing structural damages can be expected every 15-20 years, and in 40-50 years major earthquakes with high economic and social effects. With this earthquake hazard level, Hungary ranks with the medium-hazardous countries.

In Hungary, the goal should be the reduction of the expected damage during an earthquake. This provides an economic motivation for funding and executing seismic engineering research..

2. EARTHQUAKE RISK ANALYSIS

2.1 Proposed process to derive earthquake risk

Calculating earthquake risk requires the cooperation of several disciplines: seismic engineering and architects. Many factors must be considered as shown in table 1. Data obtained from paleoseismic studies and seismic engineering research will further enhance regional hazard assessment and development of microzonation maps. Such efforts would consider local site effects and examine a significant database of buildings with computed vulnerability so that earthquake risk can be assessed:

RISK = HAZARD×VULNERABILITY×EXPOSURE (1)

Table 1 Factors affecting hazard and vulnerability (EMS)

Factors affecting the earthquake hazard:	Factors affecting building vulnerability:
type of soil thickness of layers lateral variation of layers the potential of liquefaction master faults	construction system and period quality of materials, workmanship regularity in plan and elevation position of the building changes in function, damages, state of the building dynamic characteristics

First of all the hazard map of the investigated area should be performed taking into account the local site effects, the potential of liquefaction, type of the soil, etc. The obtained PGA with 10% PE in 50 yrs (this value is used at design) will be the input parameter for vulnerability analysis.

The second step can be the identification of the building classes due to the construction systems. The vulnerability functions of each building class considering the sample can be derived based on the determined damage grades as a function of PGA and natural period of vibration of the building.

Afterwards the building inventory can be made considering the vulnerability functions. For a given district of the city the buildings belonging to different building classes can be listed, and the mean damage of every building class can be calculated with the help of Eq. (2) below (Fäh et al. 2001):

$$MDF = \sum_i P(DG_i | S_d) \cdot CDF \tag{2}$$

where CDF is the central damage factor and DG is the damage grade to a given earthquake. The overall damage concerning a city district can be obtained with the help of the following formula (Fäh et al. 2001):

$$OD = \underset{cell \subset district}{mean} \left(\sum_{class} P_{class} \frac{VF_{class}(S_d)}{100} \right) \tag{3}$$

where VF is the vulnerability function of a given building class.

Based on these data and expected PGA, vulnerability functions can be obtained for each building class. With given vulnerability curves, there is a possibility for rapid evaluation of buildings on-site. Mean damage can be obtained concerning a building class, and overall damage can be derived based on all building classes, resulting in assessment of earthquake risk.

2.2 Defining vulnerability

One of the basic tasks in determining vulnerability of buildings is the classification of buildings from the point of view of earthquake risk. The classification worked out researchers and agencies (EMS 1998, Vaseva 2002) is largely based on inspections of structural systems, possibly the time of construction and the proximity to earthquakes. The aim of this study is to work out a more precise method, which takes more factors into consideration such as the regularity in the layout, the direction of earthquake wave propagation to the building, etc.

Vulnerability is the possibility of damage or loss of buildings due to a seismic event. It is a characteristic of the building and can be expressed in probabilistic or statistical terms. A vulnerability function is typically expressed as a function of ground motion intensity.

The vulnerability function of each building class is derived from the load-bearing capacity of the buildings and the seismic demand expressed by spectral acceleration. The extent of damage can be represented by damage grades related to the onset of cracking, the yield point and destruction. The purpose is to build up a more complex method, which takes into account more parameters influencing the vulnerability: type and material of the structure, the irregularity of the layout, the number of stories, dynamic characteristics, etc.

Vulnerability as an input parameter to earthquake scenarios requires evaluation of a large building population in a rather short period of time using a simple method, which describes the seismic performance of the buildings adequately. There are different methods to analyze the vulnerability of the buildings: methods used during the post-earthquake study as well as analytical or numerical methods. Vulnerability can be determined by observation or based on expert opinions; usually based on post-earthquake studies. Other methods offer a possibility to estimate the possible damages before an earthquake occurs.

In the case of observed vulnerability (Haddar 1994, Castano 1994, Porro et al .1989) the damage is defined with the repair cost as a ratio of the replacement cost or the amount of loss of all affected buildings considering the number of casualties as a ratio of their value. The relation between damage and earthquake intensity is valid only for the region where it was developed. Another method is to ask experts to estimate the expected percentage of damage cause by a given intensity, which are implied in macroseismic scales. These scales are used to evaluate the possible damages after an earthquake (Fäh et al. 2001).

Analytical approaches are based on identification of collapse mechanisms yielding the equivalent shear capacity (Benedetti et al. 1996). The vulnerability is expressed as the critical acceleration causing the mechanism to take place. In the case of score assignment, the structural deficiencies are identified and scores for different deficiencies are calibrated by experts (Calvi 1999).

Detailed analyses are the most time-consuming evaluation of vulnerability. These analyses correspond to the methods of design: linear static analysis (lateral force method); modal response spectrum analysis which is a linear dynamical analysis; pushover analysis (Lang et al. 2000), an increasingly popular non-linear static analysis; and a fully non-linear time-history dynamic analysis. The analyses above are listed in increasing order of complexity, work demand, cost, and difficulty of interpretation. For regional applications finding a balance between available resources and level of sophistication is a major challenge.

3. VULNERABILITY OF BUILDINGS

3.1 Shear capacity of buildings

First, the differences between evaluation and design should be understood. The aim of design is to create a building that resists expected forces with a margin of safety. A simplified model should be used that may neglect the positive influence of some elements. The calculation should be on the safe side: material strength reduction factors are used and applied forces are enhanced.

In the case of evaluation, the most important information is the building response to given forces. So the model should be as close to reality as possible, taking into account all structural elements. Actual material properties and true loading levels, without safety factors, should be taken into account.

As mentioned before all structural elements, which contribute to the load bearing capacity of the building should be considered. This means walls thicker than 12 cm are considered. The non-structural elements add to the mass only. The walls are joined by floors and spandrels, these elements transfer horizontal forces.

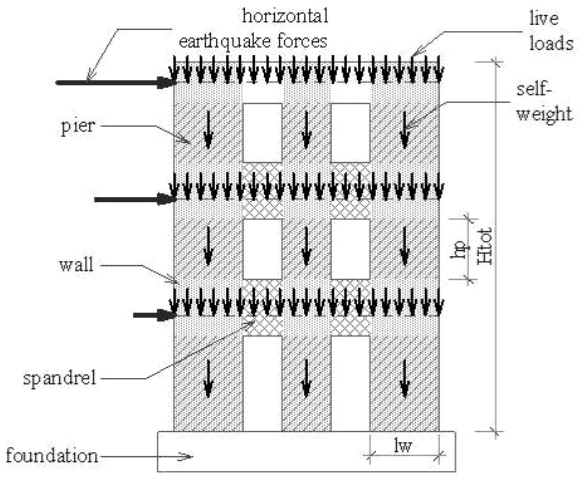

Figure 1 Structural model of a masonry building

The equivalent horizontal earthquake forces act at the floor levels, where the mass is concentrated. The vertical forces imply self weight of all elements and live loads.

The piers transfer all forces to the ground and are the most critical part of the building. The height of the piers is assumed equal to the height of the adjacent opening. Early cracking of the spandrels reduces the stiffness of the spandrels. As the walls are joined by spandrels a coupling effect will take place depending on the extent of spandrels.

The capacity curve of a wall element can be calculated by increasing the shear gradually until the material condition is exceeded. The base shear can be plotted as a function of top displacement.

The horizontal deformation (δ) is calculated by the principle of virtual work. A constant drift over the building height is hypothesized and drift corresponds to the first mode shape assuming a linear distribution of the force.

Drift can be calculated with the following formula:

$$\delta = \frac{d}{h_p}, \tag{4}$$

where hp is the height of the pier, d is the horizontal deformation.

Displacement can be obtained as a ratio of the drift and the total height of the building:

$$\Delta = \delta \cdot H_{tot}. \tag{5}$$

According to a bilinear approximation, the capacity curve of a wall element can be characterized by three parameters: the maximum shear strength of the wall element, the nominal yield displacement (Δy) at the top of the wall and the ultimate displacement (Δu) at the top of the wall. The transition between the linear elastic and perfectly plastic region is called the yield point even if masonry structures do not truly yield.

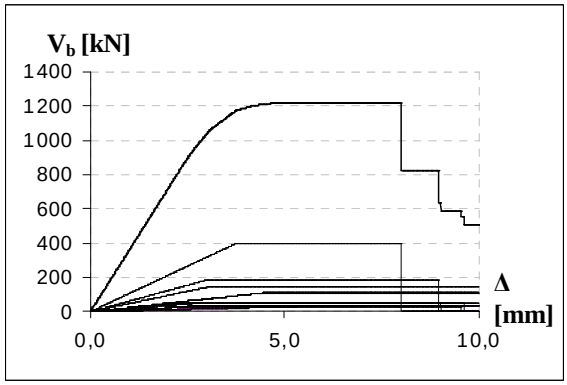

Figure 2 Shear capacity of a building

$$\Delta_y = V_m \cdot H_{tot} \cdot \left(\frac{h_p \cdot (3h_0 - h_p)}{6 \cdot E \cdot I_{eff}} + \frac{\kappa}{G \cdot A_{eff}} \right) \tag{6}$$

$$\Delta_u = \mu_w \cdot \Delta_y \tag{7}$$

3.2 Identification of damage

Identification of damage grades is required to determine the vulnerability function of the building. In the European Macroseismic Scale, five grades are differentiated from slight damage to total destruction.

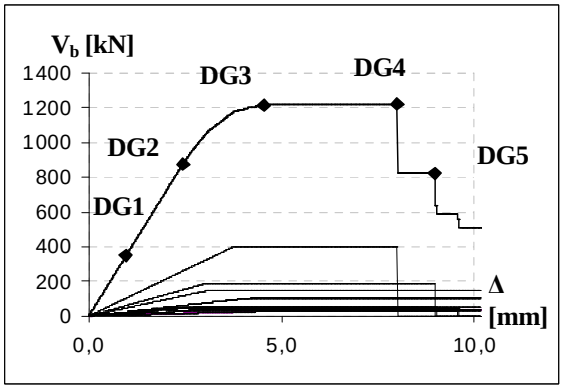

Figure 3 Identification of damage grades

Many studies relate the damage grade to monetary loss

and the number of casualties, which can be useful in the case of post-earthquake studies. The method, which defines indicators, allows the identification of points were the capacity curve of the building enters the next damage grade. The damage grades given in EMS 98 are related to the displacements at the top of the building and are given in Table 2.

Table 2 Identification of damage grades

DG	EMS 98	after Lang [14]
1	negligible to slight damage	point of onset cracking
2	moderate damage	yield of the first wall
3	substantial to heavy damage	yield of the last wall
4	very heavy damage	failure of the first wall
5	destruction	drop of the base shear capacity below 2/3 of maximum V_{bm}

3.3 Seismic demand

The seismic demand is determined using an elastic acceleration response spectrum. It represents the maximum response of equivalent single degree of freedom system as a function of their frequencies.

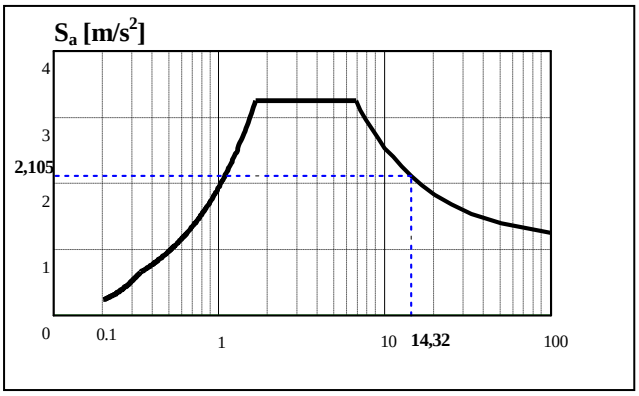

Figure 3 Elastic acceleration response spectrum medium stiff soil, 5% damping, ag=1,1 m/s2

The displacement demand can be calculated from the following equations:
fundamental frequency of the equivalent SDOF system:

$$f = \frac{1}{2\pi} \cdot \sqrt{\frac{k_E}{m_E}} \tag{8}$$

modal participation factor:

$$\Gamma = \frac{\sum m_i \cdot \phi_i}{\sum m_i \cdot \phi_i^{\,2}} \tag{9}$$

spectral displacement:

$$\Delta = \Delta_{by} \cdot \frac{1}{2} \cdot \left(\left(\frac{k \cdot \Gamma \cdot S_d}{V_{bm}} \right) + 1 \right) \tag{10}$$

displacement demand:

$$S_d(f_1) = \frac{S_a(f_1)}{(2\pi \cdot f_1)^2} \tag{11}$$

The spectral displacement should be then compared with the displacement capacity of the building.

3.4 Vulnerability of buildings

From the figure of the shear capacity of the building and the seismic demand the third curve, the vulnerability function can be plotted. Varying the intensity of seismic demand for every case the displacement of the building can be plotted. With increasing displacement demand the top displacement of the building increases as well.

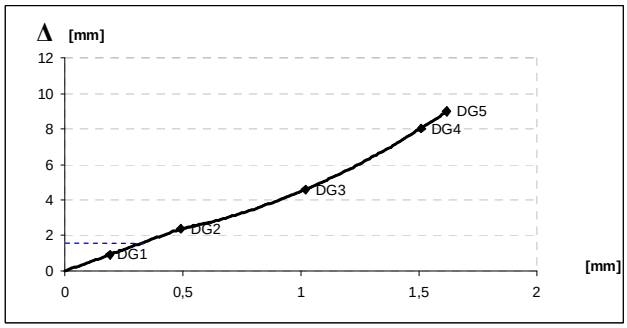

Figure 4 Vulnerability function

Plotting the damage grades on the figure will provide the vulnerability function of the building shown in figure 4.

4. EXAMINED AREA

4.1 City of Győr

Győr is the most important city of northwest Hungary often referred to as the City of Associations or Meetings. The city is the sixth largest in Hungary, and it is the capital of Győr-Moson-Sopron county and Western Transdanubia region, an important economic, industrial, ecclesiastic, educational, cultural and sports centre. The dynamically developing city lies halfway between Budapest and Vienna, on one of the important roads of Central Europe with an excellent accessibility.

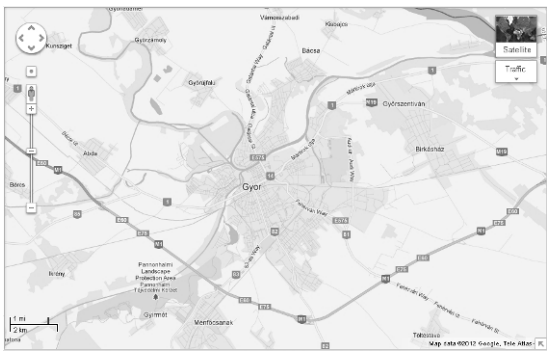

Figure 5 City of Győr, main roads and rivers crossing

Győr is also referred to as the City of Waters as it lies at the bank of river Rába, just at the confluence of the Moson-Danube, the Rába and the Rábca not far away from the main chanel of the Danube and it is rich in thermal water

as well. Győr is Hungary's second richest town in historic buildings outside Budapest. Characteristic corner-balconies and narrow lanes, churches, museums are all reminders of a historic past, mainly situated in the centre of the town.

From a geological point of view Győr lies in the eastern part of Little Hungarian Plain. The Little Hungarian Plain is a deflational lowland of ca. 7700 km^2 on the western part of the Carpathian Basin System. Its medium altitude is 125 m a.s.l., a little higher than that of the Great Hungarian Plain. The river Danube divides into a southern and a northern part.

The southern marginal hills consist of gently undulating hilly country, dissected by a deep valley. They are composed of sandstones, gravel and clay. The present morphology was formed during the Quaternary period by fluvial erosion, tectonic movements and deflation processes. The northern margin of the Little Plain consists of similarly hilly country dominated by thick loess cover. The rivers entering the Little Plain flow eastward.

The Little Hungarian Plain is a structural basin, subsided along step faults and the basement can be found beneath thick basin sediments. Two large tectonic lineaments in the basement determine the geological structure.

4.2 Seismicity of Győr

The tectonics of the Carpathian basin is determined by the counterclockwise rotation of the Adria microplate and the north-northeast directed movement originating from the rotation. The seismicity of the area is moderate. Earthquakes causing light damages occur every 15–20 years, while stronger, more damaging 5.5–6 magnitude quakes happen about every 40–50 years.

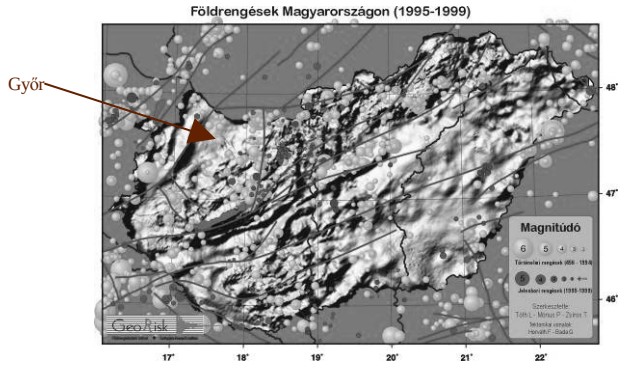

Figure 6 Seismic activity and fault lines in Hungary (Georisk)

The distribution of earthquakes is diffuse; however, there are certain areas where the occurrence is higher. For example at the surroundings of Komárom-Mór-Berhida, known as Móri-trench, where the largest earthquake of Hungary occurred in the city of Komárom in 1763 with estimated magnitude of 6.1. This is shown also in the seismic hazard map of Hungary computed for 475 years return period. PGA values were computed for bedrock and are expressed in m/s^2.

Aerial distance between Győr and Móri-trench is 60 km. Historic data show that major earthquakes of this area had significant effect on buildings in Győr. The importance of the city as a regional centre, the number of inhabitants and the closeness to the above-mentioned fault emphasizes the necessity of earthquake risk analysis of this town.

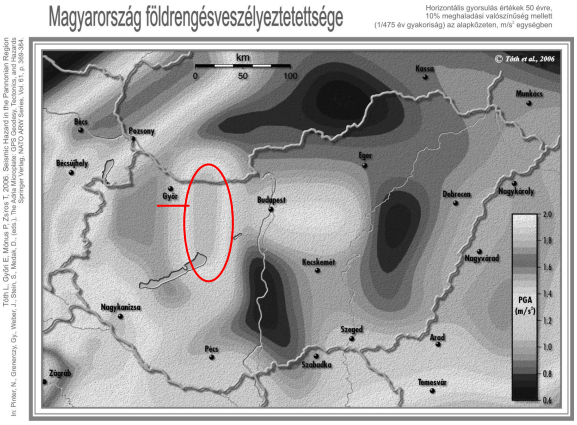

Figure 7 Seismic hazard map of Hungary indicated Móri-trench and Győr (Georisk)

The other significant fault lies beneath the river Rába and meets the fault beneath river Mosoni-Duna at Győr. Recorded earthquakes with epicenter at Győr mainly occur due to these faults.

Table 3 Historical earthquakes with epicenter at Győr and approximately 8 km depth

Date	Magnitude	Maximum intensity

4.2 Examined zones and buildings

Twenty six selected zones were examined more closely. The zones differ from each other not only in location, but also in types and ages of buildings. Building data were gathered with the help of a questionnaire and the screening evaluation of trained staff. Data concerning the soil types and layers were collected in parallel.

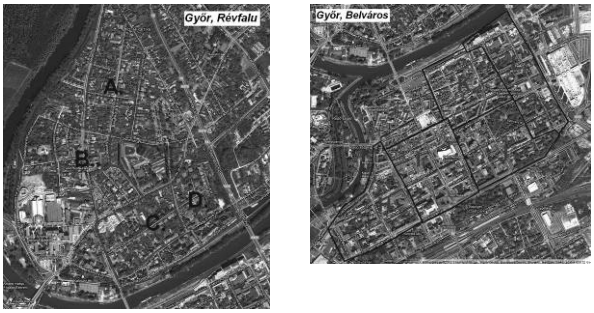

Figure 8 Zones from the town part called Révfalu and the inner city

The checklist consisted of questions about:

- General data of each building (age and function of the buildings, regularity in plan and elevation, position of the building, changes in function, previous damages, state of the building, etc.)
- Structural data of each building (dimensions, construction system, quality of materials, workmanship)

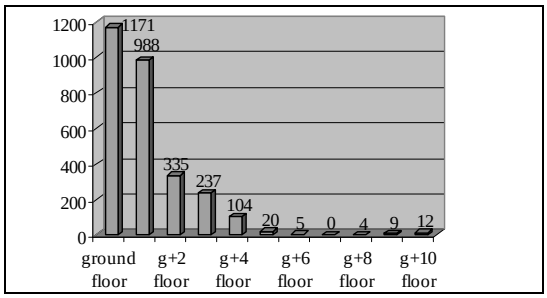

Figure 9 Building heights of the analyzed town parts

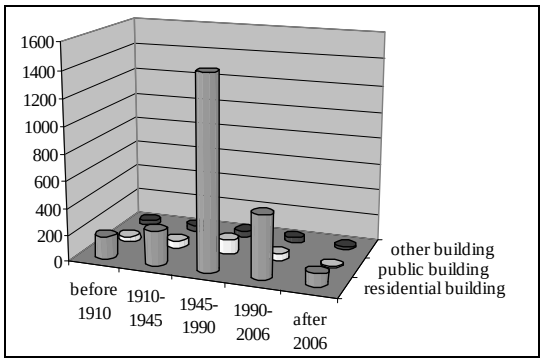

Figure 10 Building functions and construction period

Data from 2885 building were analysed, and buildings are classified based on these results. For each building class a vulnerability function is assigned. The above figures give an overview about the analysed building-stock.

5. CONCLUSIONS

First, it should be emphasized that a large percentage of building stock was built without considering of earthquake loads and these buildings are very vulnerable to a moderately strong seismic event. Focus of efforts should be directed toward prevention: a relatively large building stock needs reinforcement, highlighting the importance of this research.

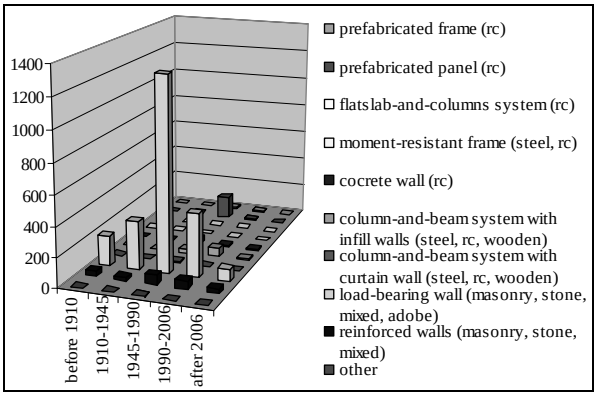

Figure 11 Structure of the buildings and construction period

The vulnerability functions are being derived for typical layouts, this way offering many curves, and with these experts could decide on-site which group belongs just based on visual screening. With the given value of possible PGA it can be stated the expectable damage.

This way the method offers a fast evaluation method and allows the accomplishment of earthquake scenarios to a given settlement. This is very important because it provides useful information for governments, authorities and insurance companies and helps to set up a priority order, which buildings should be strengthen first.

Abstract: Condition assessment of a building is an important step in preparation for an earthquake. In the Philippines, FEMA-154 and ATC-20 are the assessment tools adopted to evaluate buildings. However the scores in these forms are based from the fragility curves developed for buildings found in the United States and hence exhibit different seismic capacity compared to buildings in the Philippines. This was observed when a school building in Cebu City was judged safe using FEMA-154 but was judged otherwise by the local engineers after entering the building based on excessive deflection seen on the beams and large cracks on the interior walls due to settlement. This created the motivation to pursue a study in developing a pre-earthquake assessment tool that is rapid, visual and is reflective of the structural condition of the buildings in the Philippines. The assessment tool is patterned after FEMA-154 with its structural and cut-off scores modified by employing the fragility curves developed by the UP-ICE applicable for low to mid-rise reinforced concrete buildings in Metro Manila. In addition, a damage modification factor based from the quantified residual seismic capacity was employed. These scores were calibrated by conducting several building assessments using the developed tool.

1. INTRODUCTION

In 2004, Japanese researchers collaborating with scientists from PHIVOLCS conducted the Metro Manila Earthquake Impact Reduction Study (MMEIRS). Their work included risk assessment due to scenario earthquakes caused by movement from different active faults in the country. Their results indicate 40% of residential buildings will be damaged in the event of magnitude 7.2 earthquake occurring in the West Valley Fault, resulting in 34,000 deaths and 110,000 injured (Solidum et al. 2004). At present, PHIVOLCS continues to warn the public in the Metro Manila area of a possible earthquake event occurring in the West Valley fault (formerly called the Marikina fault).

Noting that earthquake is just one type of hazard that the Philippines is subjected to, the national government, through the National Disaster Risk Reduction and Management Council (NDRRMC), is responding to the challenge by conducting appropriate programs and projects that strengthen the capacities of LGUs and communities in preparing for and responding to hazards. In particular, the Department of the Interior and Local Government (DILG), an integral part of the NDRRMC, is implementing a locally-funded project entitled, "Enhancing LGU Capacity on Climate Change Adaptation and Disaster Risk Management." The project encourages LGUs to integrate disaster-resiliency and Climate Change adaptation in local development planning, programming and implementation. One of the project steps is the Mandatory Inspection of Local Government Infrastructure Projects and Public Buildings. This initiated the development of assessment tools on Infrastructure Audit, both for buildings and bridges. These were initially introduced in twenty-eight (28) LGUs in Region IV-A before they will be institutionalized at the LGU level (correspondence of USec Panadero to Dean Matias July 22, 2011). However, the infrastructure audit developed lacks the mechanism for identifying which among the existing buildings should be prioritized in the detailed investigation and possible retrofit, should this be recommended.

In the US, the Federal Emergency Management Agency (FEMA) released the second edition of the widely used Rapid Visual Screening of Buildings for Potential Seismic Hazards: A Handbook - the FEMA 154. The principal purpose of the FEMA 154 is to identify (1) older buildings designed and constructed before the adoption of adequate seismic design and detailing requirements, (2) buildings on soft or poor soils, or (3) buildings having performance characteristics that negatively influence their seismic response (FEMA 154). These buildings should then be recommended for detailed investigation to determine if they endanger occupants in the event of an earthquake. Each building is provided an overall score which allows ranking of the buildings in terms of need for detailed investigation.

Likewise, the American Society of Civil Engineers

(ASCE) published Seismic Evaluation of Existing Buildings - the ASCE 31-03. This is the first national seismic evaluation standard in the US, previously released as FEMA 310: Handbook for the Seismic Evaluation of Buildings - A Prestandard. Using this standard, existing buildings are evaluated to either the Life Safety or Immediate Occupancy Performance Level, considering structural, nonstructural, and foundations/geologic hazard issues.

Currently there is a program that is geared towards response to reduce the damage caused by quick-onset events like earthquake. It is known as the Earthquake Quick Response Program (EQRP formerly known as DQRP-Disaster Quick Response Program). The program utilizes inspection surveys of structures before and after an earthquake.

The pre-earthquake inspection survey tool is based on FEMA-154 Rapid Visual Screening of Structures for Potential Seismic Hazards while the post-earthquake inspection survey is based on ATC-20 Post Earthquake Safety Evaluation of Buildings. These instruments were developed in the United States and the conditions of structures considered were not locally based.

Movement of the West Valley fault will definitely affect building structures in Metro Manila. It is therefore necessary that existing buildings be assessed for structural integrity and if found lacking be recommended for repair, rehabilitation and/or retrofit in preparation for the large magnitude seismic forces that may be developed by the existing fault. Therefore, a tool that can be used for rapid condition assessment, applicable to buildings locally constructed and capable of identifying which buildings should be prioritized for detailed investigation should be developed. This study is focused with the development of basic structural scores for low to mid rise reinforced concrete frame buildings since these are the most common building types seen in the country. Moreover, this study aims to develop an assessment tool that can be used even by someone with basic knowledge in structural engineering.

2. DATA COLLECTION FORM

The data collection form for structural component has two major parts. The first part quantifies the performance of a building based on the building attributes such as structural configuration and soil condition. This part is in general patterned after FEMA 154 with its basic structural hazard scores and score modifiers altered using the locally developed fragility curves for the Metro Manila.

The second part, on the other hand, takes into account the damages incurred in the building components. This portion was patterned after the quantification of post-earthquake damages in RC buildings in Japan using residual seismic capacity. By visually classifying and accounting the damages in columns and walls, the ratio of the residual seismic capacity to the initial seismic capacity can be estimated, which became the basis for the formulation of the procedure in quantifying the damage modification factor. This factor represents the percentage of the remaining seismic capacity of the building.

Additional information on the structural integrity of the building can be reflected through sketches, photos and commentary boxes that are also provided in the form.

2.1Basic Structural Hazard Score

In the second edition of the FEMA 154 *Handbook*, the Basic Structural Hazard Score is defined, for a particular type or class of building, as the negative of the logarithm (base 10) of the probability of collapse of the building, given the ground motion corresponding to the maximum considered earthquake (MCE). This can be written as follows,

$$\text{BSH Score} = -\log_{10}[(P|\text{Collapse given MCE})] \quad (1)$$

The probability of collapse of a building is the product of the probability of being in the complete damage state, multiplied by the fraction of buildings in the complete damage state that collapse written as follows, (FEMA 155)

$$\text{BSH Score} = -\log_{10}[P(\text{Collapse}|\text{Complete Damage State}) \times P(\text{Complete Damage State})] \quad (2)$$

The basic structural hazard score is generic for one building type. The default structure for reinforced concrete moment frame (C1) used in this study is a regular low-rise building on soil type D.

To compute for the basic structural hazard score for C1, fragility curve for C1L on soil type D is needed as shown in Figure 1.

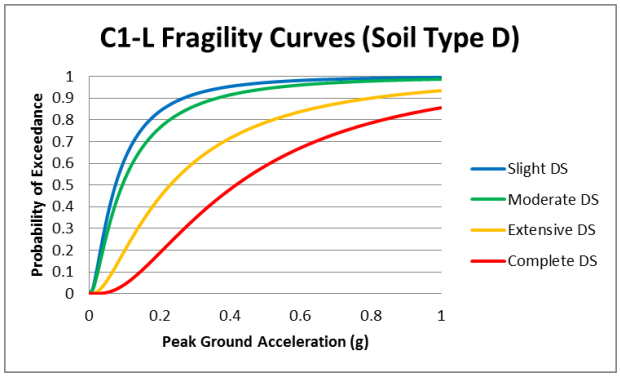

Figure 1: Fragility curves for reinforced concrete moment frame low-rise on soil type D. (SOURCE: UPD-ICE, Development of Vulnerability Curves of Key Building Types in Greater Metro Manila Area, [an ongoing research])

Before determining the probability of exceeding complete damage state at the given MCE, the peak ground acceleration of the maximum considered earthquake must be calculated first.

The maximum considered earthquake is the largest earthquake event applied in building code design. According to the collective opinion of the Seismic Design Procedure Group (SDPG), the minimum seismic margin contained in the 1997 NEHRP Provisions is about 1.5 times the design earthquake ground motions. (BSSC 1998, Appendix A, Commentary)

Since in the development of the fragility curves utilized in determining scores, the demand spectrum comes from the design response spectra, the maximum considered earthquake will be computed from the same, wherein the seismic coefficient Ca represents the peak ground acceleration in g. Hence to determine the MCE, the design earthquake in terms of the seismic coefficient will be multiplied by 1.5.

In determining the seismic source type it is necessary to determine the maximum moment magnitude for a given site which can be estimated from the nearest fault or seismic source. Since the area of interest is in Diliman Quezon City, wherein the West Valley Fault is the nearest seismic source capable of producing a maximum credible earthquake of 7 (Nelson et.al. 2000), the seismic source type is classified as A. Using the National Structural Code of the Philippines 2010 (NSCP-2010) Chapter 2- Minimum Design Loads, the near source factor Na is equal to 1.0 and consecutively the seismic coefficient Ca for soil type D under seismic zone 4 is computed as 0.44Na. Hence the design earthquake is equal to 0.44 g.

Multiplying the design earthquake by a factor of 1.5 gives the MCE equal to 0.66 g. To determine the probability of exceeding the complete damage state, the MCE is projected to the fragility curve for complete damage state and the corresponding probability is determined. Hence the probability of being in or exceeding the complete damage state is equal to 71%.

The collapse rates for different structure types may be found in HAZUS-MR4 Table 13.8 which is reposted in Table 1. Using equation (1), BSH is computed as follows,

$$\text{Score} = -\log_{10}[(0.71)(0.13)] = 1.04$$

2.2Basic Structural Hazard Score Modifiers

The default structure for reinforced concrete moment frame is regular, low-rise and on soil type D. If the inspected building differs from the default structure, score modifiers are used to take these variations into account. The parameters that can vary include the following: elevation of the structure that can either be low-rise (1-2 stories) or mid-rise (3-7 stories); the irregularity present in the structural configuration (plan and vertical irregularity); the code used in the design of the structure which can be identified with the age of the structure namely pre-code (buildings designed before 1972) , low-code (buildings designed between 1972-1992) or high-code(post-1992 buildings); and the soil profile type where the structure is constructed (in Metro Manila only three soil types exist: soil type C, soil type D, and soil type F). The score modifiers for each variation are quantified by taking the difference between the structural score for each variation with the basic structural score based from the default structure.

Table 1. HAZUS MR4 Collapse Rates of different Structure Types.

	Model Building Type	Probability of Collapse Given a Complete Damage State*
1	W1	3.0%
2	W2	3.0%
3	S1L	8.0%
4	S1M	5.0%
5	S1H	3.0%
6	S2L	8.0%
7	S2M	5.0%
8	S2H	3.0%
9	S3	3.0%
10	S4L	8.0%
11	S4M	5.0%
12	S4H	3.0%
13	S5L	8.0%
14	S5M	5.0%
15	S5H	3.0%
16	C1L	13.0%
17	C1M	10.0%
18	C1H	5.0%
19	C2L	13.0%
20	C2M	10.0%
21	C2H	5.0%
22	C3L	15.0%
23	C3M	13.0%
24	C3H	10.0%
25	PC1	15.0%
26	PC2L	15.0%
27	PC2M	13.0%
28	PC2H	10.0%
29	RM1L	13.0%
30	RM1M	10.0%
31	RM2L	13.0%
32	RM2M	10.0%
33	RM2H	5.0%
34	URML	15.0%
35	URMM	15.0%
36	MH	3.0%

Summarized in Table 2 are the structural scores computed for each variation.

2.2.1 Score modifier for Mid-rise Buildings

The score modifier for mid-rise buildings was calculated using two sets of structural scores. One for low-rise reinforced concrete buildings and the other is for mid-rise reinforced concrete buildings, both having the same soil type. From Table 2, the basic structural hazard score is 1.04 which was based from low-rise and having designed under high code, and the structural score for C1M designed under high code for the same soil type is 1.30. Hence the score modifier is +0.26.

Table 2: Summary of Structural Scores.

	Mean	BETA	MCE	Pcomplete	Collapse Rate	BHS
C1-L (D)	0.42	0.82	0.66	0.71	0.13	**1.04**
C1-L (C)	0.43	0.81	0.6	0.66	0.13	**1.07**
C1-L(E)	0.28	0.89	0.66	0.83	0.13	**0.97**
C1-M(PRE)	0.54	0.74	0.66	0.61	0.1	**1.22**
C1-M(LOW)	0.54	0.74	0.66	0.61	0.1	**1.22**
C1-M(HI)	0.66	0.73	0.66	0.50	0.1	**1.30**
Plan	0.3	0.82	0.66	0.83	0.13	**0.97**

2.2.2 Score modifier for Plan Irregularity

According to FEMA-155, there was no Score Modifier for plan irregularity that is straightforward to calculate, principally because eccentricity is specific to each building. Hence, to approximate the effect of plan irregularity the spectral response values were increased by 50% where the fragility curve will be based and correspondingly the structural score. Employing such increase will yield a structural score of 0.97. Hence the Score Modifier for Plan Irregularities is -0.07.

2.2.3 Score modifier for Vertical Irregularity

The score modifier for vertical irregularity cannot be quantified due to large variation in the configurations and conditions. Hence the value is approximated using engineering judgment. But since this study already modifies the scores in FEMA-154, score modifier for vertical irregularity presented in FEMA-154 cannot be utilized directly. To be consistent with that of FEMA 154, an initial value of -0.45 was selected.

2.2.4 Score modifiers for Pre-code and Post Benchmark Construction

The same procedure as how the score modifier for mid-rise was calculated is employed here. However since there is only one vintage used in the development of the fragility curve for C1L, score modifiers for vintages will be based on C1M. Hence three sets of structural scores will be determined with the one in high code as the default score. Again as summarized in Table 2, both structural scores for pre and low code is given by 1.22 while for high code it is 1.30. Hence the score modifier for both pre and low code is -0.08.

2.2.5 Score modifiers for soil type C, D, and F.

Employing the same procedure, structural scores for C1L on soil types, D, C, and E were computed as 1.04, 1.07 and 0.97 respectively. Hence the score modifiers for soil type C and E are +0.03 and -0.07 respectively.

The score modifiers are summarized in Table3.

Table3. Score Modifiers

Score Modifiers	
MID RISE	0.26
VERT. IRREGULARITY	-0.45
PLAN IRREGULARITY	-0.0692
PRECODE	-0.08
LOW CODE	-0.08
SOIL TYPE C	0.03154
SOIL TYPE E	-0.0695
SOIL TYPE F	**

2.3 Damage Modification Factor

Part of the limitations observed in using FEMA-154 is it evaluates buildings based on exterior attributes only. The final score acquired by the building after being assessed using this tool represents the initial seismic capacity of the building before earthquake damage. Thus, it lacks the ability to consider existing interior damage which could be observed when access to the building is allowed.

In the Guideline for Post-Earthquake Damage Evaluation and Rehabilitation of RC Buildings in Japan, the damage rating procedure was based on the residual seismic capacity ratio index R. Utilizing a similar concept, by quantifying the residual seismic capacity and determining its ratio from the initial seismic capacity, the factor can be used to represent a modification factor for the structural scores to account for the damage incurred by the building approximated from visual assessment of interior components such as columns and walls.

With the employment of a normalized strength index for each typical member section which often appears in existing RC buildings in Japan considering ultimate shear stress and effective sectional area of each section type, an alternative simplified procedure of calculating the R-index is proposed in the same paper. By classifying and accounting the type of columns and walls with its corresponding damage classification, the R-index can be approximated. (Maeda et.al. 2004)

DAMAGE MODIFICATION FACTOR				
COLUMN TYPE	NO DAMAGE	MODERATE DAMAGE	HEAVY DAMAGE	TOTAL FACTORED ***
LONG: h/d>6	*1	*0.5	*0	
SHORT: h/d<=6	*1	*0.3	*0	
TOTAL # OF COLUMNS				

Figure2.Portion in the data collection form that quantifies for the damage modification factor.

Since the study is focused on low-rise reinforced concrete moment resisting frames, the procedure presented in the previously mentioned paper can be further simplified by considering only the columns in the evaluation. Assuming ductile columns are associated with long columns, defined as columns with clear span to smallest depth ratio greater than or equal to 6, and short columns otherwise, which will be associated to brittle columns. Furthermore, the damage class will be reduced from five classes to only three namely, "no damage", "moderate damage", and "heavy damage" for ease in classifying damages in a rapid visual inspection. The same factors for Damage Class 0, Damage Class III, and Damage Class V respectively will be adopted. Hence a portion that quantifies the damage modification factor was formulated and is shown in Figure2.

2.4 Cut-off Score

According to the second edition of FEMA-155 which provides the technical manual for the FEMA-154, the selection of the cut-off score is a prerogative of the community utilizing the inspection tool. The cut-off score of about 2.0 was recommended after fifteen years of experience in the use of FEMA-154 that validated this decision. There are cases wherein users opted to use higher cut-off scores which imply a safer environment, at a correspondingly higher cost. (FEMA-155 2nd edition).

In order to come up with a rational choice of the cut-off score in this case, DQRP case studies and reports were reviewed. One of the major observations from DQRP case studies and reports is that concrete hollow block (CHB) and wood low-rise structures that were inspected received only either a yellow or a red tag. CHB structures are low-rise structures with walls made of concrete hollow blocks interlocked at the corners and have no reinforced concrete frame. The floors consist of either plywood or board sheathing, supported by wood subframing. The roofs are corrugated galvanized iron sheets attached to wooden or light metal wood trusses. The received tags on these structures imply that these structures may pose a greater threat to the safety of its occupants during and after an earthquake. Thus, it may be rational to say that these existing structures must be evaluated in detail for seismic considerations even before conducting a rapid condition assessment.

Fragility curves developed by the UPD-ICE for wood structures are based on the MMEIRS data. In MMEIRS, they defined two types of damages one being "partly damaged" and the other being "heavily damaged". Consistency with the damage state definitions is still being reviewed. Fragility curves for CHB, on the other hand is based on a compilation of empirical observations of damage for corresponding ground motion intensities in terms of Modified Mercalli Intensity (MMI) from past earthquakes in the Philippines. Hence this data will be used in calculating the cut-off score. However, the resulting fragility curve is in terms of MMI and needs to be converted to PGA before utilizing it to compute for the probability of being in or exceeding the complete damage state given the MCE.

Using the mean and standard deviation of 7.4 and 0.14 respectively of the fragility curve under complete damage state for CHB as reported in the UPD-ICE report, the probability of exceedance is computed for an arbitrary set of ground motion intensities in MMI. This is shown in the first two columns of Table 4. The ground motion intensity in MMI is then converted to Peak Ground Acceleration in (g) using the Gutenberg-Richter MMI to PGA relationship defined in the following equation.

$$log_{10}(a) = \frac{I}{3} - 0.5 \qquad (3)$$

Where a is acceleration in terms of gals (cm/s^2) and I is the ground motion intensity in terms of MMI. The corresponding conversion is presented in column 3 of Table 4.

The probability of exceeding complete damage state is plotted against the peak ground acceleration. These points will be regarded as the data points where a lognormal cumulative distribution curve will be fitted and the corresponding mean and standard deviation will then be used to compute for the probability of being in or exceeding the complete damage state at the given maximum considered earthquake. This is illustrated in Figure 3 wherein the corresponding mean and standard deviation is also presented.

Illustrated below is the computation of basic structural hazard score for CHB.

$$\mathbf{BSH} = -\log_{10}\big((0.99)(0.15)\big) = 0.83 \qquad (4)$$

Table 4.Tabulation of Probability of Exceeding the Complete Damage State for CHB.

MMI	Probability of Exceedance	PGA
1	1.154E-46	0.000694
2	4.5843E-21	0.001496
3	5.6275E-11	0.003224
4	5.5595E-06	0.006945
5	0.00255275	0.014962
6	0.06706613	0.032235
7	0.34571046	0.069449
8	0.71119124	0.149623
9	0.91896982	0.322352
10	0.98425206	0.694487
11	0.99768376	1.496228
12	0.99972285	3.223525

The probability of being in or exceeding complete damage state with the mean and standard deviation of 0.097 and 0.8 respectively is 0.99. Since there are no CHB building type in HAZUS the collapse rate used was for Unreinforced Masonry equivalent to 15%. Hence the basic structural hazard score for CHB which will also be used as the cut-off score is 0.83.

3. SAMPLE APPLICATION

The proposed Rapid Visual Assessment tool was applied to two existing buildings in Metro Manila.

3.1 Building A

Building A was built in 1973. It has three stories above ground and a story below ground. Based on its structural configuration and structural system, it can be classified under mid-rise reinforced concrete frame with vertical irregularity. Originally, it was intended to be used as a library and a museum but currently it functions as a classroom building, a library, an office and sometimes a venue for seminars, hence a change on the floor live loads of the building. The building occupancy was estimated to be around 100 people. There were no major structural repairs or renovations done on the building since its completion.

Listed below are the key damages observed during the first visit.

1. Beam deflections were observed on beams located at the basement.
2. Diagonal wall cracks were seen in the middle portion of the walls. Some cracks appeared around the columns. Cracks with width of approximately 1.00 mm were seen mostly at the corner of the building in the fourth floor.
3. Floor cracks were seen around the columns on the second floor of the overhang side of the building. There was also suspected floor subsidence on the west wing in the first floor, above of which a suspected beam deflection was observed. A long line of floor crack which extends approximately 3 to 4 meters in the second floor on the overhang side of the building was also observed .
4. Bulging of partition walls was evident.
5. Ceilings were highly damaged due to water leaks. This was seen to be the major factor that deteriorates the function of the building.
6. Windows in the second floor at the overhang side were rusted while the concrete that holds the windows already spalled.
7. Walls in the fourth floor around the center stair way are unsecured.
8. No visible damages in columns and beams.

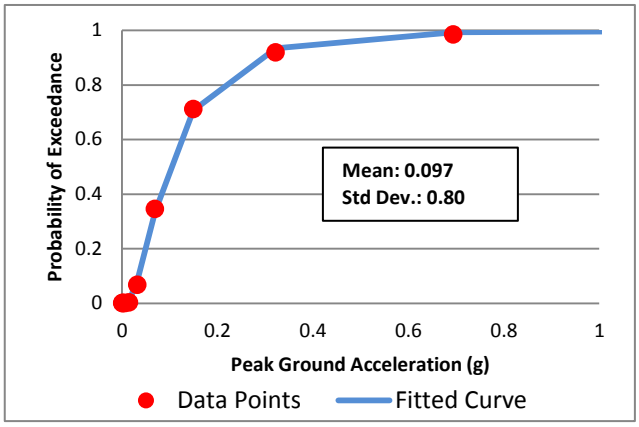

Figure 3. .Fragility Curve at Complete Damage State for CHB.

Presented in Figure 4 is the completed Data Collection Form for the assessment of building A.

3.2 Building B

The construction of building B finished in 1950. It is a 4-story symmetric building with a Parthenon-like façade at the middle. There are no irregularities in the structural configuration of the building. It can be classified as mid-rise reinforced concrete moment frame under pre-code. The default soil type is assumed.

Listed below are the key observations on the damages seen in the building.

1. There are cracks on the ground floor causing rainwater leaks on the basement of the building. Overtime these leaks had caused rusting in embedded reinforcements which then caused some spalling in the concrete cover. However, these were only observed in the ground floor of the building.
2. One part of the building have a lot of cracks/delamination in the concrete finish of window ledges. This may be caused by rusting of reinforcement

due to water dripping from air-conditioners outside of the building.

3. Because of the interior paneling on walls and ceiling, and carpets in the offices, the existence of damage/cracks in structural and non-structural members of the building cannot be visually observed. Thus, our rapid condition assessment tool (RCAsT) has limited use in identifying existing damage present in the building.
4. Parts of the building that do not have interior paneling, e.g. stairways on the sides of the building, were checked. Although some hairline cracks were observed in the walls, no damages were observed in the structural beams and columns.
5. There is sagging of the floor due to overloading in the mezzanine of one of the offices on the south wing because of the volume of documents stored in the area.
6. Cracks at the bottom part of the pair of small columns on the viewing deck were observed. The cracks appear to be limited to the concrete finish of the column and therefore should cause little concern.

Presented in Figure 5 is the completed data collection form for building B.

3.3 Discussion of the Results

The basic structural hazard score for C1L was computed to be 1.04. This is under the assumption that the building is regular in both plan and vertical configurations, built using the high code and constructed on soil type D. This cannot be directly compared with the 2.5 basic structural hazard score for C1L found in FEMA 154 because this corresponds to a different set of basic assumptions. FEMA 154 assumes that the basic structure is one with regular structural configuration, constructed on soil type B since this is the most common soil type in the U.S., and constructed using low code. Using the scores in FEMA 154 to calculate the structural score of the basic structure considered in this paper results to a score of 3.3. This results to an even higher score than the one derived. Following the equation used to compute the BSH, the high score can be attributed to the computation of the probability of being in or exceeding the complete damage state since this is the only parameter that was varied from the rest of the procedure. Same collapse rates were used and same definition of the basic structural hazard score was employed.

No direct conclusion can be drawn based from the scores computed since these were derived using different fragility curves. However, this lifted the issue of redefining the derivation for the basic structural hazard score. Understandably, the probability of collapse is calculated by multiplying the probability of complete damage state exceedance and the probability of collapse given complete damage state, which are two mutually exclusive events. Since the product of two small numbers is an even smaller number, the additional step of getting the negative of the logarithm of base 10 of the product of probabilities, is seen as a way to make use of the probability as a convenient measure of the building performance. Hence a closer look in the derivation of the BSH formula is recommended.

The derivation of the score modifier for the vertical irregularity is based on a trial and error method which is ultimately based on the FEMA 154 results. It is recommended to formulate a procedure of quantifying building performance with vertical irregularities.

Note also are the score modifiers for pre-code and low-code which are one and the same. This is due to the fact that the complete damage state fragility curve of C1M for pre code almost coincides with that of the low code.

Application of the proposed rapid visual assessment tool to two buildings already poses the limitations in the tool. Currently, the rapid visual assessment tool is focused on the assessment of columns because it is expected that these elements will carry most of the lateral loads caused by seismic excitation. However, as what is observed during inspection, notable damages in the form of cracks are mostly seen on walls and floors and seldom on beams. Partition drifts, spalling due to corrosion (especially in windows) and possible deflections of members are also evident. Moreover, pre-earthquake damages are mostly seen on non-structural members such as windows, ceilings that are mostly damaged due to water exposure which are matters of building maintenance, though not brought about by earthquake excitation, can affect the structural integrity of the building. Since the tool is supposed to be a rapid visual assessment, it is recommended to devise a way to estimate the degree of damage incorporating these visual evidences.

Lastly, the inspections conducted are all pre-earthquake assessment hence there is as yet no verification for the post-earthquake assessment specifically the quantification of damage modification factors.

4. CONCLUSION

A rapid visual assessment tool was formulated that quantifies the building performance based on the exterior attributes of the building and the interior state of building components. The tool is patterned after FEMA 154 with its scores modified by employing the locally developed fragility curves of moment frame buildings in Metro Manila. In addition, quantification of the damage modification factor was formulated using similar concepts employed in quantifying post-earthquake damage of RC buildings in Japan.

The resulting basic structural hazard score for C1L is 1.04 which is less than that of FEMA 154. The difference is brought about by the difference in the method of developing

fragility curves and hence raises the proposal of redefining the basic structural hazard score formula. For the score modifiers, it is recommended to improve on the derivation of score modifier for vertical irregularity and a verification on the values derived for pre and low code modifiers. It is also recommended to incorporate in the assessment the damages in non-structural elements and other structural elements such as beams, walls and floors since most of visible damages are seen in these components.

DAMPING PERFORMANCE ANALYSIS AND VERIFICATION OF HEAVY-LOADING HYDRAULIC DAMPER

Jing Long Tong [1],Kuang Yuh Huang [2]

1) Ph. D. student, Dept of Mechanical Engineering , National Taiwan University, Taiwan
2) Professor, Dept of Mechanical Engineering , National Taiwan University, Taiwan
kyhuang@ntu.edu.tw,tongjinglong@gmail.com

Abstract: Architecture and weight of the building is quite diverse. The hydraulic damper must be designed and developed in order to prevent and reduce vibration, and the performance requirements of the vibration energy dissipation. Building structure can be securely and safely stands. Hydraulic damper is usually customized products. Sure that the performance of the damper will spend a lot of time and cost by trial and error and experimentation. Hydraulic oil in the damper produce the effect of absorbing energy by a piston gap, The damper design and operating parameters determine the damping force. The research results show that the damping coefficient and the gap is highly negatively correlated, the gap height greater the damping coefficient the smaller. When the (flow blocking hole diameter / piston diameter) is greater than 5%, regardless of the diameter size of the piston, dimensionless damping coefficient will be approaching a certain value. Damping coefficient with the choke lever length positive, the choke rod length increases the damping coefficient of the greater. The experimental and theoretical values of errors below 10%.

1. INTRODUCTION

The principles and functions of the hydraulic damper makes damping effect by viscous effects of Silicone oil and The friction between the piston and the cylinder. It is a device in mechanism that can provide the resistance movement and absorb the kinetic energy. First this study estimated damper behavior characteristics with mathematical theory and derived regression formulas between geometric dimensions and the damping force of hydraulic damper. Second we performed hydraulic damper testing by dynamic hydraulic damper test equipment. Finally this research compared mathematical models and experimental results.

Hydraulic dampers are mainly used in the equipments that needed damping as construction, aerospace, automobiles and motorcycles, military weapons. Automobiles and motorcycles used adjustable hydraulic damper damping to achieve comfortable ride.[2] The military weapons used linear hydraulic damper to Absorb the energy form impact. [3] In recent years many studies interest in the important research topic that hydraulic dampers are used in civil construction. The Strong wind or earthquake makes vibration on the high-rise building can be reduced by high damping force hydraulic damper. And it also enhances the shock resistance to prevent collapse.[5] Hydraulic damping is used in the realm of civil belongs to the passive system in the control. The basic mathematical theory is the linear Mazwell mode that showed viscous elastic fluid mechanics behavior of the hydraulic damper by Bird, RB, et al.[6] It described hydraulic damper nonlinear viscous elastic fluid mechanics behavior by Markeis et al.[7] Markeis explored the impact that the temperature effect on the hydraulic damper. They studied two vibration situations that a tiny displacement amplitude[8] and a long stroke displacement amplitude [9]of damper. And they got the analytical formula in the different vibration frequency and temperature. The analytical formula showed that the temperature is the function of heat transfer coefficient of the fluid, the piston geometry, time, and the vibration frequency. Chien-Yuan Hou constructed hydrodynamic model that assumed the fluid of hydraulic damper is a Newtonian fluid and Non-Newtonian fluid.[10] He researched the dynamic behavior of the hydraulic damper under steady-state harmonic shocks, in order to build the integrity of the structural dynamic equation. Currently Most famous manufacturers that produces hydraulic dampers in the international is American Taylor company was founded in 1955.[11] In 1980 Taylor began to study the damper was applied to the field of civil construction with the U.S. National Earthquake Engineering Research Center. The company is a professional and has complete dynamic hydraulic testing equipment. And the damper was developed through various tests and comparison analysis and published hundreds of articles related papers journals. That products with good quality and reliability were recognized by the field of structural engineering that called Taylor Device hydraulic damper.(Figure 1) [12] There had been successfully installed in over 170 large-scale engineering structures in the world. Hsu, DS has published papers about the mathematical model of the hydraulic damper, physical characteristics, designed applications in Taiwan. National Taiwan Earthquake Engineering Research Center studied

test analysis of building structures and method of reinforcement. [18]

3. ANALYSIS OF HYDRAULIC DAMPER

3.1 Working Principle and Influential Parameters

As shown in Figure 2, the literature search and inference shows that three items: the size effect, viscosity coefficient, and the compressibility of the hydraulic oil will affect the damping coefficient. This chapter focuses on the size effect on the performance of the damper using Nervier-Stoke equations to derive a relationship between the damping force and speed.

Figure 3 is the internal structure of the damper, first of all, we defined geometric algebra damper and established the mathematical model simply. It is assumed to be incompressible hydraulic oil and stable flow of the hydraulic oil. Although the assumption do not conform completely with the actual situation, but there is still a certain degree of accuracy in the case of a low operating speed. Therefore, it still needs to construct.

Damping force is constituted by the three force, that are piston ends of the pressure difference, the friction between the hydraulic oil and the tube wall, and the inertial force of the piston. According to the literature, the greatest impact is the pressure difference. Therefore, the present mathematical model is only considered for the association between the flow and the pressure difference to deduce the relationship between the damping force and speed.

This model made the following assumptions:

1. The damping force is generated by the piston ends of the pressure difference.
2. The pressure in front of the piston is equal to the inlet pressure of gap, the pressure behind the piston is equal to the outlet pressure of gap.
3. The hydraulic oil is stable and uniform layer stream, and incompressible Newton hydraulic oil
4. The friction and the inertial force are ignored.

Shown in Figure 4, according to the conservation of mass, the piston will squeeze the hydraulic oil and generate flow rate Q_1 when the external force on the piston. The flow rate of the gap (Q_2) plus flow rate of throttle hole (Q_3) equals Q_1.

3.2 Flow rate through main cylindrical gap

Hydraulic oil flows in the gap may be assimilated to the hydraulic oil flow between the plates. The Navier-Stoke equation is applied, the speed of the hydraulic oil for "u", and the sticking coefficient "μ", it is understood that the governing equation (1) with the hydraulic oil movement between the plates:

$$\rho g_x - \frac{\partial P}{\partial x} + \mu\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}\right)$$

$$\rho g_y - \frac{\partial P}{\partial y} + \mu\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}\right) \quad (1)$$

$$\rho g_z - \frac{\partial P}{\partial z} + \mu\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}\right)$$

The flow velocity of x-direction and y-direction equation (2) can be obtained in accordance with the assumptions:

$$\frac{\partial^2 u}{\partial y^2} = \frac{1}{\mu}\frac{\partial p}{\partial x}$$

$$\rho g_y = -\frac{\partial p}{\partial x} \quad (2)$$

Can be found that pressure changes as the y-direction, and solving for x velocity distribution for the formula (3):

$$u(y) = \frac{\pi}{2\mu}\frac{\partial p}{\partial x}y^2 + c_1 y + c_2 \quad (3)$$

The boundary conditions $u(0)=0, u(H_g)=V_p$ is substituting into equation (3.3), the relationship (4) of the piston ends of the differential pressure and flow can be obtained by derivation after solving:

$$Q_2 = \frac{\pi}{2} H_g D_p V_p + \left(\frac{\pi}{12} H_g^3 D_p\right)\left(\frac{1}{\mu}\right)\left(\frac{P_1 - P_3}{L_p}\right) \quad (4)$$

3.3 Flow rate through throttle hole

If a throttle hole was discussed, as shown in Figure 5. The throttle lever of adjustable flow is mounted in the throttle hole. The throttle lever is not across the throttle hole. Therefore, Two different traffic patterns Q_{31} and Q_{32} are formed in the throttle hole. Q_{31} is the elongated slit that analogy with flat panel flow. The governing equations as shown in (1). And There is no relative speed between the throttle lever and the piston because they move together. The boundary conditions are $u(0)=0, u(H_0)=0$, we could solve the relationship between Q_{31} and the pressure difference(P_1-P_2), as shown in equation (5):

$$Q_{31} = \frac{\pi}{6\mu} \cdot D_s H_{of}^3 \frac{(P_1 - P_2)}{L_s} \quad (5)$$

Q_{32} is pipe flow, so we used cylindrical coordinates Navier-Stoke equations (6) and governing equations (7):

$$-\frac{\partial P}{\partial r} + \mu\left\{\frac{\partial}{\partial r}\left[\frac{1}{r}\frac{\partial}{\partial r}(r v_r)\right] + \frac{1}{r^2}\frac{\partial^2 v_r}{\partial \theta^2} - \frac{2}{r^2}\frac{\partial^2 v_\theta}{\partial \theta} + \frac{\partial^2 v_r}{\partial z^2}\right\}$$

$$-\frac{1}{r}\frac{\partial P}{\partial r} + \mu\left\{\frac{\partial}{\partial r}\left[\frac{1}{r}\frac{\partial}{\partial r}(r v_\theta)\right] + \frac{1}{r^2}\frac{\partial^2 v_\theta}{\partial \theta^2} - \frac{2}{r^2}\frac{\partial^2 v_r}{\partial \theta} + \frac{\partial^2 v_\theta}{\partial z^2}\right\} \quad (6)$$

$$-\frac{\partial P}{\partial z} + \mu\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z}{\partial \theta^2} - \frac{2}{r^2}\frac{\partial^2 v_z}{\partial \theta^2} + \frac{\partial^2 v_z}{\partial z^2}\right)\right]$$

$$\mu = \frac{D_{of}^2}{16\mu}\left(\frac{\partial P}{\partial x}\right) + \frac{c_1}{\mu} ln r + C_2 \quad (7)$$

The boundary conditions are $u(0)=v_3, u(R_{of})=0$, we could solve the relationship between Q_{32} and the pressure difference(P_1-P_2), as shown in equation (8):

$$Q_{32}=\frac{\pi D_{of}^4}{128\mu}\cdot\left(\frac{P_2-P_3}{L_p-L_s}\right) \tag{8}$$

We could get the equation (9) according to the conservation of mass. That could be solved relationship between flow rate and pressure difference (10).

$$Q_{31}=Q_{32} \tag{9}$$

$$Q_{31}=Q_{32}=\frac{\pi D_{of}^4}{128\mu}\left(\frac{\frac{\pi D_s H_{of}^3}{12\mu L_s}\times\frac{\pi D_{of}^4}{128\mu(L_p-L_s)}}{\frac{\pi D_s H_{of}^3}{12\mu L_s}+\frac{\pi D_{of}^4}{128\mu(L_p-L_s)}}\right)(P_1-P_3) \tag{10}$$

H_{of} can be ignored because it is far less than R_{of}. We got (11):

$$Q_3=Q_{31}=Q_{32}\approx\frac{\pi D_s H_{of}^3}{12\mu L_s}(P_1-P_3) \tag{11}$$

3.4 Damping Factor for Steady Flow inside Hydraulic Damper

We could get the equation (12) according to the conservation of mass and.

$$Q_1=\frac{\pi}{2}H_g D_p V_p+\left(\frac{\pi}{2}H_g^3 D_p\right)\left(\frac{1}{\mu}\right)\left(\frac{P_1-P_3}{L_p}\right)+2K_1(P_1-P_3) \tag{12}$$

According to $F=P/A$, terms of Q_2, the area A_2 is equation (13). Terms of Q_3, the area A_3 is equation (14). We putted (13) and (14) into (11), and got (15):

$$A_2=\pi\left(H_g^2+2H_g R_p\right) \tag{13}$$

$$A_3=\pi\left(H_{of}^2+2H_{of}R_s\right) \tag{14}$$

$$Q_1=\frac{\pi}{2}H_g D_p V_p+\left(\frac{H_g^3 D_p}{12\mu L_p\left(H_g^2+2H_g R_p\right)}\right)F+\left(\frac{2K_1}{\pi\left(H_{of}^2+H_{of}D_s\right)}\right)F \tag{15}$$

According to the definition of the flow (16), and the average area (17) of the damping device was calculated by Fig 3.

$$Q_1=V_p\cdot A_{cross} \tag{16}$$

$$A_{cross}=\pi\frac{\pi}{4}\left(D_p^2-D_{pr}^2-2D_{eff}^2\right) \tag{17}$$

In (17), D_{eff} is the effective diameter of the throttle hole. (16) and (17) is brought into the (15), the relationship between the speed and the damping force can be obtained. The following shows (18) and (19):

$$V_p\left[\pi\left(D_p^2-D_{pr}^2-2D_{eff}^2\right)-2\pi\left(H_g D_p\right)\right]=\alpha F \tag{18}$$

$$\alpha=\frac{H_g^3 D_p}{3\mu L_s\left(H_g^2+2H_g R_p\right)}+\frac{2D_s H_{of}^3}{3\mu L_s\left(H_{of}^2+H_{of}^2 D_s\right)} \tag{19}$$

The damping factor C is ratio of the damping force and the velocity. We could obtain the (20) by the formula (18) and formula (19):

$$C=\left(\frac{\pi\left(D_p^2-D_{pr}^2-2D_{eff}^2-2H_g D_p\right)}{\frac{H_g^3 D_p}{3\mu L_s\left(H_g^2+2H_g R_p\right)}+\frac{2D_s H_{of}^3}{3\mu L_s\left(H_{of}^2+H_{of}^2 D_s\right)}}\right) \tag{20}$$

3.5 Normalized damping coefficients

In this mathematical model, we knew that the damping coefficient has relations with dimensions and basic properties of the hydraulic oil from the equation (20). Therefore, the relationship between the damping coefficient and the dimensions could be discussed. Apart from variables of discussed, the other variables are the same dimensions as the original design.

As shown in Figure 6, the horizontal axis is the ratio (H_g/D_p) of height of gap and diameter of piston, and the vertical axis is the dimensionless damping coefficient (C/C_0). There were several conclusions from Figure 6:

1. (C/C_0) and (H_g/D_p) are negative correlation. Therefore, at a certain value of (H_g/D_p), the dimensionless damping coefficient is decreased with reducing diameter of piston.
2. For single piston diameter, the height of gap H_g is bigger, and the dimensionless damping coefficient is smaller. In other words, at a certain velocity, the large height of gap makes damping force smaller. This is intuitive conclusion.

The throttle gap is stronger about affecting the damping force than the diameter of throttle hole. That can't be seen directly amount of influence from the equation (20), but can be inferred by diagrams.

As shown in Figure 7, the horizontal axis is the ratio (D_{of}/D_p) of diameter of throttle hole and diameter of piston, and the vertical axis is the dimensionless damping coefficient (C/C_0). There were several conclusions from Figure 7:

1. When the ratio (D_{of}/D_p) is greater than 5%, no matter diameter of piston, dimensionless damping coefficient will approach a certain value. To compare figure 6 and figure 7 proved that the throttle gap is stronger about affecting the damping force than the diameter of throttle hole.
2. The diameter of piston is smaller with reduce of dimensionless damping coefficient (C/C_0). That is because the ratio (H_g/D_p) of diameter of piston and height of gap is larger, and dimensionless damping coefficient (C/C_0) is smaller.
3. When the ratio (D_{of}/D_p) is less than 5%, the dimensionless damping coefficient will increase quickly. From this, dimension of diameter of throttle hole and throttle gap both impact greatly dimensionless damping coefficient.

Complex geometric appearance of the throttle lever will cause the complexity of the mathematical model. It was assumed that the length of throttle lever is equal to the length of piston for simplifying the model.

As shown in Figure 8, the horizontal axis is the ratio

(L_s/L_p) of the length of throttle lever and the length of piston, and the vertical axis is the dimensionless damping coefficient (C/C_0). There were several conclusions from Figure 8:

1. (C/C_0) and (L_s/L_p) are positive correlation, and increasing stability like linear flow. So the damping factor is higher with the longer throttle lever when the length of piston is fixed. The throttle lever becomes longer, so that the flow rate that through the throttle hole becomes smaller, the damping coefficient will be increased.
2. When (L_s/L_p) is the smaller and with the different length of the piston, the impact is less for the dimensionless damping coefficient. It approaches a number of values. On the contrary, when (L_s/L_p) is the larger and with the different length of the piston, the impact is more for the dimensionless damping coefficient. It will diverge.

To Measure the true value of the damper and viscosity coefficient (*5.8E-6 ton / mm.s*) (Table 1), put them into equation (20) and calculate theoretical damping coefficient $C=277.74$(*ton·s/mm*). Than to take C and $n=0.3$ into the theoretical curve $F=CV^n$,and the force was got under different velocity. Shown in figure9:

4. PERFORMANCE VERIFICATION

The performance of hydraulic damper could be estimated by theoretical analysis. But there are hypothetical conditions in theory. That will idealize the characteristics of the hydraulic damper and make the error with the actual actuation. So no matter what form or structure of the hydraulic damper can be to obtain relevant parameters or performance by physical tests. The experimental equipment of this study is a dynamic high-load hydraulic actuator. The device uses a hydraulic actuator (Actuator) dynamic from the United States. It has MTS ± 150MT (tons) of power, Load Cell, MTS Displacement Sensor, controller of MTS FlexTest IIm, and computer control software of MTS MPT. It could test variation of damping force under a different vibration of cycle, collection of data and analysis. The test architecture of the device is shown in figure 10.

As shown in Table 2, experimental loads are sine wave cycle, in order to test the behavior of the different frequencies and amplitudes, the test results are plotted into a force - displacement curve.

Results of Experimental test are shown in Figure 11~21 force - displacement hysteresis loop. Figure 11 is a hysteresis loop of hydraulic damper under the 0.1Hz of frequency and 60mm of displacement. We ignored the first half of the cycle, than taken the average of the maximum and minimum strength testing and maximum velocity every time. Therefore, relationship could be get between the strength and speed of the damping force (Fig. 22).

5. CONCLUSION

The height of gap H_g and H_{of} are bigger, and the damping coefficient is smaller. When the ratio (D_{of}/D_p) is greater than 5%, no matter diameter of piston, dimensionless damping coefficient will approach a certain value. When the ratio (D_{of}/D_p) is less than 5%, the dimensionless damping coefficient will increase quickly. (C/C_0) and (L_s/L_p) are positive correlation, and increasing stability like linear flow. When (L_s/L_p) is the smaller and with the different length of the piston, the impact is less for the dimensionless damping coefficient.

Comparing the maximum speed and maximum power of mathematical theory and experimental test shows that the error below 10%.

Abstract: BIM (Building Information Model) techniques attempt to integrate the entire life cycle information of a building together, including the design, construction, operations and maintenance phases. Although many researchers investigate BIM techniques, most of them are concerned with the design and construction phases. With the plentiful information carried by BIM, developing applications for the operations and maintenance phase can be a potential research field. For example, mitigating disaster impact is one of the most critical issues in applying BIM in such post-construction phase. During the occurrence of a disaster, first responders need up-to-date information to support their decision-making process. On the other hand, they also need simplified information to mitigate the loss as soon as possible. In a BIM environment, it promises to update information in all views and remains all versions to ensure the newest and the most complete data. However, in order to meet the information demands of first responders, the information from the BIM still needs to be simplified and transformed. In this research, the Model-Driven Architecture (MDA) framework was applied to process the BIM information in order to fit in with the needs of first responders. MDA is a state-of-the-art software developing methodology specifically for the computer science field. Since BIM is also regarded as a model, the authors defined a new mapping for BIM-related model structure and try to assist in information extraction from BIM by using this new approach. The BIM for a specific building, e.g. a concrete plant, is promoted to the model level in order to generate application program for this building. Such concept facilitates development of different application software around BIM environment, and, especially, for disaster mitigation in this research.

1. INTRODUCTION

Building Information Model (BIM) is a promising technology that can provide a communication and information exchange platform for all stakeholders involved in a building, as well as create a 3D display environment to clarify a building's virtual representations. Many researchers study BIM-related topics, such as design and engineering, linking to analysis tools, energy innovations, facility management, and so on (Becerik-Gerber and Kensek, 2010). However, most studies are concerned with the design and construction (D&C) phases of a building, few studies deal with issues pertaining to the operation and maintenance (O&M) phases (Akcamete et al., 2010)(Vanlande et al., 2008). Because costs associated with the O&M phases of a building are always higher than those with the D&C phases (Gallaher et al., 2004), and because BIM is becoming a mature software tool capable of supporting all kinds of information-intensive activities, applying the BIM technology to the O&M phases is desired.

Although researchers have shown that a building construction project and its subsequent facility maintenance projects are dissociated (Vanlande et al., 2008), it is obvious that the applications in the O&M phases require the information from the D&C phases of a building. In the D&C phases, BIM applications are designed to use parametric and object-oriented modeling techniques to represent each individual building element and help associated processes. Applications in the O&M phases may require not only original BIM-related information but the enhanced one that can be employed to record and manage various activities during O&M. Example applications include facility management systems and disaster management systems. Current practices require contractors provide a building's handover information such as Construction-Operations Building information exchange (COBie) for later usage in the O&M phases, but they usually spend minimal efforts so as to satisfy the contract (Akcamete et al., 2010). Hence, a better information bridge may be needed in order to provide transformation and customization of the handover information from the D&C phases to the O&M phases.

Applications in the O&M phases possess several unique requirements regarding interpretation of BIM. Some BIM information should be accessed and handled via an easier method while the other should be further processed

through use of a more complicated interface. In other words, customization of BIM is needed for the O&M phases. In fact, the utilization of BIM should follow the open/closed principle (OCP) – "open for extension, but closed for modification" (Meyer, 1988) as well. In the closed side, for example, structural elements in a building will not be changed during their entire life cycle (Hassanain et al. 2001); and thus, for application developers in the O&M phases, it may be a good way to operate such information at the class level, not at the metaclass level to avoid future modification. By operating BIM at the metaclass level, we mean that O&M application developers regard the structural elements as objects and use generalized classes such as Room, Column, and Wall to access each individual element. When facility managers would like to query one specific room's maintenance history, application developers need to select all rooms' maintenance objects and then filter out the records not belonging to the room specified. It is an indirect approach, and because the structural elements are constant, developers actually can regard each element as a distinct class in order to use an object to represent the current condition of an element at a specific time instance. In this way, all BIM or IFC-related functions are encapsulated in one class for an element. Application developers can have a more simple data access interface to manipulate O&M-related information. The traditional approach regards the structural elements or other elements infrequently changed as objects regardless of the D&C or O&M phases; and thus, such O&M applications may use additional redundant codes to retrieve information.

In the open side of the OCP, current materials and equipment information stored in BIM cannot accommodate various needs during the O&M phases, e.g., spare parts list management, which is an essential function from the facility management perspective. An extension mechanism of BIM may be needed and has been proposed by several studies (CRC, 2007). Among the O&M-related activities, the concept of rooms and zones forms the central management unit, which is just one of the derived attributes and is not the focus during D&C. Proper spatial containment of related building elements is essential in the O&M phases (East et al., 2012). In the D&C phases, architects design the form or the placement of each building element. But facility managers need to know the location of a specific device in order to perform maintenance work. A typical room consists of many building elements, and in BIM tools such as Revit, designers need to draw walls, windows, and doors first, and then specify the boundary of a room to link these building elements. Additional furniture or equipment elements may need to be attached to some rooms during the O&M phases. The traditional approach to transferring handover data requires manually create "polylines" of a building instead of directly using the digital building information used in the D&C phases. The traditional approach needs couple days and is labor-intensive. Even if computerized tools can be provided to assist in the transformation process, such tools describe only the geometric information and do not consider the integrity of each building element as a room or zone in the O&M phases.

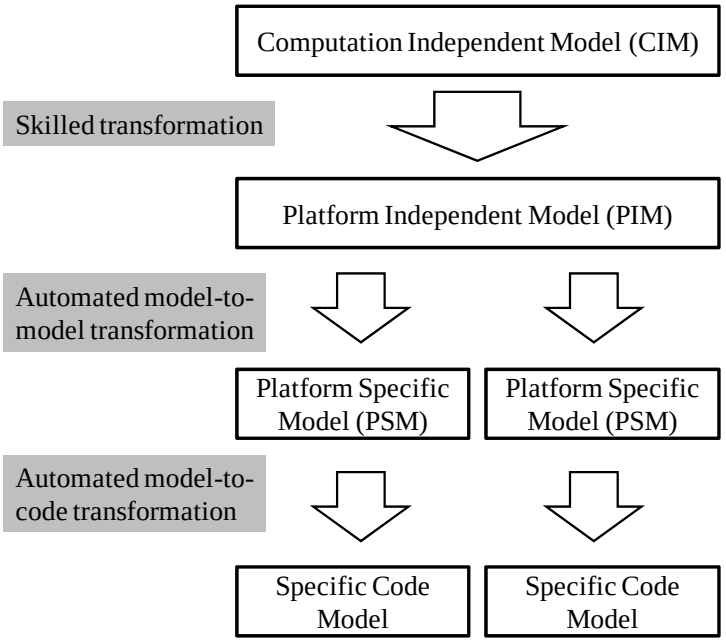

Figure 1 MDA Process

Finally, several studies have recognized the lack of 3D visualization capabilities in most applications in the O&M phases (Akcamete et al., 2010). BIM, like a spatial analysis engine (Akcamete et al., 2010), can assist facility management applications in analysis of spatial relationships between these building elements. The other issue is that the O&M phases consist of many different applications, such as disaster mitigation, security, community care, and so on. In these fields domain-specific requirements exist, and BIM cannot cover all the fields which need building information as a possible input source.

In this research, the encapsulation of BIM (E-BIM) was designed following the model-driven architecture (MDA) technique for automatic and comprehensive transformation and customization of the handover information from the D&C phases to the O&M phases. A metamodel hierarchy of a building was constructed to encapsulate the building information, not simply transforming data into an open format, but playing the role of an "interface" – users can manipulate the building information through the model instead of directly modifying it. Regarding to the designed metamodel hierarchy, we also attempted to present spatial relationships to reshape data structures of maintenance data. The proposed MDA approach was utilized with the hierarchy to generate codes for further applications of building information.

2. RELATED WORK

Nowadays, the software development process is facing

more and more complicated situations. Not only requirements become more dynamic but different platforms can be selected as the working environment. To solve these problems, MDA was proposed by Object Management Group (OMG), mainly for the purpose of integration and interoperability (Soley, 2000). This approach basically uses a series of formal models to help the software development process.

To take an overview of MDA, at first the separation of concerns should be introduced. Three MDA viewpoints of a system are described as follows: (1) Computation Independent Viewpoint (CIV), (2) Platform Independent Viewpoint (PIV), and (3) Platform Specific Viewpoint (PSV). CIV contains none of the computer-related processing details and only focuses on the business requirements; PIV deals with the operations of a system but does not contain the details for a specific platform; PSV integrates PIV with the details of using a particular platform as the development environment (Miller and Mukerji, 2003).

As shown in Figure 1, four layers and their transformation mechanisms are identified based on these views. A computation independent model (CIM) is constructed from CIV. Based on the CIM a platform independent model (PIM) is created. With the sufficiently complete and precise PIM, a platform specific model (PSM) can be generated by using model-to-model transformation mechanisms, and the specific code model – which can be viewed as implementation – can be automatically transformed from the PSM.

OMG defines a standard – Meta Object Facility – to provide metadata management and modelling language definitions. MOF is used with a metamodel hierarchy shown in Figure 2. A run-time system can be interpreted by a UML model, since the UML model is designed by people, there can be many UML models from different perspectives. To describe a UML model, we need to define UML descriptions and notations as a communicating method. The UML definitions are also based on the definitions of MOF. With the descriptions of higher layers, the lower layer can be clearly explained.

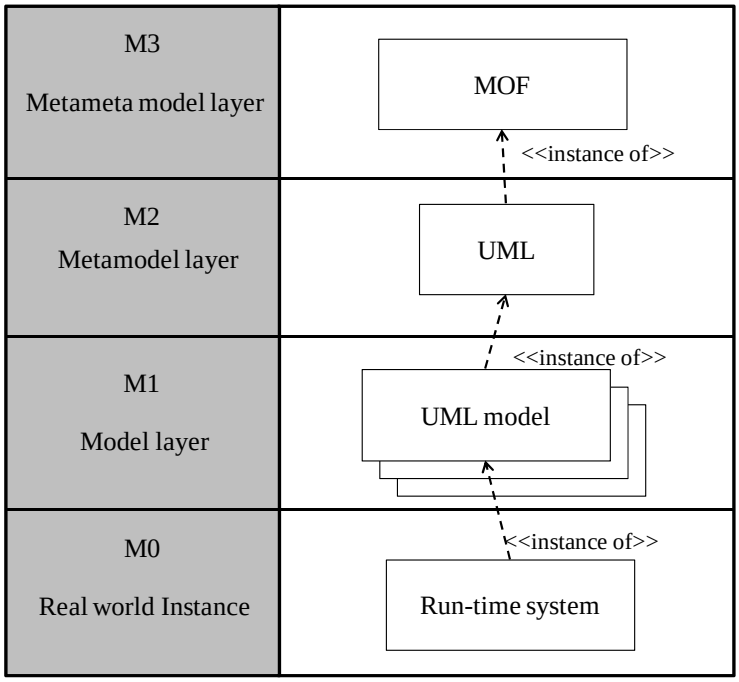

Figure 2 Metamodel Hierarchy

3. RESEARCH APPROACH

Because of the wide use of BIM, building information is available for stakeholders in the O&M phases. However, the BIM data structure is not easy to be used for users and needs extra efforts for application developers to write programs for further use of such information. In order to offer a better way for the extended use, this research defines a metamodel hierarchy for a building to interpret their various elements.

Figure 3 shows the sample definitions of the metamodel hierarchy of a residential building. This hierarchy is designed as the basis of the proposed approach.

- M3 layer: For different perspectives, the contents in M3 layer should be viewed as different roles. Inside this hierarchy, the M3 layer describes basic components of a building, such as doors, walls, windows, and so on. These components exist in any type of building, in other words, they are essential for a building; as a result they are designed to be in the M3 layer. Outside this hierarchy – which means extended applications without sufficient understanding of the building internal structure and BIM programming – for them, the layers below and those basic components are encapsulated due to OCP. Building information is available for them through the "BuildingSuperObject" but its data structure cannot be changed from the outside, that is, "BuildingSuperObject" is an interface as a communicating bridge.
- M2 layer: This layer is instantiated from basic components from the M3 layer, as well as different types of buildings and their basic units are described here. Different types of buildings may have rooms/zones/spaces for different purposes, and rooms are classified by purposes as a basic unit. For example, an apartment is classified as one type of residential buildings. Bedrooms and living rooms may only exist in a residential building, not in a factory.
- M1 layer: In the M1 layer, a "model" means a specific building and is constructed here. Most of the static components are from higher layers. Also, the constant spatial components of a building are described here, since most of the time the floor plan of a building will not be changed after the D&C phases.
- M0 layer: Finally, the instances of M1's building are

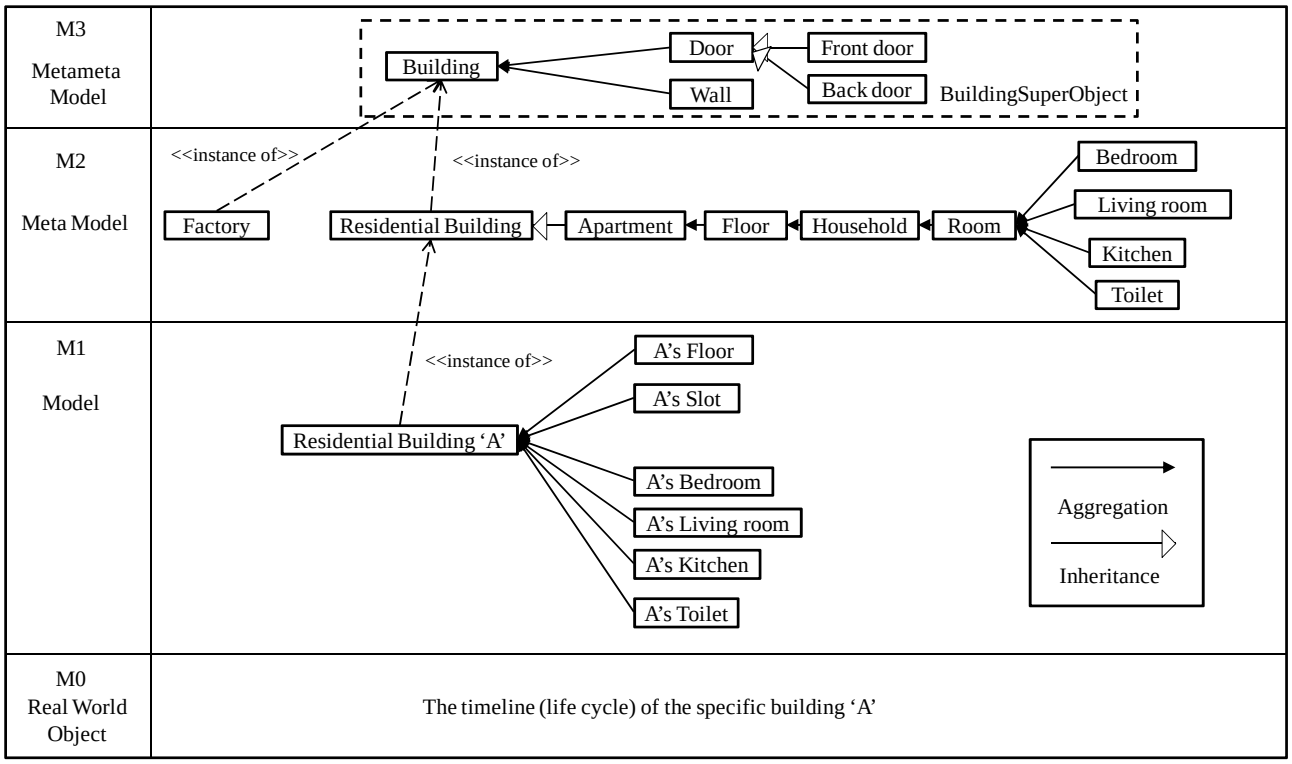

Figure 3 Metamodel Hierarchy of a Building

stretched by time as a timeline and record the whole life cycle, which means the building information covering the D&C phases to the O&M phases exists in this layer.

Suppose BIM data of a specific building is available. First its spatial relationship and the usage of spaces are re-drawn as the model shown in the M1 layer of Figure 3. The class library of this building can then be automatically generated by the model. Since attributes are also predesigned to be contained in the model, extended applications can use data they need through the model.

In Figure 4, the E-BIM process was designed referred to the MDA process; the original BIM of the specific building can be viewed as the CIM level, and then it will be transferred to E-BIM form preparing to be extended by different applications. Different application domains are considered PSM in MDA process; therefore, specific domain knowledge is used to be the additional information and taken as the foundation of the specific applications.

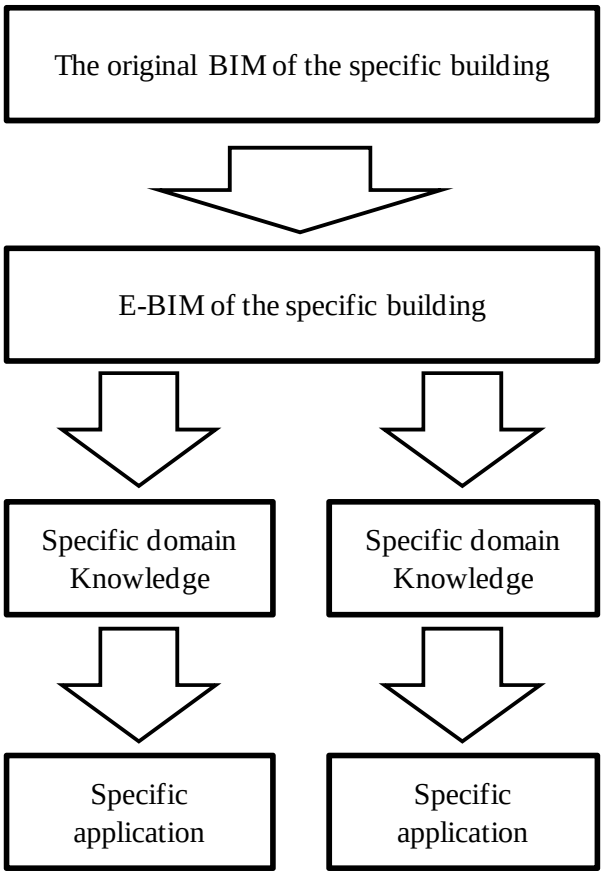

Figure 4 The E-BIM Process Referred to the MDA

4. EXAMPLE

Since the more floors and rooms a building contains, the more complicated the problem is. A three-floor apartment is presented in this section as a simple example to show the contents in metamodel hierarchy of an apartment building 'B'. Some details are also omitted for clearly interpreting the proposed approach. The relationship between contents and the expected application of the metamodel hierarchy are also interpreted in this section.

Figure 5 presents a sample model constructed following the metamodel hierarchy in previous section. In apartment building 'B', there are three floors and an elevator. There are two households in each floor, and the rule of the address assignment is the floor number, plus the serial number. Each household is assumed to have three rooms, i.e., living

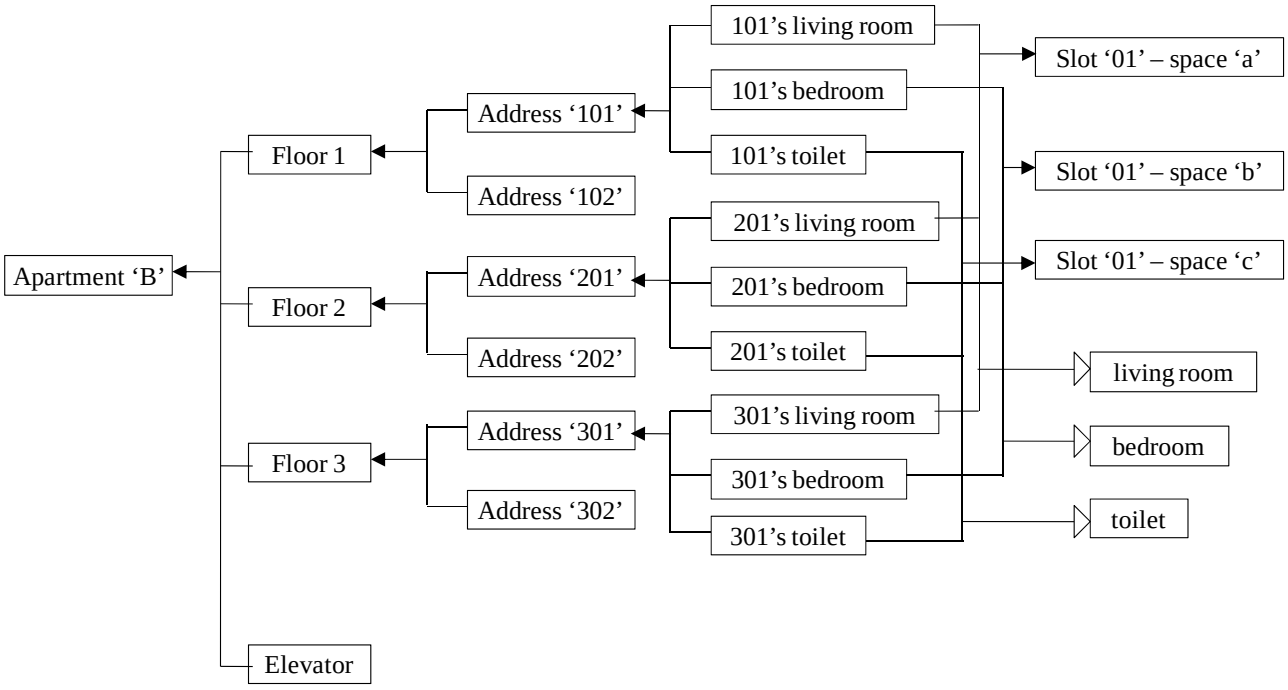

Figure 5 Model of a Specific Apartment Building 'B'

room, bedroom and toilet. In Figure 5, rooms in address '02' are omitted. These rooms define attributes from their designed usage respectively. In addition, from the spatial perspective, 'B' can be viewed in two dimensions: horizontal and vertical. The horizontal dimension is equivalent to the floor concept; the vertical dimension, named "slot" here, is composed of rooms located on the same vertical line. Usually the floor plan of a household is the same as its neighbour upstairs or downstairs in an apartment; therefore, rooms of the same purpose belong to the same slot. However, the elevator is independent of a floor or a slot since it is movable.

The model described above becomes a basis for automatic code generation; a class library of 'B' is constructed for extension. The extended applications can use BIM data through this model – more specifically, users of these applications access BIM data through this model instead of directly operating with BIM. Since it is not easy to cross the threshold of the programming issues for BIM applications, it is believed that using this model will assist the development of extended allocation for BIM.

5. CONCLUSIONS

This research has proposed a software architecture to integrate the static (BIM) information with the dynamic, O&M-related data. The MDA technique was utilized to store and synthesize the data. The BIM information is used to show the geometry aspect of the building. MDA has been successfully applied to other industries' applications, including the AEC industry. Further enhancement of the system is needed in order to integrate more dynamic information from different facility management domains and/or other BIM programs.

Abstract: We develop a system to perform estimation of urban earthquake disaster considering local soil properties under each structure. The system automatically converts structural and soil data stored in the geographic information system to inputs of soil amplification analysis and seismic response analysis of structures. Soil amplification analysis is performed on the generated soil model, and the ground motion at surface is inputted to structural response analysis. The system is designed to be run on many computation cores to speed up the analysis. By using the developed program on high performance computers, earthquake damage estimation for many structures that make up a city can be done in a short period of time.

1. INTRODUCTION

Estimating the consequences of a given hazard scenario is needed for making disaster mitigation strategies. Methods based on statistical analysis of past disasters are frequently used in practice for estimating earthquake disaster in urban areas. In these methods, cities are divided into blocks, and the statistical values of earthquake damage are estimated for each block. By using such method, we can obtain a rough view of damage of a city without detailed soil or structural data with small computational effort. On the other hand, ground motion at surface is heavily affected by the local soil structure, and response of a structure is dependent on its structural properties. Estimation of damage considering soil properties and properties of each structure provides a more detailed view of the earthquake disaster, which may lead to improvement of mitigation strategies, such as evacuation route planning or development of earthquake insurances.

Soil and structural data are stored in the Geographic Information System (GIS), and analysis methods based on physical modeling are developed and used in structural design. Aiming to perform estimation of earthquake disaster considering properties of a city, our research group have been developing an Integrated Earthquake Simulator (IES); for example, see Hori and Ichimura (2008) and Hori (2011). IES analyzes earthquake wave propagation from the fault to the city, structural response of structures in a city, and social response of a city. Since each phase of earthquake disaster is analyzed in IES, the computational size becomes large. Estimating consequences of multiple hazard scenarios are needed for considering uncertainty in the input earthquake hazard, structural or soil properties. Time is limited to obtain earthquake disaster estimation, especially when using it for real time estimation after a major earthquake. Real time disaster estimation in high resolution can help authorities to make disaster reaction decisions, such as making resident evacuation strategies or deciding fire brigade allocation. Speedup of IES is needed for performing estimation for multiple hazard scenarios or real time hazard estimation.

High Performance Computing (HPC) can be used to enhance IES, so that multiple hazard scenarios can be estimated for large urban areas in a short time. HPC is first applied to structural response analysis of IES (Wijerathne et al. 2012). We further enhance the soil amplification analysis phase of IES with HPC in this paper. Attention is paid to speed up analysis of large problems using large number of computation cores.

2. METHODOLOGY

2.1 Overview of IES

Combining information of soil and structures of a city with computation is a key to performing high resolution

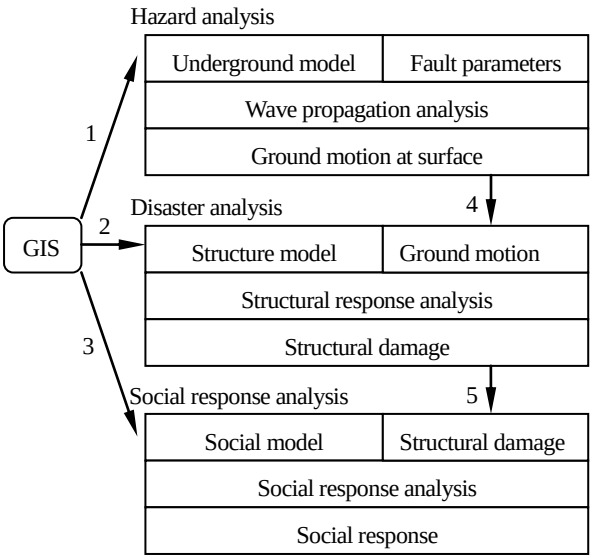

Figure 1 Overview of IES

earthquake damage estimation. Figure 1 shows the overview of IES. In IES, soil and structural data of a city, stored in GIS, are automatically converted to input city model of analysis programs (arrows 1, 2, 3 in Figure 1). Analysis methods are plugged in to IES, and connected via data conversion modules (arrows 4, 5). First, earthquake wave propagation from fault to city is performed, and output is converted to input to structural response analysis. Structural response analysis is performed, and results are converted into input of social response analysis. Since the data format of GIS, input and output formats of each analysis program differ, data conversion is needed in order to perform such an integrated simulation. For such purpose we have been developing robust and versatile data conversion methods.

In this study, we combine soil amplification analysis and structural response analysis; see Figure 2. Soil amplification analysis is used to analyze the ground response at surface using wave at bedrock, and structural response analysis is used to analyze structural response using ground motion at surface.

2.2 Analysis methods

In order to attain reliability of estimation results, we use seismic analysis methods used in the actual structural design process. We expect that users of the system need different levels of accuracy within different length of time using available computational resources. Thus, we design the system so that multiple types of analysis methods can be plugged in, and users can choose the analysis method according to their needs.

In this study, we implement 1D equivalent linear method for soil amplification analysis, although we plan to further implement 3D wave propagation methods in the future. The 1D equivalent linear method analyzes shear wave propagation from the bedrock to surface. Non-linear properties of the soil are considered by solving linear wave propagation in the frequency domain, and updating shear

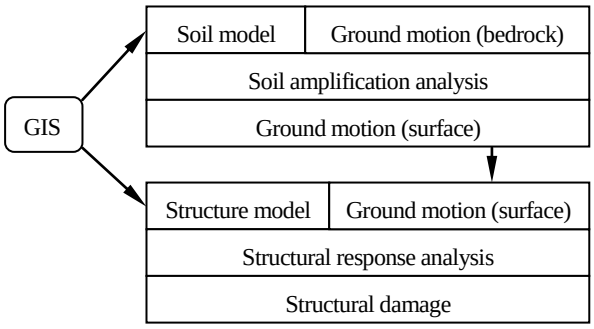

Figure 2 Overview of current system

modulus G and damping ratio h using the effective strain γ_{eff}, obtained by

$$\gamma_{\text{eff}} = \alpha\gamma_{\max}. \quad (1)$$

Here, $\gamma_{\max}$ is the maximum shear strain of each soil layer in the time history. α is a parameter to relate the two values; we use $\alpha = 0.65$, which is a typical value used in the literature. We use the Hardin-Drnevich model (1972)

$$G = G_{\max}/(1+\gamma/\gamma_{\text{r}}), \quad (2)$$

$$h = h_{\max}(1- G/G_{\max}), \quad (3)$$

for non-linear modeling of the soil. Here, $G_{\max}$ is the maximum shear modulus, γ_{r} is the reference strain, and $h_{\max}$ is the maximum damping ratio.

The multi-degree of freedom model, one component model, and fiber element models are implemented for structural response analysis in the HPC enhanced IES (Wijerathne et al. 2012). In this study, we use the one component model. The one component model models beams and columns of a structure as non-linear elements. Beams are modeled with a shear spring and rotational springs on both ends, where columns are modeled with axial and shear springs with rotational spring on both ends. Mass is modeled on the connection (node) of beams and columns. See Giberson (1967) for details of one component model.

2.3 City modeling

City models that reflect properties of a city are needed in a wide region for each structure for performing high resolution earthquake disaster estimation. We make modules that automatically convert soil and structural data stored in GIS to input city models for analysis.

We use the nationwide digital underground map provided by The Japanese Geotechnical Society. This is a dataset that stores soil structure data of major cities of Japan in a 250m resolution structured grid. We interpolate the soil structure by assuming a three layered soil structure: clay, sand, and bedrock. Interpolation is performed using spline interpolation.

For structural data, we use the outer shape of structures stored in GIS. Since we do not have information about

structural properties, such as the number, position, strength of beams or columns, we guess these properties by assuming that each structure follows the Japanese design code.

Conversion programs are designed to attain high robustness of data conversion, so that large data sets can be converted without errors. By using these methods, we can automatically generate a city model of a large city, such as Tokyo, with more than 2 million structures, in a short period of time. Validation of generated models is still undergoing; although we expect that we can obtain more detailed urban data so that few ambiguity is needed in the generation of the city model.

2.4 Application of HPC

High performance computers, which are made of many computational cores, can be used to shorten the computation time. In order to utilize these computers, programs must be designed so that the problem size and computation speed can be increased with respect to the number of computation cores.

Serial programs are developed and widely used in structural design. Since the computation of each structure is independent from each other, we run these serial programs in parallel using different input data to perform parallel computation. By properly assigning structures to computational cores, we can expect linear performance gain with respect to the number of computational cores. We distribute evaluation points to computation cores depending on the number of soil layers in the input soil structure.

For extension of 3D wave propagation analysis programs, we separate the soil analysis and structural analysis codes. We output the resulting wave form into the file system, and read it when performing structural analysis. Since the performance of the file system does not necessarily gain with respect to the number of computational cores, we need to reduce the ratio of file input and output (file I/O) in comparison with the total computation time to obtain performance using large number of cores. We use binary file I/O, and gather output data of structures within one GIS tile to one output file. This reduces the overhead of conversion of binary data to human readable text data, and manipulation of large number of files. This is further enhanced with use of collective I/O of Message Passing Interface 2 (MPI-2) standard, so that data is written to the file system from multiple computation cores without the need to gather information to one computation core. By using such method, file I/O speed of soil amplification analysis has increased from 9.39MB/s to 862MB/s, which is near to the benchmark sequential write performance of the file system (610MB/s). Performance is measured in a PC cluster of 24 computation nodes, each with dual hexacore Intel Xeon X5680 (3.33GHz) processors with 48GB DDR3 memory, connected with QLogic 12200 InfiniBand switch. File system of the cluster is a RAID-10 file system consisting of twelve 600GB 3.5 inch SAS hard disks. The same environment is used for measurement in this paper.

Figure 3 shows the speedup of the developed soil amplification analysis program. The horizontal axis indicates the number of computation cores while the vertical axis indicates the speedup with respect to 4 computation cores. A problem with 253,405 evaluation points, each with 30 soil layers and 8,192 time steps, is used for measurement.

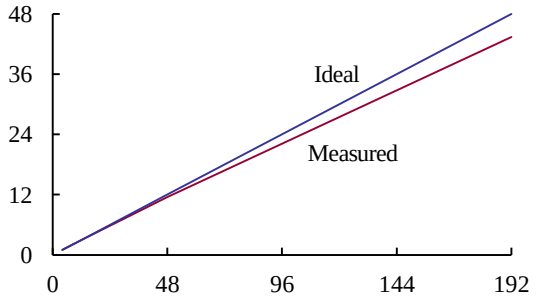

Figure 3 Speedup of soil amplification program on a PC cluster. Horizontal axis indicates number of computation cores, while vertical axis indicates speedup with respect to 4 cores.

We can see that the program scales well up to 192 cores; the parallel efficiency for 192 cores is 90.5%. By using this program, we can speed up the analysis for this problem from 23 hours using the original serial program to 364s using 192 cores. Further details of implementation of HPC to IES are described in Fujita et al. (2012).

3. APPLICATION

Analysis is performed on a target area of 2.0 x 1.5km, consisting of 13,781 structures. A 3 layered soil model is automatically generated from soil data. The soil properties of each layer are shown in Table 1, and the elevation of each layer is shown in Figure 4. We can see that the region has valleys and tables, with complex underground structure.

Earthquake wave observed in the 2007 Nigata-Ken Chuetsu-Oki Earthquake is inputted at the bedrock (z = -60m). Analysis took 20.5s using 36 cores. Figure 5 shows response at the surface. The figure shows the acceleration response spectrum at period 1.0s, 0.5s and 0.1s from the top to bottom, respectively. We can see that the response at surface is altered depending on the topography and underground soil structure. The amplification is different depending on the period; some areas are amplified larger for low frequencies, while other areas are amplified larger for high frequency components.

The ground motion at surface is inputted into structural response analysis. Analysis took 864s using 60cores. Figure 6 shows the maximum drift angle of each floor. The figure on the top shows results of all structures, where figure in the middle and bottom shows the response of high rise and low rise structures, respectively. We can see that each structure has different response, reflecting their structural properties and input ground motion. By filtering structures with its properties, such as the height of a structure, we can analyze the damage according to its classification, which can be used for planning mitigation strategies for each class of structures.

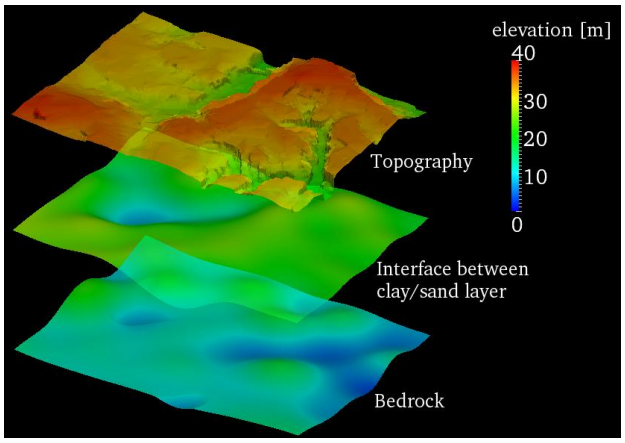

Figure 4 Target area of size 2.0 x 1.5km. Soil model consists of 3 layers; clay, sand and bedrock. Elevation is magnified by 10 times in the figure.

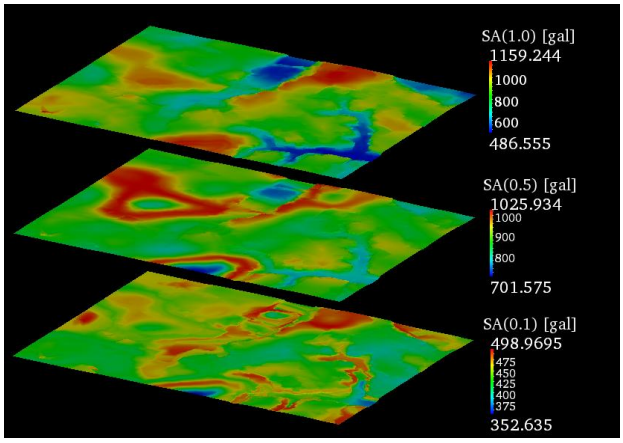

Figure 5 Ground motion at surface. Colors indicate the acceleration response spectrum at 1.0s, 0.5s, and 0.1s from top to the bottom. Damping ratio is set to 0.05 for all cases.

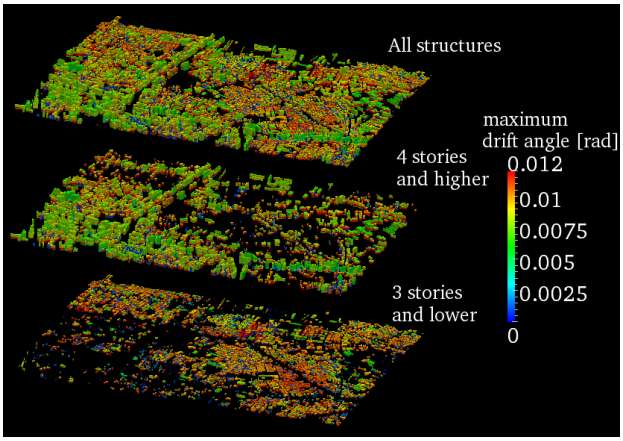

Figure 6 Response of 13,781 structures in target area. Colors indicate maximum drift angle of structures. Figure on top indicates response of all structures in target area, where figure in middle indicate response of high rise structures with 4 stories and higher, and the bottom figure indicates response of low rise structures of 3 stories and lower.

Table 1 Material properties of each layer.

Layer	V_s (m/s)	G_{max} (tf/ms^2)	ρ (tf/m^3)	h_{max}	γ_r
Clay	116	26,640	2.0	0.15	0.2
Sand	250	135,000	2.0	0.15	0.2
Bedrock	500	500,000	2.0	0.05	0.2

4. CLOSING REMARKS

In this paper, we developed a system to obtain earthquake damage estimation of a city considering local soil properties. The system is enhanced with high performance computing so that damage estimation of large number of structures can be performed in a short period of time. Load balancing among computation cores and file I/O is dealt with care for attaining performance on high performance computers.

Application shows that estimation of earthquake disaster can be obtained in a short period of time. Results can be analyzed depending on the acceleration spectrum, story drift, or other damage indicators.

Our future works are to enhance this system for application to multiple hazard scenarios. We plan to run hundreds or thousands of hazard scenarios on high performance computers to evaluate earthquake disaster considering uncertainty in the input wave form or soil/structural parameters.

Abstract: It is common knowledge that fault fracture zones capable of causing earthquakes are fluid-saturated porous solids. Therefore, the wave analyses for fluid-saturated porous solids are particularly helpful for understanding seismic wave propagation. However, in general, seismic analyses are implemented by modeling the fault fracture zones as isotropic elastic solids because the consideration of fluid effects on wave propagation complicates the numerical procedures. Boundary element method (BEM) is known as an effective numerical approach for wave propagation because BEM can treat infinite or semi-infinite regions without any modifications. In recent years, the convolution quadrature time-domain boundary element method (CQ-BEM) has been studied by several researchers to improve the numerical instability of the conventional time-domain BEM. The CQ-BEM requires fundamental solutions in Laplace-domain. Therefore, the formulation is similar to that for the frequency-domain BEM. This fact shows that CQ-BEM formulation becomes easier than the conventional one. In this paper, the wave propagation in fluid-saturated porous solids is analyzed by the convolution quadrature time-domain boundary element method (CQ-BEM). The proposed CQ-BEM formulation for wave propagation in fluid-saturated porous solids is based on the Biot's theory (1962). Basic wave scattering problems are solved to verify our proposed CQ-BEM.

1. INTRODUCTION

This paper presents 2-D wave propagation and scattering analyses for general anisotropic fluid-saturated porous solids using a convolution quadrature boundary element method.

Ground and fault fracture zones are well known as an anisotropic solid, and seismic velocity anisotropy in these solids is widely confirmed. Especially near the fault, rocks including pores and cracks produce strong anisotropy. Moreover, the pores and cracks are saturated with fluid. In recent years, the anisotropic fluid-saturated porous solids are studied by many researchers (Carcione 1996, Liu et al. 2005, Sharma 2005). Most of them, however, described the derivation of phase and group velocities in the solid only, and a numerical method applicable to realistic problems has not been proposed.

Boundary element method (BEM) is an effective numerical approach for wave analysis. BEM requires boundary discretization only, and can deal with infinite or semi-infinite domain without any special efforts. Convolution quadrature boundary element method (CQ-BEM), proposed by Schanz and Antes (1997), is known as a new time-domain BEM. In CQ-BEM, convolution quadrature method (CQM) is used for time discretization and improves the numerical stability of the time-domain BEM. Therefore, CQ-BEM can produce stable solutions, even for small time increments which are not adequate in the conventional time-domain one. Furthermore, instead of time-domain fundamental solutions, CQ-BEM requires Laplace-domain ones. This is advantageous for cases where time-domain fundamental solutions are not available, however Laplace-domain ones can be obtained (e.g. viscoelastic or poroelastic problems). Recently, CQ-BEM is applied to wave analyses for general anisotropic elastic solids (Zhang 2000, Furukawa et al. 2012) and isotropic fluid-saturated porous solids (Schanz 2001, Saitoh et al. 2012). However, there is no application of CQ-BEM, even frequency- or Laplace-domain BEM, to wave analysis for general anisotropic fluid-saturated porous solids.

This paper describes the formulation of CQ-BEM for 2-D general anisotropic fluid-saturated porous solids. Biot's theory (Biot 1962) is used for the formulation of poroelasticity. Biot proposed the theory to describe wave propagation in fluid-saturated porous solids using a set of coupled differential equations that govern the motion of solid and fluid part (Biot 1956a,b) and extended the theory to that for general anisotropy (Biot 1962). Biot's theory marks the beginning of an effort to study dynamic poroelastic problems, whereafter a number of related and extended theories were proposed (Rice and Cleary 1976, Beskos 1989).

In this paper, the brief statement of Biot's theory is described in section 2, and the formulation of CQ-BEM for

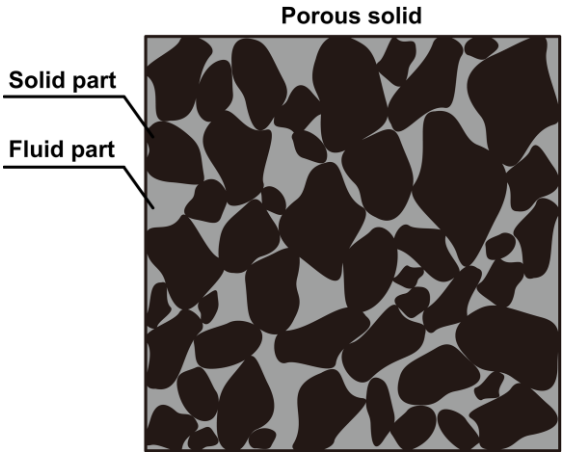

Figure 1 Fluid-saturated poroelastic solid.

fluid-saturated porous solids is presented in section 3. Moreover, in this section, we derive fundamental solutions for 2-D general anisotropic fluid-saturated porous solids. In section 4, numerical example based on our proposed method is demonstrated. At the end, in section 5, conclusions and future works are shown. Throughout this paper, small and large indices, without notice, range from 1 to 3 and 1 to 4, respectively. In addition, summation convention is valid for repeated indices.

2. FLUID-SATURATED POROUS SOLIDS

In this section, the theory of wave propagation in fluid-saturated porous solid is described. The theory is based on that proposed by Biot (1962). The solid, described in this section, is shown in Figure 1 and consists of solid and fluid parts. The main assumptions of the theory are as follows:

1. Infinitesimal transformations occur between the reference and current states of deformation.
2. The wavelength is large compared with the dimensions of macroscopic values.
3. The conditions are isothermal.
4. The fluid is viscous.
5. The fluid flows through the porous skeleton according to Darcy's law.

In most situations, the material of the skeleton is isotropic. However, in this paper, anisotropy due to a preferential alignment of the pores or cracks is considered.

In the most general case of anisotropy, the linear stress-strain relations are written as follows:

$$\sigma_{ij} = A_{ijkl} e_{kl} + M_{ij}\zeta, \tag{1}$$

$$p = M_{kl} e_{kl} + M\zeta \tag{2}$$

where σ_{ij} and e_{ij} represent the total stress and strain components of the porous solid, respectively. e_{ij} can be expressed, using the displacements of the solid u_i, as follows:

$$e_{ij} = \frac{1}{2}\left(u_{i,j} + u_{j,i}\right) \tag{3}$$

where $(\,)_{,i} = \partial/\partial x_i$. p and ζ, in Eqs.(1) and (2), are the fluid pressure and the increment of the fluid content, respectively. In addition, A_{ijkl} represents the elastic tensor of undrained porous solid expressed as follows:

$$A_{ijkl} = C_{ijkl} + \frac{M_{ij} M_{kl}}{M} \tag{4}$$

where C_{ijkl} represents the elastic tensor of drained porous solid. Moreover, M is Biot's elastic modulus. M_{ij} is expressed as $M_{ij} = \alpha_{ij} M$, where α_{ij} is Biot's effective-stress coefficients in anisotropic case.

Equations of motion for general anisotropic fluid-saturated porous solid are written as follows:

$$\sigma_{ij,j} + \rho b_i = \rho \ddot{u}_i + \rho_f \ddot{w}_i, \tag{5}$$

$$p_{,i} + \rho_f c_i = -\rho_f \ddot{u}_i + m_{ij}\ddot{w}_j - \eta r_{ij}\dot{w}_j \tag{6}$$

where $\dot{(\,)} = \partial/\partial t$, and w_i represents the flow of the fluid relative to the solid in the unit section. ρ and b_i are the mass density and body force components of the porous solid, and ρ_f and c_i represent those of the fluid part. In addition, η represents the viscosity of the fluid, and m_{ij} is the mass matrix and depends on the pore geometry. Moreover, r_{ij} represents the flow resistivity matrix given by $[r_{ij}] = [k_{ij}]^{-1}$, where k_{ij} is the permeability matrix based on Darcy's law.

According to the previous studies (Carcione 1996, Liu et al. 2005, Sharma 2005), anisotropic fluid-saturated porous solids generate four body waves: quasi-fast longitudinal wave, marked as "qP1", quasi-slow longitudinal wave, marked as "qP2", and quasi-transverse waves, marked as "qS1" and "qS2". In addition, phase velocities of the waves depend on the propagation direction and the frequency. The viscosity η has a great effect on the behavior of qP2 wave.

3. BEM FORMULATION USING CQM

Applications of BEM to isotropic fluid-saturated porous solids were studied in the past decades, and most of them were based on u_i-p formulation (Schanz 2001, Saitoh et al. 2012). Fundamental solutions for the solids, of course, were derived in u_i-p formulation by many researchers (Schanz and Pryl 2004, Saitoh et al. 2012). However, those for general anisotropy have been proposed by Norris (1994) only, as far as the authors know.

In this section, firstly, the brief statement of the u_i-p formulation is shown. Secondly, Laplace-domain fundamental solutions for 2-D general anisotropic fluid-saturated porous solids are derived. Subsequently, the formulation of CQ-BEM for fluid-saturated porous solid is described.

3.1 u_i-p Formulation

Our proposed method is based on u_i-p formulation, and we denote the generalized displacement q_I and traction s_I as follows:

$$q_I = \{u_i^{\mathrm{T}}, p\}^{\mathrm{T}}, \quad s_I = \{t_i^{\mathrm{T}}, p_n\}^{\mathrm{T}} \tag{7}$$

where $(\,)^{\mathrm{T}}$ denotes the transpose of a vector, and t_i is the traction component of the solid. In addition, p_n is normal derivative of the pressure given by $p_n = \partial p/\partial n$. Laplace-domain equations of motion in u_i-p formulation are written as follows:

$$\hat{L}_{IK}\hat{q}_K(\mathbf{x}, s) = -\hat{B}_I \tag{8}$$

where

$$\begin{aligned} &\hat{L}_{ik} = C_{ijkl}\partial_j\partial_l - \tilde{\rho}_{ik}s^2, \quad \hat{L}_{i4} = \tilde{\alpha}_{ij}\partial_j, \\ &\hat{L}_{4k} = -\tilde{\alpha}_{kl}\partial_l, \quad \hat{L}_{44} = -\frac{1}{s^2}Y_{jl}^{-1}\partial_j\partial_l + \frac{1}{M}, \end{aligned} \tag{9}$$

$$\hat{B}_i = \rho\hat{b}_i + \rho_f^2 Y_{ik}^{-1}\hat{c}_k, \quad \hat{B}_4 = -\rho_f\frac{1}{s^2}Y_{jl}^{-1}\partial_j\hat{c}_l \tag{10}$$

and

$$\begin{aligned} &Y_{ik} = m_{ik} + \frac{1}{s}\eta r_{ik}, \quad \tilde{\alpha}_{ij} = \frac{M_{ij}}{M} + \rho_f Y_{ij}^{-1}, \\ &\tilde{\rho}_{ik} = \rho\delta_{ik} - \rho_f^2 Y_{ik}^{-1}. \end{aligned} \tag{11}$$

The equations in time-domain can be derived by applying the inverse Laplace transform to Eq.(8).

3.2 Fundamental Solutions for 2-D General Anisotropic Fluid-Saturated Porous Solids

Laplace-domain fundamental solutions for 2-D general anisotropic fluid-saturated porous solids are derived in this section. The derivation is based on that used in Wang (1994) and Wang and Achenbach (1994). They used the Radon and its inverse transforms expressed as follows:

$$\check{f}(\sigma, \mathbf{n}) = \int_{\mathbf{n}\cdot\mathbf{x}=\sigma} f(\mathbf{x})\delta(\sigma - \mathbf{n}\cdot\mathbf{x})dL(\mathbf{x}), \tag{12}$$

$$\begin{aligned} &f(\mathbf{x}) \\ &= \int_{|\mathbf{n}|=1}\left[\frac{1}{4\pi^2}\int_{-\infty}^{\infty}\frac{\partial_\varsigma\check{f}(\sigma, \mathbf{n})}{\sigma - \varsigma}d\varsigma\right]_{\sigma=\mathbf{n}\cdot\mathbf{x}} dL(\mathbf{n}). \end{aligned} \tag{13}$$

Note that Eq.(13) represents the inverse transform for 2-D case.

The fundamental solutions can be obtained by solving the following equation:

$$\hat{L}_{PQ}\hat{U}_{QK}(\mathbf{x}, s) = -\delta(\mathbf{x})\delta_{PK} \tag{14}$$

where δ_{ij} is the Kronecker delta and $\delta(\mathbf{x})$ denotes the Dirac delta function. In Eq.(14), the observation and source points are located at $\mathbf{x}$ and the origin $\mathbf{O}$. Applying the Radon transform given by Eq.(12) to Eq.(14), the following equation is obtained.

$$\check{\hat{L}}_{PQ}\check{\hat{U}}_{QK}(\sigma, \mathbf{n}, s) = -\delta(\sigma)\delta_{PK} \tag{15}$$

where

$$\begin{aligned} &\check{\hat{L}}_{ik} = C_{ijkl}n_j n_l\partial_\sigma^2 - \tilde{\rho}_{ik}s^2, \quad \check{\hat{L}}_{i4} = \tilde{\alpha}_{ij}n_j\partial_\sigma, \\ &\check{\hat{L}}_{4k} = -\tilde{\alpha}_{kl}n_l\partial_\sigma, \\ &\check{\hat{L}}_{44} = -\frac{1}{s^2}Y_{jl}^{-1}n_j n_l\partial_\sigma^2 + \frac{1}{M}. \end{aligned} \tag{16}$$

For fixed $\mathbf{n}$ and s, it apparent that Eq.(15) is an ordinary differential equation for σ. Solving Eq.(15) using the Fourier transform and the residue theorem, we obtain the following expression:

$$\check{U}_{IK}(\sigma, \mathbf{n}, s) = \mathrm{i}\sum_{\alpha=1}^{4}\left[\frac{\left(\mathrm{adj}\left[\tilde{\hat{\mathbf{L}}}\right]\Big|_{k=k_\alpha}\right)_{IK}}{\partial_k \det\left[\tilde{\hat{\mathbf{L}}}\right]\Big|_{k=k_\alpha}}e^{\mathrm{i}k_\alpha|\sigma|}\right] \tag{17}$$

where $\partial_k = \partial/\partial k$ and k is wavenumber. In addition, k_α $(\alpha = 1, \cdots, 4)$ are the solutions that satisfied the following equations:

$$\det\left[\tilde{\hat{\mathbf{L}}}\right] = 0, \quad \mathrm{Im}[k_\alpha] > 0. \tag{18}$$

Applying the inverse Radon transform given by Eq.(13) to Eq.(17), and transferring the source point to the position $\mathbf{y}$, the fundamental solutions are obtained as follows:

$$\begin{aligned} &\hat{U}_{ik}(\mathbf{x}, \mathbf{y}, s) = \frac{1}{4\pi^2}\int_{|\mathbf{n}|=1}\sum_{\alpha=1}^{4}\Lambda_{ik}^{\alpha}(\mathbf{n})\Phi^{\alpha}dL(\mathbf{n}), \\ &\hat{U}_{i3}(\mathbf{x}, \mathbf{y}, s) = \frac{1}{4\pi^2}\int_{|\mathbf{n}|=1}\sum_{\alpha=1}^{4}\Lambda_{i4}^{\alpha}(\mathbf{n})\Psi^{\alpha}dL(\mathbf{n}), \\ &\hat{U}_{3k}(\mathbf{x}, \mathbf{y}, s) \\ &= \frac{1}{4\pi^2}\int_{|\mathbf{n}|=1}\sum_{\alpha=1}^{4}\Lambda_{4k}^{\alpha}(\mathbf{n})\Psi^{\alpha}dL(\mathbf{n}), \\ &\hat{U}_{33}(\mathbf{x}, \mathbf{y}, s) = \frac{1}{4\pi^2}\int_{|\mathbf{n}|=1}\sum_{\alpha=1}^{4}\Lambda_{44}^{\alpha}(\mathbf{n})\Phi^{\alpha}dL(\mathbf{n}) \end{aligned} \tag{19}$$

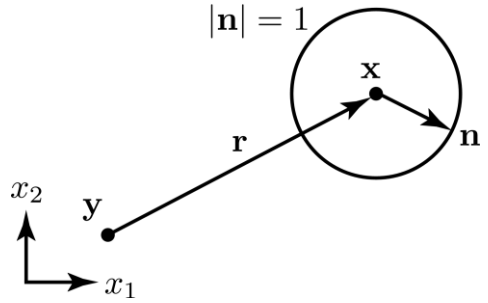

Figure 2 Integration on the unit circle ($|\mathbf{n}| = 1$).

where

$$\Lambda_{IK}^{\alpha}(\mathbf{n}) = k_{\alpha}\frac{\left(\mathrm{adj}\left[\tilde{\tilde{\mathbf{L}}}\right]\Big|_{k=k_{\alpha}}\right)_{IK}}{\partial_k \det\left[\tilde{\tilde{\mathbf{L}}}\right]\Big|_{k=k_{\alpha}}} \tag{20}$$

and

$$\begin{aligned}\Phi^{\alpha} &= \mathrm{e}^{-\mathrm{i}k_{\alpha}|\mathbf{n}\cdot\mathbf{r}|}E_1(-\mathrm{i}k_{\alpha}|\mathbf{n}\cdot\mathbf{r}|)\\ &\quad +\mathrm{e}^{\mathrm{i}k_{\alpha}|\mathbf{n}\cdot\mathbf{r}|}\{E_1(\mathrm{i}k_{\alpha}|\mathbf{n}\cdot\mathbf{r}|)+\mathrm{i}\pi\},\end{aligned} \tag{21}$$

$$\begin{aligned}\Psi^{\alpha} &= \mathrm{sgn}(\mathbf{n}\cdot\mathbf{r})[-\mathrm{e}^{-\mathrm{i}k_{\alpha}|\mathbf{n}\cdot\mathbf{r}|}E_1(-\mathrm{i}k_{\alpha}|\mathbf{n}\cdot\mathbf{r}|)\\ &\quad +\mathrm{e}^{\mathrm{i}k_{\alpha}|\mathbf{n}\cdot\mathbf{r}|}\{E_1(\mathrm{i}k_{\alpha}|\mathbf{n}\cdot\mathbf{r}|)+\mathrm{i}\pi\}].\end{aligned} \tag{22}$$

In Eqs.(19), the small index ranges from 1 to 2, and the integrations on the unit circle ($|\mathbf{n}| = 1$), shown in Figure 2, are implemented as a consideration of the effect of the interference of the body waves propagating in every direction.

3.3 Formulation of CQ-BEM

Time-domain boundary integral equations (BIEs) in finite domain are expressed as follows:

$$\begin{aligned}C(\mathbf{x})q_I(\mathbf{x},t) &= \int_S U_{IK}(\mathbf{x},\mathbf{y},t) * s_K(\mathbf{y},t)dS(\mathbf{y})\\ &\quad -\int_S W_{IK}(\mathbf{x},\mathbf{y},t) * q_K(\mathbf{y},t)dS(\mathbf{y})\end{aligned} \tag{23}$$

where $*$ denotes the Reimman convolution, and S is the boundary of the domain. In Eq.(23), the large index ranges 1 to 3, thus we use

$$q_I = \{u_1, u_2, p\}^{\mathrm{T}}, \quad s_I = \{t_1, t_2, p_n\}^{\mathrm{T}}. \tag{24}$$

In addition, $C(\mathbf{x})$ is given by

$$C(\mathbf{x}) = \begin{cases} 1 & : \mathbf{x} \in D \\ 1/2 & : \mathbf{x} \in S \\ 0 & : \mathbf{x} \in D_c \end{cases}. \tag{25}$$

Moreover, $U_{IK}(\mathbf{x},\mathbf{y},t)$ and $W_{IK}(\mathbf{x},\mathbf{y},t)$ are time-domain fundamental solutions and its double layer kernels, respectively.

On the other hand, time-domain BIEs in infinite domain are expressed as follows:

$$\begin{aligned}C(\mathbf{x})q_I(\mathbf{x},t) &= \int_S U_{IK}(\mathbf{x},\mathbf{y},t) * s_K(\mathbf{y},t)dS(\mathbf{y})\\ &\quad -\int_S W_{IK}(\mathbf{x},\mathbf{y},t) * q_K(\mathbf{y},t)dS(\mathbf{y}) + q_I^{\mathrm{in}}(\mathbf{x},t)\end{aligned} \tag{26}$$

where $q_I^{\mathrm{in}}(\mathbf{x},t)$ represent the generalized displacement corresponding to the incident wave.

Convolution quadrature method (CQM) and collocation method with the constant shape function are applied to Eq. (26) as time and space discretization, and taking the limit process $\mathbf{x} \in D \to \mathbf{x} \in S$, the discretized BIEs are obtained as follows:

$$\begin{aligned}&\left[\frac{1}{2}\delta_{MN}\delta_{IK} + B_{MN;IK}^{(0)}\right]q_{N;K}^{(n)} - A_{MN;IK}^{(0)}s_{N;K}^{(n)}\\ &= q_{M;I}^{\mathrm{in}(n)} + \sum_{k=1}^{n-1}\left[A_{MN;IK}^{(n-k)}s_{N;K}^{(k)} - B_{MN;IK}^{(n-k)}q_{N;K}^{(k)}\right].\end{aligned} \tag{27}$$

In Eq.(27), $M, N = 1,2,\cdots,N_e$ where N_e represents the number of the element, and n is that of the total time steps. $A_{MN;IK}^{(k)}$ and $B_{MN;IK}^{(k)}$ are the influence functions given as follows:

$$\begin{aligned}&A_{MN;IK}^{(m)}\\ &= \frac{R^{-m}}{L}\sum_{l=0}^{L-1}\left[\int_{S^N}\widehat{U}_{IK}(\mathbf{x}^M,\mathbf{y}^N,s_l)dS(\mathbf{y})\right]\mathrm{e}^{-2\pi\mathrm{i}m\frac{l}{L}}\end{aligned} \tag{28}$$

$$\begin{aligned}&B_{MN;IK}^{(m)}\\ &= \frac{R^{-m}}{L}\sum_{l=0}^{L-1}\left[\int_{S^N}\widehat{W}_{IK}(\mathbf{x}^M,\mathbf{y}^N,s_l)dS(\mathbf{y})\right]\mathrm{e}^{-2\pi\mathrm{i}m\frac{l}{L}}\end{aligned} \tag{29}$$

where $s_l = \gamma(z_l)/\Delta t$ and $\widehat{U}_{IK}(\mathbf{x},\mathbf{y},s)$ and $\widehat{W}_{IK}(\mathbf{x},\mathbf{y},s)$ are Laplace-domain fundamental solutions and its double layer kernels, respectively. The double layer kernels $\widehat{W}_{IK}(\mathbf{x},\mathbf{y},s)$ are given by the following equations:

$$\widehat{W}_{IK}(\mathbf{x},\mathbf{y},s) = \hat{B}_{KJ}^{\mathbf{y}}\widehat{U}_{IJ}(\mathbf{x},\mathbf{y},s) \tag{30}$$

where

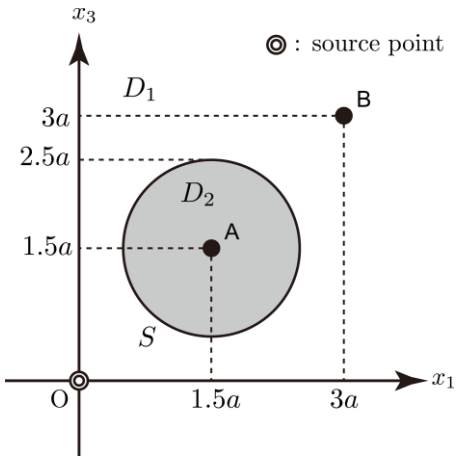

Figure 3 Analysis model for wave scattering problem.

$$\hat{B}^{\mathbf{y}}_{ik} = -C_{ijkl}n_j(\mathbf{y})\partial_l, \quad \hat{B}^{\mathbf{y}}_{i3} = \frac{M_{ij}}{M}n_j(\mathbf{y}),$$
$$\hat{B}^{\mathbf{y}}_{3k} = -\rho_f Y^{-1}_{kl}n_l(\mathbf{y}), \quad \hat{B}^{\mathbf{y}}_{33} = \frac{1}{s^2}Y^{-1}_{jl}n_j(\mathbf{y})\partial_l. \tag{31}$$

In Eq.(33), it should be mentioned that $n_i(\mathbf{y})$ represents the unit normal vector on the boundary at the point $\mathbf{y}$. Moreover, CQM parameters R and $\gamma(z_l)$, with an error magnitude $O(\epsilon)$, are written as follows:

$$R = \epsilon^{\frac{1}{2L}} \tag{32}$$

$$\gamma(z_l) = \sum_{i=1}^{k}\frac{1}{i}(1-z_l)^i, \quad z_l = R\mathrm{e}^{-2\pi\mathrm{i}\frac{l}{L}}. \tag{33}$$

Note that Eq.(35) corresponds to the backward differentiation formulas of order k. The discretized form of Eq.(23) can be obtained with the aforementioned process. Setting the boundary conditions and solving Eq.(12), we obtain unknown boundary values.

4. NUMERICAL EXAMPLE

As a numerical example, we consider wave scattering problem by an inclusion as shown in Figure 3. In this figure, the domain D_1 and domain D_2 represent the infinite and finite domain, respectively. Therefore, the BIEs for the domains D_1 and D_2 correspond to Eq.(26) and Eq.(23), respectively. In this problem, the boundary conditions on S are given as follows:

$$q^{[1]}_I(\mathbf{y},t) = q^{[2]}_I(\mathbf{y},t),$$
$$s^{[1]}_I(\mathbf{y},t) = -s^{[2]}_I(\mathbf{y},t). \tag{34}$$

Using Eqs.(23), (26), (27) and (34), we obtain the following algebra equation:

$$\begin{bmatrix} D^{[1]}_{MN;IK} & -A^{[1]}_{MN;IK} \\ D^{[2]}_{MN;IK} & A^{[2]}_{MN;IK} \end{bmatrix}\begin{Bmatrix} q^{[1](n)}_{N;K} \\ s^{[1](n)}_{N;K} \end{Bmatrix} = \begin{Bmatrix} q^{\mathrm{in}[1](n)}_{M;I} + E^{[1](n)}_{M;I} \\ E^{[2](n)}_{M;I} \end{Bmatrix} \tag{35}$$

where

$$D^{[d]}_{MN;IK} = \frac{1}{2}\delta_{MN}\delta_{IK} + B^{[d](0)}_{MN;IK},$$
$$E^{[d](n)}_{M;I} = \sum_{k=1}^{n-1}\left[(-1)^{d-1}A^{[d](n-k)}_{MN;IK}s^{[1](k)}_{N;K} - B^{[d](n-k)}_{MN;IK}q^{[1](k)}_{N;K}\right]. \tag{36}$$

Solving Eq.(35) each time step, we obtain unknown boundary values. The numerical results will be shown at the session of the conference.

5. CONCLUSIONS

In this paper, CQ-BEM for 2-D general anisotropic fluid saturated porous solid is developed. In near future, we apply the proposed method to some realistic problems in earthquake engineering and expand the proposed method to 3-D problems.

Abstract: Under the Peru - Japan SATREPS Project a building monitoring network has been implemented in Lima city, under the support of JST and JICA. The network considering a set of 5 sensors installed on different levels of three building: One is framed concrete structure, the second is a masonry and concrete wall building and the third is a hospital with concrete framed structure. The buildings are located in two kinds of soil of Lima (two in medium soil, and one in rigid soil). Since the installation of the sensors, seven moderate quakes has been register. This paper presents the monitoring response of one building and the dynamic characteristics measure from the stronger event registered for the buildings. Good agreement with simulation previously performed was found, and the results give us the confidence for the developed of parameters for the stiffness degradation under small and moderate quakes for concrete framed structures.

1. INTRODUCTION

Under the Peru - Japan SATREPS Project, with the support of JST and JICA, a building monitoring network has been implemented in Lima city since 2011.

A total of 15 sensors are to be installed on different levels of three buildings: One is a framed concrete structure, the second is a masonry and concrete wall building and the third is a hospital with concrete framed structure. One of the recorded moderate quake is shown and the response of a building analyzed and compared with previous studies.

1.1 Sensors Network Setting

Accelerations sensors are connected through internal network and IP addresses to access to Internet

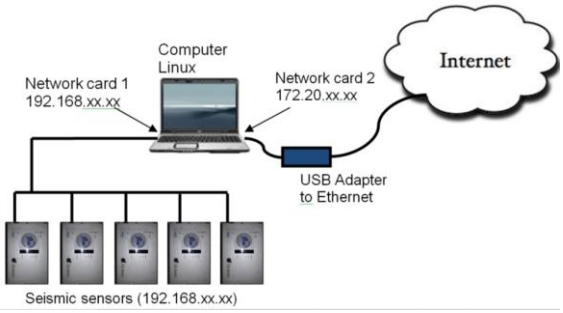

Figure 1 Connection of sensors to network through IP address and internet

After preliminar testing period in a local network (Figure 2), a set of 5 sensors has already been set in 2 buildings at UNI campus.

Figure 2 Network setting test and final placement of sensor at basement level in UNI Central Building

At each building, the 5 sensors set are aligned to a vertical line, and if possible near to gravity center. At the basement level, sensors has been fixed in a hole box in floor, and then at ceiling (slab) for each upper level.

1.2 Selected Buildings

The criteria for the selection of the buildings to be measured was the consideration of likely used structural system in Peru and also the different combination of materials.

A set of 5 sensors will be installed in each of three buildings, which was selected as representative of typical structures and material:

- Central Building of UNI is 3F+ BF Level and 16m high, irregular configuration in plan, with masonry and

concrete walls and concrete frame structure built more than 80 years ago, used mainly for administrative offices

- G2 Block at Civil Faculty of UNI, is for classrooms, a 3F framed RC building with irregular configuration of stiffness due to its distribution of masonry walls (hall at 1F, corridors and classroom at upper floors).
- Block A of Edgardo Rebagliati Martins National Hospital is a 14F+BF building, more than 50 years old, RC framed building, classified as essential type for its importance of use.

Figure 3 Central Building and G2 bldg block (North view) at Civil Engineering Faculty at UNI

2. PRELIMINAR STUDIES OF SELECTED BUILDINGS FOR MONITORING

2.1 Central Administrative Building of UNI

As shown in figure 4, plan of Central Building of UNI is irregular its longer dimension L=117m and B=23m wide for the main body. Sensors has been set to the South-East part of the building about 0.25L from gravity center

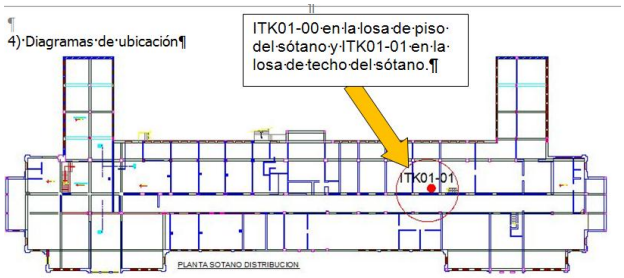

Figure 4 Plan of Central Building in UNI and location of sensors

Some previous calculation and measurement has been conducted as reference for assess dynamic monitoring results. Microtremor measurements has been conducted in 3 points (soil: center zone and at 3F: NO and SE wing of building) and showed fundamental periods (from Fourier Amplitude Spectra) of Tx=0.23s and Ty=0.28s for the building where X is longitudinal axis, and for soil Ts= 0.41s.

Figure 5 Preliminary measurement and analysis: microtremor and modeling

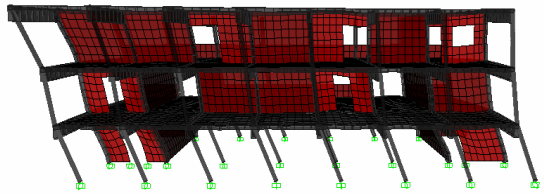
2.2 Central block of G2 building at Civil Engineering Faculty of UNI

Central Block G2 Bldg of Civil Engineering Faculty (FIC) is a 58 year old, reinforced concrete framed, 3-stories (10m high) structure with one underground floor. Half of its typical plan continue down to a basement floor. First floor is the main entrance hall, and upper levels are for classroom and corridors. So, in plan shown regular configuration (28m x 12m approximately), but some masonry thick walls (250mm) not aligned, in upper levels, changes its stiffness at each story (soft floor).

Figure 6 Location of Central Block G2 in FIC and South side view of building

Previous studies and evaluation has shown some reference values for natural period of building: From microtremor measurement (2007) Tx (longitudinal direction): 0.195s, and Ty (short direction): 1.62s

Preliminary analysis confirms a weak first level with greater relative displacements. Observing damage and failure at columns before than beams. From theoretical elastic analysis, it was obtained periods of 0.31s for first mode, which model is shown in figure 7



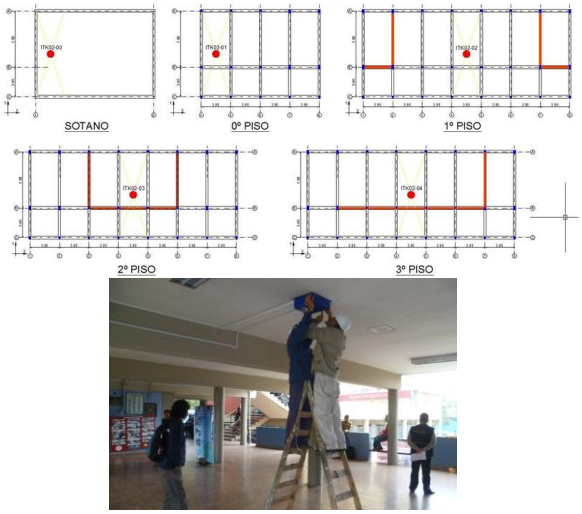


Figure 7 Modeling G2 building and deformed configuration

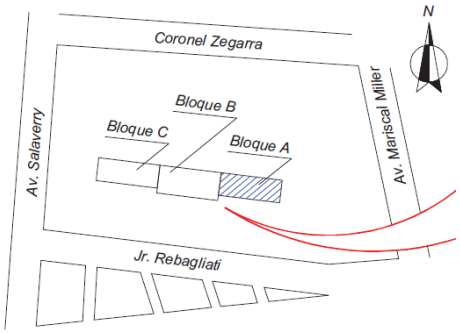
Setting of sensors was located at center of gravity in plan, aligned in a vertical line, and is shown in figure 8



Figures 8 Central Block in G2 FIC and setting of sensors to the ceiling (below)

2.3 Edgardo. Rebagliati Martins Hospital - Building A (East block)

This 14F, reinforced concrete building, 55year old, beard 2 main earthquakes (1966 and 1974), but main structure have not been damaged. "A-Block" was focused for this study and is the right block show in Figure 9. Dimensions in plan are 15.9m x 73m, and 45.6m high from ground level with 14F

Figure 9 E Rebagliati Hospital and studied block

As reference also for this building exist two previous studies: evaluation 1997 and more detailed, non linear analysis conducted for a thesis research. For intermediate level earthquake, predicted damage are expected in beams in both directions of analysis, endangering inmediatly occupancy or interrupting normal performing of functions as hospital

3. DATA ADQUISITION FROM RECENT EVENTS AND RESULTS

Since the installation of the sensors, seven moderate quakes has been registered in the network. In table 1 is shown a official List of Earthquake registered by IGP National Network in November and December 2012. Lightened row of table 1, was registered as 2.6 max response at upper level in the network notice, as shown in Figure 10.

Table 1 List of Earthquake registered, Nov&Dec 2012 Lima studied block

	Date	Time	Magnitude	Intensidad - localidades
1	03/11/2012	20:52:12	4.7 ML	III-IV Yauyos; III Lima
2	13/11/2012	00:48:58	4.0 ML	II Lima
3	15/11/2012	19:21:55	4.8 ML	III San Vicente de Cañete, Chincha Alta; II-III Lunahuana; II Lima, Ica
4	27/11/2012	04:19:59	4.4 ML	III Barranca; III II Huacho; II Lima
5	22/12/2012	01:43:39	4.2 ML	II Chila, Lima
6	28/12/2012	20:57:40	4.3 ML	II-III Huaral, Lima
7	31/12/2012	03:46:17	4.7 ML	III-IV Huacho III Lima

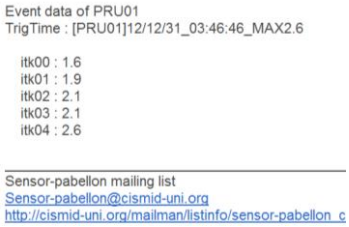


Figure 10 Notice of registered event at ITK network for UNI building

Additional data of this event to process: Depth 53Km, Latitude -11.42ºS; Longitude -77.92º

Data for G2-FIC building has been processed. Figures 11 and 12 show signal at basement and 4F. It is possible to read that acceleration on the top of the building reach a value of 20 gal, almost 3.3 times the basement acceleration.

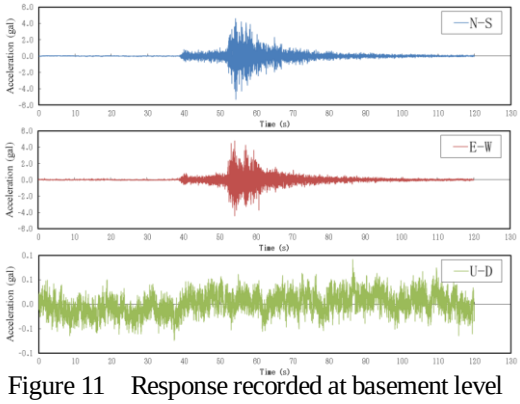

Figure 11 Response recorded at basement level

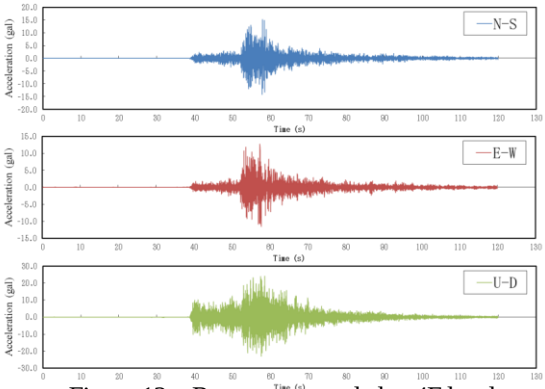

Figure 12 Response recorded at 4F level

Response of each level has been processed. Figure 13 shows predominant modal distribution and a large displacement evidence very flexible N-S direction compared with E-W.

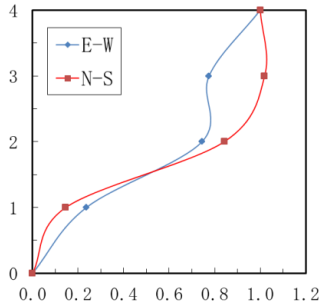

Figure 13 Predominant modal distribution

Table 2 shows predominant period for each direction of analysis. Values of periods for mode 2 in this table agree with previous measurements (see item 2.2)

Table 2 Predominant periods (s) for each direction

mode	EW	NS
1	0.22	0.23
2	0.19	0.16
3	0.15	0.12

Figures 14 and 15 shows spectra (acceleration and velocity) for basement level measurements

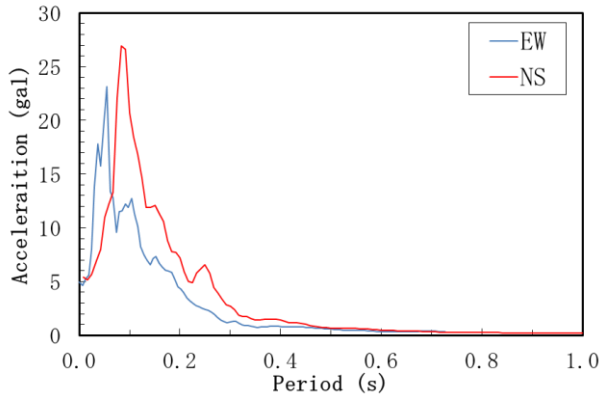

Figure 14 Acceleration spectra (h=0.05). signal from basement

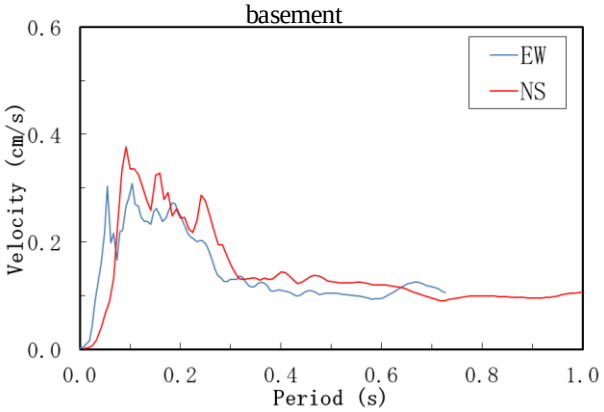

Figure 15 Velocity spectra (h=0.05). signal from basement

Both figures presents peaks values at the predominant periods and components of acceleration reach a maximum spectral component for a range between 22 to 27 gals for each direction of the building. Also the velocity indicates a peak value between 0.3 s. to 0.38 s. for this building.

4. CONCLUSIONS

First building monitoring network has been installed and is working at the present time in Lima Peru, as an output of the Project for Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru (JICA/JST), under the cooperation scheme of SATREPS.

Three sets of five sensors have been installed in Lima city. Two on buildings at UNI campus and other set at Edgardo Rebagliatti Hospital. The instalation process has been presented and the sensors are now on line.

Monitoring response of one of selected buildings and the dynamic characteristics measure from the events has been presented. Good agreement with simulation previously performed was found, and the results give us the confidence for the developed of parameters for the stiffness degradation under small and moderate quakes for concrete framed structures.

BRIDGE AND ADJACENT DOWNHOLE ARRAY RESPONSES DURING EARTHQUAKES AT EUREKA, CALIFORNIA

Ning Wang[1] and Ahmed Elgamal[2]

1) Graduate Research Assistant, Dept. of Structural Engineering, University of California, San Diego, CA 92093-0085, USA

Abstract: Recorded earthquake motions from instrumented bridge structures and adjacent geotechnical downhole arrays provide valuable information on the characteristics of structural response during seismic events. In particular, instrumentation installed by the California Strong Motion Instrumentation Program (CSMIP) in cooperation with California Department of Transportation (CalTrans) resulted in a valuable strong motion database for bridge superstructures, foundations and nearby free field seismic response at Eureka, California. In this paper, the recent Ferndale area earthquakes and several earlier small earthquakes are employed to evaluate the ground, pile foundation, and the Samoa Channel bridge responses using system identification and inverse problem techniques. Local site response and its nonlinearity are clearly highlighted. Finite Element (FE) models of the foundation-bridge system are calibrated based on the recorded motions and identified bridge/foundation characteristics. The study shows that computational modeling and analysis of ground-pile-system response from seismic sensors are effective and efficient ways to calibrate and interpret the seismic response of the entire structure-foundation-ground system.

1 INTRODUCTION

Recorded bridge deep foundation seismic motions and adjacent downhole-array records provide a unique opportunity for documenting and analyzing salient ground-foundation-structure response mechanisms. Studies based on such full-scale seismic performance data sets lead to a better understanding of the underlying actual soil-structure interaction (SSI) characteristics (Elgamal et al. 2008).

In this paper, seismic response of an instrumented pile-group in the Eureka-Samoa Channel bridge and a nearby free-field geotechnical array (Eureka Geotechnical Array) are studied using recorded earthquake data including the January 9, 2010 Eureka Ferndale event, that resulted in a moderate but substantial level of earthquake excitation. An additional set of recorded small seismic motions was studied as well for comparison.

