Abstract: To estimate effectiveness of dewatering and drain method for liquefaction remediation, a series of centrifuge shaking table tests were conducted. The following conclusions may tentatively be made: 1) The absolute and relative settlements as well as tilting angle of structures can decrease with lowering groundwater table. When it is lowered at a depth of 4m, the absolute settlement approximately becomes equal to the ground settlement, but both relative settlement and tilting angle of structures become almost zero. This claims that dewatering could be an effective method for reducing liquefaction-induced damage to existing houses; 2) Although the absolute settlement of structures may not be reduced by drain method, both relative settlement and tilting angle of structures can decrease with increasing drainpipe diameter and with decreasing spacing between drainpipes. This suggests that the installation of drainpipes around a structure in an appropriate manner is promising; 3) The tilting angle of structures founded on liquefiable soils decreases with increasing factor of safety with respect to the moment equilibrium, in which both dewatering and drainage effects are taken into account. This suggests that the dynamic overturning moment might have significant effects on the tilting of structures founded on liquefiable soils.

1. INTRODUCTION

The 2011 Tohoku Pacific Earthquake induced extensive soil liquefaction along the coast of Tokyo Bay and the floodplain of the Tone River (Architectural Institute of Japan, 2012). Accompanied by numerous sand boils and large ground settlements over 50 cm, soil liquefaction caused settlement/tilting of wooden and reinforced concrete buildings supported on spread foundations. Especially in Urayasu city, about 1/3-1/2 of wooden houses in reclaimed residential districts tilted more than 1/100 (Tokimatsu et al., 2012). There is a strong need to jack up to level the tilted buildings as well as to mitigate future liquefaction occurrence and associated damage. Although various restoration and remedial methods are available to tilted buildings as well as to buildings before construction, there seem no economically feasible measures for existing wooden houses.

To reduce liquefaction-induced damage to existing structures such as wooden houses, port facilities and embankments, dewatering and drainage methods have been occasionally used. Dewatering increases the thickness of the non-liquefiable surface layer and decreases the thickness of liquefiable underlying layer, thereby reducing potential damage induced by liquefaction; however, it is very difficult to use when the consolidation settlement of underlying clay layers is a matter of concern or when the lifetime cost including construction and maintenance becomes very expensive. The drainage method accelerates dissipation of excess pore water pressures during earthquakes using high permeability materials driven in liquefiable soils. Because of its installation cost, drain method may not be economical and realistic measures for existing houses. A small diameter plastic drainpipe (Photo 1), which has been developed recently and applied as remedial

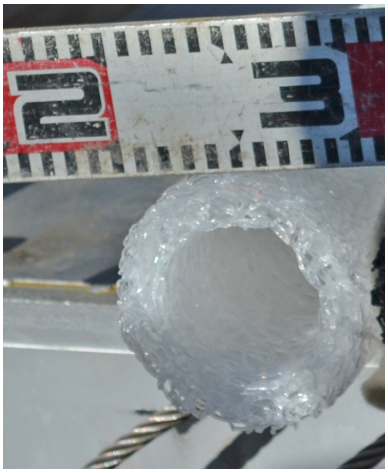

Photo 1 Plastic drainpipe

measures against uplift of existing manholes, is relatively cheap and easy to push into the ground, promising cost effective measures for existing houses.

To estimate effectiveness of drain method for liquefaction remediation, a series of centrifuge shaking table tests were conducted, in which drainpipes were installed around a house with its diameter and spacing as well as groundwater table being varied. The tests conducted with different groundwater table enables us to examine the effects of dewatering on mitigation of liquefaction damage. Detailed test procedures and results have been described elsewhere (Suzuki et al., 2013). On the basis of the result, this paper further investigates factors influencing tilting and settlement of houses founded on liquefiable soils having different groundwater table and with/without drainpipes.