For that purpose, a simple FE model of the instrumented Samoa Channel Bridge Pier S-8 and its pile group foundation was developed (to maintain focus, attention is directed herein to the bridge Transverse response). Eigenvalue analysis was performed and the results were compared with those from the system identification earthquake response analysis. On this basis, and representative stiffness of the pile foundation beneath Pier S-8 was defined. The results of this research are of immediate consequence to validate and refine deep-foundation soil-structure interaction analysis. As such, strong motion data analysis is shown to be a valuable source for gaining insights into the underlying SSI mechanisms.

2 BRIDGE INSTRUMENTATION AND ANALYSIS OF SEISMIC RECORDS

As of Jan 2012, 63 regular highway bridges, 13 toll bridge structures and 18 downhole geotechnical arrays have been instrumented in California (Caltrans 2008; Caltrans 2012). Numerous works on identification of structural systems utilizing recorded motion have been conducted in the past two decades (Werner et al. 1994; Wilson and Tan 1990). With recorded accelerations on bridge systems, modal frequencies and mode shapes can be identified using parametric or non-parametric evaluation techniques (Arici and Mosalam 2000). The invaluable data collected from such sensors helps to advance our understanding of how the bridges react to different types of seismic waves and how the dynamic SSI affects the behavior of superstructures (Hipley et al. 1998). In this paper, data from a heavily instrumented bridge (the Eureka- Samoa Channel) with embedded accelerometers inside a pile group foundation at -10.3632 m (-34 ft) and -16.4592 m (-54 ft) below mean sea level along with a nearby geotechnical downhole array (Figure 1) was employed to obtain salient resonant frequencies for the bridge system. Seismic response of the Eureka Samoa Channel Bridge was analyzed by comparing

recorded earthquake strong motion data of the CGS (California Geological Survey) station 89686 with the FE analysis result. This study provides a unique opportunity to bring insight into the challenging issue of ground-pile group/structure interaction during earthquakes.

3 THE SAMOA CHANNEL BRIDGE

The 20-span Eureka Samoa Channel Bridge near Eureka in northern California (Figure 1) is a 764 m long and 10.4 m wide structure, supported by 19 single hexagonal concrete pier bents on pile group foundations. Pre-stressed concrete I-girders along with cast-in-place concrete slabs are supported on concrete seat-type abutments and the cap beams of column type piers. Nine expansion joints allowing movement during seismic occurrence are located at the top of Pier-S4, S7, S8, S9, S10 S14, Pier S17 and two abutments supports (Figure 2). There is one hinge located at Span 8. Originally, the pile-group foundations consisted of driven pre-cast prestressed concrete piles and caps. Pile groups beneath Pier S-8 and S-9 consisted of 8 (2x4) circular (1780kN type) concrete piles.

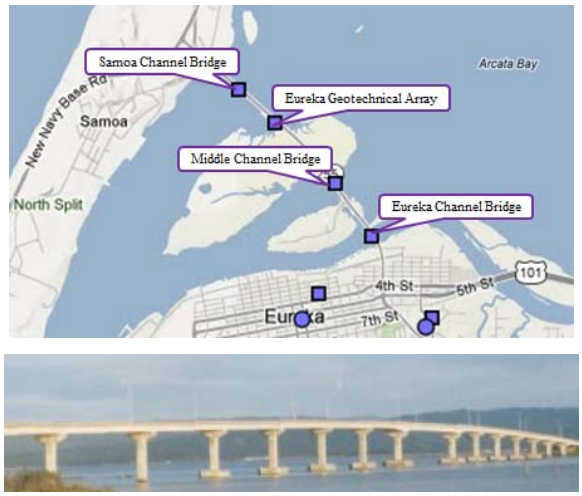

Figure 1 Location of Samoa Channel Bridge, Eureka Geotechnical Array, Middle Channel Bridge and Eureka Channel Bridge, and photo of the Samoa Channel Bridge (http://www.strongmotioncenter.org)

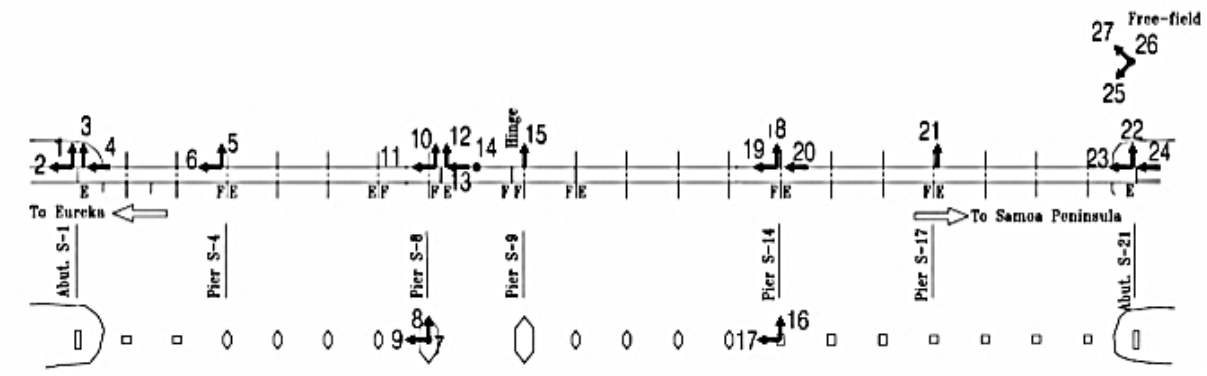
3.1 Site description

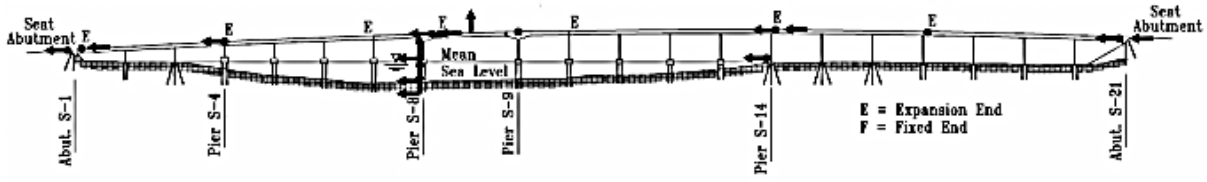
A deep soft alluvium geological profile is found at this location where the surficial foundation soil is mainly composed of very soft to soft organic silt with clay. Soil layers consisting of dense to very dense gray medium and sand underlie the surficial soil layer and continue to the maximum explored depth.

3.2 Seismic retrofit effort



The bridge was designed in 1968, built in 1971, and has been the object of seismic retrofit efforts by the California Department of Transportation (CalTrans). The seismic retrofit in 2002 included strengthening of the foundations by installing additional 0.91 m diameter cast-in-steel shell piles (e.g. 6 additional CISS piles at Pier S-8) with new or enlarged caps to cover the new piles (Figure 3).

3.3 Recorded earthquake events



The Samoa Channel Bridge is located in an area of complex interaction among three tectonic plates (North American, Pacific and Gorda). The 'Little Salmon' fault is the nearest seismic source from the site (Caltrans 2000). To obtain insights for both the properties of earthquake and seismic response of the structure, the Samoa Channel Bridge is heavily instrumented as shown in Figure 2 to measure the translational and torsional motions of the bridge as well as relative motions across the hinges. There are 33 accelerometers in total for the Samoa Channel Bridge System instrumented in 1996, including 24 accelerometers on the bridge structure, 6 accelerometers on pile foundation (Figure 3), and 3 accelerometers at a nearby free field site. Sensors on the structure are oriented in the longitudinal and transverse direction of the bridge and sensors at the free field are oriented in the north-south, east-west and vertical directions. This bridge is one of two bridges in CA with instrumentation embedded inside one of the piles (at depths of 10.3636 m (34 ft) and 16.5692 m (54 feet) below mean sea level). Side view and deck level plan view of the sensor network layout for the Samoa Channel Bridge are shown in Figure 2.

A total of seven earthquakes in the period of March 2000 through January 2010 with Magnitudes from 4.6 M_w to 7.2 M_w (M_w: regional moment magnitude) have been recorded. Corrected acceleration, velocity, displacement and acceleration response spectra are available. Varying in peak acceleration (from 0.006g to 0.150g), epicentral distances (from 40.2 km to 153.4 km), shaking duration, and frequency content bandwidth, these earthquakes provide valuable information on the soil-foundation-structure seismic behavior over a broad range of excitations. Table 1 depicts time, Magnitude, epicentral distance, peak horizontal acceleration at ground surface and structure of the recorded earthquakes (where only one event exceeds 0.1g in peak ground acceleration).

Notable in Table 1 is the Earthquake Ferndale 09 Jan 2010 which occurred approximately 35 km away from Ferndale, CA in a deformation zone of the southernmost Gorda plate (http://earthquake.usgs.gov). The maximum recorded shaking was observed in Eureka (33% g), which is deemed sufficient to cause moderate damage. The Samoa Channel Bridge at a distance of 53.8 km from the epicenter of this earthquake reached peak acceleration of the order of 0.15 g at the ground surface and 0.37 g on the bridge deck.

4 EVALUATION OF EARTHQUAKE RECORDS - THE FERNDALE 09 JAN 2010 EARTHQUAKE

From the downhole array data, ground displacement at various depths is shown in Figure 4. As may be noted, displacement amplitudes appear to clearly increase as the

seismic waves approach and reflect-off the ground surface. Displacement of the bridge, the pile below ground and the nearby free field are shown in Figure 5.

(a) Transverse direction

(b) Longitudinal direction

Figure 4 Rotated displacement time histories at Eureka Downhole Array during the Jan 9 2010 Ferndale Earthquake (transverse direction and longitudinal direction)

Comparison of the displacements in Figure 4 and 5 shows that:

i) Displacement appears similar at the nearby ground surface and in the pile below ground (16.5 m below mean sea level, estimated at about 1.2m below the mudline at this location),

ii) These displacements are also similar to those of the T-direction downhole array at comparable depth (when measured with mean sea level as a reference, that being somewhere between the 19 m and 33 m depth of the downhole array),

iii) Based on the above, the pile group at the location -16.5 m below sea level appears to be practically moving along with the ground, indicating a level of firm embedment (fixity) at this depth below ground. With this ground motion as "input", the pile cap and bridge deck displacements are noticeably different, being significantly larger in amplitude, with a clear dominant fundamental response Period, and

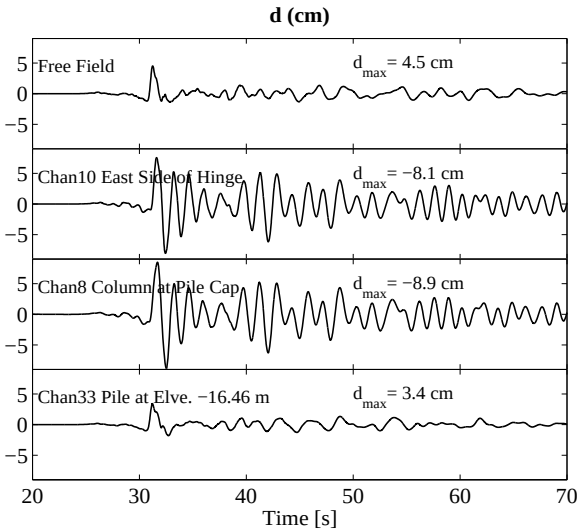

Figure 5 Samoa Channel bridge Displacement time histories at Pier S-8 during the Eureka Ferndale Jan 9 2010 Earthquake in the Transverse direction

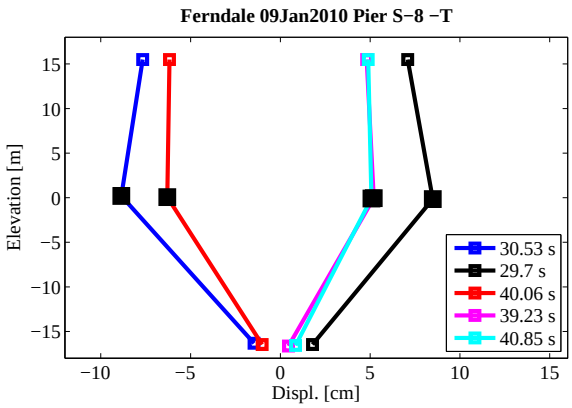

Figure 6 Displaced configuration of Pier S-8 for selected time instants during the January 9 2010 Ferndale Earthquake (Transverse (T) direction shown)

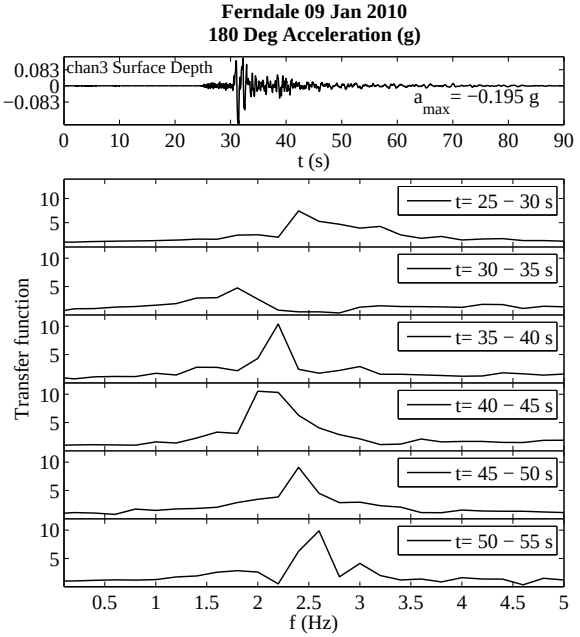
iv) much of the bridge displacements are due to deformation occurring at the pile cap level, with the

bridge deck motions only slightly different from those of the pile cap as shown from the plots of selected displacement time instants of Figure 6. This may be taken as an indication that the Pier (bridge column) above the pile cap is quite stiff in comparison to the lateral stiffness afforded by the underlying pile group.

Insights of this type concerning actual behavior of a full-scale pile foundation during an actual earthquake event are extremely valuable and will contribute considerably to our current understanding of this important SSI mechanism.

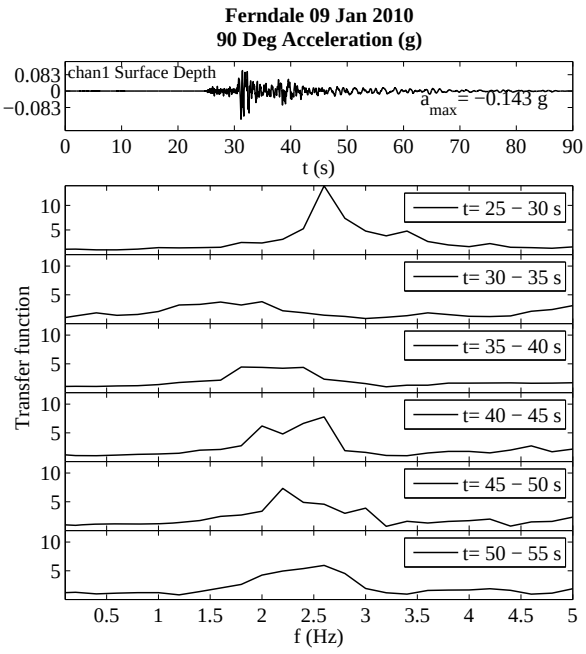
5 SYSTEM IDENTIFICATION / FE ANALYSIS

5.1 Site Response and nonlinearity



Nonlinearity of the site seismic response was evident through analysis of nearby Eureka downhole array data (Elgamal 1995; Elgamal et al. 1996). The recorded data at this downhole site allows for a better understanding of the ground seismic response in which the Samoa Channel Bridge foundations are embedded. Fourier spectral ratios between the motions at the ground surface and at 19 m depth were computed with a 5-second time window for earthquake Ferndale 09 Jan 2010 (Figure 7). Lower natural frequency (decrease of soil stiffness) is observed (~1.8 Hz) during the strong motion period (30s-35s) compared to other time windows (reaching as much as 2.6 Hz).

5.2 Bridge sub-system resonances



A Transfer Function (TF) defined as the ratio of the cross power spectral density ($P_{yx}(f)$) of input signal (x) and output signal (y) and the power spectral density ($P_{xx}(f)$) of input signal is employed to assess system and sub-system resonant frequencies.

$$T_{xy}(f) = \frac{P_{yx}(f)}{P_{xx}(f)}$$

At the Pier S-8, the fundamental frequency for Deck-Pier sub-system (deck response referenced to pile cap response) was 1.60 Hz during the Ferndale 09 Jan 2010 earthquake and in range of 1.95-2.00 Hz for all of the other small earthquakes. The same logic was then employed to relate the deck response to that of the pile at -16.5 m (taken here to be the fixed base as discussed above), and also related to the nearby free-field ground surface motion. The first natural frequency for this bent of the bridge system was found to be 0.70 Hz during the Ferndale 09 Jan 2010 earthquake and around 1 Hz during all of the other small earthquakes. A summary of the TF results for 5 different earthquakes (Table 1) employing a Hanning window and 50% overlap to reduce the effects of spectral leakage is presented in Table 2. The lower predominant frequency during the strongest earthquake Ferndale 09 Jan 2010 reflects nonlinear behavior in the structure (the Pier Deck sub-system) as well as in the pile-group response.

(a) Direction of 180 degrees

(b) Direction of 90 degrees

Figure 7 Nonlinear soil response during Earthquake Ferndale 09 Jan 2010

5.3 Insights from a simple FE model

A simple linear elastic OpenSees FE model was developed based on the identified characteristics of Pier S-8 (including the deck, the Pier, and the pile group below). This model consisted of two point masses at the

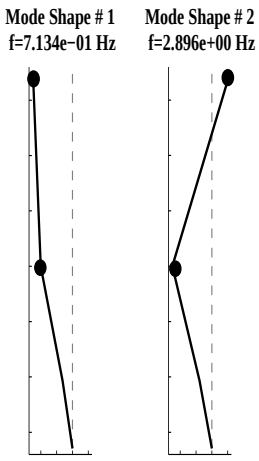
bridge deck and the pile cap levels, connected by bending beams. Input transverse excitation was imparted at the -16.5 m below mean sea level location, and the base as well as the pile cap mass location were fixed against rotation.

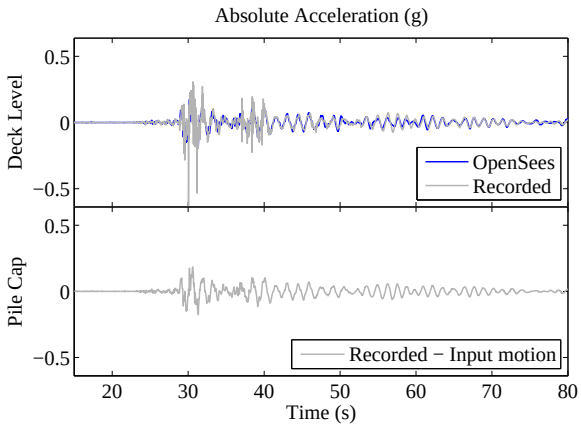
Table 2 System Identification (Samoa Channel Bridge)

Earthquake	Fundamental Frequency (Hz)		
	$\frac{Deck}{Pile\ Cap}$	$\frac{Deck}{-16.5\ m}$	$\frac{Deck}{free\ field}$
09 Jan 10	1.60	0.70*	0.67*
24 June 07	2.00	1.10	0.95
29 April 08	1.95	1.10	0.90
16 Aug 08	1.95	0.93	0.95
26 Feb 07	2.00	0.95	0.90

* The second resonance was noted at about 2.7 Hz

Actual mass was used to define the FE model point masses (center-to-center mass of the bridge deck above S-8, and mass of the pile cap). Flexural stiffness (EI) of the connecting bending beams was then based on matching the sub-system and bridge-bent resonant frequencies (Figure 8) identified in Table (for the moderate 9 January 2010 earthquake). The Pier and pile foundation stiffness defined in this fashion is contrasted below with estimates of the actual Pier and pile group foundation (taken as a single super-pile) lateral stiffness, calculated based on the following material parameters: concrete mass density ρ= 2400 kg/m^3, Young's modulus E=2.51x10^7 kPa (derived from an assumed compressive strength $f_c' = 28MPa$) and Poisson's ratio ν=0.2 for concrete ad E$_s$=2.0x10^8 kPa for steel. As such, the defined Pier stiffness includes contributions from interaction (resistance) due to the overall bridge connectivity, and the pile foundation stiffness implicitly accounts for SSI.





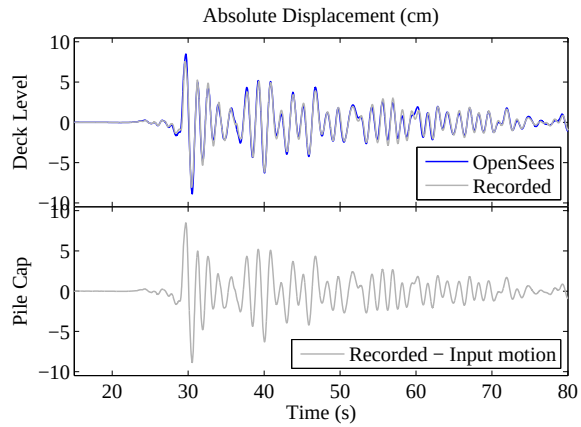


Figure 8 mode shapes of pile-column system

Computational simulation results show a reasonable match from the pile cap to the deck (Figure 9) and from the base to the deck (Figure 10). On this basis, one might contrast the identified employed stiffness quantities to those estimated above for the Pier and pile group foundation. It turns out that the employed quantities amounted to a factor of 1.1 for the column stiffness and a factor of 0.28 for the stiffness of pile group foundation. This stiffness for the Pier might be reasonable considering restrains from the overall bridge behavior. However, the pile group foundation stiffness appears to be noticeably lower than calculations might imply (only 28% of the estimated EI is engaged). For the small earthquakes (Table 2), the corresponding identified Pier stiffness reached 1.65 of that estimated, and the identified pile foundation stiffness reached a higher factor of 0.65. Such factors as obtained from this study provide a reference for seismic and SSI considerations and are to be further refined based on additional more representative investigations.

6 CONCLUSIONS

Post-earthquake ground response analysis using signal processing techniques and system identification methods provides useful information to investigate site and structure dynamic properties. In this paper seismic response measurements from downhole array and adjacent bridge foundation sensors provided unique insights into the seismic response of a soil-foundation-structure system.

A comparison of the measured displacement time-history records indicated that: (1) despite the moderately high levels of shaking, the relative displacement between the Pier top and bottom of remained relatively small, and most of the bridge lateral deflections were due to movement of the pile cap, (2) displacement time histories at ground surface and at the -16.5 m depth location of the pile followed similar wave patterns to those of the downhole array. As such, input motion for a computer model of this foundation-structure system could be selected through interpolation of downhole array motions at corresponding locations, (3) out of phase response of pile at -10.36 m below the mean sea level requires additional investigations (not discussed in this paper; see Wang 2013 for more details).

Samoa Channel Bridge structure resonant frequencies are estimated using transfer functions from Fourier spectra. An OpenSees FE model was developed and calibrated to simulate site seismic response. Computed site response was comparable to the actual measurement in the time domain along Pier S-8. This study demonstrated that the adopted strong motion data analysis techniques have captured salient seismic characteristics and was helpful for calibration of the employed FE model.

The results of this research are of significance to the current state of practice in seismic pile-ground-structure analysis. Validation and refinement of our deep-foundation soil-structure interaction analysis and design approaches will lead to more confidence and reliability. In this domain of highly expensive and time consuming foundation design, construction, and retrofit, major beneficial economic outcomes can result from adoption of analysis tools that are verified and further calibrated by such full-scale seismic performance data sets.

Abstract: This research attempts to describe steps and procedures for structural health monitoring of the Urban Disaster Prevention Research Center (UDPRC), located in Tsukuba, Japan, in order to locate possible damages to the structural and non-structural elements of buildings due to earthquakes. The SHM procedure is an addition to the regular monitoring for the purpose of detecting damage sustained since the building's construction. The methodology consists of analyzing strong motion acceleration records from the year 1999 till 2012, and microtremor acceleration records from 2009 and 2011. Dynamical properties of the structure and parameters related to stiffness are extracted from the records by applying parametric system identification methods (ARX, ARMAX and N4SID). The changes of these parameters in time indicate the possible occurrence of damage to the building. Damage detection and localization have been performed by tracing the history of changes in the extracted dynamical parameters and storey stiffness during the observed period. The results obtained demonstrate the tendency of natural frequencies and storey stiffness to decrease, and damping ratios to increase due to aging, and exposure to strong ground motion. A decrease in frequency and stiffness is most evident in the year 2011, after the Great East Japan Earthquake.

1. INTRODUCTION

Damage involves any change in a system that is unforeseen and tends to decrease or disable a system's future safe and successful exploitation. Early detection, identification and repair of damage to structures are some of the most crucial challenges in engineering. The implementation of a strategy and methodology for damage detection in building structures and infrastructure, as well as structures and devices in mechanical, aero and aerospace engineering, is known as "structural health monitoring" (SHM). Generally, the goal of SHM is to fulfill the following requirements: consideration of the occurrence of structural damage, locating the damage, evaluation of the severity, prediction of the remaining lifetime of the structure. Damage detection in structures requires a comparison of the dynamic parameters of the structure and storey stiffness, obtained at different times. The possibility of such a comparison provides a history of changes in these structural parameters and estimating possible damage location. System identification (SI) techniques play an important role in structural health monitoring processes. The structures in their physical nature can be observed as dynamic systems with their own dynamical properties. The SI procedures are based on digital data analysis and processing. They are subjected to various external influences that in system identification elaboration are called input. The input can be applied to structures according to various factors (ground motion, wind, etc.) in the form of signals. As a result of the input, the structures exhibit responses (output) with features dependent on the dynamic properties of the structure and the input. The structural dynamical properties are resonant frequencies (or resonant periods), mode shapes and damping coefficients. Those properties in SHM processes may be recognized as damage sensitive features and may be utilized in process of detecting possible damage. The identification procedure usually requires high S/N (signal-to-noise ratio) and uncorrelated sources of excitation. The SI identification techniques on buildings for the purpose of SHM include ambient vibration (microtremor) measurements, strong motion measurements (in the case of earthquakes) and forced vibration measurements (shaker test). A high S/N ratio occurs with strong motion measurements and forced vibration measurements, so identification procedures can be considered as having a higher possibility of accuracy than with microtremor measurements, which usually contain a

large number of disturbances compared to real input-output combinations (low S/N ratio).

The subject of the study in this paper is health monitoring of the structure of the Urban Disaster Prevention Research Center (UDPRC) using parametric system identification methods.

This study examines analyses of microtremors and strong motion by applying ARX, ARMAX and N4SID system identification methods for the purpose of detecting and locating damage that has occurred in the building's structural and non-structural elements due to aging and frequent exposure to earthquakes since the time of its construction.

2. CHARACTERISTICS OF THE BUILDING

The Urban Disaster Prevention Research Center (UDPRC) is a part of the National Institute for Land and Infrastructure Management (NILIM). It is an eight storey steel-encased reinforced concrete structure.

Table 1 Outline of the building characteristics

Structure type	steel-encased reinforced concrete						
Number of storeys	8-storeys						
Height	30.9 m						
Total building area	5,050 m^2						
Foundation type	mat foundation						
Storey mass (tons)							
1F	2F	3F	4F	5F	6F	7F	8F
836	785	782	931	768	744	819	300

Figure 1 Exterior of the building

The construction of the building was completed in March 1998. Since the beginning of its exploitation, strong motion acceleration sensors have been installed for the purpose of monitoring the state of the structure, and analyzing its behavior when affected by earthquakes. Microtremor measurements have also been periodically conducted for the purpose of tracing the history of changes in the structure's dynamic parameters and stiffness.

The Great East Japan Earthquake from March 11, 2011, caused damage to the structural and non-structural elements of the UDPRC building. Some of the structural damage (flexural cracks on the columns and diagonal shear cracks on the shear walls) are visible.

3. INSTRUMENTATION OF THE BUILDING

3.1 Installed strong motion sensors

Sensors are installed in 11 locations (33 channels) in the building. Accelerometers installed in the basement and 1st, 2nd, 5th and 8th storeys are used for system identification in strong motion analysis. The analyzed data represents the automatically recorded acceleration during earthquake occurrences, measured in gals (cm/sec^2) with a sampling frequency of 100 Hz. Such observation has been adopted to ensure contribution of at least the first two modes in both east-west and north-south directions in the system identification procedure (henceforth referred to as E-W and N-S direction respectively). The adopted instrument configuration provides supervision over the input-output behavior of the whole system. The vertical strong motion sensor configuration is illustrated in Figure 2.

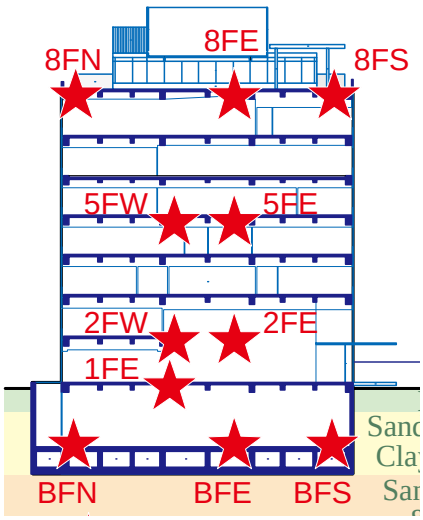

Figure 2 Vertical strong motion configuration (drawings from BRI database)

3.2 Instrumentation for microtremor measurements

The microtremor measurements were conducted on December 2, 2011. A portable ambient vibration monitoring system was used, consisting of 11 servo velocity sensors of type VSE-15D, junction box, recorder and wave monitor model SPC-51A, all manufactured by Tokyo Sokushin Co., Ltd (Figure 3). The measurement was conducted by recording ambient vibrations in east-west and north-south

directions, both with sampling frequencies of 100 Hz and 30 minutes duration each.

Figure 3 Portable microtremor measuring system

Nine horizontally oriented sensors were placed on the floors and basement. While measuring horizontal vibrations in an east-west direction, two vertically oriented sensors were placed in the basement on the east and west side to measure the rocking effect of the building due to soil-structure interaction. The same concept was applied by placing vertically oriented sensors on the north and south side of the basement while measuring horizontal vibrations in a north-south direction. The vertical and horizontal microtremor sensor configuration in both N-S and E-W directions is shown in Figure 4.

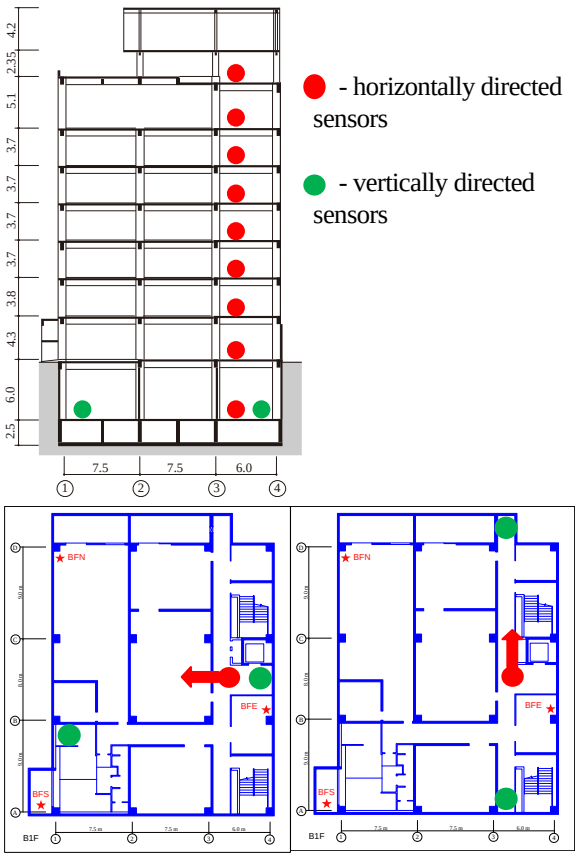

Figure 4 Microtremor sensor configuration E-W direction (left); N-S direction (right) (drawings from BRI database)

3.3 Arranging recorded data and excluding effects of rocking motion

The acceleration, recorded by horizontally directed sensors on the basement floor, is considered as input in the building, while the sensors, installed on the other floors, recorded each floor's corresponding horizontal output. The rocking effect modifies the input signal. The model of the instrumented building and the rocking effect is schematically represented in Figure 5. The input modification for each storey was assumed to exclude the effects of stiffness of the local soil, since only the dynamic properties of the building are of interest, rather than the influence of soil-structure interaction influence. The calculation of the input modification can be seen in Eq. (1).

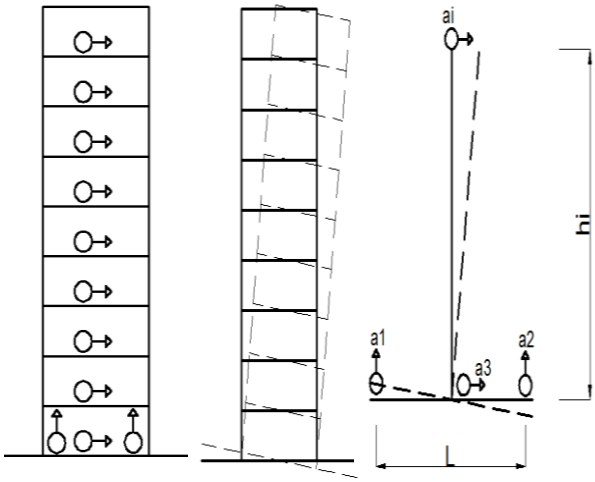

Figure 5 Model of the rocking effect

$$input_i = a_3 + (a_1 - a_2)\frac{h_i}{L} \quad (1)$$

4. DATA ANALYSIS AND RESULTS

4.1 Strong motion analysis

Observational data derives from the strong motion records from several earthquakes from 1999 until 2012. Within this period, the UDPRC building was affected by several strong ground motion events, including the Great East Japan Earthquake on March 11, 2011. The strong motion records for earthquakes with maximum peak ground acceleration not greater than 7.0 gals have been chosen. It has been assumed that such earthquakes are not strong enough to cause substantial damage or nonlinear behavior in the building, and consequently the dynamic properties and changes in the storey stiffness of the structure may be identified more clearly.

An example of time histories of the input and 8th storey response is demonstrated in the Figure 6. Measurements are represented as time-acceleration records, with units of seconds on the time axis (X) and cm/sec^2 (gal) on the acceleration axis (Y). For the estimation and validation range of response prediction, various signal durations were considered.

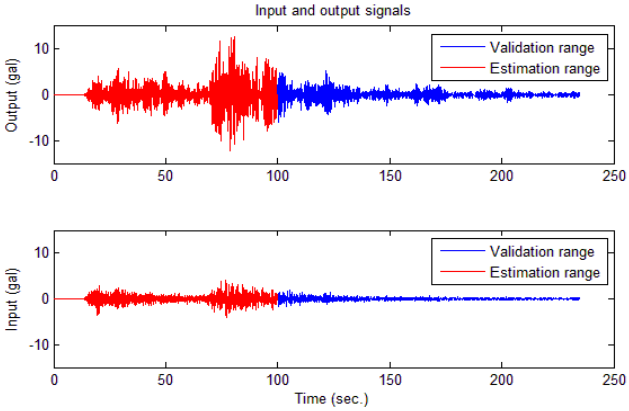

Figure 6 8th input and output, earthquake from July 16, 2007, N-S direction

The Fourier spectral ratio of the input-output relationship can be a useful starting point for locating the range of possible modal frequencies. It represents a relationship between output and input signal in their frequency domain and it is the basic type of transfer function in a nonparametric identification approach (Eq. (2)). The Fourier spectral ratio of the 8th floor's output-input relationship is presented in Figure 7.

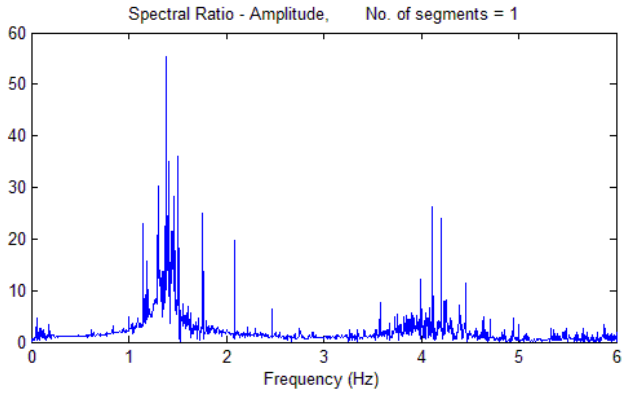

Figure 7 Amplitude spectral ratio of outpu-input relationship of the 8th floor in N-S direction, ground motion from July 16, 2007

$$G(\omega) = \frac{Y(\omega)}{U(\omega)} \qquad (2)$$

Parameter identification is based on the ARX model, applied for input-output data of vibration measurements of the 8th floor. The Akaike's Information Criteria (AIC) and Akaike's Final Prediction Error (FPE) methods have been applied for estimation of the optimal order number. In this particular case the ARX model is of order n_a=64, n_b=65, n_k=0. Such a model ensures 27% fit with FPE=0.00364. All the poles are located within the unit circle. The pole-zero plots (Figure 8) appear in pairs, symmetric on the real (X) axis, unless they are real numbers and lay on the axis. Since only four storeys above the basement are instrumented, the dynamic model of the building can be considered as a lumped mass system with four lumped masses and four degrees of freedom in each direction

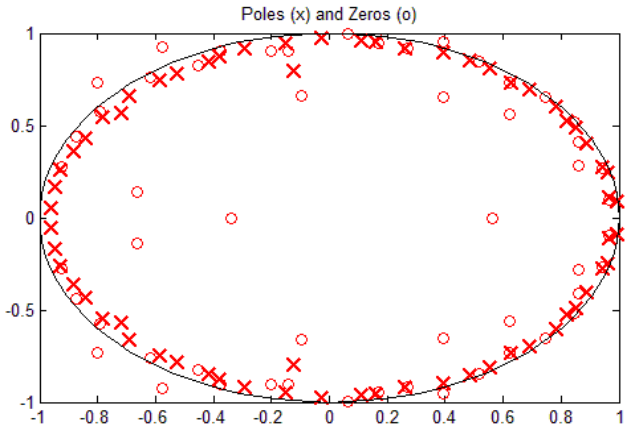

Figure 8 Location of transfer function's poles and zeros on z plane - N-S direction, ground motion from July 16, 2007

. With this assumption, only four pairs of poles represent the real frequencies of four mode shapes in the analyzed building. Locating these four pairs, and obtaining the four frequencies can be performed by developing the frequency response function from the ARX model transfer function (Figure 9). However, distinguishing the higher modes is difficult or impossible. In the particular case of the UDPRC building's parametric system identification, first and second modes are considered

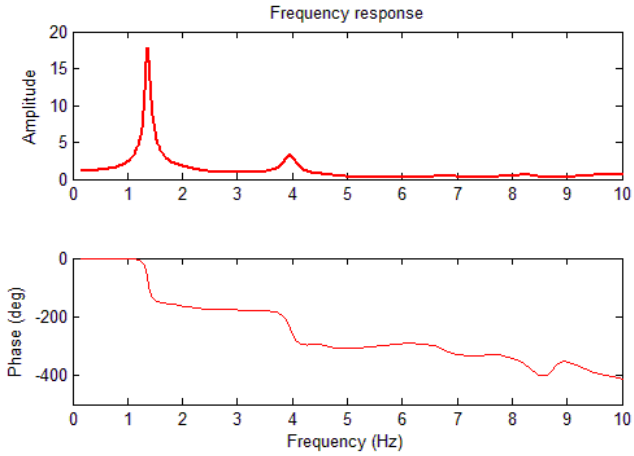

Figure 9 Estimated amplitude and phase response of the ARX transfer function, N-S direction, ground motion from July 16, 2007

The transfer function, which is in fact a relationship of input and output z-transforms, contains important data needed for the identification of building's dynamical properties. The Fourier transform, power spectral density and the Fourier spectral ratio of the signals contain a significant number of peaks from which it is often difficult or impossible to distinguish the real frequencies of the dynamic system. The mode shape's frequencies can be visible through frequency response function, which is the transfer function's representation as clearly visible spectral amplitude peaks. The frequency response function contains

amplitude response and phase response as a function of frequency. The peaks of the amplitude response indicate natural frequency on the location of the spectra. A sudden drop of the phase response indicates a transverse natural frequency in corresponding spectral locations.

The system's mode shape frequencies, damping ratio and mode shapes can be extracted from the transfer function by applying Eq. (3), (4) and (5) respectively:

$$f_j = \frac{\sqrt{\left(\ln\left|{}_z p_j\right|\right)^2 + \left(\arg({}_z p_j)\right)^2}}{2\pi\Delta t} \tag{3}$$

$$h_j = \frac{-\ln\left|{}_z p_j\right|}{2\pi f_j \Delta t} \tag{4}$$

$$\beta u_j = \Re\left[\frac{2\,{}_z p_j \sqrt{1-h_j^2}}{\Delta t\left(2\pi f_j h_j - i\,sign\left(\Im\left({}_z p_j\right)\right)2\pi f_i\left(1-2h_j^2\right)\right)}\right] \tag{5}$$

where f_j is the system's frequency, βu_j is the modal participation function, ${}_z p_j$ is a root (pole) of the transfer function, Δt is the sampling interval, h_j is the damping ratio, ${}_z r_j$ is a residue of a transfer function's partial fraction expansion.

Stiffness coefficients [K] can be estimated from mass-normalized measured mode shapes [Φ] (Eq.(6)) where [Φ] is determined from the modal participation function βu_j and frequencies [Λ] (Morita & Teshigawara, 2006).

$$[\Phi]^T [M][\Phi] = [I] \tag{6}$$

$$[K] \cong \left([\Phi][\Lambda]^{-1}[\Phi]^T\right)^{-1} \tag{7}$$

In the system identification of multistorey buildings it is often difficult to identify all mode shapes. In these cases, the stiffness matrix is obtained using a Moore and Penrose inverse matrix, which is one of the generalized inverse matrices. Parameters related to the storey stiffness will be estimated from [K] multiplying a displacement vector, in which each relative storey displacement is 1.0 from the right (Morita & Teshigawara, 2006).

To obtain the actual storey stiffness, all the system's natural frequencies and corresponding mode shapes have to be identified. In most of the cases only the first, and eventually the second mode shape can be clearly obtained. In this case, the obtained storey stiffness is lower than the actual one. The stiffness matrix [K] contains parameters related to the stiffness, which can be introduced as "storey pseudo-stiffness" which is a parameter for comparison of storey stiffness. The number of considered mode shapes is introduced as an order of the storey pseudo-stiffness. A higher order of the pseudo-stiffness means a closer value of the storey pseudo-stiffness to the value of the real storey stiffness. The highest order is the number of degrees of freedom in the corresponding direction, for which the storey pseudo-stiffness is equal to the real storey stiffness.

An example of the identified first and second mode shape of the structure, obtained by ARX model, is shown in Figure 10.

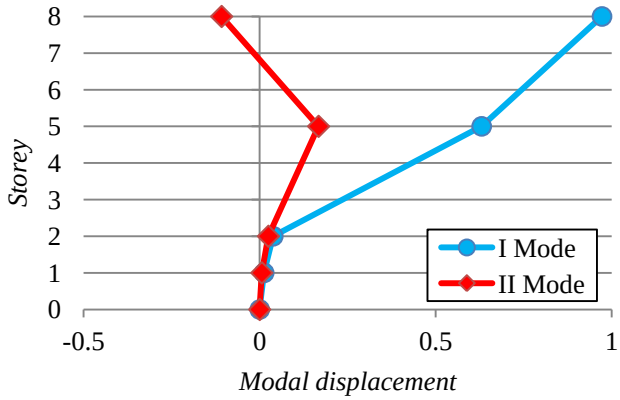

Figure 10. First and second mode shape of the building, N-S direction, ground motion from July 16, 2007

The identified natural frequencies, damping ratios and second order pseudo-stiffness, as results of the strong motion analysis, are shown in the graphs below. The analyzed strong motion data from year 2011 were recorded on March 20, 2011, nine days after the Great East Japan Earthquake.

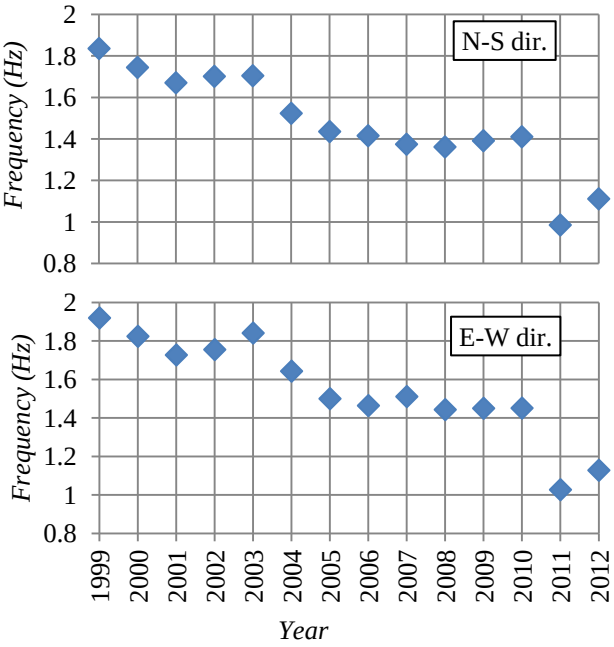

Figure 11. First modal frequencies

Decreasing frequency in the first two years of building's occupation may be due to the changes in life loads (increasing the amount of building's inventory), as so as shrinkage of the concrete that may result with micro-cracks in concrete components of the building's columns. The same effect has also been found in the identified second modal frequencies in both orthogonal directions (Figure 12). The

damping coefficients have trend of increasing due to aging of the structure. Although their accuracy depends on the ARX model order.

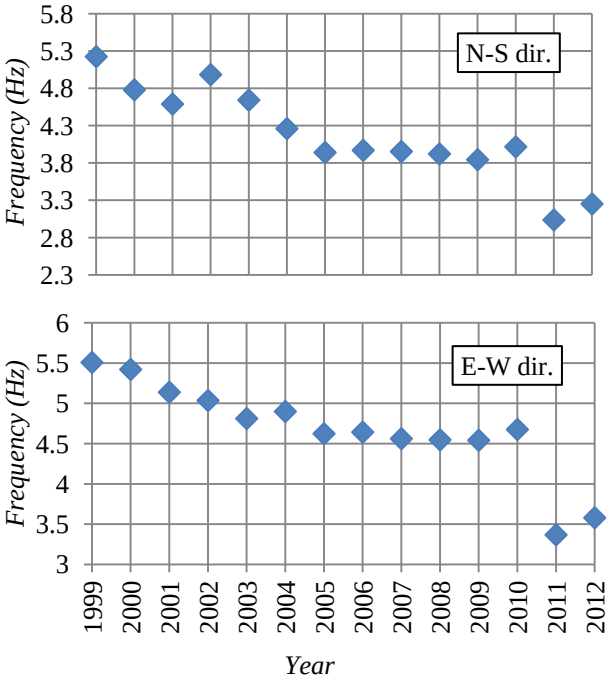

Figure 12. Second modal frequencies

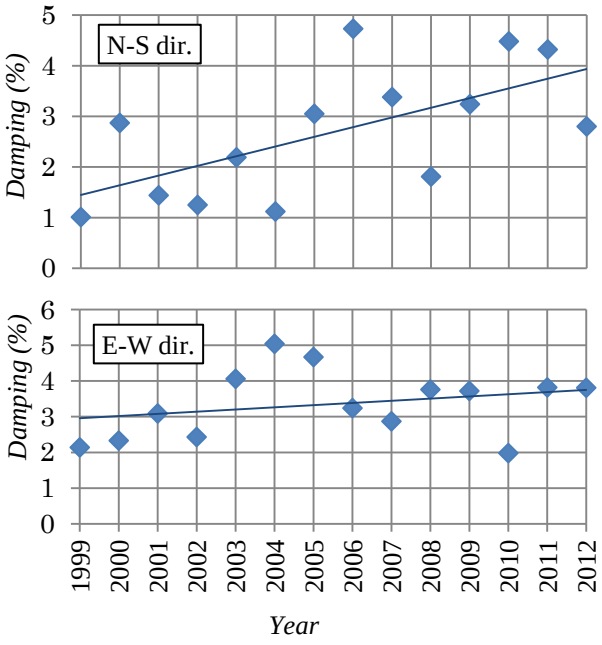

Figure 13. Damping ratios of the first modes

The charts on the Figure 14 demonstrate the identified second order pseudo-stiffness during the observed period. The results obtained demonstrate the tendency of natural frequencies and storey stiffness to decrease, and damping ratios to increase due to aging and exposure of the structure to strong ground motion. A drop in frequency and stiffness is most evident in the year 2011, which was expected since the analysis has been conducted with strong motion data recorded on March 20, 2011, after the Great East Japan Earthquake.

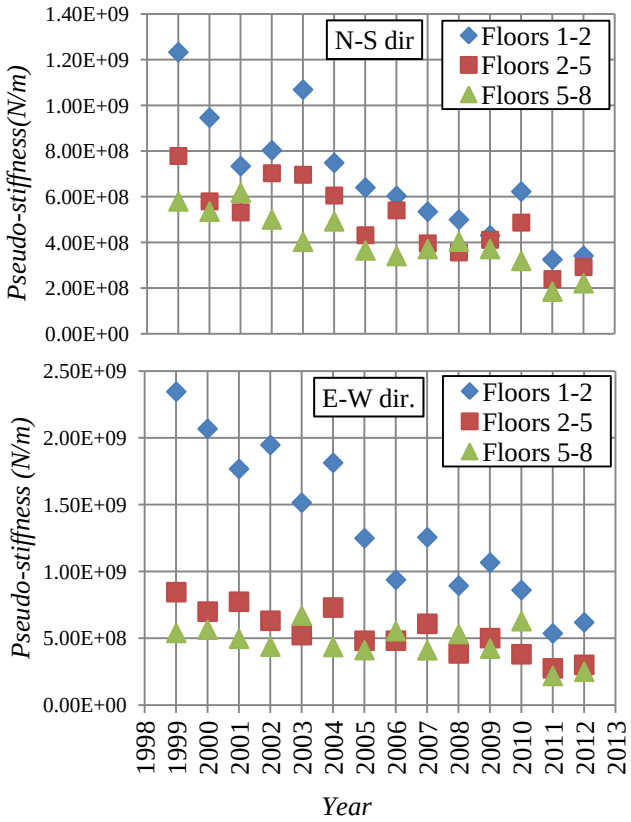

Figure 14. Second order storey pseudo-stiffness

4.2 Microtremor analysis

Microtremor observation is a nondestructive method of recording raw signals for the purpose of system identification and health monitoring of structures. Consequently, it is the most appropriate method, especially in regions of lower seismicity, for areas where strong ground motions do not occur frequently. Microtremors by their nature are vibrations provoked by ambient forces, with acceleration intensities from 10^{-7} to 10^{-4} gals that are constantly present in every environment. The biggest advantage of these measurements over strong motion measurements is that they can be conducted at any time. However, because of their low intensity, their analysis often requires more complex system identification methods than ARX due to the low signal-to-noise (S/N) ratio.

For the detection of damage in the UDPRC building due to the Great East Japan Earthquake, microtremor measurements from December 2, 2011 were analyzed, and the results compared with the analyses of measurements that were conducted on Jun 26, 2009, almost two years before the earthquake. All three system identification methods (ARX, ARMAX and N4SID) were applied, and the adopted method for identification is the one that provided the first mode shape of the building that is closest to the expected

one. Unlike the strong motion analysis, the second mode shape in the microtremor analysis was difficult or impossible to obtain. Because of this, only the first mode shape has been observed. The first order storey pseudo-stiffness has been obtained.

The first mode shape, obtained by applying ARX, ARMAX and N4SID identification methods, is shown in Figure 15. The adopted model order is shown in the chart's legend in the order ARX (n_a n_b n_k), ARMAX (n_a n_b n_c n_k) and N4SID (number of rows and columns of the system state matrix). From the 30 minute time history record, a sequence of 3 minutes had been analyzed.

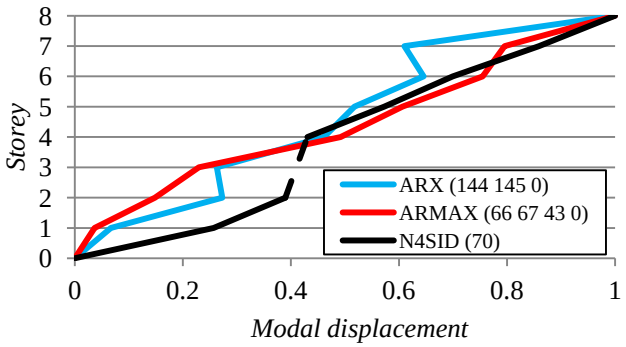

Figure 15. First mode shape, E-W direction

The dashed line of the mode shape in E-W direction, obtained by the N4SID method, is due to the inability to identify the modal displacement of the 3rd storey with this method. The chosen model for identification of the dynamic properties and pseudo-stiffness of the building in an E-W direction is ARMAX (66 67 43 0) as it identified the mode shape that is closest to the expected one.

The mode shape in an N-S direction is shown in Figure 16.

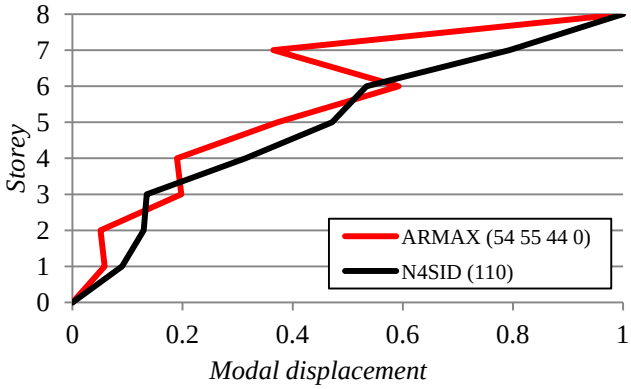

Figure 16. First mode shape, N-S direction

In the case of N-S direction, the building's properties could not be clearly identified by the ARX method. The chosen model for identification of the dynamic properties and pseudo-stiffness of the building in an N-S direction is N4SID (110) as it identified the mode shape that is closest to the expected.

For adopting the N4SID model order, stabilization diagrams for the 8th, 2nd and 1st storeys are plotted (Figure 17) in order to check the stability of the frequency, obtained from the models with various orders. The frequencies are the most stable on the 8th floor, which is expected, considering that the upper storey is the most flexible and most suitable for obtaining the whole building's dynamic properties.

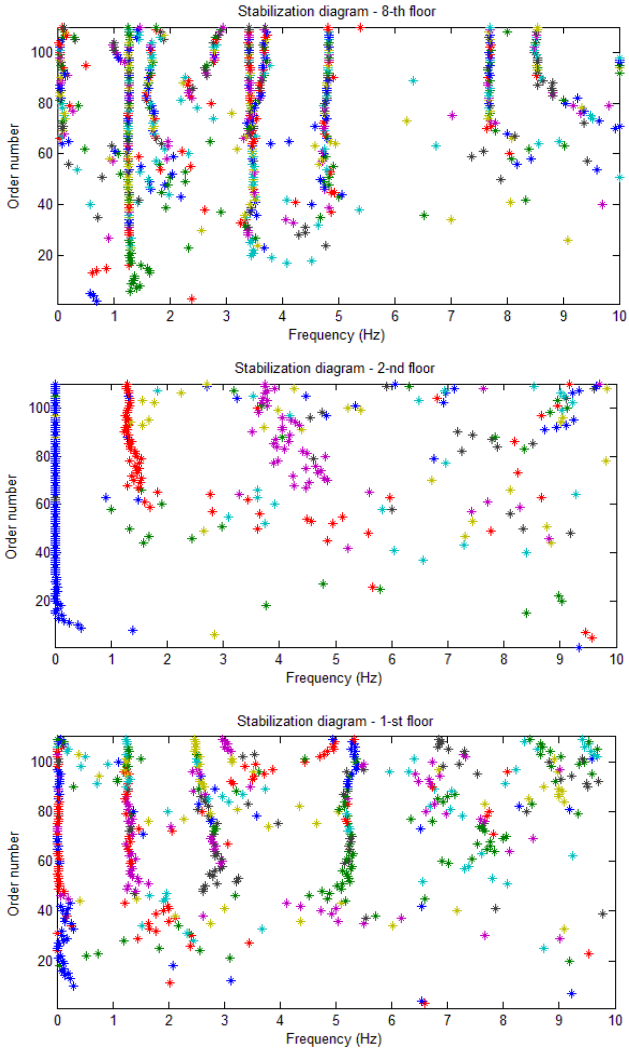

Figure 17. Frequency stabilization diagrams for N4SID model, N-S direction

The identification of the other 7 storeys is important for obtaining the mode shape. For calculating the mode shape and storey pseudo-stiffness, the model order should be higher, so that it identifies all the storeys, since the identification of the lower storeys requires a higher model order. However, the model order should be optimal, since too high model order would include modeling significant amount of noise, which should be avoided. The model order that provides computation of stable first natural frequency value is chosen as model order of the N4SID identification of the building. In the identification of the building's properties in N-S direction, from the Figure 17 it is evident that the identification of the first natural frequencies on the 8th storey becomes stable for N4SID model order higher than 20. However, the identification of the first natural frequencies on the 2nd storey becomes stable for model order

higher than 90. For that purpose, a model order of 110 has been chosen for identification since it provides stable first natural frequencies for all storeys, including the least sensitive ones (1st and 2nd).

The data from Jun 26, 2009, was provided by Mr. Ren Jun (Jun, 2009). Both sets of results refer to the microtremor analyses excluding the effects of rocking.

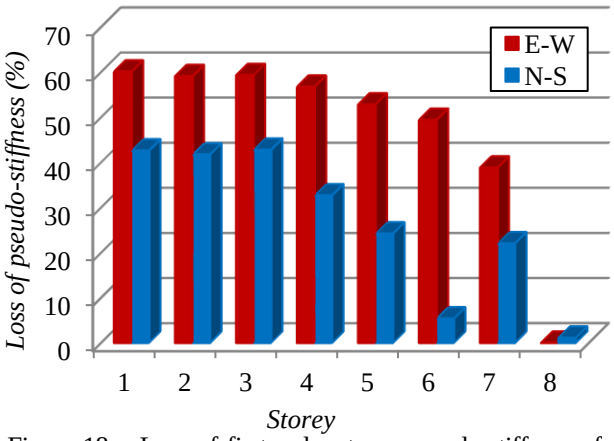

Figure 18. Loss of first order storey pseudo-stiffness of the UDPRC building due to the Great East Japan Earthquake from March 11, 2011

From the results presented above, we can see that the UDPRC building suffered severe damages due to the Great East Japan (Tohoku) Earthquake (structural or nonstructural) resulting in a loss of stiffness in nearly every storey in both east-west and north-south directions. The lower storeys suffered more severe damage than upper ones. This damage effect the structure's stiffness in the E-W direction more than in the N-S direction.

5. CONCLUSIONS

Structural health monitoring strategy has been investigated and implemented on the building of Urban Disaster Prevention Research Center (UDPRC) using strong motion data records and microtremor records analysis, excluding soil-structure interaction effects. The obtained modal frequencies were as expected, and their values are the most stable results. Changes in the modal frequencies are the initial indicator for loss of structural stiffness, which can be considered as damage. All three computational methods applied (ARX, ARMAX and N4SID) provide less stable results for other parameters, such as damping, mode shapes of the structure and the first order pseudo-stiffness, as a final result of the analysis. Further study needs to be made on algorithms for more precise structural identification projects. From the application of the three parametric system identification method, as well as tracing the history of changes in modal frequencies, damping coefficients and first order storey pseudo-stiffness, it can be concluded that:

- Modal frequencies and storey stiffness tend to decrease and damping coefficients tend to increase due to aging of the structure and its frequent exposure to earthquakes;
- For system identification and vibration-based structural health monitoring procedures, the information about the excitation data (microtremor or strong motion), chosen number of degrees of freedom of the structure and number of identified mode shapes are of crucial importance, more identified parameters provide more stable and accurate results;
- For system identification and damage detection procedures, strong motion data is more convenient for analysis than microtremor data due to the high signal-to-noise ratio. The number of identified mode shapes, obtained from strong motion data, is usually higher than that one obtained from microtremor analysis. This facilitates obtaining a higher order of storey pseudo-stiffness values and implies more stable values for obtained storey pseudo-stiffness, closer to actual values of storey stiffness. However, for an accurate diagnosis, the compared states of the structure need to be based on records with nearly the same values of peak ground acceleration (PGA);
- Microtremor requires careful attention when the model order is chosen, and often more complex identification methods than ARX due to the low signal-to-noise ratio (ARMAX or N4SID).

Abstract: A thirty-four years old eleven-story steel reinforced concrete frame building, which was seismically retrofitted in 2010, was influenced during the 2011 M9.0 Tohoku earthquake. The strengthening of its longitudinal frame adopted an innovative pin-supported wall-frame system while conventional fixed-based walls were added in the transverse direction. Although not severe, the observed damage of the building demonstrated that the pin-supported walls are less vulnerable than fixed-based ones. However, non-structural partition walls may concentrate a major part of damage, especially during mild ground motions. Furthermore, a detailed numerical model is calibrated by the recorded motions of the building during the Tohoku earthquake, which was recorded by five three-channel accelerographs. The calibrated model features the influence of the partition walls, which were not taken into account in the original model.

1. INTRODUCTION

An innovative pin-supported wall system has been developed and applied in the retrofit of three university buildings on Suzukakedai campus of Tokyo Institute of Technology during the past several years. Among them is the first application of this system, namely G3 Building, an 11-story steel reinforced concrete moment-resisting frame building completed in 1978 and seismically retrofitted in 2010. The basic idea of the pin-supported wall system is to make use of post-tensioned (PT) concrete walls as coordinators in a structural system to help producing uniform distribution of lateral deformation along the height of the building and to prevent weak story failure. Such walls are supported by specifically designed mechanical hinge bearings at the bottom that can effectively resist shear force while allowing for finite rotation without damage. Shear-type steel dampers are installed in between the PT walls and neighboring columns along the height of the building. They are expected to concentrate most hysteretic energy dissipation of the whole structure during major earthquakes so that the seismic response may be reduced and the rest of the structure may remain less damaged or even undamaged. The application of this system in G3 Building is illustrated Figure 1, where the pin-supported walls were applied to only the longitudinal direction of the building (i.e., *x*-direction in Figure 1). Conventional fixed-base shear walls were used for retrofit in the transverse direction (i.e., *y*-direction in Figure 1). More details about this project can be found in Wada et al. (2009) and Qu et al. (2012).

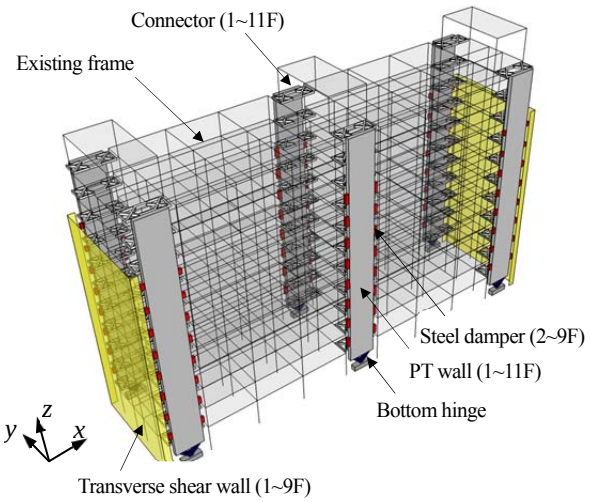

Figure 1 Pin-supported wall system in G3 Building (Qu *et al.*, 2012)

On March 11th, 2011, about one year after the completion of the retrofit of G3 Building, a M9.0 earthquake, usually referred to as the Tohoku earthquake, hit the eastern Japan and also caused considerable ground shaking even in the Tokyo metropolitan area which is more than 300 km away from the epicenter. In this study, the accelerograms obtained on G3 Building during the Tohoku earthquake are used to calibrate a finite element (FE) model of the building, which was once used to assist the design of the retrofit. The calibrated FE model is then used to simulate the seismic

response of the building before and after the retrofit. The effect of the retrofit with pin-supported wall system and the role of the partition walls are emphasized.

2. OBSERVATIONS

Five accelerographs, each with three channels for the three translational degrees of freedom, were installed in the basement (B1F), on the 2nd, 5th, 8th and 11th floor of G3 Building when the retrofit was completed. All accelerographs are located as closer to the center of the building as possible. Taking the records at the basement level (B1F) as the ground motion, the peak ground acceleration (PGA) and the peak ground velocity (PGV) is 67.3 cm/s^2 and 14.4 cm/s in the longitudinal (x) direction and is 52.8 cm/s^2 and 12.7 cm/s in the transverse (y) direction, respectively (Miura and Midorikawa, 2011). Figure 2 compares the acceleration response spectra of the recorded ground motions (B1F records) with the Level I design spectrum prescribed in Building Standard Law of Japan (BCJ, 2004). In both directions, the spectra of the records were much lower than the design spectrum in period range below 1.0 s. In addition, the building seems to have experienced quite similar shaking in both directions.

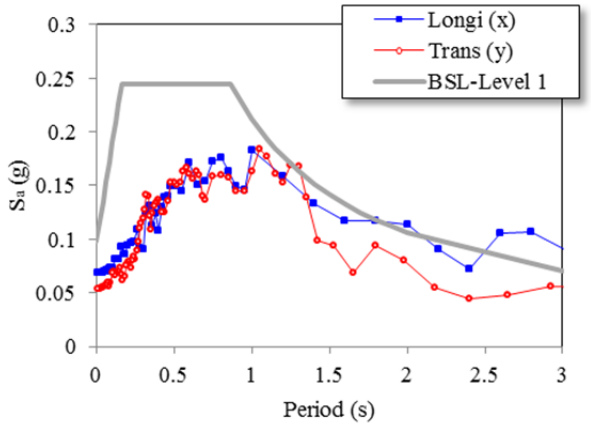

Figure 2 Acceleration spectra of recorded ground motion in longitudinal (x) and transverse (y) directions (5% damping)

The amplification of motion along the height of the building can be observed in Figure 3 by comparing the acceleration spectra at each floor levels. It can also be identified in Figure 3 that the dominant period of vibration of G3 Building is about 0.65 s in the longitudinal (x) direction and about 0.69 s in the transverse (y) direction, respectively.

The accelerograms were processed by 4th order Butterworth high-pass filter before they were integrated to get the displacement response. As suggested by Miura *et al.* (2011), cut-off frequency as large as 0.667 Hz was selected for the filtering, mainly in order to remove the influence of the unwarranted long-period contents observed in the 2F and 8F records. The corrected accelerograms were integrated twice to obtain the displacement response. Numerical integration with trapezoidal rule was used and the time increment Δt was set to be 0.01 s. The maximum lateral displacement in x-direction turned out to be 23 cm and the maximum inter-story drift ratio occurred at the first floor and is slightly greater than 0.001. The acceleration records and the above-obtained displacement response were used to evaluate the performance of the analysis models. Detailed results of floor displacement are given later together with the analysis results.

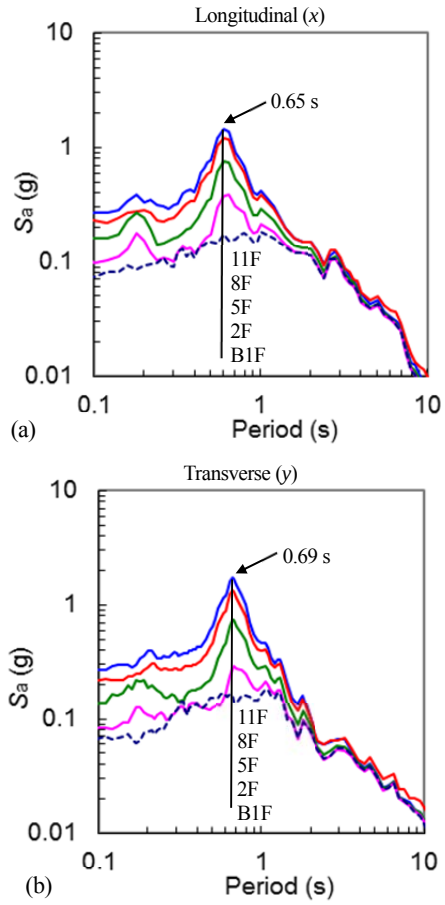

Figure 3 Acceleration spectra at each floor levels in (a) longitudinal (x) and (b) transverse (y) direction (5% damping)

The G3 Building was inspected immediately after the Tohoku earthquake. Many minor cracks of width less than 0.2 mm were observed near the bottom of the added conventional fixed-base walls at both ends of the building, while on the other hand, no visible damage was observed on the pin-supported walls in the longitudinal (x) direction except that the coating of the bottom hinge bearing was slightly peeled off, indicating that the bearing may have rotated as intended during the earthquake (Figure 4). In addition, diagonal rust marks were found on the steel web plate on the web plate of several shear-type steel dampers at lower stories (Figure 5), which indicated that these web plates may have yielded during the earthquake and the protective coating along the directions of principle strain was peeled off.

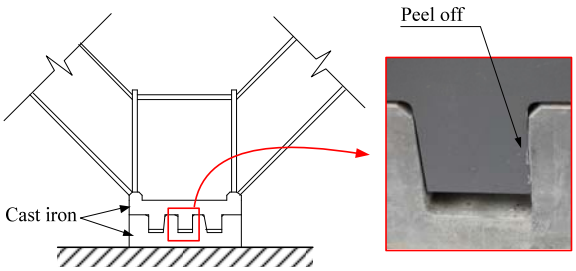

Figure 4 Peel off of painting of bottom tooth-like hinge (north, center).

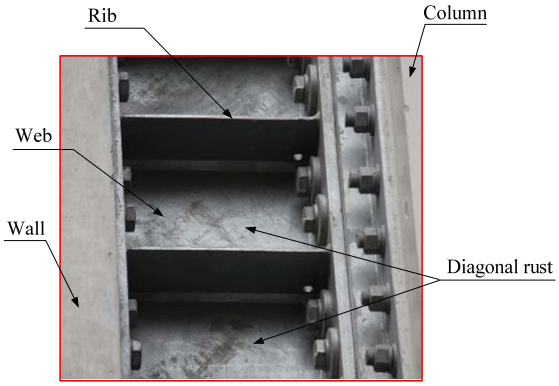

Figure 5 Diagonal rust marks on web plates (north, center at 2F).

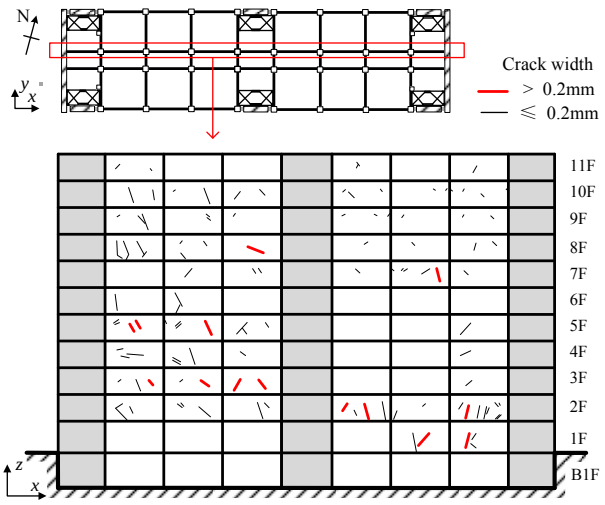

Figure 6 Observed cracks on partition walls of G3 Building (reproduced based on data provided by the Facility Department of Tokyo Institute of Technology).

Another type of obvious damage in the longitudinal (x) direction of the building was found on the reinforced concrete partition walls. As a common practice in Japan, lightly reinforced concrete thin walls in a building are usually considered as nonstructural walls and thus are not taken into account in the seismic design of the building. Such partition walls along the longitudinal (x) direction of G3 Building are located in the two inner bays of the frame (see Figure 6 for reference). The cracks observed on the partition walls in one of the two bays are illustrated in Figure 6. It can be seen that cracks were observed on the walls of every floor except the basement floor. The width of some cracks exceeded 0.2 mm. In addition, the deformation of the lower stories seems to have been greater than that of the upper ones by the fact that most cracks of width greater than 0.2 mm were found in lower stories.

3. ANALYSIS MODEL

3.1 Original Model and Its Modification

In order to better understand the dynamic behavior of G3 Building during the Tohoku earthquake, the records obtained by the above mentioned accelerometers were used to calibrate a FE model, which was used by Qu *et al.* (2012) to evaluate the seismic performance of G3 Building and to demonstrate the effectiveness of the pin-supported wall system. It was a member-by-member frame model in commercial FE software ABAQUS. The longitudinal behavior of G3 Building was modeled by three plane frames sharing the same lateral displacement at corresponding beam-to-column joints. The frame columns and beams were modeled by fiber-sectioned beam elements (B21 in ABAQUS) with user-defined materials for concrete and steel fibers. The pin-supported walls were models by elastic beam elements with rigid arms. The shear-type steel dampers were assumed to exhibit elastic-perfectly plastic hysteresis. The readers are referred to Qu *et al.* (2012) for more details of the model. This model is referred to as 'original model' hereafter because further improvement will later be made on it.

It was found that the original model would much over-estimate the displacement response of G3 Building during the earthquake. It is also evident by looking at the results in frequency domain that the dominant period of vibration of the original model is much longer than the observed one. These results will be introduced later together with the results predicted by the 'modified model', which is described below.

It is supposed that the over-estimated fundamental periods is a consequence of the omission of the RC partition walls in the original model. Following this clue, improvement of the original model was made to include those walls. As mentioned above, the partition walls in the longitudinal direction of G3 Building were located in the two inner bays of the moment frame (Figure 7(a)). Individual walls can approximately be classified into two categories, namely W1 and W2, as shown in Figure 7(b). For W1, two openings separate the wall pier of length L_w from the columns on both sides. For W2, another opening appears in the middle of the wall pier and subdivides it into two smaller wall piers of length L_{w1} and L_{w2}. All wall piers are 120 mm in thickness and are reinforced by single-layer orthogonal ϕ10 rebars at 200 mm spacing. No boundary confinement was provided. As the same as the main structure, the nominal concrete compressive strength was assumed to be 20 MPa and the nominal yield strength of rebar 394 MPa for these walls. In addition, the

center-to-center span length, L, is 7800 mm for all the spans containing partition walls. The story height, H, varies from 4500 mm for the 1st floor, to 3600 mm for the 2nd and the 3rd floor and to 3500 mm for all the other floors.

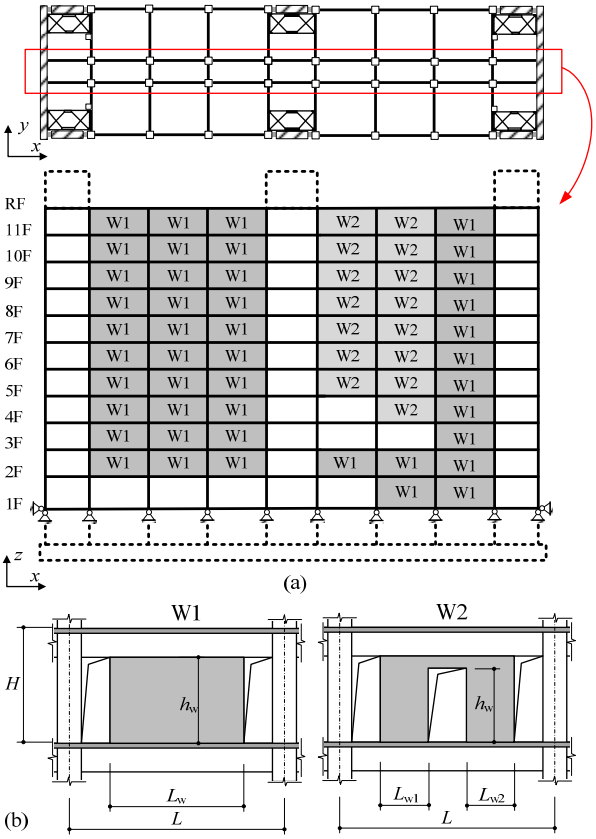

Figure 7 Two types of reinforced concrete partition walls W1 and W2 in G3 Building: (a) Locations of partition walls and (b) wall configurations

As a simple representation, an individual partition wall (both for W1 and W2) was modeled by a pair of diagonal braces connecting the beam ends in the lower and the upper stories (Figure 8). The mechanical properties of the two braces were identical and were thus determined that their horizontal behavior is equivalent to a tri-linearized partition wall model as shown in Figure 8. To this end, the relationship in Equation (1) is followed to transform horizontal responses of a single wall to diagonal ones.

$$F_b = 0.5F/\cos\theta$$
$$\Delta_b = 0.5\Delta\cos\theta \quad (1)$$

where F and Δ are horizontal shear force and lateral displacement of the wall, respectively; F_b and Δ_b are the axial force and axial deformation of a single brace, respectively, and θ is the inclination angle.

The trilinear hysteretic model shown in Figure 8 was assumed for both W1 and W2. Subjected to monotonic loading, the wall remains elastic with initial stiffness, K_0, until the cracking strength, V_{cr}, is reached. After cracking, the stiffness degrades sharply while the force keeps growing linearly until the ultimate strength, V_u, is reached. The corresponding deformation is denoted as Δ_0, beyond which the wall begins to lose its strength quickly with a negative stiffness $-K_0$ until zero force. It was further assumed that the wall completely fails, which means it contributes no more to the resistance once it loses all its strength in either direction. Besides the skeleton curve, it was assumed that the cyclic behavior of the wall follows the rules that (1) the unloading branch always points to the cracking point in the opposite direction; (2) the reloading branch would point to the cracking point or the ultimate strength point if these points have not been exceeded before, and (3) otherwise, the reloading branch points to the largest deformation point ever experienced in the loading history.

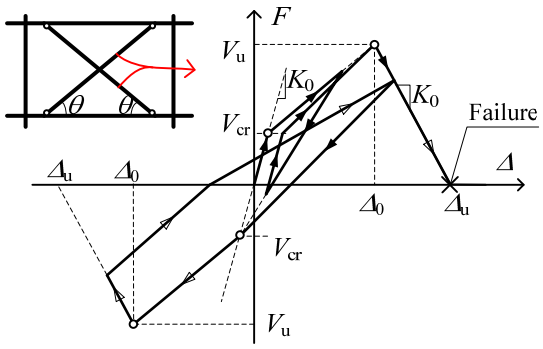

Figure 8. Model of partition walls: (a) diagonal truss elements and (b) hysteretic behavior.

For W1, the initial stiffness, K_0, can be simply estimated by Equation (2), which accounts for both flexural and shear stiffness of an elastic wall pier assuming both ends (lower and upper) fixed. For W2, the stiffness of the two smaller wall piers, which are separated by the central opening, was first estimated by Equation (2) separately and then summed up to obtain the total initial stiffness of the wall in the span.

$$K_0 = \frac{1}{1/K_s + 1/K_f} = \frac{1}{\frac{h_w}{Gt_wL_w} + \frac{h_w^3}{12EI_w}} \quad (2)$$

where h_w, t_w, L_w are the height, thickness and length of a single wall pier, respectively; E and G is the elastic modulus and the shear modulus of concrete; I_w is the moment of inertia of a single wall pier section.

The cracking strength, V_{cr}, was estimated by Equation (3) proposed in AIJ (1999) for calculating the cracking strength of concrete walls without boundary columns. The ultimate strength, V_u, was estimated by the empirical equation proposed by Wood (1990) for reinforced concrete squat walls (Equation (4)). Although very simple, this equation was confirmed by Gulec *et al.* (2008) to give best prediction of ultimate strength among several other commonly used equations. Because the partition walls in G3 Building were only lightly reinforced, the ultimate strength

was actually determined by the leftmost term in Equation (4). For W2 cases, the strength of the two small wall piers were calculated independently and then summed up to get the overall strength. The displacement corresponding to the ultimate strength, V_u, was determined by means of the effective stiffness of squat walls, K_{eff}, proposed by Li and Xiang (2011) (Equation (5) and (6)).

$$V_{cr} = \tau_{cr} t_w L_w / 1.5 \tag{3}$$

where $\tau_{cr} = 0.33\sqrt{f_c}$ is the effective shear strength of concrete.

$$0.5 t_w L_w \sqrt{f_c} \le V_u = A_{vy} f_y / 4 \le \frac{5}{6} t_w L_w \sqrt{f_c} \tag{4}$$

where f_c is the compressive concrete strength, A_{vy} is the total area of vertical reinforcement and f_y is the yield strength of rebar.

$$\Delta_0 = \frac{V_u}{K_{eff}} \tag{5}$$

$$K_{eff} = \frac{12 E I_w}{h_w^3} \cdot \frac{19}{f_y} \left(0.53 + 0.37 \frac{h_w}{L_w} + 0.31 \frac{h_w^2}{L_w^2} \right) \tag{6}$$

3.2 Analysis Results

The displacement responses predicted by the aforementioned 'original model' with the recorded ground motion in the longitudinal (x) direction are compared with those obtained by integrating the accelerograms at each floor levels in Figure 9. It is obvious that the original model much over-estimated the displacement response of G3 Building during the earthquake. By referring to the microtremor observation during the construction of the retrofit (Hirano *et al.*, 2011), it is also obvious that the initial fundamental periods of vibration of the original model both before and after the retrofit are considerably longer than the observed ones (Table 1). The fundamental period of the modified model becomes 0.52 s before retrofit and 0.49 s after retrofit (with the pin-supported walls and the dampers). These values become much closer to those obtained by microtremor observation (0.51 s and 0.47 s before and after the retrofit, respectively, see Table 1) than those of the original model.

Table 1 Fundamental period of vibration (unit: s)

	Monitored	Original model	Modified model
Before retrofit (Initial)	0.51*	0.86	0.52
After retrofit (Initial)	0.47*	0.68	0.49
During Tohoku earthquake	0.65	0.81	0.65

* Microtremor results in Hirano *et al.* (2011)

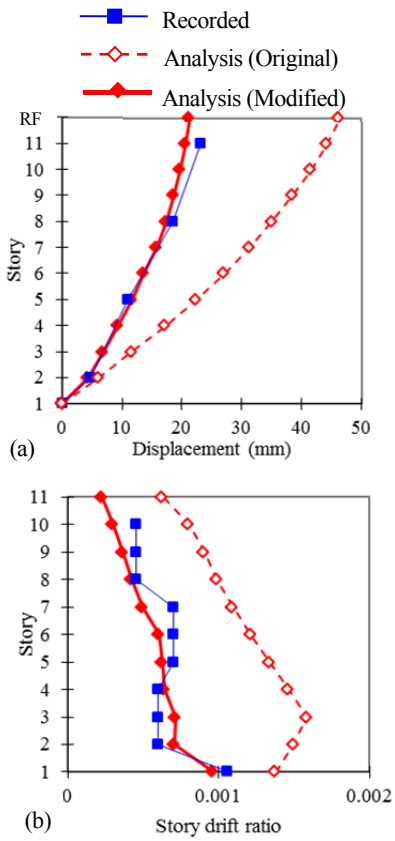

Figure 9 Displacement response of the G3 building

As can be seen in Figure 9, the prediction of the seismic displacement response of G3 Building by the modified model is significantly improved. This is also evident from Figure 10, which compares the response spectra of the acceleration time histories recorded during the earthquake and those predicted by the modified model at floors where an accelerometer is placed. The two sets of spectra match well with each other. The modified model seems capable of capturing the dominant period of vibration for both the 1st and the 2nd equivalent modes of the building in its inelastic state.

However, the time history response obtained by the analysis does not match the observation as well as the maximum response. Take the displacement at 11F for example. Figure 11 compares the time history displacement response from 50 s to 200 s of the earthquake. It is seen that the analysis result succeeded in capturing the maximum response at around 135 s. However, it underestimated the displacement response in the following 20 s. The responses in duration of 12 s from 92 s to 104 s and from 132 s to 144 s are enlarged in Figure 11 (b) and (c). The elongation of period of vibration can be seen by comparing the two figures.

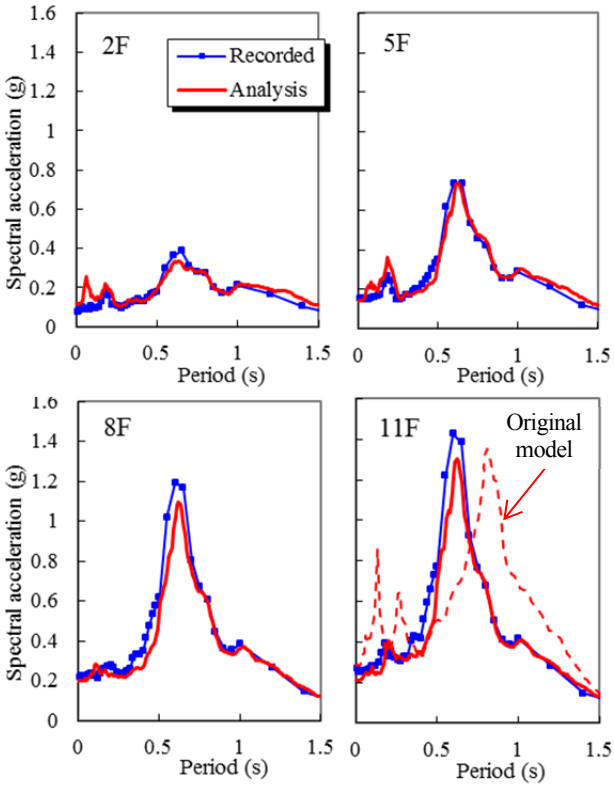

Figure 10. Acceleration spectra of floor motions (modified model, 5% damping)

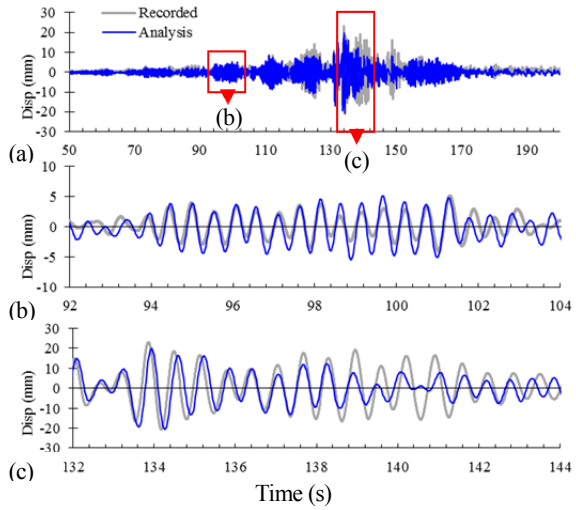

Figure 11. Displacement time history responses at 11F

In addition, Figure 12 summarizes the damage of the steel dampers and the partition walls. They generally agree with the observations after the earthquake. Several steel dampers in the lower stories slightly yielded during the earthquake and the maximum ductility factor is only around two. At the same time, most of the partition walls have cracked.

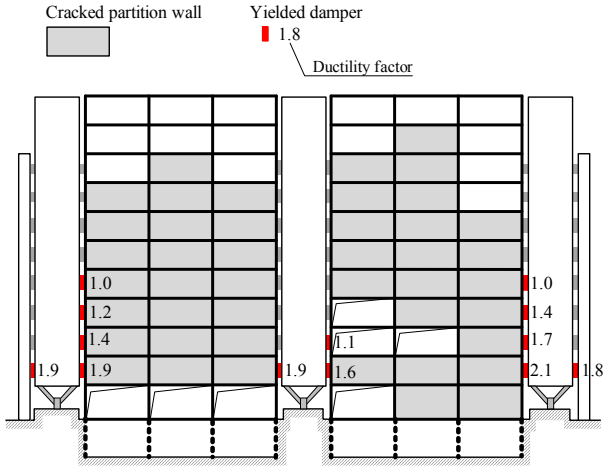

Figure 12. Damage to G3 Building predicted by modified model.

4. DISCUSSION

From the modified model for the retrofitted G3 Building, the model for the building before retrofit can be obtained simply by removing the pin-supported walls and the steel dampers from the modified model. The comparison between the seismic response of the two models, one before and the other after the retrofit, will help understand the effect of the retrofit.

Although the maximum inter-story drift would have been much larger if the building was not retrofitted before the earthquake hit, the building should have been quite safe in both cases, whether retrofitted or not, for the maximum inter-story drift ratio would not have exceeded 1/600 (Figure 13(a)). Under such small deformations, the concrete frame remains essentially elastic and the controlling of its deformation distribution is not critical for its seismic performance. Meanwhile, most energy dissipation goes to the partition walls in both cases (i.e., before and after the retrofit), which attract very large lateral force and cracked at a very early stage. Since only some of the steel dampers are slightly yielded, the energy dissipation of the dampers is quite limited (Figure 14(a)). In this case, although the partition walls are not specifically detailed for energy dissipation, they did work like large dampers in protecting the rest of the structure by dissipating energy.

Nevertheless, the retrofit would prove its value if the ground motion is strong enough to bring significant damage to the building. To give an example, if the recorded ground motion is scaled to PGV = 50 cm/s, which generally corresponding to a Level-II scenario in the seismic design practice in Japan, and is used as a ground motion input for the analysis models of G3 Building, it would make a substantial difference whether it is retrofitted or not. As suggested by the analysis results, the G3 Building without retrofit would collapse at its first floor under the scaled ground motion, while the retrofitted one would exhibit quite uniformly distributed story drift and would not experience weak story failure (Figure 13(b)). In addition, it can be seen from Figure 14(b) that the partition walls would quickly lose

their energy dissipation capacity because of their brittle nature and most of the hysteretic energy dissipation would go to the frame columns in the un-retrofitted building and to the steel dampers in the retrofitted one.

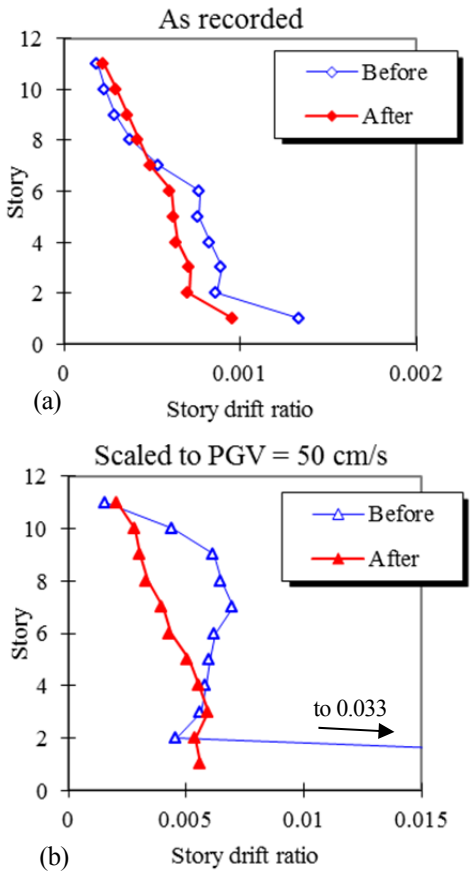

Figure 13 Deformation response of G3 Building predicted by modified model

5. CONCLUDING REMARKS

The vibration and damages of G3 Building, which has pin-supported wall-frame dual lateral system, in the M9.0 Tohoku earthquake is introduced. The observation suggests that the pin-supported walls were forced to rotate as intended and suffered no visible damage during the earthquake. A detailed numerical model of the building was calibrated by incorporating the recorded motions on the building. The significant effect of nonstructural partition walls on the dynamic behavior of the building under small or moderate earthquakes was recognized.

Abstract: Rocking effect is an important influence factor for the earthquake response of the building. This paper is about the study of the SSI effect through analyzing the measurement earthquake response of the building. The research building is an eight-story SRC building (the ANX building) which is one of the stations of the Building-Research-Institute strong motion network. 13 strong earthquake records from 1998 to 2011 are selected for the research in this paper.

This paper made use of the measurement data to calculate the component motion ratios (rocking, swaying and deformation of the superstructure), and also calculated the modal parameters (fundamental frequency, damping ratio and modal shapes) through the structure identification technology.

The calculation results show that: (1) the rocking effect is the major SSI effect of ANX building, (2) rocking effect and fundamental frequency decrease with the increase of the IJMA (seismic instrument intensity); and by comparing the fundamental frequency of the 1998 and 2011, we can find that the fundamental frequency is halved, which indicates that the superstructure stiffness decreased a lot and there may be some damage in the superstructure, (3) damping ratio becomes lager when the IJMA and PGA are outstanding, especially in 2011/03/11 TOHOKU earthquake, which means there may be much nonlinearities contributing to the damping of the building.

1. INTRODUCTION

Measurement data of the strong earthquake response is very significant for understanding the dynamic characteristics of the building, especially for the complicated SSI effect. In the past decades, some advanced accelerometers appeared and were applied in the earthquake engineering. As a result, a lot of relatively accurate measurement data could be accumulated. Because of that, many researchers made much important work through the measurement data of the earthquake response and improved the understanding of the dynamic response of the building and soil. However, although there are much research in the observation of the building response and SSI effect etc. these measurement data concerns only one or several specific buildings. Generally, different buildings have different properties and the earthquake response depends on the characteristics of the buildings (JENNINGS and BIELAK, 1973). Consequently, much more work needs to be made to enlarge the understanding of many other kinds of buildings, this paper focuses on a kind of low-rise SRC building which the longitudinal-direction length (26m) is not so different from the transverse-direction length (21m).

The building is the BRI-ANNEX (ANX) building which is one of the stations of the BRI strong motion network and installed 22 strong motion accelerometers. The ANX building is an 8-story SRC frame building, 11 acceleration meters are installed in the building and 7 acceleration meters are installed on the ground and in the soil, the distribution of the acceleration meters in the building is shown in Figure 1.

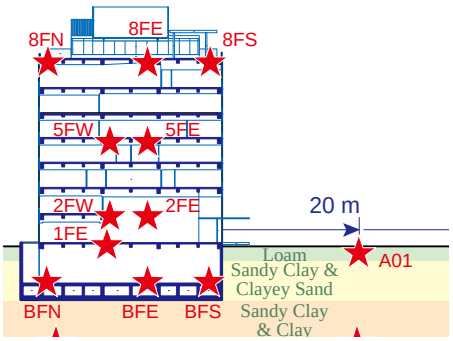

Figure 1 Distribution of the acceleration meters

The detailed information of the ANX building can be found in KASHIMA (2004 and 2006). For this paper, measurement data of 11 acceleration meters is selected which are BFE, BFN, BFS (base floor); 2FW, 2FE (second floor); 5FW, 5FE (fifth floor); 8FE, 8FN, 8FS (roof floor)

and A01 (free field). Each acceleration meter can record 3-direction motions, which are East-West motion (X direction), South-North motion(Y direction), Up-Down motion (Z direction).

This paper mainly concerns on the relationship between SSI effect (especially for rocking effect) and the modal parameters (fundamental frequency, damping ratio and fundamental modal shapes) of ANX building. In the past years, many researchers also made some research about those aspects. LUCO and TRIFUNAC etc. (1987) researched the dynamic behavior of Millikan library building, a nine-story RC building, which was also studied by other researchers before them. Their paper showed that SSI effect and dynamic properties of the building were different even conflicted with each other in different periods, especially for the contribution of rocking response to the SSI effect. They thought that these confliction and difference may come from the data errors. They also thought that the loss of the superstructure stiffness and soil stiffness caused the permanent reduction of the fundamental frequency. TRIFUNAC and IVANOCIC' etc. (2001) analyzed the earthquake response data and ambient response data of VN7SH building through Fourier analysis and time-frequency analysis, they also found that the fundamental frequency of the building changed from earthquake to earthquake, but they believed that this changes resulted from the nonlinearity of the foundation-soil response. TRIFUNAC etc. also thought that the foundation soil has the capability of the absorbing the energy and recovering stiffness. KASHIMA etc. (2006) selected earthquake records of ANX building from 1998 to 2005, he used an optimization algorithm-Evolution Strategies to simulate the ANX building earthquake response and got the dynamic properties of the corresponding MDOF model, he thought that the fall of the fundamental frequency is caused by the change of the superstructure. Totally, it can be confirmed that the fundamental frequency of the building are unstable, but we need to know how the SSI effect changes which is tightly related with the fundamental frequency; besides, other dynamic parameters such as damping ratio and modal shape needs to be studied.

This paper can be considered as the extension of research of KASHIMA (2006). Just as previously mentioned, KASHIMA (2006) selected the earthquake records of ANX building from 1998 to 2005, while for this paper is from 1998 to 2011. This paper consists of three simple basic theory and research methods, which include: (1) the methods about how to get the relatively pure rocking motion, swaying motion, and deformation motion of each floor. The key point of the methods is the application of the vector theory such as the application of the normal vector of the base mat; (2) the structure identification method---curve fitting method is used to get the modal parameters such as fundamental frequency, damping ratio and modal shapes. The calculation of the transfer function is rigorously based on the theory of the modal analysis, which is different from the method brought out by STEWART (1998); (3) the simplified SSI SDOF model is used to analyze the relationship between fundamental frequency and rocking effect, frequency of the superstructure.

2. BASIC THEORY AND RESEARCH METHODS

2.1 Calculation Methods of the Component Motions

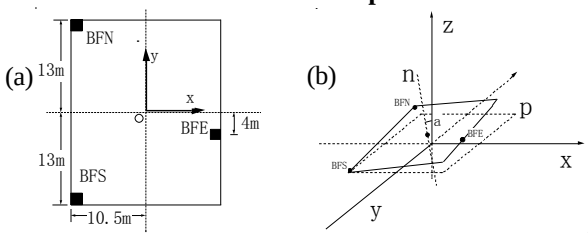

Figure 2 Rocking motion of the base floor

2.1.1 Calculation of the Rocking Angle

Calculation assumptions are as follows, (1) the base mat is considered as a rigid plane, and it has five-direction motions: x-direction horizontal motion, y-direction horizontal motion, vertical motion, torsional motion and rocking motion; (2) Normal vectors of the base mat is only related with the rocking motion, which means the horizontal motions, vertical motion and torsional motion do not affect the normal vectors of the base mat.

Just as shown in Figure 2(b), the base mat p will rock in the space, the normal vector $\vec{n}$ can be accepted as the expression of the rocking motion. And $\vec{n}$ is used to calculate the rocking angle a of the base mat, $\mathrm{BFN}(x_1, y_1, z_1)$, $\mathrm{BFE}(x_2, y_2, z_2)$ and $\mathrm{BFS}(x_3, y_3, z_3)$ are the three points and vectors $\vec{p}$, $\vec{q}$ are two vectors on the base mat, we can calculate the two vectors,

$$\vec{p} = \mathrm{BFN}(x_1, y_1, z_1) - \mathrm{BFE}(x_2, y_2, z_2) \quad (1a)$$

$$\vec{q} = \mathrm{BFS}(x_3, y_3, z_3) - \mathrm{BFE}(x_2, y_2, z_2) \quad (1b)$$

Because $\vec{n} = (x_n, y_n, z_n)$ is the normal vector of the base mat and $\vec{p}$ and $\vec{q}$ are two non-parallel vectors on the base mat, so $\vec{n}$ is normal with $\vec{p}$ and $\vec{q}$, then

$$\vec{n} = \vec{p} \times \vec{q} \quad (2)$$

Select a unit vector on the Z axis, which is $\vec{u} = (0, 0, 1)$. Then the angle between normal vector n and z-axis unit vector $\vec{u}$ is the rocking angle, which can be calculated as follows

$$\cos a = \frac{|z_n|}{\sqrt{x_n^2 + y_n^2 + z_n^2} \times \sqrt{1}}$$

Namely the rocking angle is

$$a = \arccos \frac{|z_n|}{\sqrt{x_n^2 + y_n^2 + z_n^2} \times \sqrt{1}} \quad (3)$$

Normal vector $\vec{n}$ has been normalized and the length is 1, so the projection of the normal $\vec{n}$ on the XOZ plane is (x_n, z_n) and on the YOZ plane is (y_n, z_n), which are shown in Figure 3. The rocking angle a is small, so $\cos a \approx 1$, then $|z_n| \approx 1$. Similarly, the X-direction angle a_x and Y-direction angle a_y are small, according to the

geometry shown in Figure 3, the rocking angle a_x and a_y are calculated as follows: $a_x \approx \tan a_x$ and $\tan a_x = x_n/z_n$, so $a_x \approx x_n$; similarly, $a_y \approx y_n$.

Example: According to the above calculation method, an earthquake happened in 2002/06/14 is selected to calculate the rocking angle of the building, and the results are shown in Figure 4.

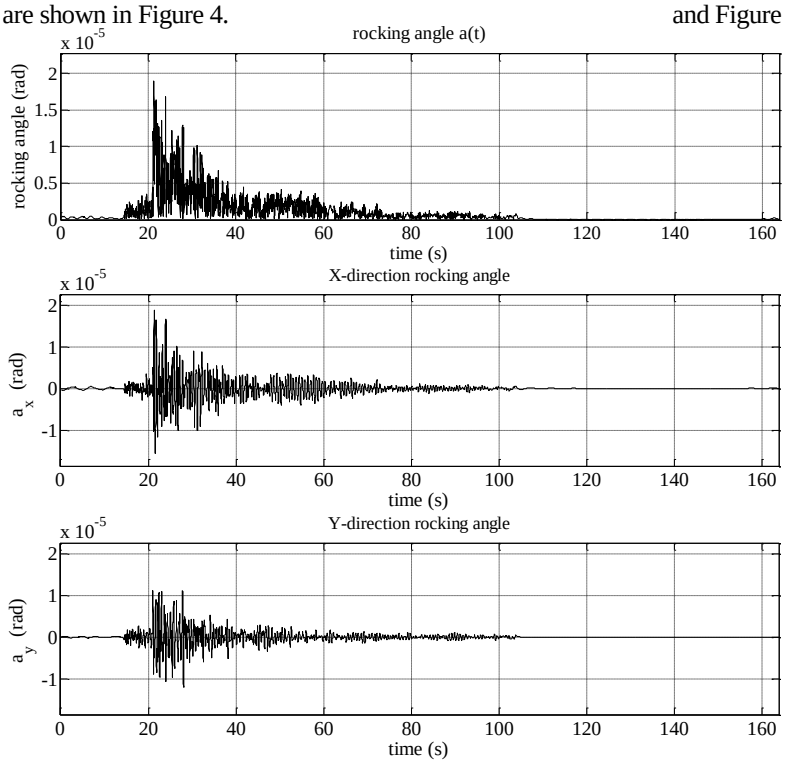

Figure 4 Rocking angle of the base mat

$$X_8 = 0.5[0.5(X_{8FN} + X_{8FS}) + X_{8FE}] \quad (7a)$$

$$Y_b = 0.5[0.5(Y_{8FN} + Y_{8FS}) + Y_{8FE}] \quad (7b)$$

Where, X_i and Y_i are the measurement motions corresponding to the measurement points shown in Figure 5 and Figure 1.

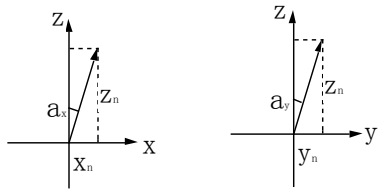

Figure 3 Projections of the normal vector $\vec{\mathbf{n}}$

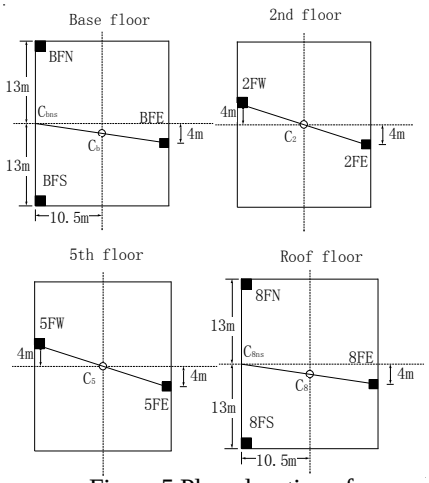

Figure 5 Plane-location of the measurement points

2. 1.2 Calculation of Motions of the Specific Floors

The object of this part is to find the motion at the center point and delete the influence of the torsional effect. The measurement points of base floor, second floor, fifth floor and the roof floor are shown in Figure 5.The motions of the center point can be calculated as follows.

<1> Center of the base floor C_b (X_b, Y_b)

$$X_b = 0.5[0.5(X_{BFN} + X_{BFS}) + X_{BFE}] \quad (4a)$$

$$Y_b = 0.5[0.5(Y_{BFN} + Y_{BFS}) + Y_{BFE}] \quad (4b)$$

<2> Center of the 2nd floor C_2 (X_2, Y_2)

$$X_2 = 0.5(X_{2FW} + X_{2FE}) \quad (5a)$$

$$Y_2 = 0.5(Y_{2FW} + Y_{2FE}) \quad (5b)$$

<3> Center of the 5th floor C_5 (X_5, Y_5)

$$X_5 = 0.5(X_{5FW} + X_{5FE}) \quad (6a)$$

$$Y_5 = 0.5(Y_{5FW} + Y_{5FE}) \quad (6b)$$

<4> Center of the roof floor C_8 (X_8, Y_8)

After the previous analysis, now the separation of the motion components including the rocking motion, swaying motion, deformation motion of the building can be carried out as follows, the similar method can also be found in other researcher' work such as Kashima (2006).

$$u_{rocki} = H_i \times a_{base} \quad (8a)$$

$$u_{sway} = u_{base} - u_{ground} \quad (8b)$$

$$u_{defi} = u_{oi} - u_{ground} - u_{rocki} - u_{sway} \quad (8c)$$

$$u_{totali} = u_{oi} - u_{ground} \quad (8d)$$

Where

H_i --- Height of the ith floor.

a_{base} --- Rocking angle of the base floor, which is a_x and a_y.

u_{rocki}--- Displacement caused by the rocking effect of the ith floor.

u_{sway}--- Displacement caused by the swaying effect.

u_{base}--- Displacement of the center of the base floor.

u_{ground}---Ground motion.

u_{defi}--- Deformation of the superstructure for the ith floor.

u_{totali}---Total displacement including swaying, rocking and superstructure deformation for the ith floor.

u_{oi}---Displacement of the center point of the ith floor.

Through the above method, the relatively pure motion components including rocking motion, swaying motion and deformation motion can be calculated. These data will be used to analysis the rocking effect and structural identification, which will be introduced later.

2.2 Structure Identification

The ANX building is modeled as shown in Figure 6, this model has 8 masses and the corresponding inertias and stiffness; soil stiffness is modeled by rocking spring and swaying stiffness. After the previous analysis, it is clear that the response of the building can be achieved through the geometry calculation.From the recording data, the rocking motion, swaying motion and deformation motion of the superstructure can be calculated. The dynamic equation of model in Figure 6 can be written as follows,

$$[M]\left[\ddot{U}^T\right]+[C]\left[\dot{U}\right]+[K][\mathrm{U}]=0 \tag{9a}$$

$$\sum_{i=1}^{7} m_i\ddot{u}_i^T+m_0(\ddot{u}_s+\ddot{u}_g)+c_s\dot{u}_s+k_su_s=0 \tag{9b}$$

$$\sum_{i=1}^{7} m_i\ddot{u}_i^T h_i+I_t\ddot{a}+c_R\dot{a}+k_Ra=0 \tag{9c}$$

Where $u_i^T=u_i+u_s+h_ia+u_g$, u_i^T is the total displacement of the corresponding m_i, u_i is the story deformation for m_i, u_s is the swaying motion, a is the rocking angle, u_g is the free field ground motion, and $I_t=\sum_{i=0}^{7} I_i$. Equations (9a) (9b) (9c) can be rewritten as follows,

$$\left[\widehat{M}\right]\left[\ddot{\mathrm{U}}\right]+\left[\hat{C}\right]\left[\dot{\hat{U}}\right]+\left[\widehat{K}\right]\left[\widehat{\mathrm{U}}\right]=-\left[\widehat{M}\right][v]\ddot{u}_g \tag{10}$$

From the measurement data, we can get u_1, u_4, u_7 (where u_1 is the deformation of the 2nd floor, u_4 for the 5th floor and u_7 for the roof floor), u_s (swaying motion)and a (rocking motion); the input data is the ground motion $\ddot{u}_g$. The structure-identification model is SIMO (single input multi-output) model. Through the FT technology and the theory of the transfer function by He & Fu (2001), then

$$\frac{\mathcal{F}\mathrm{u}_r}{\mathcal{F}\ddot{u}_g}=\mathrm{H}_r(\omega)=-\sum_{n=1}^{N}\frac{\sum_{i=1}^{N}\varphi_{rn}\varphi_{in}\tilde{m}_i}{(-\omega^2\bar{m}_n+j\omega\bar{c}_n+\bar{k}_n)} \tag{11}$$

Let $A_{rn}=\frac{\sum_{i=1}^{N}\varphi_{rn}\varphi_{in}\tilde{m}_i}{\bar{m}_n}$, and $\bar{\omega}=\frac{\omega}{\omega_n}$

Then

$$\mathrm{H}_r{}^R(\omega)=-\sum_{n=1}^{N}\frac{A_{rn}(1-\bar{\omega}^2)}{(1-\bar{\omega}^2)^2+4\bar{\omega}^2h_n^2} \tag{12a}$$

$$\mathrm{H}_r{}^I(\omega)=\sum_{n=1}^{N}\frac{A_{rn}(2\bar{\omega}h_n)}{(1-\bar{\omega}^2)^2+4\bar{\omega}^2h_n^2} \tag{12b}$$

$$|\mathrm{H}_r(\omega)|=\sqrt{\mathrm{H}_r{}^R(\omega)^2+\mathrm{H}_r{}^I(\omega)^2} \tag{12c}$$

Through transfer function, there are many classic frequency domain methods --- curve fitting methods used for the structure identification. In this paper, a simple SDOF method is used for the structure identification. Based on the theory of component analysis of the transfer function by He & Fu (2001), several analysis procedures can be used as follows.

Table 1 Input-output pairs and transfer function

input	output	Transfer function	Indicator	Fundamental frequency	Damping ratio	Modal shape
$\ddot{u}_g$	u_1	$\mathbf{H_1}(\boldsymbol{\omega})=\frac{\mathcal{F}\mathrm{u}_1}{\mathcal{F}\ddot{u}_g}$	**TF1**	w_{11}	h_{11}	$\frac{A_{11}}{2h_1}$
	u_4	$\mathbf{H_4}(\boldsymbol{\omega})=\frac{\mathcal{F}\mathrm{u}_4}{\mathcal{F}\ddot{u}_g}$	**TF2**	w_{14}	h_{14}	$\frac{A_{41}}{2h_1}$
	u_7	$\mathbf{H_7}(\boldsymbol{\omega})=\frac{\mathcal{F}\mathrm{u}_7}{\mathcal{F}\ddot{u}_g}$	**TF3**	w_{17}	h_{17}	$\frac{A_{71}}{2h_1}$
	a	$\mathbf{H_a}(\boldsymbol{\omega})=\frac{\mathcal{F}a}{\mathcal{F}\ddot{u}_g}$	**TF4**	w_{1a}	h_{1a}	$\frac{A_{a1}}{2h_1}$

<1> Calculation of the transfer functions

From the above analysis, several input-output pairs will be configured shown in Table 1. Because in this research the swaying effect is very small and the swaying motion is susceptible for the noise, then the transfer function for the swaying motion is not good, so the identification model only uses four transfer functions to get the modal parameters of the building, which are shown in Table 1.

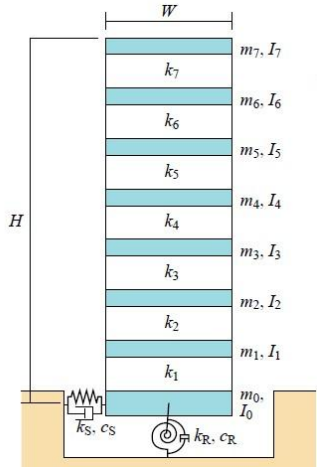

Figure 6 SSI model (Kashima 2006)

<2> Calculation of the modal parameters

In order to reduce the calculation error, the fundamental frequency w_1 and damping ratio h_1 will be calculated as follows,

$$w_1=1/4\ (w_{11}+w_{14}+w_{17}+w_{1a}) \tag{13}$$

$$h_1=1/4\ (h_{11}+h_{14}+h_{17}+h_{1a}) \tag{14}$$

for the implicit part $\mathrm{H}_r{}^I(\omega)$ of the Transfer function,

$$[Q]=\left[\frac{A_{11}}{2h_1}\quad\frac{A_{41}}{2h_1}\quad\frac{A_{71}}{2h_1}\quad\frac{A_{a1}}{2h\xi_1}\right]^T \tag{15a}$$

namely

$$[Q]=[\varphi_{11}\quad\varphi_{41}\quad\varphi_{71}\quad\varphi_{a1}]^T\frac{1}{2h_1}\frac{\sum_{i=1}^{N}\varphi_{i1}\tilde{m}_i}{\bar{m}_1} \tag{15b}$$

Vector $[Q]$ is normalized to be as follows

$$[\phi] = \begin{bmatrix} \frac{\varphi_{11}}{\varphi_{71}} & \frac{\varphi_{41}}{\varphi_{71}} & 1 & \frac{\varphi_{a1}}{\varphi_{71}} \end{bmatrix}^T \quad (16)$$

Where $[\phi]$ is the modal shape. Similarly, if we use the modulus of the $H_r(\omega)$, we can also get the same modal shapes.

2.3 Influence of SSI Effect on the Fundamental Frequency

For the superstructure, it is usually modeled as a lumped mass system. As the first mode is mostly influenced by the SSI effect, then the building is always modeled as an equivalent-single-degree system on the flexible base, which is shown in Figure 7. In order to get brief expression of the fundamental frequency of the SSI model in Figure 7, the rotational inertia of the superstructure and the mass of the foundation are neglected (Stewart, 1998), then the free vibration equations of the SSI model in Figure 7 are shown as follows.

$$\mathrm{m}\left(\ddot{u}_f + \mathrm{h}\ddot{\theta} + \ddot{u}\right) + ku = 0 \quad (17a)$$

$$\mathrm{m}\left(\ddot{u}_f + \mathrm{h}\ddot{\theta} + \ddot{u}\right) + k_u u_f = 0 \quad (17b)$$

$$\mathrm{mh}\left(\ddot{u}_f + \mathrm{h}\ddot{\theta} + \ddot{u}\right) + k_\theta \theta = 0 \quad (17c)$$

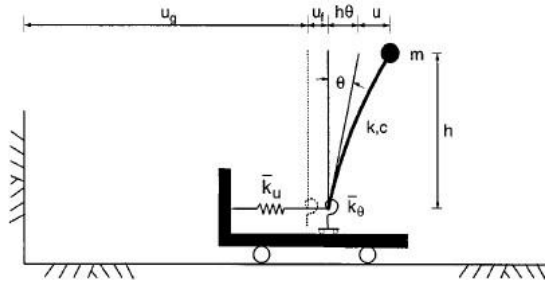

Figure 7 Simplified SSI model (Stewart, 1998)

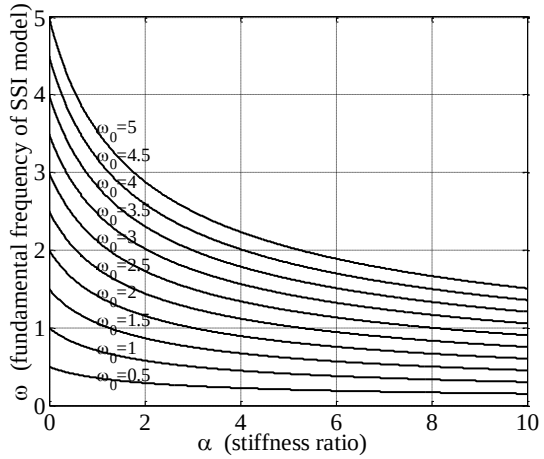

Figure 8 Fundamental frequency of the SSI model

Apply the Fourier Transformation to the equation (17), then $\mathcal{F}\left(\ddot{u}_f\right) = -w^2\hat{u}_f$, $\mathcal{F}\left(\ddot{\theta}\right) = -w^2\hat{\theta}$, $\mathcal{F}(\ddot{u}) = -w^2\hat{u}$, $\mathcal{F}\left(u_f\right) = \hat{u}_f$, $\mathcal{F}(\theta) = \hat{\theta}$, $\mathcal{F}(\mathrm{u}) = \hat{u}$, then equation (17) will be

$$-\mathrm{m}w^2\left(\hat{u}_f + \mathrm{h}\hat{\theta} + \hat{u}\right) + k\hat{u} = 0 \quad (18a)$$

$$-\mathrm{m}w^2\left(\hat{u}_f + \mathrm{h}\hat{\theta} + \hat{u}\right) + k_u\hat{u}_f = 0 \quad (18b)$$

$$-\mathrm{mh}w^2\left(\hat{u}_f + \mathrm{h}\hat{\theta} + \hat{u}\right) + k_\theta\hat{\theta} = 0 \quad (18c)$$

then equation (18) can be written as follows

$$-w^2\mathrm{m}k_uk_\theta\left(\hat{u}_f + \mathrm{h}\hat{\theta} + \hat{u}\right) + kk_uk_\theta\hat{u} = 0 \quad (19a)$$

$$-w^2\mathrm{m}kk_\theta\left(\hat{u}_f + \mathrm{h}\hat{\theta} + \hat{u}\right) + k_ukk_\theta\hat{u}_f = 0 \quad (19b)$$

$$-w^2\mathrm{mh}^2kk_u\left(\hat{u}_f + \mathrm{h}\hat{\theta} + \hat{u}\right) + k_\theta kk_uh\hat{\theta} = 0 \quad (19c)$$

add the three equations of equation (19), and divided by $\left(\hat{u}_f + \mathrm{h}\hat{\theta} + \hat{u}\right)$ then

$$w^2 = \frac{kk_uk_\theta}{\mathrm{m}k_uk_\theta + \mathrm{m}kk_\theta + \mathrm{mh}^2kk_u} \quad (20)$$

then equation (20) can be written as follows

$$w = \sqrt{\frac{k}{m}}\sqrt{\frac{1}{1+\frac{k}{k_u}+\frac{kh^2}{k_\theta}}} \quad (21)$$

If the swaying effect is very small, which means $\frac{k}{k_u} \approx 0$, then the equation (21) will be

$$w = \sqrt{\frac{k}{m}}\sqrt{\frac{1}{1+\frac{kh^2}{k_\theta}}} \quad (22)$$

For a specific building, we suppose that the mass and the height of the building are stable, while the stiffness of the superstructure and the soil will change. Let ratio between the superstructure and soil is

$$\alpha = \frac{kh^2}{k_\theta}, \omega_0 = \sqrt{\frac{k}{m}}$$

then the equation (22) can be rewritten as

$$w = \omega_0\sqrt{\frac{1}{1+\alpha}} \quad (23)$$

The fundamental frequency of the SSI model is decided by the frequency of the superstructure ω_0 and the structure soil stiffness ratio α.

3. CALCULATION RESULTS

In this part, 13 strong earthquakes happened from 1998-2011 are selected as the calculation object; the calculation results are used to show the rocking effect on the earthquake response. These 13 strong earthquakes are shown in Table 2.

Through the comparison between the rocking ratio and the swaying ratio, we can see that for X direction, the rocking ratio is about from5.61%-13.70% and swaying ratio is about from 0.75%-5.53%; for Y direction, rocking ratio 2.84%-9.81% and swaying ratio is 0.48%-4.53%.The above results show that the rocking ratio is much larger than the swaying ratio. Additionally, X-direction rocking ratio is larger than the Y-direction rocking ratio.

Table 2 Strong earthquakes happened from 1998-2011 and ratios of the component motions

4. PARAMETER ANALYSIS

4.1 Rocking Ratio

Rocking ratios have been calculated in the previous part, the results are shown in Table 2. In this part, several factors are tested to find their relationship with the rocking ratio. These factors include the utility time of the building, peak ground acceleration (PGA) and seismic instrumental intensity (IJMA), which are shown in Figure 9.

In Figure 9, the numbers (1, 2, 3, … , 13) are the indicators of earthquakes happened from 1998-2011 shown in Table 2. Figure 9 shows that the rocking ratio seems to decrease with the increase of the utility time of the building, in the first years the rocking ratio is about 12%-14% (X direction) and 7%-10% (Y direction), but after several year the rocking ratio is about 6% (X direction) and less than 4% (Y direction); it is not clear that the relationship between the rocking ratio and the PGA; however, the rocking ratio seems to decrease with the increase of the IJMA.

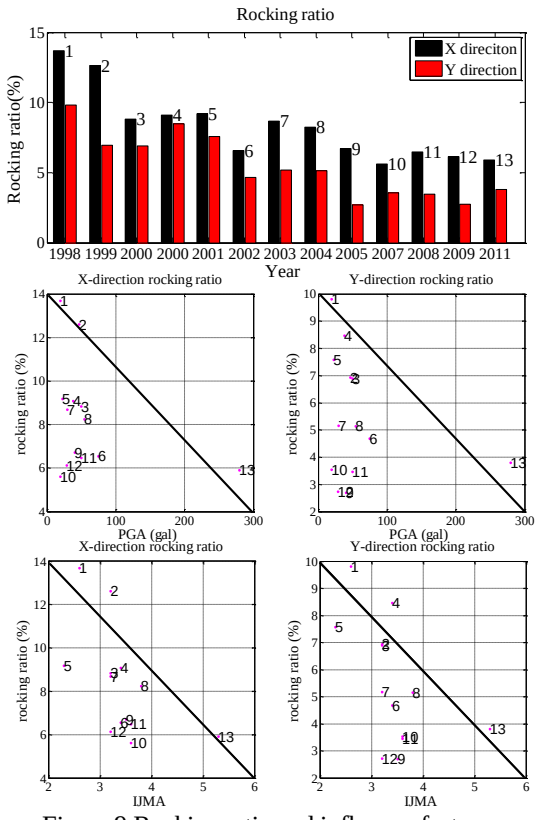

Figure 9 Rocking ratio and influence factors

4.2 Fundamental Frequency w_1

Figure 10 shows the relationship between fundamental frequency and the potential influence factors such as the utility time of the building, PGA, IJMA and the rocking ratios.

As what is shown in the Figure 10, w_1 seems to decrease with the increase of the utility time to some extent; but this trend is not continuous, which means the change of the fundamental frequency maybe very complicated. The change of the fundamental frequency is based on three major

conditions as follows. According to the equation (23) and Figure 8:

Condition 1: if the structure soil stiffness ratio α does not change, the fundamental frequency $\boldsymbol{w_1}$ will decrease when superstructure stiffness decreases; if the superstructure stiffness is stable, the fundamental frequency $\boldsymbol{w_1}$ will decrease when structure soil stiffness ratio α increases.

Condition 2: it is reasonably assumed that the superstructure stiffness decreases, then ω_0 will decrease, and on the condition: (1) if α becomes larger, the fundamental frequency $\boldsymbol{w_1}$ may be become smaller; or (2) if α becomes smaller, there will be two situations, when the influence of the decrease of α is more outstanding than the influence of the decrease of ω_0, $\boldsymbol{w_1}$ will increase, or else $\boldsymbol{w_1}$ will decrease.

Condition 3: it is reasonably assumed that the superstructure increases, then ω_0 will increase, and on the condition: (1) if α becomes smaller, then the fundamental frequency $\boldsymbol{w_1}$ may become larger; or (2) if α becomes larger, there will be two situations, when the influence of the increase of α is more outstanding than the influence of the increase of ω_0, $\boldsymbol{w_1}$ will decrease, or else increase.

By the summary of the above analysis based on equation (23) and Figure 8, we can get some conclusions as follows:

The increase of fundamental frequency $\boldsymbol{w_1}$ is corresponding to the each of the following conditions:

(a) Structure soil stiffness ratio α is fixed, superstructure stiffness increases.

(b) Structure soil stiffness ratio α becomes smaller, and ω_0 decreases; at the same time, the influence of the decrease of α is more outstanding than the influence of the decrease of ω_0.

(c) Structure soil stiffness ratio α becomes smaller, and ω_0 increases.

(d) Structure soil stiffness ratio α becomes larger, and ω_0 increases; at the same time, the influence of the increase of α is less outstanding than the influence of the increase of ω_0.

(e) Superstructure stiffness is fixed, that means ω_0 is stable; and structure soil stiffness ratio α becomes smaller.

The decrease of fundamental frequency $\boldsymbol{w_1}$ is corresponding to each of the following conditions:

(f) Structure soil stiffness ratio α is fixed, and superstructure stiffness decreases.

(g) Structure soil stiffness ratio α becomes smaller, and ω_0 decreases; at the same time, the influence of the decrease of α is less outstanding than the influence of the decrease of ω_0.

(h) Structure soil stiffness ratio α becomes larger, and ω_0 increases; at the same time, the influence of the increase of α is more outstanding than the influence of the increase of ω_0.

(i) Structure soil stiffness ratio α becomes larger, and ω_0 decreases.

(j) Superstructure stiffness is fixed, that means ω_0 is stable; and structure soil stiffness ratio α becomes larger.

On the one hand, from the Figure 9 we learned that the rocking ratio decreases with the increase of the utility time. On the other hand, from the Figure10, $\boldsymbol{w_1}$ has a trend that it decreases with the decrease of the rocking ratio. That phenomenon can be explained as follows: According to the previous analysis, the decrease of the rocking ratio means rocking effect falls and the structure soil stiffness ratio α becomes smaller. Subsequently, only condition (g) is in a good agreement with this situation. That means the ω_0 may decrease which indicates the superstructure stiffness decreases, besides the influence of the decrease of α is far less outstanding than the influence of the decrease of ω_0.

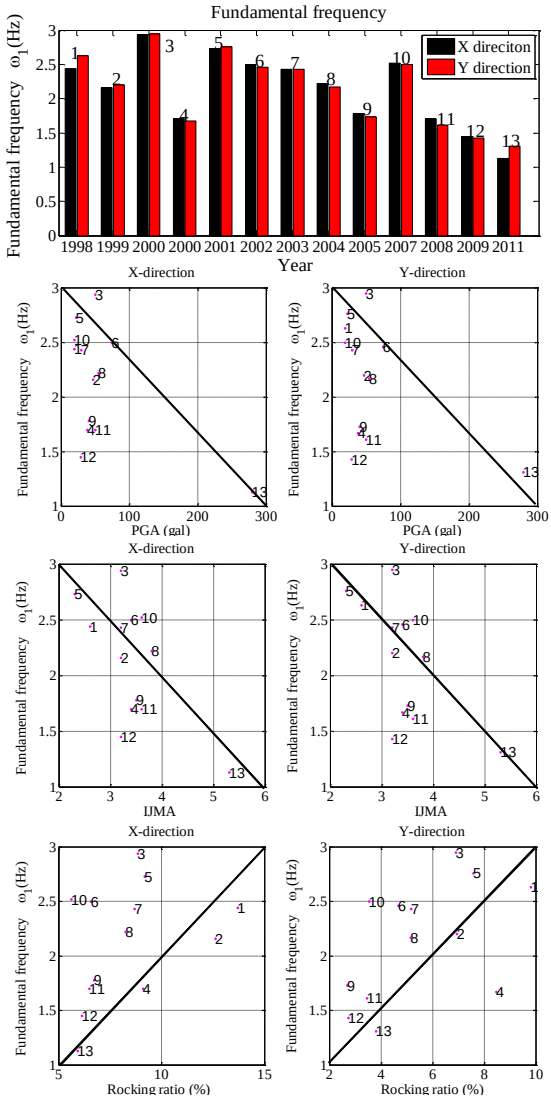

Figure 10 Fundamental frequency and influence factors

Totally, although in the first years the rocking effect is large, the stiffness of the structure is larger. So the fundamental frequency of the building is still on the high level; after several years, although the rocking effect is small, the stiffness of the structure becomes smaller. So the fundamental frequency of the building will be on the low level. KASHIMA (2006) also found the fall of the natural frequency with the increase of the utility time of the building and he thought that the decrease of the fundamental

frequency was caused by the change of the property of the superstructure. The results of this paper show good agreement with his estimation through more data results.

Additionally, the fundamental frequency appears to decrease when the IJMA increases. But this trend for PGA is not clear. It can be easily understood that the larger IJMA means stiffness degradation of the superstructure, then the ω_0 will decrease. The results are in a good agreement with the previous analysis.

By comparing the fundamental frequency of the 1998 and 2011, we can find that the fundamental frequency is halved, which decreases from 2.44Hz to 1.13 Hz (X direction) and 2.63Hz to 1.31Hz (Y direction). Based on the previous analysis, the superstructure stiffness decreased a lot and there may be some damage in the superstructure.

4.3 Damping Ratio h_1

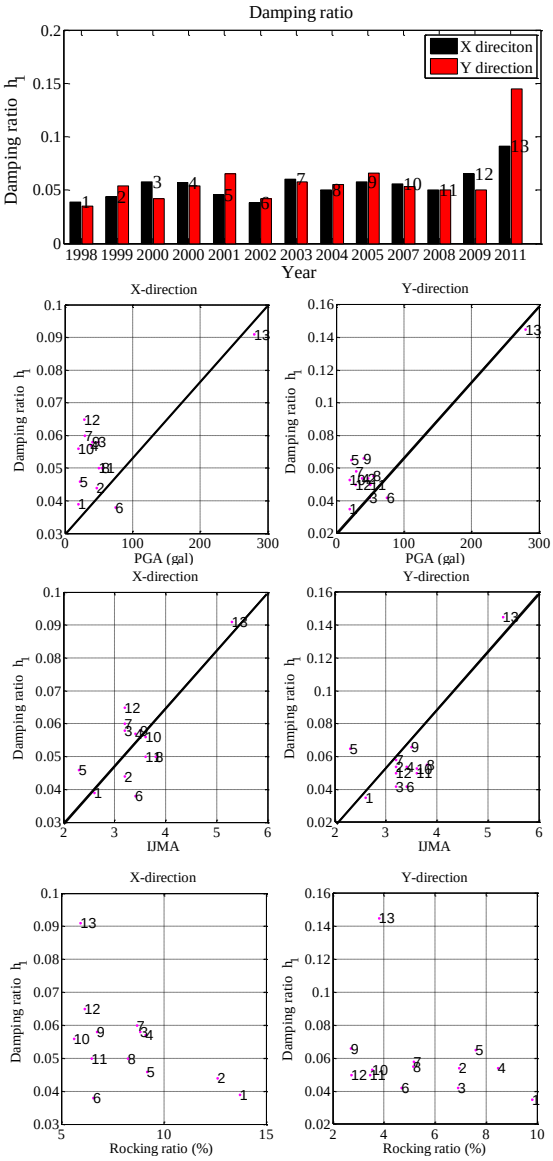

Figure 11 Damping ratio and influence factors

Figure 11 shows the relationship between fundamental frequency and the potential influence factors such as the utility time of the building, PGA, IJMA and the rocking ratios.

Damping ratio is an index of the energy consumption ability of the building. The Figure 11 shows the damping ratio changes with the time, we can see that from 1998-2009 the damping ratio is less than 6.5%, but in 2011/3/11 earthquake the damping ratio becomes very large, which are 9.1% (x direction) and 14.5% (y direction).

Considering that 2011/03/11 earthquake is a very large earthquake (PGA=279.3, IJMA=5.3), there may be much nonlinearities (maybe structure damage) contributing to the damping of the building during the earthquake. And the damping ratio seems to increase when the IJMA or PGA increases. But for the rocking ratio, it has small or no correlation with the damping ratio.

4.4 Rocking Mode (Component of Modal shape)

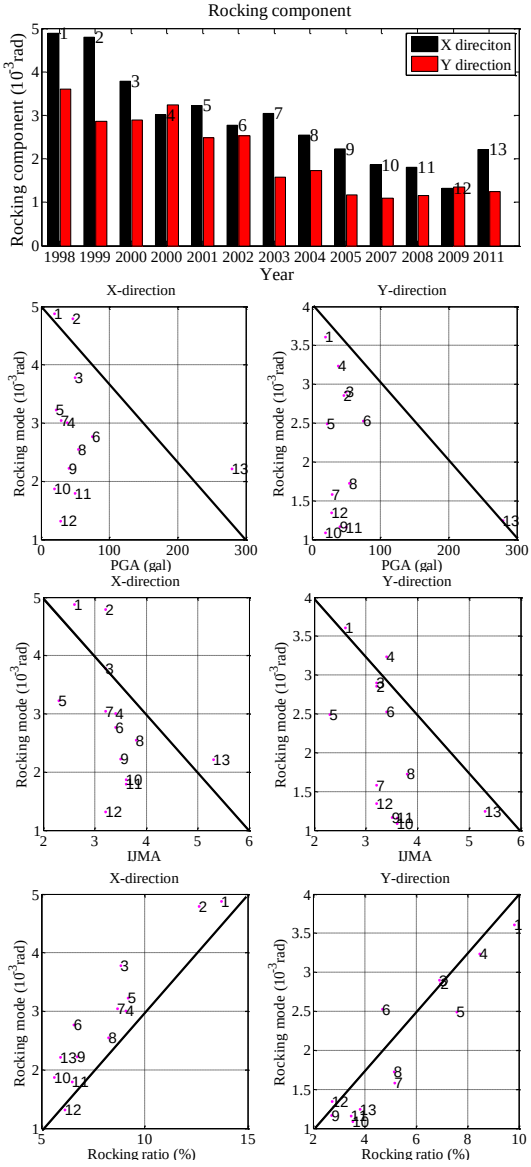

Figure 12 Rocking mode and influence factors

Rocking mode (rocking component of the modal shape) is the rocking angle of the modal shape Table 3.

Figure 12 shows the relationship between fundamental frequency and the potential influence factors such as the utility time of the building, PGA, IJMA and the.rocking ratios. Rocking mode is also the measurement of the rocking effect, which is similar with previous rocking ratio. Figure 12 shows that the rocking mode seems to decrease with the increase of the utility time of the building, in the first years the rocking mode is about 0.00488 rad (X direction) and 0.00361 rad (Y direction), but after several year the rocking mode becomes smaller and it is less than 0.0025 rad (X direction) and less than 0.0015 rad (Y direction); it is not clear that the relationship between the rocking ratio and the PGA either; however, the rocking ratio seems to decrease with the increase of the IJMA.

More importantly, the rocking mode has a good agreement with the rocking ratio. The rocking mode increases with the increase of the rocking ratio.

5 CONCLUSION

This research calculated each component motions of the building response, and identified the modal parameters through the spectrum curve fitting method. The parameter analysis is based on the SDOF SSI model. Several conclusions can be made as follows:

(1) Three measurement points located on the base mat is benifical for getting relatively pure rocking motion; two measurements on the floor will be helful to elimate the torsional effect and get relatively pure horzontal motions of the corresponding floors.

(2) X-direction rocking ratio is about from5.61%-13.70% and swaying ratio is about from 0.75%-5.53%; Y-direction rocking ratio 2.84%-9.81% and swaying ratio is 0.48%-4.53%. The above results show that the rocking effect is much larger than the swaying effect. Additionally, although the X-direction length is 21 meters and Y-direction length is 26 meters, X-direction rocking effect is apparently larger than the Y-direction rocking effect.

(3) Rocking mode has a good agreement with the rocking ratio. The rocking mode decreases with the decrease of the rocking ratio. Rocking ratio and rocking mode seem to decrease with the increase of the IJMA. In fact, the larger IJMA or PGA means more nonlinearity and structure damage which account for the stiffness degradation, especially for the superstructure.

(4) Fundamental frequency $\boldsymbol{w_1}$ has a trend that it decreases with the decrease of the rocking ratio and rocking ratio. This phenomenon will happen only on the condition that structure soil stiffness ratio α becomes smaller (it has been confirmed by the decrease of the rocking ratio and rocking mode), and ω_0 decreases; at the same time, the influence of the decrease of α is less outstanding than the influence of the decrease of ω_0. So it is reasonable thought that the decrease of the fundamental frequency is mainly caused by the stiffness degradation of the superstructure. By comparing the fundamental frequency of the 1998 and 2011, we can find that the fundamental frequency is halved, which decreases from 2.44Hz to 1.13 Hz (X direction) and 2.63Hz to 1.31Hz (Y direction). Based on the previous analysis, the superstructure stiffness decreased a lot and there may be some damage in the superstructure.

(5) And the damping ratio seems to increase when the IJMA or PGA increases. But for the rocking ratio, it has small or no correlation with the damping ratio. Damping ratio becomes from less than 6.5% in other relatively smaller earthquakes to 9.1% (x direction) and 14.5% (y direction) in 2011/3/11 stronger earthquake. Considering 2011/03/11 Tohoku earthquake is a very strong earthquake (PGA=279.3, IJMA=5.3), there may be much nonlinearities (maybe structure damage) contributing to the damping of the building.

ON DEVELOPMENT OF SEISMIC RESISTANT DESIGN FOR STRUCTURAL STEEL BUILDING IN INDONESIA

Muslinang Moestopo

Associate Professor, Faculty of Civil and Environmental Engineering
Institut Teknologi Bandung, Indonesia

mmoestopo@gmail.com, moestopo@si.itb.ac.id

Abstract: Recently, the development of seismic resistant steel structures in Indonesia is considered far behind the reinforced concrete structures, although more comprehensive seismic building codes for steel and concrete structures have been published at the same time in 2002. Although the cost and the availability of steel products are considered as the reasons, other issues have also contributed to this condition: the lack of knowledge of the high seismic performance of various steel structures, the limited portion for seismic resistant steel structures in civil engineering curriculum, the less intensive dissemination of the codes. Following the publication of new Indonesian Seismic Map and the draft of new Seismic Building Code, the new revised seismic resistant steel building code will be published. This will enhance the design requirement and performance of previous steel building code: the more reliable design based on most current earthquake data, knowledge and methodology. Further development would be expected that includes improvement in education and research program, implementing policies and regulation for steel production,

1. INTRODUCTION

Indonesia is considered as one of the most seismic prone country since its archipelago lies among four major active tectonic plates: Eurasian, Indian-Australian, Pacific and the Philippine plates. The strong earthquakes occurred in last few years that were recorded with high magnitude as well as damages and casualties : Aceh-earthquake (Mw=9.2 in 2004), Nias-earthquake (Mw=8.7 in 2005), Yogyakarta-earthquake (Mw=6.3 in 2006), Bengkulu-earthquake (Mw=8.4 in 2007), Tasikmalaya-earthquake (Mw=7.3 in 2009), and Padang-earthquake (Mw=7.6 in 2009).

Preceeding the occurrence of those large earthquakes, three Building Codes have been published. The revised version of Indonesian Seismic Building Code (BSN 2002a) was published in 2002 in the document SNI 03-1726-2002, where SNI identifies an Indonesian National Standard (Standar Nasional Indonesia). Other documents are the revised version of Concrete Building Code - SNI 03-2847-2002 (BSN 2002b) and the 'new' Steel Building Code - SNI 03-1729-2002 (BSN 2002c), both have included a special chapter on seismic resistant design.

The Steel Building Code that was published in 2002 was the first Indonesian steel building code that provides a complete chapter on seismic resistant design, which was adopted from Seismic Provisions for Structural Steel Buildings (AISC, 1997). Previous steel building code only covers non-seismic steel structures and did not provide specific requirements on material and stability for sesimic components. No specific design requirement was specified for any specific seismic resisting structure. Therefore, there were quite many issues that needed to be introduced to the engineers when the code was first published. However, after ten years of its publication, the seismic resistant building code has not been fully adopted by all engineers. Meanwhile, the new revised version of the current steel building code is being prepared by the team under the Ministry of Public Works.

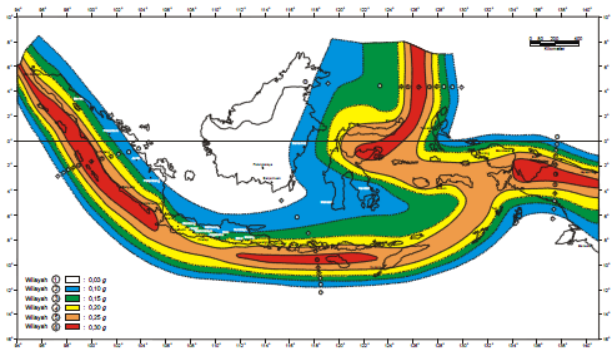
2. SEISMIC BUILDING CODE

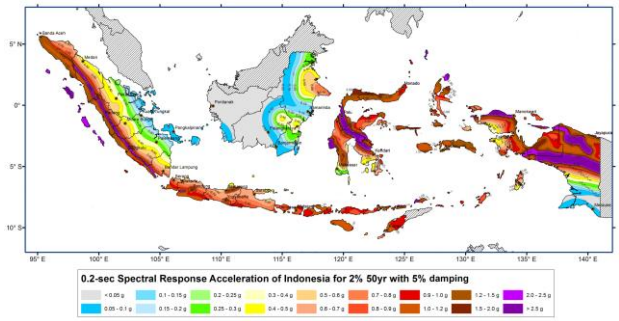
Following the series of strong earthquakes that occured in different region in Indonesia, a number of intensive studies have been conducted prior to the publication of the new seismic map. The report by the Team for Revision of Seismic Hazard Maps of Indonesia (Irsyam, et al. 2010) that was supported by different institution and agencies, including United States Geological Survey (USGS) and Australia-Indonesia Facility for Disaster Reduction (AIFDR), includes proposed seismic hazard maps for Indonesia by adopting the most recent data and current state of knowledge in probabilistic as well as deterministic seismic hazard methodology. The maps have been proposed and then were adopted and published by the Ministry of Public Works as the new Indonesian Seismic Maps.

Recently, a draft of new revised version of Indonesian Seismic Building Code (BSN 2011) has been written and will be published. This version provides the updated concept for seismic design requirements and the new Indonesian Seismic Maps. The material of the seismic design requirements was taken from the relevant chapters on the American loading code document (ASCE 2010). The seismic design criteria is not only based on seismic hazard but also on probability of collapse of the buildings. The code includes the seismic maps that shows Risk Targeted Maximum Considered Earthquake (MCE_R) for short period (T = 0.2 second) and for long period (T =1.0 second). The design spectral values are then assigned to be (2/3) of the spectral values derived from MCE_R based on the two spectral values of S_S (special value for short period) and S_1 (special value for long period) that represents the spectral response accellerations.

The draft of new revised Seismic Building Code is expected to provide higher seismic design load especially for building with higher importance, such as school buildings and other buildings that are designed to be a shelter during earthquake. More over, the type of seismic resistant structure will be determined based on the design spectral values, the importance factor and the risk category.

In the current seismic building code (BSN 2002a), the design spectral value is simply determined by directly using the only one Indonesian Seismic Map with 6 (six) seismic zones (Figure 1). This map shows the maximum peak ground accelleration at bed rock for Indonesia for 500 years return period, and was constructed based on four available study reports. For each seismic zone, three design spectral values are provided for hard, medium, and soft soils.





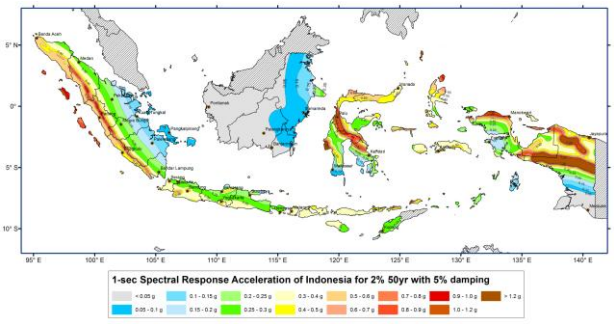


Figure 1 Current Indonesian Seismic Map based on PGA. (BSN 2002)

The new Indonesian Seismic Maps provides a number of maps includes peak ground accelleration and spectral response accellerations. Figure 2 shows spectral response accelleration for short and long period. More detail values could be calculated using available program software that would accompany the publication of the document. In general, the new revised seismic building code (BSN 2011) would provide more reliable seismic design based on the most recent and complete earthquake data as well as current knowledge and methodology to better determine the seismic risk.

At this time, some intensive program to disseminate the concept and design of the new seismic building code have been carried out by the Ministry of Public Works, the Indonesian Society of Civil and Structural Engineers, and some universitites. However, since the new Seismic Building Code has not formally been published, the application of this updated seismic building code for building construction project is still limited.

(a)

(b)

Figure 2 New Indonesian Seismic Maps Spectral Response Accelleration for 2% Probability of Exceedance in 50 years: (a) T= 0.2 sec,(b) T = 1.0 sec

3. SEISMIC RESISTANT STEEL BUILDING CODE

The current Indonesian steel building code (BSN 2002c) is the first document to elaborate the design provisions for steel resistant structures, includes the requirements for material, section, component, connection, as well as the types of seismic resisting structures: moment resisting frames (special, intermediate, and ordinary), special truss moment frames, concentrically braced frames (special and ordinary), eccentrically braced frames. and steel resistant structures. This seismic provision is presented as one chapter in the current steel building code document, and was adopted from the 1997 version of AISC Seismic Provision for Structural Steel Building.

Although it has been published for ten-years, the application of the seismic provisions in the construction project was very limited, whilst most of it was applied only to the ordinary moment resisting frame or the ordinary concentrically braced frames. During that period, dissemination of this provision as well as the introduction to various seismic resisting structures were also limited, while most of the dissemination, including seminars and short-courses, were conducted in the area of seismic resistant reinforced concrete structure. This is understandable, since most of the multy-story residential and office buildings in Indonesia are preferably constructed with reinforced concrete structures.

However, at this time, the revised version of the steel building code has been written and will be published. This version adopts the 2010 version of AISC Seismic Provision for Structural Steel Building as well as the Prequalified Connections for Special and Intermediate Steel Moment Frames for Seismic Applications. Beside some updated version of the requirements, some new seismic resisting structures are introduced in the revised version: shear plate shear wall and buckling restrained braced frames.

4. DESIGN AND CONSTRUCTION

Currently, the use of structural steel buildings are mostly for one-story industrial building and low-rise residental and office buildings. This is far behind the use of reinforced concrete that includes most of the high-rise building in many urban areas in Indonesia. Some reasons behind this condition are the cost and the availability of steel products. There are only few steel-mills that produce the large section such as H-beam.

The increasing demand for high-rise buildings in urban area has initiated the use of steel structure especially for saving construction time. The moment resisting frames are commonly designed for this purpose, yet with limited consideration for seismic requirements. Report on past Padang earthquake (Franco et al. 2009) presents lessons learned from failures and collapse of some steel moment resisting frames. The common failures include:

a. The use of non-compact sections.
b. The requirement of strong column – weak beam is not satisfied.
c. Poor connection detailing, including lack of continuity plate, weak panel zone and column splice.
d. Poor quality control.

As compared to the requirement for seismic resistant concrete structure, the strong column-weak beam for steel structures is directly related to the need for strong connection design, that is more complicated than for concrete beam-column joint. Most of the beam-column joints use the end-plate connection that is relatively simple to install. The use of in situ welding connection for low-rise builidng is very rare and not preferable. Therefore, the performance of the connection is rarely been designed for high seismic loading so that the structure is designed with limited ductility as an ordinary moment resisting frames. For end-plate connection that has a limited moment resisting capacity, the design should be more carefully checked.

The concept of capacity design that was adopted by the seismic resistant steel building code requires the reliable values of material overstrength ratio, i.e. the expected yield stress divided by the nominal yield stress. These values are adopted directly from the American code (AISC 2010). A study has been conducted (Moestopo 2012c) to verify these values based on more than 2900 tensile-test data of steel plates and H-beam from four Indonesian steel-mills. It was found that not all data satisfy the seismic design requirement. More over, the result indicated that the adopted values for certain steel plate are underestimate the real value based on the test data. Further study is needed to secure the reference values that will be used by in structural design and will affect the safety of the building.

The need for constructing high-rise building has also been increasing due to very limited space in the urban area. Since most of the urban area are located in the seismic region, the drift criteria would most likely govern the design for higher-rise building. However, the use of large diagonal bracing is not commonly preferable for most of architects. In addition, the availability of heavy steel sections in the domestic market is still limited, due to the limited capacity of very few steel company. In this case, the use of composite sections in addition to reinforced concrete shear-wall is considered more acceptable.

The advantages of using steel structures as seismic resistant structures need to be promoted, especially to the architects, including to both lecturers and students. Introduction to the high performance of various types of seismic resisting structures including the use diagonal bracings will give broader perspective in obtaining the optimum design. Moreover, the high performance of buckling restrained braces, for example, would be expected as an effective solution for strengthening the existing structures that was indicated not sufficiently performed, based on the new seismic building code.

Although the number of damages of steel buildings from the previous earthquakes was reported much less than of the reinforced concrete and masonry structures, the above common failures and concerns show serious problems as well as important issues to be solved in the design and construction of seismic resistant steel structures. The more intensive dissemination of the seismic design code for steel building is neccessary to improve the knowledge of the engineers. More seminar and short course should be organized especially in many seismic prone region in the country.

On the other hand, the increase in structural steel production has been supported by the government, but still need to be further implemented by supporting policies and regulations as well as commitment from steel industries. This will in turn support the development of innovation and design for more advanced and optimum seismic resistant steel building.

5. EDUCATION AND RESEARCH PROGRAM

The seismic resistant design for steel structures are not specifically taught in civil engineeering undergraduate program at most of universities in Indonesia. This topic is partly covered in the course of seismic resistant structures that is a compulsory course in Master's degree program but an elective course in undergraduate degree program. Therefore, the knowledge in seismic design for steel structures are limited even for one-story and low-rise building. This will at least contributes to the lack of concern of fresh graduate engineers toward the detailing of the steel connection. Seminar and short courses are the effective means to overcome this concern.

In Institut Teknologi Bandung, the oldest and the leading university in engineering area, this topic is more comprehensively covered in the course of Structural Steel Frames for Master's degree program in civil engineering. The concept of design capacity as well as the ductility and stability requirement for material, section, element, conections and building structures, are comprehensively discussed as well as the seismic provision in the steel building code.

The research topics in the seismic resistant structures are mostly conducted for concrete structures, both reinforced and pre-cast concrete. For seismic resistant steel structures, more works have been done in numerical works as compared to a few number of experimental works. Recent experimental works to improve the performance of shear links in eccentrically braced frames are on replaceable links (Moestopo 2012a,b) and diagonal web stiffener (Yurisman 2010). On going research work includes preliminary work on development of more economical and reliable buckling restrained braces for low-story building (Moestopo 2012d). Furthermore, development of new seismic devices becomes the research agenda, which will involve collaboration with construction industries.