2. Outline of centrifugal model tests

Shaking table tests were conducted on various soil-structure models with/without drainpipes under centrifugal acceleration of 25 or 50G, i.e., a reduced scale of 1/25 or 1/50. Pipe diameter and spacing, groundwater table and sizes of structure were varied in the test. Table 1 summarizes the soil-structure models tested and Table 2 shows the location of drainpipes placed around a house. Numerals in parentheses in the tables stand for the prototype scale. Each case ID consisting of four characters in Table 1 specifies both soil and structure conditions. The first numeral indicates the groundwater table in the prototype scale (1: 1.0m, 2: 2.0m, 3: 2.5m and 4: 4.0m), the second one the structure dimensions (S: 4.5m x 4.5m, L': 8.0m x 8.0m and L: 9.0m x 9.0m in a plan in the prototype scale), the third one the drainpipe diameter (0: without drain, 1: 130mm and 2: 250mm in the prototype scale) and the forth one the spacing between drainpipes (0: without drain, 1: 5.0m, 2: 3.0m, 3: 1.5m and 4: 1.0m in the prototype scale). Case IDs with an asterisk in Table 1 (1S00 and 3L00) were shaken twice to confirm reproducibility of the model tests.

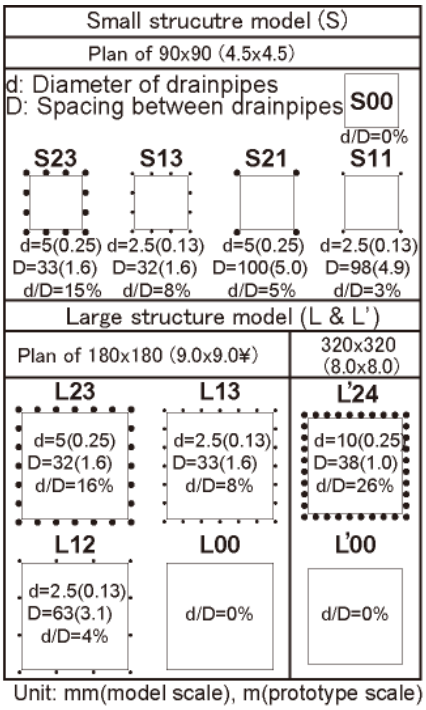

Figure 1 shows a typical test setup (e.g., cases IS00 and 1S23) conducted under a centrifugal acceleration of 50G. All the soil-structure models run with a centrifugal acceleration of 50G were constructed in a laminar box with a height of 300mm, a width of 220mm and a length of 700mm (Suzuki et al., 2013). In each container, two structures with/without drainpipes were founded on a sand deposit consisting of two layers. The lower layer was Silica sand #7 having a thickness of 180mm, which was overlain by finer Silica sand #8 with a thickness of 20mm. A relative density for both layers was about 50%. Dry Silica sand #7 was firstly air-pluviated in the box. When the height of the sand layer reached the groundwater table (20mm, 50mm or 80mm), the sand layer was saturated using silicon oil with 50cst under vacuum. The layer above the groundwater table was then prepared by air-pluviation. The coefficient of permeability of the liquefiable layer below the groundwater table (Silica sand #7) was 2.8×10^{-4} cm/s.

After completion of sand layer, a pair of either small or large structure models was placed on the sand layer with an embedment of 3mm. The small structure model (S) had a plan dimension of 90mm x 90 mm, a height of 118mm and a weight of 323g and the large

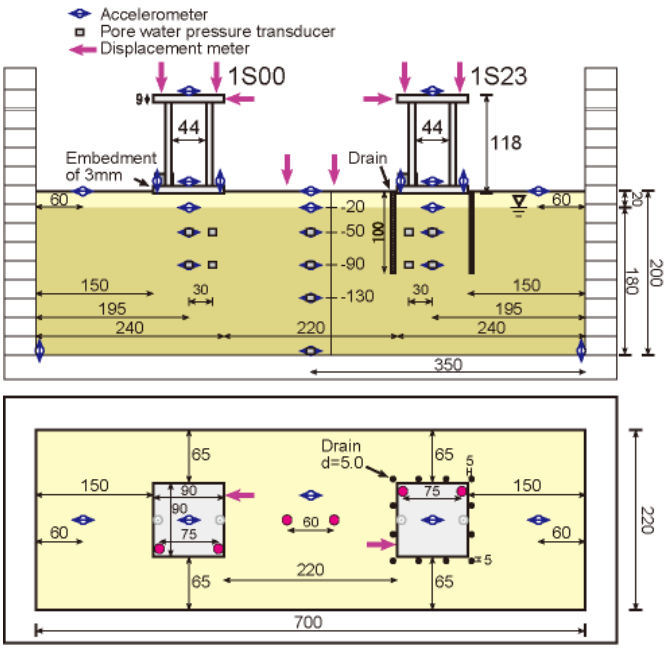

Figure 1 Typical test setup (50G)