3. CONCLUSIONS

The Indonesian seismic building code has been updated by the most current data and knowledge in the area of seismic resistant structures. However, the development of seismic resistant steel structures in Indonesia is considered far behind the reinforced concrete structures. Some reasons that contribute to this condition are the cost and the availability of steel products. However, more issues need to be addressed to develop the seismic resistant steel building in Indonesia including the government supporting policy and regulation as well as commitent from the steel industry.

More intensive education and research program are required toward the development of more reliable and economical steel building, especially for seismic resistant low-rise building in the seismic region. For high-rise building, application of the updated seismic design provision could be carried out toward an optimimum design.

Telecommunication at the Time of Earthquake

Takanobu Ito

Executive Vice President, FUN, Inc, Japan
taka@c-ball.jp

Abstract: The Great East Japan Earthquake has left a large impact on the society and economy of Japan. As Japan has been facing various challenges to reestablish the society and economy, we are recognizing to get a clear picture of what is going wrong. Communication problems include the PSTN, cell phone networks or the internet for any devices (landline phone, smart phone, cell phone, PC, or PDA) are one of the major returning problems and we are convinced that they are avoidable. However, there are improvements among government agencies and business operators. Business Continuity Management (BCM) and Business Continuity Planning (BCP) have become an integral part to reestablish the society and economy regime. Important part of BCM or BCP approach is the restoration and the establishment of some level of communications between employees responsible for critical systems as well as command and control. Maintaining communication during disasters and its incorporation into BCP are clearly at the forefront of practically all post the Great East Japan Earthquake regulatory activity dealing with disaster preparedness.

1. INTRODUCTION

In response to lessons taught by the Great East Japan Earthquake of March last year, earthquake and tsunami countermeasures are being widely studied and numerous plans are being reviewed.

These reviews present an opportunity to consider of modern science and technology as well as next generation for decent lifestyles. Also as Japan's social and economic conditions change by this catastrophic damage, people's lives have changed accordingly. Lifestyles and economic activities based on corporate activities have been transformed through information communication and rapid progress of worldwide contents.

The earthquake and tsunami were wiped-out the information and communication systems. It is impossible to prevent and mitigate disasters without information and communication systems confirming to various proposals from related institutions. In other words, the communication systems collapse in disaster areas, making it difficult if not impossible for people in these areas to communicate with the outside world and among themselves. What with the loss of power, the collapse of relay towers and parabola antennas, the destruction of cables and switches, the flooding of tunnels, telephone services are discontinued, and those services which somehow manage to survive the disaster become so congested that it may not be possible to get through, certainly not in a timely fashion.

This communication systems collapse is nothing new or startling about the description above. It appears that when it comes to addressing the problem of communication during disasters, most of the attention has focused on addressing the problem of communication interoperability among rescue and first response teams from different jurisdictions and agencies. However this is a great opportunity to accumulate knowledge and experience to develop advanced and diverse disaster protections along with business continuity, disaster recovery and emergency response.

Interoperability is important, especially during disasters, but for communication systems to interoperate with each other they must first survive the disaster. In any event, for businesses in disaster areas the issue of survivable communication systems is more important than the problem of interagency communication interoperability.

The imbalance in addressing these two important communication issues which are interoperability problems and survivability problems is now being redressed as one of the major returning problems. More companies include telephone carriers and emergency services directors are thinking long and hard about how to provide for continuing communication before, during, and after a disaster business continuity operations or wreaks havoc on a community. The challenges related to these discussions are described below.

2. PURPOSE IN PROMOTING BCP

According to the Cabinet Office (Disaster Management)at APEC Workshop on Private Sector Emergency Preparedness about 5 months after the Great East Japan Earthquake, refers to the Purpose in Promoting BCP: "To avoid a halt of corporate activity caused by a natural disaster such as an earthquake, and avoid its undesirable impacts to the company, economic growth, and

employment not only in the affected areas but also in other areas connected through business relationships. To minimize disaster impacts, it is crucial to promote the formulation of a Business Continuity Plan(BCP), which is a management strategy aimed at ensuring business continuity in times of disaster, ensuring socio-economic stability in Japan, and improving the reliability of Japanese firms for foreign countries.".

Also in the "Business Continuity Guidelines 1st and 2nd edition.", the Cabinet Office(Disaster Management) made explicit five messages such as "Characteristics of these Guidelines", "Necessity for Making Efforts to Ensure Business Continuity at the time of a Disaster", "Concurrent Requirements Other than Business Continuity", "Transmitting Information Outside and Information Sharing" and "Backing up the Information System".

"Necessity for Making Efforts to Ensure Business Continuity at the time of a Disaster" has stated that in Japan, where disasters occur frequently, it is desired to build a disaster-resistant country with cooperation among government, corporations, and citizens. In particular, under circumstances where the interruption of corporate activities might have adverse effects on a global scale due to the globalization of economies, it is becoming more important for the business sector to develop its own preparations to continue business at the time of a disaster, and recover critical operations to the level prior to the disaster. Looking to communities, it is desired to make companies disaster-resistant to secure employment and supply chains in a disaster-affected area. On the other hand, it must be emphasized that elaborate and systematic preparations for disasters by companies have recently been highly valued by client companies and markets. In particular, it has become widely recognized that promoting good practice in business continuity by companies, which is the focus of companies in Europe and the United States, is effective in terms of increasing corporate value. Thus Business Continuity Plan(BCP) plays important roles in this regard.

2-1 Right After a Disaster Occurs

In the "Characteristics of these Guidelines", the Cabinet Office has expressed the following. It is made clear that business continuity is not the first priority of companies, but immediately after a disaster occurs, the focus should be on securing safety of life and preventing secondary disasters. The response to business continuity should involve cooperation with communities to secure consistency with previous disaster countermeasures.

Adding to mentioned above, in the "Concurrent Requirements Other than Business Continuity" was state accurately the actual circumstance in immediately after a disaster occurs. It says that the significance and the importance of business continuity are stated above as important matters to be considered by companies when a disaster occurs, and at least the following three points also need to be considered. Basic disaster responses had been previously taken in Japan. It is true that there are many overlaps, and it is unlikely that the idea putting too much priority on business continuity can be understood. In fact, the type and the level of priorities are left to the judgment of each company.

[1] Securing Safety of Life

In industries where customers visit shops or remain in facilities, priority should be put on securing the safety of life of customers. Naturally, securing the safety of life of people engaged in business includes officers, employees of the company, personnel of affiliates, temporary workers, and personnel of cooperating companies.

[2] Preventing Secondary Disaster

In manufacturing industries, for example, it is necessary to carry out drills to prevent secondary disasters in terms of securing the safety of a neighborhood, which includes fire, collapse of buildings and structures in neighboring areas, and leakage of chemicals.

[3] Contribution to and Symbiosis with Local Communities

In the event a disaster occurs, the earliest possible recovery of local communities should be sought in cooperation with citizens, administration, and client companies. Among local contributions, provision of aid funds, premises, and materials are generally conceived. It is desirable to give support using the assets of the company, such as dispatching engineers and volunteers. It is also desirable that there is close cooperation.

These are very important points out that the Cabinet Office(Disaster Management) refers to major rules, immediately after a disaster occurs, which are securing safety of life, preventing secondary disasters and cooperation with communities include citizens, administration, and client companies. In order to deal with these criteria mentioned above, it is clear that we must have some communication tools or systems. Without communication in any forms, you are alone by yourself and you may be wondering what to do. The first 72 hours after a disaster are the most critical time for victims. In the first 72 hours, site assessment, emergency mobilization and rescue/recovery efforts monopolize first responders. While this may seem like a shocking affirmation, it is the basis of emergency preparedness. In the first 72 hours, the focus of first responders, local, state and criteria federal authorities, medical personnel and Business Continuity is on assessment of those who are damaged by the earthquake and tsunami, on life support, infirm, disabled, or those trapped. Especially earthquakes which occur in or near major cities are very dangerous for knocked out communications. Telephone lines can be knocked out by saturation or by technical failures. If a person hears about injured people, destruction and casualties, he or she will not rest until being in contact with their loved ones by landlines or cell-phones include smart phones/pads, laptops, PC. This is perfectly normal human behavior. However, all communications (data, voice and text) are wiped all out, including those partly used by emergency services.

Hence you are in the middle of trouble to communicate with people you want to talk, family, business people or government authorities. Even though, you can't call for 119 (ambulance/fire department) or 110 (emergency call/police department) for HELP. You can not call for your family,

friends, your business partners or clients, so you may be loose your business. The important issue here is that you must survive by yourself in order to help another people, the community you belong to, or take any action for your business. That was what happened not only disaster area in Tohoku but also Tokyo Metropolitan area. At the same time, communication got down from foreign nation. Since Cellular phones and landline phone services are suffered major disruptions in the affected area. On the day of the quake, American broadcaster was unable to reach anyone in Sendai with working phone or Internet. Internet services were largely unaffected in areas where basic infrastructure remained, despite the earthquake having damaged portions of several undersea cable systems landing in the affected regions; these systems were able to reroute around affected segments onto redundant links. Within Japan, only a few websites were initially unreachable. Several Wi-Fi hotspot providers reacted to the quake by providing free access to their networks, and some American telecommunications and VoIP companies such as AT&T, Sprint, Verizon, T-Mobile and VoIP companies such as netTALK and Vonage have offered free calls to (and in some cases, from) Japan for a limited time, as did Germany's Deutsche Telekom. It might be difficult to be named on this situation as a Secondary Disaster, but it is clear that the Great East Japan Earthquake made this happen immediately after this disaster occurred.

2-2 Face to Communication Problems

First of all, "Transmitting Information Outside and Information Sharing" in the "Business Continuity Guidelines 1st and 2nd edition." by the Cabinet Office (Disaster Management) will be a focus on these issues. The Cabinet Office describes current problems that after a disaster, it is important to share information with business partners, consumers, employees, stockholders, citizens, and local municipalities. In this context, measures should be taken to prevent a so-called "blackout" situation, where corporate activities are invisible to interested persons, and people do not have the least idea what is going on . This also emphasizes the importance of prior consultation with interested parties. Providing information to business partners and customers in the supply chain is an essential requirement for middle-standing small or medium-sized enterprises as well. When examining a business continuity plan, there are some points to be fully considered in association with the item "transmitting information outside and information sharing" which include:

[1]Establishing systems for information collection, distribution, and public relations

[2]Developing systematic communications with the authorities concerned, residents in the neighborhood, supply chains, etc.

[3] Securing means of communication and information

Also with the relation of this issue here, The Cabinet Office has expressed about "Backing up the Information System" the following. Information systems are among the key infrastructure functions of a business. It is essential that necessary information and data be backed up and stored at two or more places that are unlikely to be affected by a disaster at the same time. In particular, a well-maintained backup system is needed for information systems that support critical operations. If a disaster should occur, the business continuity plan would be put into practice with priority given to the critical operations. However, if the company has moved out of the emergency response phase and finally changed over from alternate facilities and means to regular ones toward the full restoration of its business, problems could arise due to loss or mismatch of data required for regular operations. A detailed comeback plan should, therefore, be developed in advance to prevent such problems. When examining business continuity plans, there are some points to be fully considered in association with the item "backing up information systems" which include:

[1] Clarifying the relationship between the critical operations to be protected and the information system

[2]Developing backup operation, changeover, and comeback plans

[3]Implementing redundancy measures for private electricity generation equipments, power supply, power lines, etc

[4]Active use of document and electronic data storage service in a remote area

In any cases mentioned in both "Transmitting Information Outside and Information Sharing" and "Backing up the Information System", it requires to communicate with information and communications technology (ICT), information technology (IT) professionals, telephone carriers or IT venders in order to solve, or make improvement in communication problems. During non-emergency circumstances, it is easy for anybody to call somebody you need or send text message, emails to your contact person in order to proceed what you want to do. Since widely spread cell-phone (mobile telephone) or rapidly growth of smart devices are the most familiar communication devices for modern people or business person, it becomes quite difficult to proceed anything without it for them. Also PC and laptops are still major tools for your business, and it might be difficult or almost impossible to do any job without them.

During and after the disaster, the authorities and networks such as telephone carriers manage by cutting or limiting VOICE communication based on earthquake alert levels for high magnitudes and limiting bandwidth for medium size earthquakes. The levels of triggering such automatic cuts and according messages would be provided in cooperation with seismologists/geologists based on the authorities. Also they include internet providers are blocking all graphic internet data (pictures / advertisements / videos) for internet data traffic, but text only takes a very small portion of the data bandwidth capabilities. The circumstances demand by reserving enough bandwidth for voice and data for authorities and all kind of rescue services. If the automatic triggering would not be accepted, a similar system can be triggered manually by the government emergency authorities.

It is so clear that emergencies circumstances demand on communication processes which are often significantly different than the demands of non-emergency circumstances.

Emergencies often involve escalating and evolving events that demand high performance and flexibility from the systems that provide emergency communication services. Message prioritization, automation of communication, fast message delivery, communication audit's tags, and other capabilities are often required by each unique emergency situation. Inadequate emergency communications capabilities can have consequences that are inconvenient at best and disastrous at worst. Once again, the Great East Japan Earthquake and the surrounding area destroying tons of houses and escaping millions of people without electricity without internet, mobile phones, or landline communications. Telephone carriers have strengthened its ability to respond to a disaster since the communications problems during the Great Hanshin-Awaji Earthquake in 1995. Communications have been steadily improving, but it is not enough yet.

3. SURVIVABILITY PROBLEMS

What happens to communication networks during a disaster. the three links in the communication chain which are likely to fail during a disaster. The failure of each one of them would cause massive problems. Of course, we can't do anything when all three collapse at the same time as in the case of the Great East Japan Earthquake.

[1]Power:

Without power nothing will work. Some central offices and cell phone sites may have emergency power back up sources such as batteries and stand-alone generators which may suffice for a few hours or days of operation. In cases of the Great East Japan Earthquake, however, power may be interrupted for several days or even several weeks. In a major disaster it is the case that power plants (the Fukushima Daiichi nuclear plant), central offices, or cell towers in the affected areas may be inaccessible for most of that time, making it impossible to change spent batteries or refuel generators.

[2]Local loop:

The last-mile communication of service to the customer depends on copper wires or fiber optic cables extending, either above ground or below ground,
from the carrier's central office to the customer's premises. This last mile connectivity between the business and its telephone provider, Internet provider,
or application service provider may be severely disrupted, if not cut-off altogether, during a disaster as wires and cables are torn and underground tunnels flooded.

Cell towers and the equipment mounted on them are often also destroyed during a disaster, as are the last mile circuits which connect these cell towers to the local Telephone network.

[3]Long haul:

Copper wires and fiber optic cables also connect the local telephone company's central offices to other central offices in the region and to long-distance providers, cell phone carriers, and Internet and data communications service providers around the country and around the world. These inter-exchange or "long haul" circuits provide for interconnectivity and communication beyond the local area. The cables and wires used for long haul are as vulnerable to disruption as those used in the local loop, but there is a difference. There are many more subscribers who use these long haul circuits, and these circuits carry many more calls, so carriers would typically employ "circuit diversity," that is, they would construct the system so that there are multiple paths available for voice and data on which to move. If one path which is part of the long haul circuit is blocked, then the voice or data would automatically use another path to reach their destination. It notes that this may work well in cases of isolated disasters such as localized fires and floods, but when the level of destruction is catastrophic and wide-spread, as was the case in the Great East Japan Earthquake, then this circuit diversity would not be of much help because the alternative paths are also destroyed in the disaster.

4. INTEROPERABILITY PROBLEMS

According to the Partnership for Public Warning, a fundamental problem is the lack of technical and procedural interoperability among warning originators, system providers, delivery systems, and warning recipients. Some originators of warnings must undertake expensive, redundant tasks using multiple, different tools and techniques to take full advantage of today's warning systems. Also, there are multiple ways that an emergency communication system might obtain an original warning. The ability to interoperate should consider the need to be both forward and backward compatible with older and coming technologies in the future. Introduction of a new system that can not interoperate with previously deployed equipment creates potentially serious barriers to effective operation.

5. CONCLUSION

Robust voice continuity will allow enterprises to coordinate recovery actions during and post disaster and enable continuous communications with their customers and suppliers as required by in-house regulations. It starts with careful evaluation of the vulnerabilities of the existing corporate voice continuity solution. In many cases there is no such solution. In many more cases the solution is limited to headquarters of the organization and no provision is made for branch and field offices. Regardless of the situation, it generally results in inadequate coverage of required critical personnel. In almost all cases the solution itself is ineffectual during certain disaster conditions. In other words, there exist coverage gaps in the exiting voice continuity approach contained in the organization's BCP.

Insufficient coverage by the existing voice continuity solution is usually a result of reliance on the infrastructure protection approach. However, it may also result from the degree of coverage required in today's business climate in relation to when the solution was crafted and its design

requirements. IT department is no longer the only department affected by disasters. Also IT personnel the only ones needed to respond during a crisis. What the Great East Japan Earthquake and other disasters have taught is that some organizations are required to successfully resume business operations in the event of a disaster. Voice continuity solutions that were designed to cover a small number of IT personnel are no longer viable in today's business climate where 24x7 operations is crucial.

Finally, to address in the communications portions of the BCP and create a verifiable and auditable solution it is necessary to implement voice continuity that meets the following minimum requirements:

[1] Location Independence:
Executives and staff must be able to receive calls made to their work number regardless of where they are located. Executives and staff must be able to rapidly, and without limitation maintain continuous communications while changing location as frequently as necessary as dictated by changing disaster conditions.

[2] Network Independence:
To assure continuous telephone service, the voice continuity solution must be capable of automatically moving calls through all surviving and operating networks, whether PSTN (landline, cell) or IP (soft phone, VoIP, laptop, PC, PDA) as required by existing conditions to ensure call completion.

[3] Device Independence:
The effective solution must allow executives and staff to utilize any communication device available to them during the disaster. The solution must be capable of delivering telephone service via the user's cell phone, laptop, PC, PDA, landline phone, smart phones/pads or any other standard voice-capable device.

[4] Survivable Telecommunications Network:
The voice continuity solution must be capable of delivering calls throughout the disaster event itself, be self-healing and be relatively immune to the disaster's effects. The service must have geographic diversity and be capable of maintaining service through dynamic re-routing even when service points have been destroyed. The emergency voice provider must have no single point of failure anywhere in their system.

[5] Isolation and Independence from the Disaster Site's Local Loop:
To increase communications reliability, the solution must reduce or eliminate any dependence on the local loop at the disaster site. The emergency voice provider must provide both forwarding capability and independence from the local loop in case carrier forwarding is lost or is unattainable, the executives and staff can still be reached.

CONFIRMATION OF BUILDING SAFETY FOR REGIONAL CONTRIBUTION ACTIVITIES OF COMPANIES IN A TIME OF THE TOKYO INLAND EARTHQUAKE

Hiroaki Maruya[1)]

1) Professor, Center for Urban Earthquake Engineering, Tokyo Institute of Technology, Japan, and Chief Executive Researcher, Policy Research Institute, Ministry of Land, Infrastructure Transport and Tourism
h-maruya@tiara.ocn.ne.jp

Abstract: When the Tokyo Inland Earthquake occurs during working hours, more than three million people are estimated to have difficulty returning home in the Tokyo metropolitan area. The governments have requested companies to ask their workers not to go home on foot in three days because people walking along main roads will disturb rescue and relief activities. Moreover, companies which have a large building in downtown are requested to provide tentative stay facilities for passengers facing difficulty returning home. Considering the probability that major aftershocks occur, safety of the tentative stay facilities should be properly confirmed before receiving passengers. The governments showed a guidelines and it includes a simple check list for safety of building structure and equipments. However the companies seem to worry about a method of confirming safety of the facilities concretely and risk of a damage compensation claim from refugees. Based on the discussion between researchers of building structure, engineers of construction related firms and disaster management staffs of companies, the author proposes several kinds of checklists according to the type of building structure, the methods comparing photographs of the normal state and the damaged state after the earthquake, and so on.

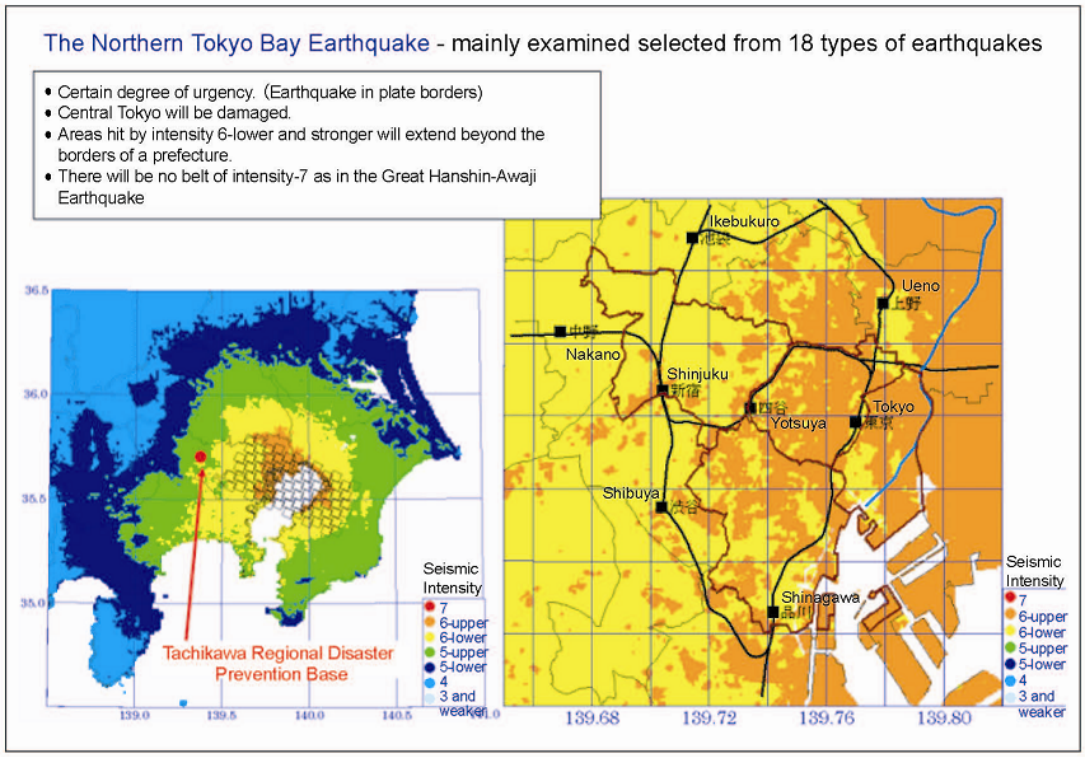
1. INTRODUCTION

In Tokyo, although the Great East Japan Earthquake (GEJE) of March 11, 2011 did not caused serious damage on buildings in general, many persons had difficulty returning home and had to stay for a night in facilities urgently provided public and private organizations. As there is considerable concern about Tokyo Inland Earthquakes (TIE), it has been recognized more than before that the countermeasures of controlling this problem are very urgent.

To tackle with the problem, cooperation of private sectors is necessary in addition to the governments' effort. These days, business operators consider bearing the cost of the cooperation preparing for TIE as a part of corporate social responsibility and the local contribution. However, if there is probability that refugees whom a company accepts are damaged in its tentative stay facility and they claim a high amount of compensation for the damage, the company seems to hesitate to cooperate.

Therefore, discussion is necessary on how to increase the companies' cooperation to the problem.

2. ESTIMATED DAMAGES OF TIE



2.1 The Expected Worst Type

It is scientifically understood that in the greater Tokyo capital area, massive trench-type earthquakes with a magnitude of 8 or greater, like the Great Kanto Earthquake (1923), occur at intervals of 200-300 years. Additionally, it is estimated that smaller several types of TIE (magnitude 7 (M7) class) occur before a M8 scale earthquake.

Japanese government published the estimation that a M7 class will occur in the probability of 70% in next 30 years.[i] The Central Disaster Management Council of Japanese government has carried out damage estimations for 18 types of TIE (M7 class). Among those, the type whose epidemic center is at northern part of Tokyo Bay (assumed scale of M7.3 at 6pm in winter) is estimated to cause most serious damage. It would include a death toll of approximately 11,000 people, total collapse of 85,000 buildings and a maximum economic loss of 112 trillion yen.

2.2 Distribution of a Seismic Intensity

Figure 1 shows maps of the seismic intensity distribution of the expected TIE whose epidemic center is at northern part of Tokyo Bay. On this earthquake, most places in east half of the central districts of Tokyo is predicted to experience a seismic intensity[ii] 6-upper. The standard damages by the intensity 6-upper earthquakes are defined by Japan Meteorological Agency as follows.[iii]

Material of the Cabinet Office (Disaster Prevention)

Figure 1 Distribution of Seismic Intensity during the Northern Tokyo Bay Earthquake (7.3-magunitude)

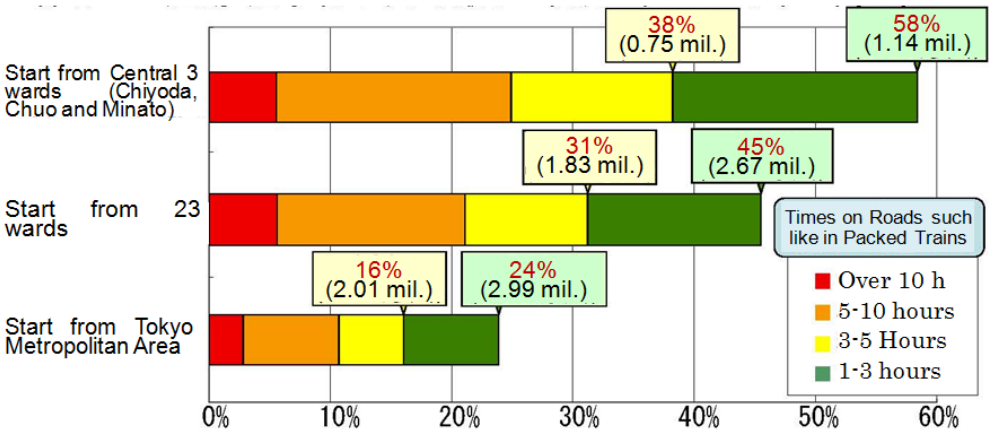
- One cannot stand. One cannot move unless crawling.
- A lot of furniture moves unless it is not fixed, and some of them fall down.
- Of many buildings, tiles on walls and windowpanes are damaged and drop.
- Most of fences made of blocks which are not reinforced are fall down.
- Some wooden houses with high quake resistance have crazing and cracks on walls.
- Many wooden houses with low quake resistance have crazing and cracks on walls. A considerable number of those incline or fall down.
- Some steel reinforced concrete buildings with high quake resistance have crazing and cracks on walls, beams, pillars etc.
- Some steel reinforced concrete buildings with low quake resistance have diagonal or X-shaped crazing and cracks on walls, beams, pillars, etc. Of these, there are buildings that collapse caused by breaking down of pillars of the first floor or intermediate floors.

Additionally, the Tokyo Metropolitan Government published the revised estimation of TIE in 2012 based on the new information of the Philippine Sea Plate under Tokyo. According to this, the max seismic intensity is 7 and area of 6-upper is wider. About 70% of 23 ward area of Tokyo suffers from 6-upper and more.

Cabinet Office also has been revising the damage estimation of TIE since 2012.

2.3 Estimation of Number of Persons Who Have Difficulty Returning Home

The Cabinet Office conducted an examination of TIE including of the problem of persons who have difficulty returning home in 2004. Of the damage assumption on the northern Tokyo Bay type (M7.3), the number of such persons would be approximately 6,500,000 in the Tokyo metropolitan area (i.e. Tokyo and neighboring prefectures), and approximately 3,900,000 in Tokyo.



The newest estimation of persons who have difficulty returning home is 5,166,126 people in Tokyo which were published in 2012 in the Regional Disaster Prevention Plan of the Tokyo Metropolitan Government.

Additionally, the condition of people returning home on foot seems to be very severe. "The Return Action Simulation" of Cabinet Office in 2008 showed that after a TIE, among the people trying to walk home, 1,830,000 persons would be in the condition similar to the state of packed trains (more than six people per square meter) for more than three hours along the street, if any countermeasures had not been executed (Figure 2).

3. SPREAD OF RECOGNITION AFTER THE GEJE

3.1 The Situation of the GEJE in Tokyo

Although the ground motion of the GEJE was a seismic intensity 5-upper or lower in Tokyo, most of the railroad (including the subway) of the metropolitan area stopped

(Share of people by length of time on the road in the condition similar to the state of packed trains.)

Source: Cabinet Office (2008)

Figure 2 Simulation of Returning Home Activity in TIE (Starting Point, Basic Case)

services for check and recovery. The damaged points were not so many but needed considerable time for repair. As a consequence, Japan Railway East, for example, announced the restoration of each route would be only from next morning. The confusion of the railroad traffic continued until afternoon of the next day.

With respect to road traffic, a large quantity of substitute traffic demand was arisen by the stop of railroads (including the car to pick up persons waiting in Tokyo) and closure of the Metropolitan Expressway for check, and they caused a large traffic jam on all the main streets of the whole Tokyo. Therefore, buses and taxis did not function substantially. People who were usually commuting by public transport in the metropolitan area lost the means of returning home and approximately 5,150,000 (Cabinet Office estimation) had difficulty returning home.

There were a lot of persons who walked along the roads for a long time. Some of them were able to come home but many other persons had to stay in the tentative rest facilities which were provided by various public and private organizations in urgent.

3.2 The Ordinance of Tokyo Metropolitan Government

For the problem of persons who have difficulty returning home, the Tokyo Metropolitan Government and the Cabinet Office have already executed some countermeasures.

The Tokyo Metropolitan Government established "the Ordinance of Measures for Persons Having Difficulty Returning Home" at the end of March, 2012, and it will be enacted on the beginning of April, 2013. Outlines of the ordinance are:

- An obligation to make efforts to let the employees of each company wait in its facilities
- An obligation to make efforts to accumulate stockpile (drinking water, food, etc.) for 3 days for the employees of each company
- An obligation to make efforts to protect the customers in stations and large-scale facilities
- An obligation to make efforts to ensure safety of children and students in schools and so on
- To develop the system of safety confirmation and offering disaster related information by public and private sectors
- Cooperation between Metropolitan, national and municipal governments and private companies to securing of temporary stay facilities
- To support returning home (cooperation for securing Support Station for Returning Home)

3.3 The Council on the Persons Who Have Difficulty Returning Home

The Cabinet Office, the Tokyo Metropolitan Government and other related organizations set up "the Council on the Persons Who Have Difficulty Returning Home at the Time of TIE" (CPDR) in September, 2011. The final report of the CPDR is published in September, 2012 showed following items:

(1) To let employees wait in the company's facilities as the control measures against returning home all at once.
- Development of the waiting plan in the company's facilities
- Example of quantity and item of stockpile
- Recommendation of 10% extra stockpile for outer persons who have difficulty returning home
- Securing method of safety confirmation of employees and their family
- Setting the rule of returning home (gradual return, return in group, etc.)
- Development of "Guidelines on Measures on Persons Who Have Difficulties Returning Home in Business Places"

(2) Type of targeted facilities, standard of establishment and role of facility managers of the temporary stay facilities
- After the outbreak, operating up to three days as a standard
- Accommodation of two people per 3.3 square meters as rough standard

(3) Securing of temporary stay facilities in each organization
- Concluding agreements between companies and the municipal governments for providing the temporary stay facilities

(4) Consideration for the facilities to ensure the security
- The quake resistance standard which buildings for the facilities should fulfill
- A Examples of a check list for safety check of buildings and equipments of the facility
- Recommendation of showing the enduring rules for using the facility at the entrance, etc.

(5) Governments' support measures
- Development of the management manual based on local conditions of each facility
- Substantiation of support measures

(6) Development of "Guidelines on Securing Temporary Stay Facilities and their Management"

4. COMPANIES' CONCERNS ABOUT THE COOPERATION AT THE TIME OF TIE

4.1 The Type of Concerns

There have already been a considerable number of companies in the Metropolitan Area indicating the intention of cooperation to the problem of the difficulty returning home. However, the companies would turn to be reluctant if the burden of cost and labor for the cooperation are more than the ability of each company. The companies' various concerns seem to be classified as follows, taking reference to Nakano and Suzuki (2012)).

(1) In ordinary times
  a) Cost of procurement, storage and renewal of the stockpile
    - Those for the company's employees
    - Those for the persons who evacuate to the temporary stay facilities prepared by the company
  b) Necessary investment and preparation for securing safety of the company's temporary stay facilities

(2) When the TIE occurs
  a) Regarding the company's employees
    - Availability to detain employees who hope to return home earnestly
    - Sufficiency of stockpile for employees (and the company's visitors)
    - Ensuring safety of the employees while the company detains them
    - Company's responsibility of safety of its employees when the company permits them to return home
  b) Correspondence when the company establishes its tentative stay facility
    - Method of safety confirmation of the temporary stay facility and its sufficiency
    - How to deal with the people if more than the capacity burst in
    - Availability of separation between the evacuate facility and the company's business area (keep out area for outsiders)
    - Handling and restraining of a person who harms or annoys other evacuees
    - Safety management measures when the company asks temporary refugees for a volunteer activity in the facility
    - The risk of offering wrong security/traffic information by which a evacuee who has departed from the facility meets with an accident
    - Cost of stockpile which the company provides to the evacuees

In the discussion in the CPRD, it attracts attention that the company members requested the system of exemption from responsibility, if they are claimed compensation by an evacuee who has got some damage in the facility, in addition to the public aid to cost of stockpile.[iv]

The author considers that companies should not evade burden to some extent from the viewpoint of self-help and mutual assistance. However such compensation for the damage would threaten the continuation of the company' business if the damage is mortal or very severe injury and the amount of compensation is very large. Therefore it seems rational that governments establish some system to take this damage compensation risk.

4.2 The Extent of Concerns of Companies

At the beginning of December, 2012, the author asked approximately 20 attendants to reply how their concerns were at a study meeting of companies located around the Tokyo Station. The results were as follows:

a) Can you detain your company's employees in general for three days after the TIE occurs?
  "There is worry": about half
  "No worry": approximately one-third

b) Can you really detain the employees who strongly hope for returning home?
  "There is worry": approximately two-thirds,
  "No worry": a few

c) Regarding safety management of your temporary stay facilities, including risk of damage compensation
  "There is worry": more than half
  "No worry": approximately a quarter

d) Risk of too many people bursting into your temporary stay facility, including a stockpile being insufficient for them
  "There is worry": approximately three-fourths
  "No worry": a few

e) Risk of appearing a refugee harming or annoying other refugees, including compensation claim from the damaged refugees
  "There worry": approximately two-thirds
  "No worry": approximately a one-third

f) Necessity of safety management measures (ex. provide with helmets) when the company ask refugees to be volunteers
  "Not necessary": several companies
  "Same measures with the company's employees are necessary": less than half

"Should not ask to be volunteers": several companies (more than the first option)

Most of the respondents were in charge of disaster management and knew the problem of persons who have difficulty returning home well. Therefore, their concerns are thought to be suggesting broad concerns.

5. CONCERNS OF SEFETY CONFIRMATION OF TEMPORARY STAY FACILITIES

5.1 Preventive Measures for Safety on Facilities

"Guidelines of Securing Tentative Stay Facilities and their Management" prepared by the CPRD prescribe that buildings for the tentative stay facility need to fulfill the latest earthquake-resistant ability (i.e. the new earthquake proofing standard introduced in 1981).[v] Additionally, the guideline also requested to prevent the office fittings in the facilities against turnover, fall or move, and prevent the glasses against scattered.

As these preventive measures are effective for the safety of the company's employees and its guests, cost for these is not the waste for the company. However, companies seem to be bewildered how to keep enough physical safety of their tentative stay facility in the aspect for which the guideline does not prescribe in detail. This point is related to the content of the example of the check list in the guideline mentioned in section 5.3.

5.2 Safety Check after the Outbreak

The safe confirmation of a building and equipment of a tentative stay facility after the occurrence of TIE seems to be a matter which each company gets anxious about, considering the probability of aftershocks. The guideline prescribes that the company should perform safe confirmation within six hours after the earthquake. Additionally the guideline also demands the confirmation should be done by using the check list which the company and the local municipal government should work together to make up beforehand.

Considering these procedures, once a company has executed the safety confirmation by using its check list and it has not found any problems, it is desirable from the standpoint of the company that compensation responsibility of the management of its tentative stay facility will be exempted even the tentative refugees sustain damage by some troubles of the building or the equipments.

5.3 The Example of the Checklist

The guideline shows an example of the check list (Table 1)[vi]. Reviewing in detail, there seems to be some items that are not concrete enough.

For example, as for "Incline and sink of the building," of the whole facility, the check list prescribes "the building is prohibited to use" in case of "it looks inclined." While, "the company should ask judgment of an expert" in a case of "it is thought to be inclined." It is not clear how to distinct "it looks incline" and "it is thought to be inclined." In addition, the confirmation method of the degree of incline is not shown, either.

As for "wall and ceiling materials" of non-structure materials, the checklist suggests that "it is necessary to pay attention and ask an expert for examination in case of the gap of ceiling materials is seen." It is uncertain how much gap corresponds to this instruction.

It is understandable that the check list needs to be simple and concise because a person without building structure expertise will use it. However, as it is directly related to the safety of tentative refugees, sufficient quality of safety check are requested seriously.

6. PROPER SAFETY COMFIRMATION ON THE FACILITIES

6.1 Precedent Study in 2010-2011

Not only the temporary stay facilities, but all the company's buildings where its employees work need the safety confirmation to some extent just after an earthquake. It is ideal that the confirmation is executed by engineers of building structure and facilities/equipments with the ability of emergency risk judgment. However, in most cases, it takes a few days or even a few weeks before companies can get these engineers. Therefore companies are recommended to ask these experts to provide with advices on what and how should the person in charge without expertise perform the safety check beforehand.

On October 12, 2011, Center for Urban Earthquake Engineering (CUEE) of Tokyo Institute of Technology and a non-profit organization "Business Continuity Advancement Organization (BCAO)" organized joint symposium of "Damage of Buildings and Business Continuity after an Earthquake" based on several meetings of opinion exchange and related researches since 2010.

From this symposium, the ideas and points to be discussed became clear as follows.

a) For judgment of the building damage, it is necessary to know the characteristics such as structure classification and quake resistance. Therefore, it is desirable that the experts prepare the judgment manual one by one for every building.
b) It is preferable to create the social rule that all buildings are provided with a damage diagnosis manual based on the characteristic of each building, which is similar to a medical record of family hospital for each person.
c) A non-expert person in charge of safety confirmation may have difficulty judging even if he/she has a diagnosis manual. Therefore it seems effective to take photographs of the points to be checked of the building in the ordinary time, and to take the photographs on the same points after the suffering from an earthquake for the comparison. If necessary, the person in charge is able to send both photographs to an expert by electronic method and ask the judgment.
d) The safety confirmation manual which has many pages and from which every user has to look for suitable parts

Table 1 An Example of the Check List for Safety Confirmation on Temporary Stay Facilities

Check Items		Content of Check	Judg -e	Correspond and Emergent Response If Applicable
Whole Facility				
1	Building (Incline, Sink)	Be inclined or sink		Leave the building
		Seems to be inclined		Caution needed →Ask experts to diagnose in detail
2	Building (risk of collapse)	There are many large x-shape cracks and exfoliation of the concrete is remarkable. The exposure of the reinforcing rod is remarkable. The other side of the wall is transparent.		Leave the building
		There are diagonal or x-shape cracks, but exfoliation of the concrete is limited.		Caution needed →Ask experts to diagnose in detail
3	Neighboring buildings and ground	Neighboring buildings, towers, etc. incline to the facility		Leave the building
		The neighboring ground sinks or rise greatly		Leave the building
		There are damages on the neighboring building . There is a crack of the neighboring ground. However, it seems that no effect to the facility.		Caution needed →Ask experts to diagnose in detail
Inside of the facility (Room, Pass, etc.)				
1	Floor	Be incline, or sink		Off limit
		Damage in flooring is seen.		Caution needed / repair required
2	Wall, ceiling materials	Damage is seen in partitioning walls		Caution needed / repair required
		Ceiling materials drop		Off limit
		Gap of ceiling materials is seen.		Caution needed →Ask experts to diagnose in detail
3	corridors and stairs	There are a lot of big X-shaped cracks. The exfoliation of the concrete is remarkable. The exposure of the reinforcing rod is remarkable. The other side of the wall is transparent.		Off limit
		There are diagonal or x-shape cracks, but exfoliation of the concrete is limited.		Continue the checks →Ask experts to diagnose in detail
4	Doors	A door comes off or is transformed		Caution needed / repair required
5	Sash, windowpane	A sash comes off, or is transformed.		Caution needed / repair required
		A window is broken, there is a crack		Caution needed / repair required
6	Lighting equipment, appliance to hang	Lighting equipment or appliance to hang drop		Caution needed / repair required
		The gap of the lighting equipment or appliance to hang is seen.		Caution needed / repair required
7	Household articles (furniture, etc.)	Household articles (furniture, etc.) turn over.		Caution needed / repair required / fix required
		Documents are scattered.		Caution needed / recovery needed
Facilities				
1	Electricity	Power supply from outside stops. (Stop of the commercial power supply)		Securing substitute means / recovery needed →(ex.) To operate emergency power supply
		Lighting is off.		
		Air conditioning stops		
2	Elevator	Elevator stops		Recovery needed →To contact a maintenance supplier
		A warning lamp turns on. A buzzer rumbles.		
		A person is shut in the elevator car.		To contact a maintenance supplier or the fire department
3	Water supply	Supply stops		Securing substitute means / recovery needed →(ex.) To use stockpile
4	Swage, toilet	Water does not flow. (overflow)		Stop using / securing substitute means / recovery needed →(ex.) To use emergency toilet
5	Gas	A bad smell, abnormal noise, smoke are generated.		Off limit / recovery needed
		Supply stops.		Recovery needed
6	Telecommunication, telephone	Operation stops		Securing substitute means / recovery needed →(ex.) To use satellite cell-phone or transceiver
7	Facilities for firefighting	Be out of order or damaged.		Securing substitute means / recovery needed →(ex.) To contact a firefighting facility supplier
Security				
1	Fire shutter	Closed		Recovery required
2	Emergency staircase, emergency exit	Closed (impassable)		Recovery required →When recovery is unavailable, off limit
3	Entering or leaving a room, facility management	Security does not functioned.		Recovery required / Placement of a guard required →Watch out for invasion of a person from outside. (Off limit by the condition)

would be worthless at the time of disaster.

e) The manual will be available by which even a non-expert person able to show "this building is dangerous." On the other hand, the manual by which a person (including the expert) is able to show "this building is safe" should be hardly available.
f) The manual will be a significant material if it can prevent the executive of company from ordering the employees to use or enter their dangerous building.
g) Even using a good manual, it will be difficult to judge an invisible risk from the outside. For example, the damage of structural elements that cannot be seen without tearing off the interior decoration. The manual will be able to show at best what kind of risk lies in the building.
h) To spread a safety confirmation manual, containing photographs and illustration which are usable for judgment will be effective.
i) There seems to be the graded connections in the investigation actions. If a certain abnormality is found, then related matters should be deliberately examined.

6.2 The Second Joint Symposium

Based on the result of this precedent symposium and related study, CUEE and BCAO performed a joint symposium[vii] on January 28, 2013 focusing on the method of safety confirmation of the building and equipments of temporary stay facilities at the time of TIE. The main opinions and ideas were as follows.

a) As it is necessary to perform the safe confirmation in several hours, the check list should be simple, and the person in charge can judge by viewing only. On the other hand, check items should be increased in order to confirm the safety precisely and reliably. This is the dilemma.
b) It is important that once a company performs safety confirmation by the check list, the company is admitted to have achieved the safe consideration duty.
c) Necessary items of the safety confirmation are building structure, non-structural elements (including the ceiling), facilities (including the possibility of fall), utilities and risks of neighboring area (including fire risk).
d) For the confirmation by a non-professional, it is effective to attach photographs of damaged facilities and equipments by an earthquake to the check list.
e) Even the buildings which fulfill "the new earthquake proofing standard" are not necessarily available to use continuously after an earthquake of seismic intensity six upper and more.
f) The items to be checked are different by structure classification (steel reinforced concrete, steel-frame, large space and so on), scale classification (super high, high and middle), etc.
g) As for a steel reinforced concrete building, even if a non-structural wall is shear-failed in X-shape, the building is available to use. On the other hand, if structural column is shear-failed in X-shape, the building is not available to use. It is difficult for non-professionals to distinguish these cases.
h) As for a steel-frame building, even if a board of the wall is broken, the building is available to use. However, non-professionals are apt to judge that it is danger from the appearance. On the other hand, a break of the beam is dangerous structurally. However, as the beam is often covered by fireproof coating and hides in the ceiling, the damage is not easily found.
i) The current earthquake-resistant diagnosis is not applied to a ceiling, and its risk is not checked. (The government is preparing an earthquake-resistant standard of a ceiling.)
j) Although the damage investigation of a building should be performed for every floor, it does not seem to be able to secure enough time.
k) An expert should decide the points to be checked and methods of the safe confirmation beforehand. Particularly, the check method of the main structural parts that are not easily seen should be decided in advance.
l) It is recommended that a person carrying out the safe confirmation goes around the points to be checked with an expert and experiences a judgment trial by the check list as his/her training.
m) As the judgment of the safe confirmation is not easy and covers only residual transformation of the damage, monitoring of the motion of the building should be useful. A method to examine an interlamellar variation between a floor and its upper floor with a marking off tools may be proposed as a simple and inexpensive method.
n) It will be useful to prepare the document indicating the points of the safe confirmation for individual building similar to the medical record. The structural engineers can advise because they recognize from which point the building is more likely to break by an earthquake. The document does not entail additional cost so much if it is prepared with the building certification.
o) When an expert of building structure checks the safety of the building, a judgment will be fast if there is a structural calculation sheet or the above-mentioned document similar to the "medical record" of the building.
p) It is realistic to narrow down the candidates of tentative stay facilities from many buildings in the district. The criteria of narrowing will be the location of the building (including expected number of tentative refugees and neighboring risk), the quake resistance of the building, the size of available floor, the probability of securing persons in charge of safety confirmation (by time zone, the day of the week).

8. CONCLUSION

At the time of the TIE, if persons who have difficulty returning home are not properly control, they will disturb transportation of urgent staff and supplies and fire fighting and so on. Therefore, it is very significant that companies establish temporary stay facilities as many as possible.

However, companies have various concerns when they establish the facilities. Among them, the responsibility of safety confirmation of the facilities is one of the most anxious matters because aftershocks may cause fatal and very severe damages to tentative refugees. It is important to support the companies which have intention to establish temporary stay facilities by providing useful sample of check lists, manuals and advices for proper and practical safety confirmation. The governments, researchers and experts should work together for this support.

Abstract: This document describes the information collecting system under the emergency condition and manage it. This proposal is focusing the management cost and keep good working under the emergency condition. A by-product of the system, user of the system are hard to make a mistake.

1. INTRODUCTION

From late of 20's century, we had some serious disaster, Hanshin-Awaji Earthquake in Japan, Big Tsunami in Indian Ocean and the Great East Japan Earthquake. Its make a heavy loss of lives. In case of Japan, central government founded Central Disaster Prevention Council (CDPR) by the law. CDPR is working to prevent and mitigate the natural hazards. And CDPR is focusing to business continuity of public and private sector such as to create the BCP (Business Continuity Plan)/BCM (Business Continuity Management). Assuming that natural hazard is happened and makes damage in particular area. If it has a restoration power (e.g. socio-economical aspects) from the disaster, it's damage is relative low. Because public/private sector has a BCP/BCM, they know the way to recover from the disaster and can manage limited resources (human/physical resource). Public sector and private sector is setting same aim, saving a life under the emergency activity, however their aims are different under the recovery process.

2. AIMS AND OBJECTS

2.1 Aims

In this paper, it focused on the public sector's activity under the emergency situation when disaster happened. This paper aims to clear the conditions collecting the information about damages by disaster and related information.

Generally, natural hazards (Earthquake, Tsunami and more) has uncertainty. In other words, no one knows exact time these hazards happened. Science has been progressing, unfortunately we can not predict the occurrence time, place and its scale accurately. So it needs that to make the strategy to prevent natural hazards and mitigate the damage by it. If the society has equipped these strategies, this society will recover from the damage.

In this paper, it discusses the way of collecting and using the information by the public sector. Nagoya Port Office set the test case

Focusing an Emergency Activities, its aims to save suffers and enable to prevent the second disaster. Most important things are to get the accurate information about damages and adequate correspondences. Nowadays, some systems to support the emergency activities. Considering the error (system based error and human based error), dual use (Emergency use and Daily use) is suitable. That is, the frequency of using the system is very high under the dual use case. Then stuff who use the system are familiar with the system and system based error is easy to find out. Finally, average cost of the system is getting low.

2.2 Objectives

According to cost of the system, it is to be desired that installation and maintenance cost is getting low. However, it is not able to cut down on expense of the system. Because proposed system is needed the high reliability, the cost is very expensive at the result. Considering the cost benefit, cost is not changed depending on the system requirements. Then solution is frequency of using the system is getting higher.

In this paper, it shows that requirement for integrated information system to collect and deliver the information in public sector.

3. SYSMTEM REQUIRMENT FOR EMERGENCY RESPONSE ACTIVITY

3.1 System Requirements

Focusing the information collect process, that's not to say that all information collect process are automated. For example, it is able to get the transfer pathway data by the people using the GPS sensor and make the alert for a landslip automatically.

Most of the information collect process is human activity based. In other words, observer is going to the damaged area, they observe the damage and evaluate.

Therefore, evaluation result has an ambiguity. To prevent the vagueness, a third person is able to assess the damage. To give an actual example, to take the photo for damaged area with a measure.

It is desired that information collecting and reporting process are real-time processing. That is, conditions of the damaged area are changed time by time. Two of them are quite different, human and physical resources for emergency response are wasted.

According to former researches, members of the disaster countermeasures office are showing a tendency to keep on working in a few days. After emergency activities are converged, they fall ill. To prevent it, transferring their duties, it needs to easy to transfer. However, transferring process is different from normal transferring process. Most important point are quickness and accuracy.

3.2 Framework

As noted that requirements of the system are easy operation and easy to understand the damages. According to these conditions, GIS (Geographical Information System) is suitable.

3.3 Management of the system

To focus the management of the system, there is some possibility of doing that it is not working perfectly. Because, most of them (system) are specialized for emergency use only. Moreover, users of this system are not familiar with it, there is some possibility to make a mistake. To prevent, this system is usually used for lesson for emergency activity or inspect the berth. After all, users are to get skilled and difficult to make a mistake. Furthermore average cost of the system is getting lower. Consequently, the system is able to use daily and emergency case.

4. CASE STUDY OF NAGOYA PORT

4.1 About Nagoya port

According to the brochure of Port and Airport Department, the Chubu Regional Bureau (CRB-MLIT) shows that Nagoya Port is important role, that is the hub function of the industrial sector in Chubu region. Figure 1 shows that current status of international logistics in Chubu Area. It is clear that Nagoya Port is dominating other ports. More specific, imported items are industrial raw materials (e.g. LNG and crude oil) and exported items are machinery products, such as automobiles and industrial machinery.

Otherwise, Chubu region is designated as an affected area for “Tokai Earthquake”, “Tonankai Earthquake” and “Nankai Earthquake”. CDPR is setting an Expert Study Panel for predict the effect by these earthquake. Figure 2 shows that expected Tsunami heights and arrival times at coastal areas of Chubu region. It is clear that outside of Ise Bay, huge Tsunami is arriving up to 30 minutes after the earthquake. Otherwise inner area of Ise Bay, medium level (up to 3 m) is arriving more than 30 minutes after the

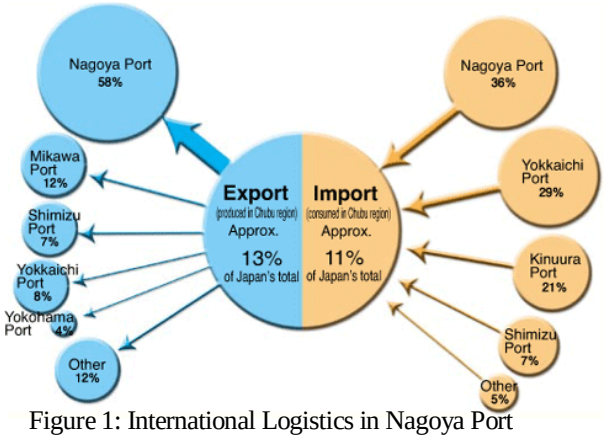

Figure 1: International Logistics in Nagoya Port earthquake.

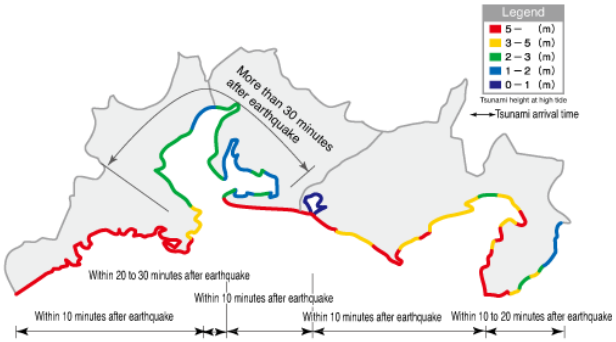

Figure 2: Tsunami Alert Area Map

50 years ago, Ise Bay was attacked by Big-scaled Typhoon, “Isewan Typhoon”. It made a high tide water, enormous people were suffered. Since 2008, the Chubu Regional Bureau (MLIT) has setting an Expert Study Group about high tide water and flood which is tackling to predict the damage by it.

CRB-MLIT is stated that “In the hinterland of Ise Bay, is an area of enormous manufacturing industry concentration and lively economic activity, with Nagoya as its core”. Nagoya Port is located the front line to face a natural hazards such as high tide water, Tsunami. Nagoya Port Office (NPO) has prevent and mitigation programs for each natural hazards, which aims to shorten the recovery time.

4.2 Emergency Program in Nagoya Port Office

NPO is assigned a role in an emergency action program which to assess the berth by their officer under the emergency case (such as Earthquake, Tsunami, High Tide Water). Moreover, if their own berth was safe, they have to support other local area office which damaged heavily.

However, no one has exact information that who came to the office within one hour after disaster happened. Because, disaster has much uncertainty (time, location and scale). And nobody knows exactly time to assess the damages of the berth. It is clear that key player of emergency action program is NPO’s officer.

In this case study, it focuses the officer's activity. An emergency action program is decomposed three parts, first one is checking officers' safety, second one is gathering condition for every officer, last one is to assess damages for each berth.

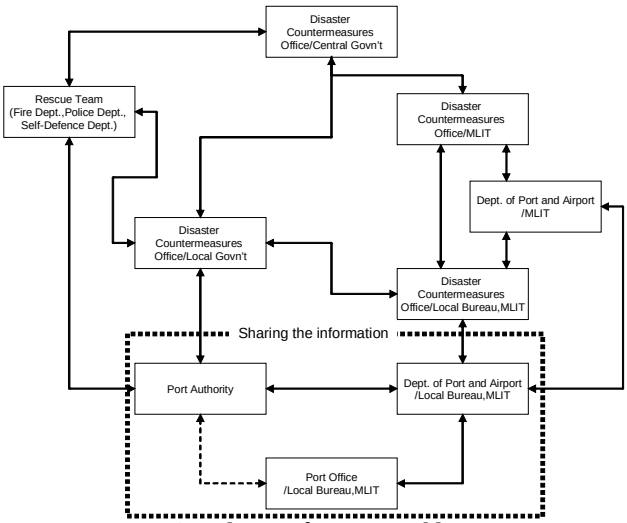

Figure 3: Relations for every public sector

4.3 Experimental System in Nagoya Port

NPO has equipped "Saigai-Infoweb" system which enables to collect the damages at the berth using the mobile phone (Show Figure 4). To specify the system, officers of the NPO are going to every damaged area, then they are taking a photo by their own/public mobile phone which include GeoCode (latitude and longitude). And they send the data (photo with GeoCode) via email by the mobile phone. NPO is collecting above data, they can check the damage easily.

Figure 4:Screen-shot (saigai-infoweb)

However, NPO has only Saigai-Infoweb, which does not cover all emergency activities. Then they can not handle with all data seamlessly. At the result, they can not supply effective information to emergency activities. We are discussing about the integrated system based on the LBS (Location Based Service) to support the emergency activities (Figure 5).

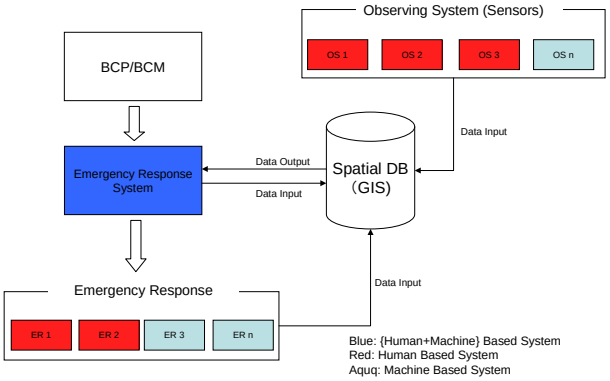

Figure 5: Integrated System Concept

Figure 5 is the overall concept for new integrated system. It mentioned below, NPO is working for assessing their own berth, emergency response and supporting other damaged local office/port. Again it note that these activity is depended on their officers. In other words, NPO is eager to get the information, number of officers within one hour after disaster happened.

Hereafter, introducing collaboration work with NPO, WAVE (Waterfront Vitalization and Environment Research Center) and author.

Figure xxx is concept based system. NPO has the BCP (Business Continuity Plan) for "Tokai Earthquake". We are just making the "Emergency Response System" which based on the BCP of the NPO. This system is issuing some emergency activities, which include assessing the berth, restoration work and supporting the other damaged local office to officers.

As it note that if Disaster Countermeasures Office does not have accurate information about officers' condition, it does not take an effective action. In the right side of Figure xxx, we set the observing system using some sensors. In Figure xxx, "OS 1, OS 2, …, OS n" means that observation system one to n. OS 1 is the "Confirmation of the safety for officers". It enables to confirm the officers' safety and grasp the number of officers to involve the emergency activity. These observing system is get data (e.g. damaged road, berth and more) every moment, then spatial DB is collecting these data. Finally, Disaster Countermeasures Office is easy to make a decision.

From 2008, we are tackling to make the system focused on the Emergency Response System.

5. CONCLUSION

In this paper, it explored the logic integrated Emergency Response System And to inform the Nagoya Port Office experimental study.

DISASTER AND ECONOMIC STRUCTURAL CHANGE AN EMPIRICAL ANALYSIS USING INPUT-OUTPUT FRAMEWORK

Yasuhide Okuyama[1)]

1) Professor, Graduate School of Social System Studies, University of Kitakyushu, and Center for Urban Earthquake Engineering, Tokyo Institute of Technology, Japan: okuyama@kitakyu-u.ac.jp

Abstract: In 1995, the Kobe Earthquake occurred in the second largest economic region of Japan, and its economic damages were accounted around 10 trillion yen. A catastrophic event in this magnitude would have surely created some long-run effects to the regional economy as well as to the surrounding regions. In addition, the recovery and reconstruction activities would have affected the economic structure of the region and interdependencies between regions. While these long-run economic effects may have become sizable, few studies have conducted to empirically measure such effects, due to the significant noises in economic data disturbed by macroeconomic influences from the outside. This paper presents an empirical investigation of long-run economic effects of the Kobe earthquake, using structural analysis methods. The results indicate significant changes in economic structure of the Kobe economy, and the changes are quite different across sectors and among factors. An additional investigation using shift-share analysis yields the regional specific changes; however, the corresponding decomposed factors of structural analysis with shift-share results appear complicated, and the difficulties to factor out earthquake specific effects exist.

1. INTRODUCTION

While significant progress has been made in recent years for the economic analysis of disasters, especially in the field of economic modeling of disaster impact (for example, Okuyama and Chang, 2004; and an excellent compilation of related papers by Kunreuther and Rose, 2004), the recent advancements have been more toward short-run impact analysis rather than toward the evaluation of long-run effect of such events. This tendency is partly resulted from the improved data availability of disaster damages and losses and from the increased multidisciplinary research activities about disasters for more detailed analysis and simulation of the impacts. Meanwhile, the uniqueness of each natural hazard and of the distribution of its damages and losses presents enormous challenges in economic analysis of disaster impact and effects. In particular, while some research suggests that impact from a catastrophic natural hazard may spill over not only to the surrounding regions but also to the distant regions via tightened interdependency of economic activities (for example, Okuyama et al., 1999), some other researchers claimed that the impact of even a large disaster ends up "insignificant total impacts" (Albala-Bertrand, 1993).

These arguments should have led to empirical ex-post investigation of disaster impact and effects; however, few studies have engaged such attempt. Most of those impact studies estimated, not measured, the impacts of a particular disaster based on the available damage data and some economic models, like input-output models and so on. Because in usual macroeconomic indicators, such as gross domestic products (GDPs) or gross regional products (GRPs), economic impact of a particular disaster can be potentially hidden within macroeconomic fluctuations and/or can be more likely to be cancelled out between negative impacts from damages and positive impacts of recovery and reconstruction activities, and also partly because the disaster statistics are not standardized even among developed countries and are even "somewhat crude measures," (Skidmore and Toya, 2002), the extraction of disaster impact and effects from empirically available macroeconomic data appears enormously entangled. Yet, the empirical measurement of disaster impact and effects is crucial to understand how a disaster affects economies and to improve the accuracy of impact estimates derived based on economic model.

In this paper, the economic effects of the Great Hanshin-Awaji Earthquake (also known as the Kobe Earthquake) occurred in 1995 are investigated empirically using a time-series of input-output tables and structural analysis methods. Next section briefly summarized the previous studies and findings related to economic impact and effect of natural disasters. Section 3 presents the data for the case study and the methodology for structural analysis. The results of analysis are illustrated and discussed in Section 4. Section 5 concludes this paper with the discussion of findings and some remarks.

2. ECONOMIC IMPACTS OF DISASTERS

The economic impact and effects of disasters have been studies in various contexts and with a range of time durations. Ex-ante analysis of a hypothetical or potential hazard occurrence is often performed for the decision-making of preparedness and mitigation strategies; and ex-post analysis of actual hazards and disasters is usually carried out to investigate how the event affected the economy and to examine to what extent the relief efforts by various levels of public sector and by other institutions are needed. Economic analysis of disasters can be also divided into two categories: analyses of short-run impact and of long-run effect. Short-run impact analysis of disaster intends to estimate the total (flow) impacts of a hazard for the duration of a few years, and usually employs input-output model, social accounting matrix, or computable general equilibrium model of a particular region, regions, or a nation. By its nature, short-run impact analysis estimates only flow changes and is able to distinguish between the negative impacts from losses and the positive impacts of recovery and reconstruction activities, which serve as concentrated demand injections to the region. Several short-run analyses of disasters were compiled in Okuyama and Chang (2004) and the methodologies are summarized in Okuyama (2007). On the other hand, long-run analysis of disaster effects aims to measure the effects of damages on stock, which may affect the long-run growth path of the damaged region, resulted from the changes in level of physical and human capital accumulation and technology replacement (Okuyama, 2003). The long-run analysis of disasters usually employs econometric models with time series data; and because of this, they cannot distinguish between negative and positive impacts of a disaster and can only derive net effects. Comparing to short-run impact analysis, long-run analyses of natural disasters have been limited, due mainly to the uniqueness of each disaster and also to the difference in details and extent of damage data gathered over time. Notable examples in this line of study using cross-country data to analyze the tendency between various indices of economic growth and disaster occurrences include Skidmore and Toya (2002), Rasmussen (2004), Cuaresma et al. (2008), and Cavallo et al. (2010). Interestingly, some of these studies provide conflicting or inconclusive results in terms of the relationship between economic growth and disasters. In particular, Cavallo et al. (2010) found that natural disasters, even focusing only on the largest events, do not have any significant effect on subsequent economic growth. Empirical evaluation of a particular disaster's long-run effect has been also limited and includes Odell and Weidenmier (2002) for the 1906 San Francisco Earthquake, Hornbeck (2009) for the 1930's American Dust Bowl, and Baade et al. (2007) for the 1992 LA Riot and 1992 Hurricane Andrew among others. Contrary to Cavallo et al. (2010) using country as the unit of analysis, these event specific studies found that a disaster brings some long-run effects, especially to some specific part of economy, such as regional economy (Hornbeck and Baade et al), or financial sector (Odell and Weidenmier). The contrast of the results between cross-country studies and regional and event specific studies supports the Albala-Bertrand's (2007) claim that a disaster causes localized damages and losses on capital and activities but may not affect negatively (or positively) the macro-economy, such as national economy, in both short-term and longer-term. At the same time, this claim implies that localized damages and losses may cause localized economic impacts, which may be significant to the local economy hit by the disaster. This paper investigates that how the Kobe earthquake affected the local economy structurally in the long-run, and whether or not the event follows the above studies' conclusions.

3. DATA AND METHOD

3.1 Data: Kobe Regional Input-output Tables

In Japan, designated large cities with the population greater than 700 thousand, including the City of Kobe, have compiled city's input-output tables every five years. In this study, the Kobe's city input-output tables for 1985, 1990, 2000, and 2005 are employed. Since the Kobe Earthquake occurred in 1995, this particular year's city input-output table was not constructed due to difficulties in data collection. The lack of 1995 table may create some difficulties in analysis, and they will be discussed in the analysis below.

Sector classification of each year's Kobe input-output table is slightly different, as the Japanese national tables' sector classification had changed over these years. The number of sectors had changed from 31 for 1985 to 34 for 2005. In order to make a consistent sector classification over the years but not to aggregate to much for losing the details, the sectors are rearranged to become 28 sectors as shown in table A-1 in Appendix.

In addition, these tables are in current price; thus, they need to be in a constant (real) price. Since the Ministry of Internal Affairs and Communications of the Japanese government published the constant price national tables for 1985-90-95 (in 1995 price) and 1995-00-05 (in 2005 price), the Kobe tables above are transformed to have the constant price (2005 price) based on the sectoral inflators calculated from these two constant price national tables.

3.2 Structural Decomposition Method

A well-summarized description of structural decomposition methods can be found in Miller and Blair (2009). In this subsection, the method of decomposition employed in this paper is illustrated. The key feature of this decomposition is to identify the factors of regional structural change, potentially resulted from the Kobe earthquake, distinguishing the regional specific changes from the macroeconomic trends.

Kobe regional input-output tables are constructed as a competitive import form in the following manner:

$$\mathbf{x} = \mathbf{Ax} + \mathbf{f} + \mathbf{e} - \mathbf{m} \quad (1)$$

where **x** is a vector of total outputs; **A** is a matrix of input coefficients; **f** is a vector of final demand; **e** is a vector of exports; and **m** is a vector of imports. In order to analyze regional specific changes in technology and demand, the tables need to be transformed to a non-competitive one. This can be done by calculating import coefficients based on (1) as follows:

$$M_i = \frac{m_i}{\sum_j a_{ij}x_j + f_i} \quad (2)$$

Using these import coefficients, the relationship (1) can be transformed:

$$\mathbf{x = Ax + f + e - M(Ax + f)} \quad (3)$$

where **M** is a diagonal matrix with import coefficients. Then, this will become:

$$\mathbf{x = \left[I - (I - M)A\right]^{-1}\left[(I - M)f + e\right]} \quad (4)$$

Suppose **D=I-M**, indicating a diagonal matrix of regional purchase coefficients, (4) can be:

$$\mathbf{x = (I - DA)^{-1}(Df + e)} \quad (5)$$

This, in turn, becomes a decomposition of total output into outputs induced by regional final demand and by exports as follows:

$$\mathbf{x = (I - DA)^{-1}Df + (I - DA)^{-1}e = x_r + x_e} \quad (6)$$

where $\mathbf{x_r = (I - DA)^{-1}Df}$ and $\mathbf{x_e = (I - DA)^{-1}e}$. Following Miller and Blair above and Hitomi et al. (2000), these two are decomposed but separately.

Decomposition of $\mathbf{x_r}$

For posing a hierarchy in structural decomposition, $\mathbf{x_r}$ can be rewritten as follows:

$$\mathbf{x_r = (I - DA)^{-1}Df = L_r f_r} \quad (7)$$

where $\mathbf{L_r = (I - DA)^{-1}}$ and $\mathbf{f_r = Df}$. Suppose the changes in output induced by regional final demand between periods 0 and 1 can be set as:

$$\mathbf{\Delta x_r = x_r^1 - x_r^0} \quad (8)$$

Then, plugging (7) into (8) and taking the average of two polar decompositions[1] yield:

$$\mathbf{\Delta x_r = L_r^1 f_r^1 - L_r^0 f_r^0 = \Delta L_r \bar{f}_r + \bar{L}_r \Delta f_r} \quad (9)$$

where $\mathbf{\Delta L_r = L_r^1 - L_r^0}$; $\mathbf{\Delta f_r = f_r^1 - f_r^0}$; $\mathbf{\bar{f}_r = \frac{1}{2}(f_r^1 + f_r^0)}$; and $\mathbf{\bar{L}_r = \frac{1}{2}(L_r^1 + L_r^0)}$. This is the decomposition of upper layer. In the lower layer, $\mathbf{\Delta f_r}$ and $\mathbf{\Delta L_r}$ are further decomposed.

First, since $\mathbf{f_r = Df}$, the changes in $\mathbf{f_r}$ can be decomposed similarly to (9) as follows:

$$\mathbf{\Delta f_r = \Delta D \bar{f} + \bar{D} \Delta f} \quad (10)$$

where $\mathbf{\Delta D = D^1 - D^0}$; and $\mathbf{\bar{D} = \frac{1}{2}(D^1 + D^0)}$. The first component of (10) represents the contribution from changes in regional purchase matrix, while the second components shows the contribution from changes in (total) final demand.

Second, according to Akita (1994 and 1999), the changes in Leontief inverse matrix in general can be decomposed as $\mathbf{\Delta(I - A)^{-1} = \Delta L = L^1\left[(L^0)^{-1} - (L^1)^{-1}\right]L^0}$. Using this notion, $\mathbf{\Delta L_r}$ can be decomposed as follows:

$$\begin{aligned}\mathbf{\Delta L_r} &= \mathbf{L_r^1\left[(L_r^0)^{-1} - (L_r^1)^{-1}\right]L_r^0} \\ &= \mathbf{L_r^1\left[D^1A^1 - D^0A^0\right]L_r^0} \\ &= \mathbf{L_r^1\left[\Delta(DA)\right]L_r^0} \quad (11)\end{aligned}$$

In addition, similar to the above, $\mathbf{\Delta(DA) = \Delta D\bar{A} + \bar{D}\Delta A}$. Then, (11) can be rewritten as:

$$\begin{aligned}\mathbf{\Delta L_r} &= \mathbf{L_r^1\left[\Delta D\bar{A} + \bar{D}\Delta A\right]L_r^0} \\ &= \mathbf{L_r^1\Delta D\bar{A}L_r^0 + L_r^1\bar{D}\Delta AL_r^0} \quad (12)\end{aligned}$$

Using (10) and (12), (9) can be rearranged as follows:

$$\begin{aligned}\mathbf{\Delta x_r} &= \mathbf{\Delta L_r \bar{f}_r + \bar{L}_r \Delta f_r} \\ &= \mathbf{\left[L_r^1\Delta D\bar{A}L_r^0\bar{f}_r + \bar{L}_r\Delta D\bar{f}\right]} \\ &\quad \mathbf{+L_r^1\bar{D}\Delta AL_r^0\bar{f}_r + \bar{L}_r\bar{D}\Delta f} \quad (13)\end{aligned}$$

in which the first component indicates the contribution from the changes in regional purchase matrix, the second component shows the contribution from the changes in technology, and the third component represents the contribution from the changes in final demand.

Decomposition of $\mathbf{x_e}$

As above, the output induced by exports can be rearranged to become $\mathbf{x_e = (I - DA)^{-1}e = L_r e}$. Then, again, using the average of polar decompositions, the changes in output induced by exports can be transformed similarly to (13):

$$\begin{aligned}\mathbf{\Delta x_e} &= \mathbf{\Delta L_r \bar{e} + \bar{L}_e \Delta e} \\ &= \mathbf{L_r^1\Delta D\bar{A}L_r^0\bar{e} + L_r^1\bar{D}\Delta AL_r^0\bar{e} + \bar{L}_r\Delta e} \quad (14)\end{aligned}$$

where $\mathbf{\Delta e = e^1 - e^0}$ and $\mathbf{\bar{e} = \frac{1}{2}(e^1 + e^0)}$. The first component of (14) indicates the contribution from the changes in regional purchase matrix, the second component shows the portion from the changes in technology, and the third represents the effects from the changes in exports.

Adding (13) and (14) provide the decomposition of the total output as follows:

$$\begin{aligned}\mathbf{\Delta x} &= \mathbf{\left[L_r^1\Delta D\bar{A}L_r^0\bar{f}_r + \bar{L}_r\Delta D\bar{f} + L_r^1\Delta D\bar{A}L_r^0\bar{e}\right]} \\ &\quad \mathbf{+\left[L_r^1\bar{D}\Delta AL_r^0\bar{f}_r + L_r^1\bar{D}\Delta AL_r^0\bar{e}\right]}\end{aligned}$$

[1] Dietzenbacher and Los (1998) argued that structural decomposition does not provide a unique solution, having "a multitude of equivalent forms (p.307)", this creates a inconsistency in results among different forms. They recommended to calculate all the possible combinations (if the number of determinants is *n*, the number of equivalent

$$+\bar{\mathbf{L}}_r\bar{\mathbf{D}}\Delta\mathbf{f}+\bar{\mathbf{L}}_r\Delta\mathbf{e} \quad (15)$$

This illustrates the decomposition of total output change into 1) the changes in regional purchase matrix, $\Delta\mathbf{D}$; 2) the changes in technology, $\Delta\mathbf{A}$; 3) the changes in final demand, $\Delta\mathbf{f}$; and 4) the changes in exports, $\Delta\mathbf{e}$.

3.3 Separation of Region Specific Effects: Shift-Share Analysis

Shift-share analysis is one of the decomposition techniques to analyze the influence of economic trend of a region through identifying the components of change. In particular, shift-share analysis decomposes the economic change in a particular region into three factors: national (macroeconomic) influence, industry specific influence, and regional specific factor. Using production level (output)[2] as the indicator of economy's performance, these three factors can be defined as follows:

National Share: $NS_i = x_i^0\left(X^1/X^0 - 1\right)$

Industry Mix: $IM_i = x_i^0\left(X_i^1/X_i^0 - X^1/X^0\right)$

Regional Shift: $RS_i = x_i^0\left(x_i^1/x_i^0 - X_i^1/X_i^0\right)$

where x_i^0 is the output level of industry i in a particular region at the beginning of the period, X_i^1 is the output level of industry i in the nation at the end of the period, and X^1 is the total output of the nation at the end of the period. Then:

$$\Delta x_i = x_i^1 - x_i^0 = NS_i + IM_i + RS_i \quad (16)$$

3.4 Decomposition of Region Specific Effects: Combining Shift-Share and Structural Decomposition Analyses

In order to decompose the region specific effects in the output change, the decomposition of regional shift relationship is attempted. As in Rose and Casler (1996), Dietzenbacher et al. (2000), and De Boer (2009), a multiplicative decomposition of input-output relationship in terms of change in output levels can be performed as follows:

Using equation (5), $\mathbf{x} = \left(\mathbf{I}-\mathbf{DA}\right)^{-1}\left(\mathbf{Df}+\mathbf{e}\right)$,

$$\frac{\mathbf{x}^1}{\mathbf{x}^0} = \frac{\mathbf{L}_r^1\mathbf{F}^1}{\mathbf{L}_r^0\mathbf{F}^1}\cdot\frac{\mathbf{L}_r^0\mathbf{F}^1}{\mathbf{L}_r^0\mathbf{F}^0} \quad (17)$$

where $\mathbf{x}^t$ is the output level at time t, $\mathbf{F}^t = \mathbf{D}^t\mathbf{f}^t + \mathbf{e}^t$. Since $\mathbf{L}^r = \left(\mathbf{I}-\mathbf{DA}\right)^{-1}$, (17) can be further decomposed into the relationship below:

$$\frac{\mathbf{x}^1}{\mathbf{x}^0} = \frac{\left(\mathbf{I}-\mathbf{D}^1\mathbf{A}^1\right)^{-1}\mathbf{F}^1}{\left(\mathbf{I}-\mathbf{D}^0\mathbf{A}^1\right)^{-1}\mathbf{F}^1}\cdot\frac{\left(\mathbf{I}-\mathbf{D}^0\mathbf{A}^1\right)^{-1}\mathbf{F}^1}{\left(\mathbf{I}-\mathbf{D}^0\mathbf{A}^0\right)^{-1}\mathbf{F}^1}\cdot\frac{\mathbf{L}_r^0\mathbf{F}^1}{\mathbf{L}_r^0\mathbf{F}^0} \quad (18)$$

By reversing the time periods in the weights (0 to 1 and 1 to 0) in Equation (17), the second multiplicative decomposition can be obtained:

$$\frac{\mathbf{x}^1}{\mathbf{x}^0} = \frac{\left(\mathbf{I}-\mathbf{D}^1\mathbf{A}^0\right)^{-1}\mathbf{F}^0}{\left(\mathbf{I}-\mathbf{D}^0\mathbf{A}^0\right)^{-1}\mathbf{F}^0}\cdot\frac{\left(\mathbf{I}-\mathbf{D}^1\mathbf{A}^1\right)^{-1}\mathbf{F}^0}{\left(\mathbf{I}-\mathbf{D}^1\mathbf{A}^0\right)^{-1}\mathbf{F}^0}\cdot\frac{\mathbf{L}_r^1\mathbf{F}^1}{\mathbf{L}_r^1\mathbf{F}^0} \quad (19)$$

Equations (18) and (19) are so called polar decompositions; thus, the geometric mean of them can yield the following:

$$\frac{\mathbf{x}^1}{\mathbf{x}^0} = \sqrt{\Delta\mathbf{D}^1\times\Delta\mathbf{D}^2}\cdot\sqrt{\Delta\mathbf{A}^1\times\Delta\mathbf{A}^2}\cdot\sqrt{\Delta\mathbf{F}^1\times\Delta\mathbf{F}^2}$$

$$= \Delta\mathbf{D}\cdot\Delta\mathbf{A}\cdot\Delta\mathbf{F} \quad (20)$$

where $\Delta\mathbf{D}^1 = \dfrac{\left(\mathbf{I}-\mathbf{D}^1\mathbf{A}^1\right)^{-1}\mathbf{F}^1}{\left(\mathbf{I}-\mathbf{D}^0\mathbf{A}^1\right)^{-1}\mathbf{F}^1}$ in Equation (18),

$\Delta\mathbf{D}^2 = \dfrac{\left(\mathbf{I}-\mathbf{D}^1\mathbf{A}^0\right)^{-1}\mathbf{F}^0}{\left(\mathbf{I}-\mathbf{D}^0\mathbf{A}^0\right)^{-1}\mathbf{F}^0}$ in Equation (19), and so forth.

Plugging the relationship (20) in to the regional shift relationship in (16) can derive the following relationship:

$$RS_i = x_i^0\left(\Delta D_i^r\cdot\Delta A_i^r\cdot\Delta F_i^r \;-\; \Delta D_i^N\cdot\Delta A_i^N\cdot\Delta F_i^N\right) \quad (21)$$

Then, in order to make a comparison between regional and national changes, (21) can be transformed:

$$RS_i = x_i^0\cdot\left(\Delta D_i^N\cdot\Delta A_i^N\cdot\Delta F_i^N\right)\times\left(\frac{\Delta D_i^r}{\Delta D_i^N}\cdot\frac{\Delta A_i^r}{\Delta A_i^N}\cdot\frac{\Delta F_i^r}{\Delta F_i^N} \;-\; 1\right) \quad (22)$$

4. RESULTS AND ANALYSIS

Figure 1 below illustrates the distribution of decomposed regional shift of the Kobe economy during 1990 and 2000 using equation (22). With a casual observation, the number of negative regional shifts by sector is greater than the positive ones, highlighting the decline of the Kobe's total output. Especially, three services sectors (22: Port Related Transport Services; 23: Other Transport Services; and 24: Public Services) and sector 3: Food and Kindred Products have notably large negative values, with the sizable part of them is attributed to the changes in final demand (colored in yellow-green), including regional final demand and export (demand from outside of the region). This large share of final demand decline can be also observed in other sectors' negative portion. This tendency implies that the final demand decline is the main regional cause for the decay of the Kobe economy during this period. While it is uncertain with the current decomposition framework whether the decline from regional final demand or export is the foremost cause, this result should be related

[2] Oftentimes, number of employments, rather than output level, is used for shift-share analysis, because it is easier to obtain in a regional context and for regional employment analysis. Shift-share analysis with output level can be found Mayor and López (2008) and Márquez et al. (2009) among others.

to the population decline in the City of Kobe during this period.

In terms of other decomposed factors, regional interindustry linkage (colored in blue) has both positive and negative changes. Major positive changes of this factor can be found in sectors 22 and 23 (but both sectors have the net negative value due to a large negative change in final demand), while the large negative changes are with sectors 8 (Primary Metals Industry) and 19 (Commerce). It is a well-publicized fact that one of the major primary metal companies (Kobe Steel, Ltd.) in Kobe was heavily damaged by the earthquake and re-organized their production system throughout Japan, and this may contribute to the decline of regional interindustry linkage of this particular sector.

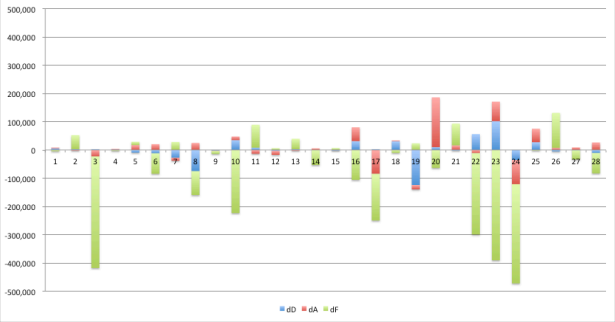

Figure 1. Distribution of Decomposed Regional Shift (1990-2000)

As for the changes in production technology (colored in red), there are some large positive gains in sectors 20 (Finance and Insurance) and 23, while some negative changes are seen in sectors 17 (Construction) and 24. Finance and insurance sector has net positive change of output during this period, their importance in financing the recovery and reconstruction activities may have led to this positive gain. On the other hand, the decline of construction sector in Kobe may be seen as a surprise, because the recovery and reconstruction demand after the earthquake should be mostly on construction sector. As a matter of fact, the regional demand (in yellow green) of construction sector is also a negative value. A caveat for Figure 1 is that these values are changes during 1990 and 2000. Year 1990 was the highest point of the ill-fated bubble economy in Japan, with the construction sector's output was the record high; while in 2000 the reconstruction activities in Kobe still continued, it was five years after the earthquake and in the middle of the Japanese economy's 20-year slump. Therefore, the output of construction sector was declined from 1990 (record high) to 2000 (some reconstruction activities, but generally a slump economy).

5. CONCLUSIONS

The above results have some implications to the recovery and reconstruction strategy for a disaster. First, as seen in Figure 1, the decline of final demand is a major cause for the total output decrease. As in the Keynesian economic view, final demand drives an economy. In a disaster situation, final demand decrease can be caused through population decline, either loss of lives, out-migration, or the combination of them. It is known that the City of Kobe lost significantly its population after the earthquake, most of them evacuated or migrated out of the city, and the city requires 10 years to regain the previous population level. If this final demand decline were caused by regional demand decline, it is crucial to regain population as quickly as possible after the event in order to maintain its final demand level. On the other hand, if this final demand decline were resulted from the decrease in export, its recovery may be more complicated. The drop of exports is originated from the change in purchase location by other regions, and it may be difficult to bring these lost exports back to the original location of purchase. Hence, it is also important that the speedy recovery of damaged production facilities to maintain the customers in other regions.

As for the weakened regional interindustry linkages, except for some light manufacturing sectors, such as 10: Industrial Machinery and Equipment and 16: Miscellaneous Manufacturing, if this trend were caused by the regional hollowing-out process, it would be very challenging to counter this trend. At the same time, services sectors including transportation sectors, for example sectors 22, 23, and 25, can be arranged to strengthen the regional interindustry linkage through reconstruction policy, such as promotion of local service utilization.

On the contrary to the regional linkages, it is rather problematic to encourage local industry to alter their technology for growth of the regional economy in a disaster situation, since many companies would be in their survival stage recovering from the damages and trying to maintain their customers. Unless the situation forces it to adapt a new production system as in 20: Finance and Insurance, this factor can be left for each company's discretion.

Abstract: The intensive reconstruction works of the Tsunami affected area by the 2011 Tohoku Pacific Earthquake have been launched since February 10, 2012 with the inauguration of the Reconstruction Agency, which consists of about 300 seconded staffs by the respective ministries of central government with its headquarter in Tokyo and three local offices in three affected prefectures. The main functions of the Reconstruction Agency are to mediate conflicts between central ministries, to designate the special district for reconstruction, and to allocate the special subsidy for promoting reconstruction. This paper reviews the ten-month activities of the Agency and to identify the current problems to be solved. The paper, thus, tries to verify whether the establishment of such Reconstruction Agency will be effective as a regular institutional scheme for reconstruction after large-scale disasters in future.

1. INTRODUCTION

Two years have passed since the occurrence of the Tohoku Pacific Ocean Earthquake on 11 March, 2011. The intensive reconstruction works of the affected areas, however, have been started since one year ago when the National Reconstruction Agency (note as the Agency hereafter) was inaugurated, as there had been no regular rule of institutional arrangement for reconstruction after disasters in Japan so far. Thus, after a violent and heated argument about the rights and wrongs of necessity of new special organization for reconstruction, it was decided that the Agency could be established as a temporally organization valid for ten-year period of time, under the legal authorization of Basic Reconstruction Law of the Tohoku Pacific Earthquake enacted on 24 June 2011. The detail institutional structure and functions of the Agency were then clarified by the Law for Establishment of a Reconstruction Agency enacted on 16 December, 2011. The Agency has, thus, started its business since 10 February, 2012. It had passed almost one year after the occurrence of the Earthquake.

The president of the Agency is concurrently held by the Prime Minister, so as to represent its full responsibility for reconstruction activities. The total number of the staff is 330 persons, who were seconded by the respective Ministries of central government. The headquarters of the Agency locates in Tokyo, and three local departments with the stuff of 30 persons and two branch offices respectively are set in the three affected Prefectures: Iwate, Miyagi, and Fukushima.

The Agency has three principal functions. They are;

(a) To appropriate, in a lump, the expenses for all public projects which are related to reconstruction works and originally handled by respective Ministries of the central government,
(b) To designate “Special District for Reconstruction”, and
(c) To allocate a special subsidy to reconstruction projects proposed by the affected local governments.

The Japanese Government decided to spend about JPY 19 trillion (US$ 224 billion, at the rate of US$ 1=JPY85) in the first 5 years of ten-year reconstruction period which were designated as the intensive reconstruction period. Thus, JPY 14 trillion (US$ 165 billion) has already been used for mainly rescue and relief activities, debris treatment, urgent recovery of public facilities, temporally housing construction and so on, before the establishment of the Agency. In FY 2012, JPY 3.775 trillion (US$ 44 billion) has been earmarked in the budget for the reconstruction. Out of them, JPY1.732 trillion is allocated to the governmental general account as the special use for reconstruction related programs including improvement of disaster management capacity of all over Japan from the nation-wide point of views. Thus, the amount of the special account that the Agency can directly control is about JPY 2,043 billion (US$ 24 billion) (Table1).

This paper reviews the ten-month activities of the Agency and identifies the current problems to be solved, and based on that, tries to verify whether this Agency will be able to effectively work as a regular institutional scheme for reconstruction after large-scale disasters in future.

Table1. Special account handled by the Agency (billion yen)

	Item	Amount
Reconstruction management cost	Lump sum subsidy to LG	286.8
	Adjustment cost	5.0
	Fukushima resettlement	4.2
	Interest subsidization	1.1
	Administration cost	3.3
	Sub Total	300.4
Lump sum account of Ministry's project	Public project	488.1
	NPP disaster	456.9
	Debris treatment	344.2
	Financing to business	121.0
	Others	332.7
	Sub Total	1,742.9
Grand Total		2,043.3

(Reconstruction Agency (2012))

2. PROGRESS OF RECONSTRUCTION

First of all, the paper reviews the current progress of the reconstruction based on the report of the Agency (2012).

2.1 Debris treatment

Debris treatment is the first and the most urgent job to initiate quick reconstruction. Total volume of debris by collapsed houses or so was about 18,020 thousand ton. In addition, 9,560 thousand ton of Tsunami sediments were remained. The central government planned to completely dispose them by the end of March, 2013. As of the end of October, 84% and 58% of them were removed but only 30% and 11% were disposed respectively. The delay of disposal was mainly due to lack of cooperation by other local governments which were afraid of contamination with radioactivity at the early stage.

2.2 Recovery of public infrastructure

Since the budget has been smoothly executed, the affected basic infrastructures including lifelines and public facilities have been quickly recovered as follows:

As to highway and national road, the recovery ratio is 100% and 97% (as of July, 2012) respectively. Railway was recovered by 89% on an operation base. The airport was recovered by 100%. With regard to major distribution harbor, 79 harbors out of 101 harbors have been under repair (78%), and are expected to be completed by the end of March, 2012.

As to fishing port, 319 ports were destroyed by the tsunami. Out of them, 111 ports (35%) were recovered on their unloading function of piers as of October, 2012. A heap of debris sunk under the fishing ground was taken off by almost 100%. Eventually, a catch of fish has come up to 65% of that before the earthquake during the period from June to October, 2012.

With regard to farm land, the total area of 21,480 ha were damaged by infiltration of seawater, and at the end of September, 2012, the cultivation could be resumed in 8,190 ha (38%) of farm land. It is planned to complete in three years.

The recovery of other public services is as follows.

- Recovery of lifelines:
  Electricity (96%), Gas (86%), Water supply (98%), Telephone (99%), and Mobile phone (99%)
- Recovery of public services:
  Post office services (91%), Mail delivery services (80%), Admission to hospital (81%), and School education (100%)

2.3 Special districts program

The scheme of "Special District for Reconstruction" is authorized by its own law enacted on 14 December 2011, aiming to encourage the creative and flexible reconstruction programs which meet to cultural and geographical features of the affected regions, and to achieve their quick and smooth implementation. Thus, in a designated district, regulations and formalities for project approval are simplified, tax and financial exception can be applied, and authorized land use can be exceptionally readjusted if necessary. The scheme is applicable to the 222 affected local municipalities of 11 prefectures.

Those municipalities which have an intention to be designated as the Special District are supposed to submit either of the following planning documents to the Prime Minister.

a. Reconstruction Promotion Plan
   To loosen and simplify regulations and formalities, and to apply exceptional tax policy
b. Reconstruction Implementation Plan
   To apply special formalities and one stop claim counter to readjustment of pre-earthquake land use plan to new reconstruction plan
c. Reconstruction Subsidy Payment Plan
   To estimate budget frame work of special subsidy needed for reconstructing severely affected area

As of 14 December, 2012, the thirty districts were designated by the Agency (Table2). Since some of them are thought of as similar schemes, they can be roughly classified into six types.

The first type, in which 14 districts can be aggregated, aims to apply the exemption from corporation tax to newly locating industries.

The second type, in which four districts can be categorized, tries to improve welfare, health, and medical services by relaxing a deployment standard of medical doctor and restrictions on selling medical appliances.

The third type, consisting of four districts, aims at relaxation of restrictions for land use so as to be able to construct prohibited buildings.

The forth type, consisting to four districts, is for applying interest supplementation to newly locating tourism and manufacturing industries.

The fifth type, consisting of two districts, aims to extend the regulated period of temporal buildings, 2 years and three months, by an extra year.

And the final type, aggregated by two districts, is for

permitting unemployed persons caused by the earthquake to interrupt the enrollment in pension program.

Table2. Designated special districts for reconstruction

Prefecture	Tax free	Medical services	Land use	Interest	Temporary building	Pension	Total
Aomori	1			2			3
Iwate	1	1	1				3
Miyagi	9	1	3				13
Fukushima	2	2		2	1	1	8
Ibaragi	1					1	2
Tochigi					1		1
Total	14	4	4	4	2	2	30

2.4 Allocation of special subsidy

In this scheme, the reconstruction projects which can be subsidized are divided into two categories: Basic projects and the related promotion projects. The basic projects are regarded as the very fundamental elements of reconstruction, and thus, 40 structural projects under the jurisdiction of the five central ministries are identified. The main projects are as follows:

- Fisheries facilities and fishing port construction
- Repair and maintenance of farmland
- Construction of public emergency houses for victims
- Mass relocation program of community village for protecting from a disaster
- Urban redevelopment and land readjustment project for urban rehabilitation
- Disaster resilient projects for fishery village
- Protection against liquefaction in built-up urban area
- Protection from landslide in developed residential land

Under this scheme, the special subsidy equivalent to half of the project cost, which normally local governments have to shoulder, can be provided by the central government. In other words, 100 % of the project cost is supposed to be shouldered by the central government.

As to a promotion project which is closely related to the basic project and responsible for being independently implemented by the local government, the central government provides 80% of the project cost as supplemental subsidy. Thus, the local government shares only 20 % of the project cost.

The Agency invited the affected local governments to propose the reconstruction projects which are applicable to this subsidy. Up to the end of December 2012, the invitations were made four times.

1st time, 2 March, 2012
2nd time, 25 May, 2012
3rd time, 24 August, 2012
4th time, 30 November, 2012

The subsidies allocated amounts to JPY 1370 billion for the total project cost of JPY 1,683 billion (81%). Among the prefectures, Miyagi shares 55% of total subsidy (Table3). Since the capacity of the local governments for implementing these proposed projects is limited, the practical implementation ratio is not so high.

Table3. Allocation of special subsidy (billion yen)

Prefecture	Total project Cost(A)	National. Subsidy(B)	% (B/A)	% Share
Hokkaido	0.02	0.02	100%	0.0%
Aomori	3.74	3.09	83	0.23
Iwate	493.38	403.55	82	29.45
Miyagi	922.12	751.96	82	54.89
Fukushima	214.29	173.73	81	12.68
Ibaragi	37.33	28.73	77	2.10
Tochigi	0.81	0.61	75	0.04
Saitama	0.05	0.04	80	0.00
Chiba	9.87	7.67	78	0.56
Niigata	0.10	0.09	90	0.01
Nagano	1.18	1.10	93	0.08
Total	1682.89	1370.47	81	100.0%

2.5 Housing reconstruction of local government

The Tohoku Pacific Ocean Earthquake gave vey severe damage to the 48 municipalities of 6 prefectures, where the reconstructions of urban area have to be made from scratch. The central government thus dispatched planning experts to these affected municipalities, and supported them to make the reconstruction plan. Eventually, 43 municipalities excluding 5 municipalities contaminated with radioactivity in Fukushima could afford to formulate the plan by the end of December 2012.

The key component in their plan is how to resettle the affected village communities in a safe condition. For this purpose, three schemes are provided under the full financial support of the central government.

The first one is to relocate a village community as a whole to safe elevated land where no tsunami risk will be anticipated in the future. This scheme is called as "Mass Relocation Program of Community Group to Protect from Disasters (note as Mass Relocation Program, hereafter)". The Program can be applied under the condition that more than five households in a community agree with relocation. The municipal government is supposed to buy the land owned by the relocating households, and to designate them as "a vulnerable area to disaster", where inhabiting is strictly prohibited (Figure1).

Currently, the Program is under consideration about 276 villages with 26,000 households in 23 municipalities. And As of 25, December 2012, the implementation plan was already authorized by the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) for 159 villages with 24,148 households in 23 municipalities (Table4).

The second is to raise low and subsidized land where tsunami risk is very high, by means of heaping up rock and soil, followed by land readjustment project for consolidating urban area (Figure2). The scheme was applied to 57 districts, and the implementation plans have been authorized on 34 districts, as of 30 November, 2012.

Table4. Mass Relocation Program

Prefecture	No. of municipalities	No. of villages	No. of households
Iwate	7	44	5,183
Miyagi	12	108	16,652
Fukushima	4	7	2,313
Total	23	159	24,148

(As of 25 December, 2012)

Figure1. Image of community relocation to elevated land

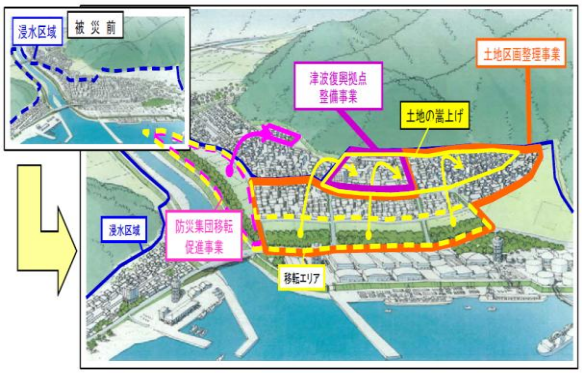

Figure2. Land raising and readjustment

The third is public disaster-house construction project for those victims who cannot afford to build their houses by themselves due to low income. About 24.000 units of houses are planned to be constructed in the three affected prefectures. Looking at the progress of implementation at the end of the October, 2012, however, it is estimated that only 57% of the houses will be able to be completed by the end of March, 2015, when the temporal houses have to be vacated. (Table5).

Table5. Public disaster-house construction (units)

Prefecture	Plan	Under construction	Land acquired	To be completed by the FY2014
Iwate	5,594	303	962	5,118
Miyagi	15,317	455	3,219	5,852
Fukushima	3,019	90	1,023	2,723
Total	23.930	848	5,204	13,693

(Yomiuri News Paper, 19 November, 2012)

2.6 Recovery of Industries

As to mining and manufacturing, the index of industrial production of the three affected prefectures recovered to 90.7% in June, 2012, while it was 97.5% before the event.

With regard to agriculture, about 38 % of farmland damaged by seawater was refreshed, and 40 % of farming bodies out of 10,200 bodies could afford to resume their cultivation. As to fisheries, 66 % of facilities for processing marine products have been recovered, and a catch of fish came up to 65 % to that in the pre-event. The recovery of tourism, however, is far behind. The tourists visiting the affected three prefectures in June decreased by 21% compared to the normal year.

In order to promote recovery of the affected smaller businesses, the Small and Medium Enterprises Agency (SMEA) under the MITI provides "The Subsidy to Recovery and Reconstruction of Equipment and Facilities for Smaller Group Enterprises (called as Group Subsidy, hereafter)" to those enterprises which play very important role in the region and suffered from very severe damage by the earthquake.

In this scheme, 75% and 25% of the project cost are shouldered by the national and prefectural government, respectively. Until the end of November, 2012, the SMEA invited the applications six times, and approved 400 groups with 8,685 enterprises. The total amount of subsidy paid was JPY 359 billion (US$ 4.2 billion). This scheme is very much appreciated by small and medium enterprises and thus the applications were far beyond the budget framework. Roughly speaking, the gap between reservation fund and requesting budget is three times, resulting in very low adoption ratio (Iwate-Nippou (2013)).

Table6. Allocation of group subsidy

	No. Groups	No. of Companies	Amounts (JPY billion)
Aomori	10	208	8.6
Iwate	63	931	64.6
Miyagi	133	3,987	204.1
Fukushima	140	2,104	61.7
Ibaragi	50	1,325	17.4
Chiba	4	130	2.6
Total	400	8,685	359.0

(Approved by the end of November, 20122)

3. CURRENT PROBLEMS IDENTIFIED

3.1 Public infrastructure

The most of major public infrastructures seem to be successfully recovered so far. The point is, however, whether all infrastructures should be recovered as they were. In particular, the production system of fishery in the region had been very traditional and individually-oriented with small scale. The reconstruction must be very good opportunity for it to be restructured and modernized into a large-scale and corporative body. In this sense, it is not always necessary for

all collapsed fishing port to be recovered, or to be partially scrapped and integrated with major large ports.

With regard to agriculture, the situation is the same. The resumption of cultivation as it was done should not be the target of reconstruction, but some more value added should be given to its production system by integrating with processing and distribution.

3.2 Special reconstruction district

As seen in the special districts program (2.3), the formalities for requesting the scheme is rather complicate and a pile of documents have to be prepared, while the programs planned by the local governments are quite similar. Therefore, the Agency should provide a prototype program so that the local governments can just select it, resulting in lightening their burden.

3.3 Housing reconstruction

The housing reconstruction makes very slow progress. As of 6 December, 2012, the total number of evacuees is 321,433 persons, who are living in temporary houses, public apartment houses, and private rental houses.

The basic reasons why housing reconstruction cannot be made smoothly lie on the difficulty of land acquisition for new residential area, while former areas are vulnerable to tsunami and partially have subsided about 60 to 100 cm.

In addition, there is an institutional reason that makes new community resettlements delay. As mentioned earlier, the Agency has an authority to appropriate, in a lump, the expenses for all public projects which are related to reconstruction works. The implementation of the project is, however, rested with the respective central government. A new community must be composed not only by houses but also by nurseries, schools, shops, industries, and so on, which are constructed by the guidance of separate central governments, resulting in the absence of integration.

In order to accelerate community resettlements, therefore, a coordination body which has strong authority is definitely needed..

3.4 Recovery of industries

As mentioned, the group subsidy scheme is very much appreciated by the affected smaller businesses for their effective recovery. However, only 30% of the applicants could be funded due to the limit of reservation fund. Apart from insufficiency of the budget to the victim's needs, some other problems are also identified. First, it can be used only for recovering to the original business shape. However, the previous system before the event cannot be well worked unless the surroundings regional economic market is recovered simultaneously. Secondly, the scheme does not allow reinstalling equipment and preparing materials without construction or repair of buildings. Thirdly, the payment of subsidy is supposed to be made after the all project is completed. The enterprises thus have to start the reconstruction by borrowing money beforehand. It is, therefore, strongly recommended that the scheme should be practically reconsidered.

4. REVIEW BY RECONSTRUCTION PROMOTION COMITTEE

For the purpose of reviewing, promoting, and guiding the reconstruction activities, the agency formed "The Expert Committee for Reconstruction Promotion", by inviting 14 professionals affected from the different fields, including three governors of the prefectures. The committee has released the interim report since 28 September, 2012.

The outline of the recommendations is as follows:

a. Early completion of community resettlement by accelerating housing reconstruction,
b. Comprehensive support to evacuating victims through restructuring their life,
c. Assistance to local industries for creating job opportunity,
d. Reconstruction of Fukushima region affected by radiation accident,
e. Cooperation of local municipalities, supporting staff, and victims through sharing information of good practices, and
f. Archives of this Tsunami disaster to be transmitted to next generation.

The committee recognizes that the pace of community reconstruction is very slow and recommends the additional supports of human resources, simplification of formalities, mobilization of the existing Urban Redevelopment Agency (UR), and so on. It also stresses the importance of project integration.

These recommendations have a point. However, they are principally proposed on a base of the current functions of the Agency, and more substantial points may lie in its institutional setting itself.

5. CONCLUSIONS

Regardless of one of the most disaster-prone countries in the world, Japan has not set up a regular rule of institutional arrangement for reconstruction after disasters, and coped with them by a makeshift legislation, even in case of the Hanshin-Awaji Earthquake in 1995. Thus, as mentioned in the first chapter, a heated discussion about the rights and wrongs of necessity of a new organization (the Agency) had been made, resulting in the delay of intensive reconstruction.

Through the overall review of the ten-month activities of the Agency, the author tries to verify whether establishment of the Reconstruction Agency will be effective scheme as a future model for reconstruction after great natural disasters.

As argued in its birth, the first verification points of the Agency is on how much authority should be given over the existing Ministries, in order to avoid their interruptions and to overcome their sectionalism.

To be its symbolic function of authorization, the Agency could operate a one-stop claim counter which could accept all types of requests for budget or approval of reconstruction projects planned by the affected local governments, which had to be normally submitted to respective Ministers separately. It was expected to simplify complicate and

troublesome petition process between the different central governments. This system has functioned to some extent, and been appreciated by the local governments (MSN Sankei News, 2012). However, the authority to implement the projects was rested with the respective ministries, and each project component thus is supposed to be separately guided by them, resulting in arresting smooth and comprehensive achievement of the projects due to sectionalism of the ministries.

With regard to the limit of authorization of the Agency, it can also be pointed out that not all reconstruction budgets are under the control of the Agency. As mentioned in the section 2.6, the group subsidy for promoting recovery of small industries is under the MITI. Needless-to-say, a community life can be recovered by together with housing, and commercial and industrial activities. The independent budget allocation system disturbs the formation of integrated community.

The lack of human resources is also another severe problem for the affected local governments. At the early stage, the Ministry of Internal Affairs and Communications issued the official notification to all local governments in the country, requesting for seconding their staff to assist the affected governments, and eventually, about 1700 officials have been dispatched by the end of September, 2012. As the reconstruction projects come into the implementation phase, however, more civil engineers who can draft specifications for development projects and order construction works to private companies has been needed. Since the assistance by non-affected local governments is limited, the affected prefectures are currently advertising for temporally staff; 200 persons in Iwate, and 129 persons in Miyagi. Thus, they have to be additionally involved in screening and appointment works of candidates. It is therefore expected that the Agency has an authority of recruiting the engineering staff and dispatching to the affected local governments when needed.

Thus, more broad and strong authority to ensure the comprehensiveness and consistency of the reconstruction projects should be definitely given to the Agency.

The second argument is more or less related to the regional development strategy itself for the reconstruction. Obviously, the earthquake caused severe damage to agriculture and fisheries in the Tohoku Pacific Ocean region, one of the best farm and marine production sites in Japan. As mentioned in the section 3.1, the production system of the region had been very traditional and individually-oriented so far. Shouldn't recovering the region, therefore, be taken as an opportunity to modernize its production system in order to meet global market standards in terms of cost effectiveness?

An overall development strategy for Tohoku region beyond prefectural jurisdiction does not appear in the plans drawn by the affected local government. Such structural change can only be made by the strong initiative of the central government, and not by simply responding to the requests of the local governments. Need-less-to-say, the recovery and reconstruction plan from this regional development point of views including structural change of farm and marine production system is very comprehensive and has to be integrated with variety of components such as construction of a large-scale processing base, installation of regional distribution network of road and railways, and so on, which are normally controlled under the respective Ministry's jurisdiction of central government. Since it must be drafted across their sectionalism, the Agency is therefore the most appropriate body to arrange it, though it has not such function at present. In order for the Agency to function as reconstruction planning body, however, an immediate start of its work must be vital on the base of regular legal arrangement.

The author thus concludes that the current Reconstruction Agency plays its role to promote reconstruction works at a certain level. The establishment of such Agency, therefore, makes a sense. However, in order for it to be more effective, much greater authority including recruitment of human resources and project implementation, and additional functions of planning integration from regional point of views that overcome respective central ministry and the affected local governments should be definitely given.

Abstract: In this study, effects of "planned electric power failure", which was conducted just after the Tohoku 2011 great earthquake, on railway services in the Tokyo metropolitan area (TMA) are analyzed in terms of the changed in railway passengers' generalized cost for route choice. We employ the optimal strategy model proposed by Spiess and Florian (1989) to model their route choice behavior. The numerical analysis with the real-scale rail network in TMA implies that the effects of electric power failure are not same across the areas in TMA. In particular, passengers from inland areas might have had bigger impact, while passengers from maritime areas as their origins would have had smaller impacts. It can be said that impact of the degradation of the level-of-service are different because of the topological forms of the railway networks.

1. INTRODUCTION

The Tohoku 2011 great earthquake that occurred on March 11 of 2011 in Japan had damaged not only Tohoku region which was directly attacked by Tsunami but also other regions which were indirectly affected. In particular, Tokyo Metropolitan Area (TMA) was significantly affected by the earthquake in various aspects. Among others, the degradation of the level-of-service of the railway transport services in the TMA which was accompanied by "planned electric power failure (PEPF)" was the one of the most serious side effects of the earthquake which affected the people living in the TMA.

The railway companies in the TMA also had faced with a lot of difficulties about the degradation of their rail networks after the earthquake. Until getting back to steady states, they had continued to save the use of electricity energy with "reduction of the frequency of railway trains running", "stop of mutual line operation" and "suspension of express trains" among others.

Although there have been a lot of trial calculations about the economic losses caused by the PEPF in the past, there have been no trial calculation focusing on disutility of traveling railway passengers. Figuring out it must be helpful also for developing strategies of railway companies for future earthquakes.

Considering the above mentioned situations, the main purpose of this study is to quantitatively evaluate the impact accompanied by PEPF on the disutility of railway passengers in the TMA rail network. The evaluation of railway passengers' disutility is carried out with the concept of "hyperpath-based modeling", particularly for considering the changes of route choices between before and after the earthquake. This evaluation method is originally proposed by Kurauchi et al. (2006) employing the original idea by Spiess and Florian (1989). Kurauchi et al. (2006) accommodated the model to the bus transport in the Kyoto urban bus network for evaluating the utility. In this particular study, the same methodology is applied to the railway transport in TMA for evaluating the disutility mainly due to the network degradation caused by the earthquake.

2. PROCEDURE OF COMPUTING GENERALIZED COSTS OF RAILWAY PASSENGERS WITH "HYPERPATH-BASED MODELING"

2.1 Definition of Hyperpath

A hyperpath is defined as a set of routes from one origin to one destination and proposed by Spiess and Florian (1989). They call the modeling considering hyperpath "optimal strategy". The modeling assumptions about traveler behavior, congestion effects and the level of service supplied by the transport system are as follows:

- passengers have no explicit knowledge about carrier arrival times at transit stops and the available capacities of arriving carriers;
- the vehicle arrivals of different lines at the stop are not synchronized and for each line, follow a Poisson distribution ;
- passengers arrivals at stops are not timed to coincide with vehicle arrivals; and

- passengers try to minimize their total expected travel time to the destination.

Then passengers' route choice can be modeled as the optimal strategy, rather than the single shortest path between the origin and the destination, which is topologically represented as the shortest (or minimum cost) hyperpath on "Hyperpath-based modeling". For more detailed explanation, an example transit network, which is shown in Figure 1, is presented.

In this modeling, it is assumed that passengers only choose the routes that are included in the minimum cost hyperpath (the shortest hyperpath), from their origin to their destination. The generalized cost of the hyperpath is composed of a weighted linear sum of in-vehicle time and waiting time. The hyperpath means a set of route choices which minimizes the expected generalized cost (Figure 1(b)). This is a formulation of passenger route choice behavior which can consider the specific features of waiting time in public transport services.

Since the shortest hyperpath is a set of routes, only one route from this set has to be chosen (Figure 1(c)). In this study, a route represents a train line service. The more often a certain line from a set of lines runs, the more passengers can use the line (Figure 1(d)). Therefore, a probability of choosing a line from a set of lines depends on their frequencies.

In this study, it is assumed that the information of rail operation which can be available for passengers is only about a next coming train when waiting trains at a certain node. In other words, passengers cannot get information about other lines with using mobile phone. It can be acceptable assumption during the period of "planned electric power failure".

2.2 Formulation of generalized cost

Hyperpath p can be expressed with a set of nodes I_p, a set of links A_p and diversion probability T_{ap}. The expected generalized cost g_p can be represented as follows. Increase in travel time and disutility in a train due to overcrowd is not considered.

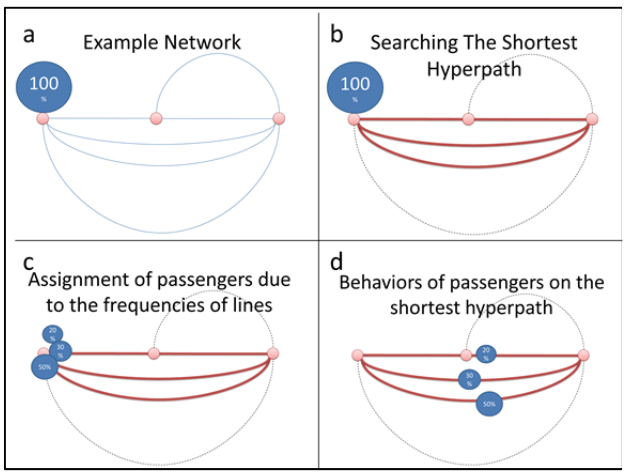

Figure 1 Illustration of hyperpath

$$g_p = \phi \sum_{a \in A_p} \alpha_{ap} t_a + \psi \sum_{i \in I_p} \frac{\beta_{ip}}{F_{ip}} \quad (1)$$

where,

t_p : travel time of link a
ϕ : value of time in traveling
ψ : value of time in waiting
α_{ap} : probability of using link a in hyperpath p
β_{ip} : probability of using node i in hyperpath p
$1/F_{ip}$: expected waiting time at node i

The first term of Eq. (1) represents the cost for in-vehicle time and the second term represents the cost for waiting time. F_{ip} is called "combined frequency" and represents the expected waiting time at node i in hyperpath p. It is formulated as follows:

$$\frac{1}{F_{ip}} = \frac{1}{\sum_{a \in A_p} f_a} \quad (1)$$

Minimum cost hyperpath, the shortest hyperpath in other words, means the optimal set of routes.

2.3 Spiess and Florian Algorithm

Spiess and Florian (1989) proposed the procedures of searching the shortest hyperpath and assigning passengers. The algorithm is composed of two parts. In a first part, from the destination node to all origins, the optimal strategy $\bar{A}^*$ and the expected total travel times u_i^* from each node $i \in I$ to the destination node r are computed. In a second part, the demand from all origins to the destination is assigned to the network according to the optimal strategy.

The algorithm is outlined as follows:

Part 1: Find optimal strategy

1.1 (Initialization)
$u_i = \infty, i \in I - \{r\}; u_r = 0;$
$f_i = 0, i \in I;$
$S = A; \bar{A} = \emptyset$
1.2 (Get next link)
If $S = \emptyset$ then $STOP$
otherwise find $a = (i, j) \in S$
which satisfies
$u_j + t_a \leq u_{j'} + t_{a'}, a' = (i', j') \in S;$
$SS - \{a\}$
1.3 (Update node label)
If $u_i \geq u_j + t_a$ then
$u_i = \frac{f_i u_i + f_a (u_j + t_a)}{f_i + f_a}$,
$f_i = f_i + f_a, \bar{A} = \bar{A} + \{a\};$
go to step 1.2.

Part 2: Assign passengers to links according to optimal strategy

2.1 (Initialization)
$V_i = g_i, i \in I;$
2.2 (Loading)
if $a \in \bar{A}$ then $\nu_a = \frac{f_a}{f_i} V_i,$
$V_j = V_j + \nu_a,$
otherwise $\nu_a = 0$

where,

u_i :expected travel time from an origin to all destination
f_i :all links which can be used at node i
combined frequency
V_i :leaving volume at node i
volume on all linkes and entering volume at node i
g_i :trafic volume from node i to node r
ν_a :volume on link a

In the step 1.1 the node labels u_i, i.e. the expected travel times to reach the destination, are set to be infinity for all nodes except the destination, for which it is initialized to zero. The auxiliary variables f_i, $i \in I$, that contain the combined frequencies of all selected links at node i, are initialized to zero. The set S is used to identify the links that have not yet been examined, and the set $\bar{A}$ is used to identify the optimal strategy.

In step 1.2 the link which is the nearest to the destination is selected among the links not yet examined. The time considered is $u_j + c_a$, that is, the time from the i-node of the link to the destination not including the waiting time at node i. If this time is smaller than the current time associated with node i, u_i, link a is included in the optimal strategy and u_i and f_i are updated according to the formulas given in step 1.3. Note that when the label of a node i, u_i, is improved for the first time, we have $f_i u_i = 0 \times \infty$. In order to keep the algorithm as compact as possible we adapt the convention $0 \times \infty = 1$ whenever this case occurs. (when $\alpha \neq 1$ is used in Eq. (4), this convention becomes $0 \times \infty = \alpha$.) The part 1 of the algorithm terminates when all links have been examined.

In the second part of the algorithm the demand from node i to the destination, g_i, is assigned to the network according to the strategy $\bar{A}$. This is done by assigning to each link $a \in \bar{A}$ the proportion of the node volume V_i that corresponds to its frequency. Since the links are processed in reverse topological order (decreasing $u_i + c_u$), the node volumes may be updated in parallel, hence making it possible to examine every link only once.

3. NETWORK AND DEMAND SETTINGS FOR THE NUMERICAL ANALYSIS

In this study, a railway transport network status during planned electric power failure is reconstructed based on a railway network in 2005 constructed by Yaginuma et al. (2010). He input the railway frequency on the basis of timetable data of each company. The changes of the railway network data between the base one in 2005 and the new one in 2011 are shown in Table 1.

The model formulation explained in the previous section is used in order to calculate the increase in generalized cost before and after the earthquake. The generalized cost is decided with respect to each OD pair. Calculating the generalized cost of some OD pairs which a lot of passengers use is meaningful because it is possible to evaluate the impact on many passengers. Calculating that of some OD pairs which is different from OD pairs which a lot of passengers choice. Therefore, we choose stations in Tokyo, Shinjuku, Yokohama, Saitama and Chiba as node D (destination) and the other all stations are decided as node O (origin). The generalized costs of these OD pairs are calculated.

Table 1 Updating the rail network

■ New stations Musashi-kosugi, Nishi-omiya, Koshigaya-lake town, Nishifu (JR), Hiyoshi, Futako-tamagawa, Futako-Shinchi, Takatsu, Mizo-no-kuchi (Tokyu), Haneda airport international terminal (Keikyu)
■ New line services Green line (Nakayama - Hiyoshi), Fuku-toshin line (Wako-shi - Shibuya)
■ Summary of the railway network number of stations : 1483 number of links : 14,607 number of lines : 116

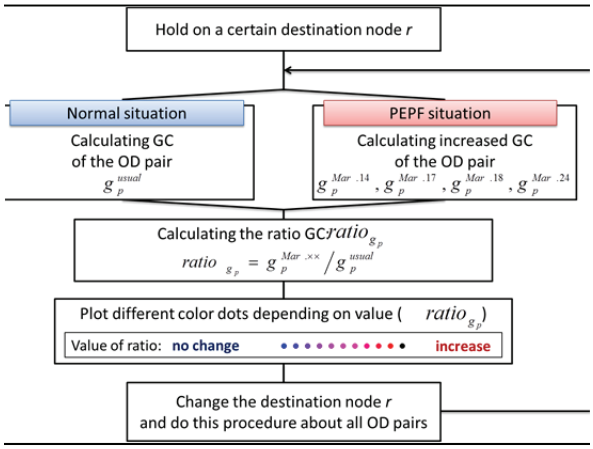

Figure 2 Procedure of Numerical Analysis

Values of time are referred to Kato et al. (2010). In their studies, $\phi = 35.90$ JPY/min and $\psi = 44.60$ JPY/min are applied and we follow these numbers.

4. RESULTS AND DISCUSSIONS

4.1 Computation Results

The procedure of evaluating the variation of generalized cost is shown in Figure 2. Passengers, whose destinations are Tokyo, Shinjuku, Yokohama, Omiya and Chiba, are objectives. Through this procedure, the variations of these passengers' generalized cost between on 14th, 17th, 18th and 24th March are eventually calculated. Figure 3 shows the variations of the all passengers' generalized costs whose destination was Tokyo station on 18th March.

4.2 Some Discussions

By closely investigating Figure 3 we find that the degradation of the level-of-service caused increase in waiting time. That would make passengers from far places have serious impacts.

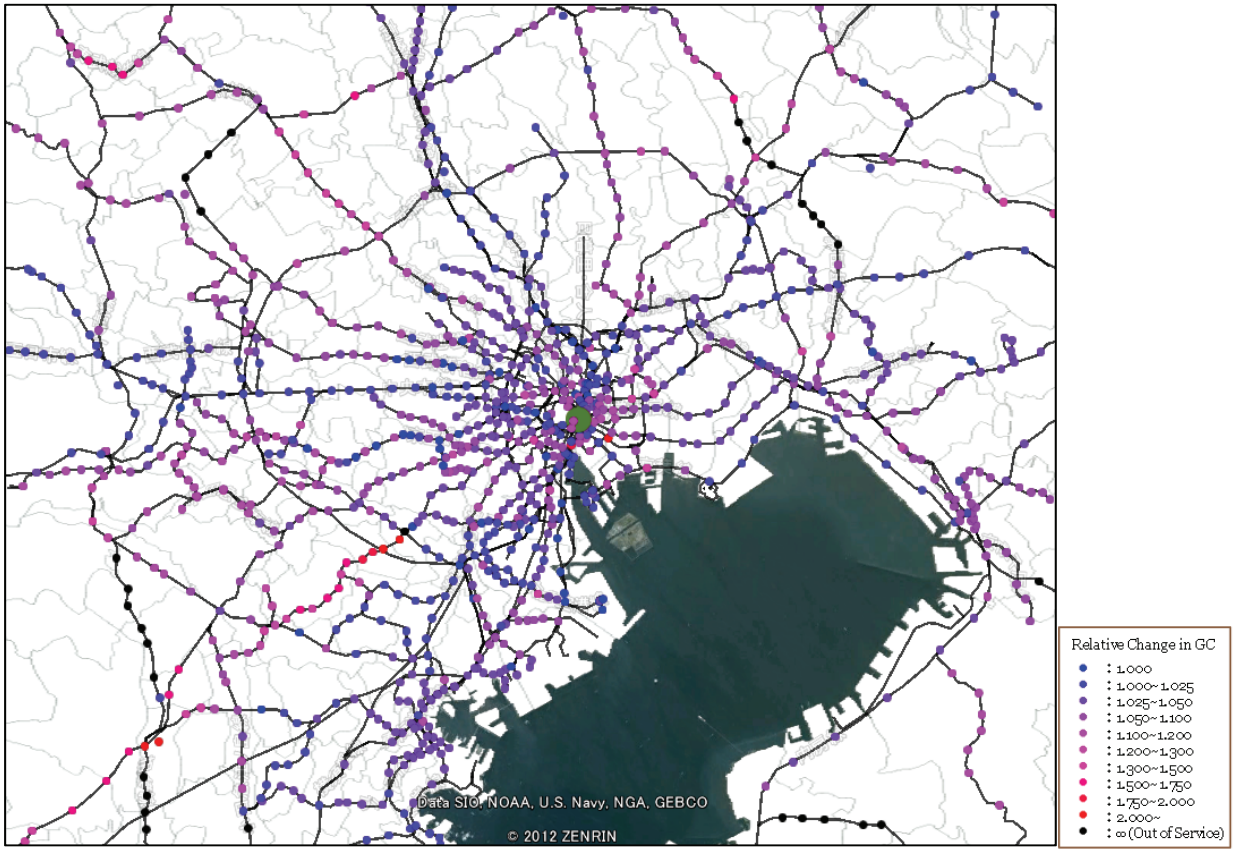

Figure 3 Generalized Cost (GC) increase due to PEPF (Destination: Tokyo Central Station, March 18, 2011)

However similar situations are not seen in all areas. In some areas, impact is much smaller than in other areas even if distances from Tokyo are same. In particular, passengers from in-land areas had bigger impact, while passengers from maritime areas had smaller impact. It can be said that impact of the degradation of the level-of-service are different because of forms of the railway networks. That is because that there are complex networks in maritime areas and that there are simple networks in in-land areas.

4.3 Variation of the shortest hyperpath

Figure 4 shows a hyperpath of passengers from Omiya to Yokohama station. On 14th March when the impact of planned electric power failure was the most serious, the passengers had used routes, which are never used under normal conditions, such as Tokyu line. This means that the optimal route under normal conditions was removed from the shortest hyperpath because of the degradation of the level-of-service of the line.

5. CONCLUSIONS

This study investigated the effects of electric power failure, which was caused by the 2011 Tohoku earthquake and tsunami, on railway transport service in the Tokyo metropolitan. Due to the severe shortage of electric power supply, the degradation of train service frequency occurred for some days just after the earthquake and that effect on railway operation for the whole metropolitan area was very severe. It had taken several weeks for train operations to be recovered to normal conditions. We investigate the increase in passenger's travel cost mainly due to the reduction of service frequency and the termination of mutual rail service operation based on the concept of hyperpath which can exactly capture the behavioural change of rail passengers due to the change in the service frequency of rail operations. We find that there are large disparities of the disutility caused by the service degradations: some area with more alternative rail routes were not so affected but others were unbenefitted more. The impacts of the degradation on passenger demand and the relationship between train operation and electric power supply are also reported and discussed. Finally, based on the evidence on the time-of-day pattern of electric energy demand for railway operators, socially desirable train operations for the future are suggested.

ANALYSIS ON URBAN LAND USE CONTROL SYSTEMS IN TSUNAMI AFFECTED AREAS BY THE 2011 GREAT EAST JAPAN EARTHQUAKE

Shoichi Ando

Director, International Institute of Seismology and Earthquake Engineering (IISEE), Building Research Institute (BRI), Professor, Faculty of Engineering, the University of Tokyo
e-mail: ando@kenken.go.jp *(IISEE/BRI),*ando@mps.t.u-tokyo.ac.jp *(The University of Tokyo), Dr.*

Abstract: Author analyzes the effect of "Area Division" including Urbanization Promotion Area of City Planning Law, "Disaster Risk Area" of Building Standard Law and other urban land use control systems during and after the Great East Japan Earthquake. Some cases of these systems in tsunami affected areas of Tohoku region are evaluated and the limitation to apply these systems to tsunami prone cities such as Kesennuma city in Miyagi prefecture, Kamaishi city in Iwate prefecture. Several issues of land use control are analyzed based on the views of municipalities.

Miyagi prefecture and Iwate prefecture were taking different recovery policy and program soon after the Great East Japan Earthquake. Although many municipalities have similar geographical and socio-economic conditions and were affected similar damage by tsunami, they are now facing different challenges. Miyagi prefecture restricts permanent reconstruction while Iwate prefecture admits individual reconstruction activities. The difference was caused by the future prospect, trend in population and economy and reconstruction plan of each affected area. The paper analyzes the current conditions and challenges of reconstruction from view point of land use control and disaster management.

1. INTRODUCTION

Tsunami disasters by the Great East Japan Earthquake that occurred on March 11, 2011 posed a question about the past urban land use control systems. In order to avoid such huge disasters in future this paper tries to verify the current systems.

Before establishment of the "Law on Creating Regions for Tsunami Disaster Management (Tsunami Law)", the word of "tsunami" was not included in the Japanese City Planning Law (CPL) itself. The word was used only once in the Ordinance of CPL, however the interpretation of "areas with risk of flood, water logging, tsunami and high tide etc." depends on decision by local governments. It means that the urban planning system in Japan has dealt with tsunami very superficially before the 2011 Great East Japan Earthquake.

On the other hand, the Building Standard Law (BSL) deals with tsunami in its Article 39 as "(Disaster Risk Area: DRA) A local government may designate areas with a frequent danger of tsunami, high tide, flood, etc. as DRAs by ordinances.2. With respect to DRAs, prohibition of building construction for use as houses and other restrictions relating to the construction of buildings, which are necessary for disaster prevention, shall be prescribed by local ordinances as mentioned in the preceding paragraph.", however the decision of frequent danger also depends on local authority similar to the CPL. Though application of the DRA against tsunami can be found in several municipalities since many decades ago and this BSL system is used more than the CPL, applied cases were very limited.

Under such circumstances, there are issues for many local governments how to establish land use control systems from a long term view point for the reconstruction of the tsunami affected areas by the Great East Japan Earthquake. Most of the reconstruction projects that will be implemented through land readjustment projects (LRP), group relocation projects (GRP) for disaster mitigation, recovery base project against tsunami (RBP), and public operated houses (POH) etc. may be finished during five or ten years from now on. However, land use control must be more permanent and sustainable from view point of equality and science.

There are some land use control systems that can be applicable to tsunami disaster management such as Area Division especially Urbanization Control Area (UCA) by the CPL, DRA by the BSL, and Special Precaution Area (SPA) against tsunami by the Tsunami Law that was established in 2011. In addition, there also exist some temporary land use control systems as shown in the Table 1.

Table 1: Land use control systems against tsunami

Type of Control System	**Term**	**Area**	**Authority**	**Art.,law**
Area Division (UCA etc.)	P	Urban	Prefecture	7, **CPL**
Disaster Risk Area (**DRA**)	P	All	Local govt.	39, **BSL**
Special Precaution Area	P	Design.	Prefecture	Tsunami
Affected area (2-month)	T	Planned	Admi. Agency	84, **BSL**
Affected area (2-year max)	T	Planned	Municipality	Special
Urban planning project area	T	Planned	Municipality	53, **CPL**

Note: "Term" P- permanent, T- temporary, "Area" Urban- urban planning area, All- no limitation, Design.- designated area as SPA by Tsunami Law, Planned- project planned

2. AREA DIVISION

2.1 Aria Division by CPL and Disaster Risk

Firstly, the Article 8 of the Ordinance of CPL is verified since it is the unique article that the word of tsunami is used in the whole legal urban planning system in Japan before the Great East Japan Earthquake.

The New CPL that was established in 1968 and enforced in 1969 provides "Area Division as a division into Urbanization Promotion Area (UPA) and Urbanization Control Area (UCA)" in the Article 7 of the Law. The Article 8 of the Ordinance of CPL provides technical criteria to determine UPA to include areas where should be urbanized within ten years principally except three types of area as well as already urbanized area. One of the three types is "areas with risk of flood, water logging, tsunami and high tide etc.", and tsunami is clearly stated.

The first Report of the Central Urban Planning Council titled "Report on principles to set up UPA and UCA and to develop UPA" was issued on November 28, 1968 and noted "areas with risk of flood, water logging, tsunami and high tide etc principally should not be included in UPA". In addition, Ministry of Construction (MOC, current Ministry of Land, Infrastructure, Transport and Tourism (MLIT)) has issued a notification titled "Principles to coordinate between Area Division of UPA and UCA by CPL and flood control works" on January 8, 1970 has set forth "those areas that corresponds to river inundation area against rainfall intensity approximately 50 mm per an hour and water logging is assumed more than 0.5 m, are regarded as areas with risk of flood, water logging, tsunami and high tide etc by the Article 8 of CPL Ordinance, and those areas principally should not be included". However this notification aimed at floods of river such as overflow and water logging, and not tsunami.

2.2 Area Division and the Great East Japan Eq.

Figure 1 shows the affected area by tsunami inundation at the Great East Japan Earthquake and UPA in the Sendai – Shiogama urban planning area, while Figure 2 shows those in the Ishinomaki wide urban planning area respectively. (Figure 3 indicates whole tsunami affected areas in Miyagi and Iwate prefectures including areas of Fig. 1 and Fig. 2.)

Sendai Plain has formed agricultural land. The city area has been designated as UPA in 1970 in Sendai-Shiogama and Ishinomaki area. Because Sendai city has not designated UPA except surrounding areas of Sendai Port and because the old city area of Sendai is mainly located inland area, there were not so much damages even in the coastal areas of Sendai city except some existed villages and few new developments such as Arahama-shin in Wakabayashi ward of Sendai city. Affected areas are located in UPA of Natori city (Yuriage) and Iwanuma city around Sendai city. New development of Arahama-shin and old village of Arahama where devastated damage by tsunami are observed, are both located in UCA of Sendai city.

Although this system is connected with UCA of Area Division that provides the strongest control mechanism for land use control, this provision has not been applied so clearly to tsunami. The following data shows the reality and author analyzed the reasons why the Article 8 of CPL was not used so clearly in the next sub section.

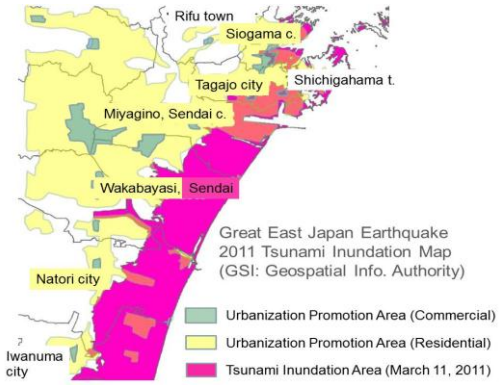

Fig. 1 UPA and tsunami in Sendai Urban Planning area

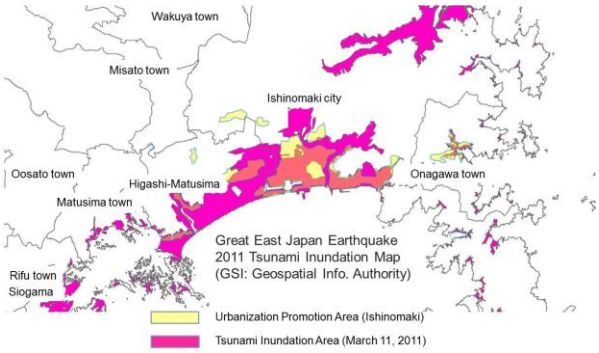

Fig. 2 UPA and tsunami in Ishinomaki Urban Planning area

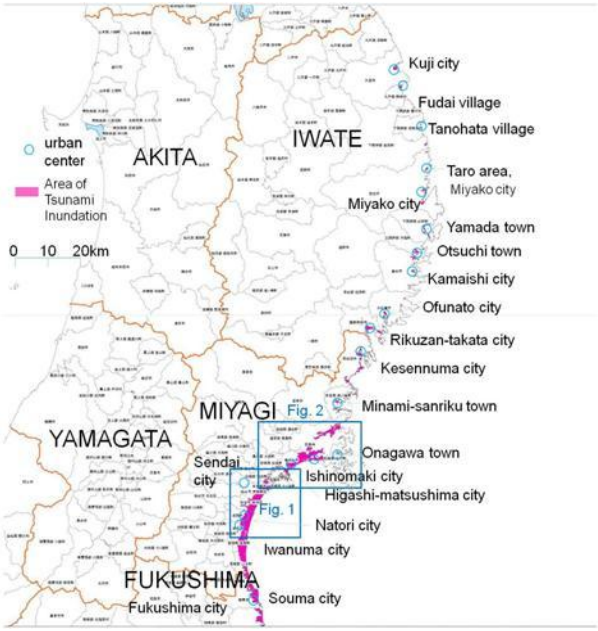

Fig. 3 Tsunami affected areas by the Great East Japan Eq.

2.3 Reasons why Article 8 was not well utilized

The reasons why CPL did not function well against tsunami in spite of Article 8 of its Ordinance are listed according to the type of reasons as follows:

(1) **Social Reasons**

- When the UPA was firstly designated, the areas where

consensus could be easily obtained were selected. Already urbanized city areas had the first priority.

- UPA was basically set in the regions that rapid increase of population occurred like surrounding cities of Sendai.
- Many new public facilities and care houses for the elderly were constructed in the UPC areas with tsunami risks, because of consolidation of municipalities, progress of aged society and long-term trend in decrease of population.

(2) **Physical Reasons**

- People thought that it will be easy to evacuate from tsunami, since the most advanced information technology and early warning systems are established.
- People who lived in the coastal area thought that seawalls, river gates and tsunami evacuation buildings would protect residents from tsunami disasters.

(3) **Economic Reasons**

- UPA tends to be designated in and around already urbanized area, because of efficient use and maintenance of infrastructure, such as roads, sewerage and water supply.
- To move to safer area, in particular change of urban setting is almost impossible in normal time even though all people recognized their high risk as well as partly because of financial reason of municipality and prefectural government.
- The movement to protect agricultural land becomes weaken as demand of agricultural land will not increase and because of higher exchange ratio (strong yen) and excessive domestic rice production etc.
- Even if the risk is judged, agreement with local residents would not invest against tsunami because the probability of occurrence is quite law compared with floods

(4) **Institutional Reasons**

- This provision is applied for new areas to include in UPA within 10 years. It regulates only newly urbanizing areas.
- There were no concrete criteria with numbers as shown in the old notification and it is hard for local governments to judge the risk of tsunami on their own responsibility.
- There is no detail explanation on how to set up the CPA against tsunami in the MLIT guideline of urban planning.
- Some urban planning may not be realized when other urban function is not conscious except disaster management, and so on.

3. DISASTER RISK AREA

3.1 Disaster Risk Area by BSL

Disaster Risk Area (DRA) system was introduced when the BSL was established in 1950. The Article 39 of BSL provides "local government can designate highly hazardous areas against tsunami, high tide and floods etc. as DRA by its bylaw". There is no detailed ordinance or regulations in BSL, however notification of administrative vice minister of MOC on October 27, 1959 (after Ise Bay Typhoon occurred on September 26, 1959) entitled "disaster prevention for buildings against storm and flood damages" recommended to positively designate DRA based on the Article 39 of BSL, especially in the low land areas, to strengthen the structure of buildings in the area and to develop evacuation facilities.

In addition the notification noted "buildings in DRA must be constructed as strong buildings such as reinforced concrete structure unless there exist effective embankment etc." and "residential use buildings should be prohibited to construct in the heavily hazardous area". However definition of "heavily hazardous area" was not mentioned as well the target of this notification did not include tsunami so clearly but mainly for storm and flood disasters.

3.2 Disaster Risk Area and Tsunami

Detailed explanation of "strong buildings" and "heavily hazardous area" is firstly found in the Notification No.1318 of MLIT in 2011 on "Definition of safe structural systems against tsunami to presume tsunami inundation" based on Tsunami Law. In addition, technical guidelines on land use against tsunami disaster are issued continuously such as a technical advice to the additional knowledge issued by the Director General of Housing Bureau on November 17, 2011, a technical advice on enforcement of Tsunami Law by the Cabinet Office on March 9, 2012, and a technical advice on enforcement of the Section 9 of Tsunami Law on July 31, 2012, recently.

As the reference, in the guidance textbook on BSL issued by the Architectural Institute of Japan (AIJ) in 1950, DRA was referred as "Target of DRA is areas prone to tsunami as Sanriku region, and/or river side areas prone to flood disasters. However as an actual condition, designation of DRA is quite hard issue and the issue is a regional issue of the area, therefore the system provides designation of the area and contents of control for building restriction are all trusted to the local ordinance". The risk of Sanriku region against tsunami was recognized.

Table 2: Designation of DRA (as of Mar. 2009, by MLIT)

Area Type	Number (places)	Area (ha)	Number of Buildings in the Area			
			Houses (unit)	Incl. unfit houses (unit)	Non residential	Total (unit)
Steep slope	18,785	36,898	339,785	122,343	37,371	377,156
Landslide	64	252	283	217	229	512
Flood	111	2,781	1,696	676	1,179	2,875
Tsunami	**2**	143	0	0	38	38
Tsunami/flood	**5**	6,504	74,002	0	39,020	113,022
Snow-slide	3	21	3	3	6	9
Avalanche	8	149	14	4	28	42
Avalanche etc.	2	548	531	0	0	531
Lava flow	2	41	0	0	0	0
Subsidence	1	0.4	1	0	1	2
Land deform	5	13	0	0	0	0
Erosion	1	0.5	3	0	9	12
Fall of rocks	5	15	129	0	48	177
Mud flow etc.	4	13	0	0	0	0
Others	0	0	0	0	0	0
Total	**18,998**	47,383	416,447	123,243	77,929	494,376

3.3 Reasons why DRA was not so used against tsunami

The following (1) to (7) analyzes the reasons why DRA was not so utilized in the hazardous areas against tsunami.

(1) As shown in the guidance textbook on BSL by AIJ, designation of DRA was quite hard issue. Before BSL was established, principally all construction activities were free and no restriction. Even though the restriction by BSL is set up as "minimum standards", it was told that the then owners, architects, and contractors could not easily accept the BSL. From the legal view point, when a certain restriction violates some property rights, compensation measures to the owner

must be provided. However because the restrictions based on BSL provide minimum standards in order to protect lives, health and properties of the people, no compensation system is prepared and authorized.

(2) In 1950 when BSL was established, there seemed almost no scientific knowledge on tsunami hazards. Since BSL prescribes technical standards, it was impossible to regulate standards without any scientific bases. In contrast to tsunami standard, seismic standard in BSL has been created from the first as well as fire codes, because of experiences of Nobi earthquake in 1891 and the Great Kanto Earthquake.

(3) DRA aims to prevent disasters utilizing locally applicable control codes through designation of the area. There exist approximately 19,000 DRA in Japan as shown in the Table 2 (2009 MLIT). However most of them were designated against landslides to restrict housing construction in the steep slope areas. DRA against tsunami risk was not established except few cases as the frequency of occurrence is quite rare and residents do not agree to prohibit from building their houses. There is no national financial support.

(4) As shown in the Table 3, DRA provides permanent restriction while other building control system in the disaster affected area like the building control based on the Article 84 of BSL, sets normally two months' limitation or in the case of the Great East Japan Earthquake maximum eight months' control. DRA controls won't be necessary for the area without any development pressure.

(5) DRA was sometimes used in the recovery projects after damaged disasters. In the case of Aonae area of Okushiri town after a big tsunami of the off coast of South-West of Hokkaido earthquake in 1993, DRA was introduced to the high risk area in the old residential zone after the new hilly safe area was developed utilizing "Group Removal project against Disasters (GRP)" with subsidies from national government (by MOC, current MLIT). This was the unique case after tsunami under DRA.

(6) As shown in the Table 3, Iwate prefecture requested all affected municipalities to set DRA to the heavily tsunami affected area in April 2011. However Kamaishi city decided not to use DRA in July 2011 and other municipalities are also reluctant to apply DRA but they changed the policy in 2012. On the contrary, Miyagi prefecture set building control in large areas using the Article 84 of BSL as well as DRA to apply CRPs. Sendai city and Yamamoto town utilized DRA to control building construction in tsunami hazardous areas.

(7) As shown in the Table 4, the basic direction toward reconstruction of Miyagi prefecture and Iwate prefecture seems to select different way as the case of building restriction in early stage. It seems that Miyagi prefecture aims to improve urban structure using this opportunity especially in the coastal zones, while Iwate prefecture seems to be struggling to maintain population in the tsunami affected areas and then restriction of building construction in Iwate pref. is not so strict compared to Miyagi prefecture because the population decrease trend is expected severer in the remote regions from big cities. However, it may be caused simply because of the difference of urban planning settings of both prefectures, i.e. Miyagi prefecture sets UPA and UPC and most of coastal areas are prohibited to construct buildings. In Iwate prefecture, construction of buildings is not so strictly controlled in the coastal cities and towns.

Table 3: Building control based on BSL after disaster

Building Standard Law	**Article 39** (Disaster Risk Area: **DRA**)	**Article 84** (Control in Affected Area)
Designation of area	Based on bylaw of local governments	By Specialized Admin. Agency
Duration of control	Permanent measures	Max. two months
Construction control	Prohibit housing, limit other building (no national intervention)	Prohibit / limit building construction in the project planned area
Application to Great East Japan Earthquake	Iwate: Urge municipality to set bylaw Miyagi: Pref. started to plan to apply	Iwate pref.: No application Miyagi: Applied to 5 municipalities
Response of municipalities	Iwate: Mayors are prudent (negative) Miyagi: Part of Minami-sanriku town	Miyagi: Enterprises were embarrassed then try to permit some construction
Applied cases	Hokkaido, Okushiri town, Aonae area	Great Hanshin-Awaji Eq. (Kobe etc.)

Table 4: Comparison of Miyagi and Iwate prefectures

	Miyagi Prefecture	**Iwate Prefecture**
Total population	2,360,218 persons	1,385,041 persons
Estimated pop.	1,894,000 persons	962,000 persons
Ratio(2040/2005)	- 19.8% (affected area - 46.8%)	- 30.5% (affected area - 48.8%)
Aged ratio (05-40)	20.0% (2005) → 34.3% (2040)	24.6% (2005) → 38.0% (2040)
Basic Concept for Reconstruction (part of land use & development)	**Miyagi Prefecture Recovery Plan:** Recovery focusing on tsunami disaster management of coastal areas applying removal to high land, separation of work and home, multiple protection against tsunami from the lessons	**Iwate Prefecture Recovery Basic Plan:** Based on agreements with residents, improvement of residential area for safety and development connected with land use plan considering tsunami disaster management
Current situation (building control)	Pref. set building control based on City Planning Law etc. after BSL Article 84. BSL Article 39 (DRA) is also used in many areas in Sendai, Kesennuma, Minami-Sanriku etc. in order to apply GRPs.	Pref. recommended municipalities to use BSL Article 39. Some GRPs areas are under planning to apply DRA in Kamaishi and Miyako cities, Yamada town and Noda village as of Sept. 2012.

Table 5: Major project systems for reconstruction

Basic Projects	**Group Relocation proj. against Disasters (GRP)**	**Recovery Base project against Tsunami** (new system after 2011) **(RBP)**	**Project on Land Readjustment for Urban Recovery (LRP)**	**Project on Urban Redevelopment (URP)**	**Public Operated Houses project against Disaster (POH)**
Subsidies	Cost for public works incl. land development except sell land	Total mounding cost, Development of evacuation building and Public works etc.	Cost for public works incl. land, totally mounding (40 persons/ha)	Cost for design, common facility and public space etc.	Land purchase, design and construction cost, low rent subsidy
Area	No relation to Urban Planning	Principally within Urban Planning Area	Within Urban Planning Area	Within Urban Planning Area	No relation to Urban Planning
Scale	More than five (usual 10) houses	Principally 2 projects per urban, and approx. 20 ha per project	No condition	No condition	No condition
Condition	Designation of Disaster Risk Area is requisite	Define area for land purchase, Step by step extension will be possible	Consolidated area to develop road system. Division of project area	Consolidated area to build co-owned houses and/or building	Demand to public houses for low income household after disaster
Urban Planning	No relation	Area is designated	Area and project is designated by UP	Area and project is designated by UP	No relation
Process	Agreement of MLIT minister on removal plan	Planning decision as urban facility, project approval of prefecture (or MLIT)	Urban planning procedures are needed (from planning decision to liquidation)	Urban planning procedures are needed (from planning decision to liquidation)	Municipality and prefectural govt. construct and operate the houses
Aid ratio	All costs will be covered (special case by national grant + special tax).				

4. DAMAGE AND URBAN PLANNING

4.1 Analysis on Damages by Tsunami

The data on damages of the Great East Japan Earthquake from the view point of building control and urban planning are analysed, and observations can be pointed out as follows:

(1) Fig.4 indicates the characteristics of urban planning with UPA by Area Division. The damaged houses include

collapsed, half collapsed and partially damaged one. That means in UPA such as in the Sendai plain, housing damage inundated areas turned out large number, while human damage was not so severe if compared with Sanriku rias coast areas where there is no UPA except Onagawa town.

(2) Fig.5 shows two exceptionally large damaged cities in terms of physical damage. Both Sendai city and Ishinomaki city are classified as the area of "Urban Planning with Area Division". That means the pressure of development and increase of population is expected in these cities. Therefore it is required to effectively invest resources into the UPA.

(3) Fig. 6 shows casualties per collapsed houses with classification by urban planning type. As same as the Fig. 5, all municipalities in Fig. 6 established urban planning. That means heavily damaged areas to houses and human were basically controlled under urban planning system that can apply rather strict building control.

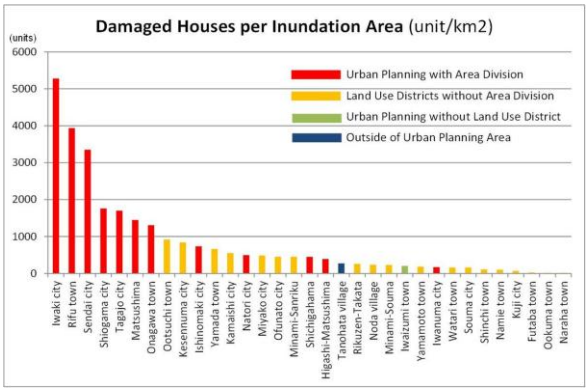

Fig.4: Totally collapsed houses by municipality

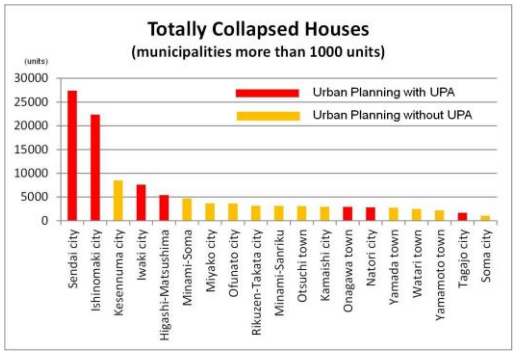

Fig.5: Damaged houses per inundation area

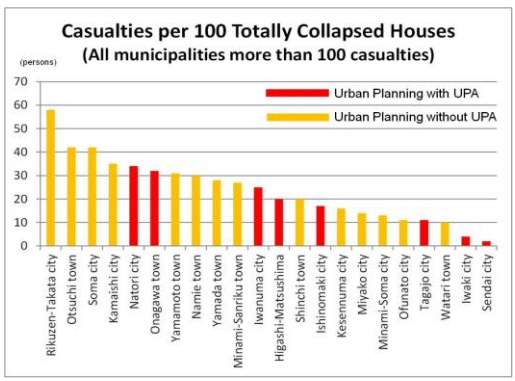

Fig.6: Casualties per 100 totally collapsed houses

(4) Fig.7 shows severity of damage of each municipality by classifying the characteristics of regions. The proposed indicator is calculated as "number of human damage per totally collapsed houses" by municipality. Coburn, Spence and Pomonis defined similar ratio as "Lethality Ratio" in 1992. The following data is formulated after extracting less damaged municipalities that have large fluctuation because of their smaller denominator.

(5) The ratio varies almost double figures (from 60 to 2-1) under this indicator. Rikuzen-Takata city recorded around 60 persons' human damage per 100 totally collapsed houses, while Sendai city's indicator shows around 1 or 2 persons. Fig.8 tries to classify the damages however not so clear difference was observed from above mentioned data according to the characteristics of the region type.

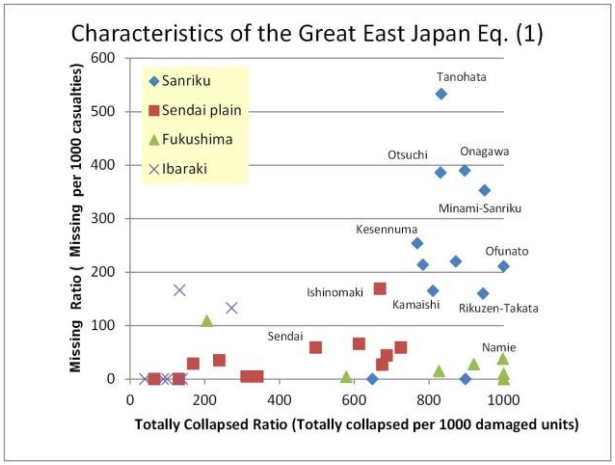

Fig. 7: Missing ratio and totally collapsed ratio

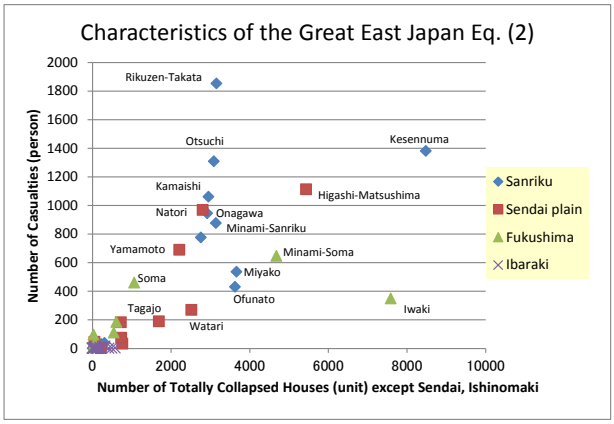

Fig. 8: Totally collapsed houses and casualties

Then, the reasons why such great difference was observed among affected cities and towns, especially as shown in the Fig. 6 (under the same physical house damage but the human damage varies a lot) will be as follows. In the case of tsunami, relation of physical damages and human damages may be significantly affected by evacuation behavior. The factors may be;

1. Evacuation from house or not
2. Time for evacuation to the refuge
3. Measure for evacuation (on foot or by car)
4. Evacuation route (and traffic congestion)

5. Safety of refuge (or evacuation shelter etc.)

In addition, except for evacuation behavior, the following factors may affect the difference of damage;

6. Judgment of "totally collapsed" differs from municipality (e.g. if tsunami reached ceiling, municipality regarded as totally collapsed.)
7. The residents who experienced few damage at the Chile Tsunami in 1960, became rather unprepared or careless against tsunami.
8. The area has no tsunami evacuation building such as 4-story close to the residential area.

4.2 Urban Planning in Pacific coastal region in Tohoku

In total 37 municipalities in the Pacific coast region in Iwate, Miyagi and Fukushima prefectures, 3 municipalities have no urban planning area. In addition 4 municipalities in these 3 prefectures have urban planning without land use districts. That means other 30 municipalities of this region have urban planning areas with land use district.

With regard to the Area Division, no municipality in this region in Iwate prefecture has urban planning area with Area Division (UPA and UCA). In Fukushima coastal region, Iwaki city only sets up Area Division. To the contrary, 11 municipalities within total 15 municipalities in the coastal region of Miyagi prefecture divided UPA and UCA by Area Division. Because there is no increase of population in Sanriku (rias coast) region, no UPA is designated in coastal areas of Iwate prefecture as well as Kesennuma city and Minami-sanriku town in Sanriku area of Miyagi prefecture.

From the analysis of the damage, it was unfortunate that objectives of the Article 8 of CPL Ordinance could not function in many tsunami affected cities (mainly in Miyagi prefecture) at the Great East Japan Earthquake. However, from the figures 1 and 2, UCA by Area Division decreased human damage in Sendai city than Ishinomaki city although this was not obvious until after the event.

4.3 Issues of Land Use Control in Reconstruction area

(1) As shown in the data and figures, damage by tsunami varied in each municipality (e.g. in Onagawa town and Ishinomaki city have huge damages even in the UPA), we need continuously investigate the reasons and factors from various points such as evacuation, traffic, land use, building structure, depth of tsunami inundation, response of administration by municipality, awareness information etc.

(2) Since there is no Area Division in coastal areas of Iwate prefecture and Fukushima prefecture except Iwaki city and land use control system is not so strict, DRA with Group Relocation Project (GRP) against Disasters, Tsunami Law and other land use control system are indispensable to safe buildings and urban areas.

(3) One of the most significant issues in the tsunami affected areas is land level raising works in urban area. Because of around 1 m land subsidence by the Great East Japan Earthquake, coastal zone are suffered from inundation every day. Municipalities are starting to raise the ground level of roads and other public facilities. However private land owners basically have to raise the land by themselves, unless the land is included in reconstruction project areas. The compensation for private properties caused by land subsidence may be one of the new discussion points as a part of public assistance as well as the level of support to the reconstruction of private houses and business facilities.

(4) Other important issue is manpower assistance. Many staffs of the affected municipalities such as Kamaishi and Kesennuma city pointed out lack of staff for urban reconstruction projects because many projects started after the first recovery stage such as debris clearance and disposal, temporary housing and so on. Many municipalities outside of affected areas have sent technical or project support staffs to the affected area. For instance, Kitakyushu city sent a team of project staffs to Kamaishi city where the same steel company is located.

Fig. 9: Land subsidence and water logging (Kesennuma)

Fig. 10: Reconstruction project area (Unosumai, Kamaishi)

5. CONCLUSIONS

Urban planning and building control systems that are prescribed in the CPL and the BSL are expected to play significant roles to prevent tsunami and earthquake disasters.

Japanese urban planning system was established in 1919 and since then Japan had opportunities to realize the urban plans after the 1923 Great Kanto Earthquake and reconstruction process from the damages by the WWII after 1945. In addition recovery from Ise Bay typhoon in 1959

and the 1995 Great Hanshin-Awaji Earthquake exposed past issues of urban planning and new legal and support systems were formed in order to achieve safer urban settings. And now after the Great East Japan Earthquake, we are requested again to reconsider the future of urban planning systems including land use control.

Land use control in the urban area especially in the disaster risk area has to be integrated with socio-economic, institutional, technical and other tools to achieve safety of buildings and built-environment. To mitigate earthquake and tsunami risk, land use control plays a quite important role. Awareness creation is also instrumental for building culture of safety and creates demands for intervention in disaster mitigation.

The demands ultimately help in creating conducive environment to policy intervention, in realizing institutional mechanism of code enforcement and land use control for the municipal authorities and in creating demand for competent professionals in the field of urban planning and disaster risk management.

As a summary of conclusion, author would like to note the following future prospect on land use control systems;

(1) Though the final goal of tsunami disaster management will be relocation and land raising of urban area, evacuation training, designation and development of safe refuges and evacuation routes against tsunami are the first measures.

(2) Land use control against disasters will be more effective when it is combined with urban planning project and disaster management project. Such combined cases will be expected to widely advance through GRP and RBP by the Tsunami Law as well as new development of LRP and projects for urban redevelopment etc.

(3) Reconstruction of the affected areas by the Great East Japan Earthquake faces long-term social issues such as aged society, decreasing population and the sustainability. New concept of compact city, smart city and eco city may help to solve them in the near future.

(4) Disaster Management Plan prepared by prefectures and municipalities are needed to closely relate to urban planning including land use control system of each area in the near future, as there is few connection now.

(5) Finally, hope and intention of residents and staffs of local governments was the key of recovery. Strong intention of local people to make safer and more sustainable region and city for the next generations is really expected.

EVACUATION SITUATION OF FUTABA DISTRICT RESIDENTS FOLLOWING THE FUKUSHIMA NUCLEAR ACCIDENT

Keiichi Sato[1)]

1) Associate Professor, Center for Social Research and Data Archives, Institute of Social Science, The University of Tokyo, Japan
keiichi-s@iss.u-tokyo.ac.jp

Abstract: This study aims to record evacuation situation of Futaba district residents following the Fukushima nuclear accident caused by the Great Eastern Japan Earthquake 2011. In this study, some administrative documents and the questionnaire survey for all residents of Futaba district conducted by Fukushima University were analyzed as follows; 1) According to the reported values of radiation doses, there is nothing for it but to admit that some spots cannot be decontaminated to the level in which people can return. 2) Survey results revealed that not all people have the desire to return, so it is anticipated that each municipality will have smaller populations than before the accident. Based on these studies, discussion about the recovery program of the whole Futaba district was developed.

1. INTRODUCTION

On March 11, 2011, the Tohoku-Pacific Ocean Earthquake destroyed the cooling functions for the reactors and the spent fuel pool at the Fukushima Daiichi Nuclear Power Station (hereinafter referred to as "Fukushima Daiichi NPS") of the Tokyo Electric Power Company ("TEPCO"), causing hydrogen explosions and the release of radioactive materials. On April 12 of the same year, the magnitude of the accident was reevaluated to Level 7 on the INES (International Nuclear Event Scale)—the worst nuclear accident in the history of Japan and equivalent in scale with the accident at the Chernobyl nuclear power plant in 1986.

This accident evoked various social concerns—the process of handling the accident, national energy policy, restarting of other nuclear power plants—but at the same time, the accident caused large scale radioactive contamination which forced many people to evacuate. All the while, universities and local municipal governments continued to investigate the situation of evacuees, with the understanding that recording and analyzing the data collected would be a critical task in assessing the evacuation programs. This paper is an English translation of an excerpt of the records of the evacuation documented by Sato (2012) over a period of 6 months from the time of the accident.

2. OVERVIEW OF EVACUATION FROM THE NUCLEAR ACCIDENT

2.1 Evacuation Procedures Immediately After the Accident

Table 1 shows the outline of the evacuation procedures, which is a summary of the interim report prepared by the Investigation Committee on the Accident at the Fukushima Nuclear Power Stations of the Tokyo Electric Power Company ("ICANPS").

On the evening of March 11, 2011, the Prefectural Governor instructed citizens on evacuation within a km radius of the Fukushima Daiichi NPS. The evacuation zone was expanded to within a 10km radius by the morning of March 12, and again to within a 20km radius that same evening by Nuclear Emergency Response Headquarters ("NERHQ"). More than one month after the accident, the government designated the Restricted Zone on April 21, and the Deliberate Evacuation Zone and Emergency Evacuation Preparation Zones on April 22.

Basically all individuals were prohibited from entering and were instructed to evacuate from the Restricted Zone established based on the Disaster Countermeasure Basic Act. Outside the 20km radius, the area with concern that the cumulative dose might reach 20mSv within 1 year period after the accident was designated the Deliberate Evacuation Zone, and residents were instructed to evacuate in a planned manner. Areas within a 20 to 30km radius of Fukushima Daiichi NPS but outside the Deliberate Evacuation Zone were designated Emergency Evacuation Preparation Zones where residents were instructed to be ready and able at all times to follow a stay-indoors order or an evacuation order in case of an emergency.

Subsequently, the Emergency Evacuation Preparation Zones designation was lifted on September 30, and the Restricted Zone designation has also been reviewed since 2012.

2.2 Status of Evacuation

As of November 2011, there are 114,000 evacuees under the evacuation programs, 73,000 of which are from the district of Futaba.

Residents of the towns of Hirono and Naraha evacuated mainly to the city of Iwaki, their southern neighbor; many

Table 1 Evacuation Procedures Immediately After the Accident

Y	M	D	Time	Organization	Orders, etc.
2011	3	11	20:50	Fukushima Prefectural Governor	Instructed citizens of the towns of Okuma and Futaba evacuation within a 2 km radius of Fukushima Daiichi NPS
2011	3	11	21:23	NERHQ	Instruction to issue evacuation orders to citizens within a 3 km radius and stay-indoors orders to citizens within a 10 km radius
2011	3	12	05:44	NERHQ	Instruction to issue evacuation orders to citizens within a 10km radius .
2011	3	12	18:25	NERHQ	Instruction to issue evacuation orders to citizens within a 20 km radius .
2011	3	15	11:00	NERHQ	Instruction to issue stay-indoors orders to citizens within a 20 to 30 km radius
2011	4	21	11:00	NERHQ	Instruction to establish the restricted zone within a 20 km radius
2011	4	22	-	NERHQ	Instruction to establish deliberate evacuation zones and emergency evacuation preparation zones; lifted stay-indoors order within a 20 to 30 km radius
2011	9	30	-	NERHQ	Instruction and notice on the lift of emergency evacuation preparation zones

Made by author based on websites of the Government's Accident Investigation Board (2011) and Prime Minister of Japan and His Cabinet (TEPCO Fukushima NPS Accident) websites

evacuees from the town of Tomioka and village of Kawauchi went to the city of Koriyama. Citizens of the town of Okuma evacuated to the cities of Tamura and Aizu-wakamatsu, while the town of Futaba moved their people to the town of Kawamata and to the city of Kazo in Saitama Prefecture. Residents of the town of Namie were transferred to the city of Nihonmatsu and those from the village of Katsurao evacuated to the city of Fukushima.

2.3 Estimated Values of the Cumulative Dose and Decontamination Criteria

Figure 1 shows the estimated annual cumulative radiation doses over a one-year period after the nuclear accident in Futaba Region and Iitate Village, and the cities of Minami-soma, Fukushima, Iwaki and Tamura plotted in based on the radiation monitoring data collected by the Ministry of Education, Culture, Sports, Science & Technology (2011).

In the towns of Namie and Tomioka, village of Iitate, city of Minami-soma, towns of Okuma and Futaba, and village of Katsurao, there are spots that exceed 20mSv per year which is the dose limit for radiation workers established under the 2007 recommendation of the International Commission on Radiological Protection (ICRP) as well as the criteria for establishing a deliberate evacuation zone. In the towns of Tomioka and Futaba, more than 75% of the monitoring posts exceed an integral level of exposure of 20mSv/year.

Moreover, there are spots in the towns of Namie, Tomioka, Okuma, and Futaba and the village of Katsurao that recorded 100mSV/year or greater, the dose at which clear evidence of cancer risks is shown under the 2007 ICRP recommendation—more than half of the monitoring posts in Namie and Okuma exceed 100mSv per year.

Ministry of the Environment (2011) is proposing a policy to reduce the annual radiation dose by August 31, 2013 to less than 50% compared to August 31, 2011, but this indicates that the decontamination efforts cannot bring the radiation dose to zero.

It is easy to assume that there are spots that cannot achieve the long-term goal of reducing the additional exposure dose to 1mSv a year in 2 to 3 years.

Table 2 Approximate Number of Evacuees under the Evacuation Programs

Municipals	Total	By zone			Major destinations
		Restricted Zone	Deliberate Evacuation Zones	Former Emergency Evacuation Preparation Zones	
District of Futaba	**72,650**	**62,400**	**2,600**	**7,650**

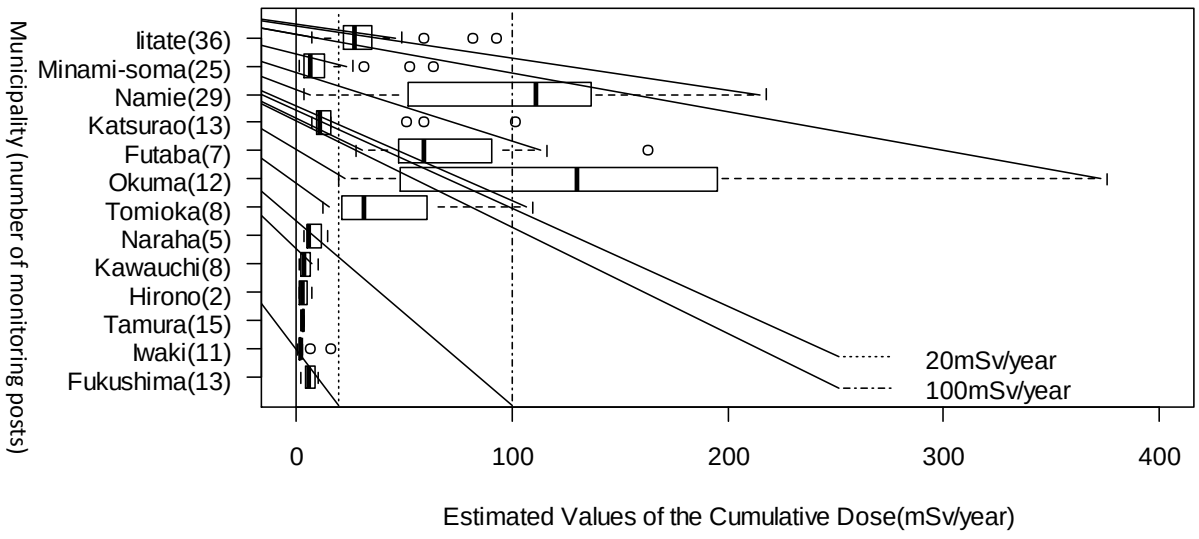

Figure 1 Approximate Number of Evacuees under the Evacuation Programs

3. QUESIONNAIRE SURVEY IN THE DISTRICT OF FUTABA

3.1 Outline of the Survey

- Title of Survey: "Survey of Post-disaster Restoration of the Residents of Futaba District"
- Subject of Survey: Evacuees that were residing in the 8 municipalities of the district of Futaba
- Method of Survey: Mail-in survey (enclosed in town/village reports)
- Period of Survey: September – October 2011
- Sample Design: Complete census based on list of evacuees prepared by municipalities
- Total Number Distributed: 28,184
- Number of Respondents: 13,630 (response rate: 48%)
- Content of Survey: Attributes of Respondents (gender, age, occupation), conditions of evacuation (place of residence before evacuation, destination of evacuation, number of times evacuated), family (family composition, break ups, if any), desire to return, life as an evacuee (living plans, mental health conditions), opinions on restoration, etc.

3.2 Desire to Return

In this survey, respondents were shown the conditions of their hometown in a step-by-step manner and asked whether they wished to return to their place of residence before evacuation (desire to return).

Four percent (4%) of the respondents answered that they would "(1)return immediately if the radiation dose decreases to the level that the government considers safe." Sixteen percent (16%) answered that they would "(2) return if the radiation dose decreases and the urban infrastructure including water and sewage system, electrical facilities and gas is restored," and 20% said they would "(3) return if the local and national governments, in addition to (1) and (2) above, develop and implement an adequate decontamination program." Moreover, 25% of the respondents answered that they would "(4) return if, in addition to (1) to (3) above, a certain number of other residents decide to return."

Eight percent (8%) remained undecided ("(6) others"), while 24% clearly expressed that they "(5) have no intention to return."

The desire to return had varying tendencies depending on the age of the respondents. A greater percentage of younger people selected "(5) have no intention to return" while fewer elder people did.

3.3 Aspiration for Restoration Measures and Policies

The survey listed 13 items that were considered important for future restoration, and respondents were asked to select up to 3 items. Many respondents selected "development of a restoration plan for the entire district of Futaba" (46%) and "industrial development including job security for younger generations" (43%), followed by "enhancement of facilities for elderly and healthcare" (31%), "construction of public and private housing" (21%), "restoration of primary industries (agriculture, forestry and fishing)" (21%), "development of medium-term restoration plans" (20%), "creation of base for renewable energy" (16%), and "development of schools and educational facilities" (16%).

Table3 Desire to Return

Choices on Desire to Return	Responses	Percentage
(1) return immediately if the radiation dose decreases to the level that the government considers safe	589	4%
(2) return if the radiation dose decreases and the urban infrastructure including water and sewage system, electrical facilities and gas is restored	2,159	16%
(3) return if the local and national governments, in addition to (1) and (2) above, develop and implement adequate decontamination program	2,762	20%
(4) return if, in addition to (1) to (3) above, a certain number of other residents decide to return	3,380	25%
(5) others	1,102	8%
(6) have no intention to return	3,284	24%
No response	354	3%
Total	13,630	100%

4. Consideration of a Restoration Plan for the Entire District of Futaba

With the exception of the town of Okuma, the population of the district of Futaba had been decreasing even before the accident. Survey results also revealed that not all people have the desire to return, so it is anticipated that each municipality will have smaller populations than before the accident. In this situation, improvement of healthcare and educational facilities will become a major issue. The majority of those who want to return home early are senior citizens, who are in need of better facilities for the elderly and healthcare. Considering the expected rates of utilization, it is perhaps necessary to consolidate several of these facilities and to enhance the transportation services between

Table4 Priorities for Restoration (multiple choices)

Restoration Measures & Policies	Responses	Percentage
Restoration of primary industries (agriculture, forestry, fishing)	2,795	21%
Industrial development including job security for younger generations	5,795	43%
Development of tourism industry	230	2%
Attraction of firms and plants	1,404	10%
Creation of base for renewable energy	2,197	16%
Attraction of universities and research institutes	437	3%
Construction of public and private housing	2,897	21%
Development of schools and educational facilities	2,167	16%
Enhancement of facilities for elderly and healthcare	4,180	31%
Incorporation of the district of Futaba	1,577	12%
Development of medium- and long-term restoration plans	2,722	20%
Development of restoration plans by individual communities	1,965	14%
Development of restoration plan for the entire district of Futaba	6,314	46%
Total	13,630	100%

locations in order to make them economically viable. This kind of scheme of enhancing public services beyond the borders of the towns and villages should be considered in developing restoration plans for the entire district of Futaba.

According to the reported values of radiation doses, there is nothing for it but to admit that some spots cannot be decontaminated to the level in which people can return. For those who wish to return home but cannot go back to their original place of residence because the radiation dose cannot be reduced to a safe level, there should be schemes to enable them to find an alternative place to live in the vicinity of their original domiciles, which may be beyond the borders of the towns and villages in some cases. Such flexibility should also be considered in developing restoration plans for the entire district of Futaba.

Abstract: Raising public awareness against disasters is one of the main pillars of disaster reduction policy in Japan. Numerous educational materials have been developed to raise public awareness on disasters. However it has been often the case that these materials are not seriously accepted by adults and have not lead to preventive action. To address this issue, we have developed a new program; 'Ichi-Nichi-Mae (the Day before the Disaster Hit) Project' for Disaster Awareness. This program interviews people who have been seriously affected by a major disaster, by posing the question 'What would you do if you were back the day before the disaster?', and edits the most impressive personal short stories which give clues for future preventive action. The interviews cover a wide variety of adults who experienced disasters, from housewives to small business owners and large enterprise employees. Wide varieties of disasters are covered. These stories are compiled and have been used for disaster awareness seminars and have proven to be effective, since the real stories make participants feel that it may happen to them. The methodology of this project is published on the Cabinet Office Disaster Management website and is voluntarily applied by various communities.

1. INTRODUCTION

Japan has been menaced by various natural disasters such as earthquakes, volcanic eruptions, typhoons and floods throughout the course of her history. To reduce the losses by such disasters, the Japanese Government formulated the Disaster Countermeasures Basic Act in 1961 and has implemented various disaster reduction measures; flood control works, anti-seismic building codes to name a few. Thanks to these efforts the number of casualties by natural disasters has shown substantial decrease compared to 60 years ago when the Basic Act was formulated. However Japan still faces disaster risks such as large scale earthquake & tsunami and floods induced by torrential rains. On the contrary, Japan now faces the dilemma that people have fewer live experiences of disasters and do not feel the threats and thus the communities may be less prepared against potential risks. Furthermore the aging population may be more vulnerable to disasters. Thus the Japanese Government decided to emphasize the importance of self preparedness of the residents & mutual assistance at the community level and organized 'The Special Committee on Promoting a Nationwide Movement for Disaster Reduction' in July 2005 under the Central Disaster Management Council chaired by the Prime Minister. Raising public awareness and disseminating knowledge on disasters for adults were identified as one of the target areas for action.

Various educational materials, mostly targeted at children, have been developed in Japan. Not many are targeted at adults. Those existing materials were mainly "Do's and Don'ts Preaching Style" and were not fully appreciated by adults, were not accepted as their own affair, therefore were said to be not effective in making the adults to take action. Therefore, for the sake of inducing spontaneous preventive action by adults, the authors developed a new program, the 'Ichi-Nichi-Mae (the Day before the Disaster Hit) Project'. The 'Ichi-Nichi-Mae Project' interviews people who have been seriously affected by a major disaster, by posing the question 'What would you do if you were back the day before the disaster?', and edits the most impressive personal short stories which give clues for future preventive action. The interviews cover

a wide variety of adults who experienced disasters, from housewives to small business owners and large enterprise employees. Wide varieties of disasters are covered. These stories are compiled and have been used for disaster awareness seminars and have proven to be effective, since the real stories make participants feel that it may happen to them. The methodology of this project is published on the Cabinet Office Disaster Management website and is voluntarily applied by various communities.

This paper introduces the development process of the 'Ichi-Nichi-Mae Project' methodology, the collection of stories and the application to various disaster awareness programs. This paper also introduces how this 'Ichi-Nichi-Mae Project' is widely appreciated after the Great East Japan Earthquake.

2. PROCEDURES FOR 'ICHI-NICHI-MAE PRO-JECT'

The following describes the standard procedures for 'Ichi-Nichi-Mae Project'. The main aim of this project is to make as many people as possible to have empathy for the disaster affected people, make them feel that they may experience a similar disaster and urge them to take spontaneous preventive action. Therefore extracting various personal stories arising from different standpoints in facing the disaster is important. Therefore we have designed our methodology to meet this purpose and have tried many tips to edit the impressive stories.

2.1 Editing Personal Stories

Seven steps are required to extract personal stories. 1. Identifying suitable interviewers. 2. Identifying storytellers among the affected people. 3. Group Interview. 4. Extract impressive personal stories. 5. Edit the personal stories. 6. Add a headline to each story. 7. Selection by disaster reduction expert.

1. *Identifying Interviewers*: Anyone who is serious in promoting 'Ichi-Nichi-Mae Project' is qualified to be interviewer. The number of interviewer for a disaster case should be more than one. This is to have plural standpoints in the later editing process and to avoid delusion in understanding the story. Volunteers from the mass media, governmental services, civil societies and the general public were briefed on the 'Ichi-Nichi-Mae Project' methodology and have served as successful interviewers.

2. *Identifying Storytellers*: Identify a few to several (5 to 6) storytellers per one disaster. Find a contact person in the disaster affected area and ask him/her to bring his/her neighbors or friends who have experienced the same disaster. Asking the local school PTA or community center to assist in gathering several may be a good way. The storytellers can be varied; company employees, small business owners, local construction engineers and community center participants may be asked to join. If the storytellers are acquaintances with each other, it will help to activate lively discussions. However this is not mandatory since it is often the case that the survivors of the same disaster are eager to discuss their stories even at their first meet. One important tip to make the storytelling meaningful is to include some who were responders; firefighters or relief volunteers, so that they may add a responder's point of view.

There are so many survivors who wish to share their experiences and lessons from the disaster they faced. Many of them sincerely wish that their fellows do not suffer as they did. However there are few opportunities for them, who are usually regarded as laymen, to tell their stories. On the other hand, many citizens seldom have chances to listen to live experiences of a disaster, which can be eye-openers for them. The 'Ichi-Nichi-Mae Project' makes an ideal opportunity to link the two.

3. *Group Interview*: Ask 2 to 6 storytellers in the locality who experienced the same or similar disaster to come and tell their disaster experience for about 2 hours. The interviewers will ask them to tell their experience in chronological order and ask them how they felt. Interviews should be conducted in a relaxed manner, in places like community centers, cafes or local schools. The interviewers are recommended to bring news photographs & articles of the disaster as a hint to bring back the live memories of the storytellers. Serve tea and cookies to make people relax and don't forget a voice recorder. The storytellers would not be previously notified of the questions that they are going to be asked, to avoid burdening them and to let them speak freely out of their memories at the interview. This will avoid their stories being didactic.

The interviewers will ask, how was their everyday life, how the disaster changed their life, how do they feel after the disaster, and 'What would you do if you were back the day before the disaster?' By taking the advantage of group interview, let the remarks of one storyteller provoke another's recollection, and bring lively discussion on their experience. Be careful not to interrupt when a storyteller is speaking.

4. *Extract Impressive Personal Stories*: When the storytelling session is over, the interviewers shall bring together their memos taken during the session, and pick up keywords and essence of stories which will attract people's ears. Interviewers should try to understand the wishes of the storytellers that others do not make the same mistakes, and pick up, failure stories which will generate sympathy, and also messages that the storytellers wish to convey. Interviewers should carefully remember the tone of the storytellers in identifying these essences of stories. The interviewers may pick up the points which they themselves felt sympathy. However it should be noted that stories which do not fit with disaster risk reduction should be avoided. The interviewers may think of the headlines to be added to each story at this stage. This will ease the workload at later stage.

5. *Edit the Personal Stories*: By supplementing the notes taken by the voice-recorders, the keywords and essence identified above shall be edited as short stories. The short stories should be edited in 200 to 600 words long, leaving the flavor of the speakers tone and dialects. The storytellers are not professional speakers. Therefore their talks might be

fragmented and may not be in chronological order. By editing their talks into short stories, their message becomes alive.

6. *Add a Headline to Each Short Story:* Add a suitable headline to each short story. This headline serves the purpose of attracting the readers to be interested in the short story; therefore it should not be too descriptive but rather should aim at drawing curiosity. The heart of 'Ichi-Nichi-Mae Project' is how to attract people to read other's experiences. Therefore every attention should be paid to make the headline of each short story attractive while using plain words so that even children can also easily pick up what the story wants to convey.

7. *Selection by Disaster Reduction Expert*: The significance of 'Ichi-Nichi-Mae Project' comes from the fact that it opened the door to all citizens to contribute to disaster risk reduction. Anyone who has experienced a disaster can become a resource person. Anyone who is willing to listen to disaster experiences can be the interviewer. However this requires some careful editing and selection process to maintain the quality of the collected material which are posted and made public through the Japanese Government Cabinet Office Disaster Management Website. The following are the important points to be taken note for quality control in the interview, editing and selection process.

Table 1 Standard 7 Steps in Editing Personal Stories

Step	Standard Procedure	Action Points & Tips
①	Identify Interviewer	Find good volunteers. Interviews to be conducted by 2 to 3 interviewers
②	Identify Storyteller	Request assistance from local community centers, school PTA, volunteer firefighters, and local shop leaders to indentify storytellers who experienced the disaster. Include volunteer firefighters and responders.
③	Group Interview	Find a relaxing place. Set voice recorder. Bring news photos and articles on the disaster. Don't interrupt the storyteller.
④	Extract Stories	Note down keywords. Try to pick up moving stories, mistakes and the wishes they want to convey.
⑤	Edit Stories	Edit the stories each into 200 to 600 words. One story should focus on one topic. Correct dialects if they are difficult to understand.
⑥	Add Headlines	Interviewers to agree on each headline. Headlines should be in oral tone.
⑦	Selection by Expert	Ask the disaster experts in the region to participate in the selection process. Don't add didactic modification. Make clear that mistakes are mistakes.

Do not interview with prejudgments. Do not guide the story telling by the interest of the interviewer. Do not add stories in the editing process even if it may make the story attractive. Do not add moralistic or didactic stories. Make clear that erroneous action taken by the storyteller can be clearly recognized as such. Even if the erroneous action led to good results by luck, make sure that it is clearly understood that such cases are very rare. When the edited stories are finalized, they are sent to the storytellers for their approval and then posted on the Cabinet Office Disaster Management Website.

Through these cautious procedures, the various experiences and lessons learnt by various citizens are widely shared. This 'Ichi-Nichi-Mae Project' story editing procedure is also posted on the Cabinet Office Disaster Management Website.

2.2 Workshops using the 'Ichi-Nichi-Mae Project' Stories

The 'Ichi-Nichi-Mae Project' stories can be used as materials for disaster reduction seminars and also as food for thought to induce discussions at workshops. The following table shows a model for conducting a workshop.

Table 2 Model of Workshop using 'Ichi-Nichi-Mae Project'

Step 1	Read	Divide the participants into small groups of 4 to 7. Let the participants do self-introduction, chat and small games for ice-breaking. Read carefully the disaster experience story. It would be effective to watch a video footage of the disaster, prior to reading.
Step 2	Write	Underline the points in the story where it was a surprise, a sorrow and a joy. Write memos on Post-It tags and put them on where the participant found important.
Step 3	Discuss	Group members tack tags on a large piece of paper in turn. If there are same content tags, place them together. Classify the tags by, things to be done by individuals, things to be done in the community, things to be done as the society, and discuss among the group what should be done to reduce disaster risks.
Step 4	Present	Discuss among the group and select several action points which the group thinks important for disaster reduction, and present.
Step 5	Act	Execute the action points identified by your group and the attractive action points which were identified by other groups. Action points which can be easily executed by oneself, for example affixture of furniture for earthquake safety, should be done on return to home.

2.3 Tips to Enlarge Participation

The 'Ichi-Nichi-Mae Project' can be applied to a wide variety of disaster risk reduction activities. The aforementioned workshop is just one example. Stories can be used as short articles in community papers and township circulars. They can be used as texts for schools and adult education centers. The 'Ichi-Nichi-Mae Project' has flexibility, and users may innovate good ways for application to their disaster reduction activities.

The 'Ichi-Nichi-Mae Project' started in 2005. In the initial years, the interviewing and editing were borne only by

us, the author group. Starting from 2009, in order to enlarge this project, advocates in local governments and mass media were welcomed to join the interviewing & editing. Hence we have transformed 'Ichi-Nichi-Mae Project' to a universal methodology where any advocate can join.

In this process, we have decided to always place a small illustration for each story to make it visible and attractive together with the headlines.

3. STORIES COLLECTED TO DATE BY 'ICHI-NICHI-MAE PRO-JECT'

3.1 Outline of Stories Collected

The 'Ichi-Nichi-Mae Project' started in 2005 and is continuing for more than 7 years to date. The disasters covered include 10 earthquakes, 14 torrential rains & typhoons and 2 volcanic eruptions. The oldest disaster event covered is the December 1946 Nankai Earthquake, the most recent is the July 2010 Torrential Baiu Rains. A total of 546 stories are collected and posted on Cabinet Office Disaster Management Website as of March 2012. Table 3 shows the number of stories classified by disaster type and region in Japan. Table 4 shows the number of stories classified by situation. As indicated on Table 4, we have made efforts to collect stories encountered at company & offices, schools and government offices, which were not adequately covered by existing public disaster awareness materials. Figure 1 shows an example of a story of earthquake damage at a company. Figure 2 shows a live testimony of a tsunami survivor. Figure 3 shows an example of a municipal civil servant who was responsible for evacuation center for volcanic eruption. Figure 4 shows a witness of urban flooding. Figure 5 shows a testimony of a earthquake survivor.

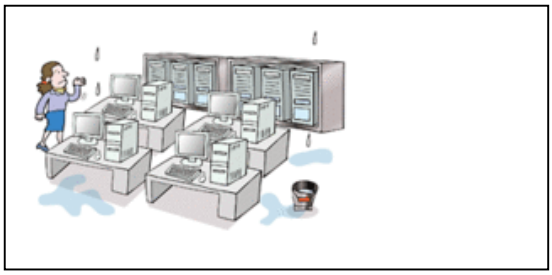

Table 3 Stories Collected by Region and by Disaster Type as of March 2012

	Earthquake & Tsunami	Torrential Rains & Tyhoons	Volcano	sum
Hokkaido	-	-	27	27
Tohoku	62	-	-	62
Kanto	-	34	-	34
Chubu	56	87	-	143
Kinki	33	27	-	60
Chugoku	40	70	-	110
Shikoku	7	7	-	14
Kyushu	42	37	17	96
total	240	262	44

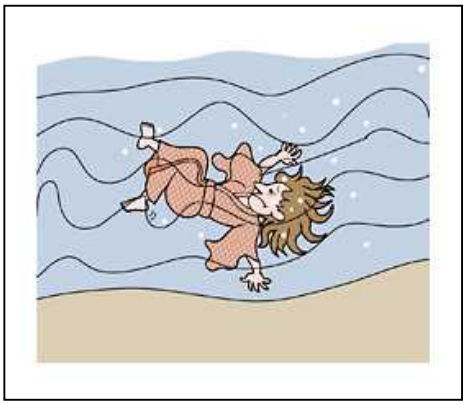
The Water Leak from the Kitchen Made My Blood Freeze (Niigata Chuetsu-Oki Earthquake 2007)

(Story by a male company employee in the 40s, Kashiwazaki City, Niigata Prefecture)

The first thing for me to do after the earthquake was to resume welfare services to our employees. Since our company cafeteria was damaged, I had to arrange delivery of 600 to 700 meals every day for about one month. Since it was summer and hot, I paid every attention to avoid food poisoning.



Since most of our major facilities were affixed against earthquakes, we did not suffer big damage. However our computer room was located one floor below the damaged cafeteria kitchen. So the water leaked from the broken pipes in the kitchen to the computer room.

Considerable amount of water fell to the computer room; it was mere luck that the water did not soak the computers themselves. If they were, we would not have been able to resume production 3 days after the earthquake. Even if the main production facilities are safe, without network services we cannot operate. Since, we have decided to waterproof our important facilities.

Figure 1 Example of a Story by a Company Employee

The necessity of the businesses to be more proactive in disaster risk reduction was pointed out in 2003 by the Special Committee under the Central Disaster Management Council. Therefore the 'Ichi-Nichi-Mae Project' paid efforts to gather as many stories which will draw concerns of company managers.

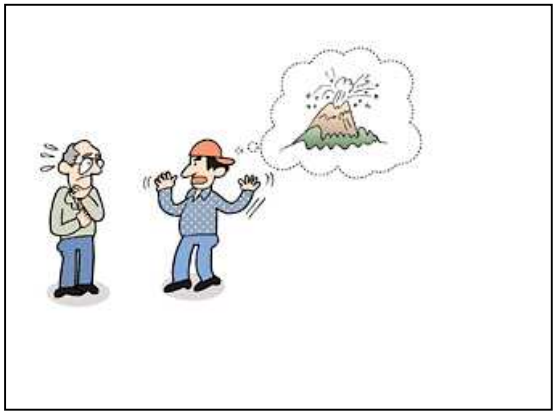
I Tumbled Round and Round in the Seawater (Nankai Earthquake & Tsunami 1946)

(Story by a female survivor in the 70s, Kaifu County, Tokushima Prefecture)

After the big shake, seawater surged in waves into my house. We had 4 family members at home. They all shouted, "Hurry! Hurry!" and ran. But the waves hit us from the back and from the side and made us so difficult to move.

The next moment, all four of us were swept away by a big wave. I tumbled round and round as if I was put in a washing machine. My mouth was filled with seawater, almost suffocated. Unless I can pop my head out the seawater, I will die! This is the end! This might be my last breath! That was all I could think in the salty whirlpool.

Luckily the next moment my head popped out of the waves! Oh my goodness! I can breathe. I am still alive. That was all I could think.



Drifting for awhile, my hand touched something like a wood. I grabbed it. Since my feet were still wandering in the water, my hands ached to keep hold of it. But if my hands let it go, I would be swept away to nowhere. I held on like grim death.

Then dim light came. I nervously looked around to see my whereabouts. Surprise! I was hanging onto the doorsill of my next door neighbor's entrance.

Figure 2 Example of a Story by a Tsunami Survivor

Quick evacuation to high land is the key to save lives in a tsunami disaster. But it is always difficult to convince people to immediately evacuate. However the real story of a tsunami survivor who was once washed away has the persuasive power.

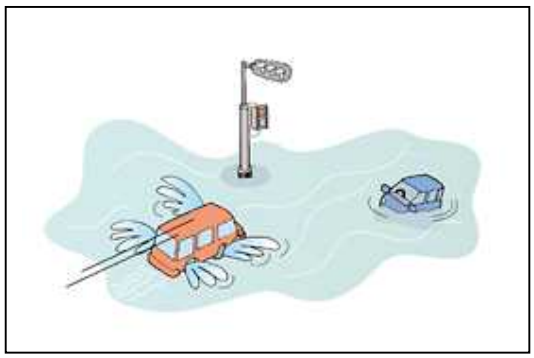
We did not know whose words to believe. (Mt. Unzen Volcanic Eruption 1991)

(Story by a municipal male civil servant in the 50s, Shimabara City, Nagasaki Prefecture)

Every day, we the municipal civil servants were tending to the evacuees in the evacuation centers all night long. There, quite often, rumors spread "On X day Y month there will be an enormous eruption!"

Such groundless rumors with no scientific evidence will spread out immediately. Since all the evacuees are full of fear and anxiety, once they hear a rumor "On X day Y month there will be zzzzzzz" indicating exact date of something to happen, they will simply react like "Oh! I have to be on maximum alert! But what can I do!" I cannot blame them for such behavior.

Actually, on X day Y month, nothing happens. But the evacuees are all afraid and anxious. We the civil servants did not have any means to ease their unnecessary fear caused by such rumors.



One day, a news media staff told me that the volcano is really in a critical situation. Since I did not have scientific background knowledge on volcanoes, I wondered whether I should believe it or not.

I really felt that there should be a trustworthy mechanism where all the local responders and the evacuees can share accurate information.

Figure 3 Example of a Story by a Municipal Civil Servant

Management of evacuation centers is one of the important tasks of municipal public servants in disaster situation. Tending to evacuees requires endurance. But it is seldom that a civil servant really faces the case that he/she has to take care of the evacuees. Hence these real stories give an image of the difficulty they will face in such disaster.

Automobiles were Swimming at the Intersection (Torrential Rains at end-August 2008)

(Story by a housewife in the 60s, Nagoya City, Aichi Prefecture)

That traffic intersection is low and has poor drainage. I was staring down from my condominium window. As the rain continued, water came from all directions and the intersection became like a swimming pool.

A small vehicle was waiting for the traffic light to change at the center of the intersection. When a 2000cc class large sedan passed by, the small vehicle would float and sway. I felt "The Olympic Games are over and now it is the automobile's turn to do the swimming." I was sure that it would be horrendous to be in that vehicle.

Many cars could not make it through, and they turned around and drove on the sidewalks and barely escaped sinking. Water in such torrential rains really swells in minutes. I think it is definitely needed to make it a rule that "If a road starts to be submerged, we must not drive." It should be one of the flood disaster countermeasures.

Figure 4 Example of a Story by a Housewife

Car drivers tend to underestimate the perils of flooding, since they do not get soaked by the rain when they are in the car. But when the roads are submerged to a certain depth, you may lose control of the car. This witness clearly describes the danger of driving in inundated roads, and the danger of quick swelling of water in built up areas.

I Really Regret Unprepared Single's Life (The Great East Japan Earthquake, March 2011)

(Story by a company employee in the 30s, Sendai City, Miyagi Prefecture)

The Earthquake came when I was working in my office. Everything in the office turned over and fell down. Fortunately nobody was injured in my office.

I reported to the main office that we were all safe. I informed my parents that I was safe. I was lucky to get my e-mail messages through and felt relieved.

Then I went home to my dormitory room. It was a terrible mess! Since I am single and living alone, I do not cook. I always dined outside or bought lunch boxes at nearby convenience stores. My refrigerator was always empty.

I asked my parents in the countryside to send me some food. But immediately after the earthquake, the package delivery service was not available. So my relief food supplies did not reach me. Supermarkets and convenience stores had empty shelves. I nearly starved to death.

I really recognized the importance of food stockpiling. If I was back the day before the Earthquake, I would buy canned food.

Figure 5 Example of a Story by a Single Male Earthquake Survivor.

In the Nationwide Movement for Disaster Reduction, the importance of self help is emphasized. Stockpiling food and water bottles for three days' ration at home are recommended. This earthquake survivor gives good evidence for such preparedness.

4. THE SIGNIFICANCE OF 'ICHI-NICHI-MAE PROJECT'

There are three main objectives for the 'Ichi-Nichi-Mae Project'. They are;

1. Edit & classify stories of disaster affected people and disaster responders into a certain format communicable to other localities and to be recorded in an organized database,

2. The stories to be read by citizens and to be utilized at disaster education opportunities such as seminars,

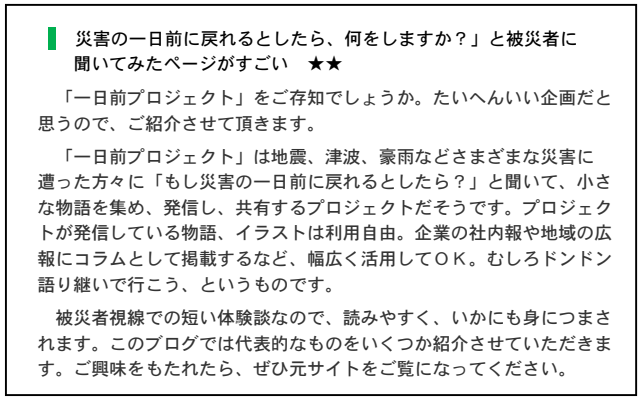
3. Voluntary workshops to be organized in various communities using the stories.

It is always a big challenge to make people aware of disaster risks and have them acquire knowledge on disasters and lead them to action. The difficulty in this process is the fact that people seldom have the opportunity to experience a real big disaster, and hence people tend to underestimate the disaster risks they face and are reluctant to act before a disaster. The 'Ichi-Nichi-Mae Project' has significant advantages to overcome this difficulty. It is human story oriented; the characters appearing in the stories are ordinary men and women in various occupations and in positions. The readers feel that the characters are no heroes or heroines, they can find characters resembling themselves in either of the stories and get the impression that the similar disaster events may happen to them. This sense of 'men & women next door' attracts the readers into the stories and gives them a feeling that such things may happen to them and this will urge them to initiate preventive action.

5. THE PROPAGATION OF 'ICHI-NICHI-MAE PROJECT'

The methodology and stories of 'Ichi-Nichi-Mae Project' are posted on Cabinet Office Disaster Management website and are downloadable free of charge. It requires neither prior permissions nor registrations to download and utilize. This is because we the authors and the Cabinet Office would like to encourage as many to access and utilize. Therefore there is no firm statistics on how many have read the stories and how much they are utilized. However there are many examples of utilization.

5.1 Utilization by Local Governments, Companies and the Media



Tokushima Prefecture, which is facing the possibility of a large scale earthquake & tsunami, is posting the stories of 'Ichi-Nichi-Mae Project' in series on its Anshin Tokushima website. 138 stories are posted as of April 2012. Fujikawaguchiko Town, located on the skirts of Mt. Fuji, introduces the aims and significance of 'Ichi-Nichi-Mae Project' on its website and encourages her citizens to look up at Cabinet Office Disaster Management 'Ichi-Nichi-Mae Project' website.

Several companies have joined in propagating the 'Ichi-Nichi-Mae Project'. Rescuenow Inc. and J-CAST Inc. are introducing stories from the 'Ichi-Nichi-Mae Project' on their websites. The Tokio Marine & Nichido Insurance Company, which is the leading insurance company in Japan and the Japanese Consumers' Co-operative Union (COOP) bought numerous copies of the 'Ichi-Nichi-Mae Project' brochures edited by the Cabinet Office and distributed them to their customers.

The mass media also joined in the propagation. The Mainichi Shimbun, one of the major national newspapers introduced it on their article. The NHK, Japanese Public Broadcasting Cooperation, on September 1st 2012, which is the designated National Disaster Prevention Day, aired recitations of the 'Ichi-Nichi-Mae Project' stories in their national radio program and called on listeners to visit the Cabinet Office Website.

5.2 Propagation through Citizens' Blogs

Recently several cases of citizen's blogs have featured the 'Ichi-Nichi-Mae Project'. Since this project aims to broaden disaster reduction activities through free access to the methodology and the stories, the Cabinet Office does not control links to this website. Therefore there is no exact numbers on how many links are made to this website from others. Nevertheless, there are many citizen's blogs citing this website and adding their comments and recommending other to read. Figure 6 is an example of these blogs.

災害の一日前に戻れるとしたら、何をしますか？」と被災者に聞いてみたページがすごい　★★

「一日前プロジェクト」をご存知でしょうか。たいへんいい企画だと思うので、ご紹介させて頂きます。

「一日前プロジェクト」は地震、津波、豪雨などさまざまな災害に遭った方々に「もし災害の一日前に戻れるとしたら？」と聞いて、小さな物語を集め、発信し、共有するプロジェクトだそうです。プロジェクトが発信している物語、イラストは利用自由。企業の社内報や地域の広報にコラムとして掲載するなど、幅広く活用してＯＫ。むしろドンドン語り継いで行こう、というものです。

被災者視線での短い体験談なので、読みやすく、いかにも身につまされます。このブログでは代表的なものをいくつか紹介させていただきます。ご興味をもたれたら、ぜひ元サイトをご覧になってください。

Figure 6 Example of a Citizen's Blog
(For translation see below)

The website asking disaster affected people "What would you do if you were back the day before the disaster" is terrific! **

Do you know the 'Ichi-Nichi-Mae Project'? I think this is a great undertaking, so I would like to introduce it to you.
'Ichi-Nichi-Mae Project' interviews people who were affected by earthquakes, tsunamis and torrential rains and poses the question "What would you do if you were back the day before the disaster". Small stories are collected and disseminated for experience sharing. The stories and illustrations are free to use. It can be copied for use on company's in-house newsletter or community papers. It encourages copying and dissemination.
The stories are compact and based on layman's view, so it is so easy to read and you can be empathetic!

These blog examples show that the aim of 'Ichi-Nichi-Mae Project' to be a tool for promotion of nationwide movement for disaster reduction was well met. The project did not follow the conventional government campaign style; off-the-shelf standard programs to be duplicated at every prefecture through the administrative layers of governments. The project encouraged various participants to choose & adopt the contents to their own needs & taste and disseminate them through various channels.

6. THE APPLICATION OF 'ICHI-NICHI-MAE PROJECT'

The 'Ichi-Nichi-Mae Project' is also actively used in disaster education programs. Ube City Office made enlarged story panels of 'Ichi-Nichi-Mae Project' and exhibited them at the Ube Disaster Reduction Educational Seminar hall for the participants to learn.

Mikiko Ikegami was invited to serve as the lecturer at the Chiba Community Center Manager's seminar entitled "The Role of Community Centers and Managers in Earthquakes" and used the 'Ichi-Nichi-Mae Project' stories related to the management of evacuation centers. Three categories of stories were used. Management of evacuation centers in a disaster, increasing disaster resilience at communities, disaster response work to be borne by civil servants. By comparing the story of the civil servants and the story of the evacuation centers, the participants were able to gain realistic images of what happens in a disaster and what are their crucial roles are. According to the post-seminar evaluation questionnaire, the participants were able to feel the reality of disaster. Table 5 shows the feedback comments of the participants.

Table 5 Positive Feedback by the Participants

The stories were based on real experience and were very useful.
The real stories were impressive and useful.
The comments by the manager who experienced the real disaster are really eye-opening.
It was really good to learn the real stories in such a concentrated way in limited timeframe.
I really felt that "At first all the evacuees act as if they are lords or princesses" is really true. How to have positive participation of the evacuees relies on our everyday communication with our residents.

After the March 2011 Great East Japan Earthquake more attention is paid on disaster awareness and education programs. Many local governments are reviewing their disaster reduction programs and 'Ichi-Nichi-Mae Project' is further highlighted.

The Kawai Town in Nara Prefecture, having assisted the tsunami devastated Rikuzen-Takada City in Iwate Prefecture witnessed the old stone monuments recording historical tsunamis. Upon return to their home town, they recognized the importance of reviewing their home town's disaster history and experience. Kawai Town initiated their own 'Ichi-Nichi-Mae Project', first by reviewing their 1982 flood experience and interviewing the survivors.

Other organizations which are not directly focused on disasters also applied 'Ichi-Nichi-Mae Project' methodology to inherit their experiences to the younger generation. The Japanese Society for Artificial Organs applied the 'Ichi-Nichi-Mae Project' methodology to record and to inherit their experiences during the Great East Japan Earthquake.

These new applications indicate the general versatility of the 'Ichi-Nichi-Mae Project' methodology.

7. CONCLUSIONS

The 'Ichi-Nichi-Mae (the Day before the Disaster Hit) Project' interviews people who have been seriously affected by a major disaster, by posing the question 'What would you do if you were back the day before the disaster?', and edits the most impressive personal short stories which give clues for future preventive action. We have developed this methodology to enable various participants to be the interviewer and the story teller. Seven steps are followed to edit the stories. The edited stories are posted on the website and may be used by anybody. The three main objectives of the 'Ichi-Nichi-Mae Project' were met; 1. Edit & classify stories of disaster affected people and disaster responders into a certain format communicable to other localities and to be recorded in an organized database. 2. The stories to be read by citizens and to be utilized at disaster education opportunities such as seminars. 3. Voluntary workshops to be organized in various communities using the stories.

After the March 2011 Great East Japan Earthquake, this project is attracting renewed attention and further applications are found. The general versatility of this project has been proved. We expect further developments in various localities and sincerely hope that our methodology is widely used to inherit the lessons learnt to the next generations.

Abstract: Kashmir earthquake of 2005 caused severe devastation in northern parts of Pakistan. Large uncertainties and complexities involved in accessing the phenomenon related to earthquake makes mitigation choices difficult. In this study 132 (qualified) professionals and researchers related to construction industry were surveyed and their opinion about seismic vulnerability of houses in Pakistan was recorded. The work was discretized into four parts as follows. First; Assessment of percentage of seismically vulnerable houses in Pakistan. Second; Concern of seismic safety of houses in general public at different time periods from Kashmir Earthquake. Third; Modification of construction practices after 2005 Kashmir Earthquake. Four; Comparison of different options to enhance seismic concern in general public of Pakistan. The result of this study showed that more than 75% of houses in Pakistan are seismically vulnerable. The study also revealed that concern of seismic safety of houses before 2005 Kashmir Earthquake was at minimum and increased rapidly after the earthquake. However, with the passage of time, the concern of seismic safety of houses has decreased. It seems that a lesson was learnt and forgotten with the passage of time. The results of this study are useful to decide the future seismic mitigation strategies.

1. INTRODUCTION

The 2005 Kashmir Earthquake was among the most devastating seismic activities in past twenty years (Fig.1). It resulted in more than 86,000 fatalities, 106,000 people injured and 4 million people left homeless in northern Pakistan and Azad Jammu and Kashmir (Peiris et al. 2005a, Ahmed et al. 2009). The damage and collapse of the houses during the 2005 Kashmir Earthquake posed a serious threat to the seismic safety of houses in other parts of the country in context of modified seismicity of the region (Kumahara and Nakata, 2006 and Nakata et al. 1991). Non-engineered structures, particularly, pose a serious threat to their inhabitants during earthquakes as proved by 2005 Kashmir Earthquake in which most of the 32,000 destroyed structures were non-engineered. Such a large scale devastation of civil structures attracted researchers from all parts of the world to analyze damage causes and suggest seismically efficient reconstruction techniques (Smith and Redman, 2009, Dowling et al. 2005 and Bartolome et al. 2004). Application of proposed approaches in local environment is challenged by a number of factors (Kazmi et al. 2012).

In context of modified seismicity of the region (Kumahara and Nakata, 2006 and Nakata et al. 1991), it is necessary to evaluate the seismic safety of houses. In essence, owing to a number of uncertainties and complexities, it is difficult to quantify the seismic safety of houses. For evaluation, we need to have a simple and robust method which must be sensitive to uncertain parameters. Meanwhile, it is required that method for the evaluation of seismic safety of houses must be free from influence of individual decisions and personal influences.

Our work encompasses assessment/evaluation of seismic safety of residential houses in Pakistan, which can be considered an important contribution in proposing the future seismic mitigation strategies. Knowing the complexities and uncertainties involved in the seismic phenomena and response of the structures, we have adopted a statistical approach based on the cumulative opinion of the researchers and professionals related to the local construction industry.

2. DISCRITIZED EVALUATION PROCEDURE

Occurrence of earthquakes is uncertain in time and space domain. On the other side, the structural damage due to earthquake is a function of excitation force and resistance of structure to lateral forces. To avoid such a terrific devastation in any future seismic event, there is a dire need to investigate the seismic safety of houses and revise procedure/guidelines for seismically safe construction.

Therefore, the process of evaluation of seismic safety of houses is discretized into four factors which need to be accessed with reasonable accuracy.

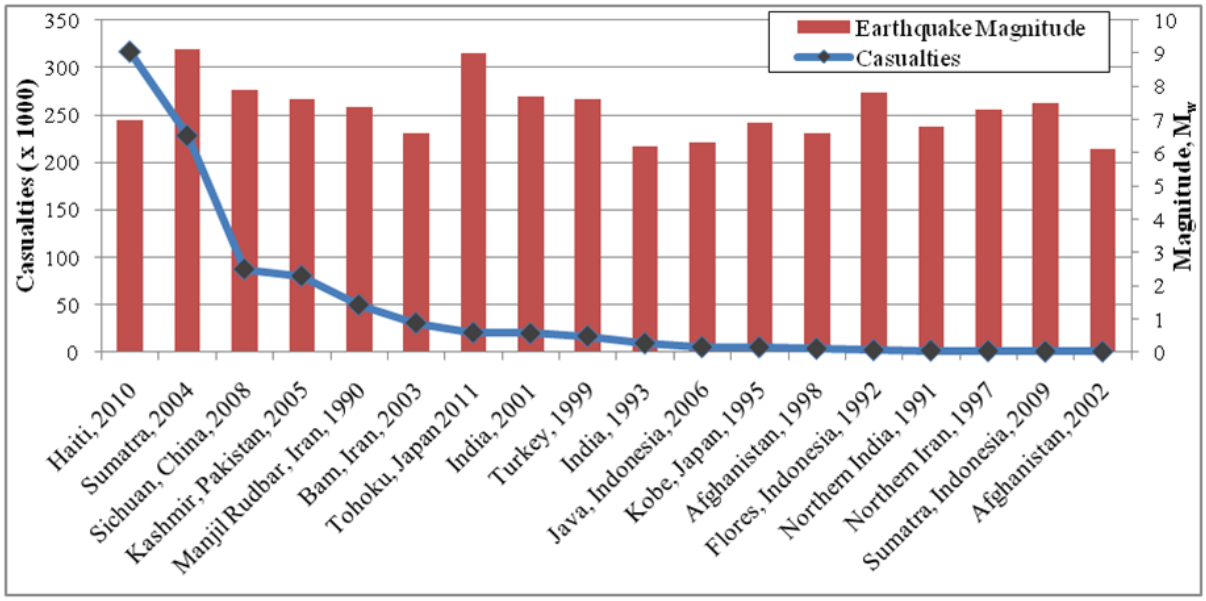

Figure 1: Fatalities and magnitude of earthquakes since 1991, which result more than 1000 fatalities

1. The percentage of vulnerable structures which pose serious threat to the inhabitants. This will index the importance and consideration of measures for seismic safety of houses.
2. The concern of seismic safety of houses in the general public.
3. After experiencing the devastation of 2005 Kashmir Earthquake, we were supposed to improve the construction practices. It is required to investigate how the construction practices are enhanced.
4. The gap between policies and their application in the local community is challenged by a number of factors. Therefore it is important to evaluate the 'most effective way' to enhance the concern of seismically safe construction in local community.

The uncertainty and complexity of seismic event and structural response are important to be considered in getting the answer of aforementioned queries and are discussed in the following sub-sections.

2.1 Uncertainty and Complexity of Seismic Events and Structural Response

Uncertainty of seismic event is fundamentally discussed in articles related to the earthquakes and structural response (Honda and Ahmed, 2011, Ahmed and Honda, 2010). But here in accessing the solution of queries, the uncertainty is exponential. For example, in assessment of seismic vulnerability of non-engineered houses, first uncertainty involved is the nonlinear response of structure under consideration; secondly the diversity of structures (Ali, 2006, Ali and Muhammad, 2007, and Badrashi et al. 2010) is required to be considered in order to be certain about the seismic vulnerability of non-engineered houses. But, this uncertainty is difficult (if not impossible) to be considered by sophisticated techniques, such as finite element method approach, etc.

The response, interest and involvement of the general public are important for successful implementation of the guidelines for improvement of seismic safety of houses. However, the response of the general public is complex due to different financial condition, social exposure and different level of preference among individuals. This complexity is to be incorporated in one way or the other to be certain about the seismic vulnerability of non-engineered houses in Pakistan.

2.2 Advantages to Survey Professionals and Researches

We surveyed 132 researchers and professionals working in the local construction industry to get a diverse opinion/information based on their experience. It is noteworthy that only qualified professionals were surveyed. The survey was designed not to test the professional competency, rather it was meant to extract information based upon individual's experience and exposure and area of assess. Survey results were analyzed to get the cumulative response, which was termed as 'cumulative response of professional and researchers'. The authors reckon that the study is worth considering for deciding guidelines to enhance the seismic safety of non-engineered houses in Pakistan. Following is the discussion on the advantages of this approach.

Diverse opinion: Consideration of diverse opinion is main advantage of this approach. Based on experience and exposure, each person being surveyed possesses different information about the questions being asked; the diversity of feedback thereby reduces the uncertainty involved. By

analyzing the opinions of 132 peoples, we are able to answer the queries (involving uncertainty) with a reasonable accuracy.

3. PERCENTAGE OF SEISMICALLY VULNERABLE HOUSES IN PAKISTAN

Kashmir Earthquake was one of the most devastating earthquakes in the recent history of south Asia. According to the detailed seismic history of the whole country since 1965, it was never subjected to such an intense shaking before Kashmir Earthquake. It is remarkable to note that there were only seven earthquakes larger than M4.0 since 1965 (Fig. 2).

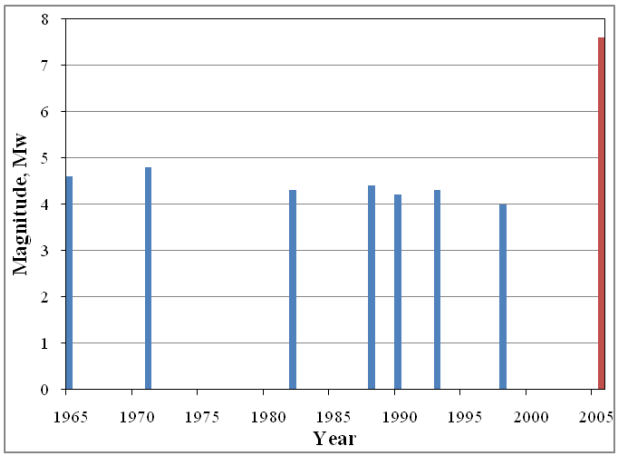

Figure 2. Earthquakes with magnitude greater than 4.0 in Pakistan since 1965.

Therefore, consideration of seismic safety of houses was not a prime concern of house owners before Kashmir Earthquake. Therefore, to assess expected damage due to future earthquake, it is necessary to know the percentage of seismically vulnerable houses. Furthermore, this percentage will show the importance and urgency of proposing measures to enhance seismic safety of non-engineered houses. To accomplish this goal, following question was asked to the professionals and researchers.

'A construction without any advice of an Architect and/or Engineer is termed as non-engineered construction. In your opinion what is the percentage of one to two floor non-engineered houses in Pakistan.'

Each of the contacted professional may have different response depending on his/her exposure and area of assess. Fig. 3 shows their response both in the discretized and cumulative percentage. It is important to note here that the response may also have spatial variation. However, we'll focus to a generalized discussion.

The most frequent value of the obtained distribution function suggests 85 to 90% non-engineered structures (Fig. 3a). It is interesting but unfortunate to note that more than 75% non-engineered houses are reported corresponding to 78% cumulative response distribution (Fig. 3b). 100% cumulative response ensures more than 50% of non-engineered houses. This reveals that all professionals and researchers are unanimously agreed that at least every second house in Pakistan poses serious threat to the inhabitants. This is really an alarming situation for the society and needs to be addressed seriously.

The seismic vulnerability of non-engineered construction is a fact, and to access the seismic vulnerability of houses we asked the following question to the professionals and researchers.

'Considering the percentage of non engineered houses mentioned by you, how do you rank the seismic safety of such construction?'

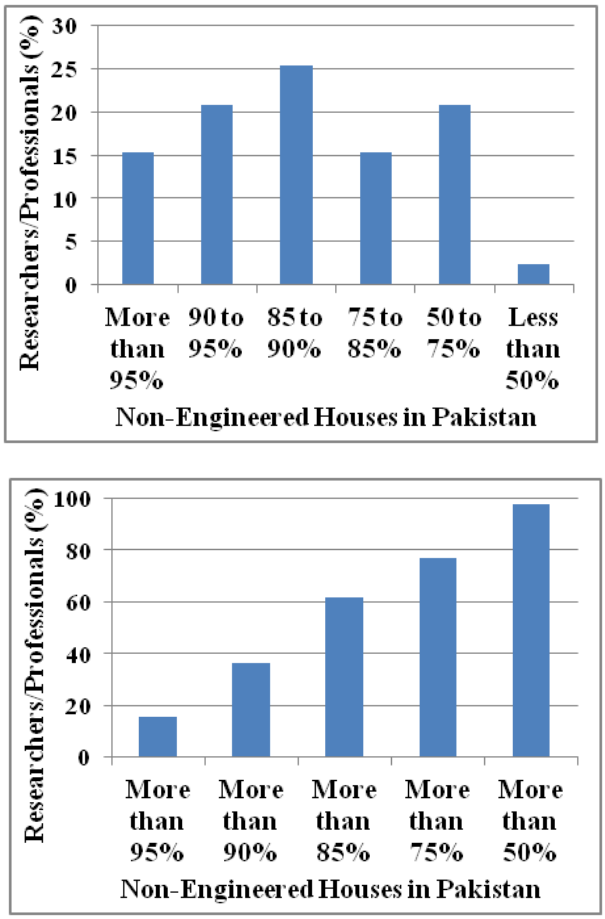

Figure 3. Percentage of seismically vulnerable houses in Pakistan in view of professionals and researchers (a) Discritized percentage (b) Cumulative percentage

The response was recorded corresponding to a scale of 1 to 5. Scale-1 ranks the seismic safety of non-engineered houses to be 'unsatisfactory' and scale-5 corresponds to a 'satisfactory' condition. The survey responses corresponding to each scale of seismic safety are plotted in Fig. 4. The peak response corresponds to scale-2. The cumulative response of the scales 1, 2 and 3 is 90% of the total; which suggests that 90% of professionals and researchers are agreed that the seismic performance of houses in Pakistan is unsatisfactory.

We can conclude from the aforementioned discussion that in view of 78 % of professionals and researchers, more than 75% of houses have unsatisfactory performance against seismic activity.

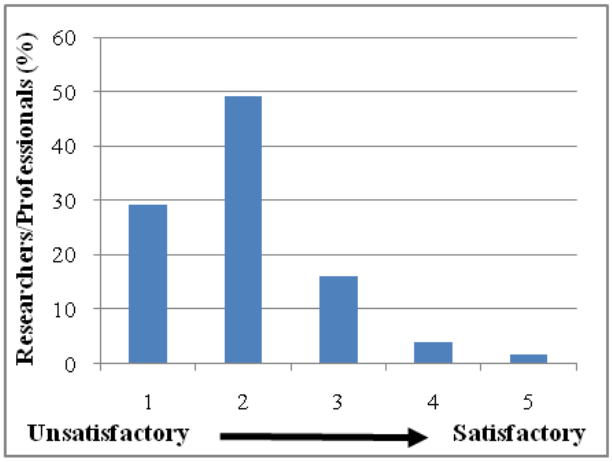

Figure 4. Seismic performance of non-engineered houses in Pakistan in view of professionals and researchers

4. CONCERN OF SEISMIC SAFETY IN PUBLIC

Human sensitivity to natural disasters gets its peak immediately after the event and dies off with the time. Therefore, change in attitude of the local community towards the seismic safety of their houses was quite natural after the devastating Kashmir Earthquake. To consider this aspect in formulating the guidelines for seismically safe construction, it is required to evaluate the concern of seismic safety of houses in general public. Concern of seismic safety and modification of construction techniques are discussed in detail by the authors (Kazmi et al. 2012) based on their field investigation of various sites in earthquake affected areas at

different stages after the 2005 Kashmir Earthquake. To evaluate the concern of seismic safety of houses in local public, we consider the following four stages for an easy discussion.

- Stage-I: Before 2005 Kashmir Earthquake
- Stage-II: From date of occurrence to two months after Kashmir Earthquake
- Stage-III: From two months to two years after Kashmir Earthquake
- Stage-IV: From two years after 2005 Kashmir Earthquake to present.

In survey, the question asked to evaluate the concern of seismic safety of houses in all above mentioned stages was:

'How *do you rank the 'consideration of seismic safety by general public' during the following time periods?*

1. *Before 2005 Kashmir Earthquake*
2. *From the day of occurrence to two months after Kashmir Earthquake*
3. *From two months to two years after Kashmir Earthquake*
4. *From two years after the earthquake till present'*

The response, for all the mentioned stages, is recorded along a scale of 1 to 5, where scale-1 corresponds to least concern and scale-5 corresponds to maximum level of concern. The response from the professionals is analysed and presented in Fig. 5(a) to 5(d) for all the four abovementioned stages. The detailed discussion is presented in the following sub-sections.

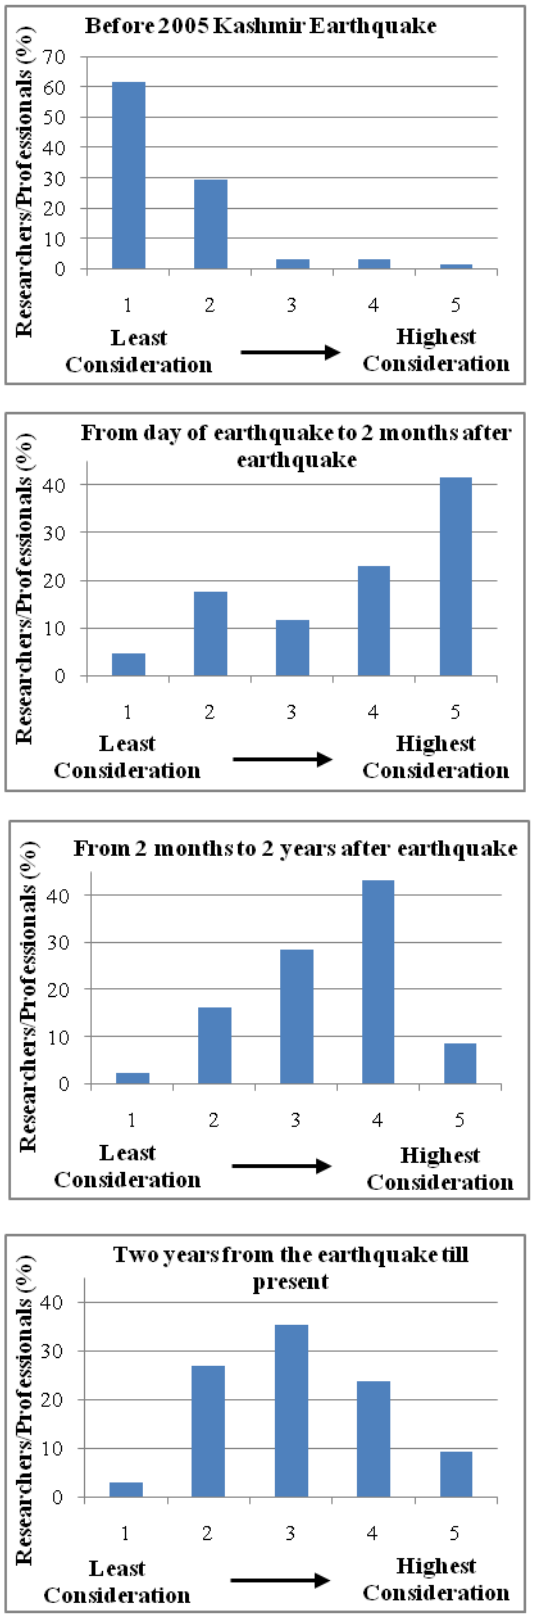

Figure 5. Variation of concern of seismic safety of houses in general public of Pakistan at (a) Stage-I (b) Stage-II (c) Stage-III (d) Stage-IV

4.1 Stage-I

Fig. 5(a) shows responses corresponding to the concern of seismic safety of houses in general public before the 2005 Kashmir Earthquake. A clear peak is observed against scale-I which corresponds to the least concern. It is also clear from Fig. 5(a) that 95 % of responses correspond to scale-1 and scale-2; depicting that researchers and professionals unanimously agree that there was least concern of seismic safety of houses in general public before the 2005 Kashmir Earthquake. Dormant seismic history of the region (Fig.2) could be most prominent among the possible reasons.

4.2 Stage-II

The first two months since the occurrence of earthquake were particularly important because curiosity about the safety of houses against earthquake was at its peak. Fig. 5(b) represents the response of researchers and professionals to concern of seismic safety of houses from occurrence of earthquake to two month after the earthquake (stage-II) and a clear peak is observed against scale-5 which corresponds to maximum level of seismic concern. Results of Fig. 5(a) and Fig. 5(b) highlight the event driven nature of response in developing countries. Seismic safety of the dwellings was not a concern of common people before the tragic event but evolved as a prime concern for the first two months after the occurrence of the earthquake.

4.3 Stage-III and Stage-IV

Along the time scale, from two months to two years after the date of earthquake is categorized as stage-III. The response of the researchers and professionals regarding the concern of seismic safety in stage-III is summarized in Fig. 5(c). In contrast with Fig. 5(b), the peak is shifted from scale-5 to scale-4 in Fig. 5(c) which is evident of a decreasing trend of seismic safety in general public with the passage of time.

Stage-IV encompasses the time from two years since the occurrence of the earthquake to the present. The survey results for stage-IV are shown in Fig. 5(d). The distribution function has shifted from scale-4 to scale-3 in Fig. 5(d), clearly showing a decreased concern of seismic safety as compared to stage-III.

To learn a lesson from natural disasters for a very short time and to forget it with the passage of time leaves us at the mercy of nature. Therefore, immediate actions are required to be taken to educate the community in context of safety of their houses and preparedness for any future seismic event. In parallel, the change in construction practices after the 2005 Kashmir Earthquake must be evaluated

5. MODIFIED CONSTRUCTION PRACTICES

After experiencing devastation of 2005 Kashmir Earthquake, it was required to modify the construction practices and techniques accordingly. Authors acknowledge the efforts and contributions by the private and public sector to enhance the seismic safety of structures.

After Kashmir Earthquake, seismic zoning of Pakistan was revised in light of modified seismicity of area (Kumahara and Nakata, 2006 and Nakata et al. 1991) and building code of Pakistan (PBC, 2007) was enriched with seismic provision. A number of public sector organizations (such as ERRA, NDA, etc) and NGOs (Non Government Organizations) strived to train labour and educate community for the said purpose.

A good number of procedures are proposed by researchers to enhance the seismic safety of houses (Smith and Redman, 2009, Dowling et al. 2005), such as PP-band method (Sathiparan et al. 2010 and Sathiparan et al. 2008), etc. Application of such sophisticated approaches in the community is challenged by a number of factors, such as financial constraints, availability of materials and tools, requirement of skilled labour, etc (Kazmi et al. 2012). Considering this background; we asked the following question to professionals and researchers.

'After experiencing the devastation of 2005 earthquake, we were supposed to improve the construction techniques. In context of seismic safety, how do you compare the present construction practices with construction procedures before 2005 earthquake?'

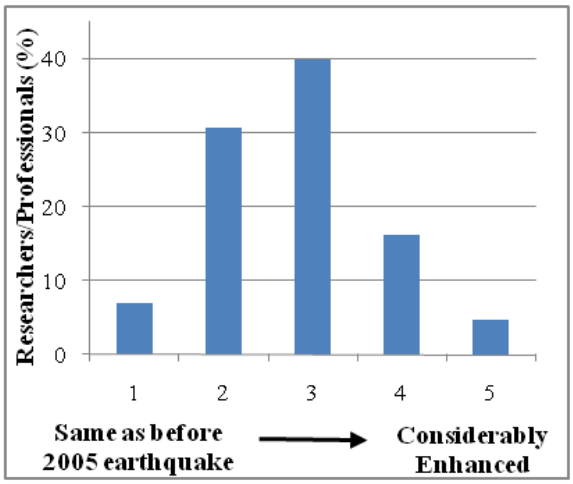

Figure 6. Comparison of pre- and post- Kashmir Earthquake construction practices

Respondents were requested to rank the modification in construction practices on a scale of 1 to 5, where scale-1 corresponds to 'same as before 2005 earthquake' and scale-5 corresponds to 'considerably enhanced'. The responses are analyzed and presented in Fig. 6. The most frequent value of the obtained response distribution function corresponds to scale-3; while scale-1 and scale-2 have 7% and 31% responses, respectively. It is pertinent to mention that scale-1 represents unimproved construction practices when compared with pre-earthquake construction; scale-2 shows slightly enhanced construction practices and similarly scale-3, 4 and 5 represent progressively improving construction practices. The sum of scale-1, 2 and 3 is 78%, showing that an overwhelming majority of 78% of respondents are agreed that construction practices in Pakistan are either unimproved or are slightly enhanced

compared to the construction practices before 2005 Kashmir earthquake.

Considering aforementioned analysis, it is required to invoke the awareness of seismically safe construction in local community. So, the professionals were inquired about the most effective way to educate general public about seismic safety of houses; as discussed in the next section.

6. MOST EFFECTIVE WAY TO ENSUR APPLICATION

The gap between polices and their application in local community is governed by a number of factors. Generally, financial conditions, coherence of new policies with culture and trends, and awareness of community regarding the importance of issues, etc. play the effective role.

In the following discussion, the main interest of authors is to discuss various options to increase the seismic safety of houses. In this discussion we relatively compare the following four options.

1- By enforcing strict laws
2- By public awareness campaigns (seminars, workshops, media campaigns, etc)
3- Providing easy access to useful information (brochures in local language, etc)
4- By giving financial incentives.

It is worth mentioning that some researches highlight the importance of financial assistance to enhance concern of seismic safety (Meguro, 2008). To evaluate the most effective means for increasing the seismic safety of houses, we asked the following question to the professionals and researchers.

'What is the most effective way to enhance the concern of seismically safe construction in local public of Pakistan?'

The responses are analyzed and summarized in Fig. 7. About 38% professionals are of the view that statutory regulations and their strict implementation is the way to assure seismically safe construction; while 34% of respondents believe that the concern of seismic safety of houses can be enhanced by initializing public awareness campaigns through electronic/print/social media, workshops and seminars, etc. Only 12% think that financial assistance can increase the seismic concern in general public of Pakistan.

It is important to mention that authors are intended to compare the four options in relative terms. The results are helpful to decide preference and relative effectiveness of different option to increase the concern of seismic safety of houses.

7. CONCLUSION

Earthquake of 2005 was a devastating experience in the recent history of Pakistan. It resulted in a huge number of casualties and posed a serious question to the seismic safety of residential houses. The main focus of this study was the seismic safety of the residential houses. The analysis sequence was discretized into four parts (i) what is the percentage of seismically vulnerable houses? (ii) concern of seismic safety of houses in local community (iii) how the construction practices were modified after 2005 Kashmir Earthquake? (iv) what is the most effective way to increase the concern of seismic safety of houses?

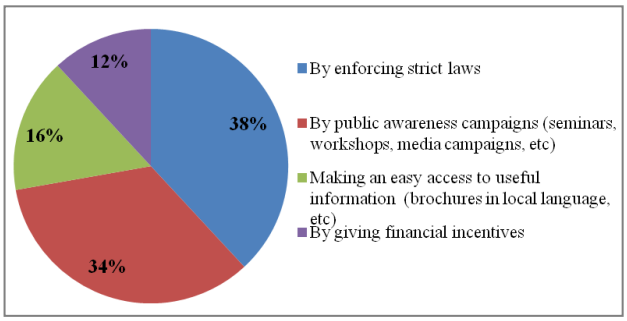

Figure 7. Effectiveness of different options to increase the concern of seismic safety of houses in general public of Pakistan

Owing to uncertainty of seismic events and diversity of structural response, it is difficult to answer the aforementioned queries. Therefore, an indirect and more practical approach was adopted to accomplish the goal. Using this approach 132 professionals (only qualified engineers and architects) and researchers working in local construction industry were contacted; and their responses were rationally analyzed.

The results of this study show that more than 75% of houses in Pakistan are seismically vulnerable which indexes damageability of structures in future earthquakes.

Concern of seismic safety of houses is the second point discussed in this work. The study also reveals that the concern of seismic safety of houses was at minimum in the community before 2005 Kashmir Earthquake. After the Kashmir earthquake, a sharp peak of curiosity towards the seismic safety of houses was observed, but died off with the passage of time. It seems like a lesson was learnt and forgotten within a couple of years of the tragic devastation.

After Kashmir Earthquake, a modification in construction practices was expected. According to this study, however, 79% of the professionals and researchers have opinion that the construction practices are either similar as practiced before Kashmir Earthquake or are slightly improved.

For enhancement of seismic safety of houses, various option were compared in this study; such as by enforcing laws, public awareness campaigns, giving financial incentives, etc. The results have shown that formulation and implementation of statutory regulations public awareness should be first priority to enhance the seismic safety of houses and it should be supported by public awareness campaigns.

THE USE OF GEOSPATIAL TECHNOLOGIES AND LOCAL AREA SPATIAL ANALYSIS TO UNDERSTAND SUB-NEIGHBORHOOD SCALE IMPEDIMENTS TO RECOVERY AFTER A CATASTROPHIC DISASTER

Andrew Curtis

Associate Professor, Director of the GIS, Health & Hazards Lab, Department of Geography
Kent State University, USA
Email: acurti13@kent.edu http://www.kent.edu/CAS/Geography/ghhlab/

Abstract: 0ne of the least understood aspects of disaster science is the complexity of neighborhood recovery after a catastrophic event. For the largest disasters this recovery period can extend into multiple years during which time dynamic processes of rebuilding, recreating social cohesion, existing and emerging health vulnerability, economic opportunity, political representation and even the presence of crime are indicators, stimulators and impediments to a return to normalcy. Although these processes play out at different geographic scales, the least understood, mainly because of data collection problems, is that of the micro-environment within neighborhoods. This paper will present a methodology which has been used to asses spatial patterns of recovery in post-Hurricane Katrina New Orleans, Louisiana and post-earthquake Haiti. By using spatially encoded video, novel data coding strategies within a geographic information system (GIS), and local area spatial analysis, patterns of recovery and the impediments to that recovery can be identified. In addition, map layers can be generated to be combined with data from cognate research, such as disaster medicine and public health. This approach is important to not only advance theories of recovery, but also to provide near-real time insight in supporting recovery efforts.

1. INTRODUCTION

Global and national attention is often drawn to significant disasters in the immediate aftermath. In the United States recent events of note have included Hurricane Katrina, the tornadoes of 2011, and most recently (2012) Superstorm Sandy. Just beyond the United States, Haiti is still struggling from the earthquake of 2010 which was followed by a cholera epidemic. This outbreak was partly spread because of the disaster related infrastructure damage and societal disruption layered onto an already impoverished nation. One connection between all these events, as well as with many other global catastrophes that have occurred in the same time frame, is that "recovery" is still not complete as of 2012. Media attention tends to wane after the first year of a disaster. Historically even academic interest is focused on the first 12 to 18 months following the event, and yet recovery in each of these disasters is still occurring, up to seven years later in the case of Hurricane Katrina.

What these recent events have reaffirmed is the need for spatially contextualized research into recovery (Mills 2008). Several questions need to be posed in order to understand, learn from, and formulate recovery policy. The first fundamental question which is beyond the scope of this paper is *what is recovery*? Is it a return to normalcy, a return to prior levels or even "building back better" as described by President Clinton after the earthquake in Haiti? The second question is, *what should we use to measure recovery, and what is an appropriate scale*? Although there are different recovery metrics available after an event; the number of homes rebuilt, the reconstruction of community services, economic recovery, a return to a benchmark of health outcomes, these are mostly reported as the aggregate, by region, or city, or at best urban subsection. Yet recovery occurs at different geographic scales, and such aggregate data may smooth out the ongoing and debilitating impediments to recovery at the neighborhood or street scale. This is not to dismiss the importance of aggregate measures of recovery because these are necessary for political assessment and to prioritize resources. This paper, though, focuses on the missing component for much recovery work; longitudinal change at the finest of geographic scales.

2. FINE SCALE RECOVERY

2.1 Impediments to Recovery at the Fine Scale

There are many reasons why fine geographic scales are intuitively important for communities impacted by a disaster:

Will my neighbors return?
How long will I have to look out on destruction?
Will my local area services return?
How far do I now have to travel for a doctor or a school?
Where can I shop?

Will the bus ever stop here again?
Will these potholes in the road ever be fixed?
Will I ever experience "community" again?

Similarly, in addition to these bottom-up impediments, there are research questions that can only be answered at a fine geographic scale and for multiple time periods:

Are there spatial patterns in rebuilding that influence subsequent time periods?
Are there street scale environmental or social factors that lead to negative health outcomes?
To what degree does the pattern of rebuilding cause or deter crime?

In order for researchers to consider these types of recovery impediments, fine scale spatial data is needed for multiple time periods. Unfortunately this poses a challenge in terms of data acquisition that limits the amount and scope of many academic investigations.

2.2 Spatial Video as a Data Collection Technology

There are four main ways to acquire fine scale spatial data appropriate for recovery research. The first is to extract map information from remotely sensed sources of data, most commonly high resolution aerial photography (including oblique imagery). This has been partly successful for assessing damage patterns after a disaster; though debate still occurs as to the degree of error with coding using this type of data source (Gerke and Kerle 2011). Besides this potential error, a larger problem for recovery research is the availability of data. Although multiple time periods of high resolution aerial photography are often collected for the time frame around the disaster, and these are often freely available, the temporal granularity in terms of flight passes decreases quickly afterwards, while the costs of access often starts to increase. As a result, any fine scale recovery research using this data source is restricted to available data, especially if reliant on freely available imagery.

The second source of data involves ground surveys; either teams of researchers asking community members recovery related questions, or walking / windshield survey teams performing a visual assessment of the area. Although these collection approaches can result in data rich analyses, the spatial dimension is often limited because of the costs involved in collection. These costs increase dramatically if the study is longitudinal, which given the nature of recovery after a disaster is a necessity. Simply put, it costs too much to keep putting larger teams of researchers into the field.

The third source of data is freely collected or created spatial data from volunteer sources. This volunteered geographic data collection has provided a paradigm shift in spatial data culture especially with regards disasters (Liu and Palen 2010). The general message is one of "can do no matter what". Data layers are created, imagery is digitized, local information uploaded, all using open source Internet based software. However, from a research perspective, the lack of data standards and consistent spatial coverage leaves this spatial data approach as a useful additional resource rather than a primary data source.

The fourth data collection approach involves mobile mapping, especially spatial video (Curtis et al 2007; Curtis and Mills 2011a). In some ways this approach combines elements of the first two strategies. Video cameras connected to a global positioning system (GPS) can be mounted to a vehicle or carried by hand, allowing for spatially encoded ground level imagery to be recorded. Although Curtis has used different systems in the evolution of this approach since 2006, the technology which has been utilized in projects since 2012 is cheap, simple to use, and comes with freely available software. Just as with high resolution aerial photography, or more appropriately in terms of comparison, oblique photography (Gerke and Kerle 2011), the streetscape is captured in a spatial context. This allows for map layers to be extracted and used for analysis. Although there are benefits of oblique photography, namely the extent of the geography covered, and the future possibility for automation in the coding, it is a notoriously expensive data source. Spatial video offers a far more cost effective method which means data can be collected for the researcher's desired area, and for multiple time periods. As a result scientific questions of a spatial nature can be posed unhindered by data availability.

Similarly, spatial video mimics ground-team data collection, especially windshield surveys. The major advantage of using a spatial video is again cost; the area can be covered and then coded by teams back in the lab. In addition there is improved accuracy as the source data is archived allowing for validation rather than assuming the field team "got it right". Data archiving also means that subsequent investigations can pose previously unthought-of questions, research which is not possible if the original data has to be entered into pre-defined categories in the field.

Finally, there is also a link to the volunteered geographic information framework, at least in terms of spatial video being a participatory data collection tool (Duval-Diop et al 2010). The simplicity of use means that the community member him/herself, in other words the most vested person in the work, can become the data collector. Instead of transporting researchers to the field, the equipment which fits into a small camera bag can be mailed or left after the initial visit. An additional benefit of involving community members in this way is the possibility of recording commentary during data collection; these spatially encoded insights providing additional context to the imagery, which makes this approach truly "mixed method".

From a technical perspective, a typical disaster recovery spatial video kit includes two high definition video cameras, usually mounted on either side of a high-riding vehicle, such as a truck or sports utility vehicle. The team at the GIS, Health and Hazards Lab (GHH) at Kent State University has used this basic approach to capture damage assessment and recovery data for neighborhoods affected by Hurricane Katrina; various tornadoes including the catastrophic touchdowns of 2011 in Tuscaloosa, Alabama, and Joplin, Missouri; Wildfire in southern California and Colorado, and

earthquake and cholera landscapes of Haiti (for examples see a series of popular media links at the end of this paper). The preferred "kit" for GHH is two cameras for each side of the vehicle, one pointing downwards to capture curbside data which was especially important for mapping water risks in Haiti. In addition, a handheld GPS unit provides a backup coordinate track, which means that there are five total GPS paths to accompany the imagery, and two different video streams for each side of the road. This level of redundancy is important for harder to reach disaster locations.

Although early spatial video technologies required propriety technology and software, making the extraction of spatial information into a geographical information system (GIS) a multiple stage process, current technologies have benefitted from the rise in extreme sports equipment to create small, relatively cheap cameras with an internal GPS, and arguably the most important advance, freely available software that allows for real time, or near real time display of data (presuming Internet connectivity is available). This allows each daily data collection route to be checked in the field for potential problems, an advantage if the research team has travelled considerable distance to the recovery location and cannot easily make a return trip.

There are, of course, data limitations with using a spatial video. Firstly, only the ground-level view is available. Parked vehicles, large walls, vegetation, all can provide barriers to "seeing" the neighborhood. One solution is to combine these data with available aerial photography (especially for damage assessment), though enough information is usually visible to assess recovery in traditional urban environments. A second problem involves the precision of the GPS path. Earlier versions of the technology had higher precision, but were considerably more expensive and difficult to use. The current extreme sports camera provides enough GPS precision to allow for coding into a GIS in conjunction with aerial photography, though having an additional higher precision GPS-only unit in the vehicle has proven to be a useful addition. As the GHH team moves into even more challenging environments, such as collecting data using handheld approaches along narrow paths in urban slums, so the question of improving GPS precision will become more salient.

2.3 Spatial Video Coding

Once video has been collected, the next stage is turning the imagery into spatial layers that can be mapped and analyzed. Earlier versions of the methodology used priority software that ran within a GIS. This allowed the coder to run the video while digitizing a map layer, which means creating spatial information in the GIS. For reasons described above, the use of freely available software is beneficial because of its ubiquitous access and dissemination potential. With this in mind, coding approaches work best when using two computer monitors, with one screen displaying the video (which in the freely available software also shows the location on the GPS path), while the second monitor has a GIS open allowing for digitizing. An alternative approach to digitizing directly into a GIS, is using Google Earth. This

Figure 1 Spatial video examples from post-earthquake Haiti (June 2012). A= A city rebuilding project; B= temporary housing; C=earthquake damage & standing water which is a disease risk

has three benefits, even though it adds an additional stage in the video-to-map process. Firstly, the imagery is exactly the same as that used in the spatial video software which makes the coding process easier. Secondly, Google Earth has more digitizing flexibility allowing points (or polygons) to have notes attached. This helps the coding categories to evolve as the researcher follows the path and immerses him/herself in the video. In a GIS the data structure is usually more fixed with categories being pre-determined. There is nothing worse than being halfway through a video route when the researcher observes the repetition of a feature, indicating that it should have been coded from the beginning. The final advantage is again the ubiquitous nature of Google Earth, which means collaborators (community members) can add their own insights into the map when watching the video, these insights being emailed as KML files for later combination in a GIS.

The most frequently applied video-to-map approach used by GHH researchers is entering data from the video into a pre-digitized GIS layer. Although different coding

systems have been utilized, the GHH recovery score standard for all post-disaster environments is as follows:

1= Unoccupied
2= Cleared
3 = Rebuilding
4 = Occupied

The first of these classes is then subdivided into:
1:2 Unoccupied but livable
1:5 Unoccupied and blighted (the building is boarded)
1:10 Unoccupied and severely blighted (badly damaged)

Although more detail can be added from the video, this scoring approach has been found to capture both the varying nature of the recovering landscape, while also minimizing between-coder error. In other words, this system can be transferred between disaster events and researchers allowing for cross comparisons. Other variables can be added to complement this score based on the particular research question or analytical approach. For example, height of each building can be added to allow for three-dimensional visualization; vegetation height might be added as an additional evidence of blight or because of its link to crime; evidence of dumping can again display a post-disaster crime vulnerability. It should be noted that entirely different coding systems can be created with the only limit being the quality of the video, and the creativity of the researcher. For example, in post-earthquake Haiti which suffered a second disaster of a cholera epidemic, the coding included various water-related features (drains, wells, evidence of standing water) and even a population count. Reiterating what was previously mentioned, the archival aspect of spatial video data means each collection run can be reinvestigated for different questions at a later time period.

2.4 Spatial Video Analysis

Once the video has been coded in a GIS, there are several options that can be used to determine spatial patterns of recovery. By displaying each coded location (usually a building) as a point, a variety of local area spatial analyses can be performed. The preferred analysis utilized by GHH is a variant of a spatial epidemiology method, the DMAP spatial filter (Rushton and Lolonis 1996). This technique layers a fine grid (user defined, but for the sake of example, 0.01 km) over the study area. For each grid node a rate is calculated within a circle (usually called a filter) which is again a researcher defined radius (for example, 0.03 km). As with most local area spatial analyses, the size of this filter will determine a smoother or more localized analysis. For recovery analysis, this rate might be a numerator of *unoccupied buildings* (score 1.2) or *blight* and *severe blight* (1.5 and 1.10). The denominator is the total number of buildings digitized along the spatial video path. The resulting grid, when displayed in a GIS allows the researcher to click on any location, such as a church, to see what the rate of blight is around that location. By running DMAP for different filter sizes, and for different variables, a comprehensive impression of recovery can be ascertained for any map location; for example how much localized blight, how much blight in the surrounding city blocks, or how many returnees are there. This grid also makes multiple year analysis possible as these rate scores can simply be compared between time periods to assess recovery stagnation, or a rebuilding progression.

The analysis can have further sophistication added to it by adding tests of statistical significance. In DMAP a Monte Carlo simulation creates a distribution of simulated maps against which each "real" node is compared. The percentage of simulated maps that exceed each rate calculation gives the researcher "confidence" in determining whether that rate would occur by chance alone. In this way "hotspots" or "cold spots" of recovery can be identified (Curtis et al 2010). An alternative method of analysis can be used if a secondary data layer is added to the grid of rates. For example, if crime locations or health events are overlaid onto the recovering neighborhood, the proximate rate node can be spatially attached as a measure of recovery for that event. In this way all crimes, or all low birth weight deliveries will have a recovery score (rate of blight, rate of returnees etc) and by using a difference of proportion t test it can be determined whether these attached rate scores significantly differ from the entire map, or even from different years (Curtis and Mills 2011b). In Figure 2 the blighted grid nodes are buffered to the size of the filter, and crime locations overlaid on top. Flood depth caused by Hurricane Katrina in 2005 is also included for reference.

This second type of analysis allows for research questions to be investigated:

Do patterns of isolated recovery lead to manifestations of stress, such as domestic violence?
Are birth weight deliveries significantly lower in households where recovery is slower (assessed by comparing time periods) in the immediate vicinity?
Has certain rebuilt properties or services stimulated proximate recovery?

As the use of spatial video becomes more widespread so will there be a development in spatially focused fine scale recovery theory. Exploratory analyses will lead to testing across disaster types and locations, while at the same time finding near-real time results that can be used for immediate intervention. There is no reason to believe that a global shared video archive can't be created, similar to other spatial data clearinghouses or geoportals. This could present research opportunities in much the same way as facilitated by genome databases.

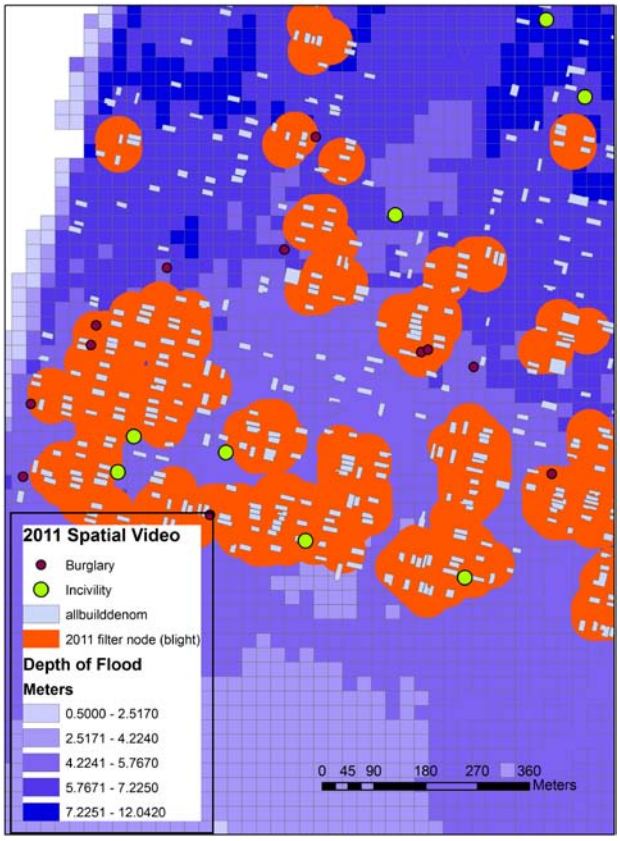

Figure 2 Buffered blight nodes from 2011 overlaid on certain crime locations, all buildings, and Hurricane Katrina flood depth for the Lower 9th Ward in New Orleans.

3. CONCLUSIONS

One unfortunate side effect of a disaster is the disproportionate impact the event may have on socially vulnerable populations. This disproportionate impact often continues through the recovery phase resulting in prolonged return, rebuilding and reestablishing community. The most socially vulnerable are especially reliant on social cohesion and community to help buffer from the stresses and challenges of day-to-day living. Therefore, those most in need for the quickest return to normalcy are also those who have to wait the longest. Obviously, financial difficulties are one major impediment to recovery. A lack of insurance, and low disposable income create a recovery gap whereby families do not have enough to both rebuild and put food on the table (Duval-Diop et al 2010). As a result recovery is not a spatially systematic pattern but often results in considerable heterogeneity, which in itself may further limit recovery or even cause re-abandonment. Added to this disaster related poverty trap are the associated problems: patterns of poor health (this population often carries a high chronic disease burden), crime (again this cohort traditionally suffers from high crime exposure). How this dynamic landscape unfolds, with multiple spatial layers interacting both through geography and time, has largely been the topic of postulation and anecdotes. New mobile mapping technologies, such as the spatial video, now allow for fine scale multiple time period research. These research outcomes may be useful in helping spatially strategize city resources including rebuilding help, where to place health intervention teams, and where to reevaluate services. By including community residents as part of the data collection process, and by simultaneously collecting their insights, hope is also generated that they have not been forgotten and their voice does count.

The GIS, Health and Hazards Lab at Kent State University is willing to work with any group interested in assessing health or hazard risk or recovery. Please contact Andrew Curtis or visit our website at *http://www.kent.edu/CAS/Geography/ghhlab/*

Abstract: A Multi Agent Systems (MAS) based mass evacuation simulation code, with moderately complex agents in 2D grid environment, is developed. The main objective of this code is to estimate the effectiveness of the measures taken to smoothen and speedup the evacuation process of a urban large area, in time critical events like tsunami. A vision based autonomous navigation algorithm, which enables the agents to move through an urban environment and reach a far visible destination, is implemented. The navigation algorithm is verified comparing the simulated evacuation time with that of theoretical. A scalable parallel computing extension is developed for studying mass evacuation of large areas; high performance computing resource utilization is necessary since the vision based navigation is computationally intensive. More than 94% strong scalability attained with 2048 CPU cores in the K-computer indicating the codes potential simulate mass evacuation involving many millions of people.

1. INTRODUCTION

Tens of thousands of casualties of the tsunamis of 2004 Sumatra earthquake and 2011 Thohoku earthquake generated emphasize the importance of mass evacuation studies in Earthquake engineering. Understanding evacuation dynamics is necessary to identify possible bottlenecks, find strategies to make the evacuation process smooth and reduce evacuation time, etc. Such analysis can save many lives at time critical events like tsunami. Out of a number of numerical models like cellular automata, social force model, etc., Multi Agent System (MAS) is a promising method for modeling heterogeneous and complex human behavior involved in mass evacuations (Hori et al., 2008, Dulum et al., 2012) MAS is able to solve mass evacuation problems with quite complicated setting, to which other numerical methods are not applicable.

There are number of studies related to tsunami triggered mass evacuation based on MAS. Most of these existing studies use simplified environment with simple agents (Gwynne et.al, 1999). Often the environment is modeled as a network consisting of 1D members representing rooms, corridors, roads, open spaces, etc. and associated with a pedestrian capacity. The most probable reasons for the use of such simplified models are that sophisticated models of environment and agents involve sophisticated algorithms, large amount of data and computationally intensive. The need of Monte-Carlo simulations to increase the reliability of MAS results is a major source of high computational demand. Considering the fact that mass evacuation is concerned with human lives, it is necessary to use complex models. The level of complexity should be chosen considering the availability of the computational resources, the significance of the complex features, etc.

In this paper we present the development of a moderately complex MAS with autonomously navigating agents in 2D urban environments, for large area evacuation simulation. The main source of information for the autonomous navigation algorithm is the agents' boundary of visibility, which is obtained from agents' vision. Simulating millions of agents with vision based autonomous navigation is computationally intensive. To meet this high computational demand, we developed a scalable parallel extension with the Message Passing Interface (MPI).

The contents of the rest of this paper are organized as follows. Section two gives a brief introduction to the developed MAS system for mass evacuation simulations. Details of the vision based autonomous navigation algorithm are given in section three while its verification is presented in the section four. Finally, some concluding remarks are presented in the last section.

2. A MULTI AGENT SYSTEM FOR EVACUATION SIMULATIONS

In this section a brief overview of the developed multi agent system for large area evacuation simulation is given. The multi agent system consists of two main parts; environment and the agents. Specifically, in this section, we focus on the basic requirements of these two main parts and the elements we have included.

2.1 Environment

We model the environment as a high resolution grid with maximum of 1*m* grid intervals. When making detailed models, the environment can be represented either with vector data or raster data. Both have advantages and disadvantages. In vector models, elements like buildings, roads, etc. are modeled with closed polygons and assembled into a graph data structure, according to their connectivity. Further, detailed information like width of the road, number of lanes, type of the building, number of occupants, etc. can be included with the polygons. An advantage of the vector environment is the ease of path planning and navigation of agents. On the other hand, the grid model does not have any of these advantages; buildings, roads, etc. are no longer identifiable single entities and path planning in grid environment is complex and requires significantly long time compared to vector environment.

However, we chose grid environment since it offers several advantages and the problem of path planning can be solved. The target problem of simulating emergency evacuation in an event of earthquake or/and tsunami requires modification of the environment to mimic the damaged to the environment like collapse of buildings, damages to roads, embankment failures, etc. Such highly localized modifications can be efficiently and accurately included in a grid environment. Also, identifying the boundary of the visibility of an agent and identifying the agents in the vicinity is more efficient in grid environments; working with concave polygons of vector models is complex and time consuming. Further, the vector model pose several difficulties in parallel computing; domain partitioning, dynamic load balancing with repartitioning and communicating graphs of vector data are much complex and have lower scalability compared to those of the grid data. When the region being modeled is several tens or hundreds of square kilometers, grid environment is much simpler to manage in parallel computing. Because of these advantages, the environment is modeled as a 2D grid.

A major problem with the grid environments is the complexity of path planning. Real-time path finding in very large grids is extremely slow and significantly reduces parallel scalability. Real-time path finding is an essential for the target problem; if an agent found the path it takes is blocked by a fallen building, it should be able to find the next closest path to the closest high ground or evacuation center. By automatically generating network of available path from grid data, the associated long path finding time can be reduced almost to that in vector environments. Path networks in a grid model can be constructed using thinning algorithms and then abstracting the resulting pixel network with a vector network. We are developing such an automated road network generation code, from grid data.

2.2 Agents

Since the target problem is directly concerned with the people's lives, it is important to mimic the real human behaviors, of significance, observed real in emergency evacuations. While an agent have data of its basic abilities like maximum speed, age, maximum sight distance, etc. its memory holds the information of past experiences, the paths it has taken, its target destination, etc. Further, an agent has several major functionalities; think, see, move. Agents with wide range of physical abilities can be generated to mimic the heterogeneous distribution of people in a selected region. Further, the agents are specialized by including more information and functionalities to represent relevant officials like police officers, fire fighters, volunteers, etc.

Visitor agents, representing visitors, do not possess any information of that area except the direction to a far visible destination like high ground and whatever visible within his sight distance. All except visitor agents (e.g. residents, police officers, fire-fighters, volunteers, etc.) have the information of their neighborhood and have the ability to find path to a desired destination. In this paper, the set of all types of agents except the visitor agents, are called non-visitor agents.

2.3 Radar vision

Vision, the main means of perceiving the environment, is an important functionality since agents are mainly responding to the data collected by that. Just as the human counterpart, agents must be able to extract information within a neighborhood of several tens of meters. We implemented radar based vision to make the agents accurately identify the features like roads, obstacles, etc., and neighboring agents, within their sight distances.

An agent scans the environment like radar and identifies the boundary of his visibility, in high resolution. The resolution of radar scanning, $d\theta$, is set such that $L \times d\theta = 0.5 \times \Delta l$, where L is the sight distance and Δl is the length of grid cell; approximately 1000 rays for 80*m* sight distance. Figure 1 shows the identified boundary of visibility and neighbor agents, by an agent with 40*m* sight distance. As it is explained in the next section, an agent identifies

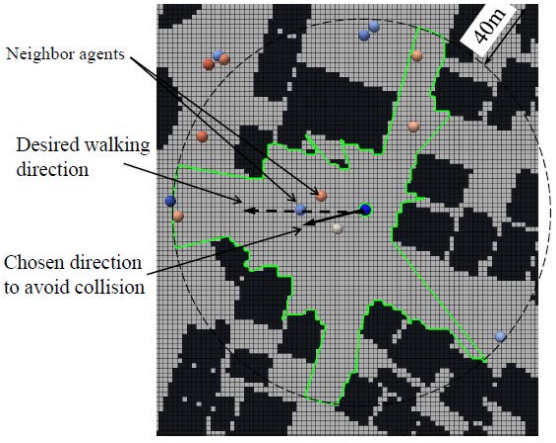

Figure 1 Indicated in yellow is the boundary of visibility identified with radar vision

the available paths in his visibility and moves towards the chosen direction, avoiding collision.

A problem with radar based vision is that identifying through which grid cells the radar rays pass is time consuming; it requires calculation of intersecting points of radar rays and grid lines. In order to reduce the amount of computations involved, several radar templates are prepared. Each radar templates contains the information of cells through which rays pass and the intersecting points. 16 sets of radar templates with their origins arranged in a 4×4 grid of 20*cm* spacing are used. An agent chooses the best radar template according to their location in a grid cell. Data of each radar template is stored in a circular container so that agents can easily identify the boundary of visibility in their front and back. Agents have different sight distances based on their abilities. The maximum of sight distance of all agents is used when preparing the radar templates.

As described in the next section, we implemented a radar vision based autonomous navigation algorithm that enables the agents to navigate in complex urban environments.

2.3 HPC enhancements

Simulation of large urban area evacuation with millions of smart and sophisticated agents involves a large amount of computations. Further, Monte-Carlo simulations with different settings are necessary to increase the reliability of the results. In order to meet this high computational demand, high performance computing resources have to be effectively utilized.

The current code is parallelized with Message Passing Interface (MPI). With a number of strategies like hiding communication, repartition, minimizing the number of communications and the volume of data communicated, etc. scalable parallel extension is developed (Dulum, 2012). Preliminary tests in the K-computer with 2 million agents produced above 94% strong scalability, with 2048 CPU cores.

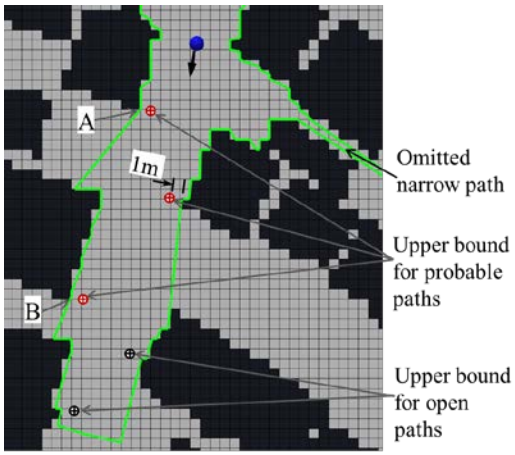

Figure 3 Upper bounds are set to prevent agents from moving to close to the obstacle corners.

3. AUTONOMOUS NAVIGATION IN URBAN AREAS

For the target problem of earthquakes or tsunami induced large area evacuations, the agents must have good autonomous navigation skills to move through complex urban environments. At least the agents should have the ability of navigating to a far visible high ground or a tall building, even if an agent represents a visitor. This skill which any human counterpart possesses is necessary for modeling tsunami induces evacuations. Details of the autonomous navigation algorithm are presented in this section while some verification tests are presented in next section.

To ensure that an agent can reach its destination, it must be able to identify the features of his visible surrounding and choose the correct direction to go. In grid environments, agents need sophisticated vision to identify available paths out of large number of cells within his visibility, each with either of two states. As mentioned in the previous section, an agent identifies his visual boundary using their radar based vision. Analyzing the boundary of visibility, agents identify the available paths. The regions visible up to an agents sight distance are categorized as *open-paths*, while the sudden jumps greater than a selected value are categorized as *probable-paths* (see Fig.3).

The saw-toothed boundaries of buildings in grid environment often produce sudden jumps similar to that produce by roads at a junction. Correct identification of probable-paths is important since moving towards these false signals not only produce longer evacuation time compared to that of the human counterparts, but also extra effort is necessary to bring the agents back to their original route. In order to eliminate these false signals, only the jumps greater than certain number of cells are considered; greater than 5 cells jumps are used in this study.

When an agent moves towards a probable path, care

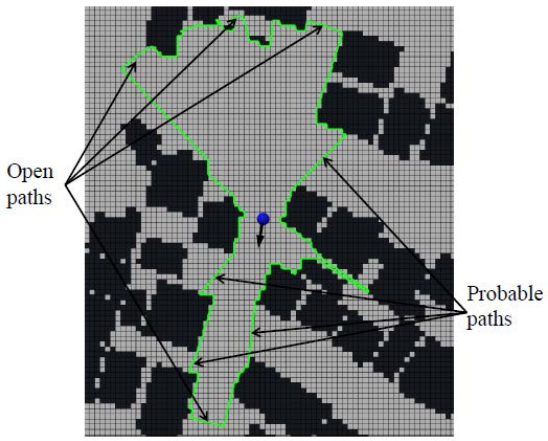

Figure 2 Open and probable paths identified by an agent shown by a blue dot.

has to be taken not to let it move too close to a corner which gives rise to sudden jumps which define probable path (e.g. point A and B in Fig. 3). Moving too close to a corner of an obstacle significantly lowers an agent's field of vision, often forcing it to turn backwards. In order to prevent this problem, associated with each open or probable paths are a set of points defining the closest they can move towards the corresponding corners of obstacles. It is found that setting these upper bound points at 1m away from the obstacle corners solves the problem of view obstruction.

The navigation of visitor agents and non-visitor agents, (e.g. residents, officials, etc.) have two main differences; only non-visitor agents have the ability to plan a path to any destination, and visitor and non-visitor agents have different navigation algorithms. As mentioned, non-visitor agents can find the paths to their destinations. Theta star algorithm (Nash et al., 2007) is used for this path planning. An advantage of *theta-star* algorithm is that the paths are defined by few landmark points, like road junctions. This not only reduces the data side of agents, but also allows the agents to freely navigate based on their vision, between the landmark points which could be a few hundred meters apart.

Non-visitor agents have no priority in choosing available open or probable paths in his 360^o vicinity. As mentioned, non-visitor agents have the ability to find the path to a desired destination. Non-visitor agents use vi-

Figure 5 Visitor agents' path selection algorithm

sion based navigation to move between the landmarks points defining the paths found with theta-star algorithm. Giving equal priority to all the visible open or probable paths in their front or back, they choose the closest path towards the next landmark point of their pre-planned path. Non-visitor agents' algorithm for choosing open/probable paths is shown in Fig. 4.

Unlike the non-visitors, the visitor agents neither have the ability to find paths nor a well-defined destination. In many cases, visitors have to depend on the non-visitor agents or mass communications to obtain information, or follow a group or a leader. In the case of tsunami evacuation, visitor agents' target can be set to a far visible high ground or tall buildings. It is challenging to navigate and agent towards a far visible target through a complex urban environment, only based on the information available within its sight distance. It is found that choosing the visible open or probable paths according to the algorithm shown in Fig. 5 makes visitor agents to successfully navigate towards far visible destination through a complex urban environment. This algorithm is not too artificial in the sense that even people, in an unknown environment, tend to have similar preferences: people prefer taking roads in their front and prefer taking roads with longest visible stretch instead of those hidden behinds bends or obstacles.

Once the open or probable path to be taken is decided, an agent checks for possible collisions with neighboring agents and slightly adjusts the moving direction to avoid collision (see Fig.2), sticking to the chosen open or probable path.

3. VERIFICATION OF THE AUTONOMOUS NAVIGATION

Verification and validation of the proposed radar vision based autonomous navigation is essential since simulated is people, with the aim of reducing casualties. For verification, it has to be tested whether the proposed algorithm can reproduce analytically expected answer for a well-posed problem. Validation requires testing whether the numerically obtained solution satisfactorily matches with the observed behavior of a real evacuation.

In this paper, we only consider the verification of radar vision based autonomous navigation of each individual agent, through an urban area. The major concern of this verification is to test whether the proposed algorithm enable both visitor and non-visitor agents to reach a far visible destination based on their vision. Even if the non-visitor agents have paths to their destination, they heavily depend on their vision to navigate between few the landmark points defining their paths. The most important in this verification is to test visitor agents' ability to reach a far visible target, which the human counterpart can easily do.

Being the objective is to verify the whether a visitor or non-visitor agent can reach a far visible destination, collision avoidance or other interactions among agents is not considered in this verification test. The problem becomes ill-posed when the collision avoidance is included; the total evacuation time and the paths taken by individual agents is highly depends on the crowd density and the each individual's response to dense crowds. Surely, it is important to study to which extent the agents' behavior deviates when the collision avoidance is included and how it varies with the crowd density. However, it is out of the scope of the current study.

3.1 Problem settings

For the verification tests, thousand agents in $800\times600m^2$ regions of Kochi city environment is considered; as shown in Fig. 6 the selected area has many buildings and a few open areas. Two cases, each with either non-visitor agents or visitor agents, are considered. It is assumed that there is a high ground, which is visible from anywhere in the selected domain, at the lower edge of the selected domain. All the agents are assumed to have the same sight distance of $50m$. The non-visitor agents follow the shortest paths to the lower edge of the boundary from their starting location; calculated with theta-star algorithm. On the other hand, visitor agents navigate only based on the information within their sight distance and the direction to lower edge, where there is a visible high ground. Apart from that both the problems have the same settings.

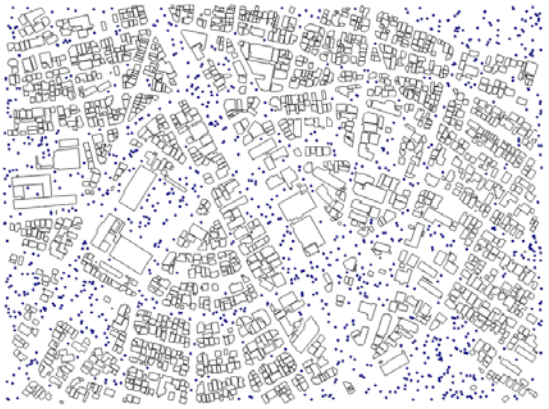

Figure 6 $800\times600m^2$ area of Kochi city and the initial agent distribution used for the verification of autonomous navigation algorithm.

3.1 Overall behavior

Figure 7 and 8 shows the graphs of cumulative number of agents exited versus time. The near perfect matching of non-visitor graph with that of the theoretical verifies non-visitor agents' navigation capabilities; even if they rely on their vision to navigate between few landmark points defining their paths, they can reach the destinations at the theoretically expected time. As seen in the Fig. 8, visitor agents also have surprisingly good navigation abilities; visitors graph is very close to the theoretical and the maximum difference is 28 agents, at 398 seconds. The difference compared to the ideal is less in this prob-

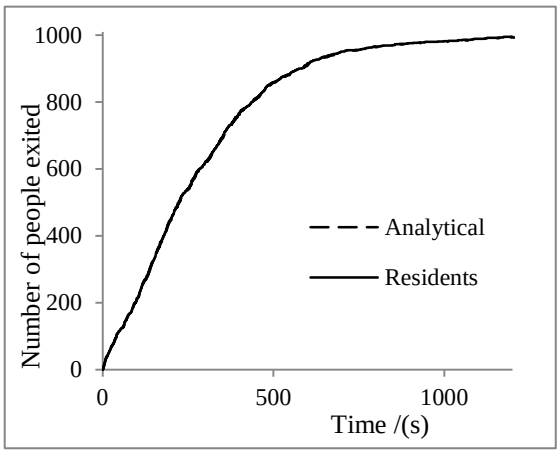

Figure 7 Cumulative number of non-visitor agents exited

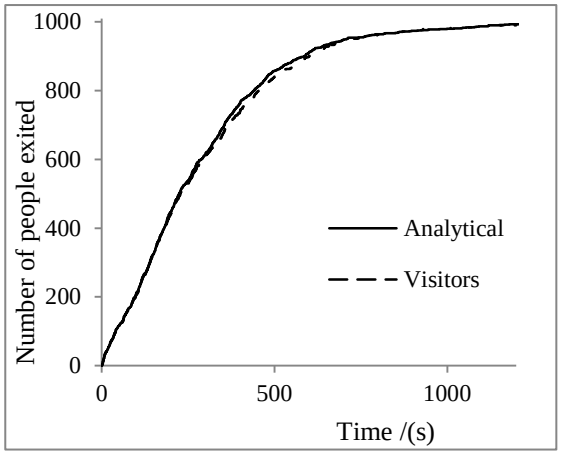

Figure 8 Cumulative number of visitor agents exited

lem since the maximum distance is an agent has to travel is only 600m. Surely, the deviation from the ideal will be more when the domain is large and more complex.

3.1 Trajectories of individual agents

In addition to the overall behavior, investigating the paths taken by each individual is important to make sure that none of the agents has taken paths which are unrealistic choices for the human counterpart.

The possibility of non-visitor agents to take an unrealistic path is very low since they are guided with intermediate landmark points. Analysis of simulation results confirmed that all the non-visitor agents have followed the shortest paths they found with theta-star algorithm.

As one can easily guess, it is the visitor agents who have highest chance of taking unrealistic paths. Surprisingly, none of the visitor agents has taken unrealistic path (see Fig. 9). Detailed analysis by comparing the paths taken by visitor and non-visitor agents with same starting position and properties indicates that the visitor agents have not taken the optimal paths. Figure 10 shows the trajectories of randomly selected five visitor and non-visitor agents; each pair with identical starting point has identical properties. Though the paths taken by visitor agents are not the shortest, those are realistic choice even for a human and the time differences between the two paths are small.

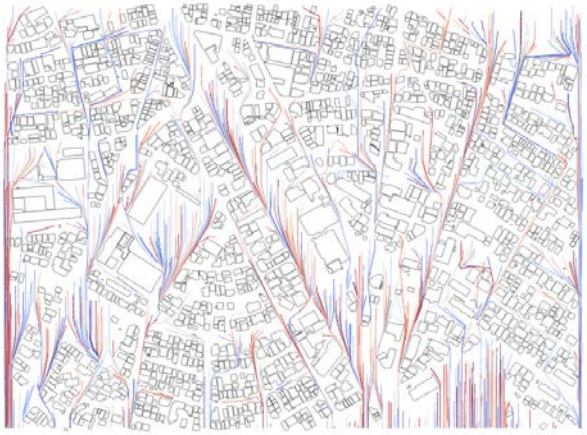

Figure 9 Paths taken by visitor agents.

Figure 10 Comparison of trajectories of visitor and non-visitor agents with same starting points.

3.1 Known limitations of autonomous navigation algorithm

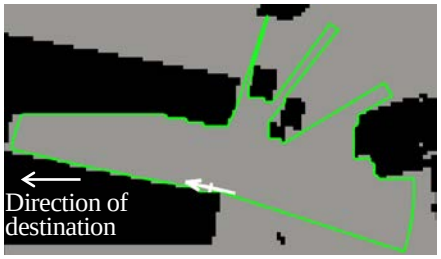

Figure 11 A visitor agent moving to a deep region with no paths except those in the opposite direction of the destination.

There are no known limitations regarding the non-visitor agents. On the other hand, visitor agents have one known limitations. A visitor agent may get lost and start to move in a loop, if it enters a region where there are no identifiable opening towards the destination in his front and depth of the region longer than the sight distance. Even though the visitors algorithm makes it to turn back and move out of such deep wells, the agent may tends to turn back and reenter the deep well depending on the arrangements of the paths in the opposite direction. Figure 11 shows an agent entered into such a region. When the agent recognizes there is no path towards its destination, it turns and starts moving out of the deep well. However the upward path at the entrance to the deep region makes it turn and re-enter the deep well, eternally making the agent to move in a closed loop. A simple solution to this problem is temporarily increasing trapped agents' sight distance and let it recognize that there are no paths in the deep well.

This simple test with a small urban environment verifies that both the visitor and resident agents have sufficient skills to navigate in an urban environment. However, further tests are necessary to verify visitor agents' abilities to navigate in more complex environments, and both visitor and non-visitor agents' navigation abilities in dense crowds with collision avoidance.

3. CONCLDING REMARKS

We implemented radar vision based autonomous navigation algorithms for both the visitor and non-visitor agents (i.e. residents, police officers, etc.). The simple verification test shows that the proposed navigation algorithms enable both the visitor and non-visitor agents to navigate successfully through urban environments. Although non-visitor agents do not take the optimal paths, their paths are found to be acceptable choices even for human counterparts. In order to meet the heavy computational demands involved in vision based navigations, we implemented a MPI based parallel extensions. With a number of strategies, near linear scalability is attained up to 2048 CPU cores in the K computer.

FOREIGNERS' EXPERIENCE AND BEHAVIOR IN THE GREAT EAST JAPAN DISASTERS 2011

Dr. Md. Faiz SHAH[1)], Dr. Osamu MURAO[2)]

1) Researcher, Faculty of Engineering, Systems and Information, University of Tsukuba, Japan
2) Associate Professor, Faculty of Engineering, Systems and Information, University of Tsukuba, Japan

Abstract: A primary challenge for foreigners living in Japan is language. Many foreigners were affected by the Great East Japan disasters in 2011 and suffered various problems due to insufficient information dissemination in proper language. The purpose of this study is to investigate foreigners' problems and decision-making in the aftermath of the disasters. This study applied a questionnaire survey method and conducted 200 interviews with foreigners from 48 different countries living in Tohoku and Kanto area during the disasters. The primary result of the study show that foreigners' information understanding ability kept them calm and they did not relocate after the disasters. However, a great number of them with language and other problems relocated or leave the country. Proper and sufficient information in proper language played an important role in foreigner's life during the disasters in Japan.

1. BACKGROUND AND INTRODUCTION

On March 11, 2011, the great East Japan disaster stroke Japan. Many cities in the Tohoku and Kanto area were worse affected by the disaster. Many of the residents could survive from the great jolt of 9.0 magnitude earthquake; a great number of them were washed away by the following high tsunami. Those who survived the initial two disaster events, were threaten by a third one and that was the nuclear radiation emission from the Fukushima Dai-ichi nuclear power plant, which was badly affected by the earthquake and tsunami. The number of human casualty was quite high among the native Japanese in the affected area: death 15,873, injured 6,114, and missing 2,744 (National Police Agency, Nov. 2012). The disaster did not only affect the native, but many foreigners who were living in Japan for specific purposes were also affected. Though the casualty among foreign residents was not high, in some cases, they were facing several problems due to lack of information and their insufficient communication capacity in Japanese. It resulted that many of them decided to relocate from Tohoku and Kanto area either to another place in Japan or to outside of the country. Henry (2012) reported that information disseminated in Japan after the disaster was mainly in Japanese. The main coverage of those information was disaster response, recovery and to reduce panic among the citizens. Since many foreigners had deficiency in Japanese, they started to follow foreign news media's news and information in English or in their own languages. However, the target of that information was different, for example, disaster mitigation, lessons learned and effect of the disaster. Thus, while native Japanese were calm after the disaster, many foreigners were panic and were deciding to relocate immediately. This study intends to consider language and other problem issues and checks their impact on foreigner's relocation behavior after the 3/11 disasters.

2. PURPOSE AND OBJECTIVE

Two major trends in foreigners' behavior have been found after the disasters: either to relocate or to stay. Present study focuses on those two trends. The purpose of the study is to check foreigners' decision-making in the aftermath of the disasters. It will focus on the problems that foreigners faced and decided to relocate. The objectives are (i) to examine the disaster information system that foreigners used during disasters, (ii) to check their first response to the situation, (iii) to understand their information gathering behavior, and (iv) to explore the reason of their decision to continue staying in Japan and or to relocate.

3. STUDY AREA

The Tohhoku and Kanto area were selected as the primary study area for this investigation. In Tohoku, most of the foreigners' were selected from Iwaki City in Fukushima Prefecture. Many of them were living in other parts of Japan and in their own countries during this study. But they had been living in Iwaki City during the 3/11 disasters. Iwaki City in Fukushima Prefecture was selected as the prime study area due to several reasons. For example (a) a good number of foreigners were living in Iwaki City. According to the Iwaki City Office, about 1800 foreigners were living in the city throughout the 3/11 disasters. It was reduced to 1511 when this study was conducted. So the number was quite good even after the disaster. (b) The City was badly affected

by the earthquake and high tsunami stroke the coastline of the city. So the devastation of the city was almost similar with other cities in the affected areas. (c) The city locates within 40 km radius of the Fukushima Daiichi Nuclear Power Plant (Figure-1). It had evacuation warning after the disaster. Therefore, sampling from this city would enable to understand the situation of foreigners in the affected region in Tohoku. The other major city selected for the study was Tsukuba in Ibaraki Prefecture. This city also had a good number of foreigners living during the earthquake. The information collected from this city may enable to make a comparative study on the behavior of foreigners after the disasters.

Figure-1: Iwaki City in Fukushima Prefecture and nuclear zone radius

4. LITERATURE REVIEW

Yun and Hamada (2012) studied the relationships between evacuation place and time, pre-disaster preparedness and evacuation behavior and survival rate in the Great East Japan disasters. Their study result show that behavior during disaster differed for survivors and actual evacuation was associated positively with high survival rate. They conducted the study with 1153 native survivors where no foreigners were included. Koresawa (2012) studied on government's respond on the Great East Japan Earthquake and Tsunami. He reviewed government's disaster mitigation and preparedness including Hyogo Framework for Action, progress in risk assessment, early warning, reducing underlying risk factors, and strengthening disaster preparedness for effective response. This paper gives a clear idea on government's response initiatives in the Great East Japan Earthquake and Tsunami. Ozaki (2012) checked Japan Metrological Agency's (JMA) tsunami warning system after the 3/11 earthquake. He found a gap between predicted tsunami heights at the early stage and actual heights. He shows how JMA is improving their tsunami warning system based on the 3/11 experience.

Henry et al. (2011) worked on disaster information gathering behavior of foreigners after the Tohoku Earthquake and brought some ever first results on the issue. They showed that people living in Japan were faced with confusing and conflicting messages from different information sources. This created an atmosphere of uncertainty and led many people, particularly foreigners to relocate to western Japan or to leave Japan entirely. In another study, Henry et al. (2012) analyzed foreign students' post disaster action and found that it was similar to their information gathering behavior. However, it was different in three cases: (i) their most and least trusted information sources, (ii) their utilized language for collecting disaster information, and (iii) their utilized language for clarifying information difficulties. There was no difference between those who remained and relocated, as they judged the situation by their language ability. Therefore foreigners' language ability is one of the important considerations for their post disaster action.

The number of literature on foreigner's experience and behavior in the great East Japan disasters is very few. Henry et al. (2011, 2012) basically checked the information gathering behavior of foreigners living in Kanto area. The present study includes the foreigners living mainly in Tohoku and their experience, problems, deciding issues to continue to stay in Japan or to relocate.

5. METHODOLOGY

This study applied few methodologies to find foreigner's information and grasp their experiences. First, foreigner's statistical information was collected from a concerned department in Iwaki City Office. Second, several short interviews were conducted with foreigners living in Iwaki city before starting the main data collection. Third, based on the key information obtained from the primary interview, a questionnaire was developed to interview foreigners. The questionnaire interview was conducted from mid-September to mid-October 2012. Total 200 samples were collected and respondents from 48 different nationalities participated. Fourth, based on the questionnaire response, few more interviews were conducted with a few selected respondents.

6. SURVEY OUTLINE

The survey covered 111 female and 89 male respondents. Many of the respondents were scattered from their living cities after the disaster. For example, present city of the respondents showed 36 cities but 3.11 living city showed 12 cities. The highest number of participation came from Iwaki City which was 124 during the earthquake and 81 at present. As shown in Figure-2, the highest number of respondents were students (78 nos. or 39%). The second and third highest number was teacher (38 nos. or 19%), and business (21 nos. or 10.5%). Another 10% respondents were engaged in other occupations. Figure-3 shows respondents' living period in Japan. The highest 54.5% respondents were living Japan for more than 5 years. About 30.5% respondents were living for less than 5 years and 15% were living for the last 2 years. The survey covered only those foreigners who were living in Japan during the 3.11 disasters.

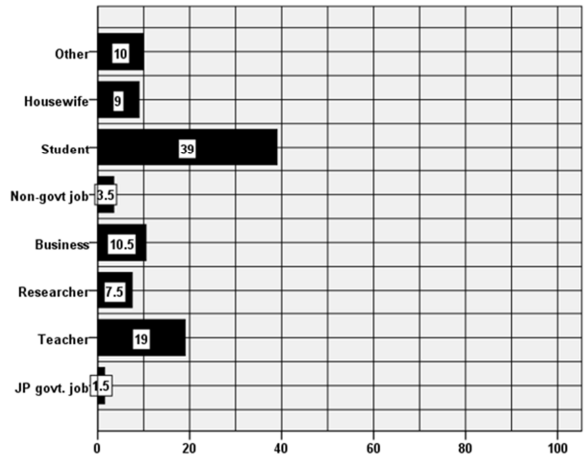

Figure-2: Occupation of Respondents (%)

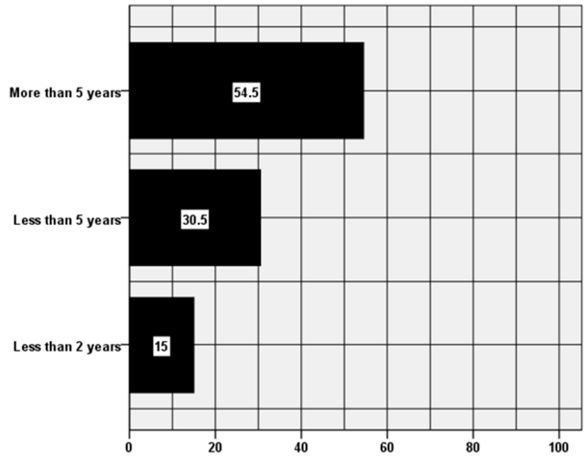

Figure-3: Living Period in Japan (%)

7. DISASTER AND AFTERMATH

This section discusses about the information and communication that foreigners used during the impending situation. Japan has progressed in earthquake and tsunami early warning system (JMA, 2012). According to this system, Japan Metrological Agency (JMA) systems receive warning for a seismic motion by a primary wave in the ground; it transfers the information to the national broadcasting system, which includes the television and radio. For a better dissemination and immediate information to the citizen, different devices receives those warning from JMA system and broadcast to the citizen. Mobile phone devices are one of the most popular broadcasters of JMA's disaster early warning system including earthquake and tsunami. Figure-4 shows that only 27.5% respondents received an early warning message or alarm during the disaster. The majority of the respondents either did not receive any warning or never knew about that (56%). The JMA transmitted a warning on earthquake 8.6 seconds after the primary wave on 3/11 (Koresawa 2012). Television, radio and other devices broadcasted the warning on time. However, many people could not get the information due to several reasons. The most important reason was that the earthquake struck at a busy afternoon on a week day when people were at work. They either did not receive any warning alarm or could not think about the severity of the disaster due to the quick and powerful jolt.

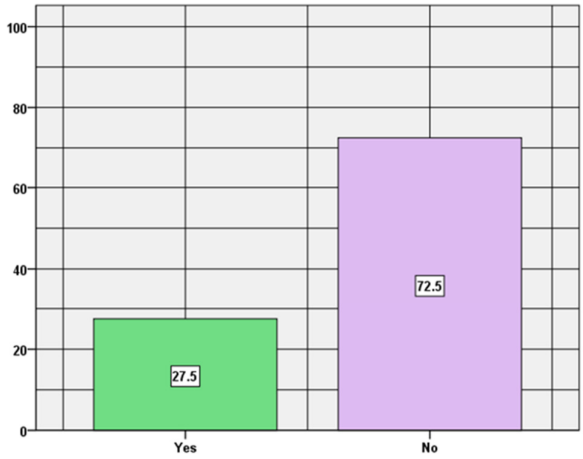

Figure-4: Got disaster warning on 3/11 (%)

Figure-5 shows that 20% respondents received a warning alarm on earthquake and only 5.5% received on tsunami.

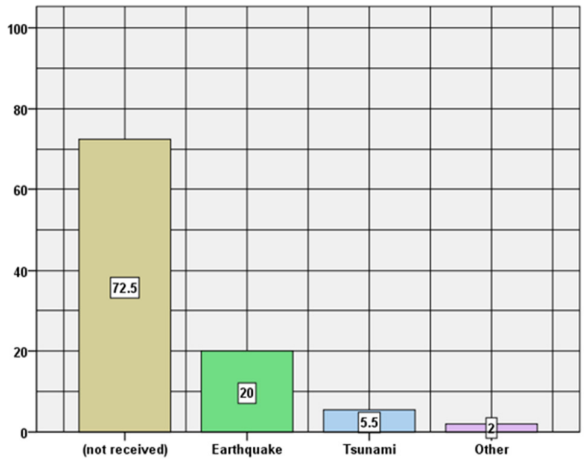

Figure-5: Event on Received Warning (%)

The surveyed foreigners' experience revealed that 13% of them received warning from mobile phone alarm as shown in Figure-6. Only 8.5% received the same from television. It happened that when they received alarm on their mobile phone, they had already felt the shaking; they turned on the television and watched the warning message broadcasting. Some of them could make phone calls to their family members and friends just at the onset of the earthquake and could warn them (1% were warmed by this). This group of respondents could manage to protect themselves during the big shaking and evacuate from their houses just after the first big shaking. Figrure-7 shows that 41% respondents tried to get more information on the

earthquake when the very first longer shaking had stopped. Another 32% respondents were calm and 20% were trying to move to a safer place within 3 hours of the earthquake. A very few respondents, only 3.5% engaged to clean up the mess. Due to the repeated large earthquakes, aftershocks and lack of information, many foreigners became panic. They had to decide by themselves either to stay at their same house or move to an evacuation center. The stopping of utility services like electricity, gas and water had important role on their decision.

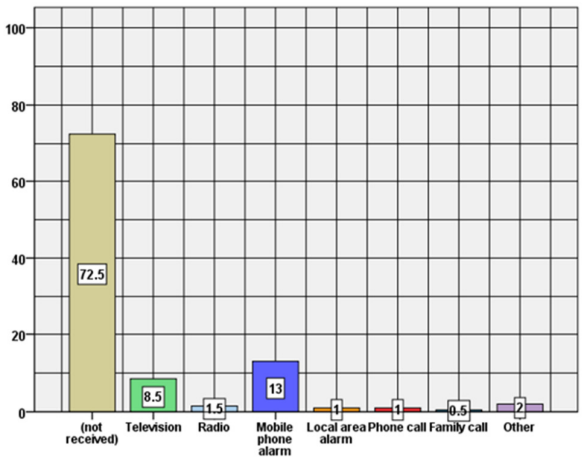

Figure-6: Warning Sources (%)

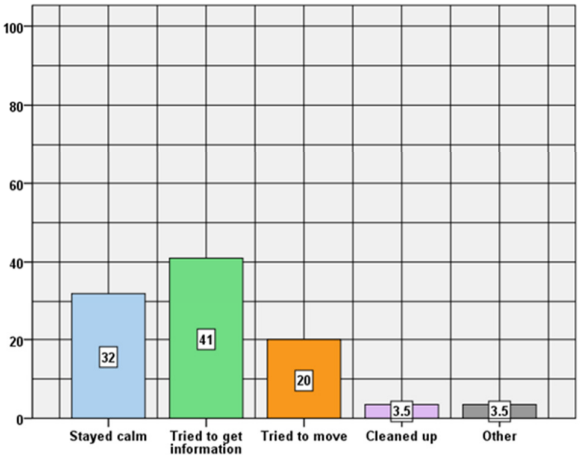

Figure-7: What did they do after the earthquake (%)

8. INFORMATION, PROBLEMS AND COMMUNICATION STAGE

It was showed in the previous section that a good number of foreigners were trying to get information just after the earthquake. Information played the main role for disaster communication since the very onset of the disasters. To get the latest update, foreigners were relying information sources. Figure-8 shows that 94% of the respondents were using different information sources to receive disaster warning, update on search and response, mitigation, utility and others. It is important to find that 6% of the respondents were not using any standard information sources. It was due to their inability to understand news in Japanese, or their lack of interest to see disaster devastation pictures. So they kept the television and radio turned off. Some of the foreigners did not want to be panic with information. They did not think about evacuation. Some of them even did not know about the Fukushima Daiichi Nuclear Power Plant accident and the subsequent evacuation warning from the 50km area of the radius (Figure-1).

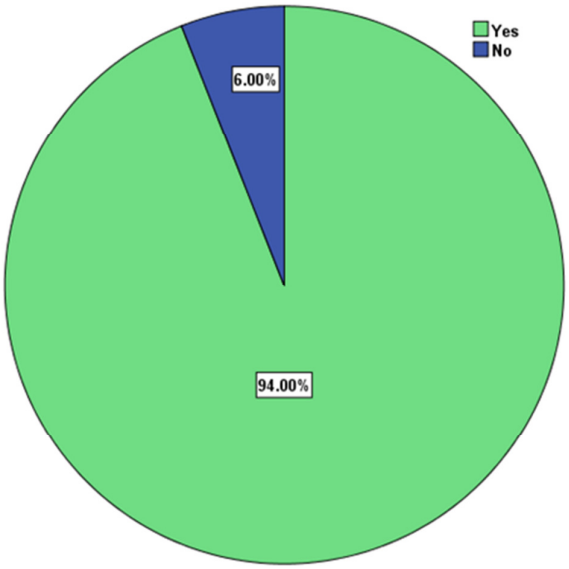

Figure-8: Foreigners used info sources

Figure-9 shows a comparative figure of used and trusted information sources of the foreigners. This particular question inquired about foreigner's use of information sources until the second week after the disaster.

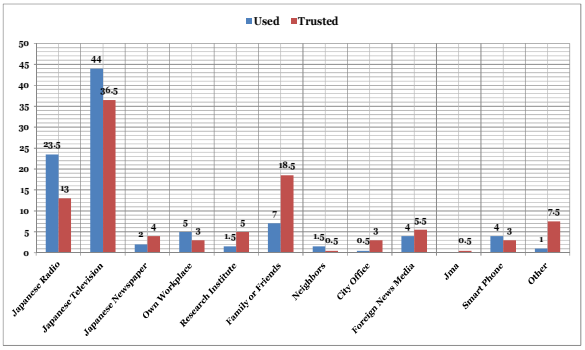

Figure-9: Used and Trusted Information Sources (%)

The figure shows that the highest 44% of the respondents used Japanese television as information source. But only 36.5% among them considered television as the most trusted information source. The second highest

information source was radio which was 23.5%. But only 13% of the respondents trusted Radio information. Few of the respondents were relying on family and friends (7%) as an information source. But more than the use, about 18.5% respondents trusted them for proper information. Some of the foreigners, having difficulty in Japanese, were using (4%) and relying on foreign news media (5.5%). It was reflected with Henry 2012 as mentioned in the introduction. This group of foreigners left Japan as they were very much panic by receiving different contextual information of those foreign news media.

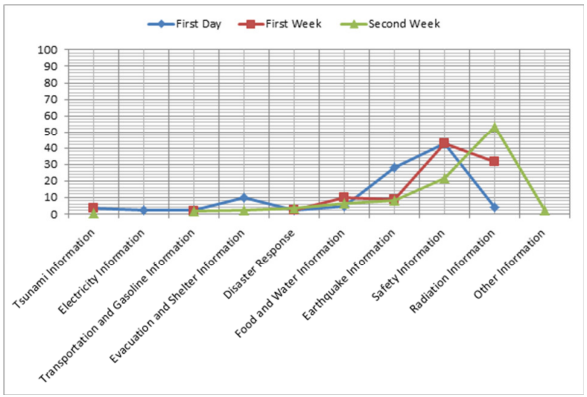

Figure-10: Change in consideration of important information (%)

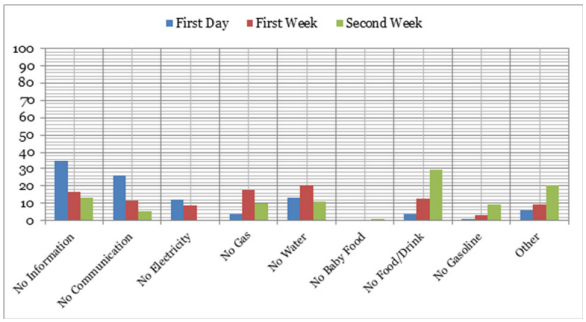

Figure-11: Problems faced by the foreigners (%)

Figure-10 shows the comparative picture of consideration of important information by the foreigners. The respondents chose ten types of information they trusted to receive as shown in the figure. The information types in the column were categorized by the information obtained in the pre interviews with some respondents. Information timeline from the first day to second week show a remarkable change. On the first day, just after the disaster, when a high tsunami was striking, foreigners did not put much interest on that information (only 2%) as most of the foreigners were living in the central place of the cities that was far from the shore. On the first day, the information line became slightly high on shelter information (9.5%) and got highest pick for safety information (48%). The first week information showed a higher trend from food and water information and reached highest for radiation information (28.5%). The radiation information took the highest pick until the second week (44.5%). It is worth to mention that foreigners trusted Japanese television for disaster information and they were solely relying Japanese government information sources. The reflection is visible in this figure. When there was not a good development in controlling nuclear emission from the affected nuclear power plant, many of them had taken relocation decision either to other part of Japan, or to their own country. Information broadcasted by foreign news media in foreigners' own country made their family members to ask them to go back to their home countries for a while, until the situation improved.

Figure-11 shows the prioritized main problems that foreigners faced until the second week of the disaster. Total nine main problems were listed. First day's highest prioritized problem was 'no information' (35%). First week's highest prioritized problem was 'no water' (20.5%). Second week's number one problem was 'no food/drink'. This group's food and drink stock was run out by this time. Many of them were requiring support at this stage. The following figure shows this information.

Figure-12 shows that 64.5% foreigners were expecting support from external sources though a good number of them did not require (35.5%).

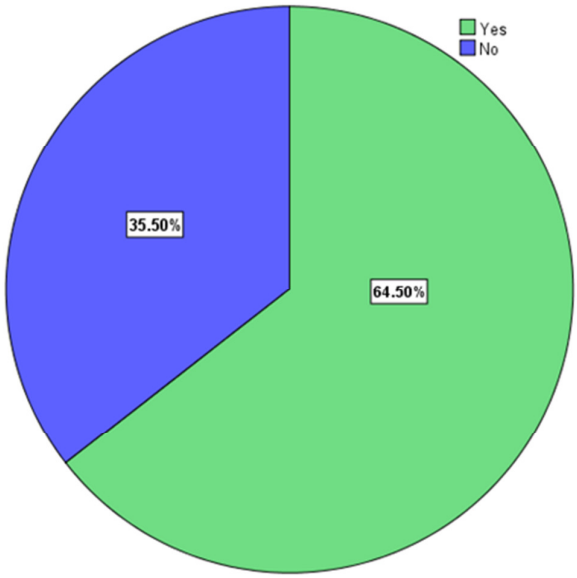

Figure-12: Support received

Figure-13 shows that the highest 33.5% respondents were supported by their friends. A good number of them (14.5%) were supported by the neighbors. In most cases, these respondents had family relation with Japanese and were integrated with the local community. For those who received support from friends, their friends shared their own belongings with others. Many of the foreigners said that a phone call by a friend also worked as a support. Since they were mentally distressed and were relieved by phone calls of their friends. Many religious groups of foreigners stayed

together in the religious sites and shared all belongings within their community. For example, most of the Muslim families in Onahama in Iwaki City evacuated and stayed at Onahama Majsid and shared their food and water. Iwaki Catholic Church also had the same experience.

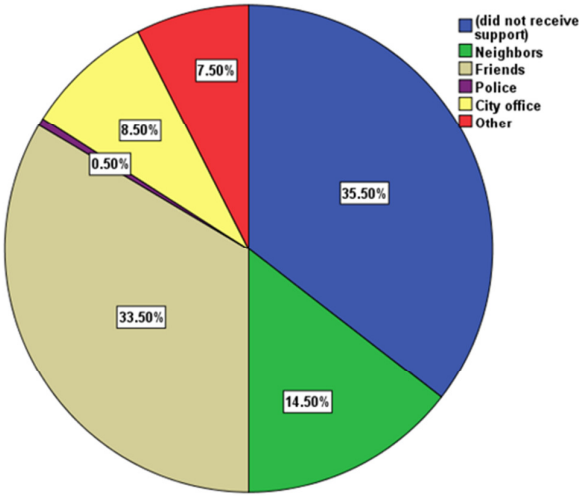

Figure-13: Support sources

Figure-14 shows a comparative figure of required and received support by the foreigners. The highest required support was reliable information (47.5%) and the highest received support was water (50.5%). Many of them required gasoline and transportation (17.5%) support and a few of them, (3.5%) received that support from their friends and neighbors. In fact daily life was stopped due to the shortage of gasoline in most of the cities in Tohoku and Kanto. The supply was not possible to resume immediately because of the disruption in road communication. Those who decided to relocate or evacuate from their cities, they required gasoline or transportation support very much.

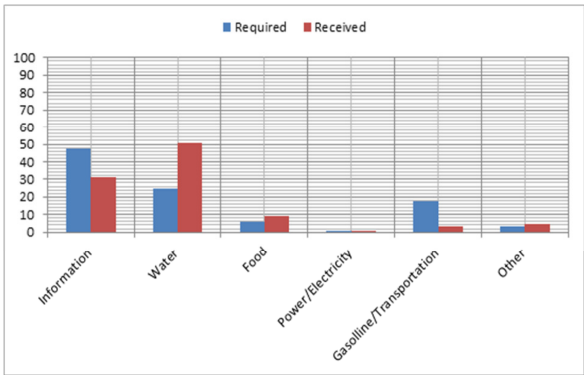

Figure-14: Support required and received (%)

9. DECIDING TO STAY OR RELOCATE

This section shows the decision stage of the foreigners, whether and how they decided either to continue their staying in their own living places in Japan or to relocate to other parts of the country or to their home countries. Figure-15 shows that 53.5% foreigners decided to relocate within the second week of the disaster, while a very good number of them decided to continue their stay in Japan, mostly at the same places. Among them, 42.5% were living at the same house, as shown in Figure-16.

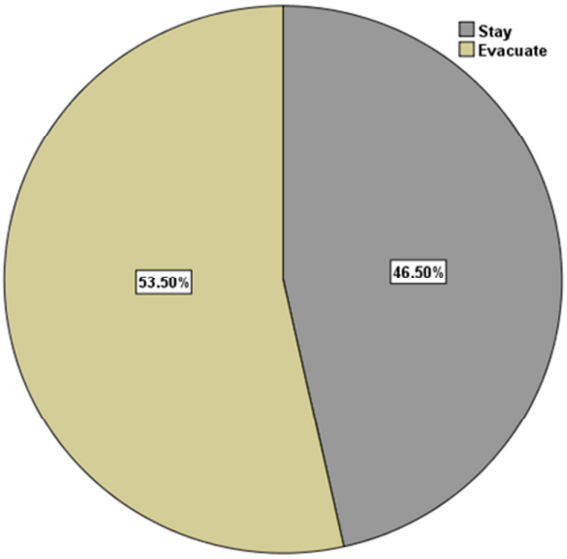

Figure-15: Stay or relocate (%)

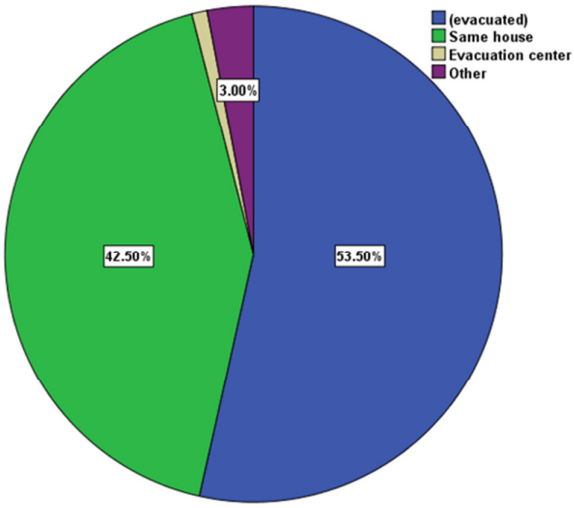

Figure-16: Staying places (%)

Only 1% had to stay in an evacuation center and 3% stayed in other places. For the evacuees, the highest 42% left Japan either to their home countries or to other countries, as shown in Figure-17. A good number of them, 11.5% relocated to other parts in Japan. This second group of foreigners did not leave Japan out of their good resident feeling and came back to their cities when the radiation situation improved.

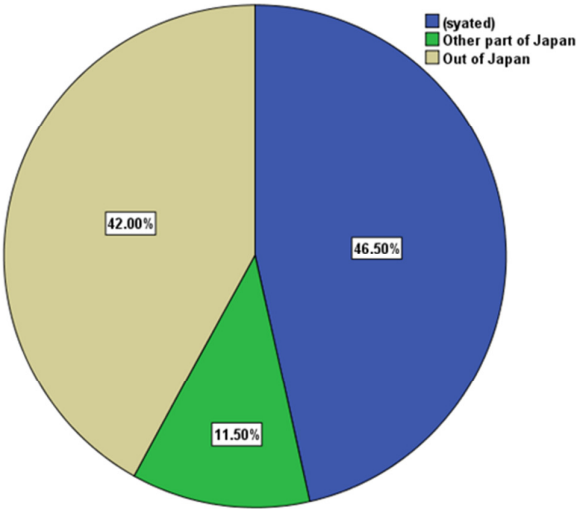

Figure-17: Evacuation places (%)

Figure-18 shows the reasons that foreigners considered to relocate. Total nine reasons were identified by the respondents. The highest consideration was nuclear radiation, which was 31%. The second highest one was fear of further earthquake and it was represented by 10% respondents. Other considerations were proportionately smaller.