one (L) had a plan dimension of 180mm x 180mm, a height of 190 mm and a weight of 1.043g. Both structures had an eccentric mass (52g or 139g) on their foundations with an eccentric distance of 25mm or 75mm from the center. These structure models had an average contact pressure of 15-18kN/m^2 between the foundation and the soil, a natural period of 0.3-0.4s and a height of gravity center of 2.5m in the prototype scale, representing a typical two-story wooden house in Japan. After placement of a pair of structures, drainpipes were push into the soil around a structure if needed, as specified in Table 2. Drainpipes were made of stainless-steel mesh (100 wires per inch, wires 0.1mm in diameter), having a diameter of 2.5mm or 5.0mm and a length of 100mm. During the preparation of soil structure models, displacement meters, accelerometers and pore water pressure transducers as well as displacement meters were installed in the soil as well as on the structures.

Soil-structure models tested under a centrifugal acceleration of 25G were prepared in a similar manner but in a larger laminar box with a height of 600mm, a width of 800mm and a length of 1950mm. A surface layer in this case was also Silica sand #8 having a thickness of 40mm but an underlying layer was Toyoura sand with a thickness of 360mm. A relative density for both layers was about 60%. Silicon oil with 25cst was used for saturating the soil. The coefficient of permeability of the liquefiable layer (Toyoura sand) was 9.2×10^{-4} cm/s. A structure model (L') had a plan of 320mm x 320mm, a height of 170 mm and a weight of 5.340kg. An eccentric mass (860g) was placed on the foundation with an eccentric distance of 120mm from the center. Its average contact pressure, natural period and height of gravity center in the prototype scale were almost the same as those of model structures S and L tested under 25g. Drainpipes used in this case were made of brass mesh (100 wires per inch, wires 0.1mm in diameter), having a diameter of 10mm and a length of 200mm.

A pair of structure models such as shown in Figure 1 was shaken, either under 50g or 25g, using an artificial ground motion called Rinkai as an input motion. The outputs from the installed sensors were recorded until the excess pore pressure in the ground had dissipated completely. This shaking and observation process was then repeated up to four times until one of the structures tilted largely. The maximum acceleration (in the prototype scale) was adjusted to 4.0m/s^2, 2.0m/s^2, 4.0m/s^2 and 4.0m/s^2 in the sequence order. This paper discusses the results only from the first shaking for a pair of structure models. Henceforth, the test results were shown in the prototype scale.

3. Estimation of effectiveness of drainage method through shaking table tests

3.1 Comparison in behavior between structures with and without drains

Figure 2 shows time histories of major outputs from cases 1S00 and 1S23 (with and without drainpipes). Straight lines in Figure 2(c)(d)(k)(l) stand for the initial effective stress, in which the initial overburden pressure from the structure is taken into account based on Boussinesq's formulas. The accelerations of the ground, footings and superstructures are significantly smaller than that of the shaking table (Figure 2 (e)-(h)(m)-(p)). Although the acceleration of the footing is almost the same between the two cases but the acceleration of the superstructure is slightly larger in model 1S23 (with drainpipes) than in model 1S00 (without drainpipes). The excess pore water pressures below the centers of footings in both cases increase with cyclic loading (Figure 2(c)(d)(k)(l)). The excess pore water pressures in case 1S00 (without drains) become approximately equal to the initial effective stresses at depths of both 2.5 m and 4.5 m. In contrast, those in case 1S23 (with drains) do not reach the initial effective stress at both depths and are kept as low as a half of those in case 1S00, probably because of the effects of drainpipes. As a result, the tilt angle in case 1S23 with drains becomes as small as 5/1000, which contrasts well