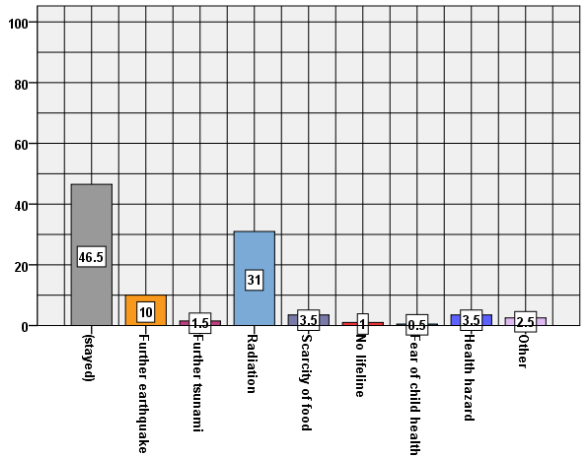

Figure-18: Evacuation reason (%)

Figure-19 shows the reasons for staying. Total seven reasons have been identified. The highest consideration was Japanese family relations and which was 14%. The second highest reason was community feeling, which was 11%, and the third one was desire of volunteering, which was 7%. In fact foreigners, who continued their staying in the affected areas in Japan, extended their supporting hands to volunteer disaster recovery.

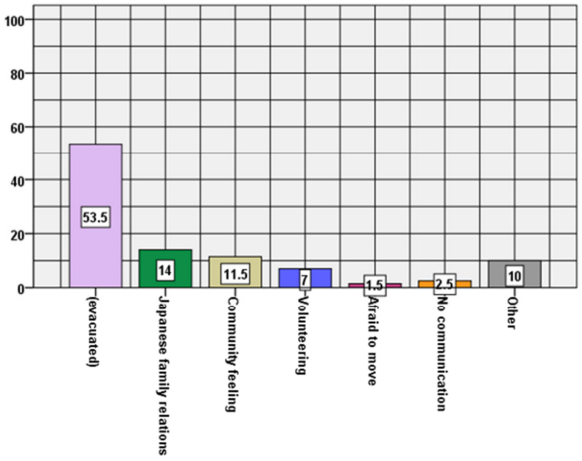

Figure-19: Staying reason (%)

10. DISCUSSION

Foreigners living in the Tohoku and Kanto region were affected by the great East Japan disasters. They had their own occupations and many of them were living in Japan for a longer period. This study included only those foreigners who were living for at least two years and have witnessed the great disasters during 3/11. Japanese family relations supported some of the foreigners to be familiar with the Japanese disaster management and early warning system. This group of foreigners could manage the difficulties after the disasters. They were calm and continued their staying in Japan. However, a major portion of the foreigners relocated from their living places in Tohoku or Kanto area due to several problems they faced in the aftermath of the disasters. Insufficient command in Japanese language was one of the problems but not the only one. The present study found that after the disaster, the highest used and trusted news media was Japanese Television. A very few of the respondents were concentrating on foreign news media. However, problems in daily life, lack of proper information, requirement of external support, scarcity of food and drink, gasoline and disruption in lifeline system compelled foreigner's relocate from their living city.

Foreigners were following news and information after the disaster that was mainly in Japanese. Proper and sufficient information in proper language may play important role on foreigner's life in Japan during the disasters. Their problems after the disasters were associated with the information and communication systems. They were not included in the local support system in the aftermath of the disasters. So their main support sources were their friends and neighbors. Consequently one group of the foreigners were relocated either to other part in Japan or outside, and another group continued their staying. The second group's decision may bring important lesson for the local authority in Japan because they did not only cope with the situation but also they extended their helping hand in the

recovery process. This study directs to analyze the preconditions of foreigners' two types of decision after the disaster. The result may bring some recommendation to include foreigners' issues in the local disaster management system in Japan.

11. CONCLUSION

This study shows foreigners' life and disaster information gathering during the Great East Japan Earthquake. It brought their first response to the situation and found that a few of them received an early warning message or alarm during the disaster. As most of them did not receive a warning, they concentrated on information gathering at the onset of the disasters. They were following information in the aftermath of the disaster and Japanese television was their most used and trusted information source. A few of them were using foreign news media as their Japanese ability was insufficient. Their information priority was changing as per the elapse of time. It was according to the problems they were facing at that time. They required same external support same as the native Japanese required. Since the support system was not adequate, a bigger portion of them decided to relocate. The rest part of them continued their staying and tried to utilize their time in disaster recovery activities. This study proposed a methodology to understand foreigners' experience and behavior after a big disaster like the Great East Japan disaster. It directs the further scope to analyze foreigners' potential in the local recovery process in the aftermath of the disasters.

PATTERNS OF AWARENESS OF CRISIS, REAL TIME DECISION-MAKING AND ACTION FOR SURVIVAL

Haruyuki Fujii[1] and Rimi Inoue[2]

1) Associate Professor, Department of Architecture and Building Engineering, Tokyo Institute of Technology, Japan
2) Graduate Student, Department of Architecture and Building Engineering, Tokyo Institute of Technology, Japan
fujii.h.aa@m.titech.ac.jp, inoue.r.ac@m.titech.ac.jp

Abstract: Patterns of Awareness of Crisis, Real Time Decision-Making and Action for Survival are extracted from the testimony of the survivors of the Great East Japan Earthquake. The patterns are examined with respect to the model of constructive action. Actions to survive and actions to design have things in common since the origin of design is to think to live, The verbal expressions in the testimony are classified in to generation, analysis, focusing, and other sub-processes articulating the constrictive methodology. The patterns of transitions from one sub-process to other sub-processes are analyzed. A model of human behavior in dynamically changing situations is being constructed on the basis of the extracted patterns.

1. INTRODUCTION

The final goal is to create a computational schema of constructive activities. The schema will be employed to design a software agent to simulate pre-quake mitigation management and post-quake rehabilitation management. This paper developes a model of action and examines, on the bases of the model, the typical patterns of action and decision-making in such situation.

2. MODEL OF ACTION

A model of constructive action is proposed. Fig.1 shows a model of process where an actor intends to do something so as to changes the situation into a preferable one. Let *Sc* be the current situation that an actor perceives. If the actor anticipates that a certain event likely occurs and the event brings about unpreferable situation *Sfa* then the actor desires to avoid facing the inpreferable situation. If the actor estimates the probability of the event to be high and the desire is strong enough then the actor plans to do something so as to change the situation into a preferred one.

In the case that the actor believes that a certain action is effective to change the situation into a preferred one, the actor intends to perform the standard action. On the contrary, in the case that the actor doesn't have the belief that such a standard action is effective, the actor, first, plans a course of actions to change the situation into a preferable one, and then, the actor follows the plan.

In the second case, a plan is made as follows. The actor pictures intermediate situation *Sfi* where the event does not bring about an unpreferable situation *Sfa* but a preferable one *Sfe* on the basis of the schema related to the event and its consequences. It is assumed that the preferable situation *Sfe* can be brought about not directly but indirectly by the actor's action since it is one of the possible consequences brought about by the event that is not controlled by the actor. It is also assumed that an actor can control the intermediate situation to some degree. Then, the actor makes a plan to directly change the current situation *Sc* into the intermediate situation *Sfi* and expect the preferable situation *Sfe* to be brought about. Here, a situation is directly made or controlled in the sense that the significant features characterizing the situation are directly changed by an actor. A situation is indirectly made or controlled in the sense that the significant features characterizing it are harnessed only indirectly by changing the features that can be changed directly. It is not necessarily straightforward to picture an intermediate situation from which the expected preferable situation is emerged through the presumed event.

Here, a situation is directly brought about or controlled in the sense that the significant features characterizing the

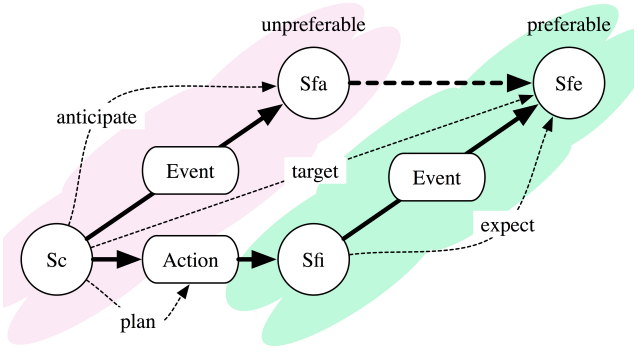

Figure 1 A Model of Constructive Action

situation are directly changed by an actor. A situation is indirectly brought about or controlled in the sense that the significant features characterizing it is changed only indirectly by changing the features that can be changed directly by the actor. It is not necessarily straightforward to picture an intermediate situation from which the expected preferable situation is emerged through the presumed event.

3. FINDINGS IN EMPIRICAL DATA

Some patterns of action and decision-making are extracted from empirical data in which survivors from a great earthquake and a tsunami retrospect and introspect their actions and thoughts while they are overcoming those disasters. The testimony of the survivors of the Great East Japan Earthquake is used as the empirical data concerning awareness of crisis, real-time decision-making, and action. The testimony contains retrospection and introspection of suvivors.

3.1 Type of Intention

Some intentions are extracted from retrospection and introspection of survivors of great earthquakes and tsunamis caused by the earthquakes. The primal desires are (Ia) to save one's own life, (Ib) to save loved one's life, and (Ic) to execute a mission so as to save people's life. The intention to save one's own life has some articulated intentions to respond to situations, i.e., (Ia1) to get out of the anticipated danger such as an earthquake, a tsunami, a fire, etc., (Ia2) to get out of the present danger, (Ia3) to flee to a place for safety such as a refuge, (Ia4) to take shelter from the severe weather such as the rain, the snow, the wind, the cold, the heat, etc., (Ia5) to procure food, (Ia6) to protect one's own property. The intention to save loved one's life has the same articulated intentions as the intention to save one's own life and an articulated intention (Ib7) to confirm loved one's safety. The intention to execute a mission is articulated in terms of an intention (Ic8) to save people's life and an intention (Ic9) to carry out a plan prepared for the crises supposed in advance. Table 1 summarizes these intentions.

Table 1. Types of Intention Extracted from Survivors

Ia) To save one's own life
Ia1) to get out of the anticipated danger
Ia2) to get out of the present danger
Ia3) to flee to a place for safety
Ia4) to take shelter from the severe weather
Ia5) to procure food
Ia6) to protect one's own property
Ib) To save loved one's life
Ib7) to confirm loved one's safety
Ic) To execute a mission
Ic8) to save people's life
Ic9) to carry out a plan prepared for the crises

Intention Ia, Ib, and Ic are sometimes incompatible with one another. A conflict among them let an actor assign an order of priority for the intentions. For example, it is often observed that one intends to save its family member's life rather than to save its own life. Even though one has succeed to flee to a place for safety, the one goes back to a dangerous place to confirm or save the loved one's safe. In these cases, only someone who fortunately found an alternative way to escape death could become survivors.

3.2 Transition of Intention

Intentions play important role to control action so as to bring about a preferable situation. The principal intention basically remains the same until it is fulfilled or avandoned. It changed for the reason of its fulfillment or development.

In a tsunami case, when an intention is fulfilled, a new intention becomes apparent in accordance with the intention to save one's own life (Ia). A typical and satisfactory pattern of transition of intentions toward saving one's life contains the sequence of intention to get out of the anticipated danger (Ia1), to flee to a place for safety (Ia3), to take a shelter from the severe weather (Ia4), and, to procure food (Ia5). Details of actions to fulfill these intentions are decided in accordance with the current situation.

While an intention is being carried out, the intention is developed in accordance with a present situation especially if the situation is unexpected and it seems to be too hard to fulfill the original intention. An alternative intention replaces the original intention. For example, one, who has intention to drive to a place for safety, gives up driving when the one gets caught in a traffic jam and intends to walk to a place for safety.

3.3 Level of Anticipation

Anticipation is performed to perceive, understand, or imagine the past, the current, or the future situation with the senses and the mind. An actor anticipates what if a certain event happens and estimates how severe the event and its consequence are.

A schema concerning the things to be perceived is used for anticipation. A schema provides a frame associating things and phenomena to see situations. It is composed of the features of things and phenomena and the relations among the features. The typical relations are the causal relations among the features, the subsumption relations among the classes of the features, and the inclusion relations among the features. A schema is constructed and updated through experience of similar or analogical situations.

Anticipation is classified into 3 levels, i.e., optimistic anticipation, moderate anticipation, and pessimistic anticipation, with respect to the probability that an anticipated situation is actually brought about and the preferableness of the anticipated situation. They are becoming clear as the situation progresses. Optimistic anticipation (Ao) lets an actor overestimate the probability that a preferable situation is brought about and the preferableness of the situation. Pessimistic anticipation (Ap) lets an actor underestimate the probability that a preferable situation is brought about and the preferableness of the situation. Moderate anticipation (Am) is the medium of the

optimistic and pessimistic anticipations. It has to be noted that the probability and the preferableness are not necessarily clear at the time of anticipation. It is hard for an actor to exactly estimate them before the situation really happens.

The level of anticipation affects the succeeding process of activities to fulfill the intentions.

Optimistic anticipation is likely to prevent an actor from being aware that there might be imminent danger so that the actor does not take appropriate actions to fulfill the intentions. The actor is thrown into difficult situations as a consequence. For example, one who thought that a tsunami wouldn't come to the area inside a breakwater failed to flee promptly to a place for safety without putting oneself in danger.

Pessimistic anticipation is likely discourage an actor to think how to save one's own or loved one's life and to execute a mission. For example, one would give up doing something to save one's life and leave one's fate to diety when one anticipates the situation that all is over.

Moderate anticipation enables an actor to make a plan to fulfill its intentions and update in accordance with the situations faced as executing the plan. For example, one who has a schema telling the unpredictable threat of a tsunami succeeded to make moderate anticipation and to save one's own and loved one's lives without a fatal sacrifice.

Anticipation could be biased by the intentions. It is often observed that the optimistic anticipation, for example, that there is little threat of a tsunami or that there is enough time to so something else than to get out of the danger is updated in accordance with the intention to save loved one's life.

Table 2. Level of Anticipation Extracted from Survivors

Ao) Optimistic anticipation
Am) Moderate anticipation
Ap) Pessimistic anticipation

3.4 Schema

An actor represents a preferable situation in terms of the features to represent the differences between the preferable situation and the current situation and the things in common. Then, the actor assumes the causalities that associate the directly controllable features with the target features characterizing the preferable situation or modifies the causalities currently employed. The decisions are made on the basis of the actor's beliefs about causalities related to the things in question and about the existing situations. The actor sets features to be expected to let the target features emerge and selects or assumes the mechanism expected to provide the features set above.

The assumptions and beliefs are made on the basis of the schema that an actor currently employs. A schema is composed of beliefs about relations among the features characterizing a world, relation among the event occurring in the world, relation between the elements organizing the world. A schema is constructed and updated through experiences in everyday life. If it is verified that a false anticipation is made on the basis of a certain schema then the schema is revised.

Retrospective and introspective of survivors show some important fragments influencing actions to survive a great earthquake and a tsunami. They are as follows (not exhaustive) ;

On a tsunami;

1) A huge tsunami necessarily comes after a great earthquake.
2) A tsunami could be immeasurably huge.
3) Mountainous waves of a tsunami comes repeatedly.
4) A tsunami never comes to the area inside a breakwater.
5) A breakwater is not strong necessarily enough to protect the inside from a tsunami.
6) A boat in the offing could withstand the force of a tsunami.

On a warning and the first motion;

7) The warning from the officials is always correct.
8) The warning from the officials is not always correct.
9) It does not have to evacuate oneself to a safe place unless it is not requested or ordered by the officials.
10) It is preferable to evacuate oneself to a safe place even though it is not requested or ordered by the officials.
11) What someone else says is more reliable than one's intuition.
12) What someone else says is less reliable than one's intuition.

On transportation;

13) A car runs faster than a human.
14) A traffic jam never occurs unless oneself gets to a safe place.

On priority;

15) The first priority in case of an emergency is to save one's own life.
16) The first priority in case of an emergency is to confirm and save loved one's life.
17) It is a default motion to go home to confirm loved one's safety.
18) One who has a mission to save someone's life has to fulfill the mission in any cases.
19) One should escape from danger of a tsunami by oneself.
20) Life is more than anything.

3.5 Imagination of Preferable Situation

An actor imagines a preferable situation that is expected to come true. It is described as the consequence to be brought about through the interaction among the actor's action, the event anticipated, and the situation where the event happens. In a tsunami example, if an actor anticipates that the actor may not survive the disaster without doing something then the actor pictures a safe situation where undesirable features are eliminated. Some people climbed up

as high as they could unless they could confirm that the place is safe. If an actor makes optimistic anticipation that estimates the probability and hugeness of a tsunami not high then a pictured situation remains the same as the current situation until the result of the estimation changes. In this case, an actor doesn't flee to a place of safety until the actor experiences a critical moment. For example, someone, who was not aware of the threat of a tsunami did not leave a house until the tsunami actually comes. The person did not imagine the situation that a tsunami reaches to its place had a narrow escape.

3.6 Situated Planning

Timing of the first motion has an influence over the development of the situation. A plan to one's own and loved one's life is made in accordance with the situation.

When an actor has, more or less, enough moment to deliberate an appropriate plan to fulfill its intention, the actor envisages an intermediate situation that can be resulted by actions and brings about the preferable situation through the interaction with the anticipated event. It is performed on the basis of the current schema. In terms of features, the actor determines the features that embody the mechanism. It is desirable that decisions are made in the conviction that the expected phenomena will emerge with minimal unfavorable effects. If the effects are favorable then they may be expected explicitly in the succeeding decision-making. The actor decides a course of actions that directly changes the current situation into the intermediate situation. For example, someone makes a plan to evacuate with helping loved ones and neighbors while someone plans to give up to do so in order to avoid the unfavorable side effect that either oneself or the loved one may not survive a disaster.

When an actor doesn't have enough time to deliberate an appropriate plan to fulfill its intention, the actor unavoidably makes promptly a transitory plan on after another to improve the immediate situation. For example, someone, who failed to flee to a place for safety, gets on the roof of a house or something higher or keeps a right grasp on a branch or a telephone wire to avoid being flowed by a tsunami. Someone, who was flowed by water, jumped on a floating large plastic container with expectation to survive.

3.7 Interaction with Environment through Actions

An actor interacts with the environment through the execution of actions in a plan. It is not necessarily the case that the course of actions are done exactly as expected since the situation may make the features that are not focused or expected explicitly when the situation is imaged. Actions are adjusted with respect to such features in the current situation as well as the features focused in advance.

An actor observes the process and the result of the action done following a plan and the consequences brought about the interaction between the behaviors of the mechanism embodied as a result of the execution and the situation. The consequence is close to or far from the pictured preferable situation. The secondary effects could be either favorable or unfavorable.

An actor evaluates whether a preferable situation is brought about. If yes, then the plan is done successfully, else, this process is repeated until a preferable situation is brought about. The plan, the assumptions on the causal relations, or the preferable situation is modified.

4. CONCLUSIONS

Patterns of Awareness of Crisis, Real Time Decision-Making and Action for Survival are extracted from the testimony of the survivors of the Great East Japan Earthquake. The patterns are examined with respect to the model of constructive action.

METHOD TO MEASURE CIRCULATION SPACE USING AN AUTOCAD APPLICATION

Xue Ma[1], Ryuzo Ohno[2]

1) Graduate student, Dept. of Build Environment, Tokyo Institute of Technology, Japan
2) Professor, Dept. of Build Environment, Tokyo Institute of Technology, Japan

Abstract: The spaces between buildings play an important role in the living environment. To describe the characteristics of these spaces, an AutoCAD application is used to measure their lengths and widths. Although this method serves as a criterion applicable to several types of evaluations, herein it is employed to evaluate vulnerabilities against earthquake disaster.

1. INTRODUCTION

The spaces between buildings are an important element when discussing the quality of a living environment. Particularly in residential areas, varying the distances between buildings provides spaces with differing characteristics, supporting air flow, natural sunlight, and diverse activities in our daily life. Hence, measuring the spaces between buildings may improve space utilization, which is one standard to evaluate the environment quality. Herein the evaluation results are concentrated mainly on earthquake disaster mitigation where the spaces between buildings play an essential role for human survival.

Continuous spaces between buildings consist of a passage to facilitate the free movement of people. This study focuses on the spaces between buildings, which provide either approach or evacuation routes. Typically distance, shape, and occupied area describe a space. The objective of this study is to measure the spaces between buildings by recording their length and widths to generate a route between each continuous space using an Auto CAD application.

2. GENERAL DESCRIPTION OF AUTOCAD SOFTWARE AND LISP LANGUAGE

The CAD (computer-aided design) system, which has been applied to recent designs and the architecture industry, uses vector graphics. CAD describes and simulates a solid physical model on a computer, which is between the real condition and electronic data, and can support both 2D and 3D formats.

AutoCAD supports a number of APIs (Application Programming Interfaces) for customization and automation. AutoLISP is a dialect of the Lisp (List Processor) programming language built specifically for use with AutoCAD and its derivatives. Aside from the core language affording mathematical and function operations, most of the primitive functions are for geometry, accessing an internal DWG database, or manipulating graphics in AutoCAD. AutoLISP code can be entered at the command prompt or loaded from external files.

3. MODEL THEORY

The CAD map records the vector information of each target area. We have developed a program, which is applied by AutoLISP, to detect the distance between buildings, automatically plot the emergency routes, and determine the space characteristics.

When a person enters a particular space from an entrance or remains at a location in the space, our program measures the smallest usable space by drawing a circle where the person is the center and the distance to the nearest object is the radius. If a person is moving, the radius changes. In this manner, circles for all positions in the target area can detect the spaces between buildings.

Routes between buildings can be generated based on the drawn circles. Among the many options for circulating in the target area, the most effective evacuation route is important in an emergency situation. This route can be detected by connecting the centers of circles following certain principles.

4. PROGRAMMING DETAILS

4.1 Rules

In our program, several rules must be followed to draw the map. Firstly, an enclosed boundary is required. Secondly, because the CAD map only recognizes straight lines (not arches, circles, or curves), all single lines exist in only one closed polygon where the interior angle between the end points of two lines does not equal to 180 degrees. Thirdly, each polygon (building) is set as one object while the

boundary of the area is set as one single object.

4.2 Possible cases to define a circle

All lines and points, which represent buildings, are classified into groups by polygons; each object is marked by the coordinates of its all points, such as [(p1,p2,p3,p4)(p5,p6,p7)… …(Pl,…,Pm)(Pn,…,Px)]. Circles are used to measure the spaces between buildings. Different scenarios can be used to draw a circle (Fig. 1). However, all drawn circles must meet one basic condition: the circle cannot cross another object.

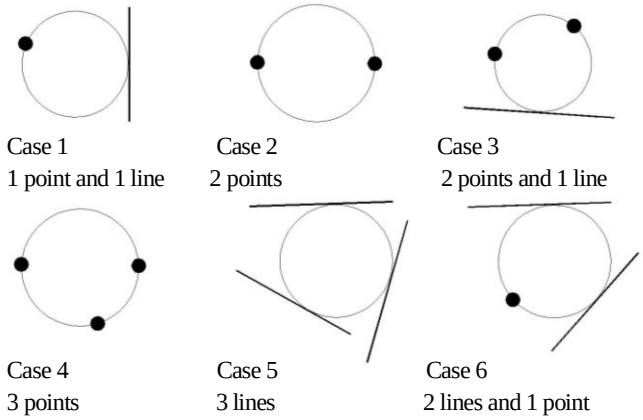

Figure 1. Possible scenarios to define a circle

Case 1: Circle passing through one point and one line

To select an object, line L1 and point P1 must not belong to the same object. Draw a vertical line from any point P (P1,P2,P3,…,Px) to the line that belongs to the other object (Fig. 2). Assume the vertical line is the diameter of the circle. A perpendicular point exists inside the line instead of on the extension line.

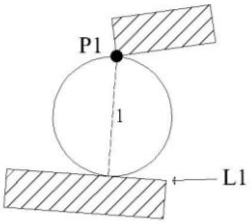

Figure 2. Drawing process

In another situation, extend the lines that share the same point P1 (P1,P2,P3,…,Px) in the direction where the intersection is potentially straight line L1 (Fig. 3). Find one point on the extension line such that the distance to the initial point equals the distance with the straight line.

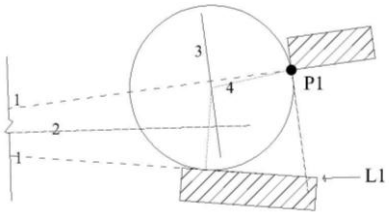

Figure 3. Drawing process

Case 2: Circle passes through two points

Connect any two points P1 (P1,P2,P3,…,Px) and P2 (P1,P2,P3,…,Px) (Fig. 4). The connection line is the diameter of the circle.

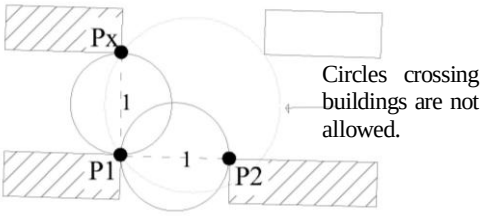

Figure 4. Drawing process

Case 3: Circle passes through two points and one line

To select an object, points P1, P2, and line Lx must be in the same object (Fig. 5). The connection line of two points P1 and P2 must not parallel to line L1 and does not cross line L1. Extend the line and the connection line to an intersection. Draw an angular bisector to connect the perpendicular bisector of the two points. Find the point where the distance to the other point is equal to the distance to the line along the perpendicular bisector.

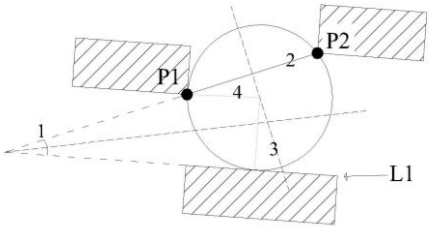

Figure 5. Drawing process

Case 4: Circle passes through three points

To select an object, the three points P1, P2, and P3 must not be in the same object, although two points can be from the same object (Fig. 6). Draw straight lines to create line segments for any two pairs of the points. Find the perpendicular bisector of two lines. Their intersection is the center of the circle. The distance between the center and any point (P1, P2, P3) is the radius of the circle.

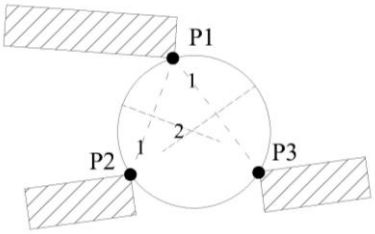

Figure 6. Drawing process

Case 5: Circle passes through three lines

(5.1) Three straight lines

To select an object, only two of the three lines (L1, L2, L3) can be in the same object (Fig. 7). Extend the three lines until intersection points appear. Take the intersection of the three angular bisectors as the center. The distance to any line

is the radius of the circle. The tangent point must be on the line instead of on the extension line.

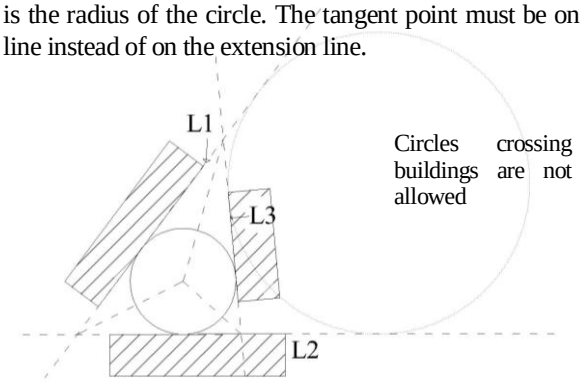

Figure 7. Drawing process

(5.2) Two parallel lines and one straight line

Take the distance between two parallel lines L1 and L2 as the diameter (Fig. 8). Draw the perpendicular bisector of the third straight line L3. Find the point on the bisector where the distance equals the radius of the center of circle. The tangent point must on the line instead of on the extension line.

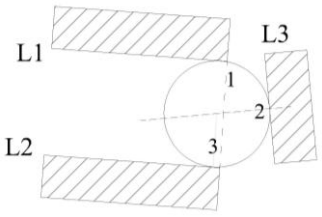

Figure 8. drawing process

Case 6: Circle passes through one point and two lines

To select an object, all lines (L1, L2) and point P1 must not be in the same object, and the point is not on a line (Fig. 9). Extend the lines to an intersection. Draw an angular bisector. Find a point on the angular bisector where the distance to the line equals with the distance to the point (Px). The tangent point must exist on the line instead of on the extension line.

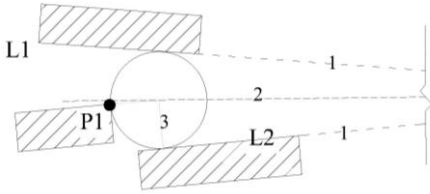

Figure 9. Drawing process

4.3 Reading data

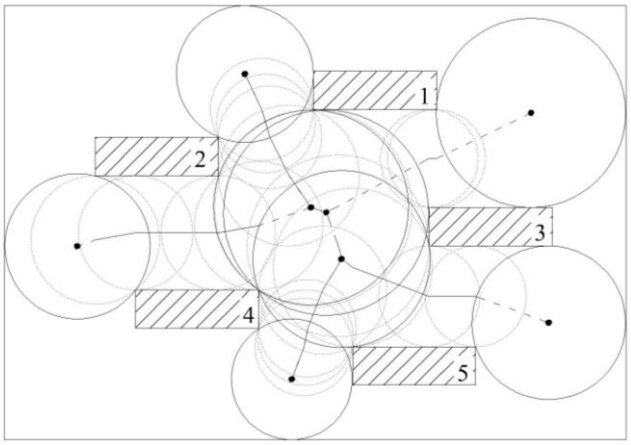
As shown in Table 1, data is recorded as three text files. File 1 is for the serial number of each circle and includes the coordinates of the center of circle and its radius. File 2 records how many objects are tangent to the circle as well as the serial number of those objects. File 3 is a list denoting the initial row of the data for each circle in File 2.

Table 1. Output of the data files

Data	File 1	File 2	File 3
Content	Coordinates of radius/radius	Number of connected object/ Serial number of connected object	Initial row in File 2
C1	(Xc1, Yc1) R1	3	1
		5	
		9	
		21	
C2	(Xc2, Yc2) R2	2	4
		5	
		15	
…	…	…	…
Cx	(Xcx, Ycx) Rx	3	X
		2	
		7	
		10	

4.4 Drawing route lines

To detect the routes between buildings, connect the centers of the circles. This process produces two situations.



Circles in contact with two objects

Pick circle C1 with its serial number. Read which two objects are in contact with the circle using File 2 and File 3. Choose all the circles that also touch only the same two objects, and sort the distance between centers with C1 from the shortest to the largest.

Connect the center of C1 with the first and second shortest distances, which are the expected route segment (Fig. 10). The connection line between two circles cannot cross any object or fully cut another circle. Repeated lines are read only once in the final result.

Circles contact with three objects

When circle P1 is in contact with three objects, circles that share any two objects (including circles that only connect to two objects) must be read using File 2 and File 3. Similar to the previous situation, repeat this process (Fig. 10). Starting points and exits must be manually set when running our program.

——— step2: Connect the route from circles that touch three objects

Figure 10. Process for drawing lines

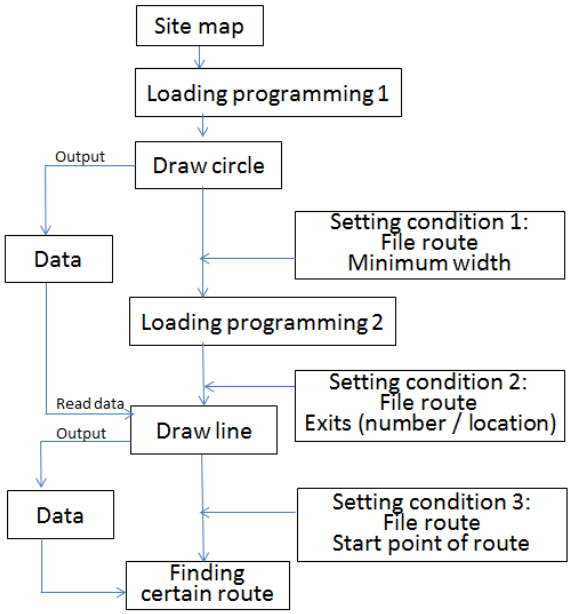


Figure 11. Running flow from drawing the sitemap to determining the route

5. ANALYSIS OF THE RESULTS

The widths and distances between the centers of the circles are recorded as numerical data. Because characteristics to describe spaces between buildings include route lengths and widths, calculating the lengths and widths of the routes can be used to evaluate open spaces.

We applied our program to several residential sites to detect the spaces between buildings and to evaluate earthquake disaster vulnerabilities. Different site layouts are compared. The high-rise building site and low-rise building site possess different space characteristics (Figs. 12 and 13). Although high-rise building sites have wider spaces, low-rise sites have longer routes.

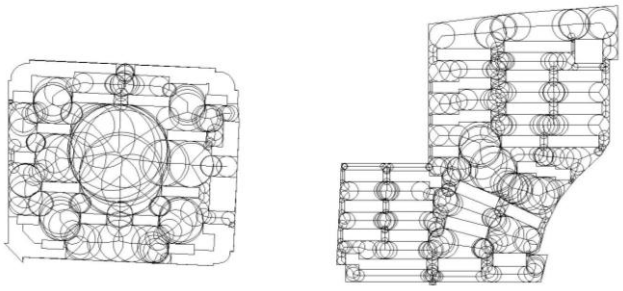

Figure 12. Site plan of high rise and low rise areas

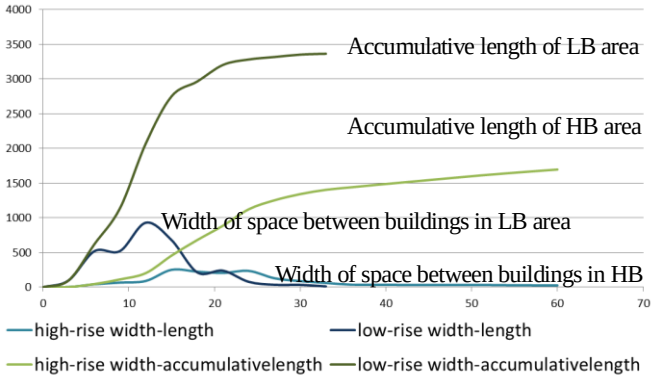

Figure 13: Comparison of route length in different width in 2 areas

6. APPLICATIONS TO EVALUATE THE VULNERABILITY AGAINST EARTHQUAKE DISASTER

Using this method, it is possible to evaluate the vulnerability of residential areas against earthquake disaster.

6.1 Analysis of usable spaces in a residential environment

The impact of fallen debris from a building is uncertain after an earthquake. By considering different scenarios, our program can analyze how the space between buildings changes as the damage becomes more severe. Figure 17 shows the results assuming different levels of damage, and confirms that vulnerabilities can be examined.

Different usages require different minimum widths. For example, the routes for fire engines must be at least four meter wide. Our program can evaluate the width of spaces to determine possible routes for different usages. Additionally, our program can measure the usable space for temporary gatherings or to distribute emergency supplies. Consequently, our program can identify key locations for specific functions.

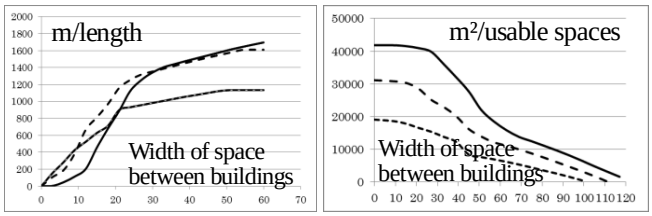

Figure 14. Accumulative length and occupied spaces for different damage situations

Figure 14 compares the information for a high-rise building with different damage scenarios. Although route changes slightly in the damage scenario, the usable space with a width wider than four meters, which is the minimum distance for a fire engine, is a quarter to half that in the normal condition.

6.2 Application to an accessibility analysis

For areas with low accessibility, adding exits can directly improve the situation. The way to add exits depends on the layout. Our program can determine the most effective solution for the number of exits as well as their locations.

Figure 15 shows the distance from the intersections of routes between buildings and the nearest exit. Adding exits at different locations decreases the distance, but not all locations have the same impact (Fig. 16).

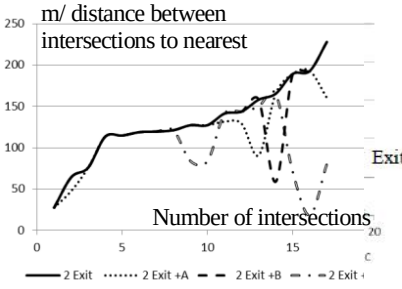

Figure 15. Shortest distance from the intersection of space between buildings and the nearest exit

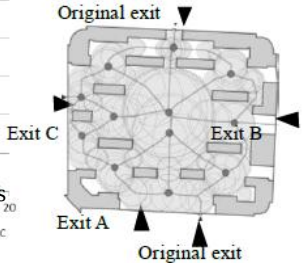

Figure 16. Location for additional exits

As a combination of the two applications mentioned above, optimization can be addressed based on the evaluation and basic information of the target site. Adding exits is a feasible way to minimize the number of potential victims while effectively using open spaces.

7 CONCLUSION

This study shows that our AutoCAD programming application can assess the spaces between buildings, and can automatically provide numerical data, which is useful for space analysis. Our method was applied to examine vulnerabilities against earthquake in a residential environment, and provided numerical measures for an objective evaluation. Future studies on environmental quality should employ our program.

Abstract: At present, Tokyo metropolitan area has two kinds of natural mega-hazard: M.7 class inner-plate earthquake and Tsunami. Central Disaster Prevention Council which is the supreme organization of disaster affairs in Japan has warned about them in published reports. Right after the 2011 off the Pacific coast of Tohoku earthquake, the railway system in Tokyo metropolitan area completely shut down so that a large number of people had difficulty in moving. So far, many expertise in disaster prevention have proposed that such people should keep staying same place where they encountered big earthquake for their safety. However, it was observed that after the earthquake a lot of people tried to go home on foot even though the trip distance was quite long, and many person who commuters unable to get home go to home through the dangerous zone which are fire dangerous zone and building damage dangerous zone. This paper analyzes the behavior of persons who commuters unable to get home under the 2011 off the Pacific Coast of Tohoku Earthquake using mobile GPS data. Authors proposed and developed smart phone application based on the previous analysis.

1. INTRODUCTION

Massive destruction was brought to the north-eastern region of Japan when the 2011 off the Pacific coast of Tohoku Earthquake occurred at 14:46 (JST) on March 11th, 2011. In Tokyo metropolitan area where maximum of 5-upper seismic intensity (JMA) was recorded, the earthquake suspended the transportation system such as bus and train services. As the result, many people tried to return home on foot. However not all were successful and many of them ended up going to emergency shelters put into place or waited the recovery of public transportation for a long time.

According to the 10th census on transportation in Tokyo metropolitan area, approximately 9,500,000 commuters use public transportation system per day and the average travel time was 68 minutes long. It is evident that once the public transportation system fails, a great number of people will face difficulty in returning home.

Nakabayashi (1992) researched the relation between the distance to home and the success rate of returning home. He mentioned that all the people could return their home if the distance is less than 10km and the rate decreases by 10% per additional kilometer. Furthermore, people face difficulty in returning home if the distance is more than 20km. However, on March 11th, 2011, there were those who could not return home even though the distance was less than 10km and those who succeeded in returning home even though the distance was more than 20km. Shimohara et al. (2010) and Osaragi (2008) examined disaster prevention plans by estimating a behavior model of the commuters in case of devastating earthquake. However, these studies may not fully reflect the actual behaviors as mentioned above.

Transportation system will be completely shut down if the Tokyo Metropolitan Inland Earthquake with magnitude-7 level occurs. Tokyo Metropolitan Government has worked on establishing new ordinance which asks companies to stock emergency supply in the office buildings. This countermeasure would contribute to keep employees staying in the building until the transportation system recovers.

In order to study the effective disaster prevention countermeasures regarding the evacuation of affected people after the large scale earthquake, we analyzed the behaviors of the affected commuters by the 2011 off the Pacific coast of Tohoku Earthquake on March 11th, 2011.

Hiroi (2011) conducts similar study and estimated choice behavior model of the affected commuters with using questionnaire survey data. However it is not verify whether they succeeded in returning their home.

In this study, we have analyzed the behavioral characteristics of the affected commuters using a GPS data. The respondents of the survey were the affected commuters who faced difficulty in returning home.

2. CHARACTERISTICS OF ACTIONS ON THE DAY OF THE EARTHQUAKE

2.1. FLAG INDICATOR OF TRAVELING

The figure-2 shows the percentage of people's traveling from the affected areas after the earthquake.

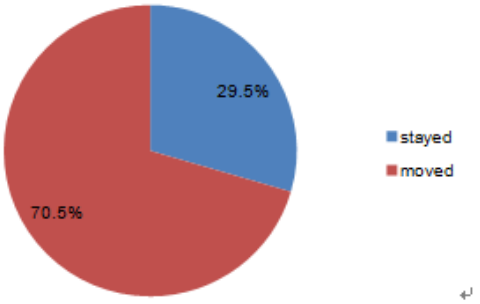

Figure 2. percentage of moved or stayed.

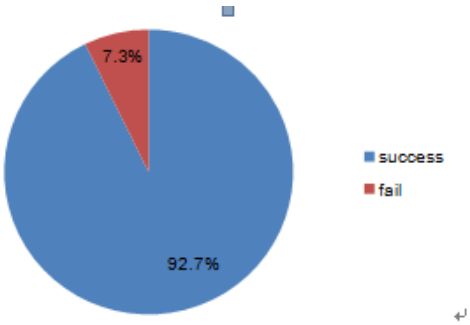

Figure 4. the success or failure of the go home.

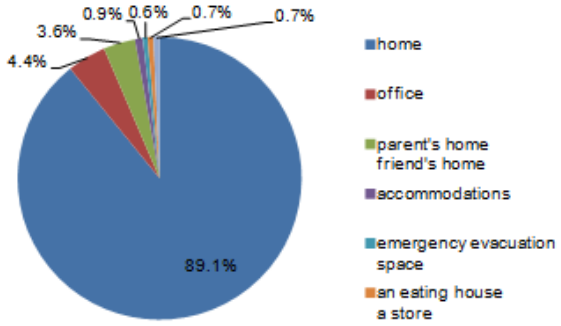

Figure 3. percentage of destination

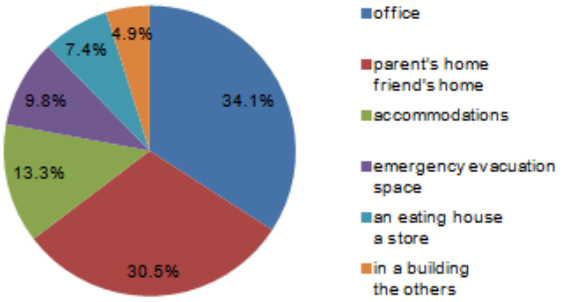

Figure 5. stay place of the return abandonment person

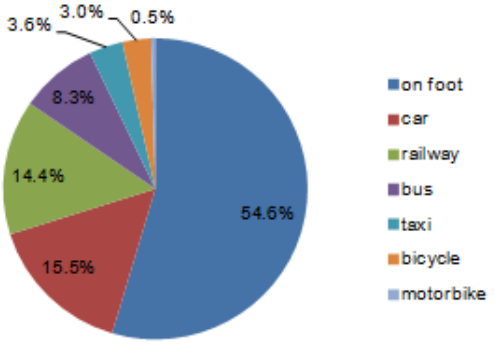

Figure 6. use transportation.

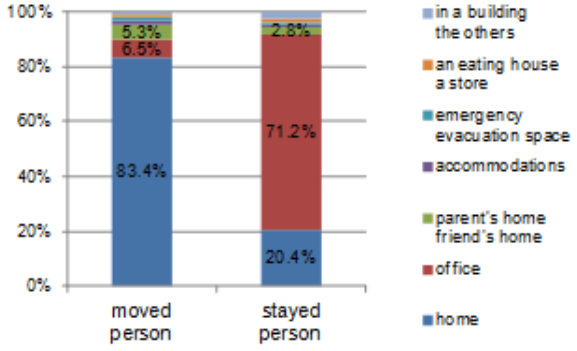

Figure 8. stay place of moved person and stayed person

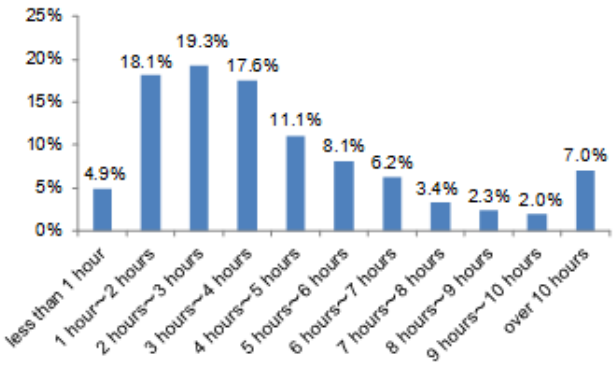

Figure 7. time required of go home.

29.5% of the people did not move at the time of the earthquake while 70.5% of the people tried to move. It became clear that 89.1% of the people who tried to move were trying to return home. Thus we decided to investigate into further details to find out the situation that affected the decision making process and to find out whether those who hoped to return home actually succeeded in returning home. The results will be presented in the next chapter.

2.2. SITUATION OF HOME RETURNING ON THE DAY OF THE EARTHQUAKE

The figure-4 indicates the result of the people's attempt to return home. 92.7% of the people succeeded in returning home. The figure-5 shows the percentage of the final place of stay of those who could not return home. 34.1% of them stayed at their company, 30.5% at family and friends' house, 13.3 % at hotels, 9.8% at emergency shelters. It became clear that people tried to return home once but chose to stay according to the situation.

2.3. RETURNING ACTIVITY ON THE DAY OF THE EARTHQUAKE

The figure-6 indicates the major means of transportation for those who attempted to return home. For those who used multiple means, each individual chose their main means of transportation in the order of car, train, bus, taxi, motorbike, bicycle, and walking. Out of those who attempted to return home, 54.6% tried to return home by walking, 15.5% by car, 14.4% by train, 8.3% by bus, 3.6% by taxi, 3.0% by bicycle, and 0.5% by motorbike. This fact indicates that more than half of the population who use train on a daily basis had attempted to return home by walking. The figure-7 indicates the amount of time spent for returning home. Most people spend about 2-3 hours and 30% of the people spent more than 5 hours.

3. ANALYSIS ON THE BEHAVIOR TO REMAIN

Firstly, we analyzed the final location of stay of those who stayed and those who moved. The figure-8 indicates the final location of stay organized according to the means of transportation. 83.4% of those who responded "attempted to move" indicated their own home as final location of stay while 71.2% who responded "to stay" indicated their companies as final location. From this observation, the affected population can be divided into two major categories, those who wish to return home and those who stay.

Secondly, we analyzed the characteristics of the desired location of stay. In this study, we have distinguished three types of initially desired location of stay namely "home", "other than home", and "remaining". The figure-9 shows the relationship between the linear distance to home and desired location of stay. The result indicated that less people wished to return home as the distance to home increased and more people wished to remain where they were. The result also showed that 27% of the affected people wished to return home even when their home was more than 40 km away.

4. BEHAVIOR ANALYSIS FUSING GPS DATA

We analyse commuters' behaviour under large scale disaster in Tokyo Metropolitan area. It became clear that stranded commuters' pass through the fire dangerous zone and building collapse zone for going his/her home. It is very dangerous for stranded commuters' under large scale disaster in Tokyo Metropolitan area as shown in fig.9 and fig. 10.

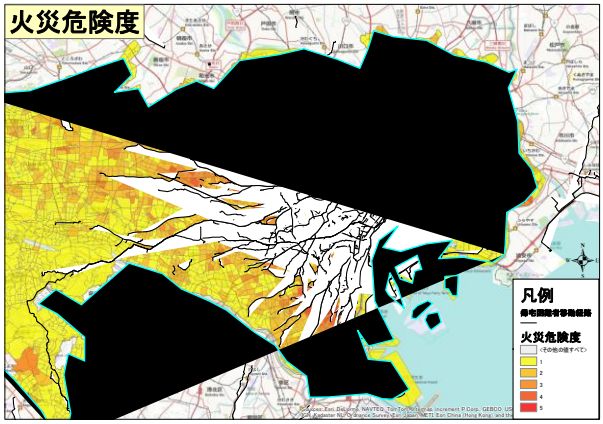

Figure .9 Behaviour route with fire zone

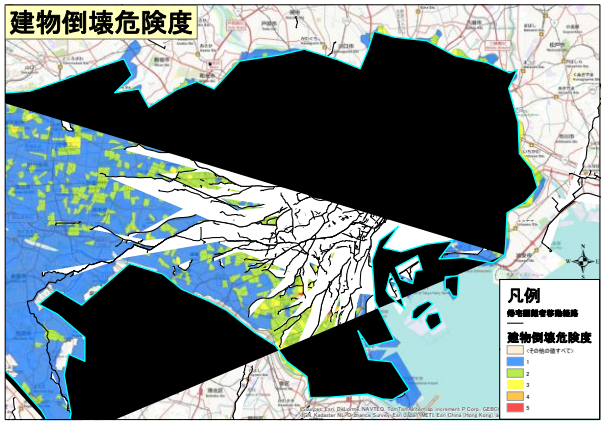

Figure .10 Behaviour route with building collapse zone

5. CONCLUSION AND FUTURE PROSPECTS

This study investigates the behaviour of the people having difficulties in going home after the 2011 off the Pacific coast of Tohoku Earthquake occurred.

As the result of this study, it becomes clear that approximately 70% of the affected people attempted to move and approximately 92% of those who attempted to return home managed to do it.

We clarified that many affected people had attempted to move and many of them succeeded in doing it. However, it is estimated that Tokyo Metropolitan Inland Earthquake

would bring more severe condition such as shut down of transportation services, massive fire, building collapse, road congestions and so on.

Thus, in order to be prepared for the coming large scale earthquake in Tokyo metropolitan area, it is necessary to prepare an effective countermeasure such as storing of necessary items and securing of safe places to stay, announcing the employees to remain until the transit system recovers, and establishing a procedure of safety confirmation of family members and friends.

On the other hand, it is desirable to prepare safe environment to return home for those who attempt to return home. In order to accomplish it, development of a method of safe evacuation is required, considering the disaster level, distance to a home, and personal attributes.

Abstract: Understanding human behavior, such as waiting, returning home, and evacuation, after a great earthquake is very critical in establishing detailed disaster prevention planning. In the present paper, we construct a simulation model to describe how human behavior varies as a function of physical damage, such as the spread of urban fires and street blockage due to collapsed buildings. The proposed model is applied to a densely built-up area of Tokyo using a database of the spatiotemporal distribution of railroad passengers, automobile users, and pedestrians. Using the model, we attempt to demonstrate some new findings that can be applied to disaster prevention planning by examining evacuation plans and various settings in earthquake simulations.

1. INTRODUCTION

1.1 Background and Objectives of Research

In recent years, people's daily lives are becoming busier due to rapid urbanization and the growth of rapid transit networks. Therefore, it is difficult to predict the effects of a large-scale earthquake on the population. The authors have investigated methods of estimating the spatiotemporal distributions of people inside/outside buildings and the people in transit with the aim of constructing the necessary database for analyzing disaster prevention plans (Osaragi and Hoshino 2012, Osaragi 2009, Osaragi and Shimada 2009, Osaragi and Shimada 2009).

In this paper, we consider not only the spatiotemporal distribution of occupants in-side buildings, but also of transient occupants, (i.e., people who are walking or otherwise in the process of using transportation in the city) in order to construct a simulation model for evacuation efforts following a large-scale earthquake. The model takes into consideration the behavioral characteristics of a variety of people, some of whom are constantly moving and some of which remain in a single location within the city. We have attempt to account for the influence both people whose movement paths stay within the city and those returning home (e.g., from offices/ schools) on the number and spatial distribution of stranded people. This influence has not been addressed in previous studies.

1.2 Comparison with Previous Studies

Early spatial models representing urban spaces were raster data models (Okada et al. 1979, Aoki et al. 1992), but those models were replaced with block models to clarify aspects of different actual urban areas. More recently, it has become more common to employ spatial models using detailed digital maps. Attempts have also been made to build models based on multi-agent simulations (MAS), in which stranded people, fires, and other factors are treated as agents. The range of applications for MAS, which originated in the life sciences, has expanded with the advance of computer technology, and MAS has come into wide use in the field of evacuation behavior simulations in recent years. Highly versatile procedures have been proposed, including analyses of simulations of evacuation activities that model activities for the rescue of people requiring aid during seismic fires (Ueda et al. 2007) and models based on commercially available digital maps (Muraki and Kanoh 2004). Many proposals have also been made for evacuation activities following tsunamis (Fujioka et al. 2002, Suzuki and Imamura 2005, Ohata et al. 2007).

However, the source data for previous research, namely, spatial distributions of populations, have been static data obtained from the population census or other similar sources that do not account for human behavior characteristics, which change dynamically with time and location. Also, depending on the time and place, one can expect the coexistence and intermingling of stranded people and those attempting to return home. No studies have simultaneously discussed evacuation activities and return home travel. Therefore, in this report, the authors have combined a model for estimating the spatiotemporal distributions of occupants remaining in the city and transient occupants (Osaragi and Hoshino 2012, Osaragi 2009, Osaragi and Shimada 2009, Osaragi and Shimada 2009) with a model describing the intention to return home and the associated return activities (Osaragi 2012), and incorporated this into a new model describing evacuation behavior.

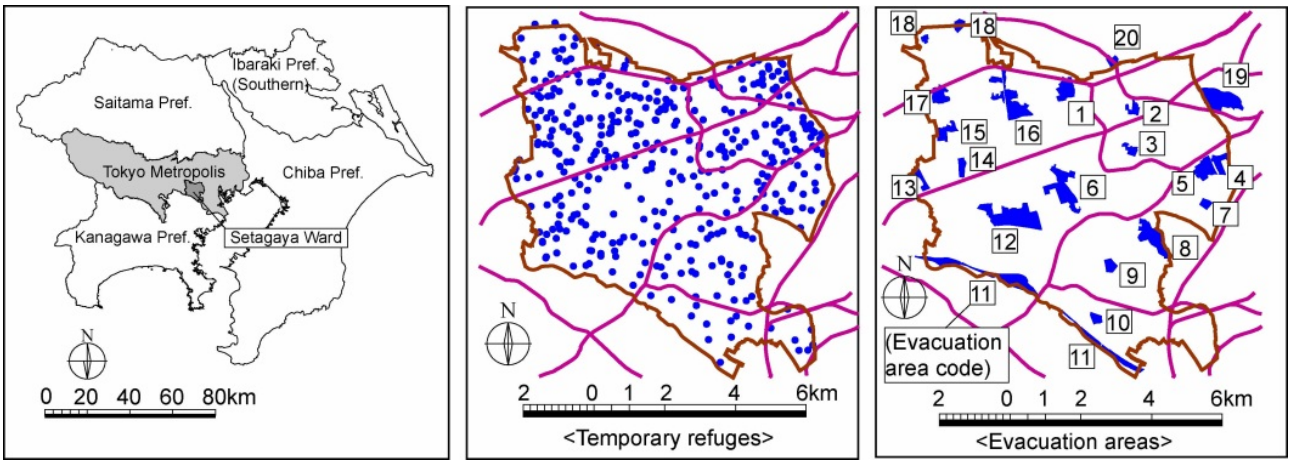

Figure 1 Study Area

There are many studies presenting models for describing property damage. Models relating to the urban spread of fire and the collapse of buildings (Tokyo Fire Dept. 2001, Murao and Yamazaki 2000). The present report uses these models in an attempt to provide a micro-simulation analysis on a unit building basis, taking into consideration the attributes of buildings.

The simulation model proposed here can be summarized as follows: (1) blockage of streets by collapsed buildings is modeled; (2) the progress of fire is predicted using an urban fire spread model; (3) the spatiotemporal distribution of train passengers, automobile users, and pedestrians is incorporated; (4) the movement of people returning home who enter or exit the region under analysis are modeled; and (5) stranded people are categorized using a detailed profile based on their, for example, the purpose of their movements.

2. ANALYTICAL DATA

2.1 People and Regions under Analysis

The region employed in this analysis was the Setagaya Ward of Tokyo (Fig. 1). Setagaya has areas that are densely crowded with wooden structures, and thus are very vulnerable to housing collapse and urban conflagration in the event of an earthquake. In addition, many workers and students live in Setagaya and commute within the Tokyo region (i.e., they would be counted as transient occupants). The subjects under analysis included all individuals residing and traveling within the ward during a disaster, not only those who live in Setagaya. This population also includes people re-entering Setagaya from outside the ward at various times after a disaster (people returning home).

Data from a Person-trip Survey (PT data) conducted in 1998 were employed to compile the daily trip destinations for Setagaya residents. It was found that approximately 96% of the trips remain within metropolitan Tokyo and these return travel activities took place across the whole of the Tokyo region.

2.2 Spatiotemporal Distribution of Occupants

Location data for occupants remaining in the city (occupants of any facility, including residences) were represented by building locations or intersections. Specifically, the location of each occupant of Setagaya was determined by selecting the building probabilistically, using the floor area of each building, the purpose of travel PT data, and the building type noted in the digital maps. For residents outside Setagaya, locations were determined by selecting positions at random from among intersections in area units (small zones) used in the PT data.

Location data for the railway passengers (Osaragi 2009), automobile users (Osaragi and Shimada 2009), and pedestrians (Osaragi 2012, Nishimura and Osaragi 2009) were predicted by employing the results of previous research together with the detailed data available on individual attributes.

2.3 Spatial Model Used in Simulation

The street network was extracted from the digital map to use as the spatial model. People were assumed to be walking on the sidewalks, and so sidewalk widths were extracted from the traffic census data (2005). In order to prevent confusion during evacuation and encourage orderly evacuation behavior, the Tokyo Regional Disaster Prevention Plan (2003) is based on a two-stage evacuation, which calls for people initially to gather in temporary refuges and then to move from there to (official, wide and safe) evacuation areas. The study area consisting of 392 temporary refuges (Fig. 1, center panel) and 20 evacuation areas (Fig. 1, right-hand panel) connected with a street network was created in order to examine the effectiveness of this evacuation scheme.

3. MODELING PROPERTY DAMAGE

3.1 Building Collapse Model and Street Blockage Model

In building collapse models, the probability of collapse can be estimated for each building unit based on its year of erection or its construction type (wood, reinforced concrete, steel frame construction, or light steel frame construction) (Fig. 2) (Murao and Yamazaki 2000). According to the damage forecast for Tokyo Metropolis (2006), a North

Tokyo Bay Earthquake (7.3M) would cause shaking of a weak 6 on the Japanese seismic scale in Setagaya. Using an empirical equation (Midorikawa et al. 1999) relating seismic intensity to seismic velocity, a velocity of PGV = 60.0 (cm/s) was assumed. We used data on building heights and street widths to make a forecast of street blockage caused by building collapse (Fig. 3).

3.2 Fire Outbreak Model and Urban Fire Spread Model

In this study, we considered a fixed number of 58 fires breaking out in Setagaya, on the basis of the numbers of fires predicted for the area (18:00 o'clock) in the damage estimate for Tokyo Metropolis (2006). The specific locations of fire outbreak can be broken down by building use, season, daytime vs. nighttime occurrence, and typical acceleration (gal: cm/s2); we used the building-type-based outbreak rates of the Tokyo Fire Dept. (2001) to estimate these locations.

The fire spread speed model of the Tokyo Fire Dept. (2001) was employed; this model can account for different modes of fire spread and different structural building types. "Spreading speed" has two categories, speed of spreading within a single building and speed of spreading between neighboring buildings (Fig. 3), the latter of which depends on the distance between the two buildings.

3.3 Basic Analysis Using the Property Damage Model

After the above preparations, we carried out 10 Monte Carlo simulations using the models of building collapse and street blockage (each a different combination of building collapse and street blockage). The fractions of blockage in relation to the total number of streets were calculated (mean numbers of streets by units of neighborhood and block) and are shown in Fig. 5 (left-hand panel). As shown, areas with many narrow streets suffered a relatively high rate of street blockage.

Next, we carried out Monte Carlo simulations using the fire outbreak model and the urban fire spread model, taking as given building collapse and assuming the conditions: winter, nighttime, and a 6 m/s north wind. The parameter of maximum acceleration in the fire spread speed model (Fig.4) was assumed to be 500 gal, which is based on an empirical formula (Midorikawa et al. 1999) relating seismic intensity and maximum acceleration. The number of buildings catching fire within 48 hours after the earthquake (mean numbers by units of neighborhood and block) were determined and are shown in Fig. 5 (right-hand panel). As shown, the number of buildings was higher in areas in which buildings of wood construction were dense.

4. MODELING HUMAN BEHAVIOR

The typical series of human behaviors when an earthquake strikes were categorized and modeled. Fig. 6 shows an example of the behavior modeled for occupants at home, from the perspective of initial reactions, searching for routes, methods of evacuation (direct evacuation versus two-stage evacuation), walking in a crowd (walking speed),

$$P_R(PGV)=\Phi[(lnPGV-\lambda)/\zeta]$$

P_R : Cumulative probability of the occurrence of damage equal or higher than rank R
PGV : Peak ground velocity (cm/s)
Φ : Cumulative probability of the standard normal distribution
ζ , λ : Parameters determined by year of erection or construction type (wood, reinforced concrete or steel frame construction)

Figure 2 Building collapse model

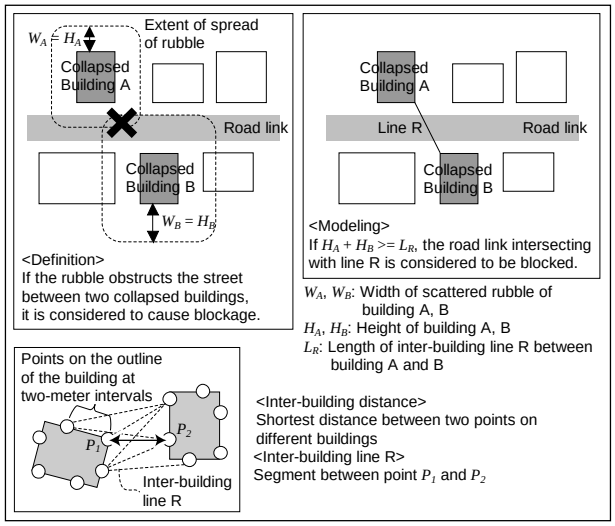

Figure 3 Street blockage model

Level 1: Speed of spreading within a single semi-fireproof building

$$Vt = \frac{6.63L}{1.17L + (\text{L-}5.0)\,f - 0.5}$$

Speed of spreading between neighboring buildings (bare wood and fire protection)

$$Vr = \frac{(a\alpha + b)\exp[(c\alpha + d)Lr]}{0.048U + 0.822}$$

f : Rate of damage (= 0.00034α - 0.054)
V_t : Speed of spreading within a single building (m/s)
V_r : Speed of spreading between neighboring buildings (m/s)
L_r : Inter-building distance (m)
α : Acceleration (gal: cm/s^2)
U : Wind speed (m/s)
The parameter a, b, c, and d is determined by structure, level, and status of collapse of neighboring buildings.

Figure 4 Fire spread speed model

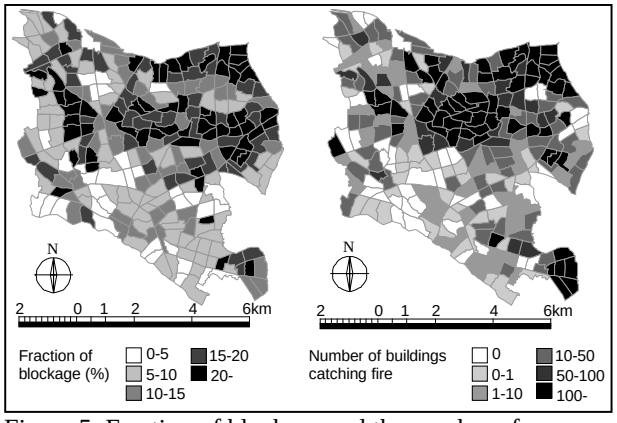

Figure 5 Fraction of blockage and the number of buildings catching fire

and activities while waiting. Specifically, the model incorporated the following: (1) a time is set for the start of evacuation after the earthquake; (2) in the case of a two-stage evacuation, the stranded people move to temporary refuges; (3) a time is set for beginning movement of stranded people from the temporary refuges to evacuation areas; (4) evacuation is complete when the stranded people have arrived at an evacuation area; and (5) the stranded people proceed directly to the evacuation area when a

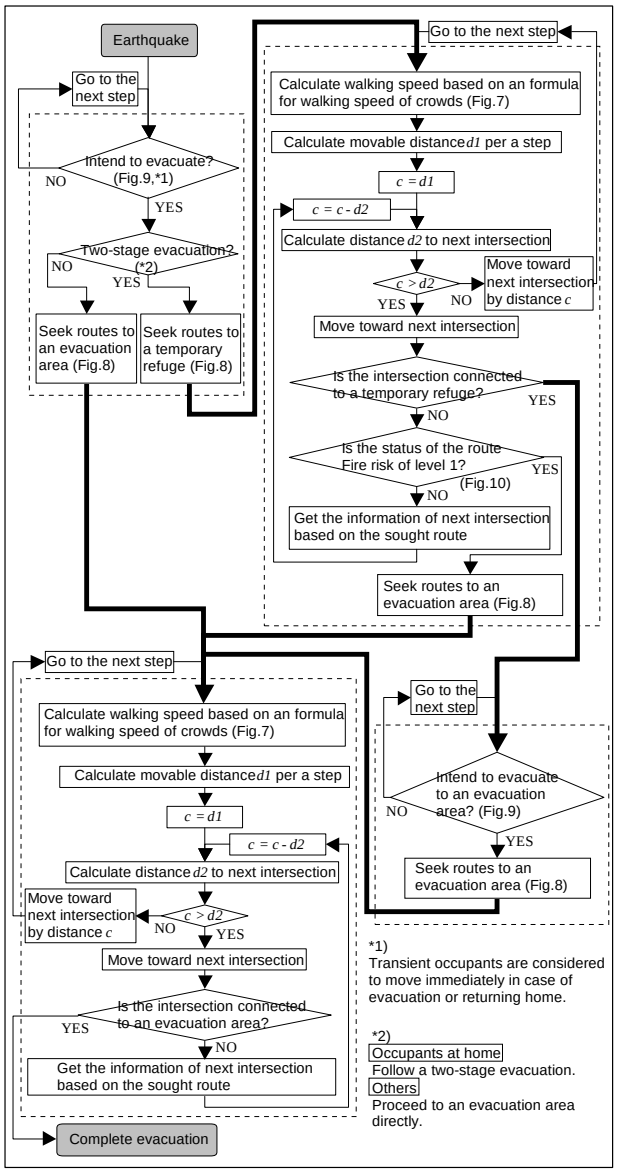

Figure 6 Human behavior model for occupants at home

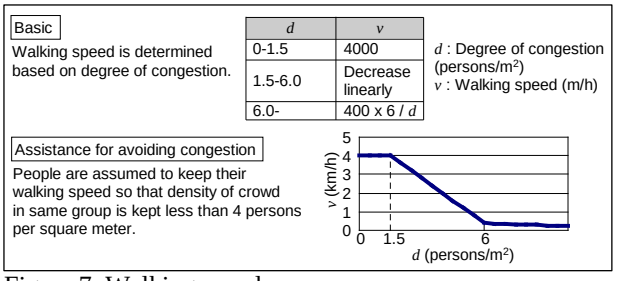

Figure 7 Walking speed

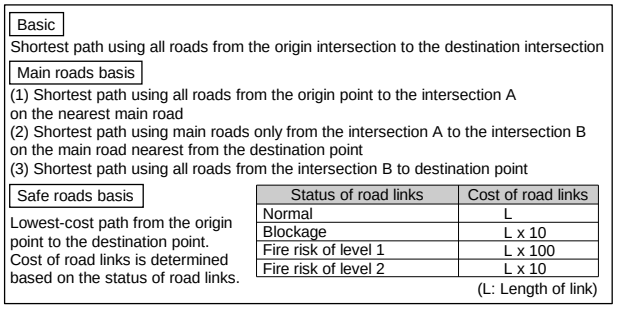

Figure 8 Route search

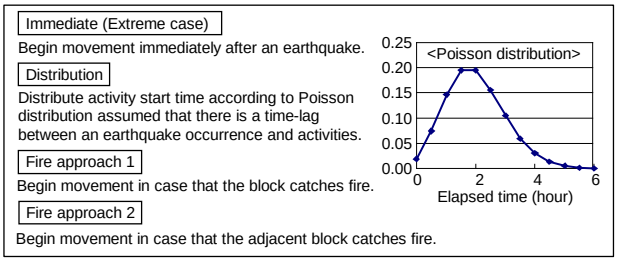

Figure 9 Definition of activity start time

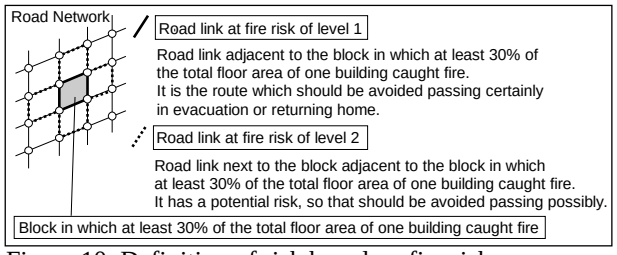

Figure 10 Definition of risk based on fire risk

two-stage evacuation is not followed. Fig. 7, Fig.8, and Fig. 9 show the details of how the walking speed is set, how routes are sought, and the time to begin activities, respectively.

The activities of transient occupants (railway passengers, automobile users, and pedestrians) are modeled as follows: (1) they decide whether to attempt to return home (the outcome is determined by the model of intention to return home) (Osaragi 2012); (2) if they decide not to return home, they are treated as occupants at home at the time of the earthquake; (3) if they decide to attempt to return home, they do so using the main streets. The routes from their location at the time of earthquake back to their homes are determined (Fig. 8); (4) if they encounter fire on their way home, they take refuge in an evacuation area; (5) if they complete their journey home, subsequently, they act in the same way as the occupants already at home at the time of the earthquake.

Occupants in facilities other than their own residences are modeled as follows: (1) they decide whether to return home; (2) if they decide not to return home, they wait in the current facility until the time to begin evacuation, and after that, they act in the same way as occupants at home; and (3) if they decide to return home, they subsequently act in the same way as the transient occupants.

5. EXECUTION OF THE SIMULATION MODEL

5.1 Performance Indicators and Settings

The danger imposed by road links was defined (Fig. 10) in order to make an assessment of the effect of urban fire spreading on safety during evacuations. It was assumed, as an approximation, that once at least 30% of the total floor area of one building in a certain block had caught fire, the radiated heat would endanger adjacent routes. However, streets that border large open areas (at least 10,000 m2), such

Table 1 Definition of risk assessment indices

Risk	Method for calculating risk
Risk1	The number of road links blocked by collapsed buildings, which stranded people passed through.
Risk2	The number of road links at fire risk of level 1, which stranded people passed through.
Risk3	The number of road links at fire risk of level 2, which stranded people passed through.

Table 2 Conditions for simulation ([ ]; Basic pattern in this paper)

Direct evacuation	First evacuation start time	At once, [Distribution] + [Fire approach 1], Fire approach 2
	Search routes using safe roads?	[Yes], No
Two-stage evacuation	First evacuation start time	[Distribution] + [Fire approach 1], Fire approach 2
	Avoid congestion?	[Yes], No
	Search routes using safe roads?	[Yes], No
	Second evacuation start time (after the occurrence of an event)	0min, 15min, 30min, [Fire approach 1], Fire approach 2

as parks or vacant lots, were considered to be safe. Next, risk assessment indices were set (Table 1) in order to quantify risks during evacuation. From the standpoint of safety, it is desirable if the above risk of evacuations should be reduced.

Evacuation methods, walking speed, path search methods, and activity start times could each be varied in the simulation model constructed. To prioritize examining the influence of transient occupants and persons returning home, however, the data were analyzed under the conditions given below in Table 2.

5.2 Preliminary Analysis of Return Home Travel

We determined fluctuations (over time) in the number of persons returning home passing through Setagaya, for different combinations of starting points and arrival points, to learn about return home travel (Fig. 11). These fluctuations depended heavily on the timing of the disaster and on the combination of starting point and destination. We also found an unexpectedly large number of stranded people would be returning to homes in Setagaya from outside the ward, even several hours after the occurrence of the disaster.

5.3 Observations on Characteristics of the Simulation Model

In order to examine the importance of accounting for the presence of transient occupants and persons returning home, we analyzed the variations in people input into the simulation for 3 specific cases: (1) the population consisting only of occupants remaining in the area, (2) that population plus transient occupants, and (3) that population plus transient occupants and persons returning home. Fig. 12 shows the increases in stranded people in comparison to the first population. This figure indicates that, in case (2), the time-based changes in transient occupants strongly affect the number of stranded people, specifically, including them increases the number of stranded people, and in case (3), the number of stranded people is greatly increased by the inclusion of persons returning home in the daytime, when there would be many persons returning home. Examining the results by age group, there is an increase in child

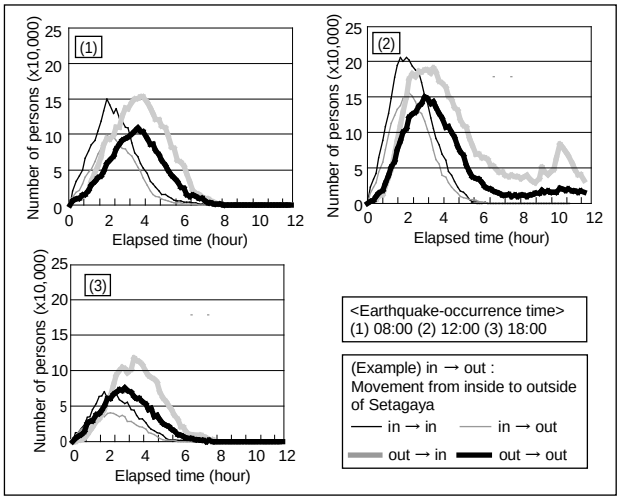

Figure 11 Fluctuations in the number of persons returning home passing through Setagaya ward

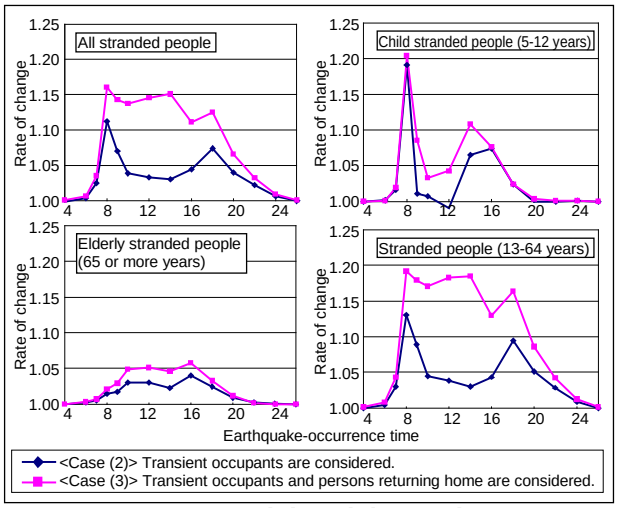

Figure 12 Increase in stranded people by considering transient occupants and persons returning home (attribute-based)

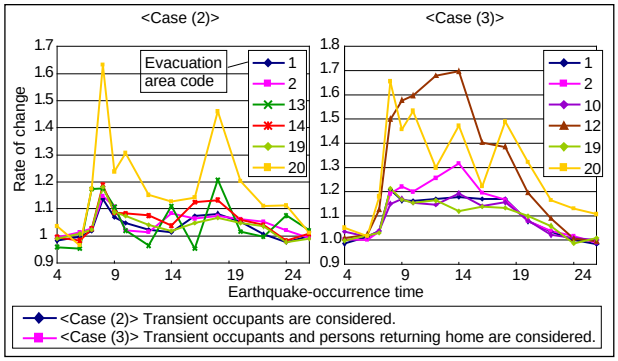

Figure 13 Increase in stranded people by considering transient occupants and persons returning home (in evacuation area)

stranded people (5–12 years) in the morning and evening, but the elderly population (65 or more years) showed little variation. In contrast, the reader can see that stranded people in the 13-to-64-year age group grew by about 20% during the 08:00-to-17:00 time frame. More specifically, the presence of transient occupants and persons returning home, which has previously been unaccounted for, may cause an approximately 20% increase in the number of stranded

people estimated for the peak hours period. This is an amount that cannot be ignored.

Next, we consider the number of stranded people in evacuation areas. Fig. 13 indicates the evacuation areas with high rates of increase in cases (2) and (3). There appeared a large influx of railway passengers at the evacuation areas around locations with high densities of railway lines. Previous investigations regarding the numbers and locations of evacuation areas have usually been based on the numbers of local residents, but in an urban area with a highly developed transportation network, it seems essential for the planning of evacuation areas to account for the presence of transient populations on railways and other traffic arteries, especially during the morning and evening rush hours.

We analyzed the effects of incorporating property damage into the simulation model to address the closure of streets due to urban fires and building collapse. Most previous simple simulations of evacuation activities did not incorporate property damage or the timing of evacuations in order to keep the models from becoming too large and complicated. In actuality, however, because the timing and routes of evacuations would vary with the extent of property damage, there is a large element of chance in the safety and efficiency of any evacuation. Therefore, the composition ratios of the stranded people was compared (Fig. 14) in terms of each sub-group of stranded people (residents, occupants of facilities other than their own residences, and transient occupants) between the case when everyone in some area is evacuated without taking into consideration property damage and the case when the time for beginning evacuation was decided after considering the property damage situation. We can see that there is a greater fraction of non-resident stranded people, especially during the day, if planners take property damage into account.

5.4 Risk Assessment in Travel to Evacuation Areas

The simulation was executed, accounting for all occupants (whether in buildings, transient, or on their way home), and the risks during evacuation to open areas were evaluated. The cases of two-stage evacuation and direct evacuation were compared (Fig. 15). Residents at home make up a majority of the stranded people at night, and so in this case, the risk is greatly reduced by organizing a two-stage evacuation. During the day, however, many of the stranded people, specifically occupants who are not home residents, would not comply with a two-stage evacuation; therefore, ordering a two-stage evacuation would have relatively little effect on risk. That is to say, planners must anticipate that during the daytime, a sizeable fraction of the occupants are occupants of facilities other than their own homes and that these transient occupants will not know where the temporary refuges are and will head directly to evacuation areas. Walking time to refuges can be longer in a two-stage evacuation, depending on how stranded people are directed, in order to avoid congestion. However, because there are many individuals who would not evacuate to an evacuation area and whose routes would terminate at temporary refuges near their homes, if we evaluate walking

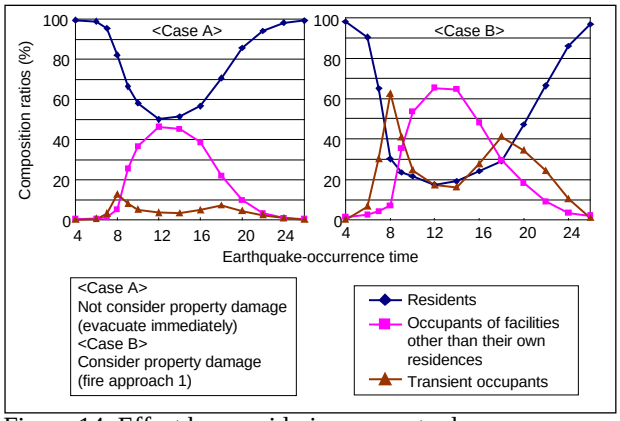

Figure 14 Effect by considering property damage

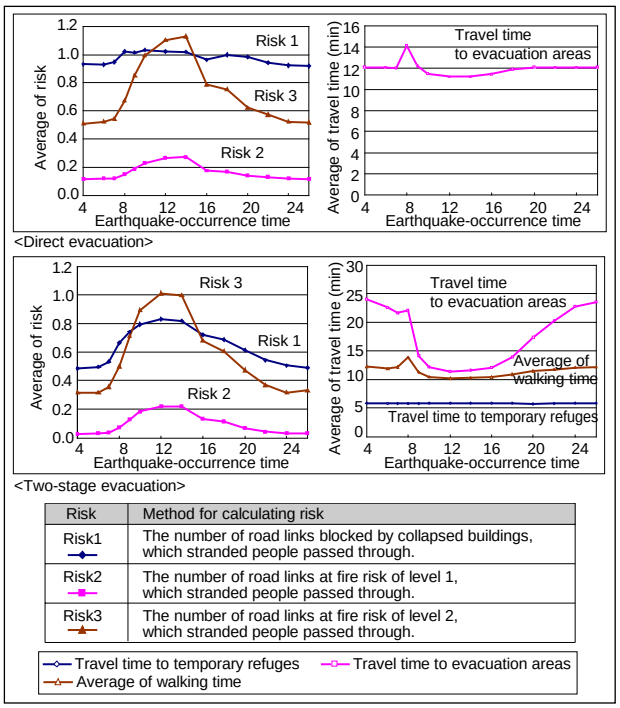

Figure 15 Comparison between direct evacuation and two-stage evacuation

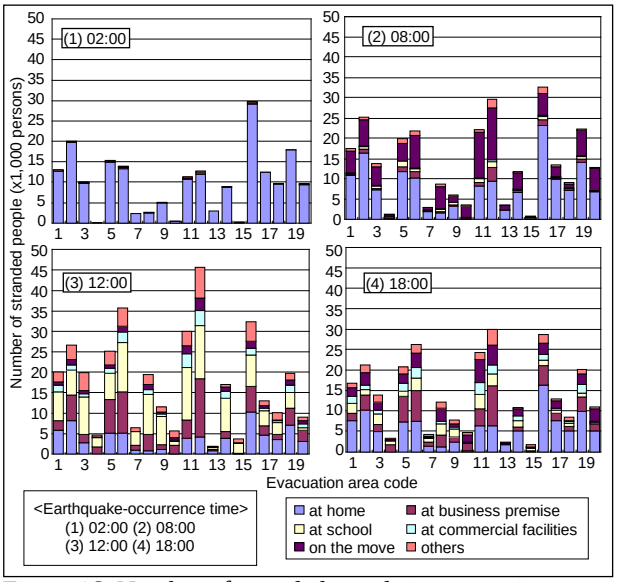

Figure 16 Number of stranded people in evacuation areas in terms of situation of persons

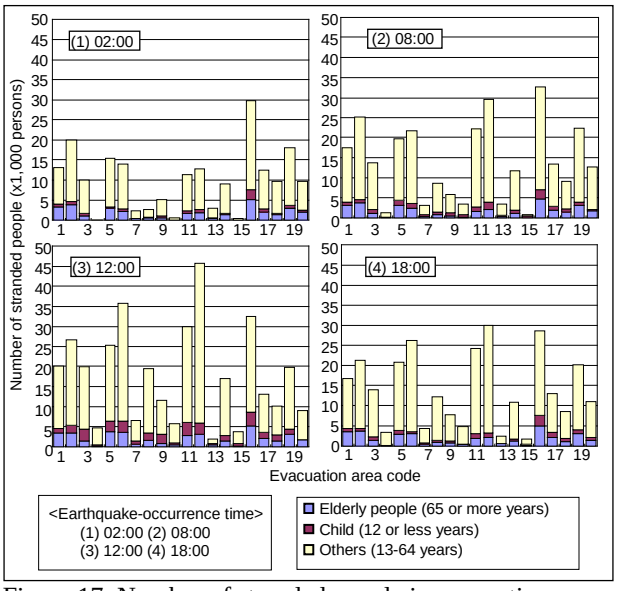

Figure 17 Number of stranded people in evacuation areas in terms of age groups

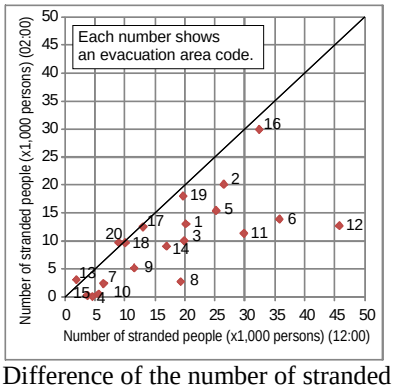

Figure 18 Difference of the number of stranded people in evacuation areas by earthquake-occurrence time

time averaged over all stranded people, travel time would be about the same in the two-stage case as in the direct evacuation case.

The numbers of stranded people moving to evacuation areas in a two-stage evacuation were compiled in terms of stranded people's attributes. Fig. 16 shows the results for different situations at the time of a disaster. In the early morning, many transient occupants would go to an evacuation area (6, 11, 12). During the day, many stranded people would go to an evacuation area from their business premises (5, 6, 12). Many would also go there from commercial facilities (6, 11, 12). Fig. 17 shows the results in terms of age group. The reader can see that not only the number of stranded people, but also the stranded people's profile varies greatly with the timing of a disaster. Comparing the cases of a disaster occurring at 2:00 AM and one occurring at noon (Fig. 18), nearly all the evacuation areas show increased numbers of stranded people in the latter case. The evacuation areas in locations surrounded by multiple railways and serving large regions tended to show particularly high differences between night and day.

All of the above results were due to the inflow into evacuation areas of transient occupants and persons returning home, who were not incorporated into previous evacuation simulations. A disaster mitigation planning must account for the fact that the numbers and types of stranded people will vary with the location of the evacuation area and the timing of the disaster.

6. CONCLUSION

A simulation model was constructed to describe human actions (waiting, returning home, and evacuating) after a devastating earthquake, taking into account property damage. A numerical simulation of people's reactions after a disastrous earthquake in Setagaya Ward of Tokyo was employed to verify the importance of accounting for the presence of transient occupants and that of persons returning home, and the importance of combining such a model with one describing property damage. Our analysis has revealed that the presence of transient occupants and persons returning home, who have not formerly been included in disaster prevention planning, may add about 20% to the numbers of stranded people during morning and evening peak periods, a quantity that cannot be ignored. Two-stage evacuations were also evaluated from the viewpoint of risks during evacuation to open areas. This indicated large variations in the numbers and attribute profiles of stranded people, depending on the location of evacuation area and the timing of the disaster.

Abstract: At present, Tokyo metropolitan area has two kinds of natural mega-hazard: M.7 class inner-plate earthquake and Tsunami. Central Disaster Prevention Council which is the supreme organization of disaster affairs in Japan has warned about them in published reports. Right after the 2011 off the Pacific coast of Tohoku earthquake, the railway system in Tokyo metropolitan area completely shut down so that a large number of people had difficulty in moving. So far, many expertise in disaster prevention have proposed that such people should keep staying same place where they encountered big earthquake for their safety. However, it was observed that after the earthquake a lot of people tried to go home on foot even though the trip distance was quite long, and many person who commuters unable to get home go to home through the dangerous zone which are fire dangerous zone and building damage dangerous zone. This paper analyzes the behavior of persons who commuters unable to get home under the 2011 off the Pacific Coast of Tohoku Earthquake using mobile GPS data. Authors proposed and developed smart phone application based on the previous analysis.

1. INTRODUCTION

Massive destruction was brought to the north-eastern region of Japan when the 2011 off the Pacific coast of Tohoku Earthquake occurred at 14:46 (JST) on March 11th, 2011. In Tokyo metropolitan area where maximum of 5-upper seismic intensity (JMA) was recorded, the earthquake suspended the transportation system such as bus and train services. As the result, many people tried to return home on foot. However not all were successful and many of them ended up going to emergency shelters put into place or waited the recovery of public transportation for a long time.

According to the 10th census on transportation in Tokyo metropolitan area, approximately 9,500,000 commuters use public transportation system per day and the average travel time was 68 minutes long. It is evident that once the public transportation system fails, a great number of people will face difficulty in returning home.

Nakabayashi (1992) researched the relation between the distance to home and the success rate of returning home. He mentioned that all the people could return their home if the distance is less than 10km and the rate decreases by 10% per additional kilometer. Furthermore, people face difficulty in returning home if the distance is more than 20km. However, on March 11th, 2011, there were those who could not return home even though the distance was less than 10km and those who succeeded in returning home even though the distance was more than 20km. Shimohara et al. (2010) and Osaragi (2008) examined disaster prevention plans by estimating a behavior model of the commuters in case of devastating earthquake. However, these studies may not fully reflect the actual behaviors as mentioned above.

Transportation system will be completely shut down if the Tokyo Metropolitan Inland Earthquake with magnitude-7 level occurs. Tokyo Metropolitan Government has worked on establishing new ordinance which asks companies to stock emergency supply in the office buildings. This countermeasure would contribute to keep employees staying in the building until the transportation system recovers.

In order to study the effective disaster prevention countermeasures regarding the evacuation of affected people after the large scale earthquake, we analyzed the behaviors of the affected commuters by the 2011 off the Pacific coast of Tohoku Earthquake on March 11th, 2011.

Hiroi (2011) conducts similar study and estimated choice behavior model of the affected commuters with using questionnaire survey data. However it is not verify whether they succeeded in returning their home.

In this study, we have analyzed the behavioral characteristics of the affected commuters using a GPS data. The respondents of the survey were the affected commuters who faced difficulty in returning home.

2. CHARACTERISTICS OF ACTIONS ON THE DAY OF THE EARTHQUAKE

2.1. FLAG INDICATOR OF TRAVELING

The figure-2 shows the percentage of people's traveling from the affected areas after the earthquake.

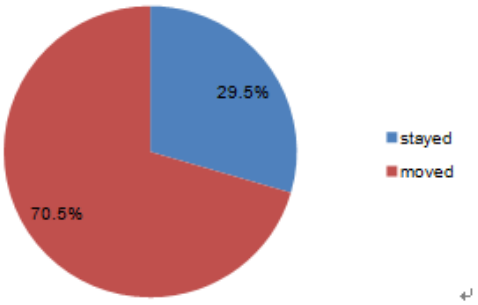

Figure 2. percentage of moved or stayed.

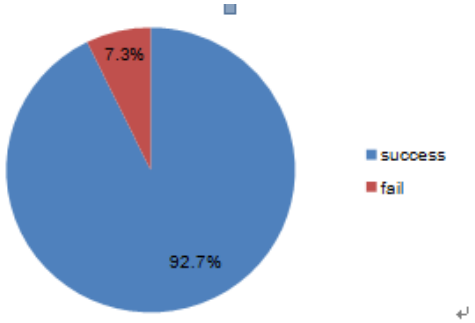

Figure 4. the success or failure of the go home.

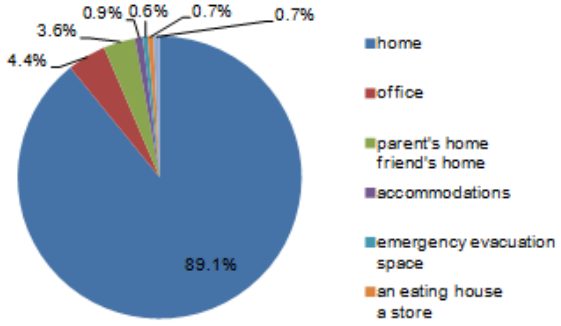

Figure 3. percentage of destination

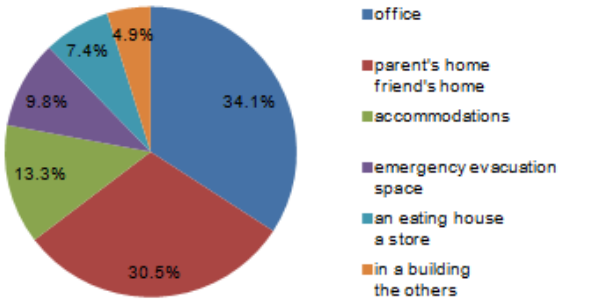

Figure 5. stay place of the return abandonment person

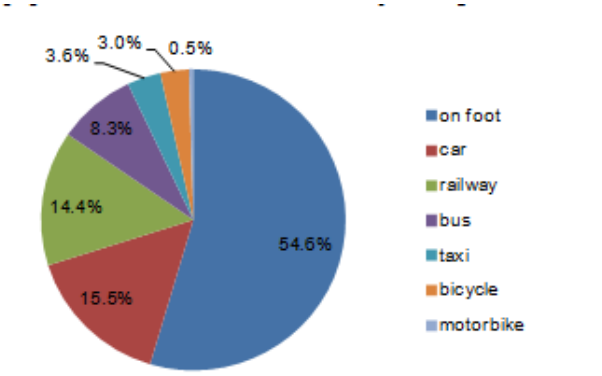

Figure 6. use transportation.

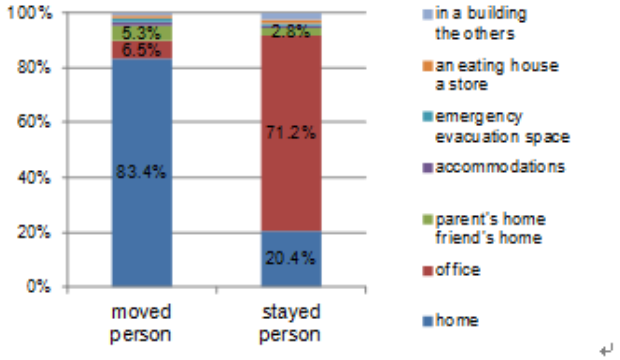

Figure 8. stay place of moved person and stayed person

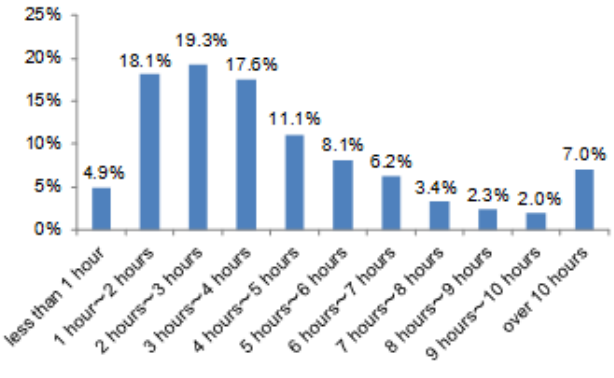

Figure 7. time required of go home.

29.5% of the people did not move at the time of the earthquake while 70.5% of the people tried to move. It became clear that 89.1% of the people who tried to move were trying to return home. Thus we decided to investigate into further details to find out the situation that affected the decision making process and to find out whether those who hoped to return home actually succeeded in returning home. The results will be presented in the next chapter.

2.2. SITUATION OF HOME RETURNING ON THE DAY OF THE EARTHQUAKE

The figure-4 indicates the result of the people's attempt to return home. 92.7% of the people succeeded in returning home. The figure-5 shows the percentage of the final place of stay of those who could not return home. 34.1% of them stayed at their company, 30.5% at family and friends' house, 13.3 % at hotels, 9.8% at emergency shelters. It became clear that people tried to return home once but chose to stay according to the situation.

2.3. RETURNING ACTIVITY ON THE DAY OF THE EARTHQUAKE

The figure-6 indicates the major means of transportation for those who attempted to return home. For those who used multiple means, each individual chose their main means of transportation in the order of car, train, bus, taxi, motorbike, bicycle, and walking. Out of those who attempted to return home, 54.6% tried to return home by walking, 15.5% by car, 14.4% by train, 8.3% by bus, 3.6% by taxi, 3.0% by bicycle, and 0.5% by motorbike. This fact indicates that more than half of the population who use train on a daily basis had attempted to return home by walking. The figure-7 indicates the amount of time spent for returning home. Most people spend about 2-3 hours and 30% of the people spent more than 5 hours.

3. ANALYSIS ON THE BEHAVIOR TO REMAIN

Firstly, we analyzed the final location of stay of those who stayed and those who moved. The figure-8 indicates the final location of stay organized according to the means of transportation. 83.4% of those who responded "attempted to move" indicated their own home as final location of stay while 71.2% who responded "to stay" indicated their companies as final location. From this observation, the affected population can be divided into two major categories, those who wish to return home and those who stay.

Secondly, we analyzed the characteristics of the desired location of stay. In this study, we have distinguished three types of initially desired location of stay namely "home", "other than home", and "remaining". The figure-9 shows the relationship between the linear distance to home and desired location of stay. The result indicated that less people wished to return home as the distance to home increased and more people wished to remain where they were. The result also showed that 27% of the affected people wished to return home even when their home was more than 40 km away.

4. BEHAVIOR ANALYSIS FUSING GPS DATA

We analyse commuters' behaviour under large scale disaster in Tokyo Metropolitan area. It became clear that stranded commuters' pass through the fire dangerous zone and building collapse zone for going his/her home. It is very dangerous for stranded commuters' under large scale disaster in Tokyo Metropolitan area as shown in fig.9 and fig. 10.

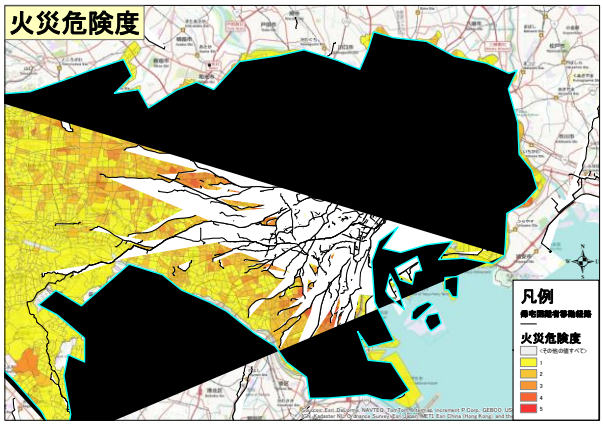

Figure .9 Behaviour route with fire zone

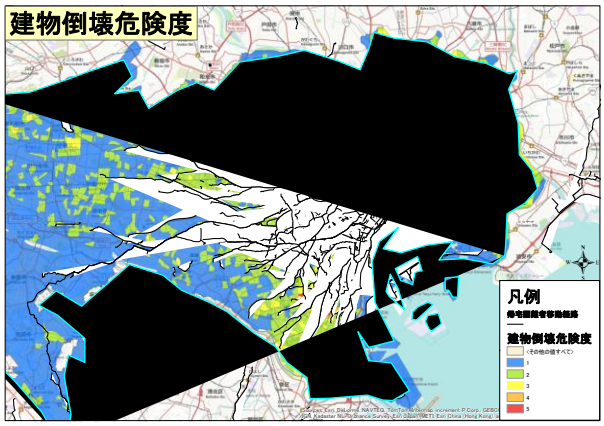

Figure .10 Behaviour route with building collapse zone

5. CONCLUSION AND FUTURE PROSPECTS

This study investigates the behaviour of the people having difficulties in going home after the 2011 off the Pacific coast of Tohoku Earthquake occurred.

As the result of this study, it becomes clear that approximately 70% of the affected people attempted to move and approximately 92% of those who attempted to return home managed to do it.

We clarified that many affected people had attempted

to move and many of them succeeded in doing it. However, it is estimated that Tokyo Metropolitan Inland Earthquake would bring more severe condition such as shut down of transportation services, massive fire, building collapse, road congestions and so on.

Thus, in order to be prepared for the coming large scale earthquake in Tokyo metropolitan area, it is necessary to prepare an effective countermeasure such as storing of necessary items and securing of safe places to stay, announcing the employees to remain until the transit system recovers, and establishing a procedure of safety confirmation of family members and friends.

On the other hand, it is desirable to prepare safe environment to return home for those who attempt to return home. In order to accomplish it, development of a method of safe evacuation is required, considering the disaster level, distance to a home, and personal attributes.

SPATIAL CHARACTERISTICS TRANSFORMATION OF SELF-BUILT AND DONATED POST DISASTER HOUSING

Syam Rachma Marcillia[1] and Ryuzo Ohno [2]

1) Graduate Student, Dept. of Built Environment, Tokyo Institute of Technology, Japan
2) Professor, Dept. of Built Environment, Tokyo Institute of Technology, Japan

Abstract: This study aim to evaluate and analyze the spatial characteristic by investigating the transformation of self-built and donated post disaster housing in Java. The development of self-built temporary and donated core structure housing to permanent housing was investigated with on-field questionnaires, interviews, and house plan data collection. The objective is to understand what residents' perceptions toward their dwelling space are and how they actualized it in the design of their restricted temporary condition to permanent self-built housing and compare it with the transformation of donated core structure post disaster housing. Results suggest that residents recognized the hierarchy of space arrangement in their dwelling as both private and social space which correlated with their space perception. Social interactions indeed important in Javanese dwelling therefore flexibility and open ended design in housing are advantageous for their post disaster recovery.

1. INTRODUCTION

There had been cases where emergency house reconstruction built in a short time without cultural sensitivity had resulted in rejection of ill designed settlement. In contrary, some community based reconstruction housing has good response to residents' lifestyle and long –term needs because its open ended design that facilitated the cultural needs. These highlight the importance of understanding cultural background in the design of a dwelling as stated in Rapoport (1987), it is necessary to consider both why environments should be culturally responsive and to whom they should be culturally responsive and, consequently, how.

Social behavior is one of the important cultural backgrounds in Indonesia dwellings and Java specifically. For Javanese, a house is living environment that represent the philosophical concept of the society itself (Tjahjono, 1989). In previous researches, traditional 'margersari' housing and other public housing so called 'core house' consist of 'guest room', 'bedroom' and 'kitchen'. (Ikaputra,1992). In the public housing also, 'core house' alteration start with the expansion of double/triple size of 'guests room' which is a social space and then private space 'bedroom'.(Yoyok S., 1993).

An earthquake measuring Mw 6.3 (USGS and ERI) hit Java island of Indonesia with an epicenter of about 20 km south of Yogyakarta on Saturday, 27 May 2006. It had displaced up to 200,000 people from their homes. Housing reconstruction program were undertaken by many parties, NGOs and government. Based on preliminary survey two-weeks after the earthquake, even in early stage of Java 2006 earthquake recovery we found the existence of 'guest area' in temporary tents and house. Although their needs of functional room (bedroom, kitchen, etc.) are not fully accomplished within the house yet, the importance to facilitate social interaction is express and actualizes in the 'guest area'. Apparently social behavior still has influence in Java dwellings. Correspondently, in this study it is believed in that social behavior inevitably still an important cultural factor even in post disaster housing. For this paper, data on physical setting as well as residents' spatial perception and activities in self-built and donated post disaster housing are interpreted in the emphasis of the dwellings usage and adjustment for personal-social space. Residents' evaluation and participation in community activities are also studied to understand residents' perspective on their social interaction. It is indispensable that we grasp the transformation process of the space arrangement and its relation to residents' spatial perception and activities in the house to reveal dwelling space formation as a whole.

2. RESEARCH METHOD

Two study cases in Java 2006 earthquake self-built and donated core structure post disaster housing are investigated and considered as 'constraint dwelling' because there is a change of situation from their ideal living environment to their 'temporary' restricted condition which can acts as inhibiting environment and therefore adjustments are necessary to fulfill their lifestyle needs and ideal living

environment.

The study presumed that the development of temporary house to permanent house will be the reflection and actualization of residents' cognition of suitable dwellings in self-built post disaster housing, and the development of donated core structure house would be similar to self-built housing which reflected how the residents' spatial perception is actualized to their activities and space arrangement in their dwellings.

2.1 Research Areas

Study in Java post disaster housing was carried out in Bantul, district/regency of Yogyakarta, as the most affected region of the disaster. More than 2000 residents were killed, thousands are injured and 80% of houses were damaged or destroyed. Bantul is located 11 km to the southern part of Yogyakarta (Figure 1). The total area is approximately 508 km2 with more than 80% of its population is Moslem. The administrative area consists of 17 sub-districts, 75 villages and 933 sub-villages. The first case study area is self-built post disaster dwellings located in three sub-villages of *Ketonggo, Bawuran and Tegalrejo, Yogyakarta*. The three sub villages were selected because they were high damages areas. The respondents were chosen based on the condition of the houses after the earthquake where original houses totally destroyed and most of the residents rebuilt the permanent post disaster houses based on their own design.

Two integrated surveys were taken in 2 years difference to see the development from self-built temporary house to permanent house. In first survey, a total of 39 respondents were acquired. Most of the respondents are original residents of the surveyed area and the rebuilt houses located in their own land. The second survey targeted same respondents from first survey, but from 39 respondents, only 33 respondents able to be surveyed again because some of them moved to different areas.
The second case study area is donated post disaster housing in Tembi village, Sewon, Bantul, Yogyakarta. In Java earthquake 2006, not all Tembi houses were collapsed, therefore only few of the collapsed houses received donation. The donated house is basically a core house structure consist of six concrete column and roof. The constructions of wall as well as space arrangement were made by the residents themselves. The survey was undertaken once, by that time most of the donated core structure house had become permanent houses. A total of 23 household were interviewed and house plan were taken. Some core structure houses that were not used as permanent house are excluded from the analyses. Both case study area locations are shown in figure 1 below. The details descriptions and house modification of each respondent's houses in both study cases are shown in table 1 and table 2.

2.2 Questionnaires and Interview

Questionnaires, in-depth interview and observation with the residents were conducted with the help of Gadjah Mada University volunteers. Each team consists of 2 people, one person was asked to sketch the house plan while the other interviews the resident. Information acquired as follows:

a. Background: Residents (age, sex, family, occupation, income, etc.) and house (structure, house age, land status, etc.)
b. House plan: room space, size, etc
c. Space usage :include personal and interpersonal activities
   - Personal activities in space which include: *personal biological needs* (eating, sleeping, etc), *entertainment* (watch TV, relaxing, etc), *work* (study, etc) and *household routines* (cooking, etc).
   - Interpersonal activities which include: location and behaviors in accepting different guest types in the house and interaction and frequency with neighbors.
d. Cognition of space on front/back, hidden/seen, public/private, flexibility, etc.

3. RESEARCH RESULTS

3.1 Importance of social interaction

In self-built post disaster housing, 95% of the residents' values traditional social behavior where they still cherished traditional Javanese living practices and community values such as *gotong royong* (spirit of helping one another through good and bad) and *kekeluargaan* (feeling of extended kinship in which the community is considered to be one big family). Many recovery programs operated by NGOs and the government were community-based and designed to incorporate such traditional practices into the rehabilitation process. Woman were gather cook together in the public kitchen and arrange the usage of public kitchen and usage of wells, while the man gather together to clean up wreckage debris and built the temporary house together. Over 60% said these values grew even more significant to them following the earthquake. Accepting guest activities in the house occurs 41% for everyday occasions and 90% residents involved in community gathering of their neighborhood which required them to accept large occasion guests in their house. Borrowing behavior between neighbors also take place for more than 30% within a week which include borrowing kitchen utilities, appliances and even food materials. The high importance of social interaction had led many recovery programs operated by NGOs and the government to be community-based and designed to incorporate such traditional practices into the rehabilitation process.

Similar situations happen in Tembi donated core structure house post disaster housing. Approximately more than 90% (both heads of household and spouses) said that they participate in community activities with their own willingness, while only less than none feel obligated to participate and null for no participation. High participation to community activities is supported by their perception on the importance of the value and existence of community activities in their neighborhood. Approximately 80% head of household and 83% of spouses response is "I feel that community activities are very important" and approximately only about 10% for both heads of household and spouses said that "they are neutral, don't really have certain feeling". Unfortunately the incapability of dome house design to facilitate certain social interaction behavior results in the usage of outer space of the house and neighborhood as the 'guest area' or 'incidental social interaction space'.

3.2 Perception of space pattern in self-built and core structure post disaster housing

Space pattern development in self-built housing as well as Tembi core structure house development also showed the existence of private/public spaces even in the simplest house plan by using semi fixed element to differentiate private/public space such as the use of furniture, semi fixed partition, etc..

Perception of spaces is much related with needs of privacy and social interaction. Space pattern development also showed the existence of private/public spaces in simplest condition that can be illustrated as in Figure 2.

Respondents` cognition of privacy level toward type of room is shown in Figure 3. The highest privacy level is bedroom and respectively toilet and kitchen privacy level decreases. However terrace and multifunction room (integrated guest room and family room) and separated guestroom also family room is among the lowest priority of private space.

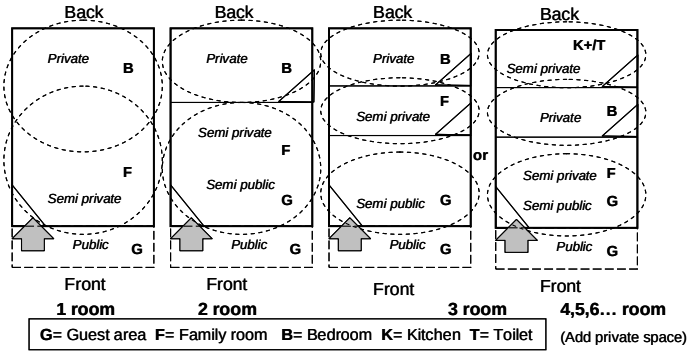

Figure 2 Development of space pattern post disaster housing

In figure 3, we can see that more than 40% respondent considered outdoor spaces; front yard and terrace, and only guest room as indoor spaces as the front part of their houses. On the other hand 45% respondent considered kitchen the highest as back part of the house. Other indoor rooms that considered as back part of the house are: bedroom and toilet, while outdoor spaces are backyard and wells.

Guestroom and family room are area that can be shown to guest by more than 45% and 30% respondents respectively and in agreement to the cognition of private/public spaces in Figure 6., bedroom, kitchen and toilet are areas that prefer to be hidden from the guests. Figures 6 and 7 indicate that front part of the house are considered as less private space and because of that the areas can be seen by their guest and back part of the house, which include especially bedroom, toilet and kitchen, is considered a more private space and thus is hidden from the vicinity of the guest

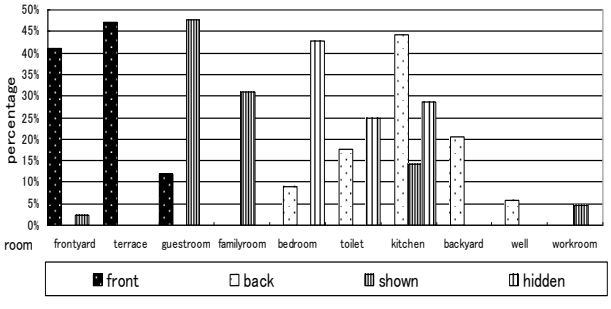

Figure 3 Cognition of front/back spaces and shown/hidden area by self-built post disaster respondents

Importance of private/public space is supported by residents' cognition of front/back area that is frequently associated to hidden/shown area to other people. These findings are relevant with previous research on traditional dwellings where front of house is outwardly-oriented domain where domestic prestige displayed in form of status

differences and formality in meeting others (Revianto, 1997). Residents' spaces cognition of private/public, front/back, shown/hidden are much related with 'self' (personal) and 'other' (interpersonal) space domain that actualize in the arrangement and allocation of the spaces. It showed embodied principal ideas underlying the formation of a domestic setting as place to live and interact with others in their post disaster housing.

3.3 Development from temporary or core structure house to permanent post disaster housing

3.3.1 Size and number of room expansion

Self-built housing expansion from temporary to permanent houses made by the residents within 2 years period after the earthquake indicates the need of guest room increases by 5 times its original size and 3.6 times its original total room number (Figure 4). However, total room number and addition of bedroom modification is still the highest overall adjustments which also indicate a high need of private space although its average room size actually decreases (Figure 4). There are also cases where both temporary and permanent house were used simultaneously by the residents show that guest area is one of the earliest function that move from temporary to permanent house which apparently have a better structures and overall appearance. This indicated the needs of having a 'good` image space for interaction with guests (findings supported by Revianto, 1997) In Tembi core structure housing, since were taken only once, the expansion analyses were made based on the condition of given core structure house at the beginning of donation that still being used. The spaces mostly contain multifunction room (which include accepting guest area and family room) and bedroom. The result indicates that multifunction room had changes to separate guestroom and family although some multifunction room still remained but overall of social space had increased (Figure 5). Terrace addition as social space is a new function in permanent house that large in overall size.

The expansion and separation tendency of guest area have relevant founding with public housing complex in Yogyakarta where most `core house` alteration cases started with the expansion of guest room to the front area and had doubled its original size (Yoyok, 1993).

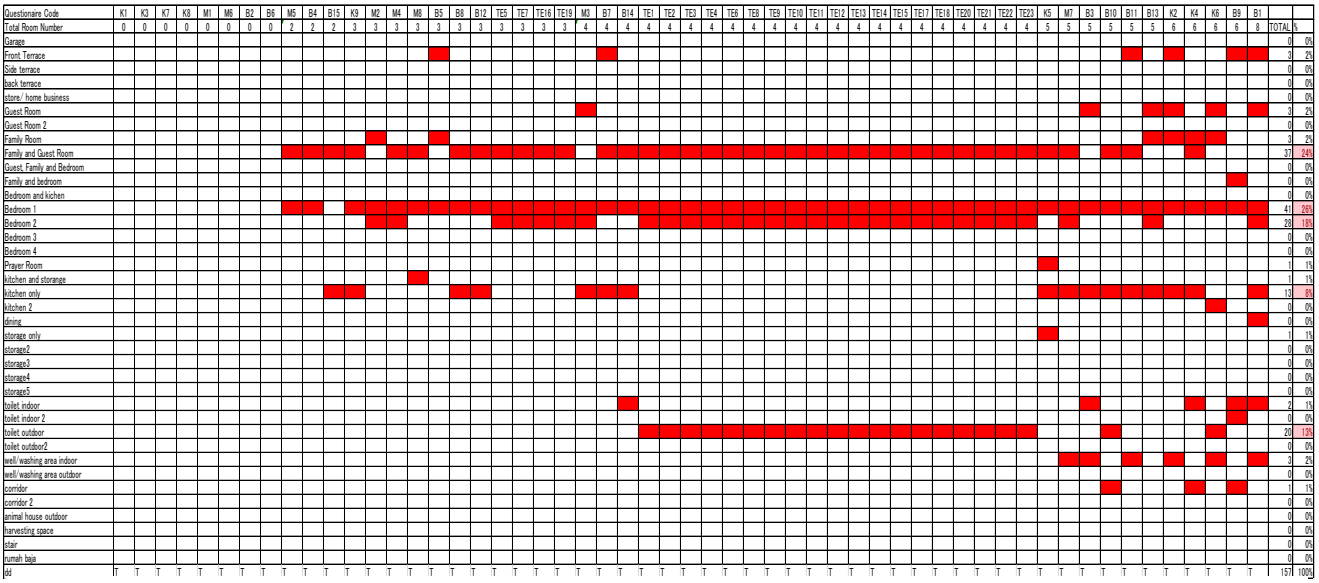
MF:multi function room	TI:toilet indoor	

Figure 5 Diagrammatic charts of size expansion in donated Tembi

3.3.2 Room modification and space arrangement

Room modification from temporary house to permanent house in self-built housing as well as core structure house to permanent Tembi housing shows that bedroom is the highest modification that shows the need of more private space is high. The second highest room modification is the changes of location of outside guest room to inside the house, new addition to with family room in multi-function house that show the importance to have a separate guest room inside the house. The kitchen and toilet are also important spaces to have in the house. Details of space arrangement in temporary and permanent condition can be see in table 3 and 4.

Table 3 Space arrangement in self-built temporary and Tembi core structure post disaster houses



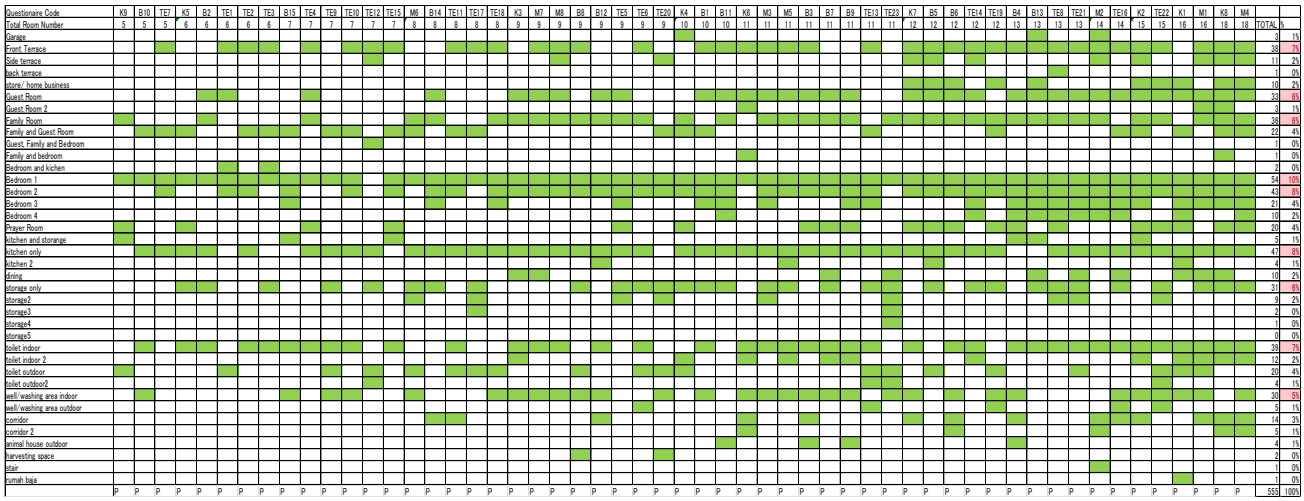


Table 4 Space arrangement in self-built t and Tembi permanent post disaster houses

4. Summary and Conclusion

In self-built as well as Tembi donated core structure post disaster dwellings, physical changes and development from temporary to permanent such as size and room number expansion, space modification, function changes, apparently show that guest area is inevitably an important social interaction space to be provided in the house. On the other hand, total room number and addition of bedroom is still the highest overall adjustments which also indicate a high need of private space. These show that both needs of social interaction space and private space are simultaneous exist. The duality spheres in the house also actualize in their cognition of spaces.

Respondents' cognitions of private/public, front/back, hidden/shown spaces are much related with the arrangement and allocation of 'self'(personal) and other'(interpersonal) space and how it is interrelated in spatial arrangement of fixed and semi-fixed elements of the house. These findings are relevant to Java traditional housing that contains both interrelated `self` and `others` domains (Revianto, 1997).

This research has once again highlighted the importance of social behavior (space) in Java dwelling even at in constraint situation. Meaning, values and ideals of social behavior are reflected on their cognition of spaces in the dwellings as well as their physical-behavior adjustments. As a dwelling, the house is not merely a shelter, but it's an actualization of meanings (Rapoport, 1969). For Java people, a house is living environment that represent the philosophical concept of the society itself. It is necessary that even in constraint dwelling such as temporary post disaster housing need to consider social behavior importance as culturally sensitive design for reconstruction recovery. Flexibility and open ended design in physical built environment would give an advantage in their critical transition to the new environment

Abstract: Tsunami fragility function is developed to assess damage to buildings because of tsunami. The fragility functions are expressed with respect to the inundation depth to predict the damage ratio of buildings. Asahi City, Chiba Prefecture, suffered from serious damage after the 2011 off the Pacific coast of Tohoku Earthquake and Tsunami. In this study, the fragility function is constructed using the results of numerical simulation of tsunami propagation and the building damage dataset compiled by Asahi City after the earthquake. Employing the fragility function, the numbers of damaged buildings in Chiba Prefecture are estimated assuming the occurrences of historical earthquakes.

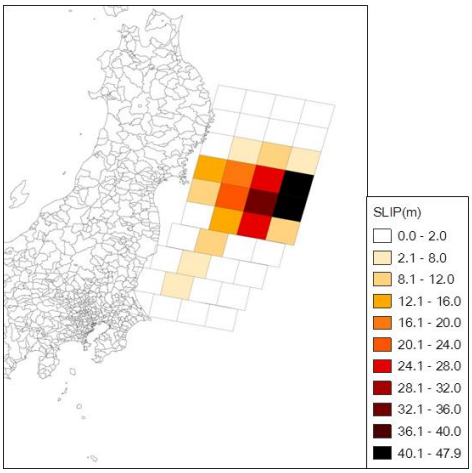
1. INTRODUCTION

The 2011 off the Pacific coast of Tohoku Earthquake, which occurred on March 11, 2011, triggered an extremely large tsunami. The run-up reached a maximum height of 40.4 m in Tohoku district (The 2011 Tohoku Earthquake Tsunami Joint Survey Group, 2011). The Japanese National Police Agency (2011) confirmed more than 15,000 deaths and 2,900 people missing. According to the Cabinet Office, Government of Japan (2011), 92.4% of the fatalities in Iwate, Miyagi, and Fukushima prefectures resulted from drowning.

The tsunami also hit Chiba Prefecture. With 13 fatalities in Asahi City and two people reported still missing, the eastern part of the prefecture was severely affected. In Asahi City, 336 family units collapsed as a result of this event (Asahi City, Chiba Prefecture, 2011). These buildings were mainly affected by the tsunami, and liquefaction, although they were away from the most severely affected areas.

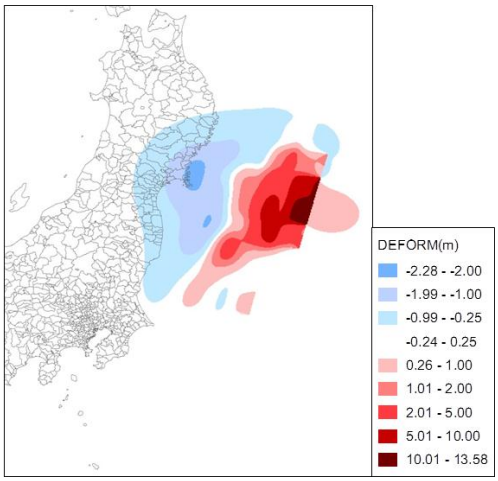
In this study, the damage ratio of buildings in Asahi City is evaluated with respect to the inundation depth obtained by numerical simulation. The damage dataset compiled by Asahi City is employed for the evaluation. Based on the relationship between the damage ratio and inundation depth, the fragility function is constructed. Finally, the number of damaged buildings in Chiba Prefecture is predicted assuming the occurrences of historical earthquakes.

2. NUMERICAL SIMULATION OF TSUNAMI PROPAGATION



Numerical simulation of tsunami propagation after the 2011 off the Pacific coast of Tohoku Earthquake was performed to estimate the inundation depths in Asahi City, Chiba Prefecture. The seismic fault model developed by Fujii and Satake (2011) was employed to estimate the vertical displacement of the seabed. Figure 1 shows the fault model developed by Fujii and Satake (2011) (Fig. 1(a)) and the vertical displacement (Fig. 1(b)) estimated by Okada's method (Okada, 1985). Assuming the water layer to be incompressible, the estimated vertical displacement of the seabed was regarded as the initial profile of the tsunami.

We used the TUNAMI-CODE (Imamura, 1995) for modeling tsunami propagation and the resulting coastal inundation. The model employs a set of nonlinear shallow water equations where bottom friction terms are discretized by the leap-frog finite difference scheme. This model is widely used to simulate tsunami propagation and inundation on dry land (Koshimura *et al*., 2006). Based on the shallow water theory, the continuity equation can be expressed as



$$\frac{\partial \eta}{\partial t} + \frac{\partial M}{\partial x} + \frac{\partial N}{\partial y} = 0 \tag{1}$$

where M and N are the discharge fluxes in the x and y directions, respectively; η is the vertical displacement of the water surface above the still water level. The equations of motion are written as

$$\frac{\partial M}{\partial t} + \frac{\partial}{\partial x}\left(\frac{M^2}{D}\right) + \frac{\partial}{\partial y}\left(\frac{MN}{D}\right) = -gD\frac{\partial \eta}{\partial x} - \frac{gn^2}{D^{7/3}} M\sqrt{M^2+N^2} \tag{2}$$

(a)

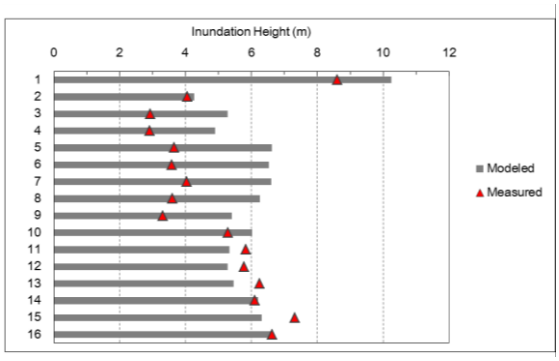
(b)

Figure 1 (a) Fault model developed by Fujii and Satake (2011) and (b) vertical displacement of seabed as estimated by Okada's method (1985)

$$\frac{\partial N}{\partial t}+\frac{\partial}{\partial x}\left(\frac{MN}{D}\right)+\frac{\partial}{\partial y}\left(\frac{N^2}{D}\right)=-gD\frac{\partial \eta}{\partial y}-\frac{gn^2}{D^{7/3}}N\sqrt{M^2+N^2} \quad (3)$$

where D is the summation of η and the still water depth h, and n is Manning's roughness coefficient.

In the numerical simulation, the target region was divided into five sub-regions having grid lengths of 1350, 450, 150, 50 and 16.7 m. The sub-region characterized by coarse grids was set in the deep sea and the one with fine grids was set closer to the shore (Shuto, 1991). h for each grid cell was assigned using the bathymetry data collected by the Japan Coast Guard. The elevations of the land, determined by the Geospatial Information Authority of Japan (GSI) were also considered for estimating the inundated areas.



Manning's roughness coefficients were assigned with respect to the land use classifications, as listed in Table 1

Table 1 Definition of Manning's roughness coefficient in this study

Land use	Manning's roughness coefficient ($m^{-1/3}s$)
Residential district	0.040
Agricultural land	0.020
Forest land	0.030
Body of water	0.025
Others	0.025

Figure 2 (a) Locations of measurement points of tsunami inundation heights by the 2011 Tohoku Earthquake Tsunami Joint Survey Group and (b) comparison between the measured tsunami inundation heights and those estimated by numerical simulation in Asahi City, Chiba Prefecture

(Kotani *et al.*, 1998). We considered that tsunami propagation occurred for three hours after the earthquake. The time step in the numerical simulation was selected to be 0.15 s.

The result of numerical simulation was compared with the findings of tsunami surveys conducted by the 2011 Tohoku Earthquake Tsunami Joint Survey Group (2011). Figure 2 shows a comparison of tsunami inundation heights estimated by the numerical simulation with those measured in the eastern part of Asahi City. The locations of

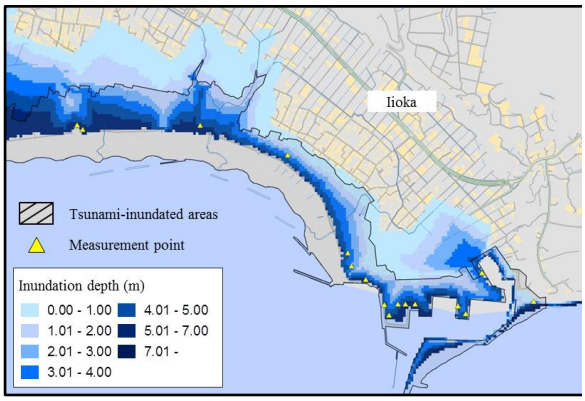

Figure 3 Comparison between inundation depths estimated by numerical simulation and the tsunami-inundated areas identified in the previous study (Kitamura *et al.*, 2012)

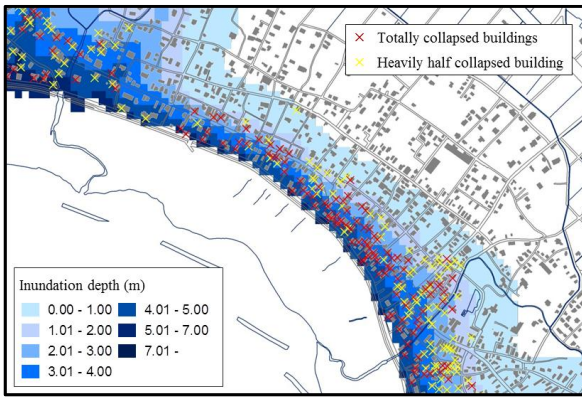

Figure 4 Distribution of damaged buildings according to estimated tsunami-inundation depths

measurement points of tsunami inundation heights along the coastline compiled by the group are also illustrated in Fig. 2. The inundation height collected by the survey group is defined as the elevation of water level with reference to the sea level (Tokyo Peil: T.P.). According to the comparison, the estimated inundation heights show good agreements with the observations especially in the residential areas, which are labeled as 10-16.

Figure 3 shows a comparison of the tsunami-inundation depths obtained by the numerical simulation with the tsunami-inundated areas identified in our previous study (Kitamura *et al.*, 2012). We focus on the eastern part of Asahi City, where the inundated areas were verified through different sources. The simulated distribution of the tsunami-inundated areas and the distribution identified by our previous study show similar trends especially in Iioka district, where serious damage to buildings was observed after the tsunami.

3. CONSTRUCTION OF FRAGILITY CURVE FOR BUILDINGS

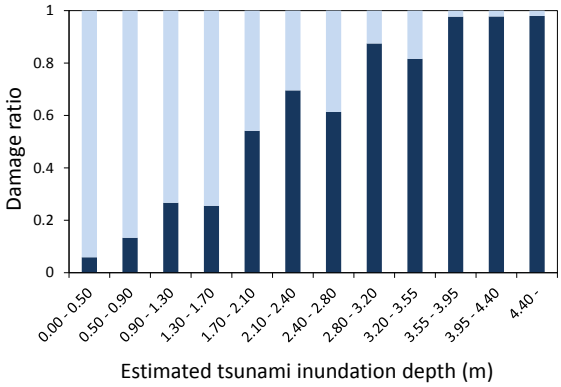

Figure 5 Relationship between the damage ratios of buildings and estimated tsunami inundation depths in Iioka district, Asahi City, Chiba Prefecture

This study tries to evaluate the relationship between the damage ratio of buildings and the inundation depth in Asahi City, Chiba Prefecture. To achieve the objective, the damage dataset of buildings compiled by Asahi City, Chiba Prefecture was employed. In the dataset, the location and damage level of building can be identified. Four damage levels are defined in the dataset, which are totally collapsed, heavily half collapsed, half collapsed and partially collapsed. In this study, the ratios of the number of totally and heavily half collapsed buildings to that of residential buildings with respect to the inundation depths were obtained. We obtained the damage ratios only in Iioka district, where many damaged buildings were found and the result of numerical simulation could be validated in the previous chapter.

Figure 4 shows the distribution of damaged buildings according to estimated tsunami-inundation depths in Iioka district. Building inventory compiled by Zenrin, a Japanese map publisher, in 2009 was used to detect residential buildings. Figure 5 shows the relationship between the damage ratios of buildings and estimated tsunami inundation depths. The damage ratio increases in accordance with the increment of inundation depth. The damage ratio is larger than 50% when the inundation depth is in the range of 1.7-2.1 m.

The damage ratio, P, is assumed to be as follows:

$$P = \Phi((\ln d - \lambda)/\zeta) \tag{4}$$

where $\Phi(x)$ is the cumulative distribution function of the standard normal distribution, and d is the inundation depth. λ and ζ are the mean and the standard deviation of ln d, which are determined by the least-squares method on the lognormal probability paper. Figure 6 shows the fragility curve based on the building damage dataset in Iioka district, Asahi City, Chiba Prefecture after the 2011 Tohoku earthquake.

The fragility curves developed after the previous events are also shown in Fig. 6. Koshimura and Kayaba (2010) and

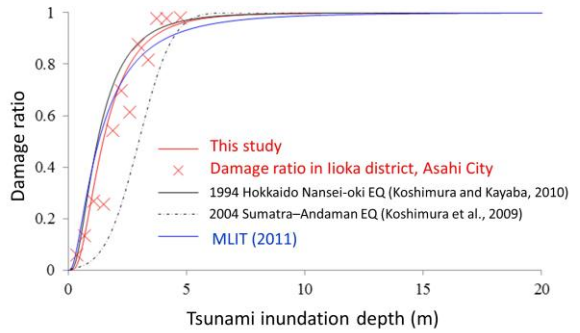

Figure 6 Fragility curve constructed by this study and those developed after the previous earthquakes (Koshimura and Kayaba, 2010; Koshimura *et al.*, 2009)

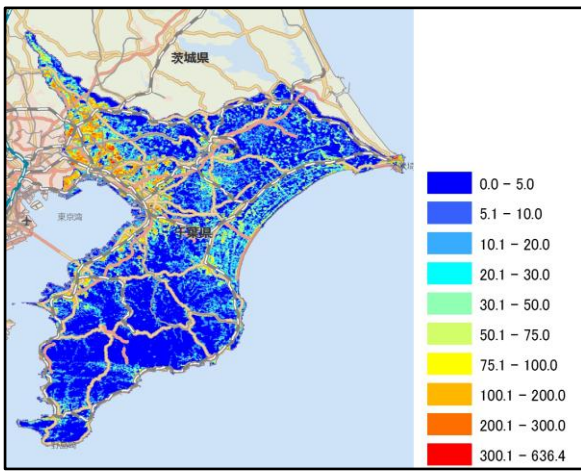

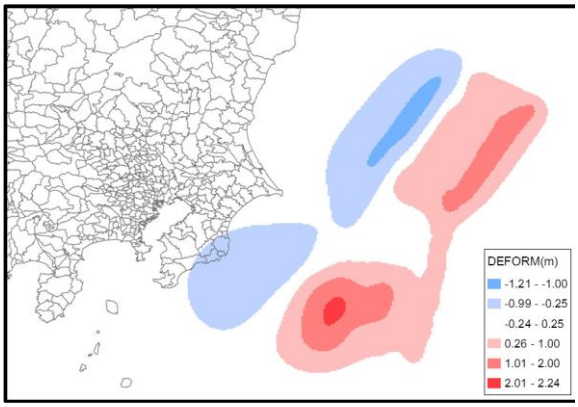

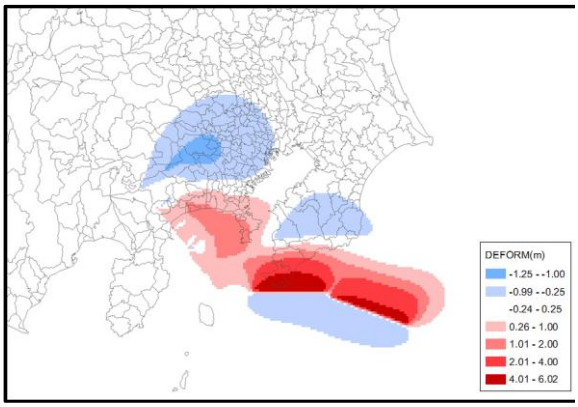

Figure 7 Number of buildings in Chiba Prefecture compiled in 2008

Koshimura *et al.* (2009) constructed fragility functions after the 1994 Hokkaido Nansei-oki and 2004 Sumatra–Andaman earthquakes. In the study, pre- and post-event satellite and aerial images were employed to perform visual damage inspection. The buildings were interpreted as "survived" or "destroyed" by detecting if the roofs were remained or not, and the fraction of "destroyed" buildings was used as the damage ratio. Ministry of Land, Infrastructure, Transport and Tourism (MLIT) published the results of survey after the 2011 Tohoku earthquake. The damage ratios of buildings in the entire regions affected by the tsunami are compiled with respect to the inundation depth in their report (MLIT, 2011). Using the dataset, a fragility curve was also constructed (Fig. 6). The fragility curve constructed by this study show the similar damage ratios with the curve after the 1994 Hokkaido Nansei-oki earthquake. In addition, the fragility curve based on the damage ratios of buildings in the entire tsunami affected regions show a similar trend with the curve constructed by this study.

Based on these findings, the fragility curve constructed by this study will estimate the damage ratios with a reasonable accuracy. Although the fragility curve was constructed based on the damage dataset of a municipality, it shows similar estimations with the curve for the entire affected regions. Hence, it can be applicable for prefectural damage assessment after tsunami.

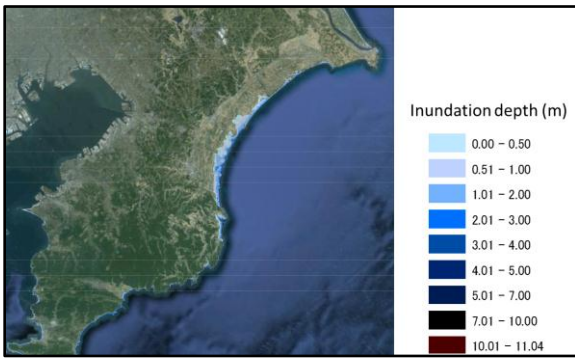
(b)

Figure 8 Vertical displacement of seabed assuming (a) the 1677 Enpo Boso-oki and (b) the 1703 Genroku Kanto earthquakes



4. DAMAGE ASSESSMENT OF BUILDINGS AFTER TSUNAMI IN CHIBA PREFECTURE

The damage to buildings in Chiba Prefecture due to tsunami is estimated using the fragility curve constructed by this study. Figure 7 shows the distribution of the number of buildings used in this study. This dataset was compiled by Chiba Prefecture in 2008 and the number of buildings is represented in every 250 × 250 m^2 grid cell.

We assume two historical earthquakes to evaluate the number of damaged buildings in Chiba Prefecture. In 1677, the Enpo Boso-oki earthquake occurred and tsunami hit the Pacific coast of Japan. The tsunami height in the eastern part of Chiba Prefecture was estimated to be 6-8 m (Hatori, 2003). The other historical earthquake is the 1703 Genroku Kanto earthquake. This event occurred in the south Kanto region and the tsunami height in the eastern part of Chiba

(a)

(b)

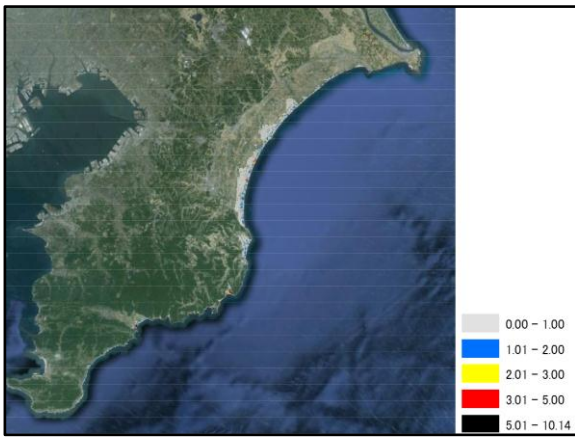


Figure 9 Distributions of estimated tsunami inundation depth in Chiba Prefecture after (a) the 1677 Enpo Boso-oki and (b) the 1703 Genroku Kanto earthquakes

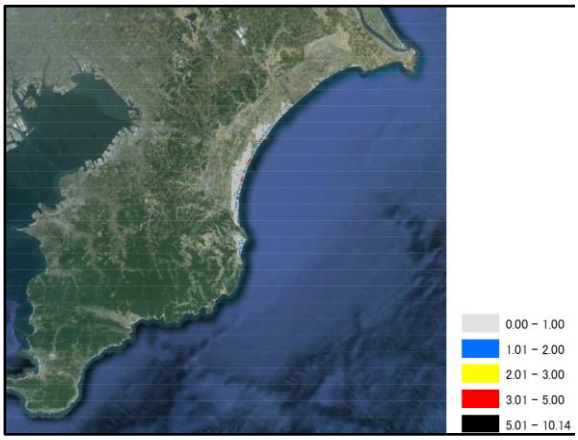
Prefecture was estimated to be 6-11 m (Namegaya *et al.*, 2011).



In order to perform numerical simulation of tsunami propagation, the fault model developed by Chiba Prefecture (2006) for the 1677 Enpo Boso-oki earthquake and that by Namegaya *et al.* (2011) for the 1703 Genroku Kanto earthquake were employed. The distributions of vertical displacement of seabed, which will be used as initial profile of tsunami, estimated by Okada's method (Okada, 1985) for the two historical earthquakes are shown in Fig. 8.

Figure 9 shows the estimated inundation depth following the two historical earthquakes. The eastern part of Chiba Prefecture is affected by tsunami with the inundation depth of 5-8 m in average in both cases. The inundation depth may reach approximately 10 m in some areas. Employing the fragility curve shown in Fig. 6 and the inventory dataset for buildings shown in Fig. 7, damage assessment for buildings is performed. Figure 10 shows the distributions of damaged buildings due to the two earthquakes. In total, more than 20,000 buildings may be affected in both cases.

5. CONCLUSIONS

(a)

(b)

Figure 10 Distributions of damaged buildings assuming (a) the 1677 Enpo Boso-oki and (b) the 1703 Genroku Kanto earthquakes

This study evaluated the relationship between the damage ratio of buildings in Asahi City, Chiba Prefecture, and the tsunami-inundation depth estimated by numerical simulation. The tsunami inundation in Asahi City was numerically obtained based on the leap-frog finite difference scheme. The results were validated by comparing with the records of field survey.

Employing the damage dataset compiled by Asahi City, the damage ratios with respect to the inundation depths were determined. Then, the fragility curve of buildings against tsunami inundation-depth was constructed assuming the log-normal distribution. Lastly, the numbers of damaged buildings assuming the two historical earthquake events were estimated using the fragility curve developed by this study. More than 20,000 buildings will be affected following the relationship between the damage ratio and the inundation depth after the 2011 Tohoku earthquake.

The structural types of buildings could not be considered in determining the damage ratios in this study. These effects should be investigated in a future study to perform a more detailed damage assessment of buildings.

Abstract: A large amount of buildings was damaged or destroyed by the 2011 Great East Japan tsunami. Numerous field surveys were conducted in order to collect the tsunami inundation extents and building damage data in the affected areas. Therefore, this event provides us with one of the most complete dataset amongst tsunami events in history. In this study, fragility functions are derived using data provided by the Ministry of Land, Infrastructure and Transportation of Japan (MLIT), with more than 250,000 structures surveyed. The set of data has details on damage level, structural material, number of stories per building and location (town). This information is crucial to the understanding of the causes of building damage, as differences in structural characteristics and building location can be taken into account in the damage probability analysis. Using least squares regression, different sets of fragility curves are derived to demonstrate the influence of structural material, number of stories and coastal topography on building damage levels. The results show a better resistant performance of reinforced concrete and steel buildings over wood or masonry buildings. Also, buildings taller than two stories were confirmed to be much stronger than the buildings of one or two stories. The damage characteristic due to the coastal topography based on limited number of data in town locations is also shortly discussed here. At the same tsunami inundation depth, buildings along the Sanriku ria coast were much greater damaged than buildings from the plain coast in Sendai. The difference in damage states can be explained by the faster flow velocities in the ria coast at the same inundation depth. These findings are keys to support better future building damage assessments, land use management and disaster planning.

1. INTRODUCTION

The East coast of Japan was extensively affected by the 2011 Great east Japan tsunami, with more than 400,000 buildings damaged or destroyed (National Police Agency, 2011). The extensive damage directly impacted infrastructure system and the economy due to the loss of houses, offices, markets and industries. In order to reduce such dramatic consequences on the population, it is crucial to improve our understanding of building damage characteristics due to a tsunami.

This study uses the complete data set of more than 250,000 damaged buildings with surveyed tsunami inundation depths. The damage inspection compiled damage level, structural material, number of stories, inundation depth and location of structures (no coordinates, only the name of the town). Using least squares regression, different sets of fragility curves (Koshimura et al., 2009) are derived to demonstrate the influence of structural material, number of stories and coastal topography on building damage levels.

2. DATA AND METHODS

2.1 Data

The MLIT conducted field surveys of damaged buildings and tsunami inundation depth (Tohoku Earthquake Tsunami Joint Survey Group, 2011) in the whole tsunami affected areas covering seven provinces (Hokkaido, Aomori, Iwate, Miyagi, Fukushima, Ibaraki and Chiba). The main affected areas by the 2011 Great East Japan tsunami are shown in Fig. 1. The data of damage inspection is available through the MLIT website (MLIT, 2012) with 251,301 buildings in their database. Each damaged building was measured and classified according to its damage level (six levels were defined by MLIT), structural material

(Reinforced concrete (RC), steel, wood or other light weight structure such as soil or block) and number of stories (one, two or three stories and higher).

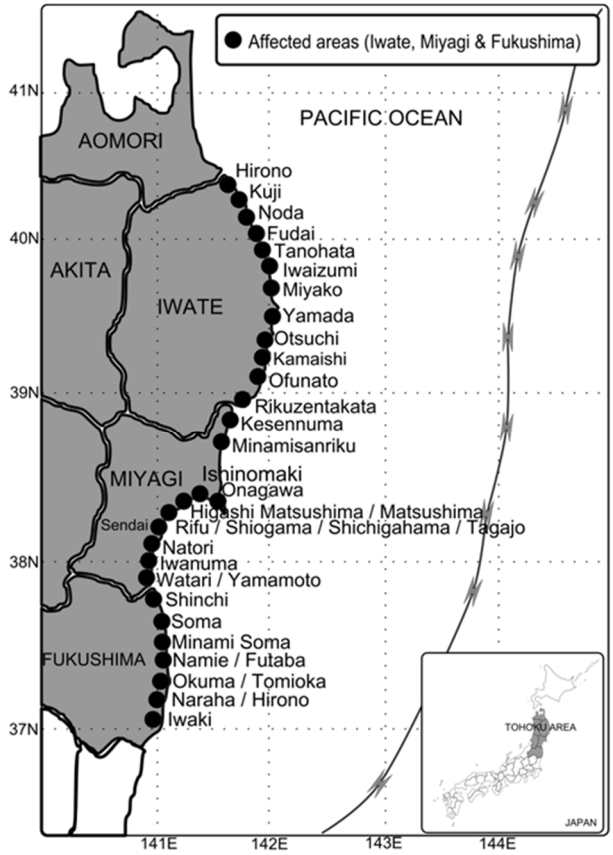

Figure 1 Main affected areas by the 2011 Great East Japan tsunami

Table 1 Damage levels, classification description and condition of building

Class	Description	Condition
Minor damage	No significant structural or non-structural damage, possibly only minor flooding.	Possible to be use immediately after minor floor and wall clean up.
Moderate damage	Slight damages to non-structural components.	Possible to be use after moderate reparation
Major damage	Heavy damages to some walls but no damages in columns	Possible to be use after major reparations
Complete damage	Heavy damages to several walls and some columns	Possible to be use after a complete reparation and retrofitting
Collapsed	Destructive damage to walls (>50%) and several columns (bend or destroyed).	Loss of functionality (system collapse). Non-repairable or great cost for retrofitting.
Washed away	Washed away, only foundation remained, total overturned	Non-repairable, requires total reconstruction.

Similar to Shuto (1993), the damage levels are: (1) Minor damage, (2) Moderate damage, (3) Major damage, (4) Complete damage, (5) Collapse and (6) Washed away. Descriptions of each damage level are summarized in Table 1. The measure of tsunami inundation depths on an interval of 0.5 m are shown together with each damage level. Tsunami fragility curves will be developed for each affected area and compared to demonstrate a boundary of probable maximum and minimum damage probability for each damage level, structural material and number of stories at a specific inundation depth.

2.2 Method

Similar to Suppasri et al. (2012b), the probabilities for each damage level were calculated and shown against a median value within a range of every 0.5 m inundation depth. Linear regression analysis was performed to develop the fragility function. The cumulative probability P of occurrence of damage is given either by Eq. (1) or by (2):

$$P(x) = \Phi[(x-\mu)/\sigma] \quad (1)$$

$$P(x) = \Phi[(\ln x-\mu')/\sigma'] \quad (2)$$

where, Φ represents the standardized normal distribution function, x stands for the hydrodynamic feature of tsunami used as demand parameter (e.g., inundation depth, current velocity or hydrodynamic force), and μ and σ (μ' and σ') represents the mean and standard deviation of x (ln x) respectively. Two statistical parameters of fragility function, μ and σ (μ' and σ'), are obtained by plotting x (ln x) against the inverse of Φ on normal or lognormal probability papers, and performing least-square fitting of this plot. Consequently, two parameters are obtained by taking the intercept (= μ or μ') and the angular coefficient (= σ or σ') in Eq. (3) or (4):

$$x = \sigma\Phi^{-1} + \mu \quad (3)$$

$$\ln x = \sigma'\Phi^{-1} + \mu' \quad (4)$$

Throughout the regression analysis, the parameters are determined to obtain the best fit (in the least squares sense) of fragility curves with respect to the inundation depth.

3. RESULTS

3.1 Damage level

Building damage data for the whole of Japan from 2011 Great East Japan tsunami event was summarized by MLIT was used to plot six different damage levels without separation of structural material, number of stories or coastal topography as shown in Fig. 2. It is reasonable that the expected damage probability will be higher for lower damage level classes at the same inundation depth reference point. For example, the damage probability for level 2 (moderate damage or greater) should be higher than the damage probability for level 5 (collapse or greater). The results show for mixed structural material that the damage

probability at an inundation depth equal to 2 m for damage levels 1 to 6 is roughly 0.2, 0.4, 0.6, 0.8, 0.95 and 1.0 respectively. The 2 m inundation depth is a key threshold value because the damage probability for each damage level is nearly the same. According to Fig. 2, the probability of damage occurrence reaches their maximum value for all type of damage levels when the inundation depth exceeds 10 m.

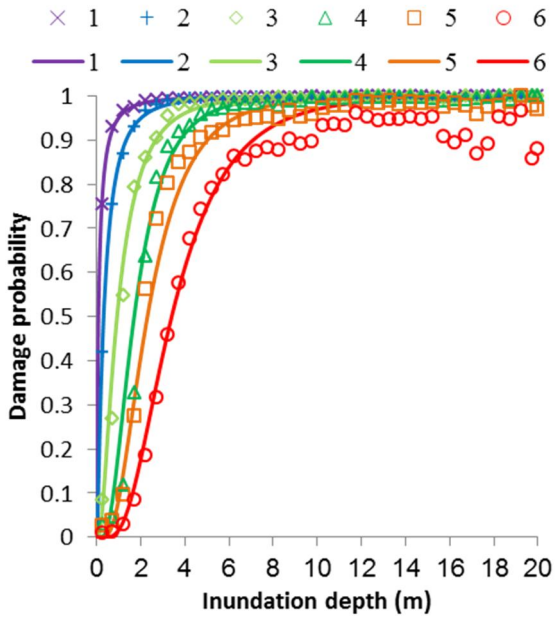

Figure 2 Tsunami fragility curves for the whole area with mixed structural material in different damage levels

3.2 Structuralmaterial

Using the data of the whole affected areas in Japan, we separated it into different structural materials. The results based on the structural materials are shown in Figs. 3.For most of the structural material data - except for wood -, when inundation depths were greater than 10-15 m the sample size of surveyed number of building to calculate the damage probability was comparatively less. Since data prepared by MLIT was summarized at fix intervals of inundation depth – every 0.5 m depth, there is less number of surveyed buildings within intervals over 10 m depth, compared to lower inundation depths. Therefore, in some cases we discounted the data on higher depth intervals to avoid underestimating the damage probability.

It can be seen from the results in Fig. 3 that RC is the strongest structure followed by steel, masonry and wood. For example, a probability that 2 m inundation depth would damage buildings as level 5 (collapsed and wash away) for RC, steel, masonry and wood is about 0.1, 0.2, 0.25 and 0.45 respectively. All wood buildings and most lightweight buildings were washed away when inundation depth was greater than 10 m while only 50% or less for steel and RC. It is noticed that the damage probability for level 1-4 is not very different for the different structural material: for steel, wood and masonry buildings, the damage probability for level 4 varies around 0.4-0.5. These results indicate that RC and steel are structural materials that play very important role in preventing a building to be collapsed or washed away.

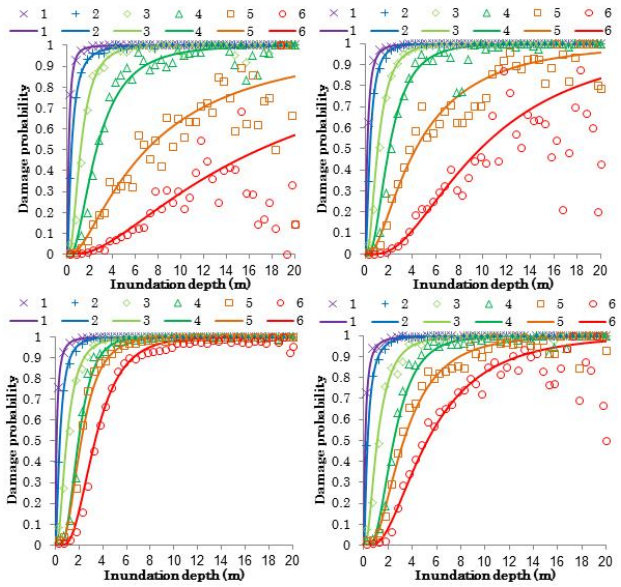

Figure 3 Tsunami fragility curves for the whole area with separated structural material RC (upper-left), Steel (upper-right), Wood (lower-left) and Masonry (lower-right)

3.3 Number of stories

The MLIT dataset for the whole Japan was then separated again for different number of stories categorized as one story, two stories and three stories or higher. This dataset was only provided for two structural types (RC and wood). Results are shown in Figs. 4 and strongly support the findings of previous studies that a building with high number of stories is stronger than the ones of one or two stories. This can be explained by the fact that the supporting members of buildings with a large number of stories are designed to withstand greater gravity loads, therefore, are more resistant. Building damage characteristics based on the number of stories are discussed for every inundation depth of 3 m which we assumed equal to the floor height. Damage level 5 (collapse or wash away) is given as an example to compare the differences in damage probability.

For RC building, an inundation depth of 3 m caused damage by 0.30, 0.20 and 0.15 for one, two and three stories or more respectively. An inundation depth of 6 m increased the damage probability to 0.6, 0.5 and 0.25 respectively. Inundation depths of 9-15 m, which would totally overtop one and two-story buildings, caused 0.7-0.9 damage probability while only 0.45-0.70 for three stories or more.

However, for buildings of wood construction, a 3 m inundation depth caused 0.75, 0.60 and 0.40 damage probability to one, two and three stories or more respectively. Unlike RC building, a 6 m inundation depth caused nearly 1.0 damage probability to one and two story buildings that were overtopped and as high as 0.8 for buildings higher than three stories. Finally, a 9 m inundation depth is enough to destroy or wash away wood building no matter of the number of stories.

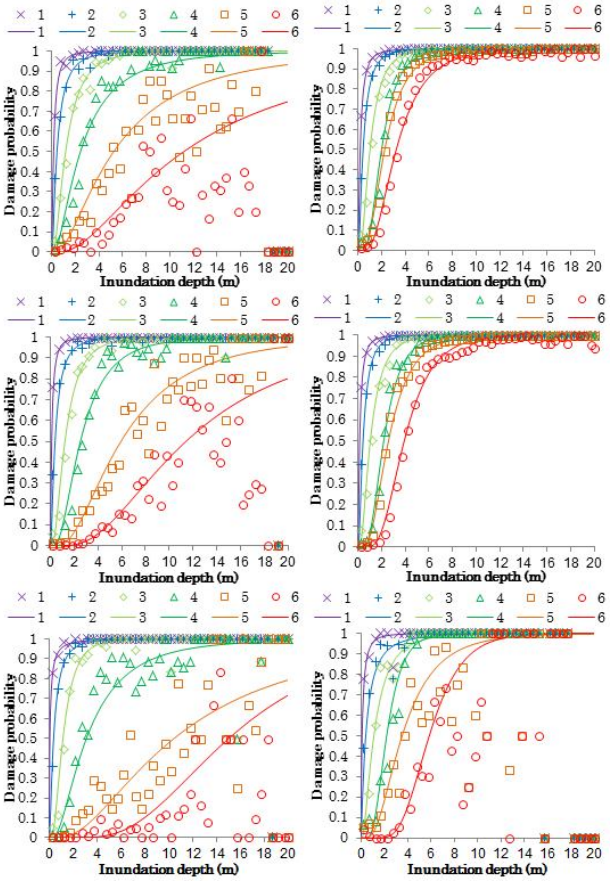

Figure 4 Tsunami fragility curves for the whole area with separated structural material and number of stories RC-1 story (upper-left), Wood-1story (upper-right), RC-2 stories (center-left), Wood-2 stories (center-right), RC-3 stories or more (lower-left) and Wood-3stories or more (lower-right)

The differences in damage probability between one story and two story buildings were not very large. However, especially for wood buildings, the damage probability is significantly reduced for the case of three stories or more. For example, a 3 m inundation depth caused 0.45 and 0.30 probability for level 6 (wash away) but almost zero for wood buildings over three stories. An inundation depth of 6 m could definitely wash away wood buildings of one or two stories, but only about 0.5 probability for wood buildings over three stories. In addition, damage probability for damage levels 5 and 6 also greatly decrease in case of RC building having at least three stories. Therefore, for a given structural material, buildings having three stories or more might withstand better the impacts of tsunami for the same tsunami height. In other words, the damage is not only controlled by the tsunami height, but is also dependent on the number of stories and structural class of the building hit.

3.4 Coastal topography

In order to compare the effects of the two different coastal topographies, we need a dataset from a location having both plain and ria coast. Ishinomaki city was the only heavily damaged area that geographically combined both mentioned topographies (Fig. 5). Building damage and tsunami inundation depth data (mixed structural material) provided by Ishinomaki city (Suppasri et al., 2012a) which is separated into two categories (plain coast and ria coast) were used to create the fragility curves. The building damage was classified into five levels similar to the data provided by MLIT, washed away, collapsed, major damage, moderate damage and minor damage for every 0.5 m interval of the measured maximum tsunami inundation depth. Therefore, building damage probability for each damage level can be plotted against the inundation depth.

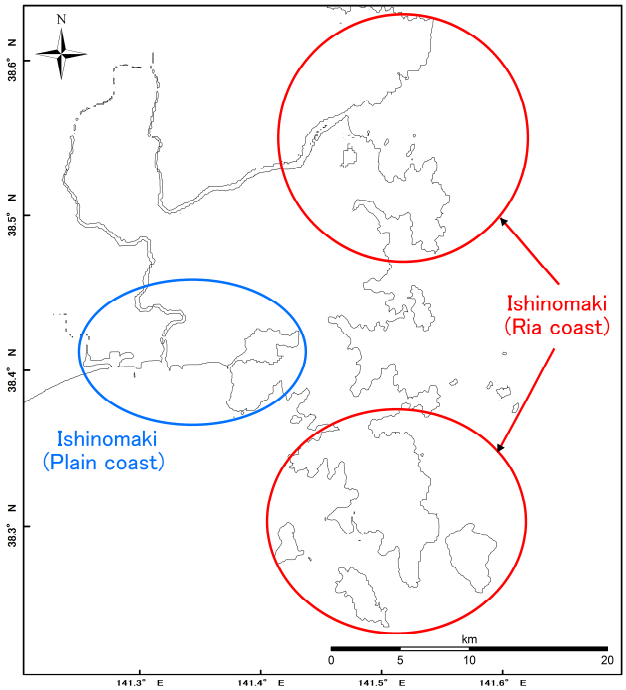

Figure 5 Area map of Ishinomaki city showing the ria coast and plain coast

Tsunami fragility curves for plain and ria coasts in Ishinomaki city are shown in Figs. 6. It can be seen that, for example, damage probability for washed away at 2 m inundation depth is less than 0.05 in plain coast while about 0.4 in ria coast. The damage probability in plain coast increases to 0.5 at 5 m inundation depth while the damage probability is 0.8 for ria coast. It can be noticed that the damage probability for the plain coast abruptly increases from inundation depth 3 m to 6 m and becomes greater than the ria coast when the inundation depth reaches nearly 7 m. Finally it reaches almost 1.0 when the inundation depth is equal to 8 m. On the other hand, the damage probability for the ria coast abruptly increases from 0.5 m to 3 m inundation depths and slightly increases until the damage probability is nearly 1.0 when the inundation depth is about 10 m. These results show that the coastal topography differences between the plain coast and the ria coast noticeably affect the damage probabilities due to tsunami. The damage probabilities for buildings in the ria coast generally increases more and is higher than those in the plain coast.

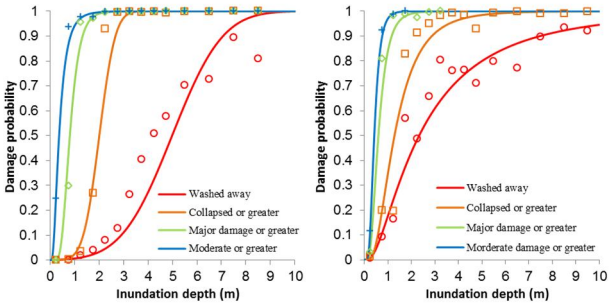

Figure 6 Tsunami fragility curves using data from Ishinomaki city only (mixed structural material) for a comparison between Plain coast (left) and Ria coast (right)

4. CONCLUSIONS AND FUTURE WORKS

4.1 Conclusions

By using one of the largest and most complete tsunami-induced damage dataset provided by MLIT for the 2011 Great East Japan tsunami, this study clarified the importance of structural characteristics on building damage probabilities, and provided a very valuable insight into the influence of coastal configuration on building damage. The first part of the analysis was based on, damage level, structural material, number of stories; and the next part of the analysis included effects from the coastal topography. The statistical parameters that were derived and used to construct the tsunami fragility curve in this study are summarized in Table 2. The main findings of this study and their applicability are summarized as below.

(1) The results show a better resistant performance of reinforced concrete and steel buildings over wood or masonry buildings.

(2) Buildings taller than two stories were confirmed to be much stronger than the buildings of one or two stories under the same inundation depth.

(3) It is also found that coastal topography can have a significant influence on building damage. At the same tsunami inundation depth, buildings along the Sanriku ria coast suffered greater damaged than buildings from the plain coast in Sendai due to higher flow velocity present in the ria coast.

These are important considerations in designing a tsunami evacuation building and assessing future tsunami risk for land use and evacuation planning.

4.2 Limitations and future works

The large number of buildings in the MLIT dataset is crucial for the reliability of the least squares regression analysis (i.e. many studies rely on a small number of data points), however highly aggregated databases such as this one may not capture certain trends in the data. Building-by-building comparison, if such data was available, would be desirable to compare or refine the results in some areas.

Future work in this research field should include the investigation of other physical parameters of the process that might have effect on the building damage such as flow velocity, distance from the sea, building orientation with respect to the sea occupancy type and reduction effect by surrounding buildings (sheltering). Work is currently being carried out in this area, in to take into account such effects as sheltering during a tsunami attack. In addition, the damage probability associated with the building function (i.e. individual house, apartment, business office, factory or public building) is also an important factor for further economic loss assessment. Indeed, buildings with a similar functionality mostly share similar structural characteristics, such as structural material and number of stories. For example in Japan, an individual house is typically 1-2 stories and made of wood or masonry; an apartment can be from higher than two stories made of wood or RC; business offices are mostly tall RC buildings; factories are mostly steel framed with 1-2 stories and public buildings such as schools and hospitals are mostly RC buildings with 3-5 stories. For public buildings, design consideration for tsunami force was applied as most of them are designated as an evacuation building.

Abstract: The Great East Japan Earthquake occurred on March 11, 2011. Building structures were severely damaged by the tsunami that followed this earthquake. A quantitative evaluation of the tsunami load is essential for designing and constructing buildings that are resistant to tsunami loads. However, a tsunami presents a non-constant load. The accumulation of observed damage data is necessary for analyzing the tsunami load. In this study, it is one case of analyzing the tsunami load . The design guidelines developed by a task committee under the Japanese Cabinet Office proposed design loads for practical shelter design in 2005. The guidelines were primarily developed based on laboratory tests of a two-dimensional scale model (Asakura et al. 2000). However, because studies on tsunami loads against structures based on damage observations are insufficient, the damaged caused by the tsunami following the Great East Japan Earthquake was devastating. In this stu dy, the steel building structures damaged by the tsunami that followed the 2011 Great East Japan Earthquake were observed by the authors. The authors investigated the relationship between the lateral strength and observed damage of the structures to verify the appropriateness of the design formula.

1. INTRODUCTION

The damage resulting from the disastrous tsunami triggered in the ocean by the 2011 Great East Japan Earthquake on March 11 of that year reached shocking levels that far outweighed the damage to land structures caused by the earthquake itself. It is vital to make quantitative estimates of loads arising in structures due to a tsunami and take these into account when planning structures that must resist tsunamis. At this time, however, there are very few published methods for quantitatively estimating tsunami damage or loading or other such analyses in structural design procedures or in the research literature. A great volume of data must be gathered based on many cases of damage in order to analyze tsunami loads, since these events are so variable and indeterminate. The present study provides an example of an analysis of such data.

In the present study, a survey of tsunami damage to steel-frame buildings in 2011 was conducted. The methods for estimating tsunami loads have been described in previous publications[1),2)]. This report begins with an explanation of the methods for estimating tsunami loads described in previous reports[1),2)] and then shows actual calculations for one of the buildings surveyed by the authors for tsunami damage. The results of this survey are summarized and compared with the results of the previous publications[1),2)].

2. BASIC APPROACH TO STRUCTURAL REQUIREMENTS UNDER GUIDELINES FOR TSUNAMI EVACUATION FROM BUILDINGS

2.1 Equations for calculating tsunami pressure in Cabinet Office guidelines

The Japanese Cabinet Office's guidelines for tsunami evacuation from buildings[3)] provide Eq. (1) for calculating the wave pressure. Here, q_z is the wave pressure in the direction of wave propagation to be used in structural calculations (kN/m^2), ρ is the volumetric density of the water in the tsunami (t/m^3), g is the gravitational acceleration (m/s^2), h is the design water depth (m), and z is the height of the given structural component above ground level ($0 \leqq z \leqq 3h$)(m).

$$q_z = \rho g (3h - z) \quad (1)$$

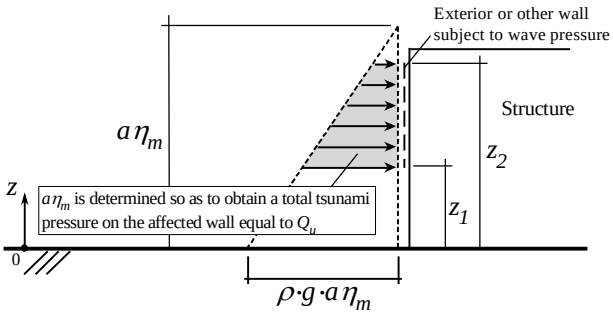
Eq. (1) is based on the results of a 2-dimensional experiment performed by Asakura et al. using a hydraulic model[4]. However, their experiment took no account of the influence of obstacles such as breakwaters or other coastal hardening.

Based on Eq. (1), the tsunami pressure Q_z exerted on the wall of a structure is expressed in Eq. (2). Here, B is the width of the wall (m) and z_1 and z_2 are the lowest and highest extents of the affected wall, respectively ($0 \leqq z_1 \leqq z_2$)(m).

$$Q_z = \rho g B \int_{z_1}^{z_2} (3h - z)\, dz \tag{2}$$

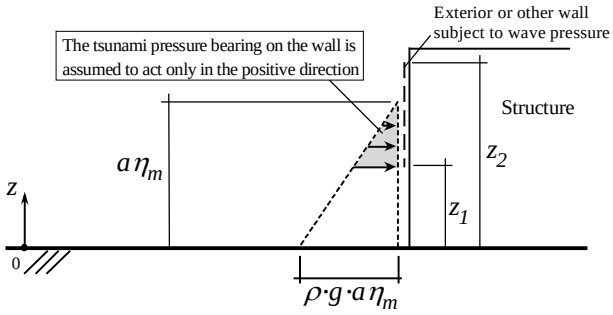
2.2 Estimating tsunami pressure from damage survey results

The interim reports from the Institute of Industrial Science, University of Tokyo[1),2)], described a survey of the area affected by the Great East Japan Tsunami for damage to buildings of RC construction and other artificial structures, and compared this to predictions based on the tsunami pressure equation. Those reports identified an equivalent water depth $a\eta_m$, indicating the immersion depth that would exert a hydrostatic loading equaling the lateral strength of a given structure. This was then divided by the measured tsunami inundation depth η_m to find the water depth coefficient a, and the trends in a were compared with parameters of the damaged buildings and other structures. a was modified by replacing the $3h$ term in Eq. (2), representing triple the design immersion depth, with the values for the equivalent water depth $a\eta_m$ found in the above interim reports. Since this is equal to the ultimate lateral strength Q_u for the building, we derive Eq. (3) below and rearrange to find Q_u:



$$Q_u = \rho g B \int_{z_1}^{z_2} (a\eta_m - z)\, dz \tag{3}$$

Eq. (3) indicates that the sum total of the static water pressure corresponding to $a\eta_m$ equals the total lateral strength of the building. Here, the maximum height z_2 of the affected wall must be less than $a\eta_m$.



In this paper, the authors calculated a for buildings struck by the tsunami in conformity with the investigative method used in the above interim reports. The application of $a\eta_m$ is shown in Figure 1. The calculations for buildings with unusually low values for Q_u revealed some cases where $a\eta_m$ did not actually attain the maximum height z_2 of the affected wall. To account for those cases, Eq.(3) was re-written and a was calculated using the domain from $a\eta_m$ to the lowest extent of the affected wall z_1 as the region for integrating the tsunami pressure. Eqs.(4) and (5) were employed to calculate a.

・$a\eta_m \geqq z_2$

$$a = \frac{Q_u}{\rho g B\, \eta_m (z_2 - z_1)} + \frac{z_2 + z_1}{2\eta_m} \tag{4}$$

(a) $a\eta_m \geqq z_2$

(b) $z_2 > a\eta_m$

Figure 1 Diagram describing equivalent water depth $a\eta_m$

・$z_2 > a\eta_m$

$$a = \frac{1}{\eta_m}\sqrt{\frac{2Q_u}{\rho g B}} + \frac{z_1}{\eta_m} \tag{5}$$

The above results indicate that it is vital to evaluate the area of the exterior wall, exterior furnishings or other components under tsunami pressure in order to find a. Steel-frame buildings are quite commonly fitted with exterior furnishings in the form of light concrete panels or slate panels that are attached by dry methods. It seems likely that when such exterior walls are struck by a tsunami, the furnishings will be carried away before transmitting the loads to the building structure. Actually, the tsunami damage survey conducted for this paper found quite a large number of building structures that were in perfectly serviceable condition, despite losing exterior walls or furnishings. The walls impacted by the tsunami after exterior furnishings had been torn away can be assumed to consist only of columns, beams and other structural components, so the load from the tsunami would have been considerably reduced with the disappearance of the exterior furnishings. For this report, the tsunami damage in each building was inspected to determine whether or not the tsunami loads had been transmitted to the structure by the exterior furnishings.

3. EXAMINATION ABOUT SOME RESEARCH EXAMPLES

In this paper, Simple examples of the methods for estimating tsunami loads are introduced. Figure 2

shows the location of buildings damaged by tsunami in T zone. Building (A) and (B) are Port facilities that we surveyed. Overview of building (A) is shown in photo 1, and overview of building (B) is shown in photo 2. The measurement of tsunami height in T zone is 15.0m.

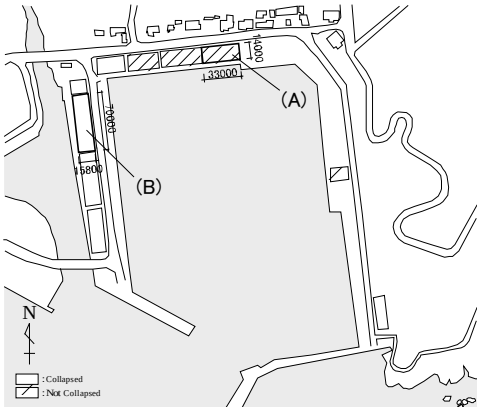


Figure 2 Location of buildings in T zone.

Photo 1 Overview of building (A)

Photo 2 Overview of building (B)

Outline of building (A) based on the present survey is shown in Figure 3. Building (A) is Steel structure, 1-floor. Span direction and ridge direction of building (A) are rigid frame. Building (A) is shown that beams and columns have no damaged by the tsunami. Exterior walls and roofs of building (A) subjected to the tsunami wave pressure are carried away. In the case of building (A), tsunami load subjected to span direction. Therefore, the ultimate lateral strength Q_u for the building (A) is calculated by the single span direction. Material of the beam is assumed to SS400 (lower limit of yield stress σ_y = 235.0 N/mm^2), material of the column is assumed to BCP (lower limit of yield stress σ_y = 325.0 N/mm^2). In this paper, Q_u for the building (A) is 692.1kN.

In the calculation of building (A), we assume that the exterior walls was carried away before transmitting the tsunami loads to the building structure. Tsunami load can be assumed to consist only the beams and columns. Thus, the equivalent water depth $a\eta_m$ for the building (A) is 26.18 m, and the water depth coefficient a for the building (A) is 1.74.

Outline of building (B) based on the present survey is shown in Figure 4. Building (B) is Steel structure, 1-floor. Span direction is rigid frame and ridge direction is X-bracing. Building (B) is collapsed by tsunami load. It caused by damage in column bases. Now, in the case of building (B), tsunami load subjected to ridge direction. The ultimate lateral strength Q_u for building (B) is calculated by the whole ridge directions. The whole ridge direction of building (B) has 16 span X-bracings. Material of the bracing is assumed to SS400 (lower limit of yield stress σ_y = 235.0 N/mm^2). In this paper, Q_u for the building (B) is 2,167kN.

As shown in Photo 2, we can confirm that the exterior furnishings of building (B) has a mix of the structural members. From this point of view, the assumption that only structural members, as beams and columns, was subjected to tsunami load is open to question. Thus, in this case, tsunami wave pressure receiving surface of building (B) is assumed for the all of entire surface of structure. The equivalent water depth $a\eta_m$ for the building (B) is 5.28 m, and the water depth coefficient a for the building (A) is 0.35.

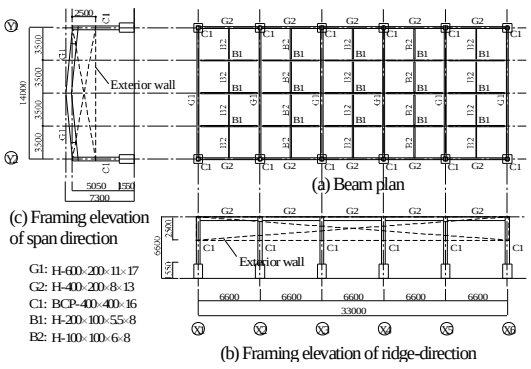

Figure 3 Outline of building (A)

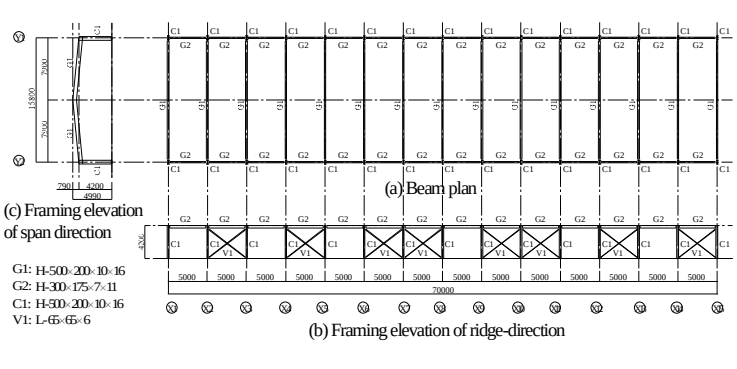

Figure 4 Outline of building (B)

Table 1 Results of Present Survey

	Loc.	Building under investigation	η_m	Condition	Surface bearing tsunami pressure	a
1	O Town	Steel, 2-floor, 2-layer ridge-direction bracing	15.0	Intact	Beam-column only	1.05
2	O Town	Steel, 2-floor, 1-layer ridge-direction bracing	15.0	Deformed	Beam-column only	0.82
3	M City	Steel, 1-floor, span-direction rigid frame structure	7.8	Deformed	Beam-column only	0.92
4	T Zone	Steel, 1-floor, span-direction rigid frame structure	15.0	Intact	Beam-column only	1.74
5	T Zone	Steel, 1-floor, ridge-direction bracing	15.0	Collapsed	Full spanwise wall	0.35
6	O City	Steel, 1-floor, span-direction rigid frame structure	11.8	Collapsed	Beam-column only	0.90
7	O Zone	Steel, 1-floor, span-direction rigid frame structure	9.7	Intact	Beam-column only	1.84

※Units for measured tsunami inundation depth were meters.

4. TRENDS IN WATER DEPTH COEFFICIENT FOUND IN SURVEY RESULTS

The water depth coefficient a was calculated for 7 cases from the present survey of steel-frame buildings that had suffered tsunami damage and was compared for consistency with the actual damage. Table 1 shows the results. Reference 1) summarized a survey of tsunami damaged-areas after the 2011 Great East Japan Earthquake, considering 78 affected RC buildings and other structures, and investigated the suitability of the equation for estimating tsunami pressure. The results indicated that a value of 1.0 was acceptable for a when calculating tsunami loads on RC buildings and other structures in regions where η_m was less than 10.0 m, but the damage from tsunami loads suggested values of $a <$ 1.0 in regions where η_m exceeded 10.0 m. Figure 5 shows how η_m varied with a in the cases presented in Reference 1, with data added for η_m and a in steel-frame buildings calculated by authors.

As shown in Figure 5, the results for tsunami loads form this survey were converted to a values and suggest that a = 1.0. There were a few exceptions, which is consistent with Reference 1) when η_m was less than 10.0 m; exceptions appeared in the case of building #2 and others when η_m exceeded 10.0 m. In this paper, however, it was assumed that the exterior walls or furnishings of steel-framed buildings would be torn away at an early point, leaving only structural components such as columns and beams, and that assumption, warranted or not, may well have some effect on the estimates for the surfaces bearing the tsunami pressure. It is extremely difficult to assess whether a building's external furnishings affect its lateral strength from a survey of tsunami damage. Estimating the area of steel-frame building walls that bears the load of a tsunami wave is a topic for future research.

5. Summary

This report describes a survey of tsunami damage, concentrating on steel-frame buildings affected by the tsunami after the 2011 Great East Japan Earthquake. Tsunami loads were estimated using the procedure followed in previous reports[1),2)]. The results in this paper

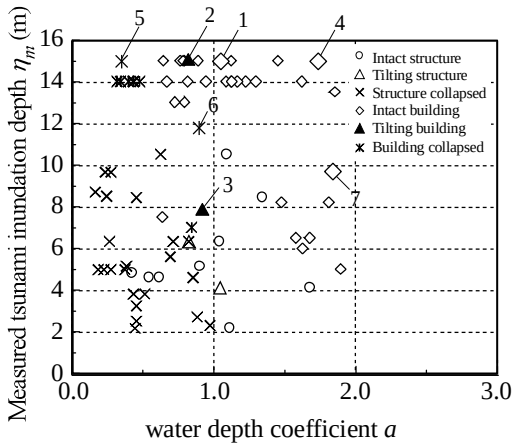

Figure 5 Variations in measured tsunami inundation depth η_m with water depth coefficient a

closely resembled those noted in the previous reports[1),2)]. A few cases showed inconsistencies from the trends noted before, though these were minor. These were attributed to necessary adjustments in the equations for the surface bearing tsunami pressure to account for the exterior walls and furnishings on steel-frame buildings.

Abstract: Numerical simulations are used to investigate the mechanisms of failure of the Kamaishi breakwater during the 2011 tsunami. Results indicate that the bearing stress at the heel of the caisson increased far above its allowable limit due to the overtopping jet pulling away from the landward side of the caisson as the surcharge height above the caisson increased. In addition to the scour-induced failure of the rubble-mound foundation reported by other researchers, measures to prevent geotechnical punching failure are also necessary to ensure integrity of deep breakwaters during overtopping events.

1. INTRODUCTION

The Great East Japan Tsunami of March 11, 2011 caused widespread devastation, though in some locations its impact was mitigated by coastal defensive structures such as the bay-mouth breakwater in Kamaishi (Takahashi et al, 2011), the largest and deepest breakwater in the world, constructed exclusively for mitigating tsunami impacts. Figure 1 shows the location of the Kamaishi breakwater, and Figure 2 shows a profile-view geometry of one of this breakwater's typical deep-water caissons and its rubble mound foundation. During the tsunami, the breakwater was overtopped. After the event, many caissons were no longer visible above the waterline, and sonar surveys later showed these to be lying on the seabed, having fallen off their rubble mound foundations in the landward direction (Arikawa et al, 2012). Other caissons were still emergent from the water, but were no longer standing vertical.

In addition to showing caisson displacement, sonar measurements showed significant erosion of the rubble-mound foundation. Arikawa et al (2012) carried out laboratory experiments to replicate the overtopping of the Kamaishi breakwater, and concluded that hydrodynamic scour was the fundamental cause of caisson displacement. Scour due to the overtopping jet plunging down the landward side of the caisson dug a trough beside the heel of the caisson, eventually causing the caisson to tumble. Additionally, the 1-m gap between caissons may have caused a flow strong enough to cause scour between caissons as well.

However, Arikawa et al's experiments did not consider the possibility of rubble mound geotechnical failure. Takagi (2009) showed that one of the most common modes of caisson breakwater damage during storms is punching failure of the rubble mound foundation (Goda, 2010). Furthermore, Yaoi et al (2012) ran centrifuge experiments and showed that foundation bearing capacity failure may have occurred during overtopping of deep-water caissons.

The work presented here uses a 2-dimensional shallow water equation model to reproduce the actual overtopping conditions experienced by the Kamaishi breakwater. The water levels seaward and landward of the breakwater are then used as boundary conditions in a 2-dimensional profile-view volume of fluid (VOF) computational fluid dynamics (CFD) model to analyze the forces experienced by the caisson and its rubble mound foundation. The result shows that punching failure of deep-water caissons was a likely mode of failure of these caissons. As such, scour prevention measures (such as armor blocks), though necessary to prevent scour-induced caisson failure, may not be sufficient to prevent geotechnical failure of deep-water caissons during overtopping.

2. METHODS

2.1 Shallow water modeling of tsunami behavior

Behavior of the tsunami near the Kamaishi breakwater was simulated using the Delft-3D hydrodynamic model, operating in two-dimensional depth-averaged mode. Domain decomposition was used, with the coarsest grid having 2 km resolution, an intermediate grid with 200 m resolution, and a fine grid with 20 m resolution (Figure 1). 500-m resolution bathymetry data were used in the open ocean (Japan Oceanographic Data Center, 2012), while

50-m resolution bathymetry data were used for Kamaishi Bay (Ministry of Land, Infrastructure, and Transport, 2012). Topography was 50-m mesh survey data (GSI, 2012).

Bottom roughness was assumed to be uniform everywhere, with a Manning's n of 0.02. Since the goal of this simulation was to replicate the behavior of the wave near the breakwater, and not the inundation experienced on land, the use of a uniform Manning's n was assumed to be sufficient. The 2km-resolution Pacific domain utilized the Reimann boundary condition in Delft-3D. In order to minimize reflection of the tsunami wave from the boundaries, the grid was oriented parallel to the tsunami wave front. The model time step was 0.3 sec, in order to ensure stability.

Initial conditions consisted of a water surface elevation near mean low water. In the 2-km resolution Pacific domain, the tsunami source used was based on that of Saito et al (2011). However, the source of Saito et al (2011) alone produced a tsunami near Kamaishi smaller than that measured by PARI (2012). As such, Saito et al's (2011) source was modified so as to be slightly larger (similar to the source determined by Takahashi et al, 2011), and to extend further to the northeast. The resulting source water elevation used is shown in Figure 1. Figure 3 shows a comparison of the tsunami water level resulting from this source, with the water level observed by the Port and Airport Research Institute (2012) at the three buoys closest to Kamaishi. The modeled water surface elevation is in good agreement with the measured water surface elevation.

The tsunami behavior was simulated for 2 hours. Since observations showed the breakwater caissons to have been displaced in the landward direction, it is likely they failed during the incident tsunami wave. Figure 4 shows the spatially average elevation of the simulated water surface on each side of the breakwater, starting at the time when overtopping began (the crest of the breakwater was 6 m above mean low water) until after the crest of the tsunami had passed. The maximum modeled water surface elevation on the seaward side of the breakwater was about 13 m, and the maximum water level difference across the breakwater was 9 m. This is in agreement with the numerical shallow water simulations discussed in Arikawa et al (2012).

2.2 CFD modeling of breakwater overtopping

In order to model forces on the caisson and its foundation, the OpenFOAM CFD model was used. Within OpenFOAM, the InterFOAM VOF module was applied, so as to simulate both air (density 1 kg/m^3) and water (density 1020 kg/m^3). Figure 2 shows the two-dimensional profile-view model domain. For purposes of calculating forces on the caisson, the domain was assumed to be 30 m long (normal the paper). Within the domain, the rubble mound and caisson were both no-slip hydraulically rough boundaries with roughness length 1 mm. The left and right sides of the domain were free-slip walls. The top surface was open to the atmosphere. Turbulence was modeled using the standard Reynolds Averaged Navier Stokes k-ε formulation.

Simulating a laboratory flume, water was allowed to upwell and drain through the seabed on each side of the mound (as shown in Figure 2), with the flow rates set so as to reproduce the water levels of Figure 4 on each side of the caisson. Setting up the model in this way (instead of using water level and flow speed boundary conditions in place of the side walls) enhanced model stability.

The model consisted of a variable size rectangular grid, with grid cell area shown in Figure 5. In the region of the overtopping jet, grid cell dimensions were as small as 2 cm by 2 cm, while far away from the area of energetic flow grid cells size increased up to 1 m by 1 m. Landward and seaward of the rubble mound (the location of inflow and outflow), horizontal model resolution was coarsened to 10 m. The lower resolution on the sides of the model domain was implemented in order to reduce model run time. Since flow velocity was quite small in these regions, they were not of concern for the overtopping flow or calculation of force on the caisson. The model time step was varied automatically, in order to assure Courant number stability, but was typically on the order of 0.001 sec. Also, in order to preserve a well-defined free surface, anti-diffusion (interface compression) was applied to the free surface.

3. RESULTS

Figure 6 shows the simulated caisson overtopping. Two important phenomena are visible here. First, the overtopping jet, even though gaining buoyancy due to entrained air, strikes the rubble mound with speeds up to 8 m/s, corroborating the conclusion of Arikawa et al (2012) that scour due to the overtopping jet was a cause of caisson failure. Second, the pressure behind the overtopping jet is significantly reduced from the hydrostatic pressure, due to the overtopping jet pulling further and further away from the landward side of the caisson as the overtopping water level increases, and due to the eddy that forms behind the jet.

3.1. Calculation of forces on caisson

Pressure is calculated by OpenFOAM at each grid cell along the top and side surfaces of the caisson. Since the bottom of the caisson sits upon the rubble mound, which is modeled as a solid, water pressure is not calculated there. In reality, the rubble mound is a porous body, with water flowing through the gaps between stones (groundwater flow). In order to calculate the total force on the caisson, water pressure along the bottom surface of the caisson is assumed to vary linearly from its value at the bottom of the caisson's seaward wall, to the pressure value at the bottom of the caisson's landward wall (Goda, 2010).

The net horizontal and vertical forces on the caisson due to water pressure are determined by equations (1) – (3). The overturning moment about the heel of the caisson due to water pressure is given by equation (4).

$$\vec{F}_k = P_k \, dA_k \, \hat{n}_k \quad (1)$$

$$F_{drag} = \sum \vec{F}_k \cdot \hat{\imath} \quad (2)$$

$$F_{lift} = \sum \vec{F}_k \cdot \hat{j} \quad (3)$$

$$M_{overturning} = -\sum \vec{r}_k \times \vec{F}_k \quad (4)$$

in which $\vec{F}_k$: force acting on the k^{th} cell along the caisson surface, P_k: pressure acting on the k^{th} cell along the caisson surface, dA_k: area of the k^{th} cell along the caisson surface, $\hat{n}_k$: unit vector normal to the k^{th} cell along the caisson surface, F_{drag}: total drag force acting on the casson, $\hat{\imath}$: horizontal unit vector, F_{lift}: total lift force acting on the caisson, $\hat{\jmath}$: vertical unit vector, $M_{overturning}$: overturning moment acting about the heel of the caisson, and $\vec{r}_k$: vector pointing from the heel of the caisson to the k^{th} cell along the caisson surface.

To find the punching pressure on the rubble mound foundation at the heel of the caisson (Goda, 2010), the normal force W_e on the caisson due to the rubble mound foundation is found by equation (5)

$$W_e = mg - F_{lift} \quad (5)$$

where m is the mass of the caisson, and g is the acceleration due to gravity (the effect of buoyancy is already included in the term F_{lift}). The moment M_e about the heel of the caisson due to the normal force is given by equation (6)

$$M_e = mgt - M_{overturning} \quad (6)$$

where t is the horizontal distance between the heel of the caisson and its center of mass. The horizontal distance t_e between the heel of the caisson and the location of the resultant normal force W_e is given by equation (7)

$$t_e = \frac{M_e}{W_e} \quad (7)$$

The punching pressure P_e at the heel of the caisson is then calculated by equation (8)

$$P_e = \begin{cases} \frac{2W_e}{3t_e} & : t_e \le B/3 \\ \frac{2W_e}{B}\left(2 - 3\frac{t_e}{B}\right) & : t_e > B/3 \end{cases} \quad (8)$$

where B is the width of the caisson (23 m as shown in Figure 2).

3.2. Resulting forces on caisson

Figure 7 shows the calculated drag force on the caisson as a function of time during overtopping. The solid line shows the result of the CFD model. The dotted line shows the hydrostatic drag force, which is the horizontal force the caisson experiences due only to the difference in water level across the caisson. The difference between these two lines is the non-hydrostatic force on the caisson, mostly due to the suction induced on the landward side of the caisson as the overtopping flowrate increases and the overtopping jet pulls further and further away from the caisson (this suction is evident as dips in the pressure contours on the landward side of the caisson in Figure 6). The dashed line represents the frictional force resisting caisson sliding, which was calculated assuming a coefficient of friction between the caisson and the rubble mound of 0.6 (Goda, 2012) and a uniform bulk density of 1900 kg/m^3 for the caisson and its fill. Figure 7 shows that the horizontal force on the caisson was never strong enough to cause sliding.

Figure 8 shows the lift force on the caisson. As before, the hydrostatic component (dotted line) is due to the buoyancy of the caisson itself. The full lift force (solid line) is slightly greater than the caisson buoyancy due to dynamic lift above the caisson during overtopping, but this effect is minimal. The lift force is much smaller than the weight of the caisson (dashed line).

Figure 9 shows the overturning moment about the (landward) heel of the caisson. As before, the hydrostatic component of this moment (dashed line) is due to the horizontal force on the caisson resulting from the difference in water level across it. The full overturning moment (solid line) is larger than the hydrostatic moment because of the suction discussed above. Nonetheless, toppling of the caisson due to the overturning moment is not possible, because the restoring moment due to the caisson's weight (dashed line) is larger than the overturning moment.

Figure 10 shows the punching pressure at the heel of the caisson. The hydrostatic component (dotted line), due to the water level difference across the caisson, exerts a punching pressure of up to 900 kPa, while the total punching pressure (solid line) reaches up to 1400 kPa. The allowable design punching pressure (dashed line) is 600 kPa (Goda, 2010), while Uezono and Odani (1987) showed that a critical punching pressure of 800 kPa caused rubble mound foundation failure during experiments on similar structures in the field. Figure 10 shows that the Kamaishi breakwater caissons experienced a punching pressure much greater than either the design or critical value, for about 2 minutes.

4. COMPARISON WITH EXPERIMENTS

In order to verify the CFD model results, qualitative comparison of overtopping jet's behavior with the experiments of Mitsui et al (2012) was carried out. Mitsui found that the InterFOAM VOF simulation overestimates the rate at which air trapped under the overtopping jet is entrained into the jet, thus causing the jet to spuriously pull close to the landward wall of the breakwater. This is evident in Figure 6 at t=29 minutes, where the jet has already pulled right up against the caisson and points vertically downward. In the simulation the air that had existed below the overtopping jet was rapidly entrained into the jet, and since there is no path for new air to replace the entrained air, the jet had to pull up against the caisson wall. In experiments, however, much of the air under the overtopping jet remains in place, and so the jet never pulls right up against the caisson.

The reason for the spurious entrainment of air in the simulation is due to the turbulence model implemented. In InterFOAM, the standard k-ε formulation is implemented, but lacking the buoyant production term. In this model, the kinematic eddy viscosity is continuous across the free

surface, resulting in a large diffusive flux of momentum between water and air. However, Nakayama & Yokojima (2003) showed that in reality the kinematic eddy viscosity in water rapidly decreases to nearly zero at the air-water interface, because turbulent eddies from the water do not jump up into the air, and eddies in the air do not dig down into the water surface. Thus, simulations in which the eddy viscosity does not decay to zero at the air-water interface experience too much flux of momentum and scalars across the interface.

To account for the decay of turbulence at the air-water interface, another simulation was run with the k-ε turbulence model modified such that the turbulent eddy viscosity was set to zero in cells where equation (9) was satisfied.

$$0.01 < \alpha_1 < 0.99 \quad (9)$$

Here, α_1 is the phase fraction of water (α_1=0 indicates a cell with only air, while α_1=1 indicates a cell with only water). In effect, this reduced the flux of momentum across locations with an air-water interface.

Figure 11 shows the effect of this modified turbulence model on the overtopping jet. At t=28 min, air still exists under the overtopping jet, so the jet has not pulled all the way up against the landward wall of the caisson. This is close to the behavior seen in the experimental results of Mitsui et al (2012), an improvement over the result of the standard turbulence model with continuous kinematic eddy viscosity shown in Figure 6. However, at later times, the original turbulence model produces results in better agreement with experiments, with the jet plunging to the depth of the rubble mound instead of remaining near the water surface. This indicates that the modified turbulence model handles the plunging jet in air well, but that after plunging into the water it's underestimating the eddy viscosity, as air entrained into the water causes α_1<0.99 in this region. In future work, the turbulence model will further be modified to allow a continuous kinematic eddy viscosity below the elevation of the free surface.

Figure 11 shows that the modified turbulence model does not cause a strong jet pulling gradually away from the caisson, and as such the pressure difference across the caisson does not vary greatly from its hydrostatic result. The resulting forces are thus similar to the hydrostatic results shown on Figures 7, 8, 9, and 10. The maximum bearing stress of 900 kPa is much less than the 1400 kPa resulting from the standard turbulence model, but is still large enough to cause foundation failure according to Uezono and Odani (1987). Since the modified turbulence model simulates the initial phases of overtopping more in line with experiments, while the standard turbulence model simulates the later phases of overtopping better, the actual forces are expected to lie somewhere in between those hindcast by each of these models, and will be better estimated as the turbulence model is refined.

5. CONCLUSIONS

Numerical simulations were used to evaluate potential failure modes of the Kamaishi breakwater during the 2011 tsunami. In addition to the scour reported by Arikawa et al (2012), punching failure of the rubble mound foundation is shown to be a major cause of breakwater failure. The amount of punching stress hindcast by the CFD simulation is greater than the critical value of 800 kPa reported by Uezono and Odani (1987). Using a standard turbulence model with continuous kinematic eddy viscosity across the air-water interface, the maximum hindcast punching stress is 1400 kPa, while a turbulence model with zero eddy viscosity in regions where air is entrained into the water hindcasts a maximum punching stress of 900 kPa. The actual punching stress experienced by the breakwater's foundation must have lied in between these two limiting values.

PROBING ON THE MECHANISM OF THE 2011 GREAT EAST JAPAN EARTHQUAKE AND TSUNAMI

Jiagui Zhang[1), 2)]

1) Professor, Key Laboratory of Neotectonic Movement & Geohazard, Ministry of Land and Resources, China
2) Institute of Geomechanics, Chinese Academy of Geological Sciences, Beijing 100081, China
jiagui62@sina.com

Abstract: It is impossible to explain seismic mechanism within two dimensional tectonics because earthquake occurs in global sphere space, and it is also impossible to explain mantle convection because no driving force achieves it. Hence not every tectonic earthquake is generated by fault slip. In the author's opinion, many earthquakes are generated by the lithospheric interlayer-slide in the deep flow and thrust process. There exists a NWW-ward deep flow and thrust zone from west Pacific to north Japan, Japanese Sea and NE China with axis across the 2011 Great East Japan Earthquake epicenter, north Fukushima, the center of Japanese Sea and DPRK's Kilju to Chinese Changbai Volcanos. The 2011 Great East Japan Earthquake with Mw 9.0 might be given out by the lithospheric interlayer-slide in the zone. The tsunami might be raised by the disorder seabed uplift in the lithospheric interlayer-slide process. There is no subduction of the Pacific plate into the Eurasian plate along Japan Trench. The regional lithosphere especially in the "T"-form spatial hypocenters' region was highly destroyed by the Mw 9.0 earthquake and its aftershocks, and the NWW-ward deep flow and thrust has been continuing. Strong earthquakes will occur often in the deep flow and thrust zone, but no Mw≥9.0 earthquake will occur there in at lest 100 years.

1. INTRODUCTION

On 11th March, 2011, Great East Japan earthquake with Mw 9.0 occurred at an epicenter of 38.30°N and 142.37°E, and at a depth of 29 km (*USGS* 2012a), and huge tsunami was raised by the earthquake. The earthquake and tsunami resulted in extensive and catastrophic damage in coastal northeast Japan and a death toll of some 20,000 (*from the First Announcement of 10 CUEE*). On the former plate tectonic theory (*Dewey at al.* 1970, *Dewey* 1972, *Bird* 2003, *Yakupov* 2011), there was Benioff zone along the east coastal Japan, and the Pacific plate had been subducting into the Eurasian plate along the Japan Trench with dip 30° (*Shi et al.* 1973) in the mantle convection process. On the former seismic ideas, huge earthquakes were often given out by slip faults (*Seismo-Geological Teaching and Research Section of Peking University et al.* 1982), and it is difficult for any huge earthquake to be given out by reverse faults or subduction. Hence why there occurred so gigantic earthquake in the subduction zone is incomprehensible. On the other side, was this (the Mw 9.0 earthquake) a foreshock (*Boyle* 2012)? The author reminds that, for 40 years ago or earlier, it was pointed out that to explain the seismic mechanism within two dimensional tectonics was impossible because earthquake occurred in global sphere space (*Chang et al.* 1973, *Seismo-Geological Teaching and Research Section of Peking University et al.* 1982), and to explain mantle convection was also impossible because no driving force achieved it. Hence not every tectonic earthquake is generated by fault slip, and no plate subduction exists along the Benioff zone, which were further showed by the seismic process of the 2011 Great East Japan earthquake (see the follows). What is the mechanism of some gigantic earthquakes involving the 2011 Great East Japan earthquake? How is the tsunami raised by earthquakes? In the author's opinion, the different idea on the mechanism of some gigantic earthquakes should be put forward. The interlayer-slide might be a type of seismic mechanism (*Chang et al.* 1973). In 1996 or earlier, it was pointed out that, many earthquakes were generated by the lithospheric interlayer-slide in the deep flow and thrust process (*Zhang* 1996). The 2011 Great East Japan earthquake might be given out by the lithospheric interlayer-slide in the NWW-ward deep flow and thrust process under the Pacific, and the tsunami might be raised by the disorder seabed uplift in the lithospheric interlayer-slide process.

2. DESCRIPTION ON THE DEEP FLOW AND THRUST

The lithosphere of the earth is consisted of upper crust, lower crust and upper mantle. The upper crust is consisted of sedimentary cover and crystalline basement. In many regions, there exists middle crust with high conductivity and low P-wave velocity between upper crust and lower crust. Those could be defined as the multi-layer property of the

lithosphere. There exist G-face between sedimentary cover and crystalline basement, Conrad discontinuity between upper crust and lower crust and Moho discontinuity between lower crust and upper mantle (Fig. 1). Those could be

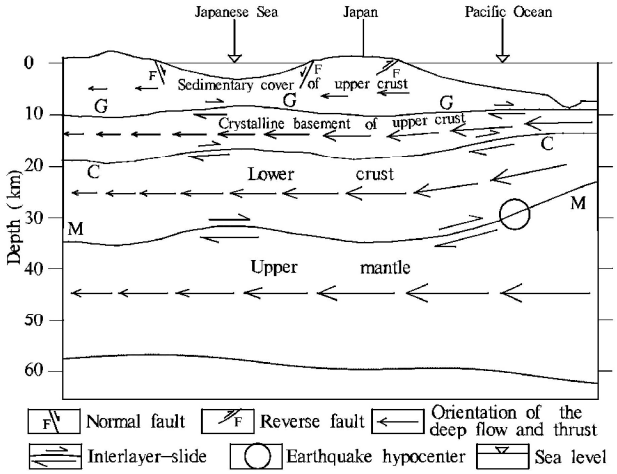

Fig. 1 Schematic Diagram of the Deep Flow and Thrust Framework within the Lithosphere across the 2011 Great East Japan Earthquake Region. In the diagram, G means the top face of the crystalline basement, C means Conrad discontinuity and M means Moho discontinuity.

defined as the discontinuities of the lithosphere. In fact, there exist not only those layers and discontinuities, but also exist many sub-layers and sub-discontinuities. In the geological time scale, any part of the lithosphere bears the rheological property (*Zhou* 2000). In the lithosphere, from the bottom to the surface, the upper mantle bears the strongest rheological property because of the high pressure and high temperature, and the upper crust bears the slightest rheological property, there mainly exist three types of geodynamics which are the gravitical equilibrium, the westward dynamic gravitation generated by earth rotation and cosmic gravity (*Zhang* 2003, 2004). Along the west Pacific margin, the main geodynamics is the westward dynamic gravitation generated by earth rotation, which pushes the lithosphere flowing westward. The flow velocity in each layer is different (Fig. 1). The velocity of upper mantle flow is fast because of its strong rheological property, and the velocity of upper crust flow is slow. Hence the deep flow takes the leading role, and the upper crust flow is mainly dragged by the deep flow. The deep flow is accompanied by the deep thrust because the thrust means pushing. That is the meaning of the deep flow and thrust.

3. THE MECHANISM OF THE 2011 GREAT EAST JAPAN EARTHQUAKE AND THE TSUNAMI

3.1 The Deep Flow and Thrust Zone

There exist deep flow and thrust everywhere. But the deep flow and thrust are uneven not only on horizontal scope, but also on vertical scope. The uneven on horizontal scope shapes many deep flow and thrust zones (*Zhang* 2001, 2003, 2004, 2008, 2012). There exists a deep flow and thrust zone from west Pacific to north Japan, Japanese Sea, DPRK and NE China with axis across the Mw 9.0 earthquake epicenter, north Fukushima, the center of Japanese Sea and DPRK's Kilju to Chinese Changbai Volcanos (*Zhang et al.* 1999, *Zhang* 2001, 2003) (Fig. 2). Along the zone, there exist two

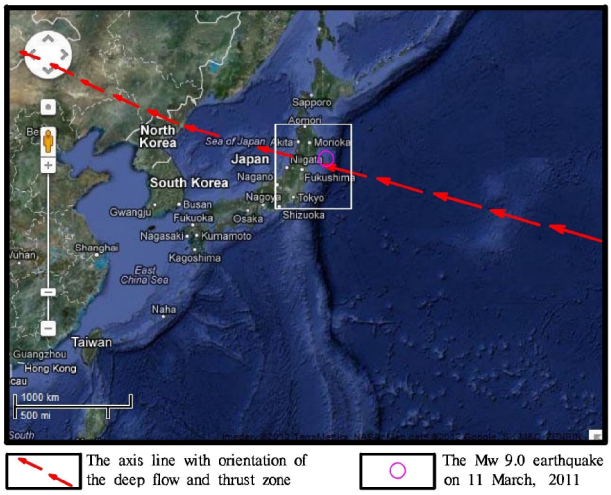

Fig. 2 Map Showing the Deep Flow and Thrust Zone from Pacific Ocean, Japan to China across the 2011 Great East Japan Earthquake Region. The white rectangle frame denotes the outline of Fig. 3 (a). The background image is from *google map*, and the epicenter of the Mw 9.0 earthquake is from *USGS* (2012a). The drawing software MAPGIS was purchased from *Zondy Cyber Group Co., Ltd.*

extremely similar curves, respectively the curve composed by Kuril Trench, Japan Trench and Marianas Trench and the curve composed by the west coast line of Japanese Sea. By the stress measurement results (*Lin et al.* 2011), the principal compression orientation of the stress in the surface layer of the deep flow and thrust zone was NWW in coincidence with the deep flow orientation. Why is it not westward orientation? The reason is the westward dynamic gravitation is interfered by the deep flow and thrust zones in lower latitude region (*Zhang* 2003, 2004). The uneven on vertical scope generates the interlayer-slide in the lithosphere (Fig. 1).

3.2 The Mechanism of the Earthquake

The interlayer-slide may cause earthquake, but does not cause earthquake everywhere. The curve segment of discontinuity is capable of stress concentration, hence there is plentiful of seismic pregnancy (*Zhang* 1996). Is there any curve segment of the discontinuities under the west Pacific margin and east Japan? Yes, the Moho isobathes varies radically from 20 km under the west Pacific margin to 36 km under central Japan (*Institute of Crustal Dynamics et al.* 2001).

The 2011 Great East Japan earthquake was generated by the interlayer-slide of curve segment along the Moho discontinuity (Fig. 1). The epicenter of the earthquake lay near the axis of the deep flow and thrust zone (Fig. 2), which indicated the deep flow and thrust along the axis was the strongest, and there was capable of strong stress

accumulation, and finally the interlayer-slide started there.

Why there occurred so huge earthquake? The dynamic gravitation under the vast Pacific Ocean put forward the huge-scale NWW-ward deep flow and thrust, and the curve segment along the discontinuities are very broad under the west Pacific margin and east Japan (Fig. 1). Hence, the stress could be abundantly concentrated there, and the enormous energy could be highly accumulated there, and finally the enormous energy was released in the interlayer-slide process and the huge Mw 9.0 earthquake came out.

3.3 The Mechanism of the Tsunami

Around the seismic hypocenter, the interlayer-slide was very strong, and the upper mantle slid from the east was accumulated under the seismic hypocenter and its surroundings. The crust above the seismic hypocenter and its surroundings was uplifted massively by the accumulated upper mantle, and consequently the seawater was raised by the surface layer of the crust (also named as the seabed). There was not only the uplift, but also the fall-down followed because of the elasticity of the lithosphere. Those together with the seismic waves put forward the tsunami in horrible massive disorder form.

4. EXPLANATION ON THE PHENOMENA IN THE SEISMIC PROCESS

4.1 The Foreshocks and aftershocks

There occurred few foreshocks and a great deal of aftershocks. The aftershocks occurred not only along the so-called interpolate (*Asano et al.* 2011), nor only above the subduction face as former note (*Shi et al.* 1973), but occurred in three-dimension spatial region.

From 1st March to 30th September, 2011, 77 earthquakes with M≥6.0 excluding the Mw 9.0 earthquake, including 3 foreshocks and 5 7.9≥M≥7.0 earthquakes were recorded (*USGS* 2012a). 3 foreshocks occurred on the close east side of the mainshock, which put forward a low stress space for the sudden huge-scale flow and thrust in the mainshock. Most of the aftershocks occurred along the off coast in a zone with 20° strike, 160 km wide and 600 km long, or along the axis of the deep flow and thrust in a zone with 110° strike, 140 km wide and 330 km long (including the overlap segment of the coast zone), which shaped a "T"-form horizontal region (Fig. 3 (a)). The epicenter of the Mw 9.0 earthquake lay at the juncture area of the "T"-form.

All of the seismic hypocenters lay at a depth of less than 57 km (Fig. 3 (b)). 57 of the seismic hypocenters lay at a depth from 20 km to 56 km, and 11 of the seismic hypocenters under the east side of Japan Trench lay at a depth from 9 km to 47 km, similar to the depth of those under the west side. Those shaped a "T"-form spatial hypocenters' region. In the "T"-form region, the aftershocks under the off coast zone exhibited the curve segments of the lithosphere were capable of stress concentration, and the aftershocks along the axis of the deep flow and thrust zone showed the strongest flow and thrust generated strong stress concentration. It could be deduced the "T"-form region with

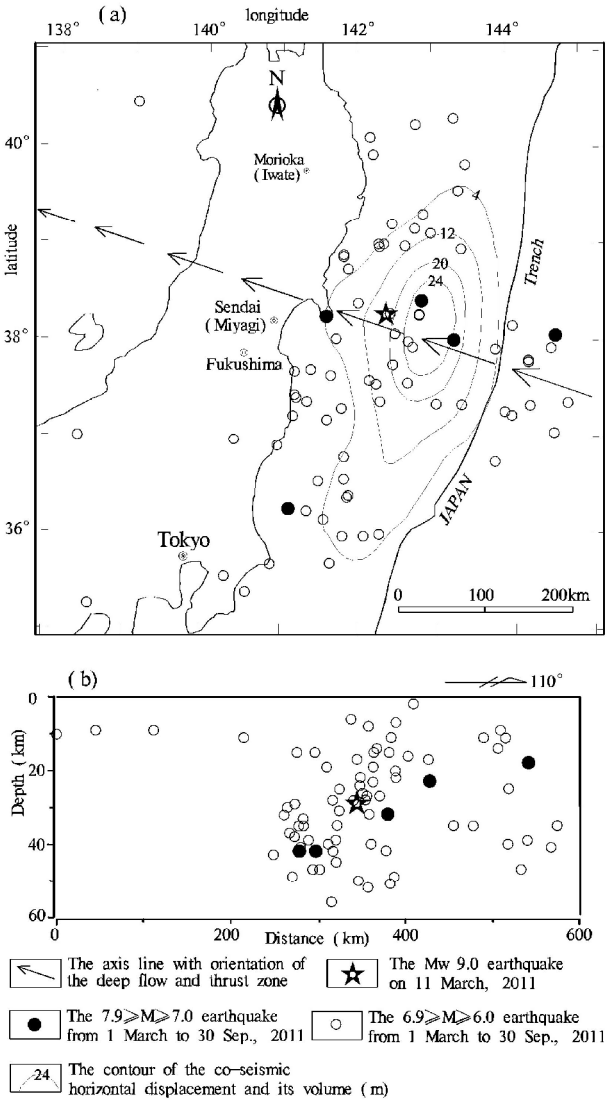

Fig. 3 Distribution of the Earthquakes Determined in This Study, Tectonic Landform and the Deep Flow and Thrust Zone. (a) Shows Horizontal Distributions, and (b) Shows Depth Distributions along the Axis Line. The position data of the earthquakes are from *USGS* (2012a). The co-seismic horizontal displacements are from *Geospatial Information Authority of Japan* (2011). The coastlines are from Japan map in *Guang.org*. Japan Trench position is from *Yakupov* (2011). The drawing software MAPGIS was purchased from *Zondy Cyber Group Co., Ltd*, and the projection software drawing the (b) was MAPSIS developed by *CSBGIS*.

high stress concentration was severely fractured while the mainshock occurred. After that, the residual stress rapidly transferred to vulnerable spots generated by the mainshock, and then the aftershocks occurred in succession. Where were the vulnerable spots? The juncture area of the two sides of "T"-form around the mainshock hypocenter was severely fractured and was the most vulnerable area, and a large number of aftershocks occurred at the vulnerable spots in the area. The juncture spots of the discontinuities and the faults generated by the mainshock was another type of vulnerable spots, and there might exist a great deal of juncture spots

along the Moho discontinuity because there occurred a huge number of 7.9≥M≥4.0 aftershocks along the westward dip face at a depth from 20 km on the east side of the aftershock region to 30 km on the west side of the aftershock region also the east Japanese coast (*Asano et al.* 2011). Hence the aftershocks occurred at the vulnerable spots such as the highly fractured hypocenter of the mainshock and its surrounding, and the juncture spots of the discontinuities and the faults. It was calculated from the aftershock distribution that, the "fault" which might be the interlayer-slide face was in strike 203°, dip 15°-16° and rake 83°-101° (see File 000060436.pdf in *http://www.gsi.go.jp/cais/topic110315.2-index-e.html*), different from the dip 30° as former note (*Shi et al.*1973).

Just three aftershocks occurred isolatedly at a depth of 10 km or less in the west far from the mainshock. Those might indicated the structure and stress of crustal surface layer were affected by the Mw 9.0 earthquake in a wide range.

Generally to state, the foreshocks induced the mainshock, and the aftershocks released the residual stress concentrated at the vulnerable spots and further destroyed the lithosphere structure.

4.2 The Co-Seismic Displacement

Geospatial Information Authority of Japan (2011) has estimated the spatial distribution of co-seismic displacement from GPS data. They showed that the large co-seismic horizontal displacement (>8 m) area extended from off south Iwate to off Fukushima and that its largest peak (>24 m) was located off Miyagi (*Asano et al.* 2011).

The 4.0 m contour of the horizontal displacement shapes a ellipse-like region with long axis at orientation about 20° and length about 430 km, short axis at orientation about 120° and length about 200 km, and the maximum displacement at the "ellipse" center (see File 000060400.pdf in *http://www.gsi.go.jp/cais/topic110315.2-index-e.html*) (Fig. 3(a)). The displacement orientation is SEE-ward, just reverse to the orientation of the deep flow and thrust. The distance of the "ellipse" center perpendicular to the Japan Trench is 90 km west, and just a short part of the 4.0 m contour is in coincidence with or near the trench west. Hence, the co-seismic horizontal displacement area was not exactly correlated to Japan Trench – "the boundary of the two plates", or controlled by the subduction between the two "plates". The "ellipse" center also the seismic epicenter determined by *Geospatial Information Authority of Japan* (2011) lay near the axis of the deep flow and thrust zone (Fig. 3(a)). The land part from Utsunomiya on south to Morioka on north moved SEE-ward for 1-4 m being dependent on locations with large volume on the east coast and little volume on the west coast (see File 000060402.pdf in *http://www.gsi.go.jp/cais/topic110315.2-index-e.html*). Those indicated the surface layer of the crust above the Mw 9.0 earthquake hypocenter and its surrounding compressed by the deep flow and thrust before the mainshock rebounded to the former positions in the mainshock.

The distribution area of the co-seismic vertical displacement is similar to the co-seismic horizontal displacement area, and it is composed by two symmetrical sub areas, one is uplift area on east with maximum uplift volume over 5.5 m, and another was subsidence area on west with maximum subsidence volume over 2.0 m (see File 000060406.pdf in *http://www.gsi.go.jp/cais/topic110315.2-index-e.html*). Those indicated the rebound of the surface layer of the crust was restricted by the east part of the surface layer off the centroid area, and the surface layer in the uplift area was folded. Those also indicated there was no plate boundary along Japan Trench to give a free rebound.

The aftershocks were closely correlated to the co-seismic displacement area, especially to the vertical one. Comparing to the horizontal displacement area, the aftershock epicenters' area showed an extension to three different parts, which were the SW corner, the NW corner and the east part along the axis of the deep flow and thrust zone. Those showed the deep flow and thrust had been continuing, the stress was concentrated at the interlayer-slide ends of the mainshock, and finally the aftershocks were given out.

4.3 The Features of the Focal Mechanisms

From *USGS* (2012b) information, the moment tensor of the mainshock was with fault plane 1 in strike 203°, dip 10° and rake 88°, and fault plane 2 in strike 25°, dip 80° and rake 90° corresponding to an essentially pure double-couple mechanism (*Nettles et al.* 2011), and the P-axis of the focal mechanisms bore azimuth 115° and plunge 35°. Those exhibited the up-west part of the hypocenter was uplifted initially and new faults were generated by the sudden interlayer-slide in the mainshock, and the orientation of the deep flow and thrust to cause the sudden interlayer-slide was basically the azimuth of the P-axis.

From *Asano et al.* (2011) research results, the earthquakes occurring before the mainshock from January 1, 2003 to March 11 5:45 (UTC), 2011 were basically with thrust-type focal mechanisms, and on the other hand, the aftershocks exhibited a variety of focal mechanisms. By the author's observation at the figures in the reference (*Asano et al.* 2011), the aftershocks at shallow depth (maybe above 25 km) were basically with normal-fault-type focal mechanisms, and the aftershocks at deep depth were basically with thrust-type focal mechanisms. Those might show the surface layers of the lithosphere (maybe the whole crust above the hypocenter of the mainshock) had normal-faulting movement or had uplift movement after rebounding SEE-ward in mainshock, and the deep layers (maybe the upper mantle below the hypocenter of the mainshock) were continuously in NWW-ward flow and thrust process. Those also showed the interlayer-slide had been continuing after the mainshock occurred.

4.4 The Reason of Speed-up Earth's Rotation by the Earthquake

NASA geophysicist *Richard Gross* calculated that Earth's rotation sped up by 1.8 microseconds because of the shift in Earth's mass caused by the Mw 9.0 earthquake (*The*

Associated Press 2012). That showed the sudden NWW-ward movement of the mantle pushed by the interlayer-slide in the earthquake process was transferred to the Earth's rotation. But the change in rotation speed was less than the one at 6.8 microseconds caused by 2004's Sumatra earthquake (*The Associated Press* 2012) because of the higher latitude of the Mw 9.0 earthquake hypocenter with shorter arm of force to the earth's rotation axis.

5. CONCLUSIONS AND DISCUSSIONS

There exists a NWW-ward deep flow and thrust zone from west Pacific to north Japan, Japanese Sea and NE China with axis across the Mw 9.0 earthquake epicenter, north Fukushima, the center of Japanese Sea and DPRK's Kilju to Chinese Changbai Volcanos.

The 2011 Great East Japan earthquake was generated by the interlayer-slide of curve segment along Moho discontinuity in the deep flow and thrust zone.

The tsunami was raised by the disorder seabed uplift in the lithospheric interlayer-slide process.

The aftershocks and co-seismic displacements exhibited the huge effect of the Mw 9.0 earthquake on the regional lithosphere structure and its stability. The lithosphere especially in the "T"-form spatial hypocenters' region was highly fractured and folded, and there existed high-degree residual stress after the mainshock.

The focal mechanisms and the earth's rotation speed-up by the Mw 9.0 earthquake showed the stress in the lithosphere bears the NWW-ward principal compression orientation with low dip angle, the surface layers of the lithosphere had an uplift movement after rebounding SEE-ward in mainshock, and the deep layers were continuously in NWW-ward flow and thrust process.

There is no subduction of the Pacific plate into the Eurasian plate with dip 30° or steeper angle along Japan Trench.

Both epicenter data from *USGS* (2012a) and from *Geospatial Information Authority of Japan* (2011) have 49 km position difference. The data from *USGS* (2012a) should be the micro-epicenter showing the initial slide spot, and the data from *Japan* (2011) denoted the position on SEE side should be the macro-epicenter in coincidence with the peak spot of the horizontal displacement showing the maximum seismic intensity spot (Fig. 3(a)).

Was this (the Mw 9.0 earthquake) a foreshock (*Boyle* 2012)? On the author's opinion, the deep flow and thrust has been continuing after the Mw 9.0 earthquake occurred, and for a long time in future, strong earthquakes will occur often in the deep flow and thrust zone, but no Mw≥9.0 earthquake will occur there in at lest 100 years.

10CUEE CONFERENCE PROCEEDINGS
10th International Conference on Urban Earthquake Engineering
March 1-2, 2013, Tokyo Institute of Technology, Tokyo, Japan

DEVELOPMENT OF TSUNAMI STRUCTURAL DESIGN PROVISIONS FOR THE USA

Gary Chock[1)]

1) Chair, ASCE 7 Tsunami Loads and Effects Subcommittee; President, Martin & Chock, Inc., Honolulu, Hawaii / USA
gchock@martinchock.com

Abstract: The Tsunami Loads and Effects Subcommittee of the ASCE/SEI 7 Standards Committee is developing a proposed new Chapter 6 - Tsunami Loads and Effects for the 2016 edition of the ASCE 7 Standard. These new provisions will include loads for tsunami and its effects, and the design procedure will also incorporate certain aspects of Performance Based Tsunami Engineering. The ASCE 7 Standard classifies facilities in accordance with Risk Categories that recognize the importance or criticality of the facility, and the tsunami design requirements in the ASCE 7 Standard vary by Risk Category.

A method of Probabilistic Tsunami Hazard Analysis has been established in the recognized literature that is generally consistent with Probabilistic Seismic Hazard Analysis in the treatment of uncertainty. Structural member acceptability criteria will be based on performance objectives for a 2,500-year Maximum Considered Tsunami. It is presently anticipated that the ASCE 7 Tsunami Loads and Effects Chapter will be applicable only to the states of Alaska, Washington, Oregon, California, Hawaii, and the territories of Guam, American Samoa, and Puerto Rico. Ground shaking effects and subsidence from a preceding local offshore Maximum Considered Earthquake will also need to be considered prior to tsunami arrival for Alaska and states in the Pacific Northwest regions governed by nearby offshore subduction earthquakes.

1. INTRODUCTION

A national standard for engineering design for tsunami effects does not presently exist. Presently, tsunami risk to coastal zone construction is not explicitly and comprehensively addressed in design codes of the United States. Beginning from February, 2011, the Tsunami Loads and Effects Subcommittee of the American Society of Civil Engineers / Structural Engineering Institute ASCE/SEI 7 Standards Committee has been developing a proposed new Chapter 6 - Tsunami Loads and Effects, with Commentary for the 2016 edition of the ASCE/SEI 7 Standard, *Minimum Design Loads for Buildings and Other Structures*, These new provisions would provide prescriptive loads for tsunami and its effects, and the analysis procedure will also incorporate aspects of Performance Based Tsunami Engineering (Chock, 2011). In this paper we provide a preview emphasizing the general intent and design methodologies of these developing code provisions (*these are the Dec. 2012 draft provisions subject to final revisions*).

The International Building Code (IBC) references design provisions that are given in American Society of Civil Engineers Standard 7. The ASCE 7 Standard becomes part of an enacted building code law through adoption of the model International Building Code by the local authority having jurisdiction (such as a state, county, or city). The IBC will probably incorporate ASCE 7-16 in 2018 or 2021. Therefore, it is anticipated that the first national tsunami design provisions of ASCE 7 would be utilized soon after.

2. OVERVIEW OF THE PROPOSED ASCE-7 TSUNAMI LOADS AND EFFECTS CHAPTER 6

2.1 Organization

The Tsunami Loads and Effects design provisions (ASCE 7 Chapter 6) have been organized into the following sections:

6.1 General Requirements
6.2 Definitions
6.3 Symbols and Notation
6.4 Tsunami Risk Category Design Criteria
6.5 Procedures for Determination of Offshore Tsunami Wave Height
6.6 Procedures for Determining Tsunami Inundation
6.7 Design Parameters for Tsunami Flow over Land
6.8 Structural Design Procedure for Tsunami Effects
6.9 Hydrostatic Loads
6.10 Hydrodynamic Loads
6.11 Impact Loads
6.12 Foundation Design
6.13 Structural countermeasures for reduced loading
6.14 Special Occupancy Structures
6.15 Designated Nonstructural Systems
6.16 Non-building critical facility structures

2.2 General Requirements and Design Criteria

Mitigation of tsunami risk requires a combination of emergency preparedness for evacuation in addition to providing structural resilience of critical facilities, infrastructure, and key resources necessary for immediate

response and economic and social recovery. Critical facilities would include emergency response, medical, tsunami refuges and shelters, ports and harbors, lifelines, transportation, telecommunications, power, financial institutions, and major industrial/commercial facilities. The ASCE 7 Standard (ASCE, 2010) classifies facilities in accordance with Risk Categories that recognize the importance or criticality of the facility (Table 1). In the tsunami chapter, further refined definitions of the Risk Categories for Risk Categories III and IV are included with respect to specific occupancy/functional criteria.

Table 1 Risk Categories of Buildings and Other Structures per ASCE 7

Risk Category I	Buildings and other structures that represent a low risk to humans in the event of failure
Risk Category II	All buildings and other structures except those listed in Risk Categories I, III, IV
Risk Category III	Buildings and other structures with hazard to human life or substantial potential to cause a substantial economic impact and/or mass disruption of day-to-day civilian life in the event of failure
Risk Category IV	Buildings and other structures designated as essential facilities

Tsunami design performance objectives are similar in approach to typical U.S. seismic performance objectives. The common performance-based concept is that there are estimated hazard levels aligned with the corresponding desired building performance levels. In Table 2, the key performance levels are shown for two return periods, the 100-year period and a maximum considered 2,500-year (i.e., the 0.0004 annual probability) event. A return period of 100-years for the occasional low-level tsunami that aligns better with coastal storm flood criteria, since there will be a need to evaluate which of the two effects governs the minimum elevation of the structure's lowest floor level. A 2,500-year hazard level Maximum Considered Tsunami is selected for design consistency with the ASCE 7 seismic hazard criteria, since tsunami can occur as a coseismic effect of a nearby earthquake.

For the tsunami with a 0.01 annual probability of exceedance, buildings and other structures shall be designed and constructed to withstand tsunami loads and effects determined for the flooding associated with tsunamis. The elevation of the bottom of the lowest horizontal structural member of the lowest floor elevation shall be above the inundation depth. Foundations and vertical members supporting the lowest floor shall be designed to resist flotation, collapse and lateral movement.

Low-rise Risk Category II buildings would be at higher risk of being fully inundated during a maximum considered 2,500-year tsunami. When communities with public awareness are enabled with tsunami warning systems and emergency operations plans for evacuation, low-rise Risk Category II buildings should not be occupied during a tsunami. Therefore, these buildings are not required to be designed against the 2,500-year tsunami event.

A minimum height defines the range of taller Risk Category II buildings where design to prevent collapse would be required. Based on analysis of reinforced concrete buildings, a threshold of ~20 m (65 ft.) has been recommended as the height sufficient for both reliable life safety and reasonable economic cost to meet this goal.

Risk Category III buildings are to be designed against collapse, since these structures include school buildings with mass assembly occupancies, critical infrastructure such as power and water treatment, and also other facilities that may store hazardous materials.

For Risk Category IV essential facilities that may necessarily exist within a coastal zone subject to tsunami hazard, the design provisions address the life safety performance level for hydrostatic, hydrodynamic, waterborne debris accumulation and impact loads, subsidence, and scour effects generated by any preceding earthquake and the subsequent tsunami flow conditions..

Table 2 ASCE-Proposed Tsunami Performance Levels for Various Risk Category Types

Hazard	**Tsunami Performance Level**			
Tsunami Return Period	**Operational**	**Immediate Occupancy**	**Life Safe**	**Collapse Prevention**
100 years	Risk Category IV	Risk Category III	Risk Category II	
Maximum Considered (2500 yrs.)		Vertical Evacuation Refuge Buildings	Risk Category IV	Risk Category III and > 65-ft.-high Risk Category II

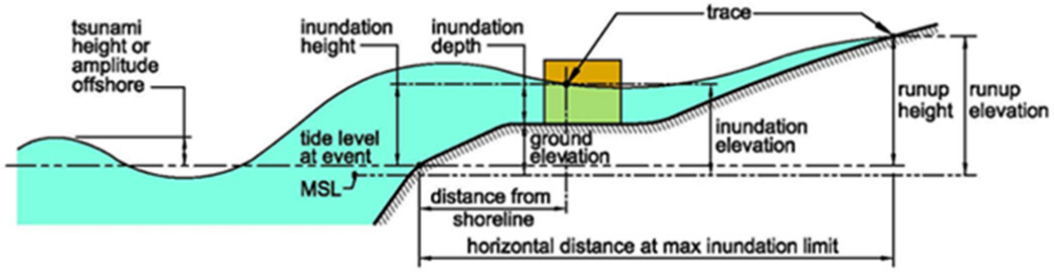

Figure 1 Illustrated Tsunami Terminology

2.3 Definitions

Key terms for tsunami definition are offshore tsunami height, inundation depth, runup elevation, and maximum (horizontal) inundation limit. Offshore Tsunami Height is measured where the water depth is 100 meters. Inundation Depth is the depth of tsunami water level with respect to the local grade plane. Runup Elevation is the elevation above mean sea level at the tsunami inundation limit. Maximum Inundation Limit is the maximum horizontal extent of the inundation zone relative to the shoreline at Mean Sea Level. There key parameters are illustrated in Figure 1.

The Tsunami Hazard Zone is the area vulnerable to being flooded or inundated by the Maximum Considered Tsunami, which is taken as having a 2% probability of being exceeded in a 50-year period, or a 2500 year average return period. The Maximum Considered Tsunami is the design basis event used for design, consisting of the inundation depths and flow velocities taken at the stages of in-flow and out-flow most critical to the structure.

It is presently anticipated that the ASCE 7 Tsunami Loads and Effects Chapter will be applicable only to the states of Alaska, Washington, Oregon, California, Hawaii, and the territories of Guam, American Samoa, and Puerto Rico. These tsunami-prone regions have quantifiable hazards due to tsunamigenic earthquakes.

2.4 General Tsunami Design Criteria

As noted above, buildings and structures would have their structural performance objective defined based on height and Risk Category, per one of the following performance level objectives.

IMMEDIATE OCCUPANCY STRUCTURAL PERFORMANCE: The post-event damage state in which a structure remains safe to occupy

LIFE SAFE STRUCTURAL PERFORMANCE: The post-event damage state is that in which a structure has damaged components but retains a margin against onset of partial or total collapse.

COLLAPSE PREVENTION STRUCTURAL PERFORMANCE: The post-event damage state is which a structure has damaged components and continues to support gravity loads but retains little or no margin against collapse.

Building failure modes differ fundamentally between seismic (high frequency dynamic effects generated on the inertial masses of a structure) and tsunami (externally and internally applied sustained fluid pressures varying with stages of depth over long period cycles of load reversal). Tsunami-induced failure modes of buildings have been examined in several detailed analyses of case studies taken from the Tohoku Tsunami of March 11, 2011 (Chock, et al, 2013a). Building components are subject simultaneously to internal forces generated by the external loading on the lateral-force-resisting system together with high intensity momentum pressure forces exerted on individual members. The tsunami provisions must maintain the physical consistency of tsunami flow conditions with respect to runup, inundation depth and associated current velocities. Because the use of a single scalar factor applied simultaneously on depth, current velocity, and force would violates fluid mechanics, the prescriptive "R" scalar reduction factors used by historical custom almost exclusively in the U.S. seismic code is not appropriate. U.S. seismic designs use an semi-empirical/customary response modification factor, the "R-factor", to account for both the structural ductility and overstrength of the lateral-load-resisting system.

Regions governed by nearby offshore earthquakes structure will need to resist the design earthquake, prior to the arrival of the design tsunami inundation. For the Pacific Northwest (Geist, 2005) and Alaska, this necessarily includes consideration of ground shaking effects and subsidence from the preceding local offshore subduction earthquake. Tsunami design must also enable a multi-hazard performance-based analysis technique with the ability to evaluate primary members both ductility for initial dynamic earthquake loading and the demand of sustained tsunami hydrodynamic fluid forces on the remaining structural capacities after an near-field subduction earthquake.

To do this analysis of performance, we propose to utilize the Analysis Procedures and Acceptance Criteria of ASCE 41 (ASCE, 2006), *Seismic Rehabilitation of Existing Buildings*. With an adaptation of this method, strength and stability can be checked to determine that the designs of the structural components are capable of withstanding the tsunami to achieve the Structural Performance level required. The tsunami adaption allows the techniques of the Linear Static Procedure and the Nonlinear Static Procedure. Strengths of structural components can then be checked using the ASCE 41 acceptability criteria for actual tsunami loads and depths that are correct from the standpoint of fluid mechanics without load factors. In the case of a preceding local earthquake, the reduction of structural capacity can be

conservatively accounted for with this technique. Utilizing the performance-based component acceptability criteria in ASCE/SEI 41-06, Deformation-Controlled Actions in primary and secondary components shall satisfy Eq. (1).

$$m\,Q_{CE} \geq Q_{UD} \quad (1)$$

where:

m : the pseudo-ductility factor used as a multiplier of a structural component's expected strength

Q_{CE} : Expected strength of the structural element

Q_{UD} : Deformation-controlled Force due to gravity and tsunami loading

Force-Controlled Actions in primary and secondary components shall satisfy Eq. (2).

$$Q_{CL} \geq Q_{UF} \quad (2)$$

where:

Q_{CL} : Lower-bound strength of the structural element

Q_{UF} : Maximum force generated in the element due to gravity and tsunami loading

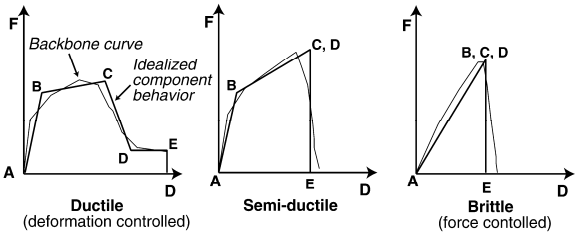

Figure 2 Sample Diagrams of Force-Displacement Capacity Boundaries of Structural Component Behavior.

Loading shall consider a minimum of two tsunami in-flow and out-flow cycles, one of which shall be at the maximum design level. This is required because the condition of the building and its foundation is altered in each tsunami inflow and out-flow cycle. Therefore, building foundation designs shall consider changes in the site surface and the in-situ soil properties during the design seismic event and subsequent design tsunami event. Foundation effects in the geotechnical investigation report shall include consideration of slope instability, liquefaction, total and differential settlement, subsidence, and surface displacement due to faulting or seismically induced lateral spreading.

Where tsunami loads or effects exceed acceptability criteria for a structural element, it shall be permitted as an alternative to apply progressive collapse provisions of UFC 4-023-03, Design of Structures to Resist Progressive Collapse, (DoD, 2009).

2.5 Procedures for Tsunami Hazard Assessment

Probabilistic Tsunami Hazard Analysis (PTHA) shall be used to determine the offshore tsunami heights for the 100-year and Maximum Considered Tsunami. A method of probabilistic tsunami hazard analysis has been established in the recognized literature that is generally consistent with probabilistic seismic hazard analysis in the treatment of uncertainty (Geist and Parsons, 2006).The runup for this hazard probability is used to define a map the tsunami hazard zone. An example of the probabilistic tsunami hazard analysis technique has been performed for California (Thio, 2010). The basics of Probabilistic Tsunami Hazard Analysis for a region are as follows:

1. Tsunamigenic subduction zones and non-subduction seismic thrust faults are discretized into a compiled system of rectangular subfaults each with corresponding tectonic parameters.

2. Tsunami waveform generation is modeled by deconstructing a tsunami that is generated by an earthquake into a linear combination of individual tsunami waveforms from a set of subfaults that describe the earthquake rupture in location, orientation, and rupture direction and sequence.

3. A statistically weighted logic tree approach is used to account for variations in the model parameters for tsunamigenic earthquake occurrence probabilities from tectonic, geodetic, historical, and paleo-tsunami data, and estimated plate convergence rates.

4. Propagate tsunamis in deep water using the linear long wave equations to take into account spatial variations in seafloor depth.

5. Determine the highest offshore wave heights at 100m depth, period, and depth-averaged celerity for the design level exceedance rates of the 100-year and the 2,500-year tsunami.

6. Disaggregate the seismic sources and associated moment magnitudes that together contribute at least 90% to the net offshore tsunami hazard at the site under consideration for each design level.

2.6 Procedures for Tsunami Inundation Analysis

Analyze each disaggregated tsunami event to determine representative design parameters (max height, depth, velocity, and flux). Regardless of soil type, the Maximum Considered Tsunami inundation shall assume an overall elevation settlement of 1 meter of the inundated region when local subduction thrust faulting is the tsunamigenic mechanism that contributes at least 90% to the net offshore tsunami hazard at the site.

7. Use nonlinear shallow water wave equations to modeling regime from 100m depth towards the shore to transform the probabilistically defined offshore height to maximum inundation. The following effects shall be included as applicable to the bathymetry:
    a. Shoaling to determine Nearshore Tsunami Height
    b. Dispersion effects
    c. Reflected waves
    d. Channeling in bays
    e. Shelf and bay resonances
    f. Fringing submerged reefs and shelves
    g. Soliton fission of short period undular waves in gradually sloping offshore bathymetry
    h. Bore formation and propagation

8. Analyze each tsunami event from the disaggregated sample to determine flow parameters. Manning's coefficient for equivalent terrain macro-roughness is used to account for friction. Maximum. runup, inundation depth, flow velocity, and/or specific momentum flux is permitted to be evaluated by either of the following techniques:
   a. by taking the weighted average of the scenario runs that bracket the offshore waveheight for the return period. Inundation limit shall be determined by the area that is inundated by tsunami waves from all the disaggregated major source zones for that particular return period.
   b. by developing the probabilistic distributions of flow parameters from the sample of computed tsunamis and construct the statistical distributions of flow parameters for at least four critical stages.
9. From the probabilistic events, capture the design flow parameters of inundation depth, flow velocity, and/or specific momentum flux at the site of interest.

2.7 Design Parameters for Tsunami Flow over Land

Where the coastline can be approximated in behavior by the use of one-dimensional linear transects of a composite bathymetric / topographic profile, in lieu of steps 7, 8, and 9 above, the tsunami inundation design parameters of minimum runup, specific momentum flux, and current velocities are permitted to be estimated by analytical formulations for substantially uniform sloped topographic profiles, or by an energy analysis approach used for terrain that can be idealized as a series of linear sloped segments. Forces determined with these analysis methods are required to be increased by an Importance Factor depending on the Risk Category. In the energy approach (Figure 3), the potential energy budget of the tsunami is first represented by the theoretical runup at the shoreline on a landward extension of the nearshore bathymetric slope.

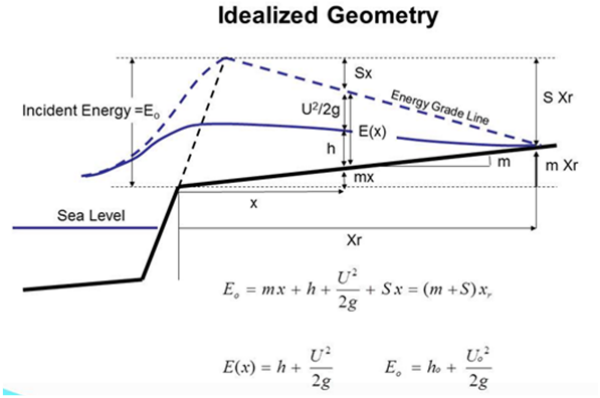

Figure 3 Energy Method Parameters

Then hydraulic analysis using Manning's coefficient for equivalent terrain macro-roughness is used to account for friction along with the profile comprised of a series of 1-D slopes, to determine the variation of high velocity-associated inundation depth across the inland profile. Velocity is assumed to be a function of inundation depth, calibrated to the prescribed Froude number $u/\sqrt{(gh)}$ at the shoreline and decreasing inland.

If only maximum tsunami depth at the site can be estimated, for Risk Category II buildings and structures a conservative simplified pseudo-hydrostatic lateral pressure can be applied to the structure to represent the effect of hydrodynamic flow on the structure. It is determined using the maximum inundation depth with a fluid density of three times that of seawater. This simplified method is similar to the approach taken in Japan using the Structural Design Method of Buildings for Tsunami Resistance (Okada et al, 2004 and Fukuda, et al 2012). For the simplified pressure, conventional strength design procedures may be used if only Life Safety Structural Performance is required.

2.8 Structural Design Procedure for Tsunami Effects

Four stages of tsunami surge loading defined by inundation depths and their associated velocities are required to be considered:

1. Near-maximum momentum flux when depth is approximately one-quarter of maximum
2. Two-thirds of maximum inundation depth
3. Maximum water depth when velocity is zero
4. Return flow when depth is approximately one-third of maximum

The design limit for the 2,500-year event is based on the inelastic capacity of primary structural load-carrying elements. For a distant tsunami, the available strength could be up to the yield point or a post-yield hardening point, depending on the performance level. When a local subduction zone creates the tsunami event, the acceptable solution point on the force-displacement capacity boundary can only be found to the right of the solution for the preceding earthquake effect. The available strength for tsunami resistance would account for any strength and stiffness degradation caused by the preceding earthquake. This is conceptually illustrated in Figure 4.

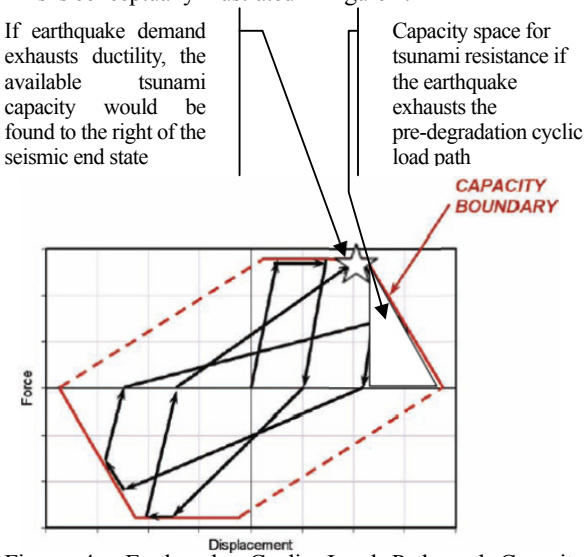

Figure 4 Earthquake Cyclic Load Path and Capacity Available for Tsunami (Adapted from FEMA P440A)

When a near-sourced high-intensity tsunami-genic earthquake occurs, structures with less initial resistance will have a greater proportion of their systemic ductility consumed. Less member ductility would then be available for sustaining subsequent tsunami loading cycles. Accordingly, the seismic performance objective may need to be enhanced for critical coastal structures near subduction zones so that adequate inelastic reserve is available for a maximum considered tsunami following a maximum considered earthquake.

Loads on buildings shall be calculated assuming a minimum closure ratio of 70% of the pressure exposed surface area of the exterior enclosure; this accounts for accumulated waterborne debris as well as trapped against the side of the structure as well any internal blockage caused by building contents that cannot easily flow out of the structure. As a practical matter based on observations of buildings subjected to destructive tsunami, "breakaway" walls cannot be relied upon to relieve structural loading, primarily due to the copious amount of external debris. Also, studs and girts may be capable of entrapping contents within a building, thus generating hydrodynamic drag forces on the internal debris that in turn transfer those loads to the structure.

As an Extraordinary Event, per ASCE 7 Section 2.5 (ASCE, 2010), the appropriate load combinations are shown in Eq. (3) and (4) below.

$$Q_U = 1.2D + - 1.0F_{TSU} + 0.25L + 0.2S \quad (3)$$

$$Q_U = 0.9D + - 1.0F_{TSU} \quad (4)$$

where: D : dead load
L : live load
S : snow load
F_{TSU} : tsunami loads and effects

2.9 Structural Loads

The following tsunami load effects should be considered for structural design of buildings and structures:

1. Hydrostatic forces, buoyant forces, and additional fluid gravity loads from retained water;
2. Hydrodynamic forces and hydrodynamic uplift forces;
3. Debris impact forces and debris damming forces
4. Foundation scour and pore pressure softening effects on the soil

The structural details of numerous damaged buildings in the Tohoku region were documented soon after the March 11, 2011 Tohoku-Oki earthquake and tsunami by a reconnaissance team sponsored by the American Society of Civil Engineers. Tsunami flow depths and velocities were determined based on analysis of video records and the observed effects on simple benchmark structures in the flow. Equations for various conditions of fluid loading were then validated through failure analyses completed for several buildings using finite element modeling and LiDAR scans. These analysis tools were applied full-scale to buildings with clearly identified failure mechanisms to validate the tsunami loading provisions in the ASCE 7 Standard (Chock, 2013b).

Hydrostatic Loads

Minimum Fluid Density for Tsunami Loads

Seawater density ρ_{sw} shall be taken as 1025 kg/m^3. The minimum fluid density ρ_s for determining tsunami loads accounting for suspended solids and debris flow-embedded smaller objects, shall be determined per Eq. (5):

$$\rho_s = k_s \rho_{sw} \quad (5)$$

where k_s , fluid density factor, shall be taken as 1.1

Buoyancy

Reduced self-weight due to buoyancy shall be considered for all inundated structural and non-structural elements of the building using Eq. (6). Uplift due to buoyancy shall include enclosed spaces without breakaway walls that have opening area less than 25% of the inundated exterior wall area. Buoyancy shall also include the effect of air trapped below floors, including foundation slabs, and in enclosed spaces where the walls are not designed to break away. All windows, except those designed for wind-borne debris impact or blast loading, shall be permitted to be considered openings. Foundation elements, excluding piles, shall be included in this calculation.

$$F_v = k_s \rho_{sw} g \forall \quad (6)$$

where
k_s : fluid density factor
ρ_{sw} : effective equivalent density of seawater
$\forall$: Volume

Unbalanced Lateral Force

Structural walls with openings less than 10% of the wall area and either longer than 30 feet without adjacent breakaway walls or having a two- or three sided perimeter structural wall configuration regardless of length shall be designed to resist an unbalanced hydrostatic lateral force during inflow given by Eq. (7).

$$F_h = \frac{1}{2} k_s \rho_{sw} g b h_{\max}^2 \quad (7)$$

where
b : width subject to force
h_{max} : maximum depth

Residual Water Surcharge Load on Floors and Walls

All horizontal floors below the maximum inundation depth shall be designed for dead load plus a residual water surcharge load to the extent that internal impounded water cannot escape in sufficient time. Residual water surcharge load f_r given by Eq. (8) . Walls shall also be designed for residual water hydrostatic pressure.

$$f_r = k_s \rho_{sw} g h_r \quad (8)$$

where $h_r = h_{\max} - h_f \le h_{bw}$

h_f = floor elevation

h_{bw} = water depth required to break non-structural walls and release trapped water.

Hydrodynamic Lateral Loads: The building lateral framing system shall be designed to resist the overall drag force F_d developed either by in-coming or out-going flow surge per Eq. (9).

$$F_d = \frac{1}{2} k_s \rho_{sw} C_d C_b b (hu^2)_{\max} \quad (9)$$

where

C_d is the drag coefficient for the building

C_b is the closure ratio of projected area of structural elements over the full projected are of the building below the flow level

u : Tsunami flow velocity

Likewise, the lateral hydrodynamic pressure load shall be applied at the mid-height of the projected area of all structural elements and enclosure component assemblages below the flow depth per Eq. (10).

$$F_d = \frac{1}{2} k_s \rho_{sw} C_d b (hu^2)_{\max} \quad (10)$$

where C_d is the drag coefficient for the element

Slab hydrodynamic uplift pressure equivalent to a minimum hydrodynamic uplift pressure of 1 kPa applied to the soffit of the slab shall be applied to sections where entrapped flow occurs .

Where enclosed spaces exist within the building that prevents flow through the section, hydrodynamic flow stagnation internal pressure shall be applied using Eq.(11).

$$P_p = \tfrac{1}{2} \rho_{sw} u_{\max}^2 \quad (11)$$

where u_{max} is the maximum free flow velocity at that location assuming no obstruction.

For nearshore bathymetric slopes that are shallow, or in the presence of reef discontinuities, tsunami bore solitons shall also be considered superimposed on the hydrodynamic surge. Instantaneous hydrodynamic loads created by bore impact can be severe (Robertson, et al, 2011). At locations specified in accordance with offshore bathymetry, bore impact forces on walls and slabs shall be considered in addition to hydrodynamic drag. Structural walls oriented perpendicular to the in- flow direction with a width greater than $3h_b$ or $3h_f$, whichever is smaller, shall be designed for a transient lateral load per unit width given by Eq. (12).

$$F_b = k_s \rho_{sw} \left(\frac{1}{2} g h_b^2 + h_j v_j^2 + g^{1/3} (h_j v_j)^{4/3} \right) \quad (12)$$

This force shall be applied at $(h_b+h_r)/3$ from the base of the wall, where h_r is given by Eq. (13)

$$h_r = g^{-\frac{1}{3}} (v_j h_j)^{\frac{2}{3}} \quad (13)$$

The resulting wall pressure shall be a triangular distribution with maximum pressure of $2F/(h_b+h_r)$ at the base and zero pressure at a height of (h_b+h_r). See Figure 5.

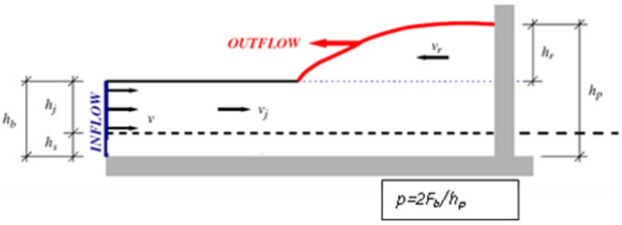

Figure 5 Tsunami Bore Travelling over Standing Water and Striking a Wall

Impact Loads: Waterborne debris impact is applied to any perimeter structural element of the gravity-load-carrying system within the inundation depth at the site. A 1,000-lb. log impact, a floating passenger vehicle force of 6,000 lbs., and a 2,000-lb. submerged tumbling boulder (or concrete mass debris) impact shall be assumed to impact perimeter vertical structural elements of the gravity-load-carrying system.

The maximum instantaneous debris impact force of waterborne floating debris shall be determined using Eq. (14) applied to any perimeter structural element of the gravity-load-carrying system subject to the in- flow or out-flow within the inundation depth.

$$F_i = u_{\max} \sqrt{k m_d} \quad (14)$$

where,

u_{max} is the flow velocity at the site,

k is the effective stiffness of the impacting debris or the lateral stiffness of the impacted structural element(s) deformed by the impact, whichever is the lesser. Logs and containers are assumed to strike longitudinally for calculation of debris stiffness.

m_d is the mass of the debris.

The impulse duration for elastic impact shall be permitted to be calculated per Eq. (15):

$$t_d = \frac{2 m_d u_{max}}{F_i} \quad (15)$$

For buildings and other structures within 1,500 ft. of a shipping port, a shipping container impact on perimeter vertical structural elements of the gravity-load-carrying system shall be assumed to occur at 3 m/s.

For Risk Category IV buildings and structures adjacent to piers and wharves, an extraordinary mass impact (e.g., ships, containers, small floating buildings) on perimeter vertical structural elements of the gravity-load-carrying system shall be assumed to occur. Extraordinary debris impacts on Risk Category IV buildings and structures shall require the application of the alternative

load path progressive collapse provisions of UFC 4-023-03, Design of Structures to Resist Progressive Collapse, July 14, 2009.

Foundation Design: Design of structure foundations and tsunami barriers shall consider changes in the site surface and in-situ soil properties during the design tsunami and provide capacity to support the structural loads. Local scour calculations shall evaluate the effects of sustained flow shear, which can be enhanced by pore pressure softening, and both effects can be prescriptively determined using Figure 6 based on empirical study. For near source tsunami hazards, the in-situ soil and site surface condition at the onset of tsunami loads shall be those determined existing at the end of seismic shaking, including liquefaction, lateral spread and fault rupture. The minimum factor of safety shall be 1.2 for potential failure limits impacting foundations (bearing capacity, uplift, lateral pressure, internal and slope stability).

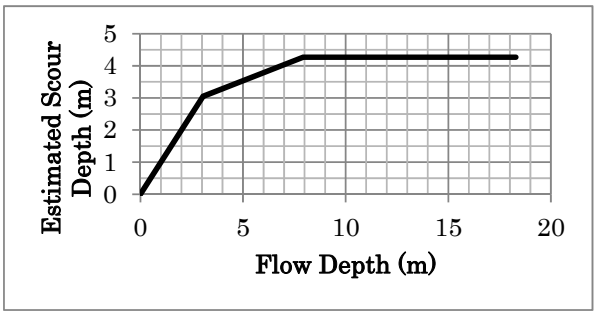

Figure 6 Design Local Scour Depth due to Sustained Flow Shear and Pore Pressure Softening

2.9 Special Occupancy Structures

Vertical Evacuation Refuge Structures are a special classification of buildings and structures within the tsunami evacuation zone designated as a means of alternative evacuation in communities where sufficiently high ground does not exist or where the time available after the tsunami warning is not deemed to be adequate for full evacuation prior to tsunami arrival. Such a building or structure must have the strength and resiliency needed to resist all effects of the maximum considered tsunami. Despite the devastation of the March 11, 2011 Tohoku Tsunami along the northeast coastline of Honshu island of Japan, there were many tsunami evacuation buildings that provided safe refuge for thousands of survivors (Fraser, et al, 2012). In the U.S., FEMA P646 (Applied Technology Council, 2012) exists as a set of guidelines but is not written in mandatory language necessary for building code and design standards. Therefore, the ASCE 7 Standard would incorporate the technical requirements for such structures, utilizing P646 as a pre-standard reference. A particularly important consideration is the elevation and height of the refuge, since it must provide structural life safety for the occupants within a portion of the refuge that is not inundated. Therefore, additional conservatism is necessary in the estimation of inundation height. The recommended minimum elevation for a tsunami refuge area is, therefore, the maximum considered tsunami runup elevation anticipated at the site, plus 30%, plus approximately 3 meters (10 feet), as illustrated in Figure 7.

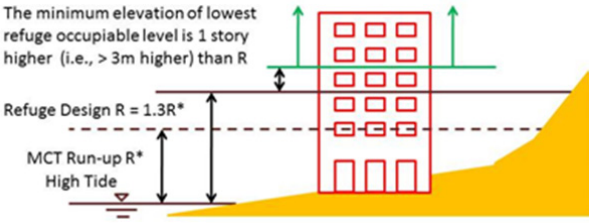

Figure 7 Minimum Tsunami Refuge Elevation

For the Pacific Northwest and Alaska, design necessarily includes consideration of ground shaking effects and subsidence from a preceding local offshore subduction earthquake, prior to the arrival of the design tsunami inundation. To help ensure adequate strength and ductility in the structure for resisting tsunami load effects, Seismic Design Category D, as defined in ASCE/SEI 7-10, should be assigned to the structure, as a minimum. The tsunami evacuation refuge should have a post-earthquake seismic performance objective of Immediate Occupancy prior to the tsunami arrival in order to receive evacuees and to have sufficient margin remaining to resist sustained tsunami loads. In addition to individual structural members, it is also necessary to compare tsunami loading to the ultimate inelastic structural systemic capacity of the building. The overall capacity of the lateral-load-resisting system can be checked using its overstrength factor, Ω (illustrated in Figure 8).

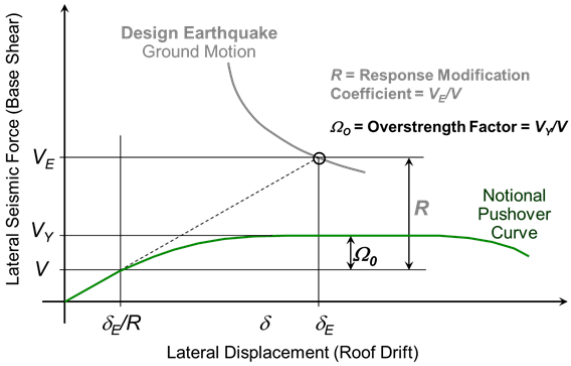

Figure 8 U.S. Seismic performance factors Ω and R, based on inelastic response capacity (Adapted from FEMA P-695)

In multi-story buildings greater than about four stories tall, once the Immediate Occupancy seismic design objective is utilized at the Maximum Considered Earthquake hazard level, most of the overall systemic lateral strength necessary will have been provided for tsunami resistance to the Maximum Considered Tsunami resulting from that event (Chock, et al, 2013b). However, structural components may need local "enhanced resistance" and ground level shear walls may also require additional strength for out-of-plane hydrodynamic forces and/or pressurization effects. Because

the tsunami evacuation refuge is assumed to be occupied at the designated levels during the event, load combinations for refuge structures are modified to Eq. (16) and (17).

Load Combination 1:

$$Q_U = 1.2D + - 1.0F_{TSU} + 1.0L_{Refuge} + 0.25L_{Non\text{-}refuge} + 0.2S \quad (16)$$

Where L_{Refuge} and $L_{Non\text{-}refuge}$ refer to the live loads in the levels used for Refuge and the levels below not occupied as refuges, respectively.

Load Combination 2:

$$Q_U = 0.9D + - 1.0F_{TSU} \quad (17)$$

3. CONCLUSIONS

- The Tsunami Loads and Effects Subcommittee of the ASCE/SEI 7 Standards Committee is developing a new Chapter 6 - Tsunami Loads and Effects, with a corresponding Commentary for the 2016 edition of the ASCE 7 Standard.
- .A method of probabilistic tsunami hazard analysis has been established in the recognized literature that is generally consistent with probabilistic seismic hazard analysis in the treatment of uncertainty.
- Methodologies for 2D tsunami inundation modeling have been further developed and utilized for various designated communities and regions.
- Structural loading and analysis techniques for determining building performance have been developed. Experimental and field validation studies of these techniques have been performed.
- Measures of seismic performance in the inelastic range have been developed that have relevant application for tsunami performance metrics.
- Analysis procedures for regions governed by local subduction earthquakes involves a multi-hazard performance-based approach to provide both ductility for dynamic earthquake loading and remaining strength for sustained hydrodynamic fluid forces
- The proposed ASCE 7 provisions for Tsunami Loads and Effects enables a set of analysis tools and design methodologies that are consistent with tsunami physics and performance based engineering.

Abstract: Finite duration of bottom deformation in a tsunami source is not usually taken into account in description of tsunami generation. Whereas theoretical estimation provide the evidence that dynamics of bottom deformation has certain influence on resulting tsunami waves. In this study, taking the 2003 Tokachi-oki tsunamigenic earthquake as example, we compare dynamic and static (traditional) approaches in description of tsunami generation.

1. INTRODUCTION

The rupture in earthquake source propagates much faster than long gravitational waves. Due to this fact the generation of a tsunami by an earthquake is usually considered as an instant process. And particular features of time-history of bottom deformation is not taken into account in tsunami simulation.

Nevertheless, in reality bottom deformation lasts during a certain time. For example, in such catastrophic earthquakes as the 2004 Sumatra–Andaman or the 2011 Tohoku-oki the bottom deformation was as long as 10 minutes or more. Moreover there are the so-called slow earthquakes that may last even longer (Kanamori 1972). This type of earthquakes also exhibits an anomalously high level of low-frequency excitation, i.e. the bottom motions can be rather slow (Beroza and Jordan 1990). Besides, such slow earthquakes are also called tsunami earthquakes for they are capable of generating devastating tsunamis despite the relatively small earthquake magnitude.

The role of dynamics of bottom deformation had been studied theoretically and experimentally in a number of works (e.g. Hwang and Divoki 1970, Hammack 1973, 1980, Dotsenko and Soloviev 1995, Dotsenko 1996, Nosov and Shelkovnikov 1997, Nosov 1998, Levin and Nosov 2009). Nowadays it is become possible to examine real cases in order to reveal the role of dynamics of bottom deformation. This study is aimed to a comparative analysis of dynamic and static approaches in description of tsunami generation by the example of the 2003 Tokachi-oki tsunamigenic earthquake which was the strongest seismic event of the year.

In this paper we shall consider the following two approaches in description of tsunami generation by an underwater earthquake: static and dynamic.

The static approach assumes that an earthquake is to instantly cause residual deformations of the ocean bottom, i.e. static (co-seismic) bottom deformations. Such deformations can be calculated from fault parameters with use of well known Okada formulae (Okada, 1985). Afterwards the bottom deformation is employed as input data in specification of initial elevation of water surface in tsunami propagation models. In common practice the initial elevation is assumed to be equal to the vertical component of bottom deformation. The imperfectness of such a common practice is due to the following reasons. First, direct transfer of bottom deformations up to the water surface artificially enriches the spectrum of the tsunami at the expense of unrealistically short waves. Second, In the case of a sloping (non-horizontal) bottom the horizontal deformation components can also contribute significantly to the displacement of the water surface. More comprehensive technique comprises the accounting of both vertical and horizontal components of co-seismic bottom deformations and “smoothing” effect of water layer (Nosov and Kolesov 2009, 2011).

The dynamic approach involves time-spatial history of bottom deformations (or dynamic bottom deformation) that occurs in tsunami source due to earthquake. Water layer perturbations could be simulated conjunctly with fault rupturing process (fully-coupled model) or separately (weakly-coupled model).

2. NUMERICAL MODELS

In present study we use the following two numerical models: 2D and 3D.

2D model is based on the linear long-wave theory utilizes static tsunami source. The classical wave equation written in respect of fluid velocity potential is accompanied with boundary conditions: fully reflective

along the shore and free pass on outer boundaries of calculation domain. The mathematical model and numerical scheme (finite difference method) are described in Nosov et al, (2012).

3D model (Nosov and Kolesov 2007) describes both acoustic and gravitational waves exited by dynamic bottom deformation. Model is weakly-coupled, so bottom motion and hydrodynamics of compressible water layer was calculated separately.

To demonstrate difference between static and dynamic approaches in tsunami generation we chose Tokachi-oki 2003 M_W=8.3 earthquake. The initial deformation of water surface for 2D model was determined in two steps. First, coseismic bottom deformation was calculated based on finite fault model proposed in Koketsu et el. (2004). Second, the "smoothing" method was applied. The dynamic bottom deformation due to seismic fault rupturing was first simulated by the boundary element method (Kataoka 1996), using the same finite fault model data. The duration of bottom motion was 128 seconds. Dynamic bottom deformation simulation technique and 3D model had been described in the paper (Bolshakova et al. 2011).

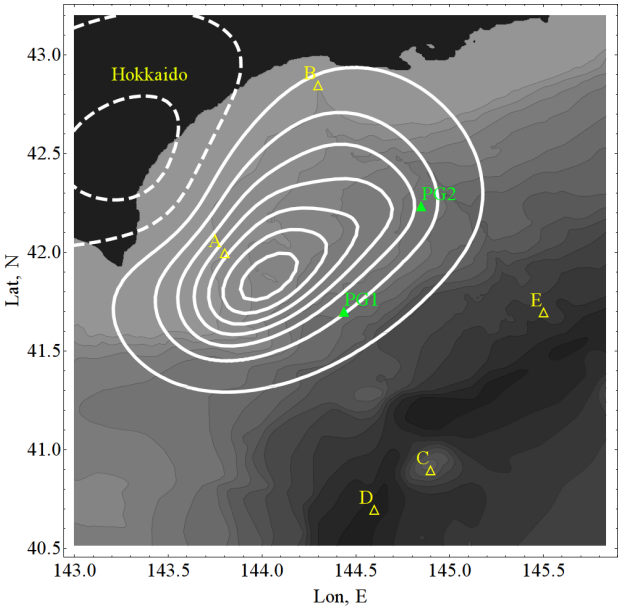

Figure 1. Calculating area. Vertical coseismic bottom deformation is shown by solid (uplift) and dashed (subsidence) white contours at 0.2-m intervals. Locations of virtual tide-gauges are shown with triangles.

3. RESULTS AND DISCUSSIONS

The calculation area (Figure 1) spans from 143°E to 145.8°E by longitude and from 40.5°N to 43.1°N by latitude. Computational grids were build using 500 m gridded bathymetric data set of Japan Oceanographic Data Center (JODC, http://www.jodc.go.jp/). For 3D model we constructed 1001x1001x49 grid. For 2D model 1 min spacing grid was used.

Seven points were chosen to watch water level evolution: two shallow water points (A, B) with depth ~500 m, three deep-water points located in the Kuril-Kamchatka trench (C, D, E) and two intermediate points (PG1, PG2) actually located in positions of JAMSTEC bottom observatories (depth ~2500 m). In present study these points are chosen just for example. The ability of the numerical model to reproduce the in situ measured signal was discussed in Bolshakova et al. (2011).

Time-histories of water level variations for both models in aforesaid positions are shown on Figure 2. Generally, waveforms are rather similar, but there are some issues worth to mention. The main difference in behavior of water level between simulation results of 2D and 3D modeling is the existence of elastic water oscillations in the beginning of synthetic records in case of 3D modeling. The amplitude of this oscillations is significantly higher in the deeply located points (D, E). The reason for it is the existence of cutoff frequency (Levin and Nosov 2009). In points A, PG1 and PG2 signals are most similar, except the very beginning. In shallow point B there are significant differences of waveforms. That could be explained by the proximity of reflecting shore boundary condition of 3D model. In case of deep-water points (C, D and E) one can see that wave generated by dynamic tsunami source arrives later and the waveform is distorted. This is the effect of dynamic wave generation process: initially formed waves start to propagate when fault rupturing is not yet finished. It should be noted that in this particular case of Tokachi-oki 2003 earthquake bottom deformation lasted for about 50 seconds (Koketsu et al. 2004). However, during catastrophic events such as Tohoku-oki 2011 earthquake the duration of rupturing processes could lasts up to 10 minutes and even more, so we can expect that accounting of time-history of bottom deformation could be important for tsunami simulation.

PHYSICAL BASIS FOR SPECIFICATION OF NUMERICAL GRID IN TSUNAMI SIMULATION

Mikhail A. Nosov

Professor, Faculty of Physics, M.V. Lomonosov Moscow State University, Russia
nosov@phys.msu.ru

Abstract: Typical wavelength of a tsunami in the open ocean amounts to hundreds of kilometers while in the shallow water zone, due to diminishing of the phase velocity, wavelength becomes many times shorter. Moreover, in the run-up zone, due to non-linear effects the wavelength might become even shorter. This is why simple regular grids are not optimal for tsunami simulation. In present study, considering physics of tsunami generation and propagation, we suggest basic principles of specification of numerical grid for physically correct and effective tsunami simulation.

1. INTRODUCTION

The efficiency of numerical simulation for studying tsunamis has long been unanimously acknowledged by the scientific community (Levin and Nosov 2009). The first numerical experiments had been carried out by Japanese scientists (Aida 1969, Abe 1978). At present, many numerical tsunami models have been developed. Without claiming to present a full list, we shall only mention the following models: TUNAMI (Imamura et al. 2006), MOST (Titov et al. 2003), COMCOT (Liu et al. 1998), NAMI DANCE (Zaytsev et al. 2010), MGC (Shokin et al. 2008), TsunAWI (Harig et al. 2008), GeoClaw (LeVeque et al. 2011). Some numerical models have no special names, but are also actively used in various scientific groups; their descriptions can be found in papers (Fine et al. 2005, Fujii and Satake 2007, Kowalik et al. 2007, Nicolsky et al. 2011, Nosov et al. 2012).

All the models listed above are based on the theory of long waves (shallow water approximation), which deals with the equations of hydrodynamics, averaged over the vertical coordinate. Within the theory of long waves, the total three-dimensional (3D) problem is reduced to the two-dimensional (2D) one.

There are attempts of 3D numerical simulations of tsunami waves in conjunction with relevant hydroacoustic phenomena (Ohmachi et al. 2001, Nosov and Kolesov 2007, Maeda and Furumura 2011, Bolshakova et al. 2011). Nevertheless, 2D models (shallow water approximation) are used nowadays and they will be certainly used in future for the following two reasons: (1) the shallow water approximation corresponds well to the nature of tsunamis; (2) the computational cost of the 3D simulation is much higher as compared with 2D one.

Tsunamis are known as slightly dispersive waves (Levin and Nosov 2009). The serious lack of the shallow water approximation consists in the neglecting of the phase dispersion of the gravitational water waves. This is why the shallow water approximation has certain restrictions in its application for reproducing of tsunamis.

The most natural way to take the phase dispersion into account is 3D simulation based on either Navier–Stokes (e.g. Ohmachi et al. 2001) or Laplace equation (potential theory) (e.g. Nosov and Kolesov 2007). The second way is 2D simulation based on Boussinesq-type approximation. This approximation allows reproducing slightly dispersive waves. The following tsunami numerical models employ Boussinesq-type approximation: FUNWAVE (Shi et al. 2012), COULWAVE (Lynett et al. 2003), GloBouss (Løvholt et al. 2010). The third way consist in the substituting of the phase dispersion by the numerical dispersion (Burwell et al. 2007). In our opinion, such approach is fundamentally incorrect and can not be recommended for wide use.

The most wide-spread method for numerical solution of partial differential equations in tsunami models is the finite difference method (FDM). As a rule, FDM employs structured (regular) grids. With use of the nested-grid approach a fine grid resolution can be specified in some predefined areas of computational domain (e.g. TUNAMI, MOST, NAMI DANCE, MGC).

In solving equations in tsunami models the finite element method (FEM) and unstructured grids are often used as well (Piatanesi et al. 1999, Walters 2006, Harig et al. 2008, Zhang and Baptista 2008, Androsov et al. 2011). FEM is more difficult as compared to FDM. But FEM has important advantage: unstructured grids can be easily adapted for any shape of calculating area, and allow a grid condensation where the increased spatial resolution is required.

Recently, the very promising approach – adaptive mesh refinement – came into the practice of tsunami simulation (LeVeque et al. 2011, Popinet 2012). The main idea of this approach consists in a dynamic grid (mesh) refinement where and when it is needed. The only

disadvantages of such a method are its excessive complexity and additional computational cost which is needed for the dynamic adaptation of computational grids. Indeed, the dynamics of tsunami waves in the open ocean is fully linear. Thus, the wave transformation obeys well-known linear laws and no need to vary the mesh in time. The space increment of the computational grid can be specified simply as a function of ocean depth.

However, the method of adaptive mesh refinement is likely the best choice for non-linear phase of tsunami evolution (propagation in shallow water including run-up on shore) when the solution of non-linear equations is really unpredictable.

The purpose of this paper is to suggest physical basis for specification of numerical grid in tsunami simulation. The main attention will be paid to correct determination of the space increment of computational grid that provides adequate and effective reproduction of tsunami waves. It is obvious that tsunami wavelength undergoes significant changes during the propagation. In each time-spatial domain the space increment must be small enough to reproduce the shortest wavelength. A grid with a fixed space increment can not be the optimal choice. Effective numerical model must employ computational grids with a variable space increment (adaptive grids) that is a certain function of horizontal coordinates.

The following three stages are traditionally distinguished in the life of a tsunami: generation of the wave, its propagation in the open ocean and its interaction with the coast (run-up). Such a division is related to the existence of essential differences in the physical processes controlling one or another stage. Thus, principles of grid specification have to vary from one to another stage. Particular features of grid specification at each stage we shall consider in the sections entitled "Generation", "Propagation" and "Run-up".

2. GENERATION

Let us restrict our consideration to tsunami generation by bottom disturbances. It might be either co-seismic bottom deformation or submarine landslide. In the open ocean tsunami amplitude (or bottom deformation amplitude) is much smaller than ocean depth. It gives us ground to consider tsunami generation and propagation as a linear process (Levin and Nosov 2009).

As is had been shown in (Levin and Nosov 2009, Nosov and Kolesov 2011) the spatial spectrum of the free surface displacement generated by any bottom disturbances is always modulated by a rapidly damped function, $1/\cosh(kH)$, where H is the ocean depth, $k = 2\pi/\lambda$ is the wave number and λ is the wave length. So, inhomogeneities of bottom deformations of scale $\lambda < H$ are not manifested on the water surface. All such inhomogeneities turn out to be smoothed out by the liquid column ("smoothing effect").

It is worth emphasizing that direct transfer of bottom deformations up to the water surface (traditional approach) artificially enriches the spectrum of the tsunami at the expense of unrealistically short waves. Being a sort of noise, these short waves may lead to artificial resonances in bays and finally to incorrect estimations of run-up heights or even to instability in the numerical calculations. Moreover, the numerical description of the short wave components requires very fine grids and, therefore, very small time steps. Ultimately, the imperfectness of the traditional approach may also result in a significant increase in the calculating time in numerical simulations of tsunamis.

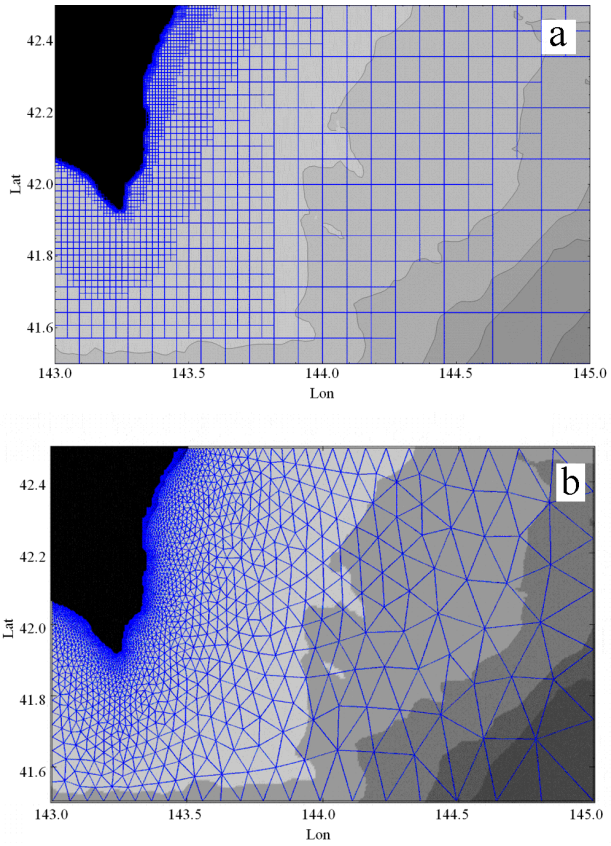

Figure 1 Adaptive Cartesian (a) and triangular (b) grids

In our publication (Nosov and Kolesov 2011) we suggested an improved practical method of calculating the initial elevation from the solution of the 3D problem in the framework of potential theory. The method takes into account horizontal and vertical components of co-seismic bottom deformation and the "smoothing effect".

Due to the existence of "smoothing effect" the shortest wavelength can be unambiguously determined as follows:

$$\lambda_{min} = H \,. \qquad (1)$$

Note that formula (1) remains valid in the case of dynamic bottom deformation as well.

For definiteness, let us assume the space increment to be equal to a half of the shortest wavelength. Therefore, within the source area, the space increment can be specified

by the following simple formula:

$$\Delta_G \le 0.5\,\lambda_{min} = 0.5\,H\,, \qquad (2)$$

where H is the ocean depth in a given point of calculating domain (Lon, Lat). Such definition for the space increment inside of tsunami source clearly requires the implementation of computational grids with a variable space increment. Grid refinement that follows the change of water depth is shown in Fig. 1. Adaptive Cartesian grids (Fig 1 a) or adaptive triangular grid (Fig 1 b) are usually associated with FDM and FEM, respectively.

Theory of tsunami generation also allows us to determine the minimal period of surface gravitational wave that can be excited at a given water depth as follows:

$$T_{min} = \sqrt{H/g}\,. \qquad (3)$$

where g is acceleration due to gravity. Note that this period is very short as compared with tsunami period (100-10000 s). According to formula (3), the minimal period vary approx. from 1 to 30 s (for $10<H<10000\,m$). It is important to stress that such gravitational waves are dispersive waves which can not be described within non-dispersive shallow water theory. We also have to point out the following fact. Being generated at the depth of (e.g.) $H = 100m$, the shortest wave has length of $\lambda = H = 100m$ and its period is of $T = \sqrt{H/g} \approx 3.2\,s$. During the propagation of the shortest wave toward deep water areas, according to the dispersion relation for gravitational waves, $\omega^2 = gk\,tanh(kH)$, the wave length does not virtually change. It means that the space increment of computational grid must be as small as $\Delta \le 0.5\,\lambda = 50\,m$ everywhere. This is both impossible and no optimal. Anyway in reality the waves of such short-periods are certainly generated in the tsunami source. But one should bear in mind that due to the phase dispersion the short waves propagate much slower than the tsunami front. So, if a non-dispersive model is in use, the short waves must not be considered because their consideration certainly results in overestimation of tsunami amplitude.

In order to avoid such an overestimation, we suggest the following approach. Let us first determine a minimal tsunami period $T_{min}{}^*$ ($T_{min}{}^* > T_{min}$) and then, according to the dispersion relation for gravitational waves, to calculate the respective wavelength $\lambda_{min}{}^*$

$$\frac{4\pi^2}{T_{min}{}^{*2}} = g\,\frac{2\pi}{\lambda_{min}{}^*}\,tanh\left(\frac{2\pi H}{\lambda_{min}{}^*}\right). \qquad (4)$$

The dependence (4), more exactly $\lambda_{min}{}^*$ versus H at given wave periods (100, 200 and 300 s), is shown in Fig. 2. Thick lines stand for calculations according to formula (4) whereas thin lines stand for simplified relation

$$\lambda_{min}{}^* = T_{min}{}^*\sqrt{gH}\,, \qquad (5)$$

which is valid in the case of non-dispersive shallow water approximation.

It is seen from the Fig. 2 that if one assume $T_{min}{}^* = 100\,s$ the shortest wavelength in shallow water area ($H = 0.01\,km$) will be of $\lambda_{min}{}^* \approx 1\,km$. So the minimal space increment must be at least $\Delta = 0.5\lambda_{min}{}^* \approx 0.5\,km$. As water depth increases the minimal wave length (and therefore the space increment) goes up approximately as $\Delta \sim \sqrt{H}$ till water depths $H = 1\,km$. At higher depths the exact formula (4) must be used.

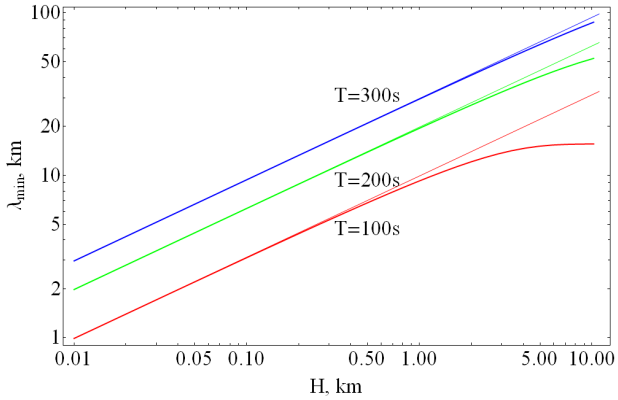

Figure 2 Wavelength at given wave periods versus water depth. Thick lines stand for dispersive theory, thin line – shallow water approximation

If one consider wave periods of 200 and 300 s the difference between thick and thin curves shown in Fig. 2 became rather small. So, if all the spectral components with periods $T < T_{min}$ are removed from the initial elevation it is possible to specify the space increment as follows:

$$\Delta = 0.5T_{min}{}^*\sqrt{gH}\,. \qquad (6)$$

The idea to specify the space increment as $\Delta \sim \sqrt{H}$ is not completely original. Such numerical grid was implemented, for example, in study (Harig et al. 2008).

Definition of the space increment (6) is approximate. More general definition which is valid without any limitations (except one – linear approximation) can be written in the following form:

$$\Delta = 0.5\lambda_{min}{}^*\,, \qquad (7)$$

where $\lambda_{min}{}^*$ is calculated from transcendent eq. (4).

3. PROPAGATION

Within the linear approximation, for a given wave-period, there is only one factor that can result in changes of wavelength – change of water depth.

Since tsunami waves are slightly dispersive, there is a certain restriction for application of non-dispersive shallow-water approximation. We shall now estimate the distance, at which manifestations of dispersion effects should turn out to be quite significant. We shall take advantage of the dispersion relation for gravitational surface waves in a liquid according to which the group velocity is determined by the formula

$$C_{gr} = \frac{\partial \omega}{\partial k} = \frac{g\left(kH / ch^2(kH) + th(kH) \right)}{2\sqrt{gk\, th(kH)}}. \qquad (8)$$

The distance of dispersive destruction of a wave, L_{cd}, can be determined as the product of the velocity of long waves by the time, required for a wave packet to lag behind the front at a distance equal to the wavelength (Kulikov et al. 1996, Levin and Nosov 2009)

$$L_{cd} = \frac{\lambda(\omega)\sqrt{gH}}{\sqrt{gH} - C_{gr}(\omega)}. \qquad (9)$$

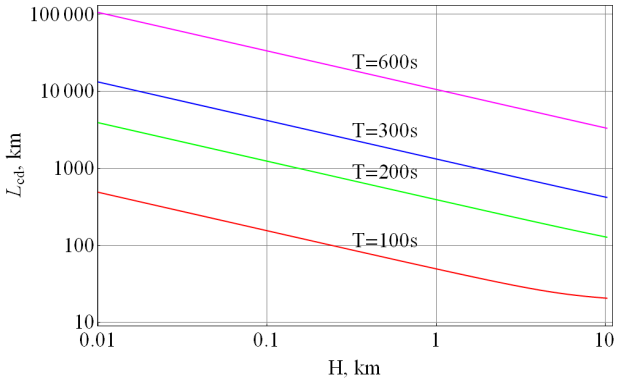

Figure 3 The distance of dispersive destruction as a function of ocean depth and wave period.

Shallow water approximation can be considered as correct approach in simulation of tsunami waves under condition that the size of calculating domain is less than the distance of dispersive destruction. In particular, Fig. 3 demonstrates that for $T_{min}* = 100\,s$ and $H = 1\,km$ the shallow water approximation is valid if size of calculating domain amounts to $L < L_{cd} \approx 50\,km$. If the period is longer, for example, $T_{min}* = 300\,s$, the size of calculating domain amounts to $L < L_{cd} \approx 1300\,km$. For simulation of transoceanic tsunamis ($L < L_{cd} \approx 22000\,km$) it is necessarily to choose $T_{min}* = 1000\,s$ and $H = 5\,km$.

If the shallow water approximation is valid the space increment can be calculated from formula (6). Models that are based on Boussinesq-type approximation have to use formula (7). In both cases smoothing of the initial elevation, i.e. the removing of spectral components of initial elevation which have periods shorter than $T_{min}*$, is the condition of great importance for correct tsunami simulation.

Shortwave disturbances on water surface during the propagation of tsunami are obliged to the following two reasons: (1) smooth change of ocean depth and (2) drastic change of ocean depth. The first issue was discussed above. The second issue is associated with the classical problem of the interaction of long waves with the abrupt (step-like) changes in the ocean depth (Fig. 4). Actually, on a discrete grid each change of water depth can be interpreted as step-like change. The key-question here is how large is such a step.

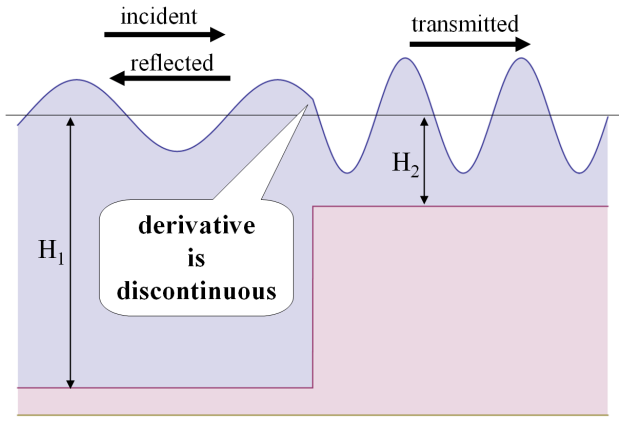

Figure 4 Interaction of long waves with step-like change in the ocean depth

Taking advantage of the continuity conditions for the free-surface displacement, ξ, and the water release, Hu, at the depth jump point, one readily derives the following relations between incident ("i"), reflected ("r" and transmitted ("t") waves (e.g. Levin and Nosov 2009):

$$x \le 0: \quad \xi_1 = A_i e^{i(\omega t - k_1 x)} + A_r e^{i(\omega t + k_1 x)}, \qquad (10)$$

$$x \ge 0: \quad \xi_2 = A_t e^{i(\omega t - k_2 x)}, \qquad (11)$$

where A_i is the amplitude of incident wave,

$A_t = \dfrac{2A_i\sqrt{H_1}}{\sqrt{H_1} + \sqrt{H_2}}$ is the amplitude of transmitted wave,

$A_r = A_i \dfrac{\sqrt{H_1} - \sqrt{H_2}}{\sqrt{H_1} + \sqrt{H_2}}$ is amplitude of reflected wave.

Typical wave profile calculated with use of formulae (10) and (11) is depicted in Fig. 4. It is seen that step-like change in the ocean depth leads to discontinuity of the first derivative of function that describes free-surface

displacement.

The derivative jump can be considered as negligible under the following condition

$$\delta \equiv \left| \frac{\left.\frac{\partial \xi_2}{\partial x}\right|_{x=0} - \left.\frac{\partial \xi_1}{\partial x}\right|_{x=0}}{\left.\frac{\partial \xi_1}{\partial x}\right|_{x=0}} \right| << 1 . \qquad (12)$$

Taking into account (10), (11) after simple transformations of relation (12) we arrive at the condition

$$\delta = \frac{|H_2 - H_1|}{H_2} << 1 . \qquad (13)$$

Ultimately, assuming that $|H_2 - H_1| \approx |grad\, H| \cdot \Delta$, we obtain the following condition for the space increment:

$$\Delta << \Delta_c \equiv \frac{H}{|grad\, H|} . \qquad (14)$$

So, in order to avoid numerical instability due to generation of shortwave disturbances at drastic changes of water depth it is necessarily to specify the space increment in accordance with formula (14).

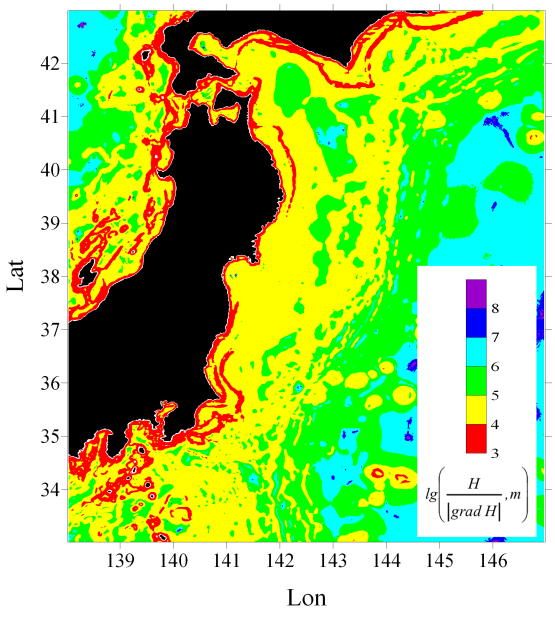

Figure 5 Function (14) calculated for part of Pacific in the vicinity of Japan (bathymetry – GEBCO).

Fig. 5 demonstrates that in shallow water areas the value of Δ_c can reach 1000 m (red areas). Within these areas the space increment must be at least 10 times smaller, i.e. $\Delta < 100m$. The same condition applied to yellow areas gives $\Delta < 1000m$.

4. RUN-UP

This section will be the shortest one. The point is that due to nonlinearity a simple and general physical outcome is next to impossible. Indeed, in the run-up zones, including shallow water areas, the behavior of tsunami become essentially non-linear. In particular, tsunami currents due to their interaction with a very complex topography and human made structures become turbulent, i.e. unpredictable in their small details. Present level of computational technique does not allow direct numerical simulation of turbulent currents of geophysical scales. Nowadays simulation of turbulent currents is mostly based on the Reynolds-averaged Navier–Stokes (RANS) equations. Tsunami run-up simulation definitely must employ not Navier–Stokes but RANS equations.

Let's go back to the problem of numerical grid. In our opinion, the method of dynamic adaptive mesh refinement (LeVeque et al. 2011, Popinet 2012) is here the best choice. Indeed, in contrast to linear problems, solutions of non-linear equations often turn out to have unpredictable details. Thus, a dynamic adaptive grid (mesh) that allows a grid condensation where and when the increased spatial resolution is required, is really a perfect solution. Alternative choice is usual structured grid with a constant and rather fine space increment.

Abstract: After the 2011 off the Pacific coast of Tohoku Earthquake, Japanese government changed their policy for huge tsunami. The former policy was to defend tsunami inundation by only civil engineering structures for example seawalls and tide embankments. However, in the new policy, they allow a part of tsunami come over the coastal structures and flood inland in the case of very rare tsunami, while expecting to reduce tsunami damage by various methods. Under the current situation, industrial companies near coast are required to make their own measures for tsunami. Their plans have to include not only precaution against tsunami forces but also precaution against the submerged effect of their facilities especially. In this study we developed 3D tsunami simulation to assist the designers in planning above. As one of demonstrations, we show a tsunami inundation simulation of a building of two stories above the ground and one underground story.

1. INTRODUCTION

The 2011 off the Pacific coast of Tohoku Earthquake (Mw 9.0) occurred on March 11, 2011 at 14:46 local time. 15,879 fatalities, 2,712 missing, 6,126 wounded persons, 129,724 collapsed and 267,666 seriously damaged houses are reported as casualties and damage of this earthquake from National Police Agency on December 26, 2012. The great part of this damage was caused by tsunami, and the earthquake magnitude, the tsunami and the devastating damage were the largest in Japanese history on record.

This event changed basic design idea against tsunami. Before the event, Japanese government have been planning inland cities on the assumption that tsunamis could not flood beyond coastal structures which were designed against highest recorded high water level in the planning region. However the 2011 Tohoku tsunami made it clear that the highest recorded level is not necessarily maximum height for a very rare tsunami. Therefore, after this event, the government changed their basic design idea. That is to give up resisting a huge tsunami by only coastal structures and to allow some part of tsunami flood inland.

From a viewpoint of an architect, the above change has great significance. The reason is that architects do not need to consider tsunami forces before the event; however, even if a building is located inland, they have to consider tsunami related forces as needed. Moreover, not only the forces but also the effect of water inundation into the building is also important and designers are required to consider them.

In the way described above, related to tsunami, the points expected for designers drastically changed. But, in the present situation, it is difficult for them to consider all of tsunami effects, especially the effect of the water inundated into the inside a building. Therefore we aimed to develop 3-D tsunami simulation to assist designers to plan and build buildings.

In this study, for the purpose above, we first describe an overview of the damage. Then we explain tsunami simulation method and finally perform a tsunami simulation as one of examples.

2. OVERVIEW OF TSUNAMI DAMAGE IN THE 2011 TOHOKU TSUNAMI

Figure 1 shows the tsunami inundation heights and run-up heights of this event (Mori *et al.* 2012). Tsunami run-up heights were over 20 m around from 38 to 40 degree north latitude and the maximum run-up height was about

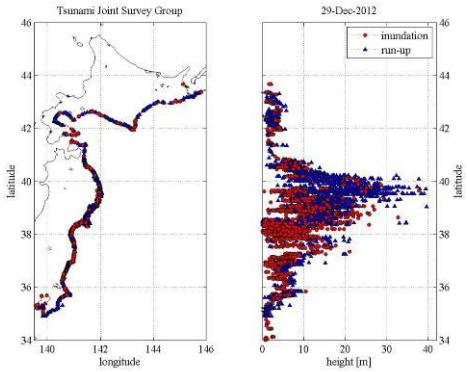

Figure 1 Measured Tsunami height (Mori *et al.* 2012)

Figure 2 Broken seawalls in Taro

Figure 3 A broken breakwater in Kamaishi

Figure 4 Damage of walls on a RC building in Onagawa

Figure 5 An overturned building in Onagawa

Figure 6 RC buildings standing close behind Onagawa port

Figure 7 A RC building standing close behind Kamaishi port

40.0m. The catastrophic tsunami broke coastal structures along the coast of Tohoku region. Seawalls in Taro and breakwater in Kamaishi, which were regarded as the largest seawall and breakwater, were also broken (Figure 2 and 3).

The tsunami flooded inland caused much damage of buildings standing on land. Figure 4 and 5 shows damage of RC structures in Onagawa, which is one of the devastated areas, and some characteristic damage of building could be seen there. Figure 4 shows damage of RC walls. Left side walls were cracked on the whole and right side walls were pushed out to the outside. Figure 5 shows an overturned building. Overturned building as tsunami damage was new damage pattern seen in this event. From the report (for example, NILIM and BRI 2011), there were 6 overturned buildings and numbers of those floors were lower than 4 stories.

While many structural damages of buildings could be seen for low rise building, high rise buildings or substantial buildings remained without any structural damage or with less structural damage. Figure 6 shows a RC building standing close behind Onagawa port. It is located closer to sea than buildings in Figure 4 and 5. A bridge connecting

with right and left buildings fell down, however, main body of the building looks sound. Similarly, a high rise building standing close behind sea in Kamaishi looks sound in Figure 7.

From the above, when we design buildings against tsunami, it is important to consider not only tsunami forces acting on the building but also the effect of water inundation into the inside of buildings to restore them rapidly after a future event.

3. NUMERICAL METHODOROGY

Flow-3D is a general purpose CFD package that is used to solve transient and three dimensional flow problems. It was developed by Flow Science, Inc., and has a comprehensive track record in CFD modeling. Though, the application in modeling tsunami on building is a new attempt. Flow-3D is developed based on the fractional volume of fluid (VOF) free surface tracking method as discussed in Hirt and Nichols (1981). Under this method, cells are defined with a value between zero and one for empty to fully filled cells with fluid. For partially filled cells, the slope of the free surface is determined by an algorithm that uses the surrounding cells to define a surface angle and a surface location. This method allows the steep fluid slopes to be defined and it is applicable to describe the breaking wave (bore or surge) in tsunami run-up zone.

The model used in this research is an incompressible and viscous flow model. Flow-3D employs the finite difference method to solve the fluid equations of motion. The computational domain is defined in a fixed rectangular grid. The fluid momentum equations, Navier -Stokes equations, can be expressed as follows (Flow-3D, 2007),

$$\frac{\partial u}{\partial t}+\frac{1}{V_F}\left(uA_x\frac{\partial u}{\partial x}+vA_y\frac{\partial u}{\partial y}+wA_z\frac{\partial u}{\partial z}\right)=-\frac{1}{p}\frac{\partial p}{\partial x}+g_x+f_x$$

$$\frac{\partial v}{\partial t}+\frac{1}{V_F}\left(uA_x\frac{\partial v}{\partial x}+vA_y\frac{\partial v}{\partial y}+wA_z\frac{\partial v}{\partial z}\right)=-\frac{1}{p}\frac{\partial p}{\partial y}+g_y+f_y$$

$$\frac{\partial w}{\partial t}+\frac{1}{V_F}\left(uA_x\frac{\partial w}{\partial x}+vA_y\frac{\partial w}{\partial y}+wA_z\frac{\partial w}{\partial z}\right)=-\frac{1}{p}\frac{\partial p}{\partial z}+g_z+f_z \qquad (1)$$

where u, v and w are the velocities in the x-, y- and z-directions; V_F represents the volume fraction of fluid in each cell; A_x, A_y and A_z are the fractional areas open to flow in the x-, y- and z-directions; ρ is the fluid density; p is the fluid pressure; g_x, g_y and g_z are the body accelerations in the x-, y- and z-direction and f_x, f_y and f_z are the viscous accelerations in the x-, y- and z-direction for which a turbulence model is required. For cells fully filled of fluid, V_F, A_x, A_y and A_z equal to one.

For an incompressible fluid, the following condition (i.e. continuity equation) must hold:

$$\frac{\partial}{\partial x}(uA_x)+\frac{\partial}{\partial y}(vA_y)+\frac{\partial}{\partial z}(wA_z)=0 \qquad (2)$$

Boundary conditions are categorized as rigid-free or no-slip walls, continuative outflow, periodic and specific pressure boundaries. No flux is allowed to cross the wall boundary; however, viscous shear stresses occur at the wall boundary.

The computational domain was discretized into an orthogonal and staggered grid of variable-sized hexahedral meshes in a Cartesian coordinates. Due to the complex building model, multi-block gridding with nested and linked grids were applied in order to reduce the computational cost. Under this discrete structural grid system, average values of the flow parameters were placed at the center of each cell (for pressure and fractional volume of fluid) and the center of cell faces normal to their associated direction (for velocity).

The basic algorithm for the computation consists of three main steps. The first step is the computation of flow velocity based on the initial conditions or previous time-step values from the explicit approximations of Navier-Stokes Equations. Next, the pressure values will be adjusted to satisfy the continuity equation. It is followed by the determination of the fluid free surface or interface and update of the new fluid configuration based on the VOF method. This computation is then advanced to the next time-step and those three steps are repeated.

On top of that, structures are constructed as obstacles in the numerical model. The flow obstacle is defined using a porosity technique in rectangular cell meshes called the Fractional Area/Volume Obstacle Representation (FAVOR) method as outlined in Hirt & Sicilian (1985). For cells without obstacle, the grid porosity is one and the fluid dynamic equations are to be hold. In contrast, the grid porosity is zero for cells within obstacle where no flow volume is allowed in the obstacle region. For cells that are partially filled with an obstacle, the grid porosity has a value between zero and one, based on the percent volume that is open. The surface angle and the surface location are determined based on the same principal of VOF as stated.

4. SIMULATION OF WATER INUNDATION INTO THE INSIDE OF A BUILDING

As a demonstration, we performed a three dimensional simulation with a building. The building model shown in figure 8 is used. This building has two stories above the ground and one underground story. A cross section of this building is shown in Figure 9. In this simulation, some of interiors, for example, stairs and tables are contained. This model including structures and interiors are regarded as rigid.

Figure 10 shows calculation areas of this simulation. The calculation areas consist of four parts. Cyan area is nested in blue one, and yellow and green ones are connected

to blue and cyan ones respectively. Though mesh sizes of each area are variable, the averages of those are 0.5 m in yellow area, 0.25 m in blue area and 0.125 m in cyan and green areas. Calculation time step, dt, is adjusted during the iteration to meet stability condition. As boundary conditions, we input 3m high water level to the yellow mesh in the direction shown in Figure 10 and allow the water go out through the one surface of blue mesh.

Figure 11 shows snapshots of the simulation results. From the snapshots, the water splashed in front of the building and the water flooded through the windows and stairs are simulated qualitatively. Though quantitative evaluation is the next subject, the behavior of water looks simulated well.

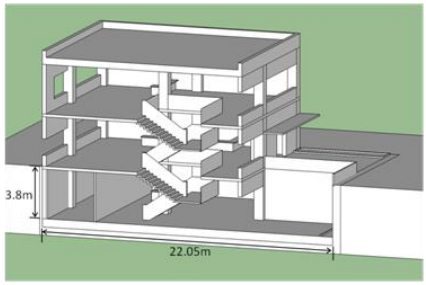

Figure 9 A cross section of the model

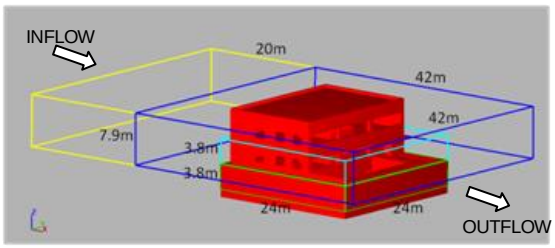

Figure 10 Calculation area

5. CONCLUSION

We performed 3-D tsunami simulation for water inundation into the inside of a building. Though the present case is just a demonstration, in the next step we will evaluate the physical values of the results and apply it for measures for tsunami.

Abstract: This paper presents the large-scale simulation of the failure of structure due surge front tsunami impacts. In order to simulate the crack propagation, the PDS-FEM which can treat discontinuous interpolation function is introduced into ADVENTURE_Solid open source framework which has highly parallel performance option. And tsunami wave propagation is simulated by solving three dimensional Navier-Sokes equation with free surface. The interface capturing technique based on VOF method is used to express the complicated free surface shapes such as a hydraulic jump and breaking wave. For the large scale The parallel computation based on OpenMP/MPI hybrid parallelization is used to reduce the computational time and to distribute the memory usage on large-scale problem.

1. INTRODUCTION

The protection systems for tsunami like seawalls and breakwaters must have an enough performance to be proof against the tsunami impacts. And the mechanism of crack growth and failure of concrete must be clarified to estimate the damage of such a protection systems under the tsunami impacts. In the numerical simulation of failure of concrete by wave force, high resolution mesh is required in order to estimate the small crack propagation and to evaluate the tsunami impact force accurately, and high resolution mesh requires a significant memory and computational time.

We develop the large-scale simulation of the failure of structure due surge front tsunami impacts. In order to simulate the crack propagation, the PDS-FEM which can treat discontinuous interpolation function is introduced into ADVENTURE_Solid open source framework which has highly parallel performance option. And tsunami wave propagation is simulated by solving three dimensional Navier-Sokes equation with free surface. The interface capturing technique based on VOF method is used to express the complicated free surface shapes such as a hydraulic jump and breaking wave. For the large scale the parallel computation based on OpenMP/MPI hybrid parallelization is used to reduce the computational time and to distribute the memory usage on large-scale problem. In this paper, the fluid and structure simulation code is not interaction strongly, yet. So this is our future work.

2. NUMERICAL FORMULATION OF FREE SURFACE FLOW

2.1 Governing Equations of Fluid

To model of free surface, we consider two immiscible fluids, α and β, with densities ρ_α and ρ_β, and viscosities μ_α and μ_β. The interface function ϕ serves as a marker identifying fluids α and β with the definition $\phi = \{1$ for fluid α and 0 for fluid $\beta\}$. In this context, the density and viscosity, ρ and μ, are defined as

$$\rho = \phi\rho_\alpha + (1-\phi)\rho_\beta, \tag{1}$$

$$\mu = \phi\mu_\alpha + (1-\phi)\mu_\beta. \tag{2}$$

The time dependent of interface function is governed by a following advection equation

$$\frac{\partial \phi}{\partial t} + \mathbf{u}\cdot\nabla\phi = 0 \quad \text{on } \Omega \tag{3}$$

The velocity $\mathbf{u}$ is obtained from the solution of Navier-Stokes equations:

$$\rho\left(\frac{\partial \mathbf{u}}{\partial t}+\mathbf{u}\cdot\nabla\mathbf{u}-\mathbf{f}\right)-\nabla\cdot\sigma(\mathbf{u},p)=0 \quad \text{on } \Omega, \tag{4}$$

$$\nabla\cdot\mathbf{u}=0 \quad \text{on } \Omega, \tag{5}$$

where p is the pressure and $\mathbf{f}$ is external body force.