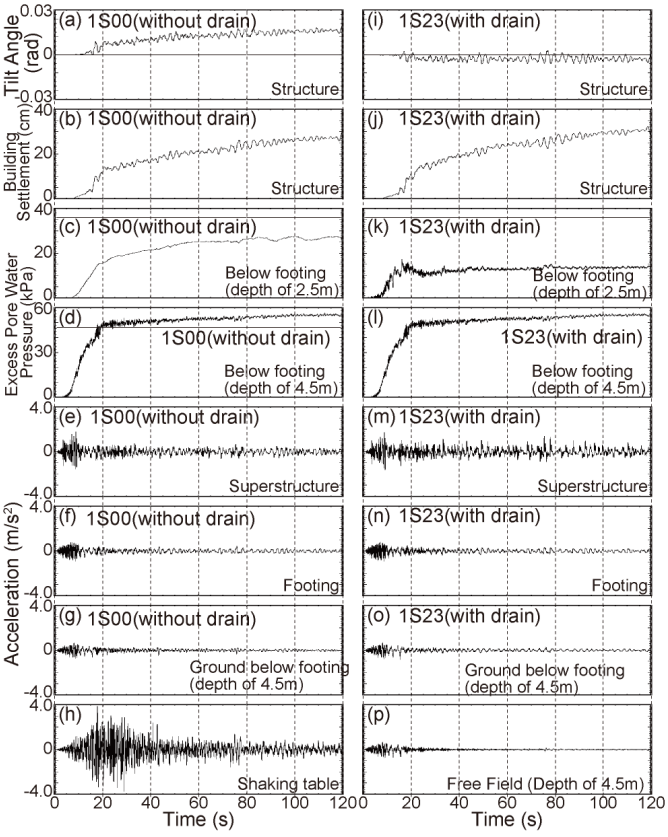

Figure 2 Time histories of major values for 1S00 and 1S23

with a larger value of 1/40 in case 1S00 without drains (Figure 2(a)(i)). It is interesting to note further that, despite its smaller angle of tilt, the absolute structure settlement in case 1S23 with drains is almost the same as that in case 1S00 without drains and significantly larger than that of the ground (Figure 2(b)(j)). This suggests that the installation of drainpipes around a structure be effective for reducing tilting angle but ineffective for reducing absolute settlement of the structure.

3.2 Effects of groundwater table on tilting and settlement of structures

Figure 3 shows the relationship between the groundwater table and the absolute settlements of both structure and ground surface for all cases after the dissipation of excess pore water pressures developed in the ground. Triangle symbols standing for the absolute settlements of the ground surface, suggest that the ground settlement is 150-170mm regardless of the groundwater table. The absolute settlement of structures decreases and approximates the order of the ground settlement with lowering groundwater table.