2.2 Finite Element Formulations

The stabilized finite element formulation of Eq. (3) can be written as follows:

$$\int_{\Omega}\psi\left(\frac{\partial\phi}{\partial t}+\mathbf{u}\cdot\nabla\phi\right)d\Omega + \sum_{e=1}^{n_{el}}\int_{\Omega_e}\tau_{IC}\nabla\psi\cdot\nabla\phi\,d\Omega=0, \tag{6}$$

where τ_{IC} is the stabilization parameter.

The stabilized finite element formulation based on SUPG/PSPG (Streamline-Upwind Petrov Galerkin/Pressure Stabilizing Petrov Galerkin) method of the governing equations of fluid Eq. (4), (5) can be written as follows:

$$\begin{aligned}&\int_{\Omega}\mathbf{w}\cdot\rho\left(\frac{\partial\mathbf{u}}{\partial t}+\mathbf{u}\cdot\nabla\mathbf{u}-\mathbf{f}\right)\mathrm{d}\Omega\\&+\int_{\Omega}\varepsilon(\mathbf{w}):\sigma(\mathbf{u},p)d\Omega+\int_{\Omega}q\nabla\cdot\mathbf{u}\,d\Omega\\&+\sum_{e=1}^{n_{el}}\int_{\Omega_e}\left(\tau_S\mathrm{u}\cdot\nabla\mathrm{w}+\frac{1}{\rho}\tau_P\nabla q\right)\\&\qquad\cdot\left[\rho\left(\frac{\partial\mathrm{u}}{\partial t}+\mathbf{u}\cdot\nabla\mathbf{u}-\mathbf{f}\right)-\nabla\cdot\sigma(\mathrm{u},p)\right]d\Omega\\&+\sum_{e=1}^{n_{el}}\int_{\Omega_e}\tau_C\nabla\cdot\mathbf{w}\,\rho\nabla\cdot\mathbf{u}\,d\Omega=\int_{\Gamma}\mathbf{w}\cdot\mathbf{h}\,d\Gamma,\end{aligned} \tag{7}$$

where τ_S, τ_P and τ_C are the stabilization parameters. And $\mathbf{h}$ represents the Numann boundary condition of momentum equation.

For the temporal discretization, interface function ϕ, velocity $\mathbf{u}$ and pressure p are discretized by using Crank-Nicolson method.

From the above discretization in space and time, a linear equation system can be obtained. GP-BiCG method is used to solve the linear equations. In larger scale problem this procedure takes long computational time and huge memory usage. In order to reduce them, the MPI and OpenMP hybrid parallelization is implemented.

3. NUMERICAL FORMULATIONS OF FAILURE ANALYSIS

3.1 Formulation of PDS-FEM

Cracking functionality is implemented in modern FEM packages. However, it is not suitable to analyze the complicated cracking processes in concrete. This is mainly because this functionality is developed to analyze a single crack or a few cracks which are initiated and propagate in two-dimensional state of plane stress. Furthermore, the functionality is not able to determine the configuration of multiple cracking, which is two-dimensional curved or branched surfaces in a three-dimensional body; it should be recalled that ordinary fracture mechanics is aimed at analyzing a two-dimensional crack of mode I, II or III.

A major difficulty in numerically analyzing multiple cracking in concrete is to determine the crack configuration, which includes branching and kinking. Local crack configuration depends on local strength, which, of course, is not uniform for composite materials like concrete; moreover, local strength is not measured until that point is actually broken. This strong dependence of local cracking on local strength is a source of variability in cracking.

We develop a new numerical treatment of local cracking, which may lead to multiple cracking. Since crack is displacement discontinuity, we introduce a set of basis functions which are not continuous like basis functions used in ordinary FEM. The set uses characteristic functions of Voronoi tessellation of an analysis domain. Since neighboring basis function has discontinuity along the Voronoi boundary, it will give a candidate of possible local cracking; discontinuity that corresponds to multiple cracking is readily provided by such a candidate.

When the set of characteristic functions are employed as basis functions of discretizing a function, it is impossible to calculate the derivative in terms of the same basis functions. Another set of characteristic functions are thus employed to discretize the derivative, and it is a natural choice to use the characteristic functions of the conjugate Delaunay tessellation; it is mathematically shown that the pair of conjugate Voronoi and Delaunay tessellations provides an optimal pair of discretizing a function and its derivation.

The governing equation dynamic elastic-plastic body is written as follows:

$$\frac{\partial\mathbf{v}}{\partial t}-\nabla\cdot\sigma(\mathbf{v})=\mathbf{F} \quad \text{on } \Omega \tag{8}$$

Here, $\mathbf{v}$ is displacement. Denoting by φ^{α} and ψ^{α} the characteristic functions of the α-th Voronoi block and the β -th Delaunay block, respectively, we discretize a displacement function and its gradient, $\mathbf{v}$ and $\nabla\mathbf{v}$, as follows:

$$\mathbf{v}(\mathbf{x}) = \sum_{\alpha} \mathrm{v}^{\alpha} \phi^{\alpha}(\mathbf{x}), \tag{9}$$

$$\nabla \mathbf{v}(\mathbf{x}) = \sum_{\beta} (\nabla \mathbf{v})^{\beta} \psi^{\beta}(\mathbf{x}) \tag{10}$$

where $\mathbf{v}^{\alpha}$ is shape function based on Voronoi diagram on block Ω^{α}. ϕ^{α} satisfies $\phi^{\alpha} = 1$ for $\mathbf{x} \in \Omega^{\alpha}$ and $N^{\alpha} = 0$ for $\mathbf{x} \notin \Omega^{\alpha}$. So, the finite element mesh for PDS-FEM is as shown in Figure 1. In this figure, red line shows Voronoi tessellation for Eq.(9), the black and blue lines show Delaunay tessellation for Eq.(10). And the distribution of displacement and strain field in finite element are as shown in Figure 1, respectively. From this discontinuous shape function, the PDS-FEM has the efficiency at the interface of crack. More details were discussed by Hori et al. (2005).

The PDS-FEM formulation is implemented into ADVENTURE_Solid open source framework, which is developed in ADVENTURE project. The parallelization scheme of ADVENTURE_Solid is based on domain decomposition method (Miyamura et al. 2002). For the temporal discretization for the governing equation, we used Newmark's β method.

4. NUMERICAL EXAMPLE

4.1 Distraction of Concrete Structure due to Tsunami Wave

We used the verified the developed program to compare the experimentally observed. The experiment have been done by the Port and Airport Research Institute (PARI) of Japan in Arikawa et al. (2007). The model of experience is shown in Figure 3. And three dimensional finite element mesh of fluid domain is shown in Figure 4, which has about 2 millions nodes and 10 millions tetrahedral elements and minimum element size is 0.1m. The tsunami wave height is about 2.5m, which is generated by the wave generator located the left side at Figure 3.

As the numerical results, figure 5 shows the time history of pressure at the surface of concrete wall (observed location is shown in Figure 6). In this figures, time starts when the wave reaches to the wall. The computed results are in good agreement with the experimental results. The free surface shapes are shown in Tanaka et al. (2012).

The time snap of pressure distribution at the surface of concrete wall, which obtained by this wave propagation simulation, will be passed to the dynamic structure analysis based on PDS-FEM as the input loading data. Model of concrete wall is as shown in Figure 6 and the thickness of concrete wall is 6cm. Figure 7 shows a finite element mesh for this model. The minimum element size is 2mm, which is appeared around steel bar. Total number of nodes of this model is 1.7 millions, and total number of elements is 10 millions tetrahedral elements.

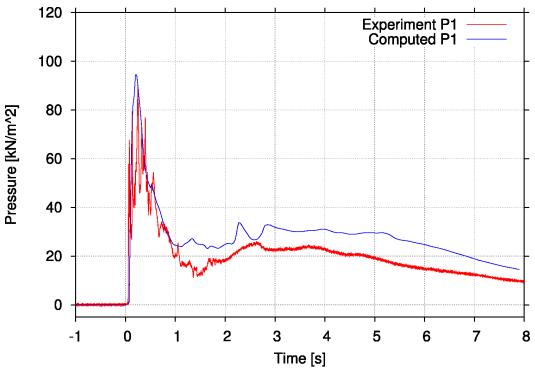

Figure 5 Time history of pressure at P1

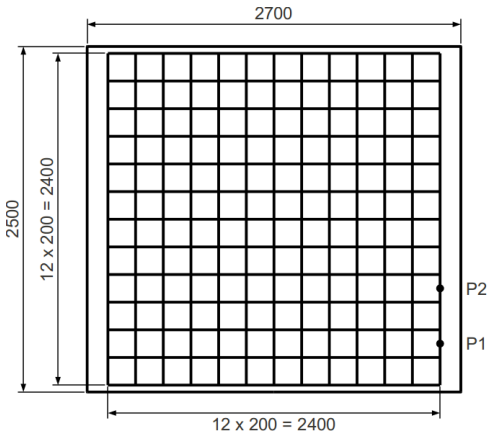

Figure 6 Geometric details of concrete wall

The pressure distribution from the fluid analysis on the concrete wall is converted to nodal force for input loading of structure analysis. The results of failure analysis using PDS-FEM is shown in the Figure 9. From this figure, the PDS-FEM can treat the Also we plan to develop the coupling scheme for fluid and structure analysis to interact between the tsunami impacts and displacement of structure on their interfaces.

5. CONCLUSIONS

We have developed a failure analysis method concrete structure by tsunami wave impact. We show the results of tsunami wave propagation simulation in large hydro flume. And failure simulation based on PDS-FEM. The presented scheme can simulate complicated multiple-cracking propagation successfully. At the next stage, we will plan to develop a FSI scheme to couple the tsunami wave force and failure analysis, and developing the large-scale simulation system on the super computer.

Abstract: From the experiences of gigantic tsunami events, authorities from communities at risk have been struggling to raise the tsunami awareness on residents. Since the 2004 Indian Ocean tsunami, Thailand had realized its exposure condition to such phenomena. Thailand was one of the most affected countries with a large amount of casualties including tourists from around the world. After the event, tsunami related information, support and technology to improve tsunami knowledge and awareness, evacuation signs, hazard maps, warning towers and numerical modeling are contributing to build a resilient community among the affected areas. It is also important to evaluate evacuation procedures as people's awareness might decrease with time when non-threatening event occurred. This paper starts by showing an analysis of human loss in Thailand and compared with Japan to show the importance of evacuation. Then, a tsunami evacuation model was then applied with the tsunami numerical simulation to evaluate the present location of tsunami evacuation shelters, the number of evacuees at each haven and the number of possible casualties for a multiple possible scenarios of combined means of evacuation, by walk or on vehicle and population distribution. Results show the feasibility of evacuation for the majority of residents under a balanced condition of evacuees on foot and evacuees on vehicles. An excessive use of vehicles might lead to undesired outcomes when the amount of evacuees increases.

1. INTRODUCTION

Throughout the years of tsunami disasters experienced around the globe, several lessons have been identified, understood and addressed by scientists, authorities and communities. For instance, after the 2004 Indian Ocean tsunami, the importance of tsunami warning systems was highlighted; at the same time awareness and knowledge of tsunami were promoted due to the aftermath observed in Indonesia, Thailand and Sri Lanka. In the 2010 Chilean tsunami, it was reported that several residents followed experiences and teachings of the 1960 Chilean tsunami, in some cases with successful outcomes. The March 11th, 2011 Japan tsunami showed to the world that tsunami warning systems, tsunami hazard maps and even structural countermeasures alone, will never be enough to save the total population at risk. However, preparedness, immediate action and an adequate system of safe havens, deployed around the possible affected area of an extreme scenario, might strongly contribute to increase the probabilities of escaping from tsunami.

In this paper, we will explore the experience of 2004 tsunami in Thailand and compared the human losses to the 2011 Japan case to stress the importance of evacuation procedures. Next, we will evaluate the feasibility of evacuation in a populated area of the Phang Nga province in Thailand, to show the advantages of the evacuation simulation technique. Results and discussions of the multiple scenarios to evaluate here may contribute to the preparedness and future improvement of the evacuation procedure at this community. The methodology used here can be easily applied to other areas at risk.

2. HUMAN LOSS DUE TO THE 2004 INDIAN OCEAN TSUNAMI AND IMPORTANCE OF EVACUATION

In Thailand, the number of deaths, missing, injured and affected people were reported by each province and it is summarized in Table 1. The area of interest for this study is located in the Phang Nga region where at least 4,225 people among resident and tourists were killed. It was reported that from the 4,225 people killed, 1,389 were of Thai nationality while 2,114 were accounted as victims of foreign nationality, the remaining 722 were not identified. It is well known that the coasts of Thailand are famous for its beach resorts and tourist areas. Phang Nga province holds most of these locations and the number of foreigners killed confirmed such unfortunate fact. The Pakarang Cape at Phang Nga province was struck by a maximum tsunami height of 12.24m. Although tsunami arrived to Thailand coasts after two hours, the lack of knowledge,

experience, warning system and preparedness contributed on the resulting outcome of casualties.

Table 1 Summary of death. Missing, injury and affected population in Thailand due to the 2004 Indian Ocean tsunami. (DDPM, 2007).

Province	Death	Missing	Injured	Affected
Phang Nga	*4,225*	*1,655*	*5,597*	*19,509*
Krabi	721	544	1,376	15,812
Phuket	279	608	1,111	13,065
Ranong	159	9	246	5,942
Trang	5	1	112	1,302
Satul	6	-	15	2,920
Total	5,395	2,817	8,457	58,550

After this event, in January 2005, the Indian Ocean Tsunami Warning System was conceived and finally activated on June 2006 following the leadership of UNESCO. The lessons from the 2004 Indian Ocean tsunami were integrated on disaster prevention activities in Thailand, especially through evacuation drills in areas like Phuket. Also tsunami hazard maps and tsunami signs were installed to advice people of the risk of tsunami (Fig. 1).

Figure 1 Tsunami hazard map showing the evacuation routes and a tsunami sign marking the hazard zone in the Pakarang Cape, Phang Nga, Thailand.

In summary, from the experience of 2004 Indian Ocean tsunami, Thailand has traveled into a journey of tsunami disaster prevention and mitigation activities throughout these years. Nowadays, although it is expected for several communities to be better prepared than before, it is important to recall that nature can exceed our expectations. Such is the case of Japan latest disaster in March 11th, 2011. It might be expected that one of the countries with the largest amount of documentation on historical tsunami events would have known about the possibility of a gigantic tsunami event in the Tohoku area. Unfortunately geological times are much bigger than our recorded history, thus, still we cannot account for the known events as the worst possible events. However, despite the huge damage and extensive inundation observed in the Tohoku tsunami event, a surprising outcome is the comparatively low casualty aftermath with the 2004 Indian Ocean.

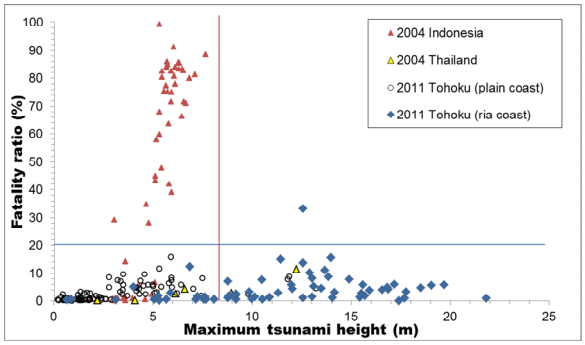

Figure 2 Fatality ratio of 2004 Indian Ocean tsunami and 2011 Japan tsunami. Although tsunami heights were bigger in the 2011 event, the fatality ratio is comparatively lower than in 2004.

In Fig. 2 it is shown that the 2011 event produced in Japan fatality ratios below the 20% of the exposed population in most areas, similarly occurred in Thailand on the 2004 event, however if we take into consideration that 2004 event arrived nearly 2 hours to the coast of Thailand and around 20min to the Japan coast; it is clearly that the Japan event could have been worse if the conditions of tsunami countermeasure, knowledge and preparedness would have been like Thailand in 2004.
Therefore, if 2004 event showed the importance of tsunami warning systems and structural protection at first, also the immediate evacuation and reaction is an important point highlighted from the beginning of tsunami experiences and somehow proven in 2011 when a great amount of population at risk in Japan flew and saved their lives at shelters and high ground.

3. FEASIBILITY OF EVACUATION: RESPONSE TIME AND CASUALTY ESTIMATION

In this study, feasibility of evacuation is evaluated based on the Human Response Capability (HRC) and the casualty estimation output for different scenarios of start time of evacuation decision and the amount of vehicles used as a mean of evacuation by the population. Following the time components described in Post et al. (2009), the Human Response Capability (HRC) can be decomposed into the Reaction Time (RT) - the time of decision to evacuate - and the Response Time (RsT) - a time of movement from an initial at risk location to a safe area (Eq. 1).

$$HRC = RT + RsT \quad (1)$$

In the model developed for this study, RT is defined through the Tsunami Departure Curves (Mas et al., 2012), a stochastic selection of evacuation decision behavior; and RsT is observed through the simulation process, varying with the percentage of vehicles involved and the emerged traffic congestion. Finally, the casualty estimation is conducted during the simulation based on the hydrodynamic features of tsunami – flow depth and velocity - and the local spatial condition of agents in the risk area. This study aims to use the 2004 Indian Ocean tsunami as an

example to evaluate tsunami evacuation process if the 2004 tsunami-type occurs again.

4. DATA AND METHODS

4.1 Study Area

The study area is near the Pakarang cape in the Khao Lak beach resort area of Phang Nga province in Thailand. The district is located at the coast of the Andaman Sea and it was devastated by the tsunami resulting from the 2004 Indian Ocean earthquake. (Fig. 3)

Figure 3 Phang Nga devastated by the 2004 Indian Ocean Tsunami - Left: Before - January 13th, 2003; Right: After: December 29th, 2004. Source: Space Imaging / CRISP-Singapore. The yellow inset shows the area simulated.

4.2 Population and shelters

The population to simulate belongs to a group of villages in the Khuekkhak subdistrict (5,172 inhabitants), in the Takua Pa district of Phang Nga province in Thailand. The total 5,172 residents are not considered as exposed population due to the spatial location of the seven villages of Khuekkhak, however the population data and its spatial distribution were provided by the Thai Meteorological Department (TMD). Finally a total of 2,649 residents were modeled. This is the night time scenario sum of population. We used a night scenario because the total is higher than the day time scenario data available. However this is a particular tourist area and higher number of population at risk might be expected; at this stage we have not included the number of estimated tourists. There are a total of 17 shelters in the inland area; these are shown in Fig. 4.

4.3 Tsunami Inundation modeling

The Tohoku University's Numerical Analysis Model for Investigation of Near-field tsunamis (TUNAMI model) was used as the tool of tsunami modeling (Imamura, 1995). The tsunami propagation is modeled from the initial sea surface displacement assumed to be similar to the initial sea bottom deformation obtained from the analytical expressions proposed by Okada (1992). A set of non-linear shallow water equations are discretized by the Staggered Leap-frog finite difference scheme to follow the tsunami propagation. The bottom friction

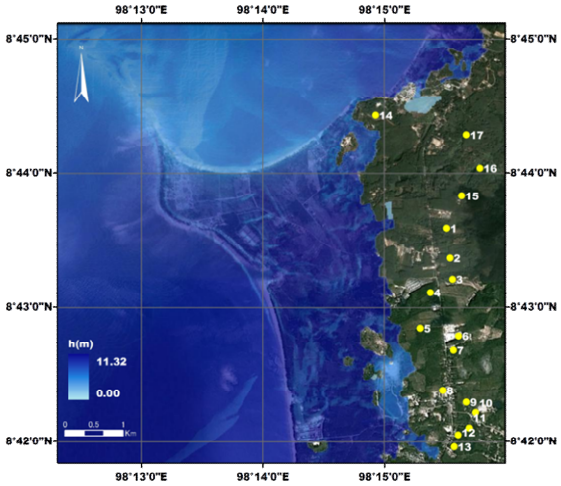

Figure 4 Area of simulation and shelters available. The maximum simulated run up height is 11.32m, closed to the 12.24m reported near the area.

condition obeys to the Manning formula and it is constant in the whole domain.

Suppasri et al. (2008) compared eight proposed source models for the 2004 Indian Ocean tsunami using measured tsunami heights and waveforms data. They concluded that the tsunami source model proposed by Koshimura et al. (2009) is the most suitable model to reproduce tsunami to Thailand. This source model was further used and adapted in various kind of others tsunami research in Thailand such as developing tsunami fragility curves for mangrove (Yanagisawa et al., 2009) dynamic effect of fault rupture velocity (Suppasri et al., 2010), boulder transport due to tsunami (Goto et al., 2010), developing tsunami fragility curves for building (Mas et al., 2012b). Finally, in this study we will use the above mentioned tsunami source model with fault parameters detailed in Table 2 and plotted on Fig. 5.

Table 2 Fault parameters for the 2004 Indian Ocean tsunami. Location of each fault with respect to the bottom left position. Source: (Suppasri, 2010)

Fault Parameters	Segment No.					
	1	2	3	4	5	6
Lat (N)	3.03	4.48	5.51	7.14	8.47	9.63
Long (E)	94.40	93.32	92.87	92.34	91.88	91.57
Strike (°)	323	335	340	340	345	7

Disloc. (m)	14	12.6	12	7	7	7
Depth (km)	10	10	10	10	10	10

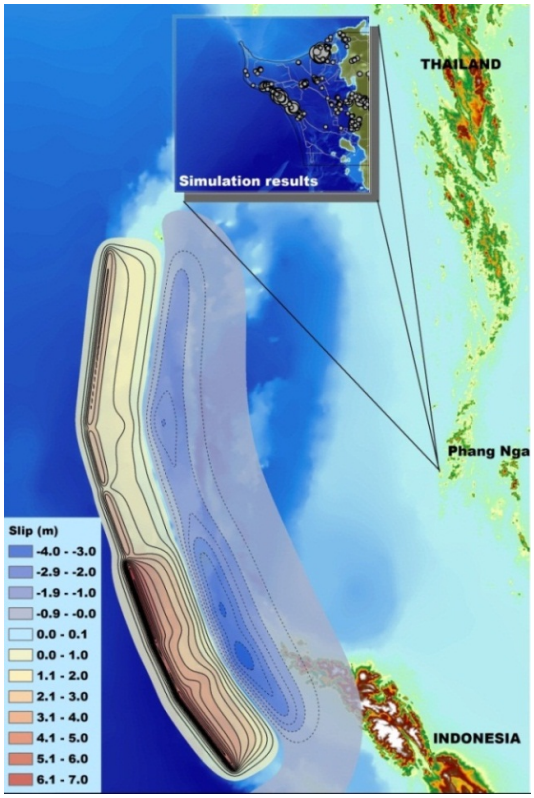

Figure 5 The source model applied on the tsunami propagation and inundation simulation. The sea deformation is located around 500km SW of the study area. The inset shows inundation results and population distribution.

The result of the numerical simulation of tsunami is shown in Fig. 5. The maximum estimated height near shore is around 12.24m and the maximum distance of inundation from the shoreline is of 1.5km to 2.0km.

4.4 Evacuation simulation

Building on the tsunami numerical simulation results in the study area, the evacuation process is evaluated for the design tsunami and several human behavior scenarios. We will explore the influence of the use of vehicles in the evacuation process combined with the different reaction time of residents. Vehicles are included in the model by assuming a set of percentage of evacuees in cars (passengers and drivers) among the population. Then 0%, 25%, 50%, 75% and 100% is discounted at each scenario from the total population and grouped in 4 passengers per car. The start time decision of evacuation for the whole population is related to the Tsunami Departure Curves (TDC), explained in (Mas et al, 2012), however instead of the stochastic method we will analyze four specific scenarios of reaction. The curves assuming a Rayleigh distribution and characterized by a mean of distribution similar to the results of a questionnaire survey applied in the area to 57 residents in different villages among Phang Nga and Phuket (south of the study area) - results are reported in Suppasri (2010), this is μ = 30min. Besides the questionnaire result distribution, another three possible scenarios are considered in the evaluation; a worst case scenario of late evacuation with μ = 120min (near the estimated arrival time of tsunami) and the intermediate scenarios of μ = 60min and μ = 90min. In Fig. 6 it is shown the rate of evacuation decision explained above with the questionnaire results provided by Suppasri (2010b).

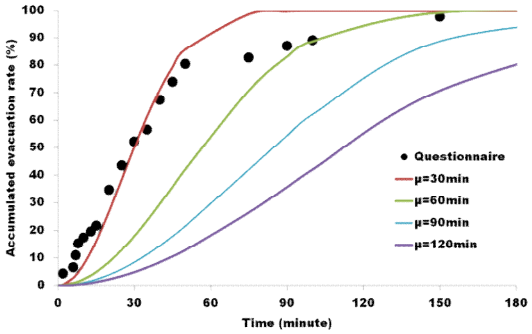

Figure 6 Evacuation decision time based on questionnaires and Rayleigh distribution curves with mean of distribution (μ) related to fast, medium and slow scenarios of evacuation decision.

5. SIMULATION CASES

We ran several cases of evacuation condition, as mentioned above the feasibility of evacuation is evaluated trough the Human Response Capability (HRC), whose components are the reaction time (RT) and the Response Time (RsT). In order to evaluate the influence of these variables, the RT is evaluated using different curves of decision for starting evacuation in the population (Fig. 6); while the RsT is related to the number of resulting casualties estimated for the scenario. Since the RsT is related to the timing of movement, which depends also on the mean of evacuation and the traffic congestion, we also included scenarios with different amount of vehicles. Therefore, the total population of 2,649 residents for the night time scenario was provided by the Thai Meteorological Department (TMD). The summary of cases is detailed in Table 3.

Table 3 Scenarios of evacuation for different start time condition and vehicle percentage.

Population in Vehicles	**Start Time of Evacuation (min)**			
	30	**60**	**90**	**120**
0%	E30V0	E60V0	E90V0	E120V0
25%	E30V25	E60V25	E90V25	E120V25
50%	E30V50	E60V50	E90V50	E120V50
75%	E30V75	E60V75	E90V75	E120V75
100%	E30V100	E60V100	E90V100	E120V100

A total of 20 scenarios where simulated using an integrated agent based model for tsunami inundation and tsunami evacuation simulation developed by Mas et al (2012).

6. RESULTS AND DISCUSSION

The result of the 20 simulated cases is shown in Table 4. The fatality ratio defined as the ratio of estimated casualties over the

total population involved in the simulation (exposed population) is shown in the last column of the table. The worst case scenario of evacuation is shown in Fig. 7 where no vehicle is involved and the total of population evacuates on foot and with a slow reaction (E120V0). In general fatality ratios varies from the 6% to the 34% of the total population to be at risk. The main reason of such variation is due to the time of reaction to start the evacuation and the mean used to evacuate to inland. It is clear on Table 4 that the highest fatality ratios occurred when no vehicle is used for evacuation. This is due to the long distance of about 2 km necessary to evacuate to the selected shelters described before (Fig. 4).

Table 4 The results of the estimated casualties at different evacuation condition

V (%)	E (μ) (min)	Safe (pers.)	Casualty (pers.)	F (%)
0	30	2049	600	23%
0	60	1968	681	26%
0	90	1854	795	30%
0	120	1758	891	34%
25	30	2400	251	9%
25	60	2288	363	14%
25	90	2102	549	21%
25	120	1971	680	26%
50	30	2462	186	7%
50	60	2383	265	10%
50	90	2227	421	16%
50	120	2077	571	22%
75	30	2484	166	6%
75	60	2386	264	10%
75	90	2237	413	16%
75	120	2091	559	21%
100	30	2452	196	7%
100	60	2352	296	11%
100	90	2248	400	15%
100	120	2072	576	22%

"V" is the percentage of population using vehicles for evacuation. Either as driver or passenger. It is assumed that each car has four passengers.
"E" is the mean of the distribution (μ) used to construct the evacuation start time curve.
"F" is the Fatality ratio (Casualty / Total Population)

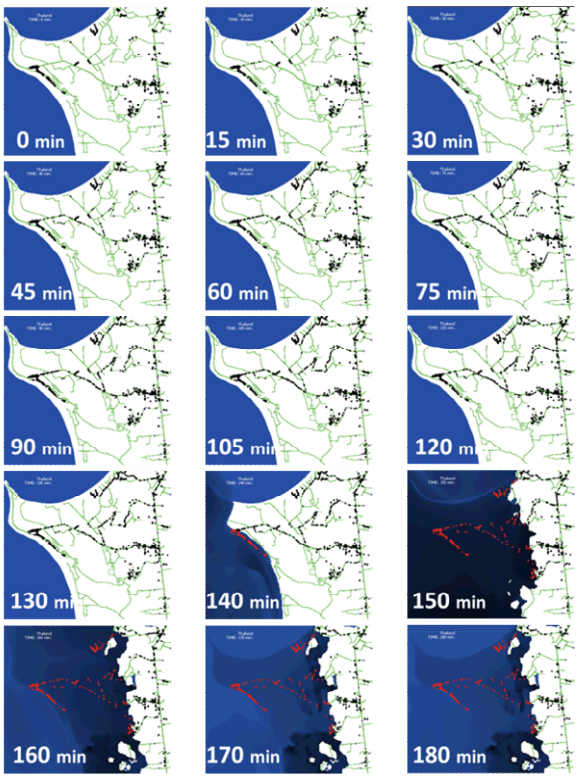

Figure 7 Snapshots of the worst case scenario of resulting fatality ratio (F in table 4). Evacuation is performed to the 17 available shelters on the right side of the area.

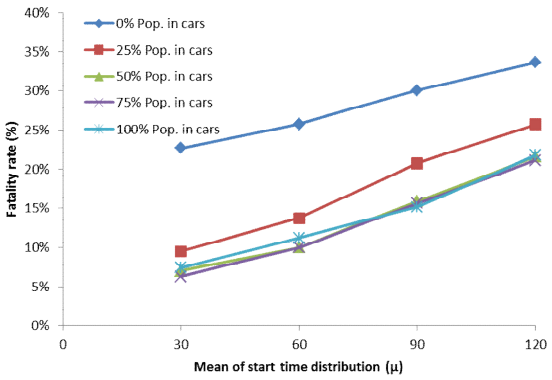

Figure 8 Fatality ratios at different timing of evacuation and percentage of population using vehicles. Notice the advantage of a fast evacuation decision, and in this area and for this amount of population, the advantage of using cars.

Based on the results shown in Table 4, Fig. 8 is presented to better discuss the influence of vehicles during the evacuation in this area and also the consequences of delaying the time for starting the evacuation. Apparently in this area the use of cars makes it convenient due to the long distance of evacuation, only a 25% of population in vehicles decreases the estimated fatality on 10%. Due to the number of people involved (2,649) and the

relatively small number of vehicles used (around 650 in the V=100% case) no significant traffic congestion was observed. However, a late reaction in the population may increase from 5% to 15% the fatality ratio.

7. CONCLUSION

A study of feasibility of evacuation in the Pakarang Cape of Thailand has been presented here. First, a comparison of the 2004 Indian Ocean tsunami fatality ratio with the 2011 Japan tsunami showed that for the case of Thailand where the tsunami arrived at more than two hours, fatality ratios were closed to the ones in Japan where tsunami arrived around thirty minutes. This drives us to a reflection on not only Japanese tsunami countermeasures, but especially tsunami awareness and preparedness for immediate evacuation. The importance of tsunami warning and tsunami evacuation procedures has been observed on 2004 and 2011 events. For the feasibility study, twenty cases of different starting time of evacuation and vehicle evacuation were conducted. Results suggest that due to the long distance of shelters vehicle evacuation might be necessary. It is possible that the use of vehicles in this area due to the small number of population and sufficient road capacity might not result on significant traffic congestions. Notice that if major population is involved than the evaluated here, traffic congestion might be possible. Future research including the estimated number of tourist remains in the agenda.

Abstract: Within the framework of the project Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru (JST-JICA SATREPS), this study aims on the tsunami inundation mapping of the coastal area of Lima city. Remote sensing data and Geographical Information System (GIS) analysis are incorporated in order to improve the accuracy of the numerical modeling results. Moreover, we evaluate the tsunami impact through the estimation of a tsunami casualty index (TCI) using our numerical results. The numerical result in terms of maximum tsunami depth shows a maximum inundation height of 5.4 m. In terms of inundation area, the maximum extension is 1.7 km with run-up height of 6 m. Additionally, the average TCI value obtained is 0.36 for the whole inundation domain where TCI equal to 1.00 represents the highest condition of risk. The mapping results presented in this paper give important information in order to understand tsunami inundation features and consequently it might be useful to design an adequate tsunami evacuation plan for Lima city.

1. INTRODUCTION

Tsunami inundation have caused an unfortunate loss of life and extensive property damage to coastal communities in seismic prone countries. For instance, tsunami events that had occurred in seismically similar areas such as Chile Tsunami 2010, Japan Tsunami 2011 and also the December 26, 2004 Sumatra tsunami are tragic reminders of the devastation that these powerful events can generate to coastal areas. In case of Peruvian seismic history, one of the most disastrous seismic event occurred in 1746, whose epicenter was located in front of the central area of Peru coast. According to some historical testimonies, the capital city of Lima was completely destroyed by the ground shaking and subsequently by the tsunami flood (Dorbath et al. 1990). Therefore, it is important to develop an efficient tsunami warning system in order to mitigate such catastrophic damages due to tsunami events.

The purpose of this study is to determine the tsunami inundation area for the coastal region of Lima city, adopting a megathrust earthquake that might likely affect Lima metropolitan region as seismic source scenario, through numerical modeling and detail topography model which includes building height information and land use classification. Additionally, numerical modeling results such as flow depths and current velocity are used to evaluate the tsunami impact by estimating a tsunami casualty index within the inundation area.

2. DESCRIPTION OF THE STUDY AREA

The study area essentially covers the central zone of Lima coast which corresponds to the constitutional province of Callao (see Figure 1a). The geographic limits for the study area are 11.95° - 12.09° South and 77.18° to 77.13° West. Morphologically, the coastal plain rises up to 15 m approximately above the sea level near the shoreline. However, whilst the coastline to the north forms a long sweeping bay, the coastline to the south of the study area presents a small peninsula which corresponds to La Punta district. In accordance with the Peruvian Institute of Statistic and Informatics (INEI), the population in Lima city is about 9 million people. For Callao province, however, there are about 950 thousand inhabitants living in this province. The urban use in the study area can be divided mainly into three types (see Figure 1a). The first one corresponds to residential type which its area is concentrated in the southern part of the inundation domain (below 12$°02’30’’). This is the most

populated area in Callao province; as a result, the land surface is largely covered by houses and avenues. The second urban use type is located in the center of the study area (between 12°01'S and 12°02'30'') this zone is covered by extensive vegetated area which corresponds to the backside of the International Airport of Lima and fields. There are also some towns placed along the coastline where the housing type are principally non-engineering buildings INEI. Finally, in the third zone type the surface along the coastline is mainly occupied by some factories.

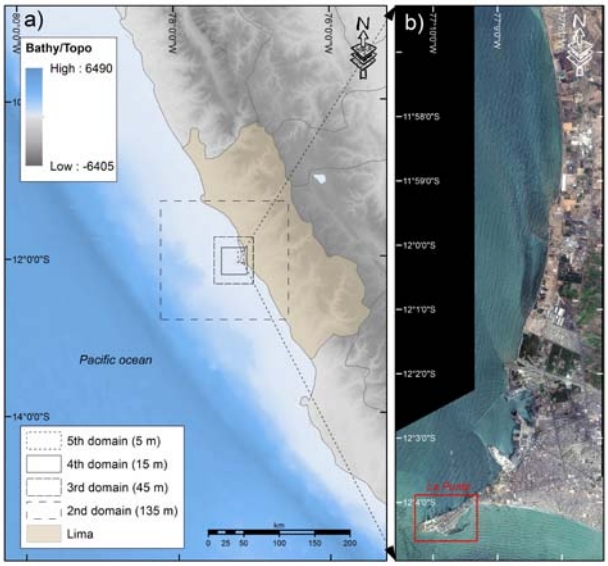

Figure 1. a) View of the first domain (405 m grid size resolution), the boundaries for the other domains are shown in dashed lines. b) Study area which corresponds to the 5th domain, background view of WorldView-2 satellite images in true composite.

3. TSUNAMI SOURCE SCENARIO

Seismic events accompanied with large tsunamis along the coastal area of central Peru have been reported since historical times. For instance, the 1746 earthquake is considered one of the most catastrophic seismic events in Peruvian history. The moment magnitude for this event has been estimated between 8.8 and 9.0 and the reported tsunami run-up height was between 15 m and 24 m (Dorbath et al. 1990 and Becket al. 1989). Two centuries later, only two event with considerable magnitude occurred. The 1966 earthquake, which epicenter was located at the north-central coastal area of Peru, had a rupture length of 100 km and a local tsunami height of 2.6 m. The last was in 1974 which occurred in front of Lima city, had a rupture length of 140 km and a local tsunami height of 1.6 m (Dorbath et al. 1990). Since then, large earthquakes have not been reported in the surroundings. Therefore, there is a clear seismic gap of approximately 250 years. Furthermore, considering the seismic history in this area, it is urgent to take into account the higher possibility of the occurrence of an enormous seismic event accompanied with a catastrophic tsunami in front of Lima city.

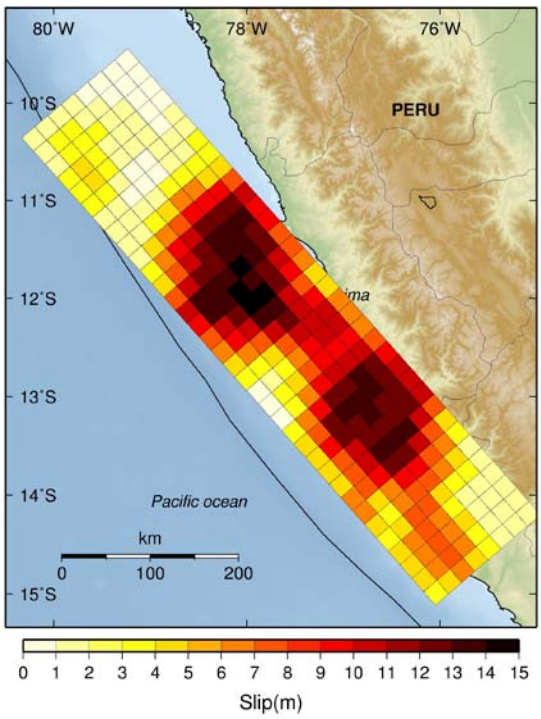

Figure 2. Slip distribution proposed by Pulido et al. (2011). The scale bar for the slip amount is shown below for each model.

In the evaluation of seismic models the application of GPS (Global Positioning System) observation and InSAR (Interferometry Synthetic Aperture Radar) makes possible to measure the strain/displacement associated with plate convergence movements in high seismicity zones. Sagiya et al. (2000) used a GPS array with about 1,000 permanent stations to recognize the coseismic deformations associated with large earthquakes and ongoing secular deformation in Japan. Hashimoto et al. (2010) and Liu and Yamazaki (2013) used pre- and post-event SAR imagery datasets to estimate the crustal movement from the 2008 Wenchuan, China Earthquake and 2011 Tohoku, Japan Earthquake, respectively. Additionally, historical information such as earthquake intensity perception, run-up measurements and wave arrival times of past earthquake events plays an important role in order to estimate seismic models for potential earthquake scenarios which can be used to evaluate a possible future impact (Kuroiwa 2004). In this study the source model is based in a megathrust earthquake that might likely affect Lima metropolitan region which is appropriate for simulation of long period wave and tsunami modeling (Pulido et al. 2011). The seismic source is based on a model of interseismic coupling distribution in subduction areas for a period of 265 years since 1746 earthquake. These data also includes sea floor deformation measurements obtained offshore of Lima city from a combination of GPS receivers and acoustic transponders (Gagnon et al. 2005), as well as information of historical earthquakes to propose the slip distribution. The seismic source is divided into 280 sub-fault segments, each segment of 20 km x 20 km in size, in a

rupture area of 700 km by 160 km with moment magnitude of Mw 9.0. The slip solution model shows two main asperities, the largest is located west of Lima city, approximately 70 km, with maximum slip amount of 15.4 m and the second one with slip amount up to 13.0 m to the south of Lima. Figure 2 shows the spatial location for the slip model distribution.

3.1 Initial Sea Floor Displacement

We use a rectangular dislocation model (Okada 1985) to calculate the ocean bottom deformation due to our source scenario. The initial sea floor displacement is assumed from the instant push up of the seismic deformation on the ocean bottom. Thus, the features of the bottom deformation reflects the initial water surface displacement that is assumed as initial condition of the tsunami propagation modeling. Figure 3 shows the displacement result. The areas in red and blue colors represent the uplift and subsidence displacement, respectively. Contour lines are drawn in 0.25 m interval. There are two regions of high uplift deformation which are consistent with the slip model distribution, the higher uplift region has a maximum displacement of 4.6 m and it is located about 150 km in front of Lima coastal area.

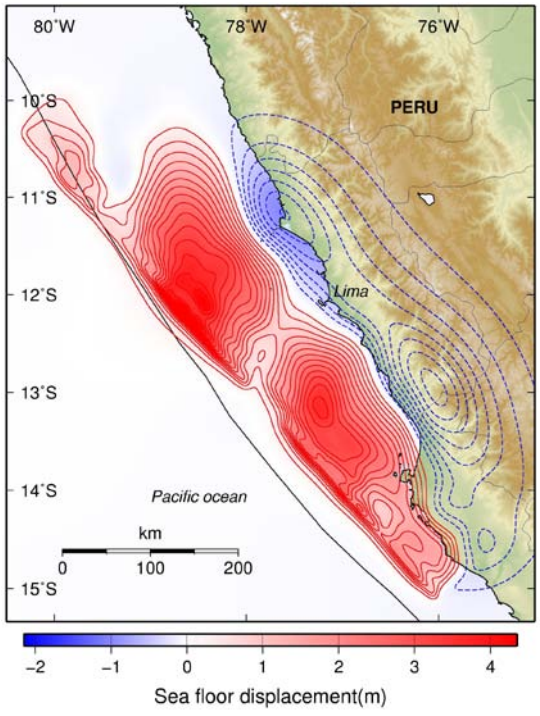

Figure 3. Sea floor displacement calculated from the estimated slip distribution (Pulido et al. 2011). The areas in red and blue colors represent the uplift and subsidence displacement, respectively. Contour lines are drawn in 0.25 m interval for each model.

4. ROUGHNESS COEFFICIENT MAP

Generally, based on the relation between the scale of an obstacle and the grid size of the computational domain, there are basically two approaches to be applied in inundation modeling (Hong 2004). The first one is the topography model which uses a constant roughness coefficient for the whole computational domain and a very detailed topography dataset including the building height informations. This approach is used when the obstacle or urban use (e.g. buildings, seawalls, roads, and fields) can be adequately represented within the grid cells in the inundation model. Thus, this model uses a finer grid size where the flow around and between obstacles can be well simulated. The second one is known as equivalent roughness model. This model is applied when the obstacles are much smaller than the grid size. Aburaya et al. (2002) introduced an appropriate methodology for this case which is based in the calculation of a building/house occupation ratio within the grid cells in the inundation domain. This method has been utilized and validated, through the comparison with field survey data, in order to developed tsunami fragility functions (Koshimura et al. 2009 and Suppasri et al. 2011). Furthermore, based in these methodologies, Muhari et al. (2011) presented a comparison of three run-up models (constant roughness model, topography model and equivalent roughness model) on highly populated area, they have concluded that the topographic model can be used to identify the distribution of inundation parameters in residential areas.

Since high grid resolution and urban use influence the estimation bottom roughness coefficient, it might change the propagation of waves considerably due to having obstacles or roughness induced energy dissipation. Consequently the final input raster should include features with appropriate elevation heights and adequate roughness surface mapping (Gayer et al. 2010). In this study, in order to improve the accuracy of the numerical results, we enhance the topography model approach by adding a specific bottom roughness coefficient for each grid cell in the inundation domain. Those coefficient values are based in a roughness coefficient map (see Figure 4a). Adriano et al. (2012) performed a land use classification using satellite images from WorldView-2 sensor and the coefficient values are assigned according to the land use (Kotani1et al. 1998) in order to present a roughness coefficient map for the coastal area of Lima city. Additionally, the topography data is combined with a height building model (see Figure 4b). For La Punta district a GIS building shape file in a single house scale is available, it includes number of stories, spatial location and construction material type fields. In this case, the height building model is constructed by multiplying the number of stories by 2.5 m (story height standard in Lima city). However, for the rest of the computational domain only the spatial location for a block scale is available. Nevertheless, in order to construct the height building model, we assume as preliminary estimation two story height for each block. However, only the historical building known as “Fortaleza Real Felipe” (location coordinate: -77.15°W, -12.06°S) was manually delineated and its height is fixed equal to 8 m which is approximately the real height of the perimeter wall.

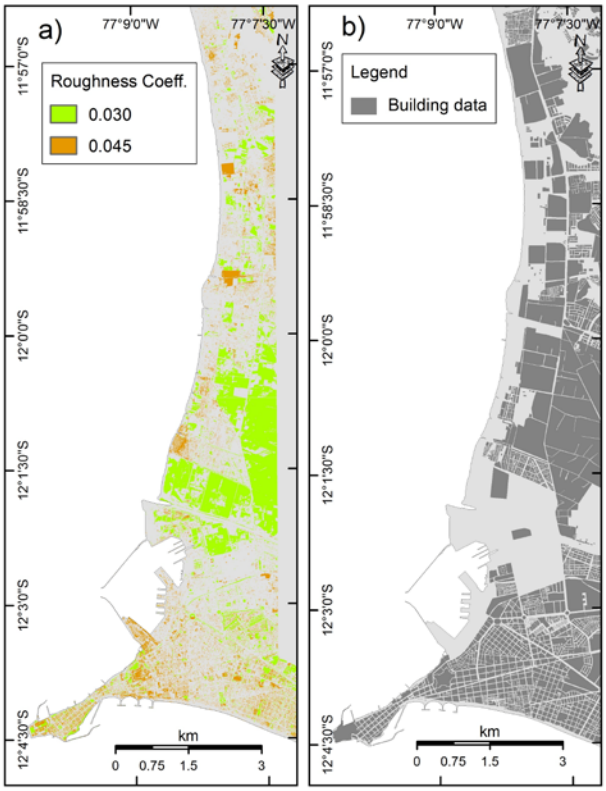

Figure 4 a) Roughness coefficient map Adriano et al. (2012). b) GIS building shape file used to construct the building height model.

5. TSUNAMI INUNDATION MAPPING

The numerical simulation was conducted by using Tohoku University's Numerical Analysis Model for Investigation of Near-filed tsunami No.2 (TUNAMI-N2) code based on shallow water theory and Cartesian coordinate system (Imamura 1995), which was developed by Disaster Control Research Center (DCRC), Tohoku University, Japan. The computation time for the tsunami modeling is 3 hours. In order to satisfy the stability condition the time step for the numerical computation is fixed equal to 0.2 s.

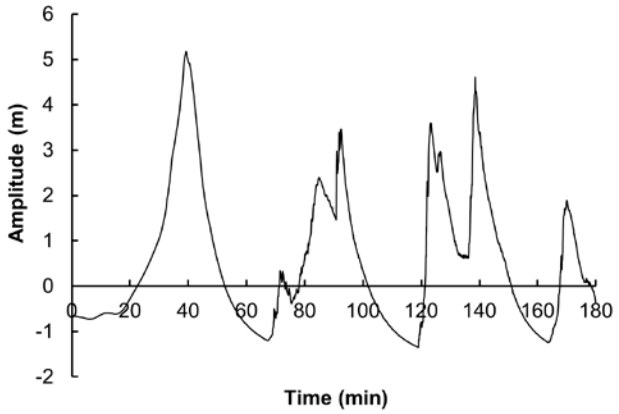

Figure 5. Synthetic tsunami height recoded at Callao tide gauge station.

The tsunami inundation is calculated on the fifth domain using 5 m resolution of bathymetry and topography grid data with 1567 x 3346 grid points along the longitude and latitude directions, respectively. Figure 5 shows the synthetic tsunami height recorded in Callao tide gauge station, which is located at 77.16°W, 12.06°S (see Figure 6) within 3 hours of simulation. The tsunami arrival time registered in Callao station is 22 minutes. In addition, the time step when the maximum tsunami height occurred is equal to 38 minutes. The local inundation depth is the result of measuring water marks on structures above the ground. The inundation depth and inundation area result are shown in Figure 6a. In terms of inundation depth, the maximum value reaches up to 6 m. Further, in terms of inundation distant; on the northern part of the computational domain, its maximum extension reach about 1 km with run-up height about 6 m and 1.4 km with run-up height about 12.4 m. On the surrounding area of Rimac river estuary (around 12°02'S latitude) the tsunami inundation extend up to 1.3 km with run-up height of 5.3 m. Based on the numerical results the inundation depth values reach up to 6 m which might completely inundate one storey buildings. The inundation depth on most of the streets in La Punta district (see Figure 1b) reach values up to approximately 4 m. However, based on the time series shows in the previous Figure 5 this state occurs three times with a time period about 50 minutes within 3 hour of tsunami simulation. The inundation area extents several blocks on land (about 1 km distant) with maximum run-up height of 4 m there is, additionally, a clear inundation zone that extend about 1.7 km which correspond to the inundation zone when buildings are completely inundated.

5.1 Tsunami impact assessment

In order to analyze the tsunami impact in the study area, we estimated the potential tsunami casualties due to the tsunami flooding. Koshimura et al. (2006) introduced a practical methodology which uses a simple human model (based on cylinder members) to evaluate the effect of hydrodynamic forces on it. Thus, it is possible to determine locations and times within the tsunami inundation zone where casualties are likely to occur. Muhari et al. (2011) presented an improvement of the previous method by considering two types of fall of the human model (stability conditions). The first one considers that hydrodynamic force exceeds the friction force on the soles of the human model feet and the second one occurs when the moment from the bottom back of the heel due to the hydrodynamic force is bigger than the resistance moment due to human body weight. Koshimura et al. (2006) also introduced the Tsunami casualty index (TCI) which is defined by relation between the time duration of the tsunami inundation flow that satisfies the two stability conditions mentioned above and the total time duration of the tsunami inundation flow. TCI can be used to illustrate the spatial distribution of potential tsunami casualty within the inundation area. The TCI result is shown in Figure 6b. Basically, the TCI follows a

consistent behavior similar as the inundation depth and inundation area. However, based on the impact assessment model, there are areas with inundation depth up to 4 m that the TCI shows values of 0.5 which might indicate that the tsunami flow velocity is not strong enough to produce a hydrodynamic force able to affect the balance of the human model within 3 hours of tsunami simulation (Muhari et al. 2011). It is important to point out that some of these areas are concentrated on La Punta district where the maximum TCI value is 0.52 on most of the streets. The average TCI value obtained is 0.36 in the whole inundation domain. Additionally, based on our numerical calculation the balance instability of the human model for each cell grid in almost the whole inundation domain occurs between 2 and 5 minutes after the tsunami wave arrived.

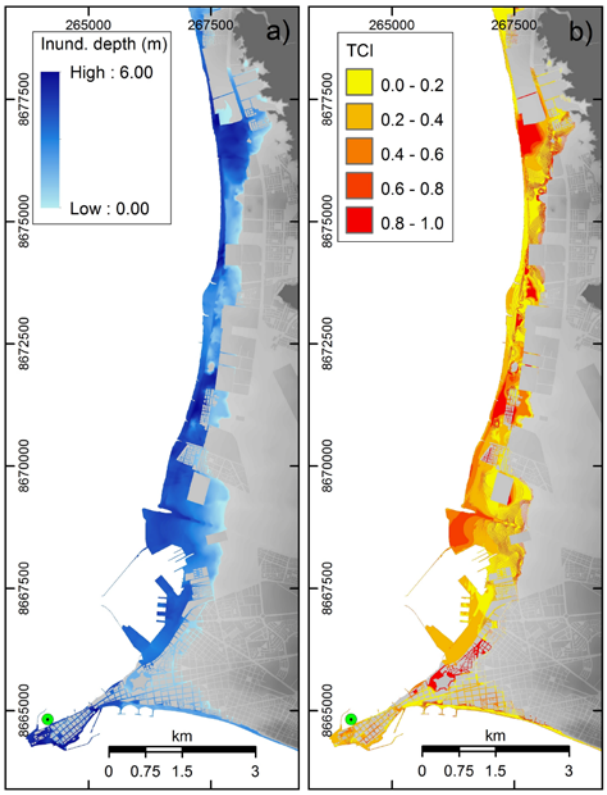

Figure 6. a) Tsunami inundation calculated within 3 hours of numerical simulation. b) TCI estimated using tsunami feature results. Green dot shows the location of Callao Tide gauge station.

6. CONCLUSIONS

The tsunami inundation modeling using detailed bathymetry raster dataset was carried out in order to determine the tsunami inundation area for the coastal region of Lima city. Additionally, flow depth and flow velocity results were used to evaluate the tsunami impact by estimating a tsunami casualty index within the inundation area. The inundation map developed using the source scenario adopted shows a maximum inundation depth of 6 m and maximum inundation distant of 1.7 km, those values represent a high tsunami risk for the study area. Therefore, if we consider the Peruvian seismic history and the lesson learned from past tsunami event occurred in other regions such as 2011 Tohoku tsunami, the mapping result should be considered in order to propose a tsunami warning system. Additionally, the TCI map estimated using our source scenario adopted shows a consistent behavior similar as the inundation map. The mean value of the TCI in the computation domain is 0.36. TCI maps might be useful in order to develop a tsunami evacuation plan, especially in case of La Punta district when the TCI value is greater than 0.5. Finally, the mapping results presented in this paper gives important information in order to understand tsunami inundation features; therefore it might be useful to design an adequate tsunami warning system which can be included in a tsunami evacuation plan for Lima city.

Abstract: In The 2011 off the Pacific coast of Tohoku Earthquake, a lot of buildings were destroyed and flowed out TSUNAMI. In order to save humans' lives and prevent buildings suffering such damage, it is very important to figure out behaviors of buildings under TSUNAMI wave load. A lot of researches about TSUNAMI wave load acting on land structures have been reported in the past. However, in most of reports, the target of research is load acting on rigid structures, such as upstanding walls. So responses of building structures under TSUNAMI wave load are hardly clarified. Therefore it can be said that the actual load on building structures is not understood. In this report, fluid-structure interaction analyses are executed to clarify collapse mechanism of building structures. The analytical target is rein-forced building structure and tried to explain the damage example in the Pacific coast of Tohoku Earthquake. The analytical results can express collapse phenomena by TSUNAMI wave load and show the behavior of wave loading.

1. INTRODUCTION

In The 2011 off the Pacific coast of Tohoku Earthquake, a lot of buildings were destroyed and flowed out TSUNAMI. In order to save humans' lives and prevent buildings suffering such damage, it is very important to figure out behaviors of buildings under TSUNAMI wave load. In this report, Fluid-Structure Interaction analysis is performed and a basic study on response to TSUNAMI wave load is made.

In previous researches, a method to consider TSUNAMI wave load as static pressure was proposed by Asakura et al [1)] and the method is employed on the design guide for TSUNAMI refuge buildings. However, it is reported that this method is underestimates TSUNAMI load in the case of acting an impulsive loading to a structure in other reports. Furthermore, there are some reports considering deformation of simple structure.

In these researches, however, the targets suffering by wave loadings were very simple and sufficient explanations for damage or response under wave loading were not given. So, in this report, responses of building structures under impulsive wave loadings are focused.

2. THE VALIDATION FOR FLUID STRUCTRE INTERACTION ANALYSIS

2.1 Analytical Model

In this section, a validation for analytical method used in this report is done with comparison to the result of the dam break test by Kleefsman et al [2)]. The analytical object is shown in Figure 1. The commercial structural analysis code called LS-DYNA is used. ALE (Arbitrary Lagrangian–Eulerian) re-meshing elements are applied to the fluid volumes, and Lagrangian elements are applied to the structure. The penalty method is adopted to consider interaction between the fluid and the structure.

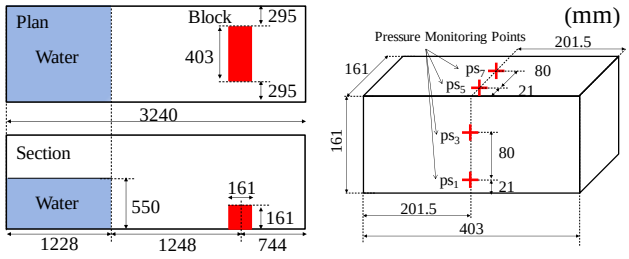

Figure 1 The Dam Break Test Model [2),3)]

2.2 Analytical Result

The appearances of the water in the experiment and the numerical simulation are shown in Figure 2. After the breaking of the water, the front edge of water reached front of the block in 0.4 second. As shown in Figure 2(b), the analysis can express the crashing and jumping of water and front edge of the water reached to end of the tank.

The pressure time histories at each monitoring point (shown in Figure 1) are shown in Figure 3. At ps1 and ps3 which is located on front surface of the block, the analytical results show good accordance to experimental results. At ps5 and ps7 which is located on the upper surface of the block, pressure oscillation has been seen, because complex behavior of water occurred, such as cohesion of reflected water and jumping water. But center of the oscillation is

coincident to the experimental result. So, this method can express the behavior of water and pressure acting on a structure qualitatively-correctly.

3. RESPONSES OF THE STRUCTRES UNDER IMPULSIVE WAVE LOAD

3.1 Outline of Analytical Model

The outline of analytical model is shown in Figure 4. The surge wave is made by dam breaking and impacts to building structure. The building structure consists of columns, beams, concrete slab and wall in front and it has one floor in section and 1×1 span in plan. The properties of the structure are shown in Figure 5. The fluid and the structure interact with each other via only slab and wall.

3.2 Analytical Conditions

Analytical conditions are classified in terms of structures' properties. In the first case, the structure is rigid. In second case, it is elastic structure, and in last case, material non-linearity of the structure is considered. Additionally, in elastic structure case, the structure's property was varied. In other words, the natural frequencies changed by tuning its mass density. So, the analytical cases are summarized as follows.

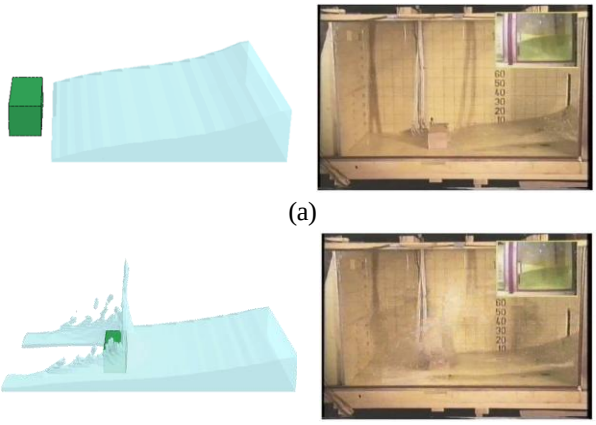
Case-1: Rigid Structure

Case-2: Elastic Structure

(a):5.1(Hz) (b):10.1(Hz)
(c):14.4(Hz) (d):20.3(Hz)
(e):25.0(Hz) (f):31.4(Hz)
(g):40.6(Hz)

Case-3: Structure with Non-linear Material Model

3.3 Material Properties of The Structure



In case-2, Young modulus is 2.5×10^4(MPa). In this section, material properties of the structure in case-3 are mainly mentioned.

The structure is assumed as rein-forced concrete building. So, the concrete material properties and steel material property for reinforcement bars are adopted. The cracking with tension stiffening and the compression crushing are considered in the concrete material model. The characteristic of the steel model is bi-linear. The stress-strain relations are shown in Figure 6.

The columns and beams are modeled by Hughes-Liu beam element which is based on a degenerated brick element formulation. In other words, they have integration points on the section. The wall and slab are modeled by laminated shell element. The integration points which have concrete and steel properties are placed on each center of inertia in section as shown in Figure 7.

3.3 Analytical Result of Wave Impact Test

The appearances of the water in Case-1 are shown in Figure 8. The overflow water makes surge wave and impacts to the structure. Some of wave force time histories are shown in Figure9.Static wave force calculated with equation

(a)

(b)

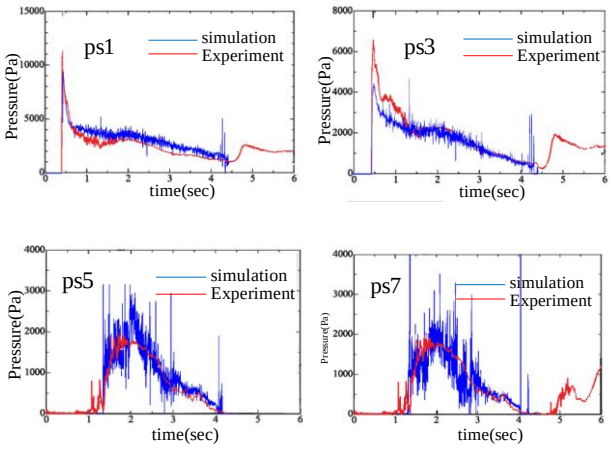

Figure 3 Pressure Time History[2),3)]

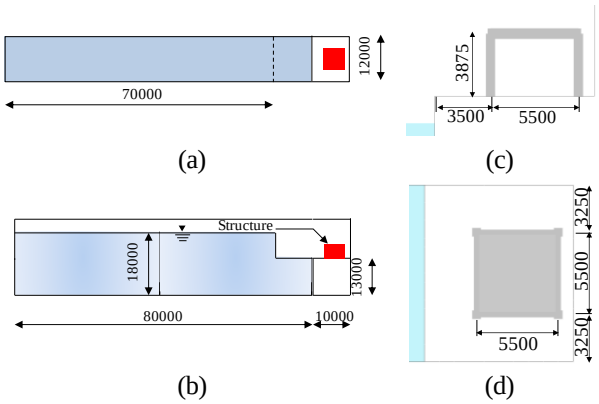

Figure 4 Analytical Model
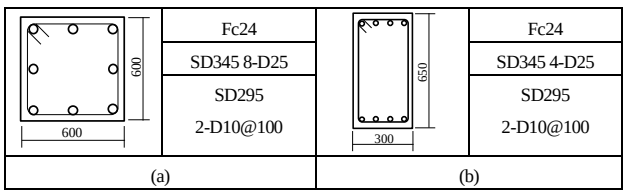
(a) Plan, (b) Elevation, (c) Elevation of the Structure and (d) Plan of the Structure



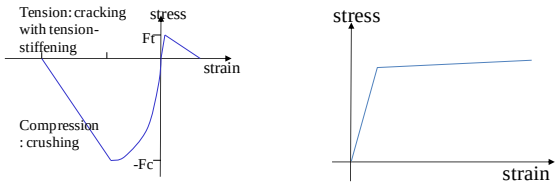


Figure 5 Section of Members (a)Columns (b)Beams

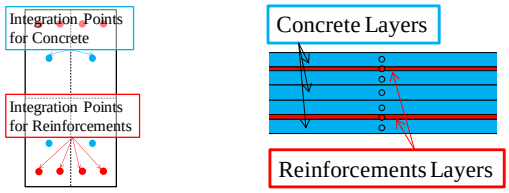
supposed by Asakura et al(2000)[1] is also shown there. Twice impulsive wave loads act on the structure. In Case-1, Case-2(b) and Case-3, first impulsive load was maximized, and, in Case-2(e), second impulsive load was maximized. So, it can be said that characteristics of structures affect those of wave loadings.



Maximum displacements of top of the structure are shown in Figure 10. Abscissa axis here is natural frequency of Case-2. Response to static load calculated with triangular pressure distribution by Asakura et al(2000)[1] is also shown here. In all cases, maximum displacement responses exceed response to the static load. So, when impulsive loads which are exceed static load calculated from static pressure distribution act on structures, these loads should be considered in order to predict responses to wave load. Figure 10 also says that responses to wave loads vary with the characteristics of structures although each structure has the same static stiffness.

Appearance of maximum principal strain distribution in Case-3 is shown in Figure 11 and the damage example in the 2011 off the Pacific coast of Tohoku Earthquake is shown in Figure 12. Aspect of the strain distribution is similar to that of the crack pattern in damage example. The wall cracked radially from the center and the damage concentrated to edge of the wall in both numerical result and damage example. So, the analysis method in this report (considering material non- linearity) can express the damage of buildings suffering from TSUNAMI wave load.

4. SIMPLIFIED RESPONSE PREDICTION METHOD BY 1-DOF MODEL

4.1 Outline of Analytical Model

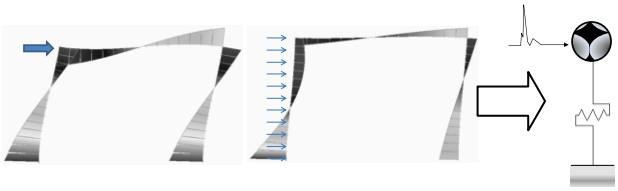
1-DOF mass spring model is considered as one of the simplified prediction methods for structures' responses to wave impulsive loads. This method is used to predict building responses to earthquakes typically. In this section, methods to make 1-DOF models for TSUNAMI load response analyses are discussed.

Almost always the characteristics of springs in 1-DOF models are made from result of non-linear push over analyses with framed models. In this report, two loading methods were used for the push over analyses. First, concentrated load was given to the frame model as shown in Figure 13(a). This loading method is a common way to make models for prediction of buildings' responses to earthquakes. This case is called Case-S1. In the other method, the distributed load was given on the wall of the structure as shown in Figure 13(b). The load is rectangular and uniformly distributed load for sake of simplicity.

The wave time history in Case-3 is used as the excitation.

4.2 Results of Simplified Models

Time histories of the displacement are shown in Figure 14. Case-S1, which is modeled with ordinary way, overestimated displacement of the structure. On the other hand, In Case-S2, the result was good accordance to that in Case-3. In the moment resisting structures, such as analytical target in this report, the load resisting mechanisms differ between against the concentrated load and the distributed load. This fact caused difference of two responses. So, when wave loads, which are distributed load, are treated with 1-DOF models, the characteristics of springs in 1-DOF models should be defined according to result of static load incremental analyses considering distributed loads.



5. CONCLUSIONS

In this report, in order to clarify responses of building structures to TSUNAMI wave load, fluid-structure interaction analyses were executed with simple structures. In addition, we studied about simplified response prediction method with 1-DOF models. As a result, the following findings were obtained

・ALE and Lagrangian elements were used to model fluid and structures, and considered interaction each other with penalty method. This analysis can evaluate load act on structure and express behavior of water.

・In case of acting impulsive loads on structures, the wave loads and responses were varied by characteristics of structures. And in every case, the responses exceeded static load supposed in previous research. So, in such cases, dynamic effect should be considered.

・1-DOF analysis was proposed as simple response prediction method. The model whose spring characteristic was defined by concentrated load overestimated the response of the structure. So, wave loads are treated with 1-DOF models, the characteristics of springs should be defined according to result of static load incremental analyses considering distributed loads.

POTENTIAL AND VORTEX RESIDUAL FIELDS IN THE OCEAN DUE TO TSUNAMIGENIC EARTHQUAKES: A FULLY ANALYTICAL SOLUTION OF THE AXISYMMETRIC MODEL PROBLEM

Gulnaz N. Nurislamova[1)], and Mikhail A. Nosov[2)]

1) Student, Faculty of Physics, M.V. Lomonosov Moscow State University, Russia
2) Professor, Faculty of Physics, M.V. Lomonosov Moscow State University, Russia
gulnaz1205@yandex.ru, nosov@phys.msu.ru

Abstract: Equations for description of potential and vortex residual fields generated in the ocean by co-seismic bottom deformation are derived within the framework of linear shallow-water theory. A fully analytical solution to the respective axisymmetric problem is obtained. On the base of the analytical solution and known relations between the tsunami source parameters and earthquake moment-magnitude the amplitude of residual horizontal displacements of water particles, the maximum vortex velocity and the energy of the residual geostrophic vortex are estimated as functions of moment-magnitude.

1. INTRODUCTION

The principal mechanism of tsunami generation during an earthquake is the displacement of water by residual (co-seismic) deformation of the bottom (e.g. Dotsenko and Soloviev 1995, Levin and Nosov 2009, Nosov and Kolesov 2011). The volume that is displaced from the source region is distributed in the ocean during tsunami wave propagations. This process, clearly, is accompanied by "residual" displacements of water particles in the horizontal direction. Besides the "residual" displacements of water particles, the rotation of the Earth leads to formation of the geostrophic vortex in the vicinity of tsunami source. Residual displacement of the water particles and the corresponding geostrophic vortex we will refer as the potential and vortex residual fields (Nosov and Nurislamova 2012).

Vortex formation in the tsunami source under the action of the Coriolis force have been discussed earlier many times (e.g. Pelinovsky 1996, Ingel 1998, Dotsenko 2001). However, attention has not been paid to potential fields. According to our information, the potential residual field for the first time was considered in our studies (Nosov 2011, Nosov et al. 2011, 2012, Nosov and Nurislamova 2012). In particular, in one of our previous work (Nosov and Nurislamova 2012) a completely analytical solution of model problem about the residual hydrodynamical fields was obtained.

The main purpose of this study is to estimate the residual fields (the residual horizontal displacements of water particles, the speed of the vortex current and the energy of a geostrophic vortex) as a function of moment-magnitude of tsunamigenic earthquake. In order to obtain these estimates we use the above mentioned analytical solution and the relations between the tsunami source parameters and moment-magnitude which had been obtained in paper (Bolshakova and Nosov 2011).

2. MATHEMATICAL MODEL

In this section, according to our paper (Nosov and Nurislamova 2012), we briefly describe the procedure for obtaining of the analytical solution.

Consider a layer of an ideal incompressible homogeneous liquid of constant depth in the field of gravity on a rotating Earth. Our mathematical approach is based on the linearized shallow-water approximation, which works pretty well for tsunami simulation in the open ocean where the wave amplitude is much less than the ocean depth, which in its turn is much less than the wave length. We shall put the origin of the Cartesian reference frame, $0xyz$, in the unperturbed free surface and direct the $0z$ axis vertically upward. $0x$ -axis is directed eastward, $0y$ -axis – northward. We assume the domain under consideration to be small enough to neglect the sphericity of the Earth. The set of shallow-water equations is written in the Cartesian reference frame

$$\frac{\partial \xi}{\partial t} - \frac{\partial \eta}{\partial t} + H\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) = 0, \qquad (1)$$

$$\frac{\partial u}{\partial t} = -g\frac{\partial \xi}{\partial x} + fv, \qquad (2)$$

$$\frac{\partial v}{\partial t} = -g\frac{\partial \xi}{\partial y} - fu, \qquad (3)$$

where ξ is the displacement of the free surface of water from equilibrium; η is the displacement of the bottom surface from the initial position; u and v are the components of horizontal flow velocity vector along the axes x and y, respectively; g is free-fall acceleration; and f is the Coriolis parameter.

According to Helmholtz's theorem, an arbitrary vector field can be resolved into the sum of a potential (curl-free) vector field and a rotational (divergence-free) vector field

$$u = \frac{\partial \varphi}{\partial x} + \frac{\partial \psi}{\partial y}, \qquad v = \frac{\partial \varphi}{\partial y} - \frac{\partial \psi}{\partial x}, \qquad (4)$$

where φ is the velocity potential and ψ is the stream function.

Integrating Eq. (1)-(3), considering (4), over time from 0 to ∞, we obtain the following system of differential equations of the second order:

$$H\Delta\Phi = \eta_\infty - \xi_\infty, \qquad (5)$$

$$\Delta\psi_\infty = f\Delta\Phi, \qquad (6)$$

$$g\Delta\xi_\infty = -f\Delta\psi_\infty, \qquad (7)$$

where ξ_∞ is the residual displacement of the free water surface in a geostrophic vortex, $\Phi \equiv \int_0^\infty \varphi\, dt$ is the displacement potential and ψ_∞ is the stream function, which describes the residual vortex field (stationary geostrophic vortex). The residual displacement of water particles in a horizontal direction is related to the potential Φ by the following formula:

$$D_\infty \equiv \int_0^\infty v dt = \nabla\Phi. \qquad (8)$$

Excluding functions Φ and ψ_∞ from the system of equations (5), (6) and (7), we come to the Helmholz heterogeneous equation for the function ξ_∞.

$$R_0{}^2\Delta\xi_\infty - \xi_\infty = -\eta_\infty \qquad (9)$$

where $R_0{}^2 = gH/f^2$ is the square of barotropic Rossby radius of deformation.

Let us assume a simple model of the residual deformation of the bottom in the form of an axisymmetric uplift described by the function

$$\eta_0(r) = \eta_{max}\left[1 - \theta(r - R_{TS})\right]. \qquad (10)$$

Note that the amplitude of the bottom deformation and the source radius are just those parameters which can be estimated by the moment-magnitude of an earthquake with use of relationships obtained in paper (Bolshakova and Nosov 2011).

In Eq. (9), let us switch to cylindrical coordinates

$$\frac{\partial^2 \xi_\infty}{\partial r^{*2}} + \frac{1}{r^*}\frac{\partial \xi_\infty}{\partial r^*} - \mu^2\xi_\infty = -\mu^2\eta_\infty, \qquad (11)$$

where $\mu^2 = R^2/R_0{}^2$ and $r^* = r/R$ is the dimensionless spatial variable.

Solution of Eq. (11), which satisfies the boundedness condition at infinity, is expressed through the modified Bessel functions, I_i and K_i (Polyanin 2002).

$$\xi_\infty(r^*) = \eta_{max}\begin{cases} 1 - \mu K_1(\mu) I_0(\mu r^*), & 0 \le r^* < 1, \\ \mu K_0(\mu r^*) I_1(\mu), & r^* \ge 1. \end{cases} \qquad (12)$$

Based on the known function ξ_∞, from Eqs. (6) and (7) we find residual displacement of water particles in a horizontal direction and speed in geostrophic vortex

$$D(r^*) = \frac{\eta_{max} R}{H}\beta(r^*), \qquad (13)$$

$$v(r^*) = -\frac{\eta_{max} R f}{H}\beta(r^*), \qquad (14)$$

where

$$\beta(r^*) = \begin{cases} I_1(\mu r^*) K_1(\mu), & 0 \le r^* < 1, \\ I_1(\mu) K_1(\mu r^*), & r^* \ge 1. \end{cases} \qquad (15)$$

In typical natural conditions, the parameter $\mu < 1$ (here and below we assume $f = 10^{-4} c^{-1}$). Under this condition on the basis of Eq. (15) we obtain $\beta_{max} \approx 0.5$. Therefore, while estimating of the maximal values of the horizontal displacement of water particles and the speed of the vortex current, we can apply simplified formulas

$$D_{\infty max} \approx 0.5\eta_{max} R/H, \qquad (16)$$

$$v_{\infty max} \approx 0.5\eta_{max} R f/H. \qquad (17)$$

Based on the spatial structure of the residual fields determined by formulae (12) and (14) one can easily calculate potential (W_p), kinetic (W_k) and full (W_{GV}) energies of the residual geostrophic vortex:

$$W_p = W_{TS}\Big(1 - \mu^2 I_1{}^2(\mu) K_0{}^2(\mu) - \\ - 4 I_1(\mu) K_1(\mu) + \mu^2 I_0{}^2(\mu) K_1{}^2(\mu)\Big), \qquad (18)$$

$$W_k = W_{TS}\big(\mu[I_1(\mu) K_2(\mu) - I_0(\mu) K_1(\mu)]\big), \qquad (19)$$

$$W_{GV} = W_p + W_k \,, \qquad (20)$$

where W_{TS} is the energy of initial elevation, similar in form to the residual deformation of the bottom (energy of tsunami).

$$W_{TS} = 0.5\pi\rho g R^2 \eta_{max}{}^2 \,. \qquad (21)$$

3. RESULTS AND DISCUSSION

In paper (Bolshakova and Nosov 2011) an empirical-analytical approach in combination with Monte-Carlo method were employed to establish relationships between earthquake moment magnitude and upper limits of tsunami source parameters. Among all other parameters, the amplitude of bottom deformation, and the radius of tsunami source were related to the moment-magnitude of earthquake in the following way:

$$lg\,\eta_{max}(m) = 0.5M_W - 3.4 \,, \qquad (22)$$

$$lg\,R_{TS}(m) = 0.5M_W + 0.8 \,. \qquad (23)$$

Now, substituting relationships (22) and (23) in formulae (16) - (21), we obtain the amplitude of the horizontal displacement of water particles, $D_{\infty max}$, the speed of the vortex current, $v_{\infty max}$, the full energy of a geostrophic vortex, W_{GV}, and the energy of tsunami, W_{TS} as a function of the earthquake moment-magnitude, M_W.

It would be interesting to compare the full energy of a geostrophic vortex, W_{GV}, and the energy of tsunami, W_{TS} with the energy of an earthquake. For this reason let us consider the following well-known relationship by Kanamori (1977)

$$lg\,W_{EQ}(J) = 1.5M_w + 4.8 \,. \qquad (24)$$

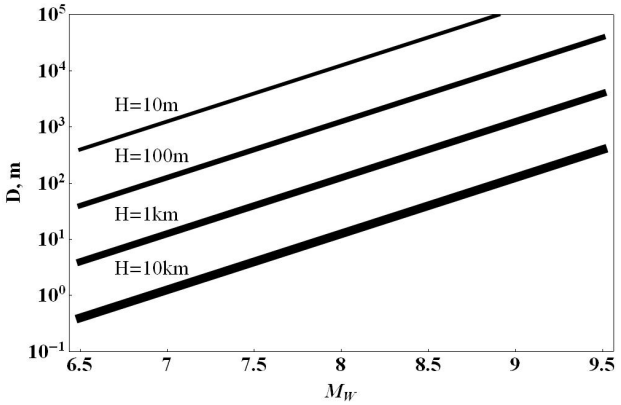

Figure 1 The amplitude of residual horizontal displacement of water particles as a function of moment-magnitude of an earthquake

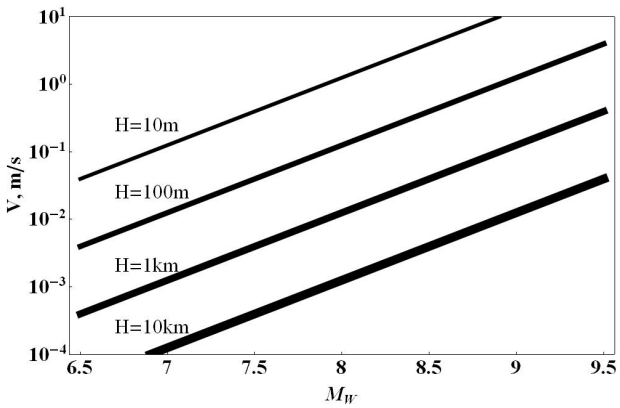

Figure 2 The amplitude of current speed in the residual geostrophic vortex as a function of moment-magnitude of an earthquake

The calculation results are presented in Figs. 1-3. Parameters of the residual fields depend on depth of the ocean; therefore we present calculations for the four depths, which cover the possible range of variation of these values in the real conditions.

In Fig.1 the amplitude of residual horizontal displacement of water is shown. It is seen that the amplitude grows exponentially as moment-magnitude goes up. Besides, amplitude is inversely proportional to the depth of the ocean. In case of a catastrophic earthquakes ($M_W \approx 9$) even in open ocean ($H > 1\,km$) amplitude of residual displacement can reach hundreds of meters. On the shelf, the amplitude may exceed 1 km.

The amplitude of current speed in the residual geostrophic vortex versus moment-magnitude of an earthquake is depicted in Fig. 2. It is seen that the speed of the vortex current is usually very slow (~0.1 m/s or less). It is next to impossible to detect such slow speeds on the background of other oceanic currents. The speed may be close to 1 m/s only in case of very small depths.

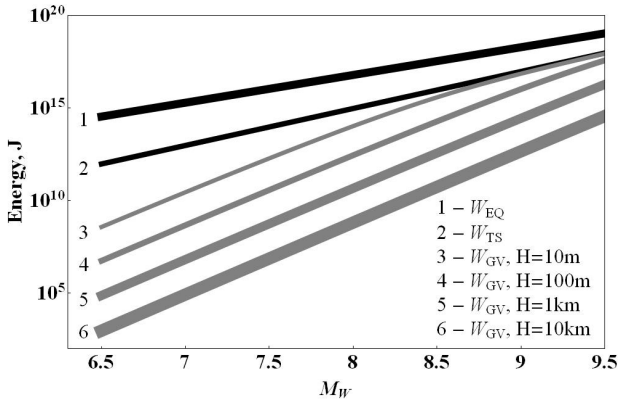

Figure 3 Energy of the earthquake W_{EQ}, the energy of the tsunami W_{TS} and the energy of geostrophic vortex W_{GV} at various depths as a function of moment-magnitude of an earthquake.

Figure 3 shows earthquake energy (W_{EQ}), tsunami energy (W_{TS}) and geostrophic vortex energy (W_{GV}) versus moment-magnitude of an earthquake (M_W). As one can judge from the figure, tsunami usually takes less than 1% of earthquake energy. In its turn, the residual geostrophic vortex takes a part of tsunami energy. And this part increases with increasing of moment-magnitude. Larger depths correspond to smaller energy of the residual geostrophic vortex.

Abstract: In this study, taking the 2011 Tohoku-Oki event as an example, horizontal motions of water in the vicinity of the tsunami source are theoretically examined by means of dynamic and static numerical models developed within the framework of linear shallow-water approximation.

1. INTRODUCTION

Devastating tsunami waves usually originate from strong bottom earthquakes (e.g. Gusiakov 2011). The first tsunami bulletin is always issued on the base of an initial seismic analysis and pre-set criteria (Operational Users Guide…2009). By this time, neither the tsunami strength nor even the earthquake parameters can be determined with a reasonable accuracy. Only when observed sea level data (vertical motions of the free water surface) became available, the level of danger can be determined more or less reliably.

In this study, we suggest considering additional sort of data – horizontal motions of water that accompany tsunami evolution. Along with the vertical motions of the free water surface (sea level variations) the horizontal motions of the water column can be used, at least in principle, in tsunami warning systems. In propagating tsunami waves that can be considered as long oceanic waves the amplitude of horizontal motions essentially exceeds the amplitude of vertical motions of the free water surface (e.g. Lighthill 1978).

The process of tsunami generation is also accompanied by horizontal motions. It is a well known fact that the main mechanism of tsunami generation is associated with residual (co-seismic) deformation of ocean bottom during strong underwater earthquake (e.g. Yamashita and Sato 1974, Okal 1988, Dotsenko and Soloviev 1995, Levin and Nosov 2009). Bottom deformation displaces a huge volume of water – up to hundred of cubic kilometers (Grilli et al. 2007, Bolshakova and Nosov 2011, Nosov et al. 2011a). The spreading of the displaced volume in the ocean has certainly to result in "residual" horizontal motions of water – displacement of water particles from their initial positions. Due to the Earth rotation, such horizontal motions of water lead to formation of a geostrophic vortex in the vicinity of tsunami source (Dotsenko 1999, Dotsenko and Shokin 2001, Nosov et al. 2011b). In present study, we shall neglect vortex motions caused by the Earth rotation because of their very low velocity ($10^{-3} - 10^{-2} m/s$, Nosov and Nurislamova 2012).

On practice, horizontal motions of water that are associated with a tsunami can be detected by means of drifters – buoys equipped with GPS (Kato et al. 2000, Falck et al. 2010, Nagai 2010, Fujii et al. 2011) or accelerometer (seismometer, Okal and MacAyeal 2006). Another option for detecting the horizontal motions of water involves processing of sequential satellite imagery (Etaya et al. 2005). There is a well-developed technique – the maximum cross correlation technique – that allows reconstructing the vector field of surface horizontal velocity from sequential satellite imagery (e.g. Crocker et al., 2007). The third technic for measuring the horizontal motions of water is bottom Acoustic Doppler Current Profiler (ADCP) (Mikada et al. 2006).

The main purpose of this study is to theoretically examine horizontal motions of water in the vicinity of a tsunami source and to show that the horizontal motions are detectable in-situ. We employ numerical models of the following two types. The first one is the dynamic model developed within the framework of the linear shallow-water approximation. The second model is the static model which is fully based on the principle of conservation of mass. The static model, as compared with the dynamic one, surely operates much faster because it omits a huge number of intermediate time steps. This is why the static model turns out to be more appropriate for prompt assessment of the horizontal motions.

2. DATA AND METHOD OF CALCULATION

2.1 Input data

Both models we use in this study take initial elevation

of water surface as input data. The calculation of initial elevation of water surface consists of two stages. At the first stage the vector field of coseismic bottom deformation should be determined. At second stage, the initial elevation is calculated using coseismic bottom deformation.

In our calculations of residual deformation of bottom in the tsunami sources we rely on the USGS slip distribution data (Finite Fault Model) that is presented on the site http://earthquake.usgs.gov/regional/world/historical.php. According to this model, the fault plane for the 2011 Tohoku-oki earthquake had dimensions of 625 km along the strike by 260 km, which was further divided into 325 subfaults: 25 km by 20 km. The bottom deformation, caused by each of these subfaults, is calculated by Okada formulae (Okada 1985). Then, the contributions of all elements are summed up. Details of our method can be found in (Nosov and Kolesov 2011, Nosov et al. 2011a).

The initial elevation in the 2011 Tohoku-oki tsunami source is determined with use of the method developed in our papers (Nosov and Kolesov 2009, 2011). The calculated amplitude of uplift and subsidence of water surface in the tsunami source amounted to 9.48 m and -1.90 m, respectively. The displaced water volume estimated with account of vertical and horizontal components of bottom deformation amounted nearly to $100\,km^3$ (Nosov et al. 2011a). The contribution of horizontal deformations to this value was about 20%.

Bathymetric data were extracted from the 1-min digital atlas General Bathymetric Chart of the Oceans (GEBCO).

2.2 Calculation of water particles displacement

Consider a layer of an ideal incompressible homogeneous liquid of variable depth in the field of gravity on a spherical earth. Our mathematical approach is based on the linearized shallow-water approximation which works pretty well for tsunami simulation in the open ocean where the wave amplitude is much less than the ocean depth which in its turn is much less than the wave length. Neglecting the Coriolis force, nonlinearity and bottom friction, we write the set of equations in vector form as follows:

$$\frac{\partial \vec{v}}{\partial t} = -g\vec{\nabla}\xi\,, \tag{1}$$

$$\frac{\partial \xi}{\partial t} + (\vec{\nabla}\cdot H\vec{v}) = 0\,, \tag{2}$$

where $\vec{v}$ is the horizontal flow velocity vector, g is the acceleration of gravity, ξ is the free-surface displacement from the equilibrium position, H is the ocean depth, $\vec{\nabla}$ is 2D (horizontal) vector differential operator.

In equations (1), (2) all the factors that can generate vorticity are excluded. Thus, the flow velocity vector can be expressed via the scalar velocity potential, φ

$$\vec{v} = \vec{\nabla}\varphi\,. \tag{3}$$

Substituting formula (3) in equations (1) we obtain the following relation between the free-surface displacement and the scalar potential:

$$\xi = -\frac{1}{g}\frac{\partial \varphi}{\partial t}\,. \tag{4}$$

Substituting formulas (3) and (4) in the continuity equation (2) we readily arrive at the classical wave equation:

$$\frac{\partial^2 \varphi}{\partial t^2} = g(\vec{\nabla}\cdot H\vec{\nabla}\varphi)\,. \tag{5}$$

In description of tsunami generation we follow the traditional approach (e.g. Titov and Gonzalez 1997, Gisler 2008, Levin and Nosov 2009): (i) an earthquake is assumed to instantly cause residual deformation of the ocean bottom which is simultaneously accompanied by formation at the surface of the ocean of a perturbation (initial elevation), ξ_0; (ii) the initial field of flow velocities is assumed to be zero. So, the wave equation (5) is solved with the following couple of initial conditions:

$$t = 0:\ \xi_0 = -\frac{1}{g}\frac{\partial \varphi}{\partial t},\quad \varphi = 0\,. \tag{6}$$

The interaction of waves with the coast is described as the full reflection from the coast (e.g. Mei 1983):

$$\frac{\partial \varphi}{\partial \vec{n}} = 0\,, \tag{7}$$

where $\vec{n}$ is the unit vector normal to the coastline. Free pass boundary conditions are specified on the ocean-crossing outer borders of the computational domain.

The wave equation (5), supplemented with the initial (6) and boundary (7) conditions, was approximated by the traditional explicit scheme of finite differences on a rectangular net. The time step was determined by the Courant condition

$$\Delta t < \frac{R}{\sqrt{gH_{max}}} Min\left[\Delta Lat,\, \Delta Lon\right], \tag{8}$$

where H_{max} is the maximum ocean depth in a calculation domain.

Static problem stays mostly equal to dynamic one, described above. However, due to numerical method we use here, we have to restrict ourselves to a basin with impermeable outer borders (closed basin). It is worth also noting that the static model we introduce here is fully based on the principle of conservation of mass (2) whereas the dynamic equation (1) is not employed.

Substituting of formula (3) in equation (2) we obtain

$$\frac{\partial \xi(\vec{x},t)}{\partial t} + \left(\vec{\nabla}\cdot H(\vec{x})\vec{\nabla}\varphi(\vec{x},t)\right) = 0\,, \tag{9}$$

where $\vec{x}$ is the horizontal position vector. By integrating equation (9) with respect to time from 0 to ∞ we reduce the original dynamic problem to the following static problem

$$\left(\vec{\nabla}\cdot H(\vec{x})\vec{\nabla}\Phi(\vec{x})\right) = \xi_0(\vec{x}) - \xi_\infty\,, \tag{10}$$

$$\Phi(\vec{x}) \equiv \int_0^\infty \varphi(\vec{x},t)\,dt\,, \tag{11}$$

where $\xi_0(\vec{x})$ is the initial elevation, ξ_∞ is a constant denoting the residual change of water level in a closed basin

$$\xi_\infty = V_0 / S , \tag{12}$$

where $V_0 = \iint \xi_0 ds$ is the water volume displaced by co-seismic bottom deformation in tsunami source, $S = \iint ds$ is the basin area. The double integrals are taken over the entire basin area. The correct mathematical solution of equation (10) for a closed basin requires considering a small but nonzero value of ξ_∞.

By formula (11) we introduce a new quantity Φ which can be interpreted as the residual displacement potential. Residual displacement of water particles in the horizontal direction can be expressed via Φ in the following way:

$$\vec{D} = \vec{\nabla}\Phi . \tag{13}$$

Boundary conditions on the coastline and on the ocean-crossing outer borders of the computational domain are the following:

$$\frac{\partial \Phi}{\partial \vec{n}} = 0 . \tag{14}$$

The computational domain was chosen large enough to avoid the influence of artificially closed boundary.

Equation (10), supplemented with the boundary condition (14) was solved numerically by finite element method on triangular grid (e.g. Norrie and De Vries 1978, Hutton 2004).

In spherical coordinates the operators take the following form:

$$\left(\vec{\nabla} \cdot H\vec{\nabla}\right) = \frac{1}{R^2 \cos^2(Lat)} \frac{\partial}{\partial Lon}\left(H \frac{\partial}{\partial Lon}\right) + \frac{1}{R^2 \cos(Lat)} \frac{\partial}{\partial Lat}\left(H \cos(Lat) \frac{\partial}{\partial Lat}\right) \tag{15}$$

$$\vec{\nabla}_{Lon} = \frac{1}{R \cos(Lat)} \frac{\partial}{\partial Lon} \tag{16}$$

$$\vec{\nabla}_{Lat} = \frac{1}{R} \frac{\partial}{\partial Lat} , \tag{17}$$

where R=6371 km.

3. RESULTS AND DISCUSSION

We recall that two different numerical models are in use: the dynamic model (Eqs. 5 – 7) and the static model (Eqs. 10, 14). In both cases the computational domain extends from 134^oE to 180^oE in longitude and from 15^oN to 55^oN in latitude.

The dynamic model uses rectangular grid with space increments of $\Delta Lat = \Delta Lon = 1 min$. The time increment was specified in accordance with the Courant condition (8), $\Delta t \approx 3\ s$.

The static model employs triangular grid of variable density. In our numerical simulation a fine grid density (approx. 4 min) is specified near the coastline and in the tsunami source area, while in the remainder of the domain, as the source distance increases, grid density gradually decreases up to 60 min.

Figure 1 shows the vector field of residual displacement of water particles in the vicinity of the 2011 Tohoku-oki tsunami source. Black arrows denote the direction and the amplitude of residual horizontal displacement. Note that the length of each vector is proportional to the value of displacement multiplied by ocean depth ($|D|H, [m^2]$). The distribution of the displacement amplitude $|D|, [m]$ is plotted in accordance with the color scale.

From Fig. 1 it is seen that the direction and the amplitude of the residual horizontal displacement is a complex function of the initial elevation in the tsunami source, the bathymetry, and the configuration of coastline. Far from shore, direction of the residual displacement of water particles is mostly defined by the initial elevation. In the vicinity of shoreline, vectors tend to be directed parallel to the shoreline. Within a very wide area (approx. 0.5 million square kilometers) in the vicinity of the tsunami source the residual horizontal displacement amounts to tens of meters (green). Residual displacements of hundreds of meters (yellow) are associated with shallow-water areas. When considering these results, one should bear in mind that in shallow-water areas the linear approximation we use may loose its accuracy. Undoubtedly, even 10 m horizontal displacement can be easily detectable in-situ.

Characteristic examples of water particles behavior in the vicinity of the tsunami source are presented on the right and bottom side of Figure 1 as the horizontal tracks. The horizontal displacement components are calculated via the horizontal velocity obtained from the dynamic model (Eqs.5-7) with use of the following obvious formula:

$$\vec{D}(t) = \int_0^t \vec{v}(\hat{t})\, d\hat{t} . \tag{18}$$

Tracks depicted in Fig 1 exhibit a chaotic-like behavior of all the displacement components after passage of the first pulse of the tsunami. Such a behavior arises due to propagation of the tsunami in the basin with highly complicated structure of bottom topography and coastline. Effects of reflection, refraction and scattering associated with topographic heterogeneities of bottom result in the chaotic-like behavior of tsunami wave field.

Let us further consider particular features of the cases presented in Fig. 1. The “least chaotic” behavior corresponds

to the cases of the open ocean (E,F, and G). The horizontal

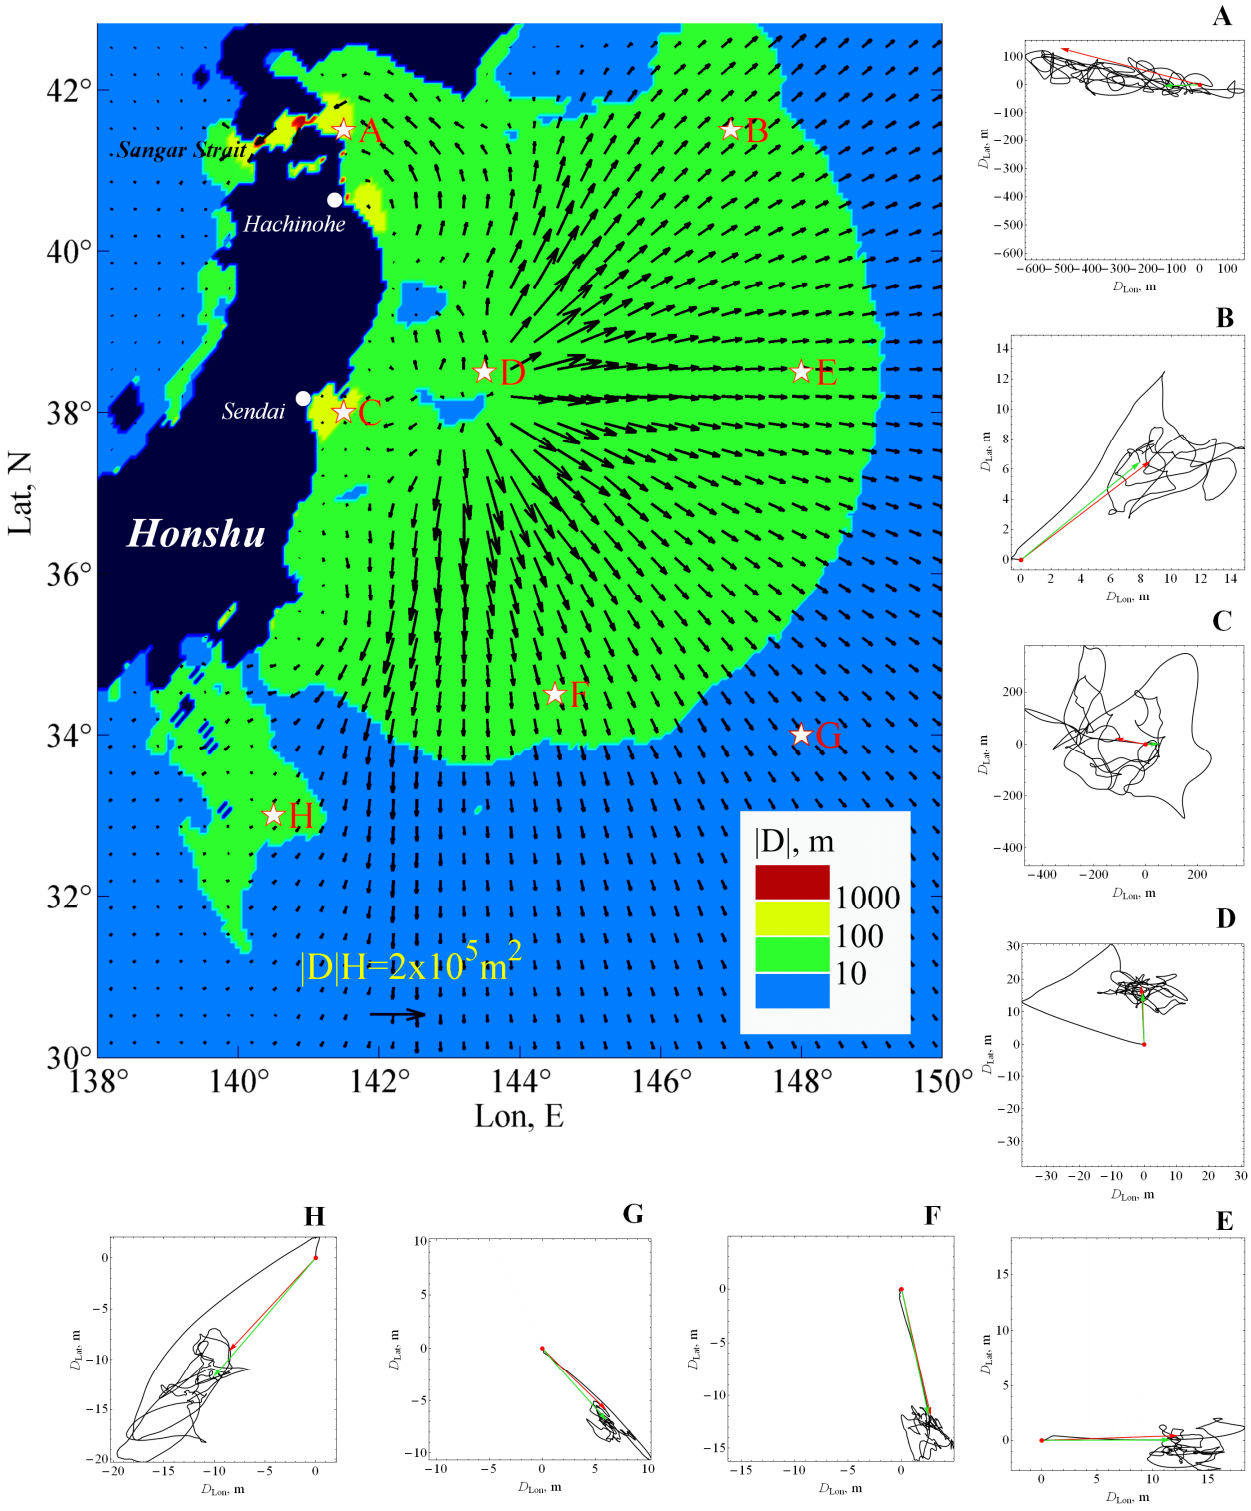

Figure 1 Residual horizontal displacement of water particles resulted from permanent bottom deformations due to the 2011 Tohoku-oki earthquake. Black arrows stand for the residual horizontal displacement; the length of each vector is proportional to the value of displacement multiplied by ocean depth, $|D|H$. The displacement amplitude $|D|$ is plotted in accordance with the color scale shown in the right lower corner. White stars denote the points, where the dynamic and static models were compared. Relevant tracks of horizontal motions of water are shown on the right and bottom side of the figure. Red arrows stand for the residual displacements calculated from the static model. Green arrows correspond to the displacement calculated from the dynamic model at the time moment of 25000 s.

displacement reaches the value prescribed by the static model rather quickly – immediately after the passage of the leading tsunami wave. The dynamic model and the static model provide nearly equal direction and amplitude of horizontal displacement. After the passage of the first tsunami wave, the displacement vector oscillates slightly in the vicinity of the value prescribed by the static model – its final position to be reached at $t = \infty$. Cases B, D, and H correspond to a noticeable influence of coastal effects whereas the ocean depth is still large enough. In these cases, the passage of the first tsunami wave result in the horizontal motion with a direction that is noticeably different from those prescribed by the static model. In the long run, after a number of loops, the displacement track turns out to be located near the final static point. The "most chaotic" behavior is observed near the shore in shallow-water area (A and C). Due to the waves trapped in the shelf area water particles undergo long-term chaotic horizontal motions with amplitude up to hundreds of meters. In the case A, a strong influence of the coastline on the direction of motions is appeared. The track is stretched along the residual displacement vector (red arrow) which in its turn is oriented parallel to the coastline. In the case C, during the passage of the first wave, the direction and the amplitude of the horizontal motions more or less correspond to the residual displacement vector. However, after the first wave a large amplitude oscillations are observed and the track exhibits a series of chaotic loops.

From the analysis of Fig. 1 one can conclude that the static and the dynamic models give results that are in a reasonable agreement. It means that the static model can be used for the prompt assessment of the direction and amplitude of the horizontal motions of water in the vicinity of the tsunami source. Exceptions to this rule are associated with shallow-water areas where the trapped waves give rise to strong chaotic motions of water. Anyway, even in such exceptional cases the static model provides a good estimate of amplitude of the horizontal motions of water.

Abstract: In this study we consider recent tsunamigenic earthquakes, those for which USGS, Caltech or UCSB provides slip distribution data and, at the same time, HTDB/WLD provides tsunami intensities according to the Soloviev–Imamura scale. Using these data and the Okada formulae, we calculate co-seismic bottom deformation. Then, taking bottom deformation and bathymetry as input data, we calculate the initial elevation of the water surface in tsunami sources. Ultimately, we obtain and discuss dependences that relate tsunami intensity and tsunami source parameters such as amplitude of initial elevation, displaced water volume, potential energy of the initial elevation.

1. INTRODUCTION

Strong bottom earthquakes are the most widespread cause for the initiation of devastating tsunami waves. In simulation of tsunamis of seismotectonic origin, an earthquake is traditionally considered to instantly displace a water column forming a perturbation on its free surface. Then, the assumption is made that the shape of the perturbation is fully similar to the vertical component of the residual deformation of the bottom. The perturbation of the water surfaces thus obtained, so-called initial elevation, is applied as an initial condition in resolving the problem of tsunami propagation (e.g. Titov and Gonzalez 1997, Kowalik et al. 2005, Gisler 2008, Levin and Nosov 2009).

Though easy-to-use in practice, this traditional approach turns out to be inaccurate in some cases. Imperfectness may be attributed to smoothing of water surface perturbations as compared with the bottom deformations (Tanioka and Seno 2001, Saito and Furumura 2009, Nosov and Kolesov 2009, 2011), contribution of horizontal deformation of a sloping (non-horizontal) bottom (Tanioka and Satake 1996, Nosov and Kolesov 2009, Nosov et al. 2011), effects of dynamics of bottom deformations (Hammack 1973, Nosov 1998) and effects of water compressibility (Nosov 1999, Nosov and Kolesov 2007, Bolshakova et al. 2011, Maeda and Furumura 2011). In particular, as it was shown in (Nosov and Kolesov 2011), the neglecting of "smoothing effect" may lead to an essential overestimation of the run-up heights.

In this study for calculation of initial elevation of the water surface in tsunami source we use the "Laplace smoothing algorithm" developed in (Nosov and Kolesov 2011).

The strength of a tsunami can be quantitatively determined with use of Soloviev–Imamura tsunami intensity scale: $I=0.5+\log_2 h$, where h is the average tsunami height on the coast closest to the source (Soloviev 1972, Levin and Nosov 2009). Relationship between the tsunami intensity and the earthquake moment-magnitude exhibits a large spread between the data (e.g. Chubarov and Gusiakov 1985, Gusiakov 2011, Nosov and Bolshakova 2012). It signifies that the relationship between tsunamis and earthquakes is complex and ambiguous.

Gusiakov (2011) in his study mentioned that the reasons for significant scattering of tsunami intensity for the earthquakes with similar magnitudes is due to the following several factors: 1) a difference in the water depth in a source area, 2) a difference in the earthquake source mechanisms, 3) a difference in the earthquake focus depth, 4) a difference in tectonic settings of the source area.

We presume that considering parameters of initial elevation in tsunami source might be more informative than moment magnitude. The reason for it is that all the factors mentioned above are taken into account while calculating initial elevation. The main purpose of this study is to relay tsunami intensity and tsunami source parameters such as amplitude of initial elevation, displaced water volume and potential energy of the initial elevation.

2. DATA AND METHOD OF CALCULATION

In calculations of the vector field of co-seismic bottom deformations in tsunami sources, we rely on Finite Fault Model (FFM) data presented on the following sites: U.S. Geological Survey (USGS, http://earthquake.usgs.gov/), California Institute of Technology (Caltech, http://www.tectonics.caltech.edu/), UC Santa Barbara (UCSB, http://www.geol.ucsb.edu/). Slip distribution for the

2003 Tokachi-oki earthquake proposed by Koketsu et al. (2004).

According the FFM, the fault plane for an earthquake is divided into a number of rectangular subfaults. The bottom deformation, caused by each of these subfaults, is calculated by Okada formulae (Okada 1985). Then, the contributions of all elements are summed up. Details of our method can be found in (Nosov and Kolesov 2009, 2011, Bolshakova and Nosov 2011). As a result we have a vector field of the co-seismic deformation of bottom $\vec{D} \equiv (D_x, D_y, D_z)$.

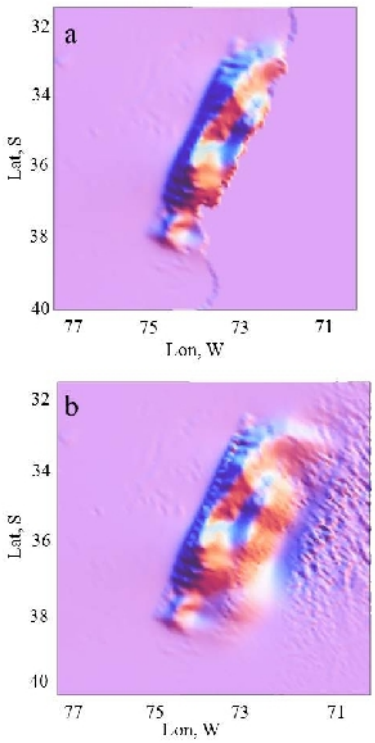

Figure 1 Initial Elevation of the Water Surface $\xi(x,y)$ in Tsunami Source (a) and Bottom Deformation $\eta(x,y)$ (b). 27 February 2010 Chile Earthquake (USGS)

Let us assume the bottom position, before an earthquake, is set by function

$$z = -H(x,y), \tag{1}$$

where $H(x,y)$ is the ocean depth. After an earthquake, due to the co-seismic deformation, the bottom takes a new position which is set by function

$$z = -H(x,y) + \eta(x,y), \tag{2}$$

where $\eta(x,y)$ is the function which describes changes of bottom position due to the co-seismic deformation of bottom. From this vector field we determine the perturbation of bottom surface as follows (Nosov and Bolshakova 2012):

$$\eta(x,y) = \frac{\partial H}{\partial x} D_x + \frac{\partial H}{\partial y} D_y + D_z . \tag{3}$$

Initial elevation $\xi(x,y)$ of the water surface in tsunami source are calculated using the "Laplace smoothing algorithm". All the details of this method can be found in (Nosov and Kolesov 2011).

Bathymetric data were extracted from the 1-min digital atlas General Bathymetric Chart of the Oceans (GEBCO).

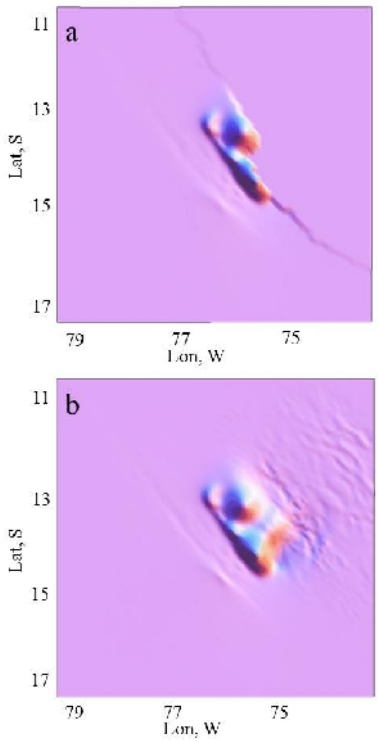

Figure 2 Initial Elevation of the Water Surface $\xi(x,y)$ in Tsunami Source (a) and Bottom Deformation $\eta(x,y)$ (b). 15 August 2007 Peru Earthquake (USGS)

Tsunami intensity data were extracted from the on-line version of Historical Tsunami Database for the World Ocean (HTDB/WLD, http://tsun.sscc.ru/nh/tsunami.php).

All the events under consideration are listed in Table 1.

Figures 1, 2 show two examples of surface disturbance and bottom deformation for the tsunamigenic earthquakes of 27 February 2010 (USGS) and 15 August 2007 (USGS) respectively.

Of all the possible parameters of a tsunami source, we shall consider those parameters which can be unambiguously calculated from initial elevation. There are three of them: amplitude (ξ_{max}), displaced water volume (V) and potential energy of the initial elevation (E_{TS}):

1. amplitude of initial elevation

$$\xi_{\max} = \left| Max[\xi(x,y)] \right| \tag{4}$$

2. displaced water volume

$$V = \left| \iint_S \xi(x,y)\, ds \right| \qquad (5)$$

3. potential energy of the initial elevation (tsunami energy)

$$E_{TS} = \frac{\rho g}{2} \iint_S \xi(x,y)^2\, ds \qquad (6)$$

where ρ is density of water and g is acceleration due to gravity. We assumed $\rho=1000\ kg/m$ and $g=9.8\ m/sec^2$. The integration in formulae (5), (6) was performed over an area where initial elevation exhibited a noticeable value.

3. RESULTS AND DISCUSSION

Results of calculation of all parameters mentioned above according formulae (3)-(5) are presented in Table 1.

Figure 3 shows relationship between Soloviev–Imamura tsunami intensity and moment magnitude. Such relationship had been already studied in some publications (e.g. Chubarov and Gusiakov 1985, Gusiakov 2011, Nosov and Bolshakova 2012). Chubarov and Gusiakov (1985) obtained the following theoretical dependence by means of numerical modeling:

$$I = 3.55\,M_W - 27.1 \qquad (7)$$

The dependence (7) is depicted in Figure 3 by dotted line.

Figures 4-6 show relationship between tsunami intensity and tsunami source parameters. Linear regression is depicted by black line. Relevant equations and correlation coefficients are also presented in Figures 4-6.

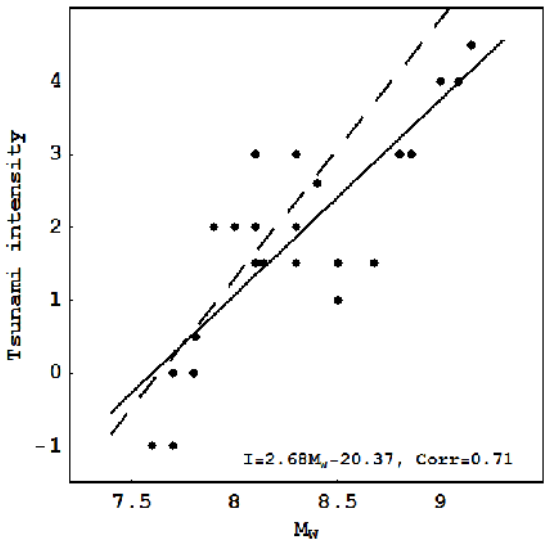

Figure 3 Soloviev-Imamura Tsunami Intensity Versus Amplitude of Initial Elevation of Water Surface. Linear Regression is Shown by Black Line. Relevant Equation and Correlation Coefficient are Also Presented. Dotted Line Stands for Dependence Obtained in Paper (Chubarov and Gusiakov 1985)

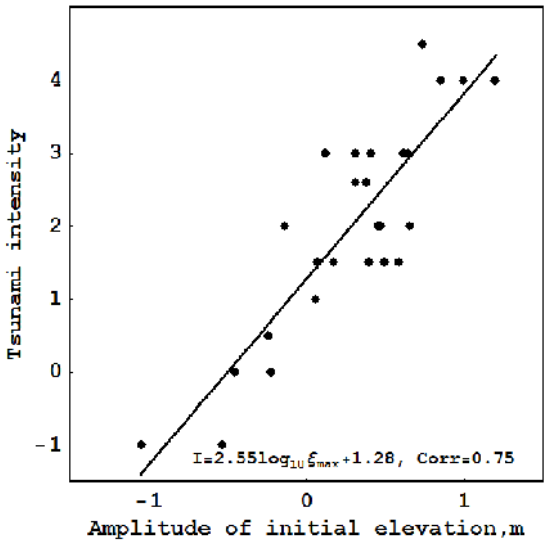

Figure 4 Soloviev-Imamura Tsunami Intensity Versus Amplitude of Initial Elevation of Water Surface. Linear Regression is Shown by Black Line. Relevant Equation and Correlation Coefficient are also presented

It is seen that dependencies exhibit rather large spread between data. Relation between tsunami intensity and tsunami source parameters is rather complex. In this study we do not take into account additional characteristics, which effect on relation between tsunami intensity and tsunami source parameters.

It should be mentioned that chosen parameters of

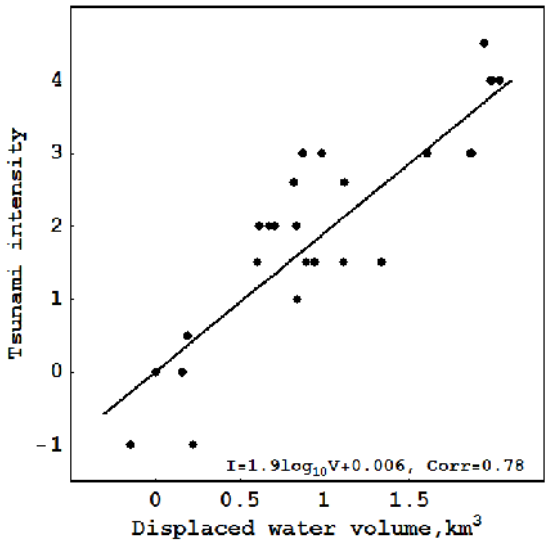

Figure 5 Soloviev-Imamura Tsunami Intensity Versus Displaced Water Volume. Linear Regression is Shown by Black Line. Relevant Equation and Correlation Coefficient are Also Presented

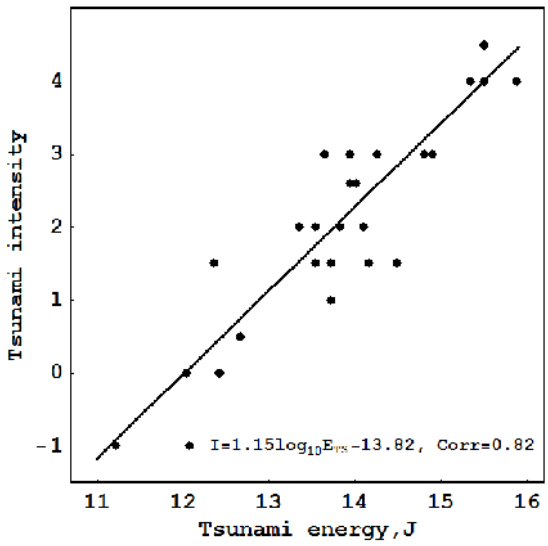

Figure 6 Soloviev-Imamura Tsunami Intensity Versus Potential Energy of Initial Surface Elevation. Linear Regression is Shown by Black Line. Relevant Equation and Correlation Coefficient are Also Presented

tsunami source can be determined, at least in principle, from in-situ measurements of horizontal movements of water particles in the vicinity of tsunami source, i.e. independently on seismological analysis (Nosov et al. 2011b).

It is seen from Figures 3-6 that tsunami intensity plotted versus tsunami source parameters displays a bit higher correlation as compared with tsunami intensity plotted versus moment-magnitude (Figure 3). Being not so high, the increase of correlation coefficient means that tsunami source parameters such as amplitude of initial elevation, displaced water volume and potential energy of the initial elevation represents better measure of tsunamigenic potential of an earthquake as compared with moment-magnitude.

Abstract: An eight-story reinforced concrete building retrofitted according to 1990 Japanese Standard was severely damaged during the 2011 Great East Japan Earthquake. The building was constructed in 1966 at Tohoku University. In 1996 the building was retrofitted using structural walls and carbon fiber. Dramatic damages were observed in coupling beams, a penthouse and a structural wall. Coupling beams failed in shear and bond. Columns and walls in the penthouse collapsed by torsion. The structural wall failed in compression at its end. Some of structural members were different from original drawings. Therefore, their strengths are re-calculated considering these differences by using 2010 Japanese Standard. Based on these calculated strengths, a pushover analysis is conducted. The failure mode in the analysis agrees with observed failure. Furthermore, it is confirmed that perpendicular walls cause large deformation of coupling beams.

1. INTRODUCTION

This paper deals with a reinforced concrete (RC) building in Tohoku University built in 1966, retrofitted in 1996 and demolished in 2012. The building had eight stories and a two story penthouse, and suffered the 2011 Great East Japan Earthquake. While it was expected to get enough strength by retrofit, the damage of this building was serious in penthouse and beams with openings. And it had been demolished

There are many reports for the damage on coupling beams due to previous earthquakes (Mitchell *at el*., 1995). The coupling beams of this building had some difference from these reported beams: the aspect ratio of the beam was large, coupling beams had openings, and the damage concentrated on the limited area of the beam.

In addition, there was non-structural perpendicular wall between this damaged area and the other area in the coupling beam. There might be some effects from the perpendicular wall. The penthouse was also greatly damaged, though the strength of penthouse was estimated to be enough (Villanova *et al*., 2011).

This paper reports observed damages based on a field investigation and discusses the cause of these damages by analyzing the frame in transverse direction.

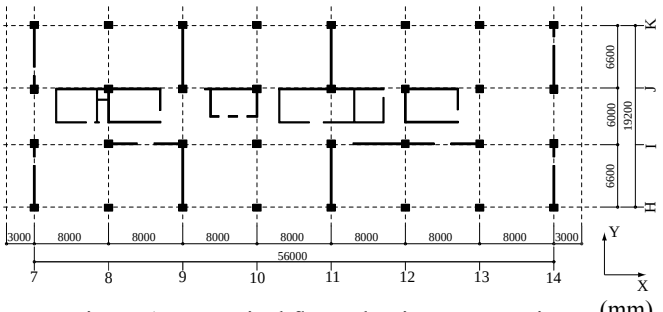

Figure 1 Typical floor plan in upper stories

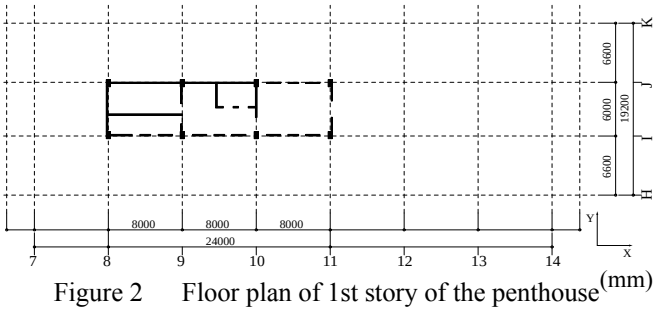

Figure 2 Floor plan of 1st story of the penthouse

2. CONFIGURATION OF THE BUILDING

The building was built in 1966 in Tohoku University, Sendai. It had eight stories and a two-story penthouse. It had seven spans (Frame 7~14) in X direction and three spans (Frame H~K) in Y direction. Figures 1 and 2 show the plan view of the typical upper floors and floor plan of the 1st story of the penthouse. In transverse direction, some frames had coupled shear walls with coupling beams. Beams had some openings for ducts.

The building was retrofitted in 1996 referred to the 1990 Japanese standard (building Research Institute 2001). The main changes during the retrofit were addition of new walls, replace RC walls for new and thicker ones and reinforcing some of the beams with carbon fiber. Addition and replacement of RC walls were described in the seismic retrofit document, but reinforcement using carbon fiber was not. The wall changes were concentrated in lower stories, from first to fifth stories, the carbon fiber reinforcement had been located mostly in the upper ones. About the location of the carbon fiber reinforcement, since there was no documentation, a deep field investigation was needed. The carbon fiber reinforcements were applied around openings in the beams. There were two kinds of fiber reinforcement: the first one is tape-shaped, the second one was a continuous fiber wrapping all beams with anchorages inside the concrete. (Photos 1 and 2) Regarding to the penthouse, no retrofit was done.

Photo 1 Tape-shaped fiber

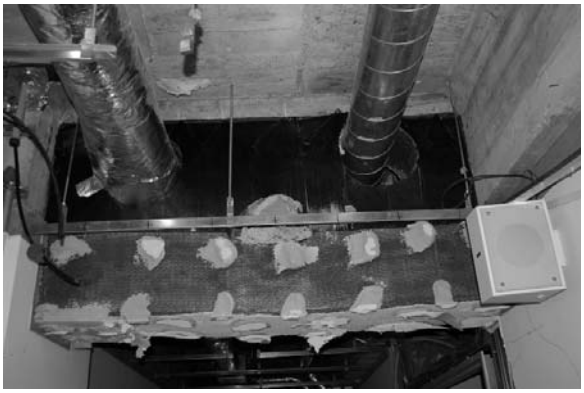

Photo 2 Continuous fiber

Figures 3 and 4 illustrate representative sections of columns and beams. The used longitudinal reinforcements were D25(#8) or D22(#7). The used stirrups were ϕ13 or ϕ9. The used materials were concrete of 18 MPa, longitudinal bars of 345 MPa for girders and columns, and 235 MPa for other elements.

In the seismic retrofit document, strength of each column and wall was described. In brief, the seismic retofit document assumes that this building collapses by columns and walls failure. The strength of each story is obtained as sum of strengths of these members. Dividing the strength by *AiWi*, we get equivalent story-shear-coefficient *C*/*Ai* as shown in Figure 5, where the contributions of the columns and walls are also indicated. In the current Japanese seismic design code (Building Research Institute 2001), *Ai* factor represents vertical distribution of a seismic story coefficient relative to that at the first story; note that *Ai* is 1.0 at the first story and very large, approximately 4.0, at the penthouse. *Wi* factor represents the weight above each story.

Based on the Japanese Standard, this building was expected to withstand strong earthquake. According to this graphs in X direction the second and eighth stories were the strongest ones and the second story of the penthouse was the weakest one. Referring to the Y direction, the second story of the penthouse was by far the strongest, and the fifth and first story of the penthouse were the weakest. However, equivalent story-shear-coefficients in the weakest storys were more than 0.6. According to Japanese Standard, these values are estimated enough strength. On the other hand, the damage of this building was serious especially in beams and penthouse.

Figure 5 Equivalent story-shear-coefficient

3. OBSERVED DAMAGES

3.1 Coupling Beams

3.1.1 Frame on Axis 14

Figure 6 illustrates that severe damages were detected in these coupling beams of the frame number 14. They have two openings near their midspans. They failed in shear at the center of beam at 3rd, 4th, 6th and 8th stories, and bond failure at the 5th, 6th, 7th stories. About bond failure they have two patterns. 5th and 6th stories failed from end to end of the beams and, 7th stories failed not center but ends.

Bar arrangements of the beams were visible because concrete had spalled. They were different from the drawing. In the drawing, the longitudinal reinforcements were D25(#8) or D22(#7) bars, diagonal reinforcements were D16(#5) bars and stirrups were ϕ13 or ϕ9 bars(Figures 7 and 8). Lack of cover concrete for window frame was expressed in the figures. Figure 9 illustrates the drawing of reinforcements around the openings of 300mm in diameter. The distance between two openings was 800mm.

Photo 3 and Figure 10 show the beam of the third floor. From these investigations, the section of this beam with openings can be estimated as Figure 11. The diameter was not constant along the beam depth and it was larger in outside part of the beam. In addition, the distance between of these openings was 600mm which was estimated from photo. There were no stirrups under

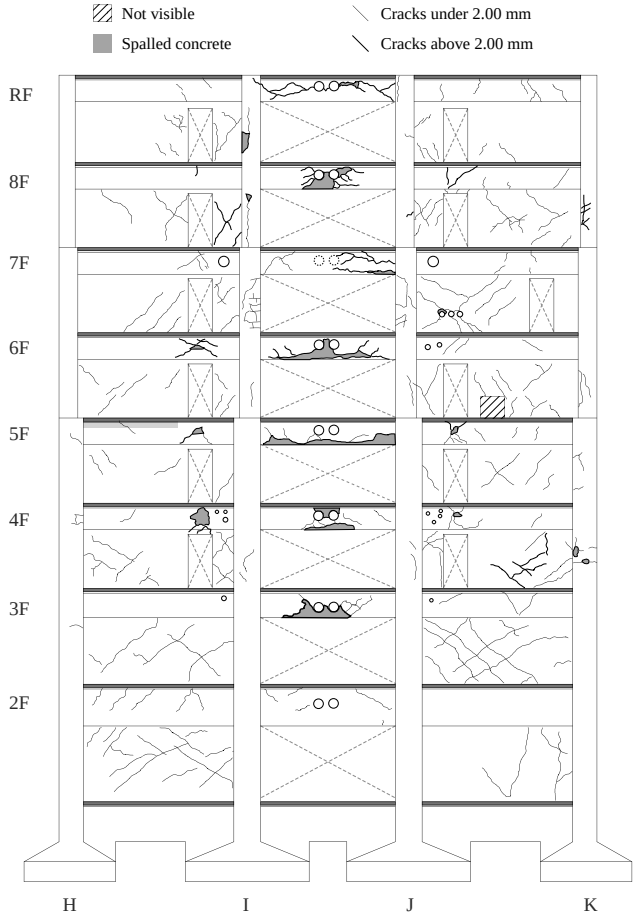

Figure 6 Frame 14 cracks schedule

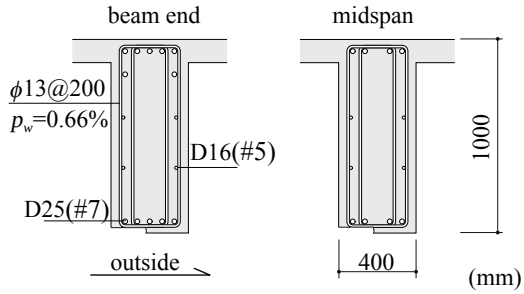

Figure 7 Section of the beam of the floor 4,5

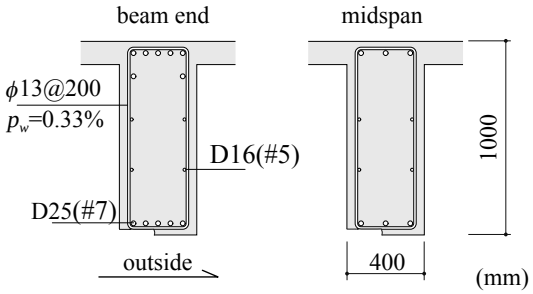

Figure 8 Section of thebeam of the floor 6,7

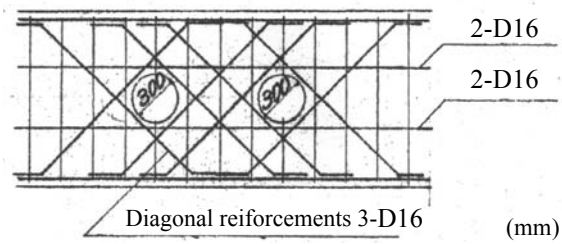

Figure 9 Drawing of reinforcement for opening

Photo 3 Beam of the 3rd Floor

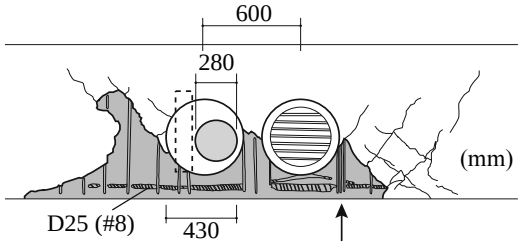

Figure 10 Detail of beam of the 3rd Floor

openings. The arrow in Figure 10 illustrates three stirrups were gathered beside the opening. In the broken area in this figure, there were no stirrups because they were cut for the opening.

Photo 4 and Figure 12 describe the beam in the fourth floor. It was different from third floor where some stirrups were gathered beside the opening. Stirrups were cut above the opening as shown in the broken area. In addition, straight anchorage of diagonal reinforcement was different from drawing which adopted bent bars. Diameter of this opening was constant along the beam width. (Figure 11)

The beam of fifth floor is provided in Photo 5. This failed in bond from end to end. Figure 13 shows the beam bottom surface viewed from below. The upper part of the figure is outside and the lower part is a window frame. Deformed bars are the longitudinal reinforcements in the beam. It shows that window frame was attached to the longitudinal reinforcement, and stirrups were cut as shown in the circle. These stirrups were cut to get the window frame into position. It was estimated that the beam got little covering depth of concrete for window frame.

The beam of 7th floor failed bond at both sides, and not shear around openings. Photo 6 was taken from inside of the building. It was detected that the beam had no opening at the 7th floor where as the ducts in the openings were found in 6th floor as shown in Photo 7.

These differences between the drawings and the practice might have caused such failure.

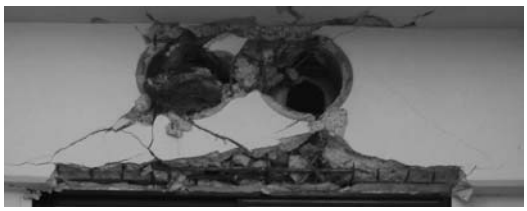

Photo 4 Beam of the 4th Floor

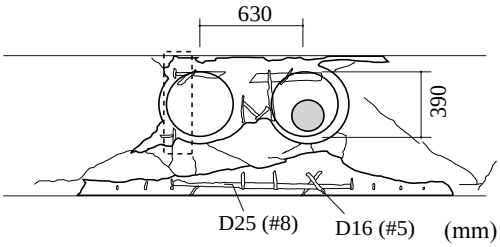

Figure 12 Detail of beam of the 4th Floor

Photo 5 Beam of the 5th Floor

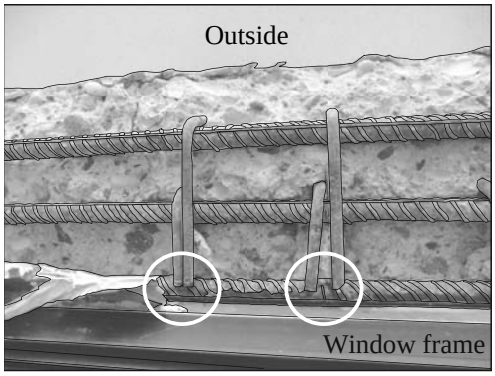

Figure 13 Look up to the bottom of the beam

Photo 6 Beam of the 7th Floor from inside

Photo 7 Beam of the 6th Floor from inside

3.1.2 Frame on Axis 11

The frames 11 were constituted of shear walls and coupling beams between these walls. Figure 14 illustrates that coupling beams of second floor and roof floor had less damage. But those of other floors suffered heavy damage as shown Fig. 15. They had perpendicular walls under coupling beams. On the South side of this perpendicular wall, the coupling beam failed in shear whereas the other side had less damage. It indicates that the coupling beam was restrained by the perpendicular wall.

Some beams were reinforced by carbon fiber around openings. The carbon fiber used to prevent shear failure. But it did not work appropriately because the anchorage length of continuous carbon reinforcements was not enough. (Photo 8) They usually need 100mm anchorage length, but actual anchorage length was 40mm. The tape-shaped fiber of the short beams were unstuck and peeled off.

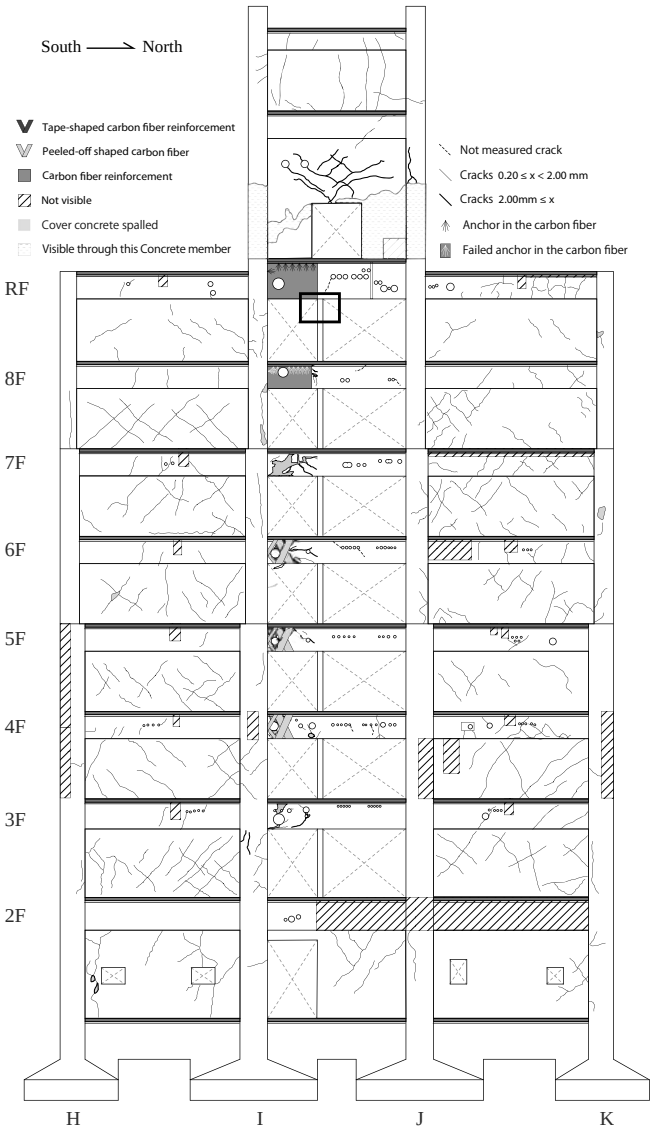

Figure 14 Frame 11 cracks schedule

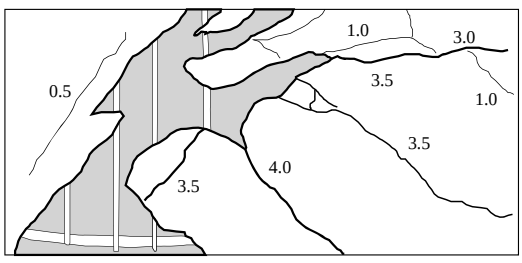

Figure15 damage of short beam of 7th floor

3.2 Penthouse

The penthouse of the building was severely damaged that required emergency strengthening just after the earthquake in order to prevent collapse. Both columns and walls were completely destroyed at the first story of the penthouse, while the second story was in a similar condition to the rest of the building. In investigation, thickness of walls was 120mm, but drawing illustrates that was 180mm. (Figure 16) Damage in the first story of the penthouse was more remarkable on transverse directions than on longitudinal one. Figure 17 shows penthouse cracks schedule of each frame. Frame 8 was less damaged. Frame 11 damaged heavily.(Photo 9) Damage in east area became increasingly hard. Capacity of walls in the first story of the penthouse was calculated in each frame as shown in the work by Villanova et al. (2012). The frame 8 had approximately twice the capacity of 9, 10 and 11 frames. Therefore, Penthouse might have torsional response. This might have caused such severe damage.

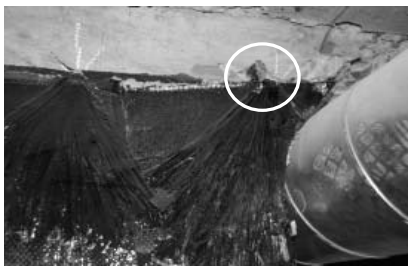

Photo 8 Failed anchorage at coupling beam floor 8

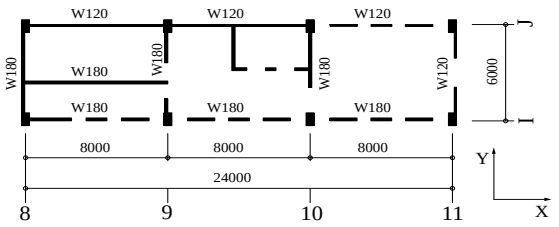

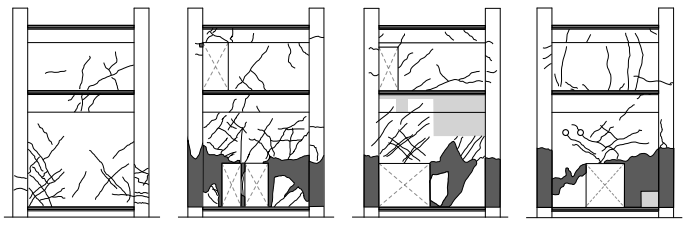

Figure 16 Penthouse 1st story (mm)

Photo 9 Wall at the first story of the penthouse

(a) Frame 8 (b) Frame 9 (c) Frame 10 (d) Frame 11

Figure 17 Penthouse cracks schedule

3.3 Structural Walls

Figure 18 illustrates frame I cracks schedule in longitudinal direction. There were few cracks in the 1st story on both X and Y directions. In the 2nd and upper stories, cracks were prominent. However, they were smaller than those of beams. Most of them were narrower than 1mm.

The pullout of bars were observed at the top of the perpendicular wall in 8th floor which is shown in Figure 19 and the square in the Figure 14. Perpendicular wall might constrain vettical displacement of the coupling beam at the mid span, and, as a result, clear span of the beam was shortened and failed in shear. Pullout of bars is a evidence of the behavior

Figure 19 Bar pullout at top of the perpendicular wall in 8th floor

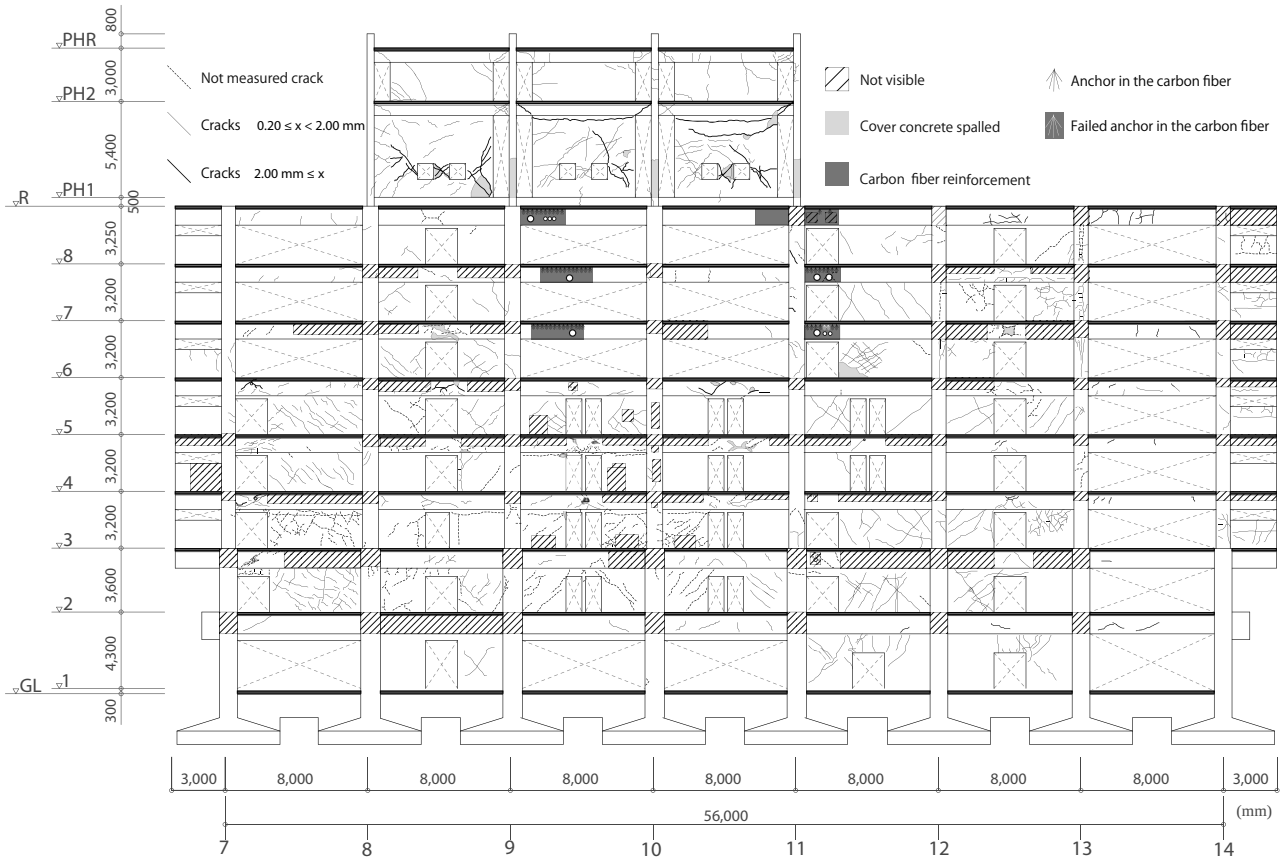

Figure 18 Frame I cracks schedule

4. PUSHOVER ANALYSIS

In this section, pushover analysis is carried out to know failure mode of this building in transverse direction, behavior of coupling beams, penthouse and perpendicular walls, and to estimate the seismic capacity of this building.

4.1 Modeling of Structural Members

4.1.1 Coupling Beams

The analytical model of the frame on 11 axis is shown in Figure 20. Coupling beams are idealized by two nonlinear rotational spring at their end and nonlinear shear spring. Coupling beams of 3rd to 8th floors are idealized with two separated beams to consider the effect of the perpendicular walls. The backbone curves of rotational springs and shear springs are represented by a tri-linear relation. The first break point in the relation represents cracked state, the second represents ultimate limit state.

There are some openings whose diameters are from 50 to 400 mm in short-span coupling beams. The shear strength of these beams are calculated considering only openings larger than 100mm in diameter. Some short-span coupling beams are retrofitted by carbon fiber. However, because the anchorage length of fiber reinforcement is shorter than demanded length, the strength contribution of this fiber reinforcement is ignored.

On the other hand, the coupling beam in roof floor is idealized a beam which is not separated and by rigid beam element with two rotational springs at its ends. These rotational springs represent the joint between columns in 8th floor and coupling beams in roof floor. Because these columns and beams are boundary columns and boundary beams, the joint fails faster than these members. However, the coupling beam depth in roof floor is twice as big as the column width in 8th floor. In brief, the column do not contributes very much to the strength and stiffness of the joint. Therefore, the backbone curves of these rotational springs use the strength and stiffness of coupling beam. The beam with wing wall in the 1st floor is also idealized by rigid beam element with two rotational springs at its ends.

4.1.2 Structure Walls

The structure wall is substituted a brace model equal to the shear stiffness of the wall. Shear behavior of the wall is idealized by two diagonal truss elements. Flexural behavior is idealized by two vertical truss elements on each side. All beams with the structure wall are assumed to be rigid.

The backbone curves of the brace model are represented by a tri-linear relation and, boundary columns are represented by a bi-linear relation. However, in the case of a wall with openings, the strength is reduced by the reduction factor based on Japanese Standard (2010).

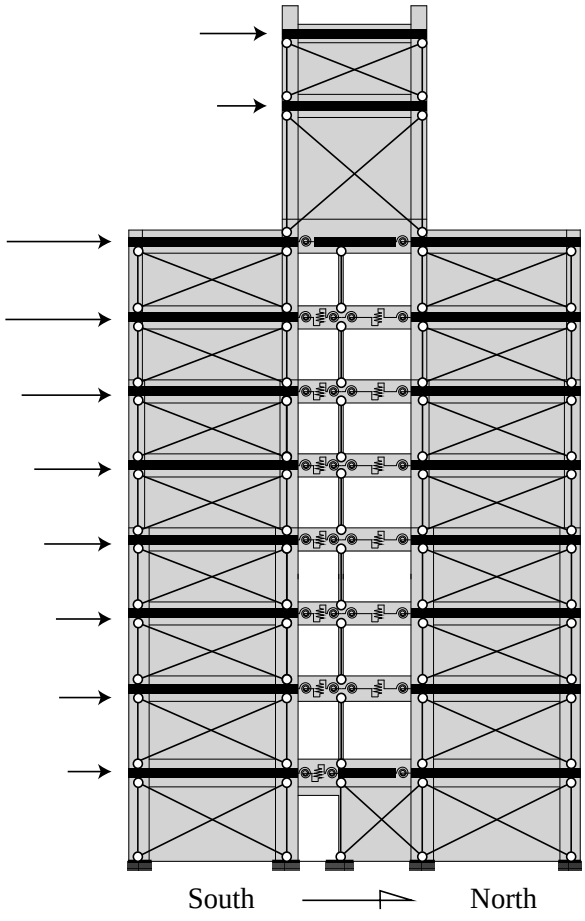

Figure 20 Analysis model

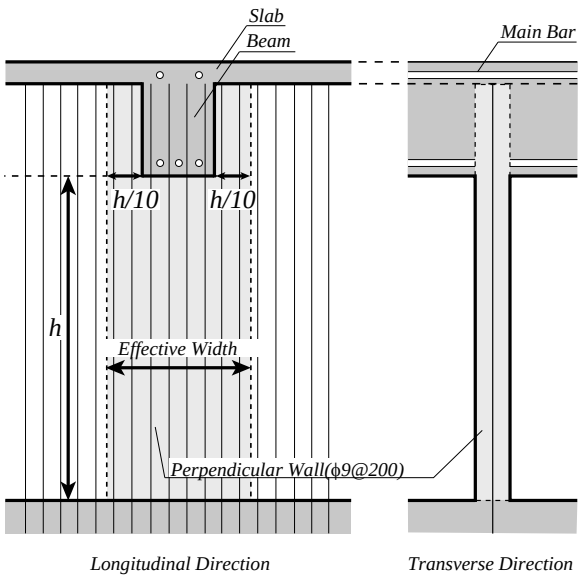
4.1.3 Perpendicular Walls

Perpendicular walls are idealized as truss elements because they do not resist to bending moment in transverse direction. The backbone curves of perpendicular walls are represented by a bi-linear relation. The compressive strength of this wall is calculated considering wall reinforcements and concrete. The tensile strength is calculated considering only wall reinforcement. However, pullout of bars is observed at the top of the perpendicular wall in 8th floor. Therefore, the tensile strength of this wall is assumed to be zero. Furthermore, the effective width of these walls in perpendicular direction is defined as shown in Figure 21. In Japanese RC Standard, a slab contributes the strength and stiffness of the beam within the width of 0.1 multiply the span length of the beam. Therefore, It assumes the perpendicular wall within the width of 0.1 multiply the clear height to resist effectively the compressive and tensile force.

4.2 Results of Analysis

Pushover analysis of the model was carried out using computer program Opensees. In this analysis, gravity loads and lateral forces are applied to each nodes in each floor. The analysis is continued to be incremented by a step to reach 1000 steps. Lateral Forces are incremented 0.001 multiplied by maximum lateral forces by every step. Therefore, maximum lateral forces are applied if the analysis reaches until final step. Maximum lateral forces are calculated by maximum story shear forces Q_{max}. Q_{max} factor represents *Wi* multiplied by *Ai*. The analysis is carried out for two cases. These parameters are the direction of lateral forces (direction from south to north, and its opposite direction).

These analyse are stopped around 500 step, because convergence test is failed. In each analysis, structure walls in 1st floor is failed in flexure. When walls are failed, story shear forces reach 0.48 Q_{max}. Therefore, the



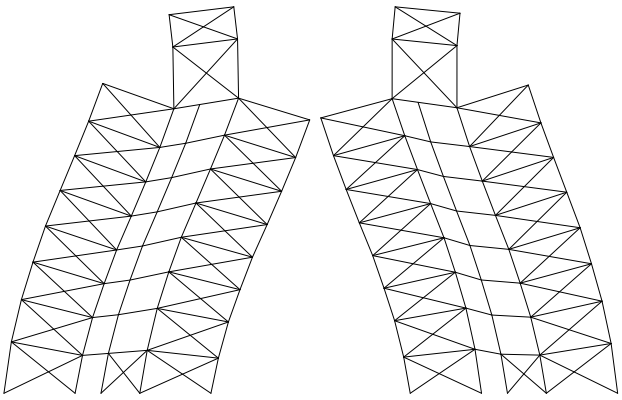


Figure 21 Effective width of perpendicular wall

base shear coefficient of this building is estimated as 0.48. Figures 22 shows the deformation of the building in the case that story shear forces are applied 0.48 Q_{max}. These displacements are illustrated by 50 magnifications. Drifts of short beams seems almost the same as long beam in Fig. 22(a). On the other hand, drifts of short beams seems larger than long beams in Fig. 22(b), Therefore, it is considered that short beam is damaged by the loading from North to South.

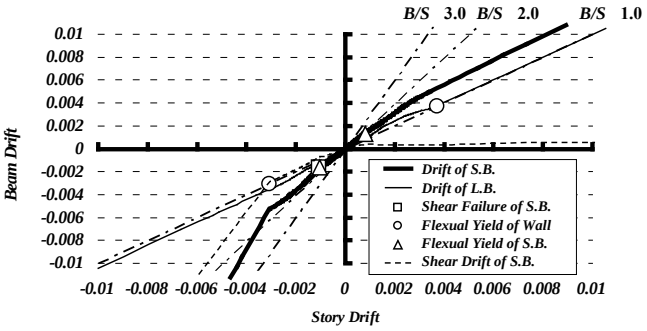

Figure 23 shows the relation between beam drift and story drift on the lower floor (1F), middle floor (4F) and upper floor (7F). Beam drift means the summation of shear drift and flexural drift. These figures show drifts in the case of both analyses. The drift of rotational spring nearby structure walls is considered larger than that nearby perpendicular walls. Therefore, flexural drift is estimated by using the rotational spring nearby structure walls. According to these relation in the area of loading direction from north to south, when walls in 1st floor failed, the drift of short beams is 1.5 to 2.0 times as large as story drift. The higher floor up, the lower the drift of short beams. On the other hand, the drift of long beam is almost the same as story drift. Figures also show the shear drift of short and long beams. It represents that the shear drift of short beams is larger than long beams. In the loading direction from south to north, the drift of short beams is almost the same as the drift of long beam. Therefore, the larger shear force acts to short beams compare to long beams in the case of loading direction south to north.

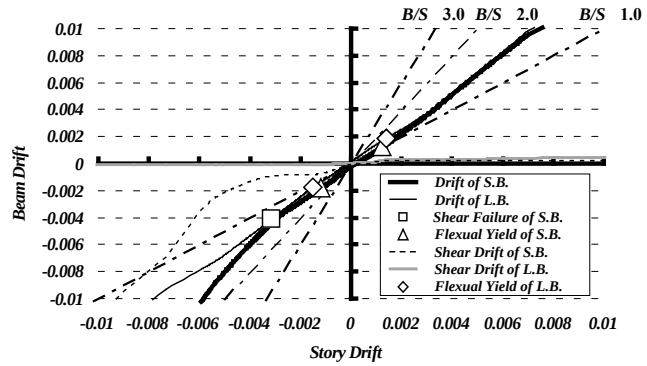
Figure 24 shows the relation between Q/Q_{max} and drifts. Q factor indicates the story shear force in each steps. Bold line indicates the drift of the building, the other indicates the drift of the penthouse first floor. The drift of the building in this graph mean the horizontal displacement at roof floor divided by the height between first and roof floor. Positive area of Q/Q_{max} in this graph represents the analysis of loading direction from south to north, opposite area represents the analysis of opposite direction. When walls in 1st floor failed, the drift of the building is about 0.65%, and the drift of the penthouse 1st floor is nearly zero in both loading directions. Even



(a)South→North (b)South←North

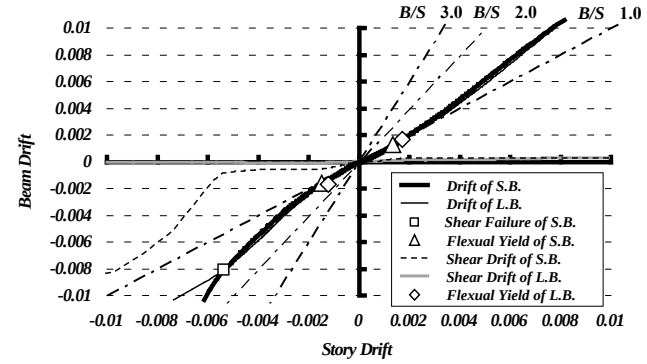


Figure 22 The deformation of the building at 0.48 Q_{max}

(a) 1st story

(b) 4th story

(c) 7th story

Figure 23 The relation between beam drift and story drift

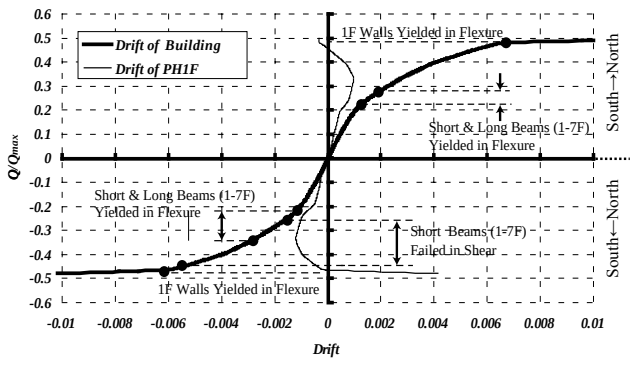

Figure 24 The relation between Q/Q_{max} and drifts

maximum drift of penthouse before walls in 1st floor failed is about 0.1%. Furthermore, in the loading direction from North to South all short beams except roof floor beam failed in flexural and shear before wall failed.

Figure 25 shows the relation between building drift and axial force of perpendicular walls. The figure represents that the perpendicular wall in 8th floor failed in bond slippage when the building drift reaches about 0.002 in south to north direction, and 0.004 in opposite direction.

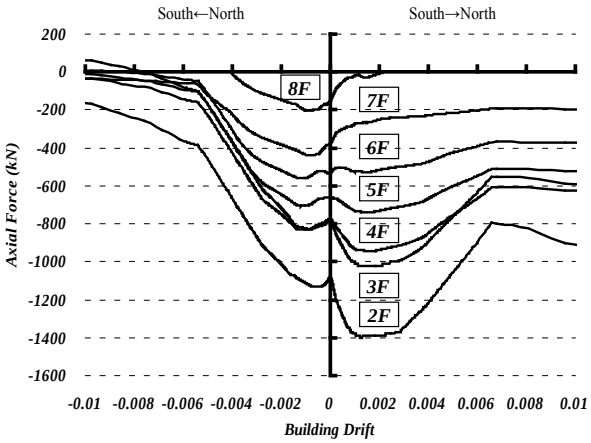

Figure 25 The relation between building drift and axial force of perpendicular walls

4.3 Discussion

Collapse model of this building in 11 axis is assumed as shown in Figure 26 and the ultimate lateral strength was calculated two patterns. The one pattern considers the work of short beam, the other one does not consider it.The strength was evaluated by using virtual work method. In this calculation, there are four assumption. First, structure walls in 2nd floor are failed in flexure. Second, the first story is considered as rigid, because it does not have significant damages. Third, top of the perpendicular wall in 8th floor is failed in bond slippage. Fourth, joints between columns in 8th floor and coupling beams in roof floor failed as shown in Fig. 27. In the result of this calculation, the ultimate lateral strength is 6.5MN without considering the effects of the beams, and 8.7MN in the other case. Furthermore, short span coupling beams are deformed 3.75 times as large as the drift of the building. According to the documents of the seismic evaluation, the ultimate lateral strength at 2nd floor is 10.7MN, and base shear coefficient is 0.8. Therefore, base shear coefficient of this calculation is estimated 0.49 and 0.65.

According to the result of pushover analysis, several behaviors of the analysis correspond with the suggested model. Regarding to ultimate lateral strength, the result of analysis is almost same as the suggested model's, but is smaller than the value of seismic evaluation. However, there are more walls in 1st than upper stories on other axes shown in Figure 28. Therefore, larger base shear coefficient than 0.48 can be expected in this building. Though drifts of short beams of the analysis are smaller than the model in Fig. 26, they are larger than story drifts as indicated in Fig. 26. Perpendicular wall in 8th floor failed in bond slippage in the pushover analysis and

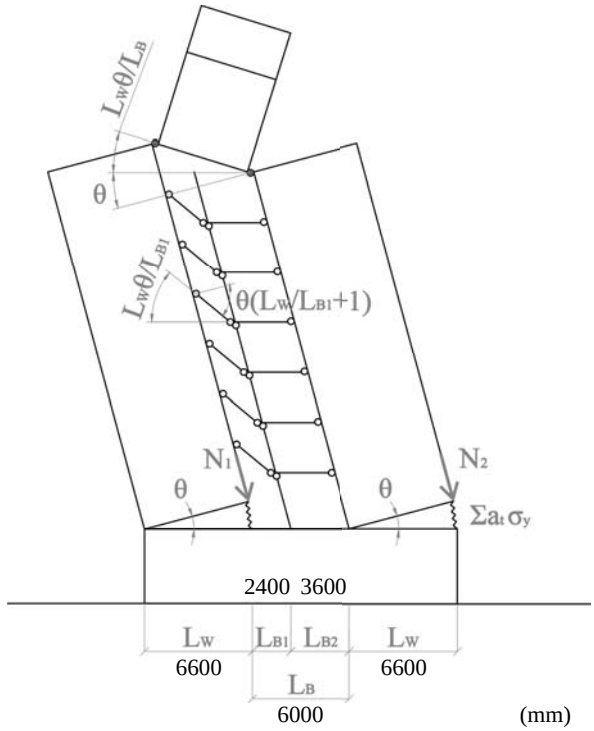

Figure 26 Model of calculation for the frame number 11

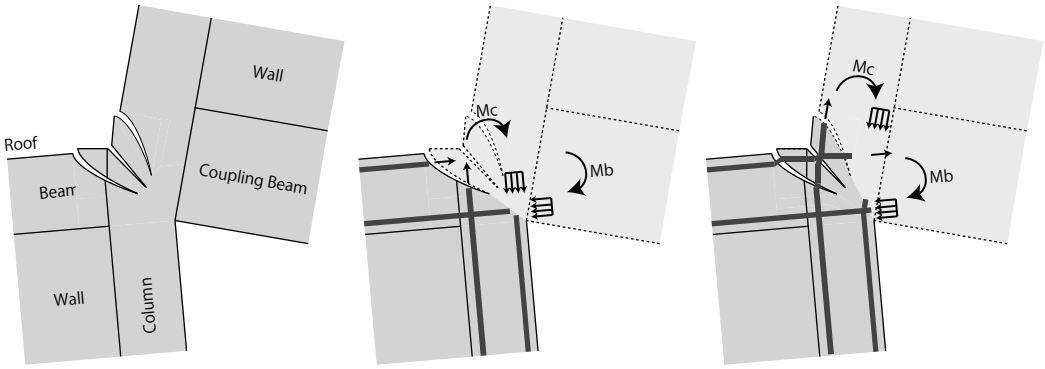

Figure 27 Assumption of the failure mode of the joint

this failure mode is also observed in field investigation. From field investigation, the failure of the penthouse is assumed to be caused by the torsional response. This failure can not be explained by the frame analysis. In fact, the result of pushover analysis shows the drift of the penthouse is much smaller than that of the main building and the penthouse does not fail.

Although the perpendicular wall is usually neglected in structural design, it has a significant role on the behavior of the coupling beam in the analysis.
It makes the short-span beam in the analysis and the failure in the analysis is similar to the observed failure.

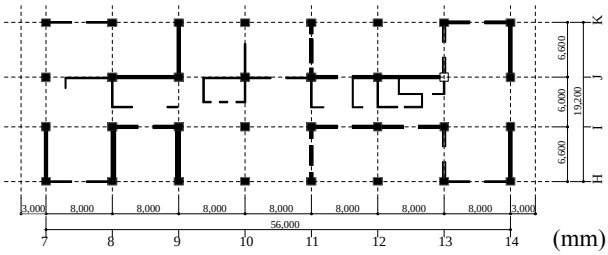

Figure 28 Floor plan of 1st story

5. LESSONS LEARNED AND CONCLUSIONS

(1)There were different points from the original drawings in coupling beams. It is one of the reason of significant damage of them.
(2)Concerning the penthouse, the capacity of wall on each frame varied widely in the transverse direction. The penthouse might have torsional response.
(3)According to the result of analysis, the building has at least 0.48 base shear coefficient. It is inferred that actual lateral forces were not over the base shear coefficient of this building because the damage of structure walls and columns were minor.
(4)Coupling beams were constrained by the perpendicular wall. It causes the large deformation of the short span beam.
(5)Short-span beam should be reinforced appropriately.

Abstract: Several buildings in Tohoku University were severely damaged by the 2011 Great East Japan Earthquake. In this paper, the damages in one of these buildings are reported and the reason of this damage is discussed. The target of this investigation was a six-story reinforced concrete building. The building was constructed in 1968 and retrofitted in 1997. This building is assumed to have enough strength to resist earthquakes in Japanese seismic evaluation. The base shear coefficient of this building is estimated to be 0.6. Severe damage was observed in short beams with web openings in upper stories. On the other hand, the mainly observed damages in columns and shear walls are thin cracks less than 1mm wide. The observed failure is different from what was considered in the seismic evaluation. Therefore, the actual strength of the frame is estimated by using the limit analysis in which the observed failure mode is assumed. In the limit analysis model, the rotation angles of short beams are much higher than those of shear walls. Shear walls might be elastic when the beam failures occurred. To prevent this failure, the coupling beam should be reinforced.

1. INTRODUCTION

A six-story Reinforced Concrete (RC) building located in the Engineering Campus of Tohoku University was severely damaged by the 2011 Great East Japan Earthquake. Remarkable damages were observed in short beams with web openings in upper stories. The building experienced several severe earthquakes since it was built in 1968, and it was retrofitted in 1997. This building was assumed to have enough strength to resist earthquakes in Japanese seismic evaluation.

The damaged short beams with web openings in transverse direction are coupling beams with stirrups (p_w= 0.18 (%)) as shear reinforcement. Shear failures of coupling beams were reported by researchers (Mitchell *et al.*, 1995 and National Research Council 1973), and it is well known that efficient shear reinforcement, such as tight stirrups or diagonal bars, is necessary. Most of the reported coupling beams have aspect ratios (clear span / depth) no more than 1.0.

In addition, various experimental programs studying the effect of shear span ratio and reinforcement of coupling beams are reported. Paulay, T. (1969) proposed a reinforcement pattern with diagonal bars to increase ductility of coupling beams. In this study, the shear span ratios ($M/Vh = l/2h$) of coupling beams were lower than 1.0. Theodosios P. Tassios *et al.* (1996) recommended that coupling beams with shear span ratios lower than 0.75 shall be reinforced with diagonal bars, and shear span ratios larger than 1.33 may use normal detailing. They also proposed alternative reinforcement patterns, with dowel bars and rhombic reinforcements.

According to the American Concrete Institute (ACI) 318-11 code (2011), diagonally oriented reinforcements are effective when coupling beams have aspect ratio less than 4.0, and coupling beams with aspect ratio less than 2.0 shall be reinforced with two intersecting groups of diagonally placed bars symmetrically.

Photo 1 Exterior view of the building (transverse side)

Photo 2 Exterior view of the building (longitudinal side)

In this building, aspect ratios of the short beams are 2.4~2.7 (except a part of rooftop beams), and these beams with stirrups as shear reinforcement experienced large deformations and severely damaged in shear. In addition, web openings through the short beams reduced their strengths.

Accordingly, the short beams of the building is a case of shear failed coupling beams with relatively higher aspect ratios compared with well-known observed damages, experimental objects and the existing code.

This paper reports observed damages based on field investigation and discusses a possible failure mechanism of the building.

2. CONFIGURATION OF THE BUILDING

The building was constructed in 1968 in Tohoku University, Sendai, located approximately 130 km from the epicenter. It is a reinforced concrete building with six stories above ground and one below and a one-story penthouse. It has seven spans in longitudinal direction and three spans in transverse direction (Fig. 1). The upper stories have the same distribution as first story plan. Storage, bathrooms and vertical communication nucleus are separated by walls in the middle longitudinal axis. The rooms are around this nucleus, giving a configuration symmetrical to the building. The penthouse has three spans between axis 4 and 7 in longitudinal direction and one span between axis B and C in transverse direction (Fig. 2).

The building was retrofitted in 1997 according to the 1990 Japanese Standard (Building Research Institute 2001). The main changes during the retrofit were addition of new walls and replacement of reinforced concrete wall panels with thicker ones for the first three stories. According to the field investigation, one of actual retrofit was different from the plan. In particular, a shear wall of longitudinal axis B, between axis 1 and 2, first story (a broken line in Fig. 1), was 180mm thick in existence and retrofitted with 100mm thicker one although it designed 120mm thick in existence and retrofitted with 130mm thicker one in the plan. But it is assumed that this difference does not affect the damages of the building. The other actual retrofits are same to the plan.

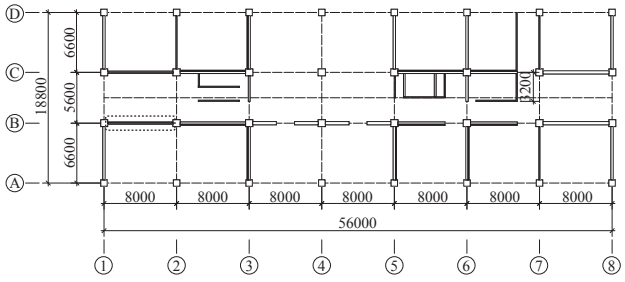

Figure 1 First story plan

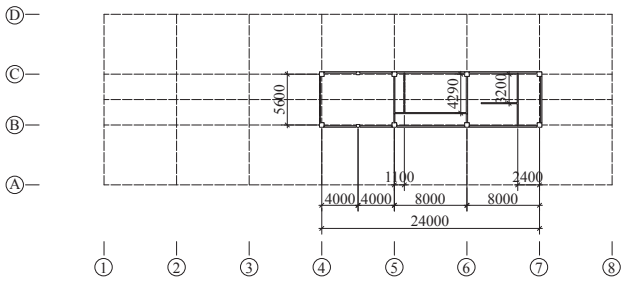

Figure 2 Story of the penthouse plan

3. OBSERVED DAMAGES

3.1. Beams

Figures 3, 4, 6 and 7 show observed cracks in selected frames. Bold lines in the figures represent cracks of more than 1mm wide. Hatched areas represent the blocked areas. In longitudinal direction, severe damages concentrated on beams above openings (Fig. 3 and Photo 3). In transverse direction, severe damages concentrated on coupling beams with web openings (Figs. 4 and 7 and Photos 4 and 5). These observed damages indicate that the short beams failed in shear. Figure 5 shows cracks observed in short beams of transverse direction (axis 3) on each story (broken lines in Fig. 4 show these

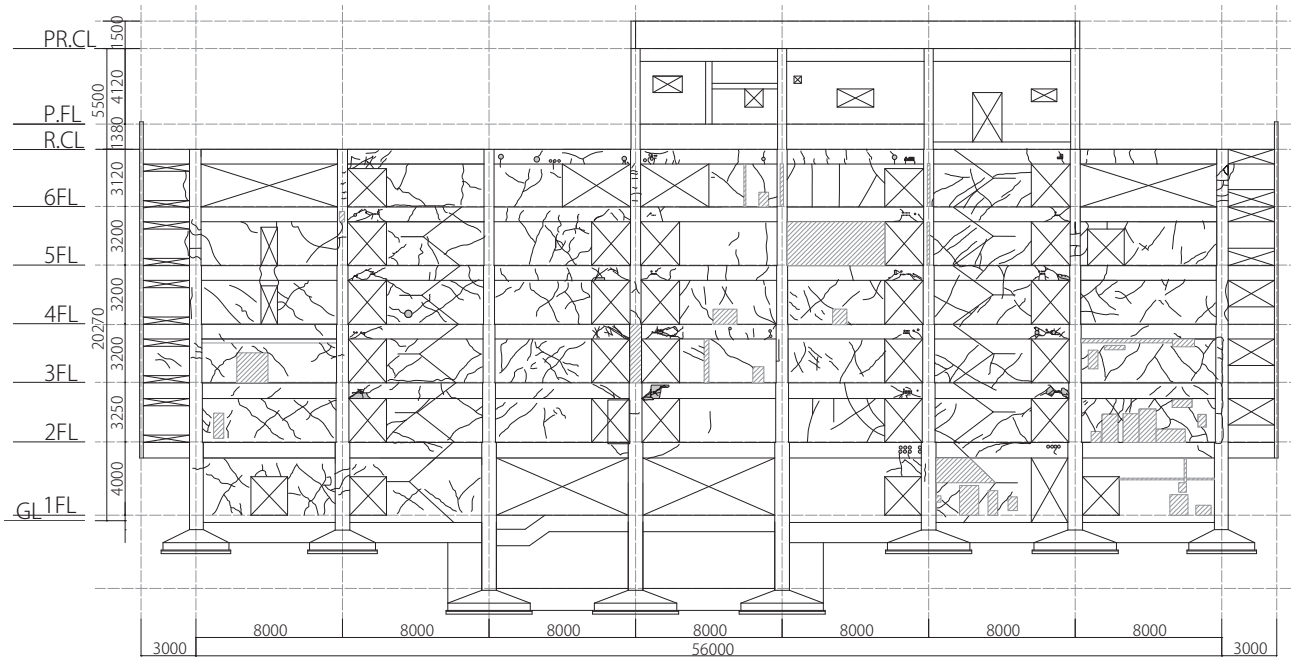

Figure 3 Observed cracks of longitudinal direction (axis C)

(a) Full view (b) Detail

Photo 3 Damaged beam above an opening (3F - axis C)

locations). Figure 8 (a) shows observed cracks of the short beam of transverse direction (axis 5) in fifth story (a broken line in Fig. 7 shows this location). Shaded areas represent web openings and spalled concrete. Numbers represent crack width measured by crack scales in the field investigation. Numbers in parenthesis are crack widths estimated from photos because it was impossible to measure them in the field investigation. Figure 8 (b) shows a section of beam in Fig. 8 (a). This shows a section of the beam end.

In both longitudinal and transverse directions, most of the short beams have web openings (diameter of 10~200mm) as shown in Figs. 5 and 8, and cracks connected with these openings were remarkable. Some cracks and detached concretes were observed in areas of cold joint especially in upper stories.

In transverse direction, axis 3, 5 and 6 are frames that have coupled shear walls as shown in Figs. 4 and 7. On the other hand, the other frames have shear walls, which are not continuous walls as shown in Fig. 6. Therefore, there are no short beams in these frames where damages were minor, and minor flexural cracks were observed.

3.2. Structural walls

In both longitudinal and transverse directions, cracks in structural walls were distributed throughout the frames. Most cracks were less than 1mm wide. The damage of structural walls was minor in comparison with that of beams, because crack widths of structural walls were less than those of beams (Figs. 3, 4, 6 and 7).

3.3. Penthouse

Maximum crack widths of 1.5mm were observed in structural walls of the penthouse, and spalled concrete was not observed. The damage of the penthouse was minor in comparison with that of the main building. In the field investigation, cold joints were observed in upper structural walls.

4. ANALYSIS

4.1. Seismic evaluation results

Prior to the seismic retrofit in 1997, the seismic capacity of this building was evaluated according to the Japanese Standard (1990). In this evaluation, beams are assumed to be strong enough. Therefore, seismic capacity is computed from contributions of columns and walls.

Figure 9 shows story shear coefficients of each story. In the penthouse story, the story shear coefficients are reduced to 76% in longitudinal direction and 86% in transverse direction. These reduction factors are computed based on the Japanese Standard (1990) and used for considering the torsional response caused by the eccentricity of stiffness in both horizontal and vertical directions. Variations in strength through stories shown in Fig. 9 were relatively small in both directions. In transverse direction, the open frames without coupled shear walls were retrofitted with additional shear walls from first to third stories. Therefore, the story shear coefficients in fourth or upper stories are relatively lower (Fig. 9). Also in the field investigation, increase

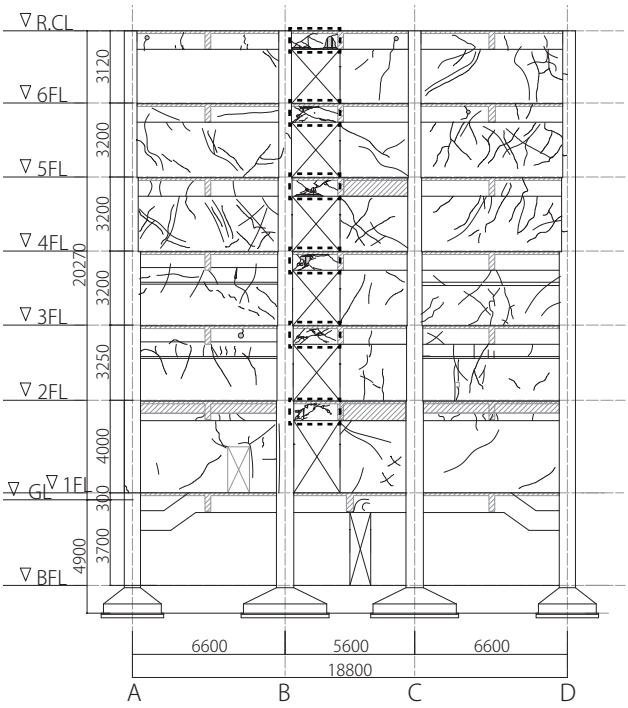

Figure 4 Observed cracks of transverse direction (axis 3)

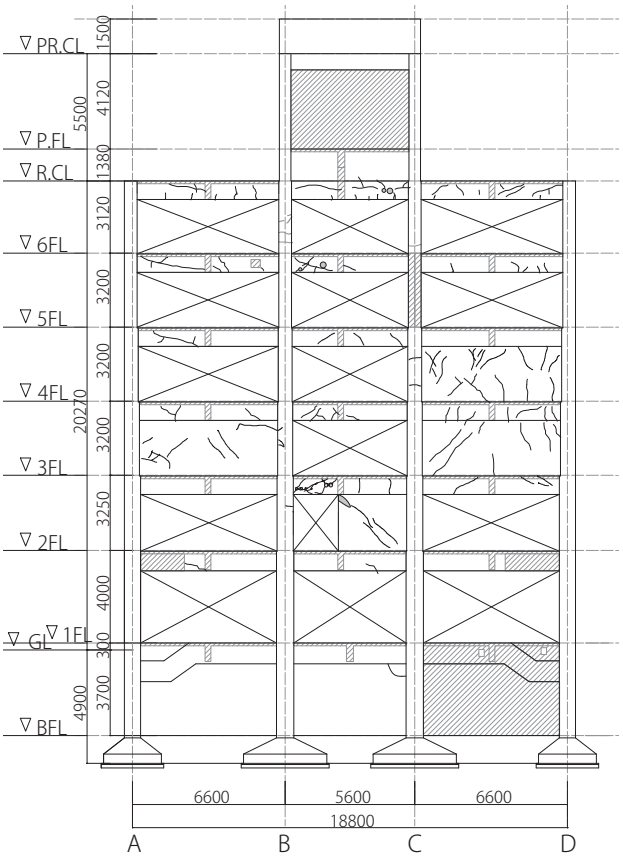

Figure 6 Observed cracks of transverse direction (axis 4)

of crack widths was observed on fourth to fifth stories. The story shear coefficients are more than 0.57 in both directions. Therefore, the building was assumed having enough strength based on the evaluation. Nevertheless

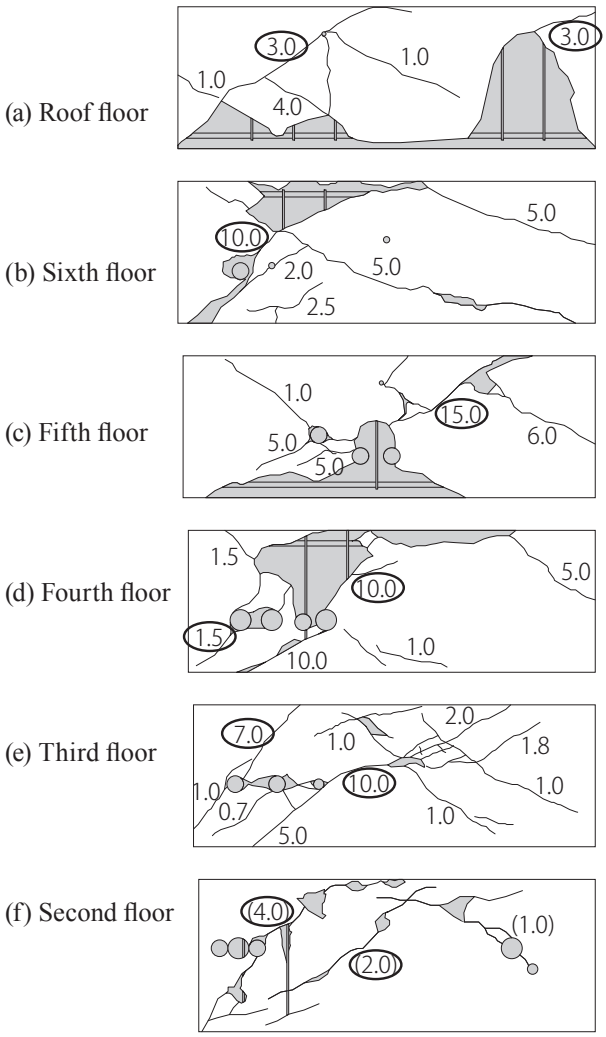

Figure 5 Observed cracks of the short beams (axis 3)

the building was severely damaged. The differences between the actual damage and the calculated values are assumed attributing to the difference of failure modes. In particular, beams were assumed to be rigid during the evaluation, but failure of the short beams take a lead over that of columns and walls actually. Therefore, a failure model considered the field investigation data is set in following section.

4.2. Calculation of the ultimate lateral strength

In this section, a failure model based on the field investigation data is assumed, and the ultimate lateral strength in the transverse direction is calculated by virtual work method.

4.2.1. Procedures

The characteristics of damage in transverse direction can be described as following: first, damage of coupled shear walls and columns were relatively small. Second, severe damage concentrated on the short beams. Axis 3 has both coupled shear walls and the short beams (Fig. 4), and it was damaged characteristically and retrofitted in first to third stories. Therefore, a failure model shown in Fig. 10 is assumed as this frame, and the calculation is conducted based on the following assumptions.

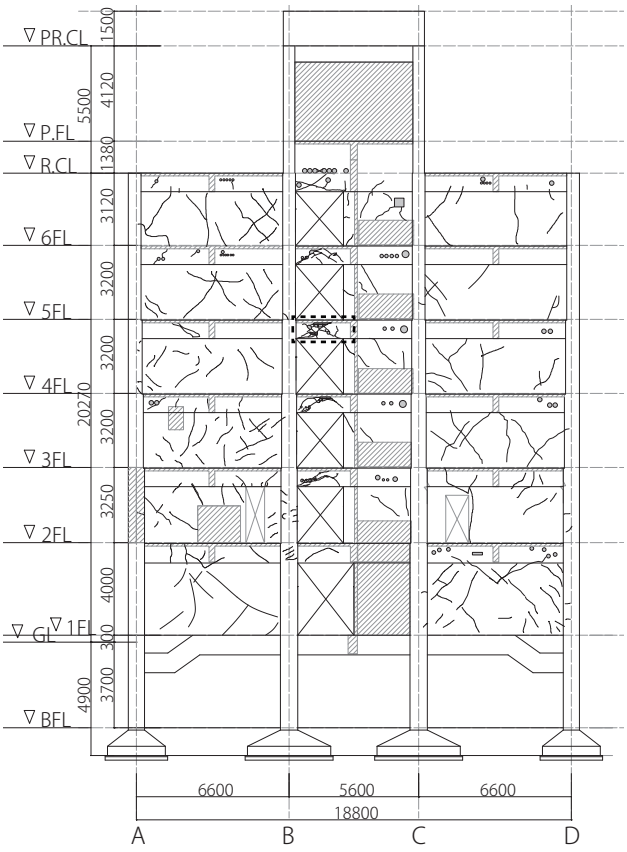

Figure 7 Observed cracks of transverse direction (axis 5)

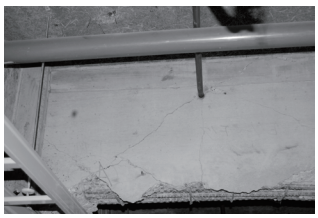
Photo 4 Damaged short beam (4F - axis 5)



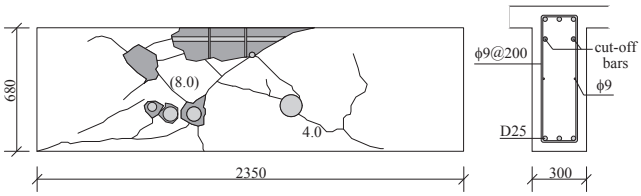


Photo 5 Damaged short beam (6F - axis 3)

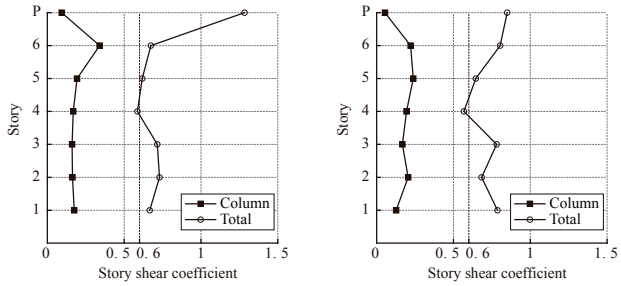
The coupled shear walls rotate as shown in Fig. 10 and vertical reinforcement bars are assumed to be yielding at the bottom of the first story, where a_t represents cross-section area of longitudinal reinforcement in boundary column and σ_y represents yield strength of the steel. N_1 and N_2 are the permanent loading axial forces on the boundary columns of the walls. The circles at beam-ends in this figure represent the plastic hinge.

In the analysis, two models have been proposed. In the first one, the short beams of the span L_B fail in shear: the beams are completely destroyed and capacity in hinges is negligible. In the second one, the beams yield in flexure at both ends.



4.2.2. Results and discussions

According to the model of the analysis, all the walls have been considered as flexural walls because of the hinge in the base of the walls of the model. This assumption is admissible since the small width

(a) Observed cracks (b) Section

Figure 8 Observed cracks of the short beam of transverse direction in fifth story (axis 5)

(a) Longitudinal direction (b) Transverse direction

Figure 9 Story shear coefficients of each story

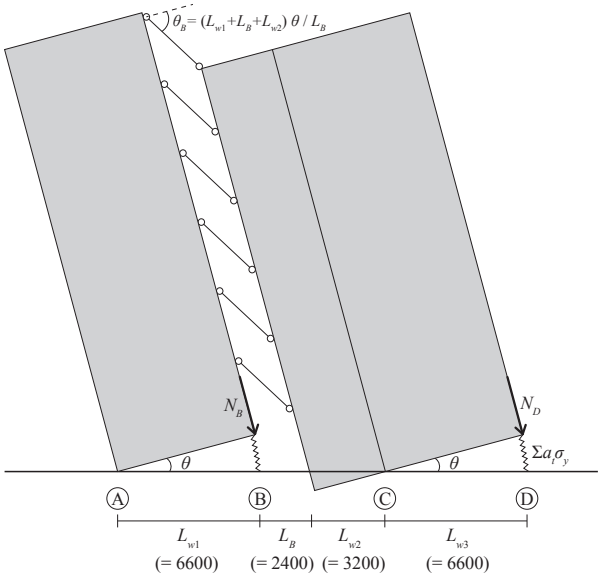


Figure 10 The assumed failure model

of the cracks found in the walls of the building. As to the results of the analysis, the lateral capacity of the frame axis 3 is 10MN, in the case of considering the contribution of the short beams. In the case of neglecting those beams, the lateral capacity is 8MN. Thus, the actual value would exist between these two results and the beams make an important contribution to the capacity of the frame actually. According to the documents of the seismic evaluation, the lateral capacity of the frame axis 3 is 10MN. It is a coincidence that this value is almost equal to the analytical result with considering beam contributions, however, this indicates that the building is assumed to have enough strength.

The rotation angles of short beams, θ_B in Fig. 10, is

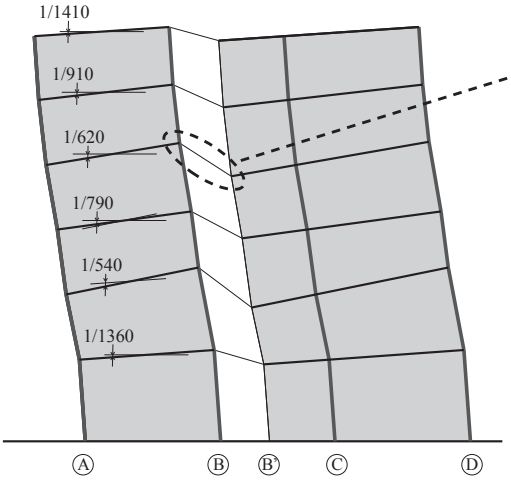

Figure 11 The assumed deformation model

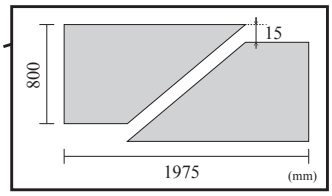

Figure 12 A pattern diagram of shear deformation

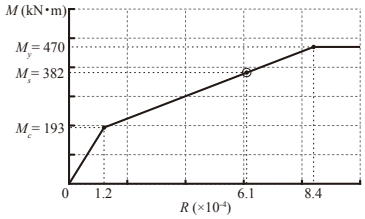

Figure 13 Moment - rotation relation

5.1 times larger than those of shear walls, θ in Fig. 10. It suggest that extremely large deformation will be induced to the short beams if the deformation of the building is relatively small.

4.3. Estimation of the actual deformation

Figure 11 shows assumed deformation model based on following assumptions.

The circled numbers in Fig. 5 are residual shear crack widths assumed to be induced by the deformation shown in Fig. 11. The rotation angle of the beam attributed to shear deformation can be estimated roughly from these crack widths and clear spans of the beams on each story (Fig. 12). In Fig. 11, a shear wall between axis A and B is rotate around axis A due to a column on axis A. This is based on the assumption that the location of the neutral axis is near the centroid of the column. A shear wall between axis B' and D is rotate around axis C due to a column on axis C.

For example, the rotation angle of the beam attributed to shear deformation in fifth story is 15/1975 ≈ 1/132 (Fig. 12). The rotation angle of the beam attributed to flexural deformation can be estimated from a moment - rotation relation based on the AIJ Standard (Architectural Institute of Japan 2010)(Fig. 13): in reaching the ultimate shear strength, the rotation angle is 6.1×10^{-4} (≈ 1/1640), and it is sufficiently small in comparison with that of attributed to shear deformation. Accordingly, the rotation angle of the shear walls in fifth story based on the model in Fig. 10 is θ = 1/620 (noted in Fig.11). In the 1990 Japanese Standard, a standard rotational deformation in ultimate is 1/250. In addition, the short beam has lower shear strength than flexural strength (Fig. 13 M_y: flexural moment, M_s: shear moment). Consequently, the coupled shear walls deformed in the range of elastic deformation, but the short beams extremely deformed, and the short beams was assumed to fail before the shear walls. It correspond to the observed crack patterns.

According to the ACI 318-11, the coupling beams with aspect ratio less than 2 shall be reinforced with diagonal bars. The coupling beams of this building failed in shear in spite of having aspect ratios larger than 2 because the shear strength of these coupling beams were not so large. The coupling beams should be reinforced to have larger shear strength than flexural strength and should not have openings.

5. LESSONS LEARNED AND CONCLUSIONS

(1) Both longitudinal and transverse directions, the damage of columns, structural walls and the penthouse was relatively minor.
(2) In longitudinal and transverse directions, severe damages concentrated on short beams. Most of these beams had web openings, and cracks connected with these openings were highly visible.
(3) From the seismic evaluation results, the story shear coefficients were more than 0.57 in both directions, and no story had an obvious weakness.
(4) The coupled shear walls deformed in the range of elastic deformation, but the short beams deformed extremely.
(5) The conventional reinforced coupling beams with aspect ratios larger than 2.0 suffered severe damage. In the previous researches and ACI 318-11 recommendation, coupling beams with aspect ratios lower than 2.0 were mainly target of special shear reinforcement.
(6) The beams shall be reinforced appropriately not only in terms of strength but also that of deformation in order to use a building continuously after earthquake damage with minor repairing.
(7) Web openings through the short beams are recommended avoiding.

Abstract: This paper presents a study of a retrofitted SRC building which was damaged by 2011 Great East Japan Earthquake. The building was severely damaged in 2011 Great East Japan earthquake. However, this building also suffered from minor damage due to the 1978 Miyagi Oki earthquake. In 2001, This building was seismically evaluated using Japanese seismic evaluation standard (JBDPA) and it was retrofitted based on this seismic evaluation. It was retrofitted by installing framed steel braces, replacement of shear walls and jacketing of adjacent beams with steel plates. Characteristics and crack Figures of the structural damage is presented. The actual damage observed was different from estimated damage of the seismic evaluation. Plausible explanation of such damage and its mechanism is presented, compared and discussed with the seismic evaluation results, virtual work method and capacity spectrum method .

1. INTRODUCTION

In Japan, seismic evaluation and strengthening have been widely applied to existing buildings especially since the 1995 Kobe Earthquake. Many existing buildings that were designed before1981in Miyagi Prefecture were evaluated, and buildings deemed to be vulnerable were retrofitted before the 2011 East Japan earthquake. Most retrofitted buildings performed well during the 2011 East Japan Earthquake. The retrofits helped to limit damage to buildings in the affected area. However, some of the retrofitted buildings suffered moderate or severe structural damage. One of the severely damaged building was the building of the Faculty of Engineering and Civil Engineering (referred as "CE building" in this paper), which was located on the Aobayama campus (Engineering campus) of Tohoku University, Sendai. The locations of the building, Sendai, and the epicenter of earthquake are shown in Figure 1.

The CE building is a 9-story composite structure constructed in 1968. Accelerometers were installed in 1968 in the 1st and 9th floors by Building Research Institute (BRI). Acceleration records were obtained for a number of earthquakes including the 1978 Miyagi-ken Oki Earthquake. In the 1978 earthquake the building suffered minor damage as reported by Shiga and Shibata (Shiga et al.1981). The damage was repaired and the building was used without disruptions until 2001, when the building went through

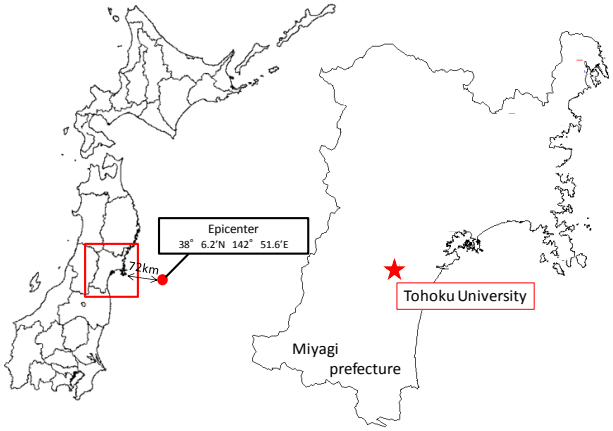

Figure 1 Location of Tohoku University

(a)from North (b)from East

Figure 2 General view of this building

major strengthening work.

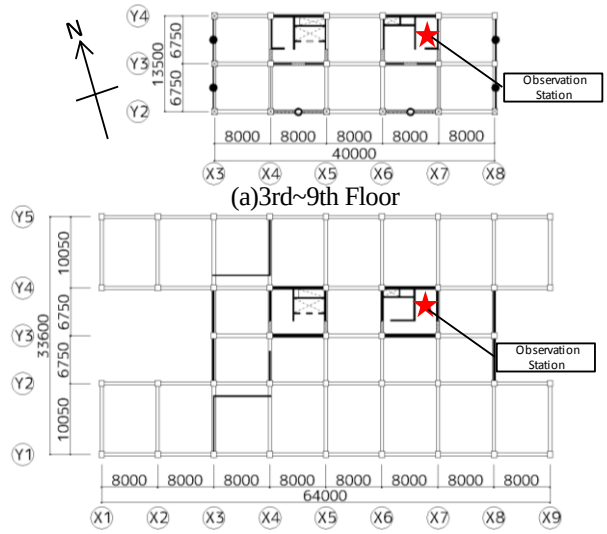
In 2011, and despite the strengthening done in 2001, the Great East Japan Earthquake caused severe damage to the building leading to its evacuation and demolition. In this earthquake, acceleration records were obtained again on the 1st and 9th floor. This fact, and the availability of 1) previous records, 2) detailed accounts of the damage caused by previous earthquakes, and 3) complete construction and retrofit drawings make the building a special case attracting the attention of many researchers (Motosaka 2012, and Kimura et al 2012).

This paper describes 1) the configuration of the building, 2) the results of the seismic evaluation that trigger the retrofit work done in 2001, and 3) damage caused by both the 1978 and 2011. Plausible explanations for the great difference in damage are studied using a simple model.

2. BUILDIN CONFIGRATION

2.1 Outline of building

Figures 2a and 2b show the North and East elevations of the CE building. The building was a 9-story steel/concrete composite building. The first two stories were larger in plan than the upper stories (Figure 2b), Figure 3). The typical floor plan for the 3rd to 9th floors is shown in Figure 3a), and the floor plan of the 1st and 2nd floors is shown in Figure 3 b). The locations of the accelerometers are indicated by the stars in Figure 3.



In the transverse direction, the main lateral-load resisting system consisted of shear walls along lines X3, X8, and the C-shaped shear walls of the staircases. As shown in Figure 3a), the structure was symmetrical about its transverse axis. Forces in the longitudinal direction were resisted by the staircase walls and two walls located along the longitudinal axis (Y3). But the structure was not symmetric about axis Y3. The asymmetry was caused by the staircase walls, which were not aligned with this axis.

Table 1 shows typical column dimensions and reinforcing details. Each column had eight vertical structural steel angles "tied" together by discrete horizontal steel plates. These plates did not form continuous webs or continuous flanges. Instead, they simply provided discrete supports for the vertical angles (Figure 20a)). These angles were embedded in concrete reinforced with twelve deformed vertical bars and widely spaced small-diameter ties made with plain round bar (Table 1).

The material of the steel angles was reported to meet Japanese standard SS400, which specifies a nominal yield stress of σ_{sy}=235N/mm^2. The deformed vertical reinforcing bars were reported to meet Japanese standard SD345, which specifies a nominal yield stress of σ_y=345N/mm^2. Ties were made from smooth round bars meeting standard SR235 (σ_y=235N/mm^2). The specified strength of concrete was Fc = 21N/mm^2.

Figure 5 C index and Ai of each story

Disaster Prevention Association) standard, Japanese Standard for Seismic Capacity Evaluation of Existing Reinforced Concrete Building, (JBDPA 2001b) to the building in order to evaluate seismic capacity and to decide seismic retrofit scheme.

I_s-Index which represent seismic performance of structure can be calculated by Eq.(1) at each story and each direction according to the standard. E_0 is a basic structural index calculated by Eq.(2).

$$I_s = E_0 \times S_D \times T \quad (1)$$

$$E_0 = 1/A_i \times C \times F \quad (2)$$

C-Index is strength index that denotes the lateral strength of the buildings in terms of story shear coefficient which namely the shear normalized by weight of the building sustained by the story. *F*-Index denotes the ductility index of the building ranging from 1.0 (brittle) to 3.5 (very ductile) in case of SRC building, depending on the sectional properties such as bar arrangement, member proportion, shear-to-flexural-strength ratio etc. *Ai* is The distribution of lateral forces along the height of the building is based on the *Ai* distribution(see Eq.(3)) prescribed in the AIJ provision (AIJ 1999).

$$A_i = 1 + \left(\frac{1}{\sqrt{\alpha_i}} - \alpha_i\right) \times \frac{2T}{1+3T} \quad (3)$$

where: α_i is ratio between the total weight supported by story *i* to the total weight of building, *T* is 1st natural period

S_D and *T* are reduction factors to modify E_0 considering of structural irregularity and deterioration after construction, respectively.

The Seismic Evaluation Standard recommends as the demand criterion that I_s-Index higher than 0.6 should be provided to prevent major structural damage or collapse.

Figure 4 shows the I_s-index of all stories for both before and after retrofit. This building was retrofitted because I_s-index was less than 0.6 for most stories.

It should be noted that the *F* index (ductility index) used here was 3.5 assuming the building has very ductile flexural walls.

Figure 5 shows the *C*-index /*Ai*. 1st and 2nd stories have higher lateral strength (*C*/*Ai*=0.4~0.5) than upper stories in both directions. In the Y direction, 3rd-8th story have approximately the same *C*/*Ai* value (=about 0.3). *C*/*Ai* =0.3 is the minimum requirement for RC buildings in the current seismic code in Japan

Figure 6 shows the *C*-*F* curve of 3rd story. Both directions have *F*=3.5, and the building was stronger in X direction than in Y direction. In Y direction, the strength index is as low as 0.29.

2.3 Scheme of seismic Retrofit

According to the seismic evaluation results, seismic capacity I_s-index was insufficient to requirement of I_s=0.6 and was classified as a retrofit candidate. In 2001, the building was seismically retrofitted by installing framed

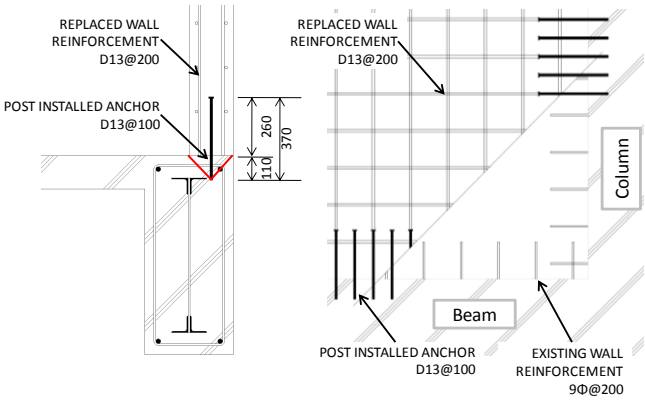

Figure8 Detail of replaced wall

steel braces in the longitudinal direction, replacement of RC shear walls in transverse direction (frame X3 and X8) from 3rd to 9th story, and jacketing of adjacent short beams with steel plates to avoid shear failure, as shown in Figure 7. The main scheme of the seismic retrofit was to increase I_s index (seismic performance index) to meet the criteria of $I_s \geqq 0.6$. The retrofit plan was to increase the ductility of the transverse direction by replacing the exterior shear walls (which had cracks from previous earthquakes) with new exterior shear wall. However, the story shear coefficient *C*-index is not increased (0.3 or less) even after retrofitting.

As for the longitudinal direction, steel braces were installed to reduce the torsion vibration induced by the irregularity of the structure in this direction.

The reinforcing details of the panels replaced in walls X3 and X8 are shown in Table 2 and Figure 8. These wall panels were replaced as follows:

1) the original concrete was removed with jack hammers,
2) 310-mm long adhesive anchors (D13 bars) with an embedment length of 110 mm were installed in beams and columns,
3) existing reinforcing bars (round 9-mm plain bars) were cut 200 mm away from beam and column faces,
4) new reinforcing bars (deformed 13-mm bars) were spliced with the adhesive anchors in both the longitudinal and horizontal directions.
5) concrete was cast in the wall panel.

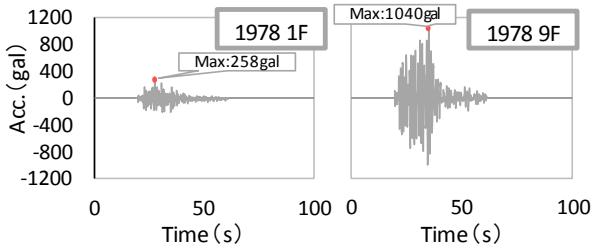
It is important to emphasize that development length of post installed anchors were 110mm according design document for seismic retrofit design. The length of anchor met the guidelines for seismic Retrofit of Existing Reinforced Concrete Building (JBDPA 2001). However, the tensile strength of anchor is conditioned on cone shaped fracture, as can be seen in Figure 8.

3. OBSERVED DAMAGES

3.1 Earthquake history

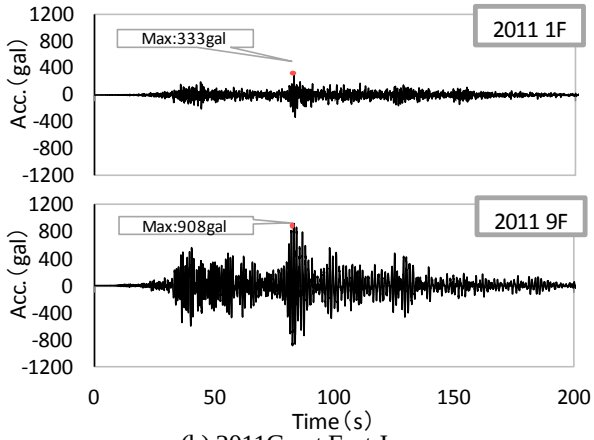
The building has experienced many earthquakes. Table 3 shows Accelerations during some of previous major earthquakes. The largest one is Miyagi Oki earthquake 1978 (Magnitude 7.4) and 2011 Great East Japan earthquake (Magnitude 9.0).

The maximum observed accelerations on the 1st floor in 1978 Miyagi Oki earthquake and 2011 Great East Japan earthquake were 258gal and 333gal, respectively. The maximum observed acceleration on the 9th floor were 1040gal and 908gal, respectively.



Comparing the two seismic records, one of the main characteristics of 2011 Great East Japan earthquake is long duration of about 180 seconds. Comparison of acceleration time history on 1st and 9th floor of the 1978 and 2011 earthquakes is shown in Figure 9.

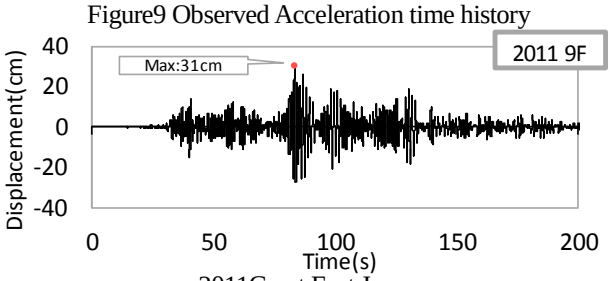
Figure 10 shows the Displacement time history, and Figure 11 zooms into the record obtained in 2011 at times between 80 and 88 sec. The Figure has two interesting features:



1) the period of the building was close to T=1 sec. before t=82.7 sec., and T=1.2 sec. after t=84 sec.

Table 3 Observed earthquake
(1st floor Acc. over 150gal)

y/m/d	Magnitude	1F maximum Acc.(gal)	9F maximum Acc.(gal)
1978/2/20	6.7	170	421
1978/6/12 (Miyagi Oki)	7.4	258	1040
1998/9/15	5.2	451	379
2011/3/11(East Japan)	9.0	333	908



(a) 1978Miyagi Oki

(b) 2011Great East Japan

Figure9 Observed Acceleration time history

2011Great East Japan

Figure10 Observed Displacement time history

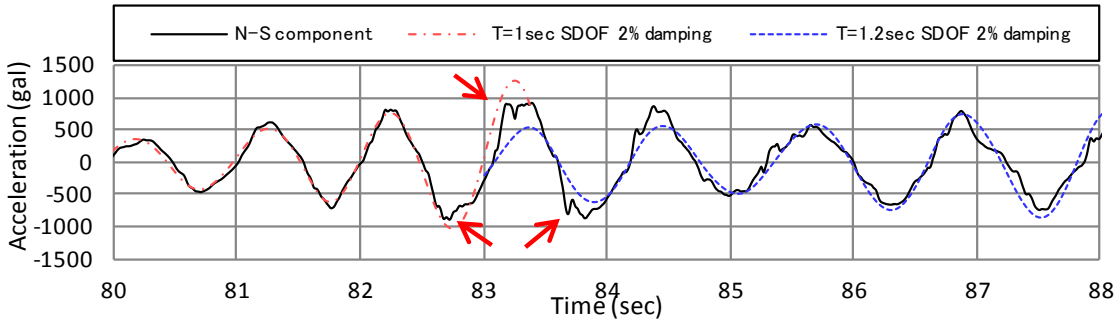


Figure 11 Zoom viewing of Acceleration time history

2) there were sudden drops in acceleration (marked with red arrows) at t=82.7, 83.3, and 83.8 sec.

These features may be evidence suggesting that something of consequence occurred in the structure as time approached and exceeded 83 sec. Integrating the record from 2011 until t=82.7 sec. leads us to believe that, up to that point, the displacement at the ninth floor had not exceeded 20 to 25 cm. Later the building may have reached displacements approaching 30 to 35 cm. Of course, we express our estimates as ranges because the integration is not a simple procedure and it required us to "adjust" the signal (by filtering it and shifting it) before we obtained results that we judged to be reasonable.

Figure 12 shows acceleration response spectra computed for both records (1978 and 2011) using a damping coefficient of 5%. In the NS direction, the two spectra are strikingly similar. The same is true for displacement spectra. It is reasonable to conclude that these two earthquakes produced comparable demands on the building in the N-S direction. This conclusion is supported by two observations:

1) The maximum displacement reached before t=82.7 sec. in 2011 was inferred not to have exceeded 20 to 25 cm. After t = 82.7 sec. the building exhibited abrupt softening and su dden drops in lateral acceleration indicating the possibility of local failures.
2) The maximum displacement inferred from the 1978 record was approximately 20 cm.

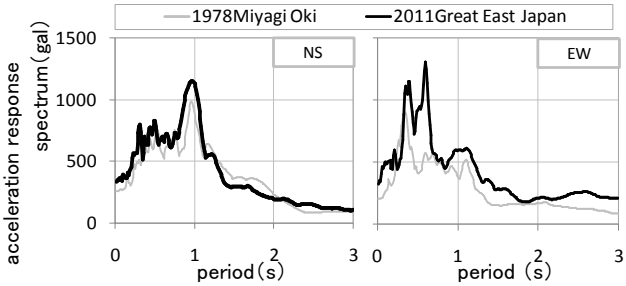
However , even though the demands appear to have been similar (according to two separate pieces of evidence), the observed damage was completely different in 1978 and 2011, especially in N-S direction.

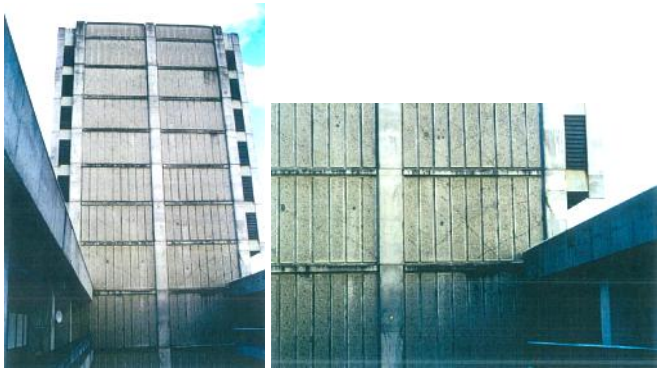
3.2 1978 Miyagi Oki earthquake

Detail damage survey was conducted after the 1978 Miyagi Oki earthquake by professors Shiga and Shibata, Tohoku University (Shiga et al. 1981). According to their report, small shear cracks and flexural cracks were observed in exterior shear walls(see Figure 13), adjacent beams and a few columns on the third and fourth floor. Typical wall and short beams crack patterns are shown in Figure14 and 15. The maximum width of shear cracks in shear walls and that of flexural cracks in columns and beams are reported about as 1.0mm. The width of shear cracks in the adjacent beams with openings was reported about as 1.5mm. Therefore, the structural damage of the building by the 1978 June earthquake, was considered to be fairly minor. As can be seen in Figure 15, exterior shear wall successfully sustained lateral force and contributed as shear resisting elements, because shear cracks were relatively uniformly distributed in the wall panels.

3.3 2011 Great East Japan Earthquake

The authors carried out detailed damage surveys of the building after the 2011 earthquake. The most severe damage took place in the 3rd story. Four corner boundary columns in exterior walls X3 and X8 (which were intervened in 2001)





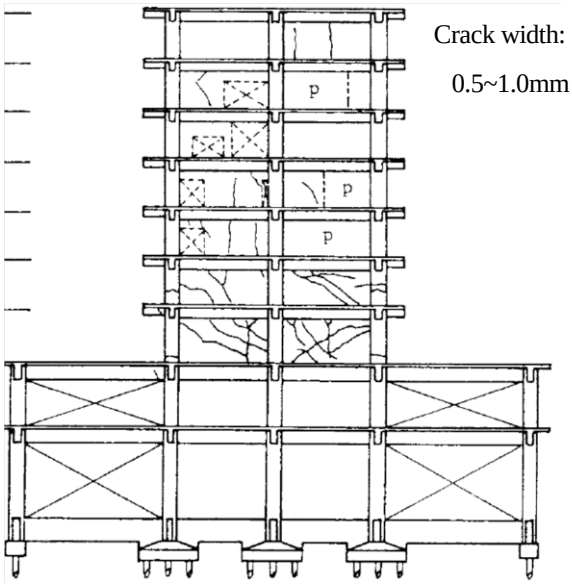


Figure 12 5% damping acceleration response spectrum

Figure 14 1978Miyagi Oki earthquake crack map (Shiga et al 1981)

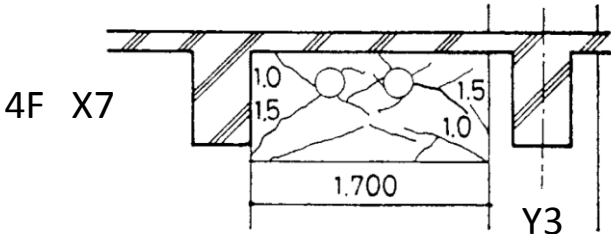

Figure 15 Damaged short beams

fractured as shown in Figures 16 and 18a). A close-up of the disintegrated near their bases, and the steel angles and reinforcing bars embedded in them either buckled or base of column X8-Y2 is shown in Figure 17.

Figure 18 shows cracks observed on the exterior walls in the transverse direction. A horizontal separation formed at the base of the third story, between the post-installed structural wall panels (shown in Figure 18b)) and the beam supporting them. The post-installed anchors that were supposed to prevent this separation appeared to have pulled out of the beam as shown in the close-up in Figure 18c) and Figure 19.

Along axes X4 to X7, shear cracks with widths of up to 1.7mm were observed on "wing walls" or "stems" forming the staircases in all stories. Spalling of concrete and a large horizontal crack were also observed at the 3rd floor level (Figure 18d), e)). The damage and cracks of the wing walls indicate the interior C-shape walls remained integral and were effective in resisting lateral loads.

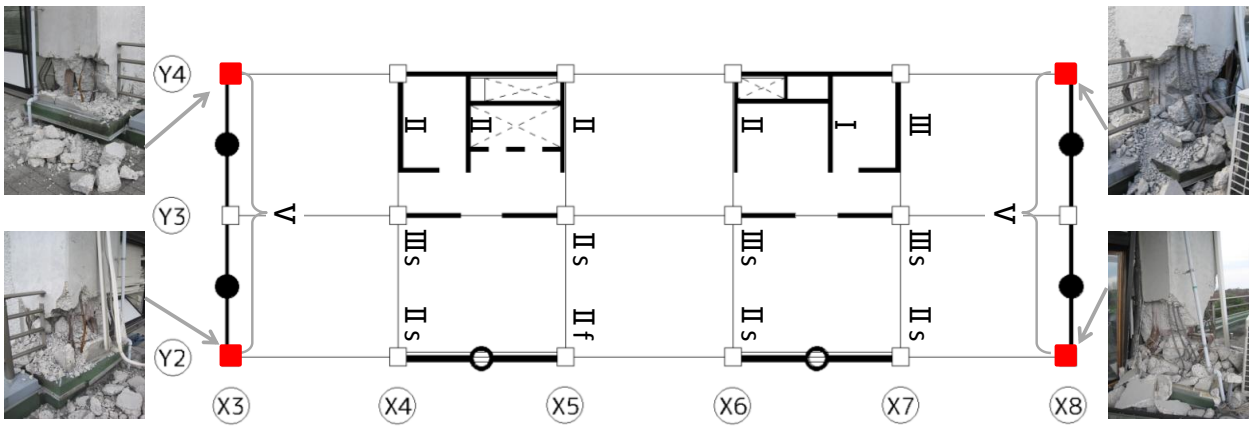
In the longitudinal direction, the damage concentrated on the walls, which had cracks of 0.2~0.5mm in width as shown in Figure 20. These walls also remained integral and were effective in resisting lateral loads. Additionally, there were horizontal cracks at the 3rd story.

Even though the bases of exterior boundary columns disintegrated, the webs of the exterior walls had little (or imperceptible) cracking in the 2nd to 3rd stories, and thin cracks (0.1~0.2mm) elsewhere. Comparing the damage caused to these walls by the Earthquakes of 2011 (Figure 18) and 1978 (Figure 14) suggests that there was a radical change in the mechanism through which these walls resisted lateral loads. It seems that in 1978 the exterior walls acted as units (composed of webs and columns connected to integrally), while in 2011 the webs did not seem to contribute much to lateral resistance. This inference and the followings facts:

1) the demands in 1978 and 2011were similar,
2) the steel braces installed in axis Y2 must have reduced problems related to torsion,
3) anchor rods installed in 2001 were observed to have pulled out,

led us to the focus on the connection between wall webs and 3rd floor beams.

Figure17 X8-Y2 column after remove the crush concrete



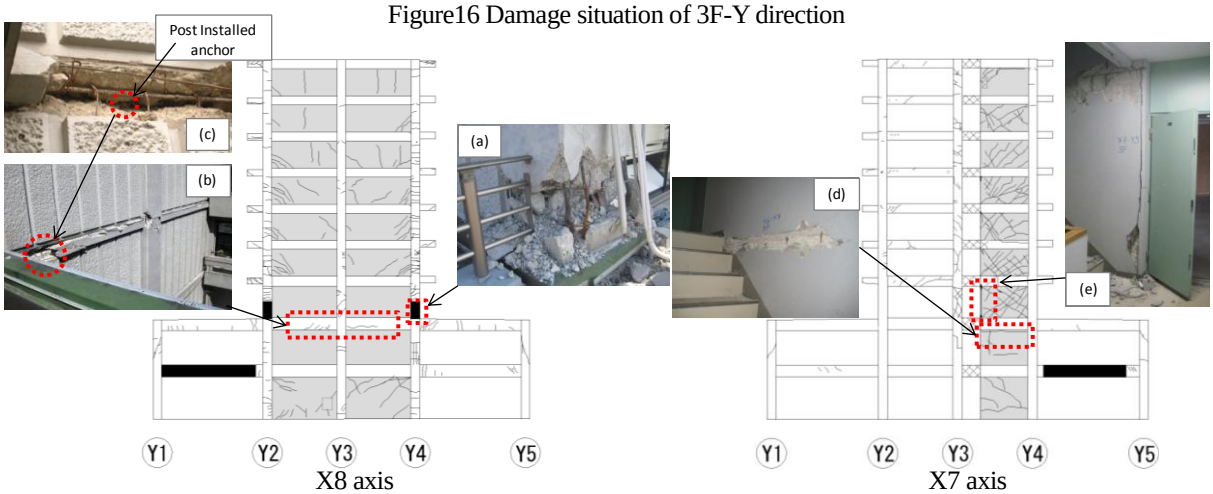


Figure16 Damage situation of 3F-Y direction

X8 axis X7 axis

Figure 18 2011Great East Japan earthquake crack map (transverse)

Figure 21 illustrates a plausible explanation for what occurred:

1) The anchor bolts installed in the retrofit had an extremely short embedment length
2) The existing reinforcement was smooth, and was cut too close to the beam face to develop its strength through bond (gained mainly through adhesion to the concrete cast in 2001)
3) If one draws lines from the bottom of the anchor bolt in Fig. 8 to the points where the wall outer and inner faces meet the cold joint at the top of the slab, one obtains a "surface" that is not crossed by any reinforcement working in tension and adequately anchored.
4) The result of 1), 2) and 3) was that, at the tops of the slabs and at every floor, the vertical web reinforcement was essentially discontinuous.
5) The discontinuity in the web reinforcement caused rotations to concentrate at the top of the third-floor slab causing the steel angles and reinforcing bars in the boundary elements to reach large tensile strains.(see Figure 19) These strains led to either fracture or buckling during load reversals.

It is believed that it was the buckling of the steel what triggered the disintegration of the concrete at column bases because even the exterior columns along axis Y3 exhibited bar buckling and spalling of concrete despite the fact they resisted no compression at peak displacements. Sliding could have damaged these columns too but no clear signs of sliding at wall bases were observed. If compression had been the trigger, we would have expected severe spalling and crushing (similar to what was observed at columns in axes X3 and X8) in the stems of the C-shaped walls that formed the staircases. That did not occur. The stems of the staircase walls did have some spalling but it was limited to the concrete cover.

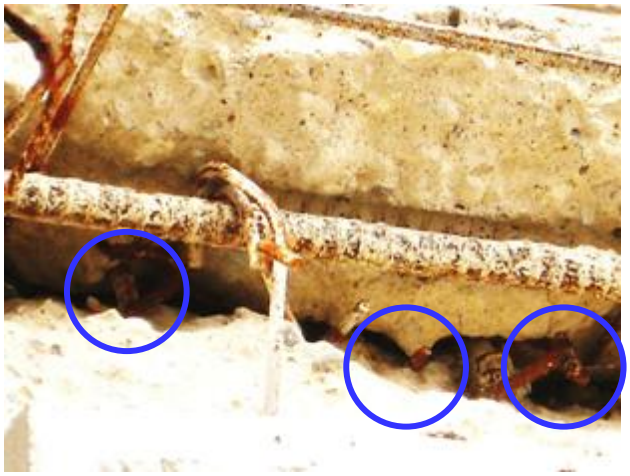

Figure 19 Zoom viewing of wall anchor

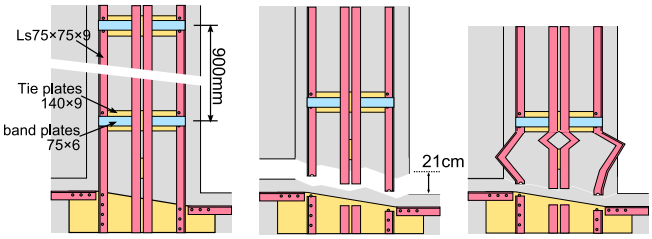

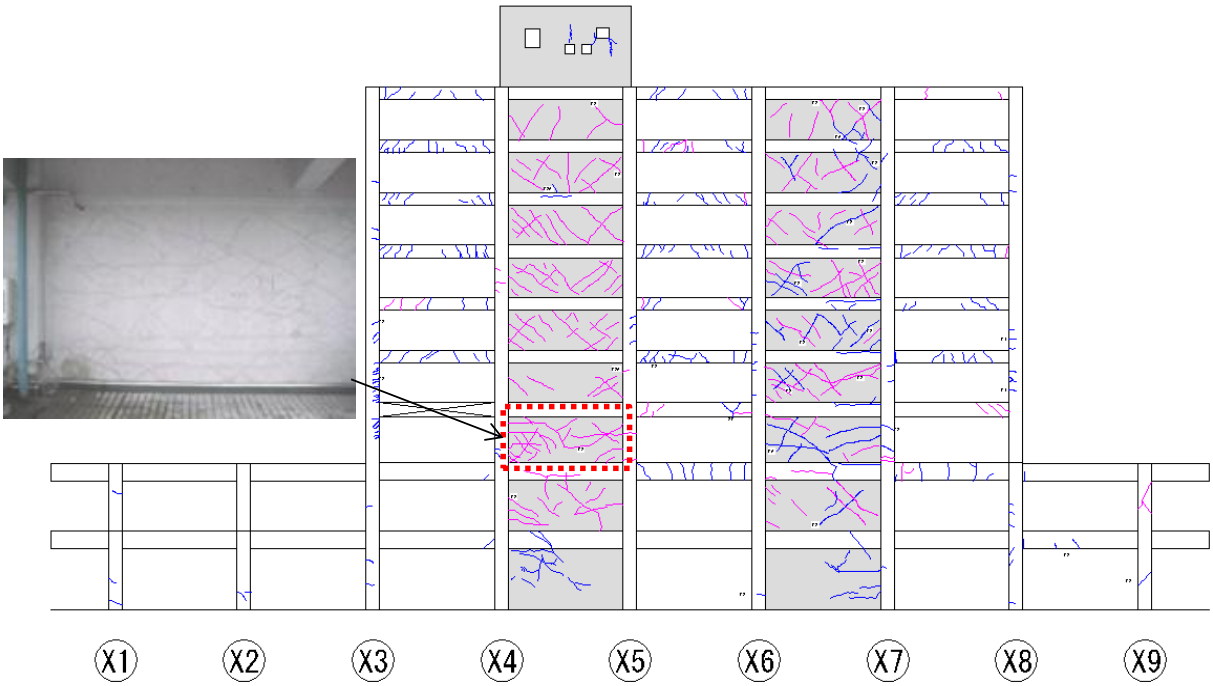

Figure 21 Mechanism of Column crushed

Y4 axis

Figure 20 2011Great East Japan Earthquake crack map(longitudinal)

4. EVALUATION OF SEISMIC CAPACITY AND FAILURE MECHANISM

4.1 Estimate the failure mechanism

The mechanisms of failure for the main structural elements (the walls) were dominated by flexure. Eventually, the ground motion caused the steel angles and reinforcing bars in boundary columns in axes X3 and X8 to buckle and fracture, and the anchor rods meant to fasten the webs to the beams were pulled out. At that point, the response of the exterior walls approached the response of a rocking block. This rocking behavior was inferred by Motosaka (2012) from wave analysis. If the lateral displacement on the ninth floor reached 31 cm, the uplift must have approached 21 cm . Walls and frames along column lines X4 to X7 are not suspected to have uplifted because their vertical reinforcement was continuous and well anchored.

4.2 Lateral strength using virtual work method

Lateral capacity of the frames in the transverse direction was checked using virtual work method. The following assumptions were considered:

・1st to 2nd stories are assumed to be stiff and strong, and acted as the base of the upper part of the building.

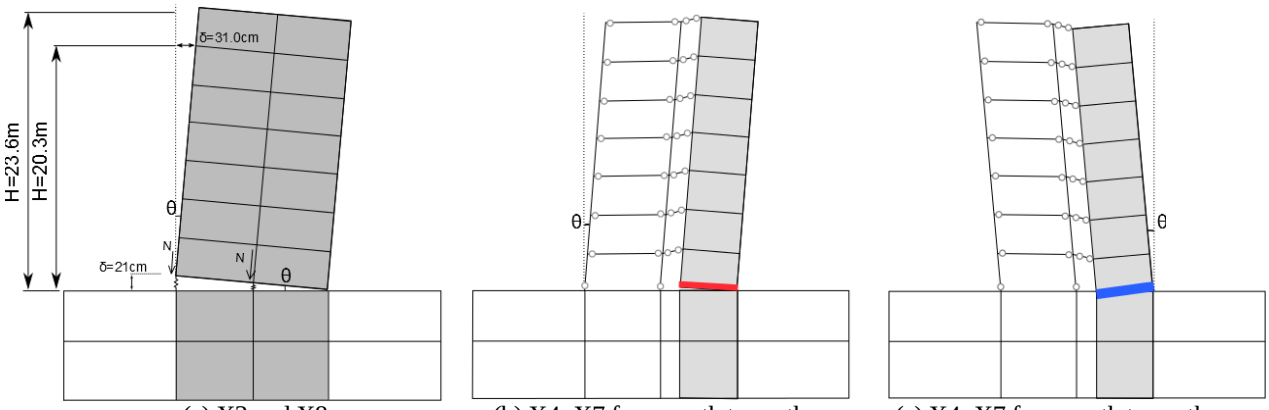
Assumption through X3・X8 axes

- The wall will break and rotate at the base of 3rd floor (see Figure 22a)).
- The strength of the wall reinforcement are assigned in the center of wall.

Assumption through X4 to X7 axes

- The seismic lateral forces were applied in different direction (from North to South and from South to North) because the wing walls strength will be different.

Two different cases are considered: Case 1 considers the exterior installed wall effective and behaved exactly as it was expected in the seismic evaluation . In Case 2, the steel in the boundary column is ignored and the wall reinforcement is 50% ineffective because the boundary column have already yielded and wall reinforcement were easily pulled out. Table1 shows the different assumptions of each case.



As it shown in the Figure 23. The difference between the two cases is more than 30% of the total strength. This building depends mainly on these exterior installed walls. Any poor detailing of the installed walls shall led to dramatic damage.

4.3 Capacity spectrum method

Two-dimensional “push-over” analyses were conducted using the computer program SNAP (version6, 2012). The analyses referred exclusively to the transverse direction. The structure is modeled from 3rd~9th story. The 1st and 2nd story are very stiff with many walls and were assumed as the base of the upper stories. 2 cases were considered; 1978 model and retrofitted model of 2011. The shear versus

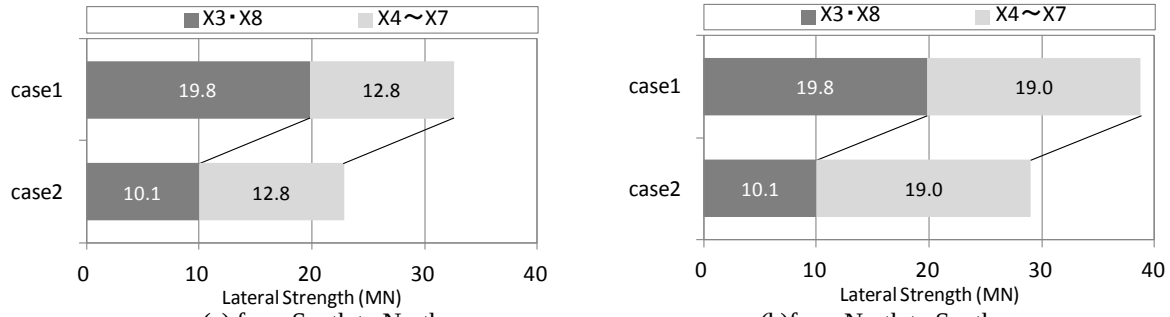


Table 4 Assumption of Virtual work method

Model ID	AxesX3 and X8

Figure 22 Estimated building collapse mechanism

(a) from South to North (b)from North to South

Figure 23 Lateral strength at 3rd floor

displacement relation of each story was converted to a single degree of freedom system expressed in spectral acceleration and displacement (Sa-Sd) relations using the procedure of the performance based method used in Japan(JABRP 2000). Eq.(4), Eq.(5), Eq.(6) and Figure 24 shows the concept of conversion to SDOF.

$$M = \frac{\left(\sum_{i=1}^{N} m_i.\delta_i\right)^2}{\sum_{i=1}^{N} m_i.\delta_i^2} \quad (4)$$

$$S_a = \frac{Q_1}{M} \quad (5)$$

$$S_d = \frac{\sum_{i=1}^{N} m_i.\delta_i^2}{\sum_{i=1}^{N} m_i.\delta_i} \quad (6)$$

where: m_i=lumped mass in the i-th story, Q_1=base shear and δ_i=horizontal displacement at i-th story

The capacity spectra (Sa-Sd) of building are plotted with response spectra of the 1978 earthquake and 2011 earthquake with 5%~20% damping. (see Figure 25).

The dotted horizontal line in Figures 25b) shows the lateral strength capacity that was previously calculated using the virtual work method for case 1 stated previously. The ultimate strength of pushover and the lateral strength by virtual work method of case 1 showed good agreement

The maximum horizontal displacement was evaluated by double integration of acceleration records observed on the 9th floor. The recorded maximum displacement at the 9th floor for the two earthquake cases (1978 EQ and 2011 EQ) is converted to the spectral displacement Sd and plotted in in Figure 24. using assumed equivalent height of the SDOF. Specifically, the 9th floor recorded deformation are converted to the equivalent height deformation by assuming the distribution of deformation as inverted triangle from 3rd~9th(see Figure26) and the equivalent height is assumed at 0.8H (=18.8m).

Using capacity spectrum method, in the case of 1978 earthquake, the estimated response drift was about 15 cm and the calculated displacement was about 23 cm, in the case of 2011 earthquake, the estimated response drift was about 18 cm and the calculated displacement was about 29 cm, each model have big difference between estimate and recorded deformation. The difference between the two values might be caused due to the rocking at the base and unique failure mechanism of this building.

However, further investigations involving different cases of structure models are needed to have better simulation of the actual damage, such as cases assuming the vertical web reinforcement of exterior transverse wall ineffective.

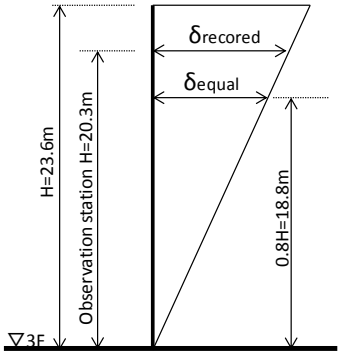

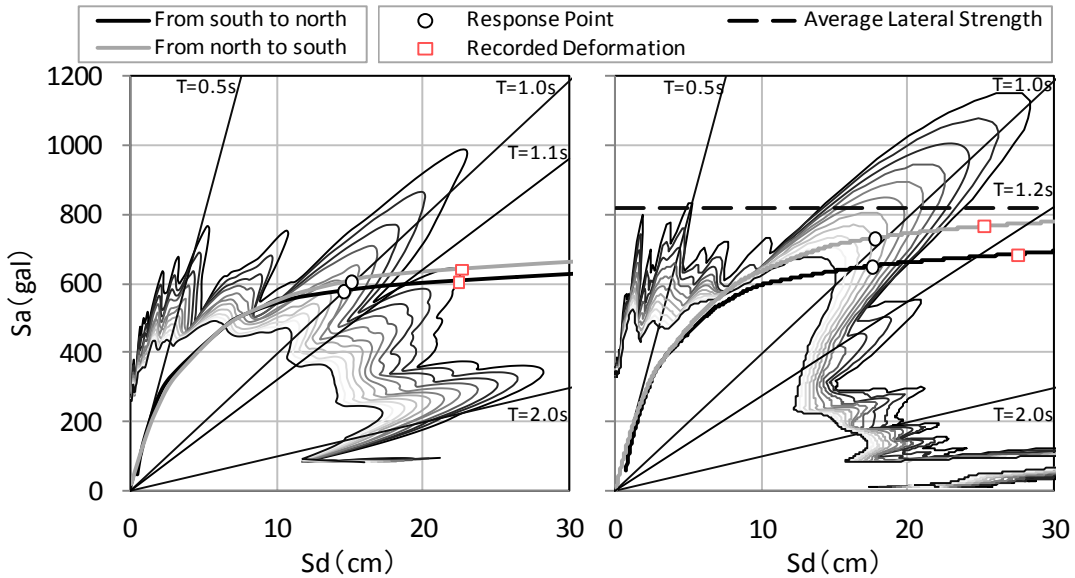

Figure 26 Deformation of equivalent height

(a) 1978 Miyagi Oki (b) 2011 Great East Japan

Figure 25 Result of the pushover analysis

5. CONCLUSION

Considering:

1. The similarities between the response spectra of the N-S components of the 2011 Great East Japan earthquake and the 1978 Miyagi earthquake. However both of damage is completely difficult.
2. The distribution of cracks and spalling throughout the building
3. Observations indicating that the vertical web reinforcement connecting walls to beams pulled out during the 2011 earthquake

We conclude that discontinuities in the vertical web reinforcement caused concentrations of rotation at the 3rd floor level which led to buckling and fracture of the vertical reinforcement in exterior wall boundary elements. This damage resulted in the evacuation and demolition of the structure.

In additional, the capacity spectrum method of both cases(1978 and 2011) couldn't estimate the actual displacement. This point needs further investigations and will be studied thoroughly in the near future.

6. FUTURE WORK

Experiments are being conducted to test the hypothesis that the discontinuity in the reinforcement at the base of the 3rd story led to the failures of the exterior columns.

The experimental program consists of six small-scale structural-wall models with identical cross-sectional properties. The web reinforcement in three specimens is cut off at the base of the wall, while in the other three specimens web reinforcement is well anchored in the foundation. Two specimens will be tested under static loading reversals and four specimens will be tested using an earthquake simulator at Bowen Laboratory, Purdue University.

Abstract: We investigate a pre-disaster preparedness against predicted earthquakes in Tokyo area using a survey. It examines (a) the role of direct experience of the 2011 Great East Japan earthquake in preparedness against the predicted earthquake; (b) the impact of participation in disaster prevention training, indirect experience with disasters, on pre-disaster preparedness. Results indicate that pre-disaster preparedness differs from the participants and non-participants in the training, and it is shown more in the participants verses the non-participants. Also, females are more likely to have taken more preparations than males while the experience of damage had an insignificant effect on the disaster preparedness behavior. These results contain insights for managing risks to reduce the human damages in future disasters.

1. INTRODUCTION

Disasters caused more than 3.3 million deaths and US$2.3 trillion in damage (in 2008 US dollars) between 1970 and 2010 (World Bank, 2010). The growth of urban population drives exposure to natural hazards ever higher. By 2050, if current trends continue, the urban population exposed to earthquakes and storms could more than double to 1.5 billion (from 680 million in 2000 to 1.5 billion in 2050).

No country can fully insulate itself from disaster risk, but it is possible to reduce human loss from it. Success depends heavily on how well residents in the area are prepared (Sendai Dialogue, 2012). An accurate prediction of disasters is the first step in preparedness for the disaster reduction against future events. Moreover, the most important step of disaster preparedness is to execute at an individual level.

On March 11, 2011, a gigantic earthquake of magnitude 9.0 struck off the Pacific coast of Tohoku, Japan (the Japan Meteorological Agency, 2011), leaving 15,867 dead and 2,909 missing (the National Police Agency, July 11, 2012). Over 90% of the dead drowned due to the earthquake induced tsunami.

In fact, before the occurrence of the Great East Japan earthquake, the Central Council of Japan for Disaster Prevention had been giving five big earthquake warnings, which has a high probability of occurrence in the near future and may cause a serious damage. Those are Tōkai (Magnitude: 8.0), Tōnankai (Magnitude: 8.1), Nankai (Magnitude: 8.4) earthquakes along the Nankai Sea Trough in the Pacific Ocean, and Northern-Tokyo Bay earthquake (Magnitude: 7.3). Also, Off-Miyagi Prefecture earthquake is estimated as a medium size earthquake of magnitude 7.5; but it actually occurred with magnitude of 9.0, that is 180 times larger than the predicted earthquake (Hamada and Yun, 2011). Therefore, after the 2011 Great East Japan earthquake, Japan revised an estimation of damages by the predicted earthquake in Tokyo area.

In addition to the effort of prediction, it showed that actual evacuation by residents was important to be saved. Although the Japan Meteorological Agency (JMA) first issued a tsunami warning three minutes after this earthquake to maximize time for evacuation and to reduce casualties (Ozaki, 2012), more than 40% of the residents did not or could not evacuate from the tsunami in an inundate area (Yun and Hamada, 2012).

In Tokyo area, persons have experienced a strong shaking by the 9.0-magnitude earthquake and over 1,000 aftershocks since the earthquake. Moreover, approximately 5.15 million of persons in Tokyo Metropolis and four prefectures - Kanagawa, Chiba, Saitama, and Ibaraki - could not go back home by the 2011 Great East Japan earthquake. The residents have an unforgettable experience and some loss of their resources.

Therefore, the aim of this study is to empirically examine a relationship between the experience with the huge disaster, the 2011 Great East Japan earthquake, and pre-disaster preparedness. Furthermore, it examines an impact of participating in a disaster prevention training related to the pre-disaster preparedness.

2. PREPAREDNESS BEFORE DISASTER

2.1 Tokyo Urban Area

Tokyo (東京, Tōkyō) is Japan's capital and the world's most populous metropolis. The population of the special wards is over 8 million people, with the total population of

the prefecture exceeding 13 million. The prefecture is part of the world's most populous metropolitan area with upwards of 35 million people. The mainland portion of Tokyo lies northwest of Tokyo Bay and borders Chiba Prefecture to the west, Kanagawa to the south, and Saitama to the north. During the daytime, the population swells by over 2.5 million as workers and students commute from adjacent areas. This makes Tokyo as the Japan's largest domestic and international hub for rail, ground, and air transportation.

As the world's largest urban agglomeration economy with a GDP of US$1.479 trillion at purchasing power parity in 2008, ahead of New York City metropolitan area, which ranks second on the list, it is critical how to predict and manage risks from the expected disasters such as earthquakes.

2.2 Disaster Predictions

After the 2011 Great East Japan Earthquake, the Tokyo Metropolitan Government's Disaster Prevention Council revised and issued a 'report for an estimation of damage caused by predicted earthquakes in Tokyo area' on April 18, 2012. According to its new issued estimate, 9,700 people may be dead and 304,300 buildings may be damaged by the 7.3-magnitude Northern-Tokyo Bay earthquake under a dry weather and 8m/sec wind speed condition. Approximately 5,600 people would be dead from shaking of the earthquake and buildings being crushed (accounted for approximately 58% of the casualties by the earthquake), and about 3,500 people estimated to be dead from fire.

In addition, a number of persons who have difficulties in getting home by the earthquake reaches (in Japanese 帰宅困難者) approximately 5.17 million compared to that of the approximately 5.15 million people who could not return home on March 11, 2011 in Table 1(首都直下地震帰宅困難者等対策協議会, 2012).

Table 1 The difficulties of returning home on March 11, 2011

Area	Numbers of persons having difficulties in returning home	Percentage of difficulties in returning home out of the total persons who were out of their homes
Tokyo Metropolis	3.52 million	40 %
Kanagawa	0.67 million	20 %
Chiba	0.52 million	24 %
Saitama	0.33 million	14 %
Ibaraki	0.10 million	16 %
Total	5.15 million	30 %

The number of persons who have difficulties in getting home refers to both persons who gave up to go home due to far distance and persons who tried to go back home on foot when there was a situation in which transportation was disrupted by disasters. As a broad definition by the Central Disaster Prevention Council in Cabinet Office of Government of Japan, within 10km distance from one's home is a distance in which they can go home, but more than 10km, persons have difficulty returning home. Within 20km distance, 10% of the number has increased by every 1km, and over 20km distance, everyone is difficult to return home on foot.

The Northern-Tokyo Bay earthquake with a magnitude 7.3 could worsen this situation because a recovery of transportation might be delayed. Therefore, it is necessary to emphasize keeping supplies as disaster preparedness.

2.3 Preparedness Before Disaster

Preparedness before disaster, according to Banerjee and Gillespie (1994a), "…refers to a series of activities which directly or indirectly should mitigate loss of life and property in disaster"; "…is predicted on the assumption that disasters of various forms will occur, but that their negative consequences may be reduced" (p.131). In other words, pre-disaster preparedness is a preplanned activity to reduce loss of life, and a basic assumption underlying the activities is that they contribute to response effectiveness.

Several studies on disaster preparedness have been examined with mixed results. Shelby and Tredinnick (1995), for example, found that someone who survives an earthquake may gain knowledge about the potential destruction to come; the value and benefits of preparation and evacuation; how to recover in its aftermath; or develop an enhanced sense of self-efficacy, new skills, and new ways of coping with subsequent disaster threats. Furthermore, someone who has taken actions to minimize damages, secure his or her family's safety, or replace lost or damaged possessions may develop an enhanced sense of self-esteem, self-efficacy (personal characteristic resources), and stronger bonds among family and community members (condition resources). Therefore, when individuals perceive risks of disasters and believe that their well-beings will be threatened, then they are likely to engage in preparedness behaviors. Additionally, individuals who feel capable of dealing with a possible future disaster are willing to initiate in preparedness behaviors. In contrary, simply being aware of risks does not seem to be a strong factor for a good predictor of preparedness behaviors (Faupel, Kelley and Petee, 1992).

Hench, we investigate preparedness before disaster, calculated based on replies to "What have you done for preparedness before disaster regarding the following categories?"

1. Keeping supplies: food, water, first-aid kit, clothing
2. Stabilizing furniture
3. Getting hazard-related information
4. Making a plan to meet up with family after disasters
5. Structurally strengthening the building

2.4 Experience With Disasters

2.4.1 Direct Experience with the 2011 Great East Japan Earthquake

Numerous studies have shown that previous experiences with disaster are positively related to preparedness (Banerjee and Gillespie, 1994b). In other words, there are some evidences about a tendency to be better trained and knowledgeable in disaster as a result of previous experience with disasters.

Although the 2011 Great East Japan earthquake caused 31 death in the Tokyo area (issued by the National Police Agency on July 11, 2012), persons in Tokyo area have experienced some loss of their home, car, furniture, etc. due to unforgettable strong shakings.

When confronted with a new disaster threat, persons with disaster experience – especially those who experienced higher levels of resource loss and psychological distress – would (a) be more likely to acknowledge a disaster threat, (b) readily experience psychological distress, and (c) efficiently choose appropriate courses of action than persons who have experienced lower levels of resource loss or distress as result of a disaster, or persons who do not have disaster experiences (Hobfoll, 1989).

Previous research provides positive evidence for the role of disaster experience in the context of disaster preparedness (Hobfoll, 1989; Freedy, Shaw, Jarrell, and Masters, 1992). For example, persons who live in areas that are frequently threatened by natural disasters may be more likely to acknowledge that a threat exists (Lindell and Perry, 2000), to take more preventive measures, and to comply with warnings than persons who are infrequently threatened by disasters. Disaster survivors who experience higher levels of property loss and psychological distress may be more attentive to news reports and have a better understanding of the destructive consequences of disasters than the survivors who experience lower levels of property loss and distress, or persons who have not experienced a disaster (Sattler, Kaiser, and Hittner, 2000).

Accordingly, this study examined the importance of range of adverse experiences of resource loss on individual adjustment following a natural disaster.

Hypothesis 1: Those who experienced damages by the 2011 Great East Japan earthquake are more willing to take the disaster preparedness behavior compared with the group that did not.

2.4.2 Disaster Prevention Training

Growing out of their indirect experience with disasters, it assumes that disaster prevention training positively affects preparedness behavior. In order to enhance viability against disasters, a disaster prevention training covered mitigation, preparedness and response aspects of natural disaster occurrence.

In Japan, the Ministry of Education, Culture, Sports, Science and Technology of Japan (MEXT) has been developing and implementing disaster education to foster the viability of disasters. As a result, while casualties number nearly 1,000 in Kamaishi and Kesennuma, 5 out of 3,244 children and 12 out of 6,054 students, respectively, are victims of the 2011 Great East Japan disaster. There is some more evidences to suggest that exposure to the education may increase knowledge of the threat and lead to more pre-disaster preparedness.

However, according to Faupel et al. (1992) stated that for any number of reasons, knowledge learned in disaster education programs does not always translate into appropriate behavior. In other words, we cannot presume that even if people know what to do in a disaster that they will necessarily act on the basis of that knowledge.

In this study, therefore, participant in the disaster prevention training and non-participant, as a dummy variable, are used. Responses from the participants are marked as '1', and non-participants are marked as '0'.

Hypothesis 2-1: Pre-disaster preparedness is shown more in the participants verses non-participants in the disaster prevention training.

Hypothesis 2-2: There is existing difference when comparing those who participated and did not participate in the disaster prevention training for pre-disaster preparedness.

3. SURVEY QUESTIONNAIRES

To satisfy our purpose of study, we designed questionnaires for a survey with three clusters. A field survey was carried out in Tokyo Metropolis and the four prefectures (Kanagawa, Chiba, Saitama, and Ibaraki prefectures).

The full questionnaire includes 27 items with two open-ended questions to measure participants' pre-disaster preparedness, experience with the 2011 Great East Japan earthquake, and participation in disaster prevention training, and Prefecture, gender and age information are included (see Table 2).

Table 2 Survey questionnaires

Ⅰ. We would like to ask you that when the earthquake occurred on March 11,2011 (10 items)
1) On the 2011 Great East Japan Earthquake (hereinafter, referred to "earthquake"), which of the following damages did you see directly or experience?
2) Did you hear the earthquake alerts before the big shake (via TV, mobile, broadcasting etc.)?
3) Do you think to protect your own body was able to act on the day?
4) When you were feeling a tremor, which of the following did you take an action?
5) On the day of the earthquake, which of the following methods did you use for gathering disaster-related information?
6) On the day of the earthquake, could you return home from your workplace, school, or other places?
7) We would like to ask to those who answered 'Yes' on 6). What was the means for coming back home?
8) On the day of the earthquake, could you get water and/or food

during your return home?
9) What kind of assistance do you need in order to return home from workplace, school, and on the road when the big earthquake would happen? Please write freely.
10) In the future disaster, what kind of preparedness or assistance for you if you would have a difficulty to go home and stay at workplace, school, and on a road? Please write freely.

II. Disaster Preparedness (14 items): awareness and knowledge, countermeasure in house and furniture, making a plan to meet up with family after a disaster, supplies, disaster prevention training

1) Do you think that your pre-disaster preparedness is enough?
2) Have you heard about the hazard-related information such as a liquefaction hazard map?
3) If you have ever heard about the information, is it helpful to prepare against a disaster?
4) Which of the following risks by the expected earthquake would happen on your living place?
5) House: when did it build up with what kind of building material (wooden house or non-wooden house)?
6) Structurally strengthening the building and stabilizing furniture
7) Making a plan to meet up with family after a disaster
8) Keeping supplies
9) Have you ever participated in disaster prevention training?
10) Where did you get the training (e.g., school, workplace, etc.)?
11) What kind of contents did you learn from the training?
12) If you did or could not participate in the education, why?
13) On the 2011 Great East Japan Earthquake, could you act as what you learnt from the training?
14) If you could not follow the instruction on that day, why?

III. Disaster preparedness for outside a home (3 items) : reaction of disaster on train, possibility of becoming a person who has a difficulty in returning home, emergency supplies

1) Reaction of disaster on train
2) Possibility of becoming a person who has a difficulty in returning home: can you go back from your workplace or school on foot?
3) Emergency supplies: Are you bringing emergency supplies for in case of becoming a person who has a difficulty in returning home?

Data items numbering 256 were collected from June 12, 2012 to July 9, 2012. The questionnaire took about 10 minutes to complete.

4. RESULT

4.1 Participants Demographic Analysis

Reflecting a response rate of 51% for the current study, 253 fully unanswered questions were excluded, and 247 items of data were used. Regarding the gender, 181 of participants were males (73%) and 66 were females (27%). The percentage of data gathered from Tokyo Metropolis and the four prefectures is illustrated in Table 3.

Table 3 Participants Area

Address	Number	Percentage
Tokyo Metropolis	50	20%
Chiba Prefecture	119	46%
Kanagawa Prefecture	64	25%
Saitama Prefecture	15	6%
Ibaraki Prefecture	2	1%
(Blank)	6	2%
Total	247	100%

Table 4 presents the result of the age analysis. According to a study of the 2011 Great East Japan earthquake, vulnerable age groups of persons more than 50 years old were more easily to become victims (Yun and Hamada, 2012). In addition, according to Tokyo Metropolitan Government's Disaster Prevention Council estimated damages by predicting disasters, the number of people who need support during a disaster such as the old is 4,900 persons, which doubled the previous estimation in 2006. Therefore, we gathered data from the aged in order to figure out their current levels of preparedness, and then the number of more than 50 years old is half of the total of data.

Previous research on predictors of preparedness behavior for disasters showed that age, income, education, locus of control, perceived threat and distress were significant predictors of preparedness behaviors for earthquakes (Sattler et al., 2000).

Table 4 Age analysis

Age (N=247)	Percentage (number)
Lesser than 20	5% (12)
20-29yrs	32% (80)
30-39yrs	5% (13)
40-49yrs	7% (18)
50-59yrs	9% (22)
60-69yrs	26% (63)
70-79yrs	14% (34)
80-89yrs	1% (2)
(Blank)	1% (3)
Total	100% (247)

4.2 Pre-disaster Preparedness

The questionnaire had five sections for the disaster preparedness behaviors. Table 5 shows the pre-disaster preparedness behaviors. An example of the items include, "Do you have drinking water in order to prepare for disasters?" The participants used a 2-point scale to answer the questions. All of the scales had descriptors to the questions (e.g., 1= Yes, I do, 0= No, I don't).

Table 5 Disaster preparedness behavior

Specific Activity
1. Keeping supplies (8 items) 1) Drinking water, 2) Food supplies, 3) Sanitary items, 4) Portable toilet, 5) Portable radio, 6) Flashlight, 7) First-aid kit, 8) Fire extinguisher
2. Stabilizing furniture (3 items) 1) Preventing furniture (e.g., desk, wardrobe, refrigerator) from falling over, 2) Not placing objects up high, 3) Securing light with chains and clamps
3. Getting hazard-related information (2 items) 1) Evacuation route and evacuation place check 2) Use a hazard map for evacuation route
4. Making a plan to meet up with family after a disaster (2 items) 1) Emergency contact method decision, 2) Decision an alternative way when families cannot contact each other
5. Structurally strengthening building (3 items) 1) Seismic diagnosis, 2) Seismic retrofit, 3) Reinforcing brick walls and stone fences to prevent collapse

To assess preparation and to create a preparedness factor, we summed the responses to the responses to the 18 items asking about preparation activities. We used these into a 5-point scale ranging from 1 (not at all) to 5 (fully) to indicate the summed data. This scale serves as a dependent variable for the regression model. The scale was reliable with Coefficient alpha (α) for it was .81. On the average, the respondents reported preparation in order of keeping supplies (52%), stabilizing furniture (35%), getting hazard-related information (32%), making a family reunion plan and other plans for when the disaster occurs (40%), and structurally strengthening the building (12%). About more than 50% of persons had the following supplies on hand: flashlight, portable radio, drinking water, first-aid kit, and food supplies.

In addition, Figure 1 reports the results of responses to the question, "do you think that your preparedness before disaster activities is enough?" Approximately 60% of respondents think that they are not sufficient for preparedness before disaster; only 3% think their preparedness against disaster is sufficient; and 37% answered they prepared averagely.

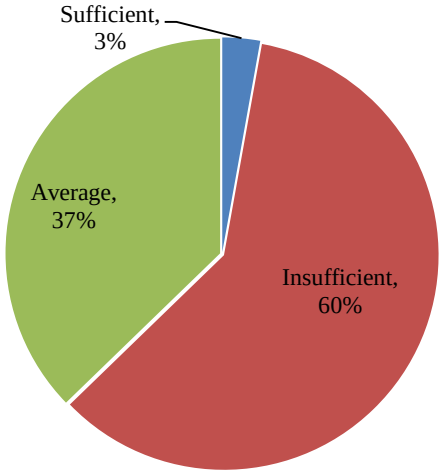

Figure 1 Self-reported preparedness level (N=247)

It implies that residents are not sufficiently prepared for the disasters. The majority of citizens are not aware of the full potential extent of earthquake-induced damages or the proneness to earthquakes. And it seems that awareness - when acknowledged at all - is not in itself a sufficient stimulus for taking actions; indeed, even the personal experience of a devastating earthquake does not imply that the individual has any greater 'real' perception of earthquakes than before.

Moreover, as it mentioned earlier in Table 1, there were approximately 5.15 million persons who had difficulties going back to their homes in Tokyo Metropolis, Kanagawa, Chiba, Saitama, and Ibaraki areas on March 11, 2011. When a predicted earthquake occurs, this problem could become more serious because much of the severe damages done by the earthquake in Tokyo area. Hence, it is important to prepare both for inside and outside a home, such as brining emergency supplies (e.g., a pair of sports shoes, food, fordable bike, clothing and blanket).

Figure 2, however, reported that the residents are not sufficiently prepared for it: nothing special (59%), keeping a pair of sports shoes (30%), food supplies (8%), fordable bike (1%), extra clothes and blankets (1%).

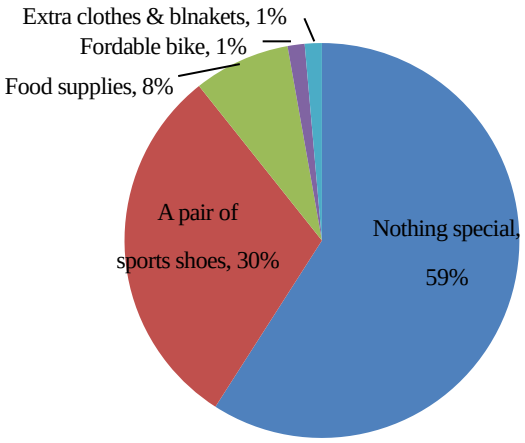

Figure 2 Preparedness actions for outside a home

4.3 Experience With Disasters

4.3.1 Direct Experience with the 2011 Great East Japan Earthquake

A total of 66% of the respondents had experienced damages by the 2011 Great East Japan earthquake. Of these data, 23% reported experiencing building damages due to shaking or vibration as a result of the earthquake, and 20% had experienced damages due to falling objects inside. In Figure 3, the damage types by the earthquake were the following: building damage due to shaking or vibration (23%), damage due to falling objects inside (20%), damage caused by liquefaction (9%), damage caused by falling or collapse wall (7%), congestion or accidents due to the disaster (6%), damage due to fire (5%), damage caused by falling objects in an outdoor (4%), damage due to the collapse of steep slopes (1%).

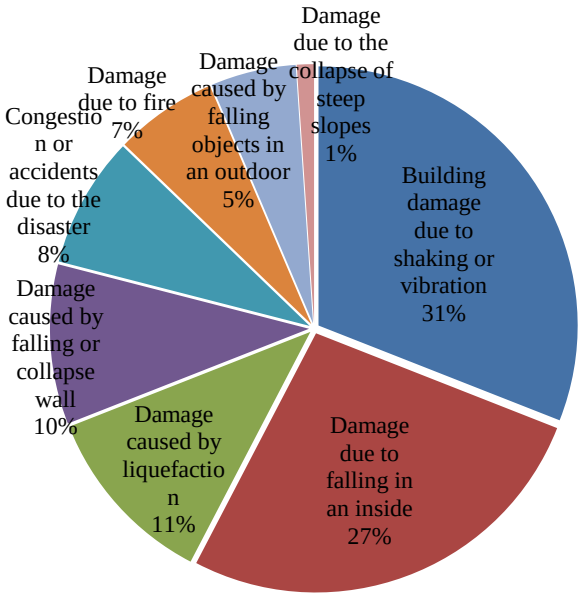

Figure 3 Damage types by the 2011 Great East Japan earthquake

4.3.2 Disaster Prevention Training

A total of 66% of the responses had participated in the disaster prevention training. Out of these answers, 54% reported participating in the training before the 2011 Great East Japan earthquake, and 7% participated in it after the disaster (see Figure 4). Reasons of unparticipation were the following: 40% had no information how to participate in the training; 25% had no available time for it; 11% had no needs for it; 6% felt no danger by the disaster in their living place; and 5% had no useful information in the training.

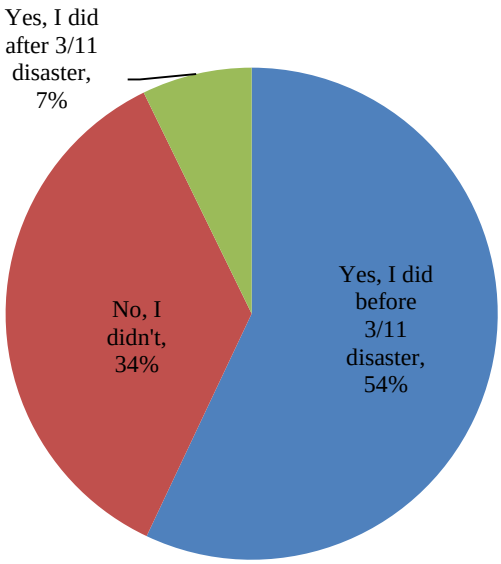

Figure 4. Participation in the disaster prevention training

Thirty-three percent had a participated at school, 25% at a local community place, 19% at their workplace, 9% at a disaster prevention event, and 6% at fire station.

From the training, the persons learned the followings: practicing a fire-fighting (19%), checking an evacuation place and an evacuation route (18%), protecting one's body (13%), and others such as practicing first-aid (12%), walking through an evacuation route (11%), experiencing shelter (4%), and serving food (4%).

The result the question, "On March 11, 2011, could you put into action that you learned from the training?" reported that 34% of persons actually followed through.

To examine the hypothesis (Hypothesis 2-1 and 2-2), we divided the total sample into two groups as participants and non-participants.

4.4 Hypothesis Testing

To test hypothesis, we used SPSS 12 (Bryman and Cramer, 2005) and reported a result of hierarchical multiple regression to examine the influence of gender, age, and participation in the disaster prevention training in predicting preparation efforts for future disasters.

Table 6 presents the correlations between participation in disaster prevention training, experience of damage by the 2011 Great East Japan earthquake, pre-disaster preparedness, gender, and age variables. It is necessary to interpret results as to whether these are significant, considering the above $p<0.05$ based on a two-tailed test. The unit of analysis is the individual respondents; the dependent variable is expressed as the dummy variable in regards to the respondent that is explained earlier.

Table 6 Correlations and descriptive statistics (N=247)

	Variable	Mean	Std.	1	2	3	4	5
1	Participation in Disaster Prevention Training	.66	.53	–				
2	Experience of Damage	.66	.47	-.12	–			
3	Pre-disaster Preparedness	2.47	1.09	.10	.07	–		
4	Gender	1.27	.47	-.04	-.01	.18**	–	
5	Age	45.62	21.41	-.14*	.08	.04	.02	–

Note) *p < 0 .05, **p < 0 .01 (two-tailed).
Gender was coded 1 = male, 2 = female.
Age represent the actual number of year.

Participation in disaster prevention training correlated significantly and negatively with age (age r = -.14, p < 0.05). Pre-disaster preparedness behavior, moreover, is strongly and significantly associated with females (gender r = .18, p < 0.01). Pre-disaster preparedness is positively and insignificantly correlated with participation in both disaster prevention training (r = .10) and experience of damage (r = .07). Despite insignificant correlation between the experience of the GEJE earthquake and training, participant in the training experienced less damage by the 2011 Great East Japan earthquake than non-participant.

Hypothesis 1 was not supported. This study tested whether persons who experienced damages by the 2011 Great East Japan earthquake were more willing to take the pre-disaster preparedness behavior compared with the group that did not. Although 66% of the respondents had experienced damages by the 2011 Great East Japan earthquake, their pre-disaster preparedness is not much different from those who had no damage. The t-test result showed insignificant difference between the two groups (Table 7).

Table 7 Result of t-test analysis: experience damage by the 2011 Great East Japan earthquake & pre-disaster preparedness

	N	Mean	S.D	t-test
Damage	150	2.53	1.07	t=1.13,
No Damage	80	2.36	1.13	df=234, p=.259

Note) Standardized regression coefficients are reported.
+p < 0.1, *p < 0.05, **p < 0.01 (two-tailed)

Hypothesis 2-1 was slightly supported in Table 8 (N = 233, F=5.387, df = 232, p < 0.1). For this study, it was hypothesized that pre-disaster preparedness is shown more in the participants verses non-participants in the disaster prevention training. The hypothesis was weakly supported (ß=0.12, p<0.1). Participants in the disaster prevention training were positively related to disaster preparedness behavior. There was a greater number of participants in the disaster prevention training program for earthquakes with a higher level of disaster preparedness behavior. Moreover, being female significantly and strongly relates to the preparation behavior (ß =0.22, p < 0.01). In other words, the disaster preparedness behavior is shown more in females than the male.

Table 8 Regression results for pre-disaster preparedness and participation in the disaster prevention training

Predictor variable	ß	t	p-value	df	F	R^2
Step 1: Gender	.22**	3.35	.001			
Age	.07	1.02	.308			
				232	6.226	.051
Step 2: Participation	.12+	1.89	.060			
Total				232	5.387	.066

Note) Standardized regression coefficients are reported.
+p < 0.1, *p < 0.05, **p < 0.01 (two-tailed)

Hypothesis 2-2 was slightly supported. Table 9 presents a matrix of t-test result for Hypothesis 2-2. T-test is used to compare the values of the means from two groups and test whether it is likely that the samples are having different mean values. There are slightly existing differences when comparing those who participated and did not participate in the disaster prevention training for disaster preparedness behavior (t = 1.87, p < 0.1).

Table 9 Result of t-test analysis: participants in the training and disaster before preparedness

	N	Mean	S.D	t-test
Participant	150	2.59	1.09	t=1.87+,
Non-participant	84	2.32	1.03	df=232, p=.06

Note) Standardized regression coefficients are reported.
+p < 0.1, *p < 0.05, **p < 0 .01 (two-tailed)

5. CONCLUSIONS

This study reports that participants in the disaster prevention training had slightly higher levels of preparation than non-participants. Also, gender were positively associated with the disaster preparedness behavior, and female were better prepared than male.

The results concerning experience of damage by the disaster and disaster preparedness behavior have no significant impact in this study. However, previous researches provided positive and significant support for the proposed hypotheses. In other words, experience with disasters and resource loss had a strong positive relationship to disaster preparedness behavior. One possible reason of insignificant result in this study is that the 2011 Great East Japan earthquake was relatively little major earthquake damage in the Tokyo area, compared with Tohoku area. From the data, about 19% of people who did not follow what they learnt from the training answered that the situation was not dangerous enough to practice what they have learned in training. Therefore, it is possible that even respondents with experience of damage have not sufficiently adjusted their expectations of future disaster to prompt increases in disaster preparedness behavior. Future research could attempt to quantify this effect and the extent to which experience of damage is measured by its degree.

It is important to note that this study had several methodological limitations. First, the survey measured the pre-disaster preparedness through self-reported answer, a possible source of error if respondents misreport the actions they have taken. Second, this study used a random sampling strategy and the unique designed survey that restricts the ability to generalize.

The findings of this study regarding predictors of the disaster preparedness behavior may have ramifications for the disaster prevention training. The significant but weak influence of training participation on the disaster preparedness behavior identified in this indicates that contents of the training should also explain direct and useful actions that individuals can take facing with disaster. Future studies should more explicitly measure that the participation in the training is a useful activity toward successful preparation.

Getting prepared for the predicted earthquake has proven to be the most effective way to reduce the damage suffered. In order to reduce the human impact by the predicted disaster, it is generally proposed the following three: the first one is to provide information on threat so that threat perception due to possible future disasters is raised. The second area is to increase the personal resources of the participants in dealing with the threat, so that the individual feels capable of dealing with a possible future disaster event. Lastly, training programs need to give community members a sense of responsibility for mitigation and preparedness. Especially, the reason of unparticipation in the training was that they had no information how to participate, and then it indicates more activities to facilitate for participation in it.

It is important to make sure persons fully prepared, and then make purposeful and effective use of that preparation. After the preparation is done, moreover, it is even more important to consider how to actually perform it. It is difficult to change human behavior, but the rewards are worth the effort.

Abstract: On September 18, 2011 at 18:25 (Nepal Standard Time), a moment magnitude (Mw) 6.9 jolted eastern Nepal including the capital city, Kathmandu which is located 272 km west from the epicenter (27.72°N, 88.06°E). It also affected several areas of India, China, Bhutan, and Bangladesh. This shallow-focus earthquake having focal depth 19.7 km, lasted for about 30-40 seconds. Although several buildings suffered extensive damage, it was fortunate to observe that fatalities in Nepal were relatively low with six reported. The earthquake displaced 12,301 persons of 4,851 families. A total of 6,435 houses were damaged completely, 11,520 damaged partially, and 3,024 houses suffered only minor damage. The Center for Urban Earthquake Engineering (CUEE) at Tokyo Institute of Technology investigation team carried out the field survey in collaboration with Institute of Engineering (IOE), Tribhuvan University, Nepal to assess the extent and nature of damage caused by the earthquake. From the investigation it was found that many non-engineered stone masonry, brick masonry, and reinforced concrete buildings suffered heavy damage, while engineered reinforced concrete buildings and buildings constructed with indigenous technology locally known as Centibera buildings, exhibited minor or no damage.

1. INTRODUCTION

A strong earthquake with a moment magnitude (Mw) of 6.9 jolted eastern Nepal on September 18, 2011 at 18:25 (Nepalese Standard Time) with shaking felt 272 km west in the capital, Kathmandu. As shown in Figure 1, the

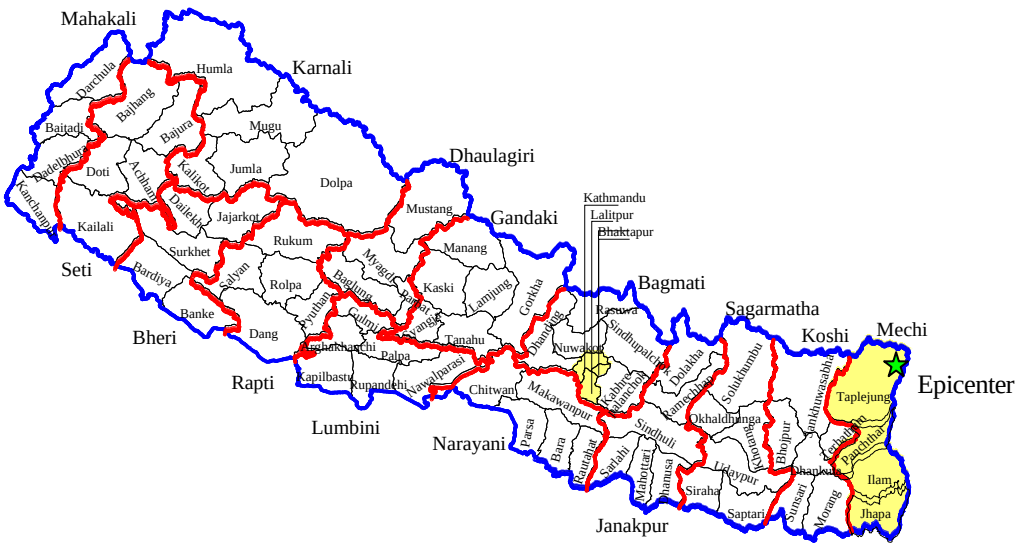

Figure 1 Map of Nepal showing epicenter and the visited districts.

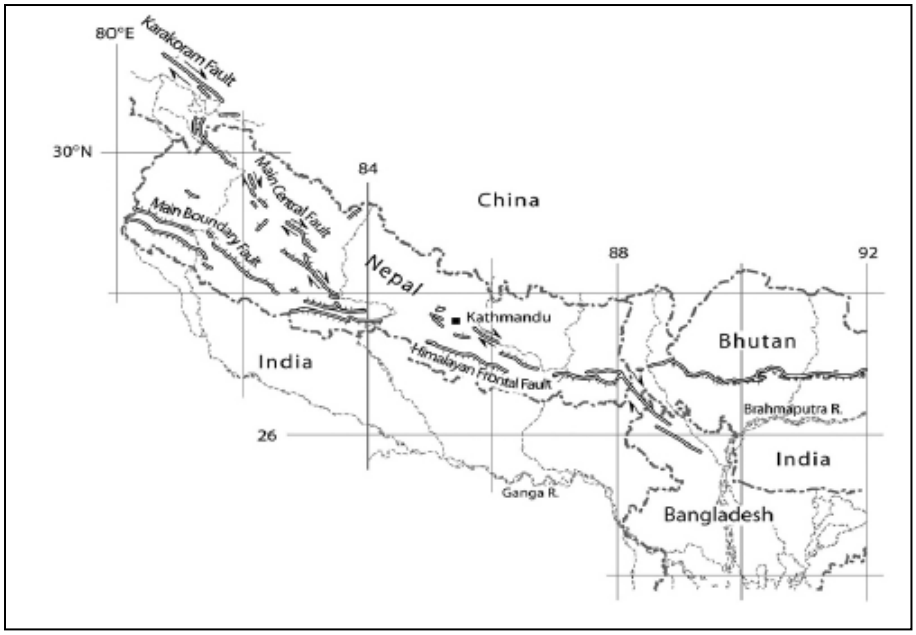

Figure 2 Active faults in and around Nepal Himalaya (Chamlagain (2009))

epicenter was located at Nepal-India border (27.72°N, 88.06°E) (Taplejung District of Nepal) and the focal depth was 19.7 km (USGS 2011). This shallow focus earthquake lasted for about 30-40 seconds and affected several areas of Nepal, India, China, Bhutan and Bangladesh. The devastating earthquake claimed the lives of 111 people with the maximum of 97 in India. A press release of the Ministry of Home Affairs of Nepal on October 24, 2011 reported a total of 6 casualties in Nepal which includes 3 deaths in Kathmandu, 2 in Sunsari and 1 in Sankhuwasabha. Similarly, 30 people were critically injured and 134 suffered minor injuries. A total of 6,435 houses were completely damaged, 11,520 were partially damaged and 3,024 houses suffered only minor damage throughout the country.

A joint team from Tokyo Institute of Technology, Japan and Institute of Engineering, Pulchowk Campus, Nepal conducted a reconnaissance survey from October 12 to October 19, 2011 to assess the extent and nature of damage caused by the earthquake in Nepal. The investigation was focused mainly in the densely populated towns such as old settlement of Bhaktapur district around the Bhaktapur Durbar Square area, some sites in Kathamndu and Lalitpur districts, Ilam Bazar of Ilam district, Ranke Bazar and Phidim Bazar of Panchthar district and several villages in Taplejung district. The districts where field investigation was conducted is highlighted in Figure 1. The damage information of remote villages with widely dispersed houses in the affected region, where our investigation team could not reach, was collected from the local authorities and organizations such as the District Administration Offices, the Nepal Red Cross Society and Local Police at Phidim. This paper presents a comprehensive overview of the performance of buildings in the earthquake-affected areas particularly in Bhaktapur and Eastern Nepal. Damage in Sikkim, India have already been reported in NICEE (2011) however, the investigation of the damage in Nepal has not been reported yet. In this paper lessons learnt from the investigation of the performance of buildings in earthquake affected areas in Nepal are reported.

2. SEISMIC HAZARD IN NEPAL AND THE PRESENT EARTHQUAKE

Nepal is a country with a diverse geographical setting varying from low lands in the southern part, to high mountains including the world's highest peak Mount Everest (el. 8,848 m) in the north. One third of the Himalayan arc, which marks an active plate boundary between the Indian and Eurasian plates, lies in northern Nepal and is a source of major seismicity in the area. The presence of numerous active faults in Nepal shown in Figure 2 (Chamlagain 2009), clearly highlights the seismic hazard in this Himalayan nation.

In the past, Nepal has experienced only two devastating earthquakes in the last century. A magnitude 8.1 earthquake occurred in January 1934, with epicenter (26.50°N, 86.50°E) close to Nepal-India border region (ASC 2011). The Kathmandu Valley experienced intensities of IX-X in the MMI scale. A total of 8,519 persons were reported dead in Nepal, out of which 4,296 persons died in Kathmandu alone (Pandey and Molnar 1988). A magnitude 6.8 earthquake occurred in August 1988, with epicenter (26.755°N, 86.616°E) in eastern Nepal (ASC 2011). The MMI estimated in Kathmandu was VII-VIII and at least 721 people lost their lives in Nepal due to this earthquake (NSET

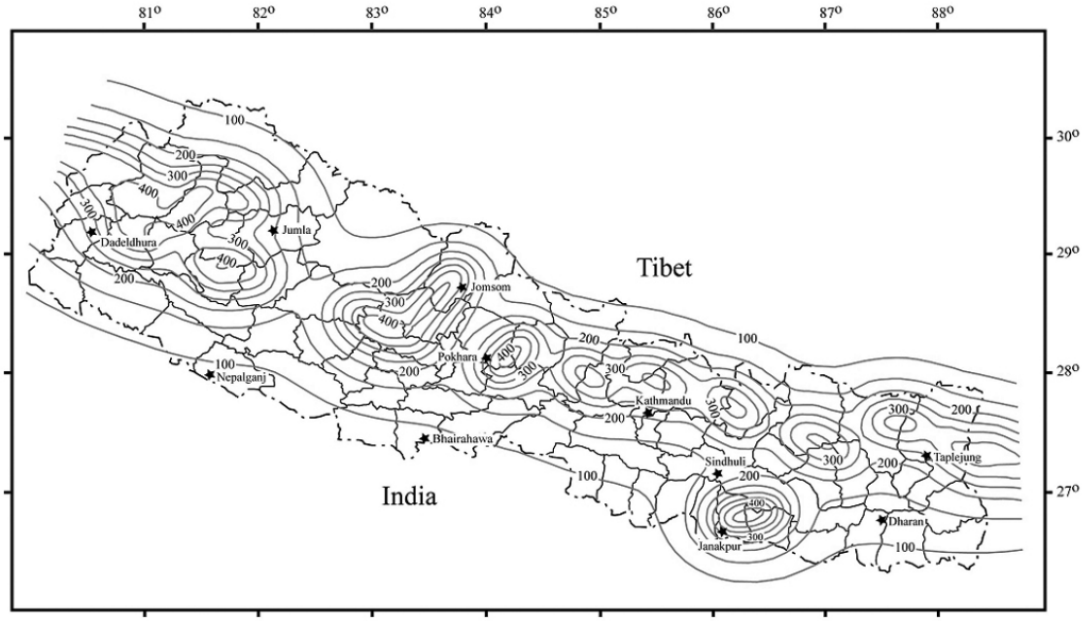

Figure 3 Seismic hazard map of Nepal showing bedrock peak ground horizontal acceleration contours in gals for 500 years return period (Pandey et al. 2002)

Figure 4 Damages in Bhaktapur (a) Vertical cracks between adjacent buildings and (b) Out of plane failure of brick masonry wall in mud mortar (Source: http://www.newscientist.com/blogs).

2011).

The Seismic hazard map produced by the National Seismological Center of Nepal shows the design-level PGA of $0.1g - 0.2g$ near the epicentral region of the September 18, 2011 earthquake (Figure 3). The upper limit of $0.2g$ is close to the PGA recorded in the severely affected regions of India during the earthquake (EERI 2012).

3. OBSERVED DAMAGES DURING FIELD VISIT

The collapse of old boundary wall of the British Embassy, Kathmandu claimed the lives of 3 people. Several old brick-masonry buildings in Kathmandu and Patan suffered minor cracks, however, the extent of damages in Bhaktapur were comparable. Surprisingly, many buildings in very poor condition, those were expected to collapse during the earthquakes, are still standing. Nevertheless, the extensively damaged buildings in Bhaktapur were old and constructed using ordinary brick in façade and sun dried bricks with mud mortar in side walls. Most of the buildings which suffered damages were not in intact condition prior to the occurrence of the earthquake. The observed major damages to the buildings include the formation of vertical cracks on walls along the mortar joint at the common face between two adjacent buildings (Figure 4(a)) and the out of plane failure of brick masonry walls (Figure 4(b)). Besides, diagonal cracks in masonry walls starting from the openings and collapse of gable walls were also common.

In eastern Nepal, all the districts of Mechi Zone was selected for the investigation. On consulting with the local people in Jhapa district, it was found that the district was not much affected by the earthquake. Hence, the study was focused in Ilam district, Panchthar district and Taplejung

Figure 5 Collapse of stone masonry buildings in Ilam (Source: District Administration Office, Ilam).

Figure 6 Damages in Ranke (a) Out of plane failure of stone masonry walls and (b) Collapse of stone masonry school building (source: Local Police).

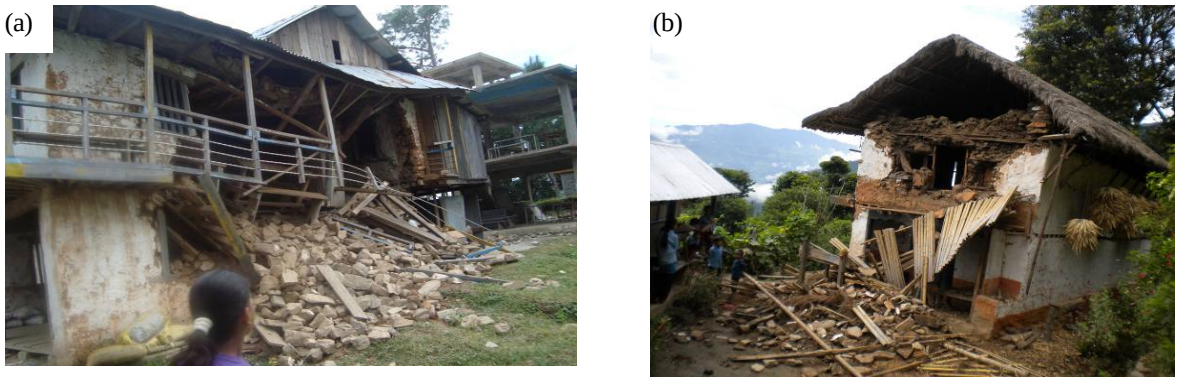

Figure 7 Typical damages in Taplejung (source: Red Cross, Taplejung) (a) Collapse of school building and (b) Collapse of stone masonry building.

district. Due to the limited time and difficulty in accessing the remote villages, the thorough investigation was undertaken only in the district headquarters and its surrounding. In Ilam Bazar, there were many recently constructed RC buildings, however, the majority of the buildings were constructed of random rubble stone masonry with mud mortar and timber. Almost all of the buildings in the locality suffered various degrees of damage from minor crack to the collapse of buildings as shown in Figure 5. The damage to the buildings constructed partially with timber frame and partially with stone masonry was less compared to that in the random rubble stone masonry buildings. In RC framed buildings, the repairable cracks were limited to the infill brick masonry walls.

In the towns Ranke and Phidim of Panchthar districts, the damages were mainly concentrated in the random rubble stone masonry buildings which offer very weak resistance to lateral loads and extremely vulnerable to seismic loads. The out of plane failure of stone masonry wall (Figure 6(a)) and the collapse of the buildings due to failure of load bearing stone masonry walls (Figure 6(b)) were very common. Only minor damage or no damage was observed

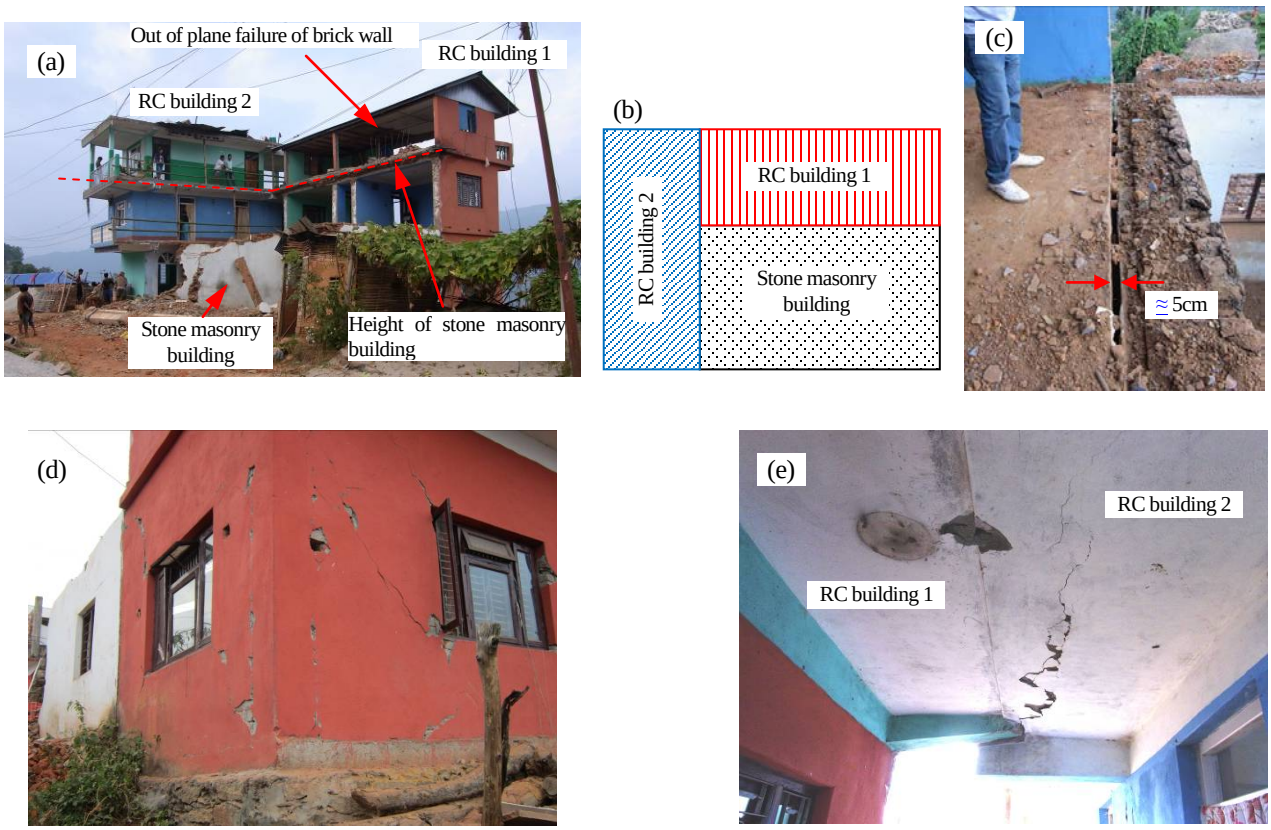

Figure 8 Seismic pounding of buildings (a) Damaged 3 buildings, (b) Building configuration, (c) Permanent gap between RC building 1 and stone masonry building, (d) Shear cracks in infill brick walls and (e) Cracks in the slabs.

Figure 9 Building construction technique (a) No cracks in the building constructed using Centibera and (b) Centibera construction technique.

in the buildings primarily constructed with timbers and reinforced concrete except in very few cases.

Since the construction practice in Taplejung also resembles to the previous sites, no difference in the nature of damages of the buildings were noticed. Typical types of damages such as collapse and out of plane failure of stone masonry walls are shown in Figure 7. Most of the buildings in the locality were not free of minor cracks. The shear cracks in the infill brick walls generated from the window openings were also noticed in the brick masonry and RC buildings.

A part from the typical damages, a collapse of a stone masonry building and heavily damaged RC framed buildings (Figure 8(a)) due to structural pounding was also observed in Phidim Bazar. The white colored demolished building in Figure 8(a) is the stone masonry building. When our survey team reached at the site, the demolition of damaged stone masonry building was in progress. There were no gaps between all the three buildings before occurrence of earthquake as shown in the building configuration of Figure 8(b). But after the earthquake there existed the permanent gap of about 5 cm (Figure 8(c)).

Due to the seismic load along with the impact loads from the adjacent RC buildings, the stone masonry building collapsed. The heavy shear cracks in the infill brick masonry walls (Figure 8(d)) and out of plane failure of infill brick masonry at the third floor (Figure 8(a)) illustrate that the RC building 1 also suffered the heavy damage. Significant amount of cracks were developed in the slabs of RC building 1 and RC building 2 (Figure 8(e)) as a result of structural pounding between RC building 1 and RC building 2. The shear cracks at the beam-column joint and the beams were observed in the RC building 2. Hence, the damages on these three buildings shows one of the good examples of structural pounding and also illustrates the vulnerability to structural pounding of buildings, if the provided gap between the adjacent buildings are insufficient.

In the Eastern Nepal, several buildings constructed using a traditional building technique locally known as "Centibera" (Figure 9(a)) were observed. The Centibera buildings are of 1-2 storys and are constructed with the stone masonry walls up to the plinth level or the first floor, on top of which the walls comprised of wooden frames together with woven bamboo mesh and cement mortar plaster or plaster composed of a mixture of mud, cow dung and rice husk are built (Figure 9(b)). No cracks were found in Centibera buildings while significant amount of cracks were noticed in the stone masonry, brick masonry and RC buildings nearby the Centibera buildings. It highlighted the suitability of construction of Centibera buildings compared to the other buildings in this region to withstand the seismic loads.

4. SUMMARY AND RECOMMENDATIONS

Since Nepal lies in an earthquake prone region, the following recommendations are provided to increase the seismic safety of buildings based on the observations made during the field investigation:

- Most of the buildings constructed with the local materials and indigenous technique suffered heavy damages hence, the existing buildings in remote villages require immediate cost-effective ways of retrofitting using locally available materials such as timber and bamboo.
- Timber-framed masonry structure in the first story and timber-framed Centibera structure in the upper story appears to be a promising technology for the construction of new seismic-resistant buildings in the villages. The construction of Centibera buildings should be encouraged in remote villages.
- Majority of the buildings throughout the country are not designed and constructed to withstand the probable earthquake. All the structures in the major towns of eastern Nepal should be thoroughly investigated for the assessment of their seismic safety and appropriate retrofitting measures should be taken for seismically vulnerable structures.
- Government authorities should ensure that only seismic-resistant structures especially bridges, hospitals, and school buildings, are designed and constructed in the earthquake prone regions such as Kathmandu, Ilam, Phidim, Taplejung.

Acknowledgements:

The authors express their sincere gratitude to Professor Kohji Tokimatsu, Director of Center for Urban Earthquake Engineering (CUEE), Tokyo Institute of Technology for supporting the field investigation and providing financial support. Thanks are due to the earthquake reconnaissance survey team members from Nepal, Mr. Purushottam Karki, Mr. Soyuz Gautam, Mr. Subash Bastola and Mr. Yadin Shrestha. The Nepal Red Cross Society and District Administration Offices of Jhapa, Ilam, Panchthar, and Taplejung, are also acknowledged for sharing their field investigation data and providing useful information.

PRACTICAL STUDY OF THE EARTHQUAKE DISASTER PREVENTION CHILDCARE FOR INFANTS WITH THE SIMULATED EXPERIENCE

Nobuyuki Yamada

Associate Professor, Dept. of Science Education, Fukuoka University of Education, Japan
nyamada@fukuoka-edu.ac.jp

Abstract: Speaking of the disaster prevention education for infants, an evacuation drill is most. The complimentary practice education by the cooperation with experts such as the firefighting is accomplished, but the effect inspection is not done enough and does not advance to the study either. Furthermore, the principal objective is put only in most fire drills moving to the outdoors early and cannot deny, becoming a dead letter. We went the practice with the development of the program of the earthquake disaster prevention education for infants in an educational practice from 2009. I will report the frame formation of the earthquake disaster prevention childcare through the simulated experience and the practice utilization while focusing on the correspondence action during strong ground motion based on past our process in this announcement, and adopting play.

1. INTRODUCTION

After the Great East Japan Earthquake of 2011, it is emphasized improvement of disaster prevention education becoming it, and various reviews and proposals are accomplished by Council concerning disaster management and disaster prevention education has received the Great East Japan Earthquake, MEXT (2012). Currently, a tsunami attracts attention in particular, but it is important that it is done in a good balance now while considering regionality for various disasters. This disaster has become one of the opportunities to raise awareness of disaster prevention. It was the effect of the spread of a surface as an extension to the spatial axis of the country. Also, it is important to the development of a permanent, progressive disaster prevention instructional activity, and the expanse as time axes is necessary. After one and a half year, it is necessary for the future trend to watch it closely from the disaster.

We have the disaster prevention education as the disaster security in an elementary school, kindergarten and nursery school in the transition period to a change. Speaking of the disaster prevention childcare for infants, So-called evacuation drills or fire drills are often found, and the complimentary practice education by the cooperation with experts such as the firefighting is accomplished, but the effect inspection does not advance to the study without being done enough either. Furthermore, the principal objective is put only in most evacuation drills moving to the outdoors early and cannot deny becoming a dead letter. In addition, about the earthquake disaster prevention measures in the nursery school, by Japan Society of Civil Engineers (2006) including a practice example, but not inflected enough. One reason for this as, the experts of the disaster, except that it caught doing the childcare in line with the actual situation and the age of children is difficult, and younger children at the time of the disaster to be completely helpless, and the like. On the other hand, the teachers are regarded the evacuation drill as transient event that was separated from the nursery of daily, and do not have a good understanding of the response when disaster occurs and there is a lack of cooperation and recognition between the two considered.

Before the earthquake disaster of the year before last more, we try making and utilization of material contributing to education to protect the body during "strong motion" of an earthquake that we may experience wherever of Japan. We produce the handmade shaking table to utilize as teaching tools of the education to protect the body by themselves which does not injure at the time of strong motion. This made much of simplicity and, as well as the education to young children, aimed at helping the disaster prevention education to teacher and parents. It is an aim to allow many teachers to work on the earthquake disaster prevention education in their school by themselves.

In this report focusing on a way of the correspondence at the time of the earthquake occurrence, and adopting activity of the play, we show a framework of earthquake disaster prevention childcare example through the simulated experience. And I will report a practice study with the development of the program of the earthquake disaster prevention childcare for the infants (e.g. from 0 to 5 years old children of kindergarten and nursery school before elementary school) for the above problems by the cooperation and the collaborative investigation with a school and the nursery school.

2. PRODUCTION OF HANDMADE SHAKING TABLE

In the concepts on making a shaking table, the thing which they can use it easily in an educational field and low-cost and the thing, carrying around that could manufacture it was possible, there is simulated experience of the shaking of a realistic earthquake, they can assemble it immediately and it is considered the safety. The power source which "shaking or rolling" produced the thing assumed it human power. In Yamada (2010 and 2011), I reported a chair type and a bed type, the stand which called itself a board type using the board which I improved more. In this report, I will report on the board type further improved.

As basic parts having one this board type at 90cm *90cm, I constituted a base part using wooden plywood and tennis ball (Figure 1). I set it for making trial and error including the installation of the frame which prevented that the placement of thickness and the tennis ball of the board, a ball rolled disorderly. When (approximately 80 kg) load hung to the stand for an adult and for each one child in a basic parts part, a ball did the number of the balls with the suitable number to become dented, and to do. In addition, the frame preventing deviation of the ball, when using a cardboard, honeycomb combined, use was spread so that it can be used in the form of bellows. As for what used many tennis balls, we thought to be flexible that not only could create the motion of the up-down by the load of weight on the board, but also could create horizontal shaking by the rolling. These tennis balls also perform as a cushion, it is considered to be the best ones do not damage the floor. Furthermore, the point using used balls unites the above concepts, and it may be said that it is a big characteristic. And the stabilization realized the low floor and safety improved at the time. When I made the table big, a plural number assembled basic size ones and allowed several-mat area to unfold with only a seat and a string without using a nail or the screw entirely. Also tried it on the surface mat cloth, as an installation on the table or the like is used to create fake paper and cardboard mock or shelf lamp, express likeness room. By the try and error in several years, we improved light weighting and compact, it became easier to carry it to convenience to a nursery school on using it. It was reduced the space in keeping it. We called this handmade shaking table to 'Gura- Gura-Dai'.

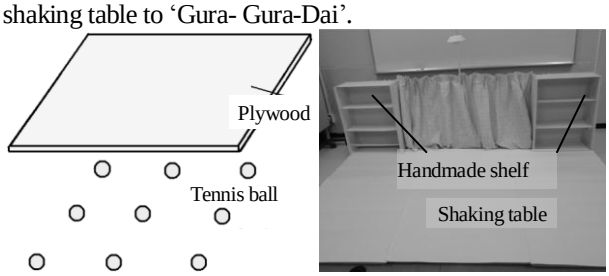

Figure 1. Basic constitution consisting of the used tennis ball and plywood (right) and completion (left) of the handmade shaking table. We call this 'Gura-Gura-dai' in Japanese. Handmade shelf is made of cardboard box.

We measured the rolling using a seismometer to compare between the human power vibration simulated ground motion and the ground motion of real earthquake. There was the point that did not seem to be reality the amplitude and period, duration of the waveform, but was able to express a time characteristic of the motion (Figure 2). Thus, we judged it when it was possible to experience the shaking that was almost real the ground motion enough. However, as for the shaking table by human power, it is thought that the manual to use and the training how to shake are necessary. Finally, we connected the base parts of the table and a real furniture (a chair and table) on the table, and we went the test to shake a university student as a subject as possible intensely several times (Figure 3). In this test, we have confirmed that can be used without any problem.

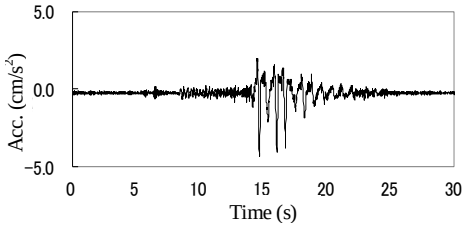

Figure 2. A vibration waveform when we shook with human power using this handmade shaking table. This record is an acceleration waveform.

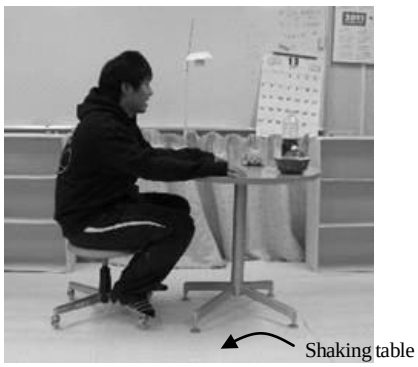

Figure 3. The photo of the vibration test with ridden a table and chair of the realistic size and college student on the shaking table of Figure 1 right. The handmade table was no problem even if we shook it intensely.

3. EXAMPLE OF THE EXPERIENCE-BASED DISASTER PREVENTION CHILDCARE

Many children and their parents do not have any sufficient knowledge what happens and what they can do during strong shaking, although they know the word of 'Earthquake'. In particular, the region that does not feel the earthquake rarely (for example, Fukuoka and Saga) for children who live in, it is remarkable. There is the child giving off the word "Run away to the mountain" considered to confuse it to hear the story of the tsunami among them. Thus, in this study, I aimed for acquiring the thing that I protected it and did something about by and own power of the body such as the reflex defense → danger inference →

dangerous cognitive → evasion at the time of the strong vibration by experience. As disaster prevention childcare to be a chance to learn, I produced the handicraft experience tool of various disasters including the above-mentioned handmade vibration stand and made a flow of a series of activity a package. Figure 4 shows the case of this content. It also includes difficult activity and the contents that they can't understand in infants, if I could feel something to the children and leaving their impression, I considered significance for the disaster prevention childcare in the early stages of the education.

As the role of the introduction, the song, dance and drama of Figure 4, imitate a look at how to deal with the earthquake including a physical expression that takes into account the process of learning to experience dance and pose become a description of all activities, it is important to relieve the tension and fear of children, increase the effectiveness of the activities. The contents of Figure 4 have given the role of experience as a corner, although, they are first experiences for children. By a series of activities children can learn and enjoy experientially to be bound to a smooth evacuation and how to protect themselves in case of emergency. Then, at the goal of the activities, to the children incorporating the praise that passes the participation certificate. This certificate is so that it can be utilized as a card in an emergency in a nursery school, after filled with family at home. I was made to be an opportunity to discuss and reflect of disaster prevention childcare for parents and children at home.

In addition, in the case of the enforcement in the kindergarten, I have them participate in not only the kindergartener but also parents at the same time because there are many parents who can participate in disaster prevention childcare. After the disaster reduction training, I conducted lecture on disaster prevention and safety to parents, we are incorporating the provision of point of view on topics such as the disaster environment surrounding the kindergarten.

1. Plays of Paper Theater + Song & Dance
   a) Do you know 'earthquake'?
   b) What do you do during a strong motion?
   c) When you need to flee …
   # Learning with looking, listening, singing and dancing
2. 'Gura Gura dai' (Shaking table)
3. 'Yura Yura kabe' (Rickety wall)
4. 'Jyari Jyari michi' (Dangerous underfoot)
5. 'Moku Moku tonneru' (Tunnel filled with smoke)
6. 'Makkura tonneru' (Tunnel with no light)
   # Learning with experience
7. Goal: participation certificate
   & emergency personal information card
   # Learning with family

*Option: Lecture for parents
about the risks around the children

4. PRACTICE TO DISASTER PREVENTION CHILDCARE

The photos of Figure 5 show the scenes that is to keep the posture of personal safety utilizing the handmade shaking table in chapter 2. These practices for infants have been carried out with the cooperation of the some nursery schools and kindergartens (Yamada, 2012). In these practices, we could try with public and private ones. Although we improved the methods and contents after the try and error, we were able to incorporate the contents of the Figure 4. And we were able to carry it out for children who were more than 600 people of the age from 0 year old children to 5 years old children in all. All of them could enjoy and learn with dancing, singing, seeing without big problems. However, there are some children of 0 year old and 1 year old who dislikes or crying in the experiences, we need to improve the method in some points. It is important for us that how reduce the fear at first. In addition, we asked the teachers to make the children to look back on the activities after the disaster prevention training in order to achieve the established.

A series of activity had a parent and a childcare person, kindergarten teachers who came do a thing same as children on that day and had adults experience them. These things indicate the height of awareness of disaster prevention education, and help to understand the activities in the nurseries and kindergartens for parents. In the lecture of disaster prevention for parents, I aimed to raise the awareness for it to parents and nursery teachers. As a result, although most adults were the circumstances "in my head I know" or "indifference" with respect to safety and disaster prevention, I guess that gave a little motivation into action.

Figure 5a. Photo of the disaster prevention childcare (3 years old children) in practicing protecting the body on Gura-Gura-dai.

Figure 5b. Photo of the disaster prevention childcare. I was talking about earthquake and strong motion.

5. GREW UP CHILDREN AND QUESTIONNAIRE TO THE PARENTS

The figure of the breeding of remarkable children is reported in daily life by such a series of disaster prevention childcare, by Yamada and Choji (2012). For example, the appearance and behavior give handrail to walk by the hand of the younger child appeared immediately after the implementation. The other example, six months later of the disaster prevention childcare they were able to respond to independently deal among children about the earthquake, and the like. Further that, the thing we have done in child care as play among the children continued for some time that has been also reported by teachers. Therefore, it includes not only the effects of education by doing experientially, also lasting effect. Also, there are some comments the teachers said 'we can do it ourselves', this practices gave a ripple effect.

Cooperation with the teacher Principal for kindergarten was some questionnaires to parents and teachers. As a result, for the implementation of disaster prevention such childcare, calls for further enrichment and positive opinion has been obtained from persons over 95 %. Therefore, we found that there is a need for education of disaster prevention for infants. In addition, after this disaster prevention childcare, the home of nearly 100 %, some talked about disaster prevention has been shown. After the children back home, they talked about them. In addition, the results suggest that the dancing and singing in the educational practice became some pretends, 'Gokko-Asobi' in Japanese, among children was also effective in the long term not only spread awareness to their parents.

Moreover, by our teachers to implement these experiences, there was a comment that has been improved awareness about disaster prevention. There were also reports from the nursery school and kindergarten that was carried out to mimic their own methods and contents. Not only each families, parents and children, but also there was a ripple effect to the nursery itself.

6. CONCLUSIONS

In this study, these educational practices for the younger children have become one of the disaster prevention education or childcare to develop "proactive attitude to act" for the disaster in time of danger, defend the lives of their own children. As a problem, it was thought that it was necessary for imminent adults including the nursery school teachers and the parents to educate for every "emergency" as well as the natural disaster such as earthquakes. The person in a position to protect the children in the case of emergency wants to take this point in their heart.

Acknowledgements:

The contents of this report, the Department of Early Childhood Education in the Faculty of Education, Wakayama University was carried out by cooperation and guidance by Prof. Kaoru Choji. Also, the handmade shaking table is the results of the graduate studies in Fukuoka University of Education by Ms. Yui Nakashima of elementary school teacher at Kama city in 2011 and by Mr. Kazushige Mori of elementary school teacher at Munakata city in 2010. These studies were able to do the educational practices with the cooperation of kindergarten, nursery and some students of Fukuoka University of Education. Finally, this study was supported by Grant-in-Aid for Young Scientists (B) 23700957 of the Japan Ministry of Education, Culture, Sport, Science, and Technology (MEXT).