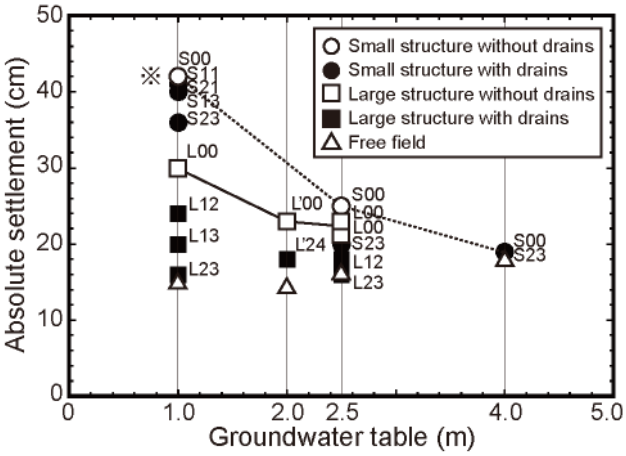

Figure 3 Relation of groundwater table with absolute settlement

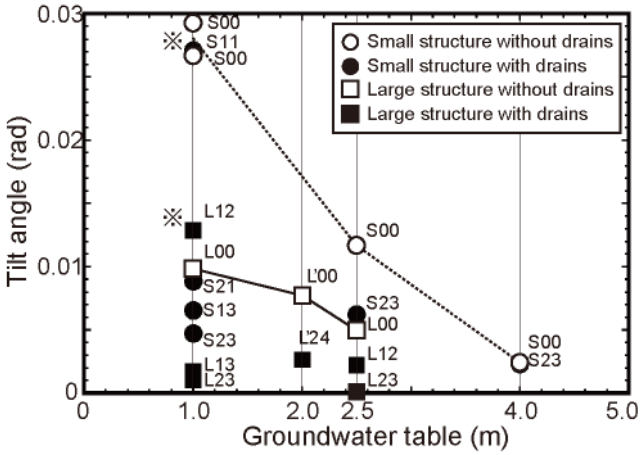

Figure 4 Relation of groundwater table with tilting angle

For example, in the case with the groundwater table of 4.0m, the settlement of structures with and without drains becomes almost equal to the ground settlement. This confirms that the dewatering is effective for reducing relative settlement of structure. Figure 3 shows that the absolute settlement tends to be larger in small structures (S) than in large structures (L). The difference in plan dimension might have affected the liquefaction degree of the soil below the structure and resulted in the different settlement between the two cases. Figure 3 also shows that the absolute structure settlements are almost the same regardless of the presence of drainpipes if their groundwater tables are the same. This confirms the finding in the previous section that the installation of drainpipes around a structure is ineffective for reducing absolute settlement of the structure.

Figure 4 shows the relationship between the groundwater table and the tilt angle of structure for all cases after the dissipation of excess pore water pressures. There is a strong trend in which the tilting angle of structure decreases with lowering groundwater table and becomes almost zero at 4.0 m regardless of the presence of drainpipes (cases 4S23 and 4S00). This claims that dewatering could be an effective method for reducing liquefaction-induced tilting of existing houses. There is another strong trend in which the tilting angle of the structure becomes significantly smaller when drainpipes are installed. However, the tilt angle of structures with drains varies from case to case, i.e., it becomes smaller with increasing drainpipe diameter and/or with decreasing drainpipe spacing.

3.3 Factor influencing tilt angle of structures

To estimate effects of spacing and diameter of drains on tilt of structures, normalized diameter is defined as a ratio between diameter, d, and spacing, D, of the drainpipes installed around a structure. It is assumed that d/D is zero in the case without drainpipes. Figure 5 shows the titling angle for the cases with the groundwater table of 1.0m with respect to the normalized diameter (d/D). There is a strong trend in which the tilt angle increases with decreasing the normalized diameter (d/D), suggesting the effects of drainpipes on reducing tilting of structures. Figure 6 shows the excess pore water pressure ratio at a depth of 2.5m below the edge of the footing with respect to the normalized diameter (d/D). The excess pore water pressure ratio increases with decreasing the normalized diameter (d/D), suggesting that both drainpipe diameter and spacing might have contributed to reduce the excess pore water pressure generation. Figure 7 shows the tilt angle of structures with respect to the excess pore water pressure ratio. As might be expected, the tilt angle of structures decreases with decreasing excess pore water pressure ratio.

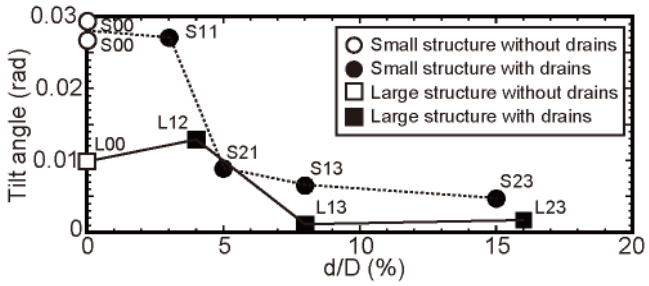

Figure 5 Relation of normalized diameter with tilting angle

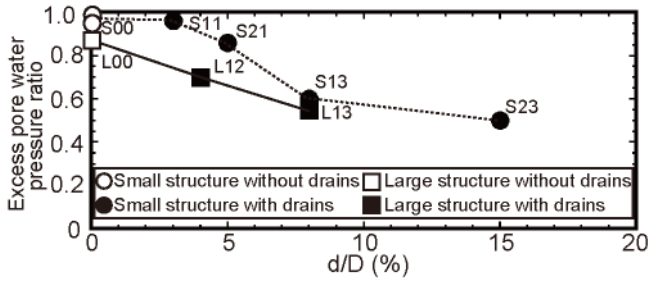

Figure 6 Relation of normalized diameter with excess pore water pressure ration

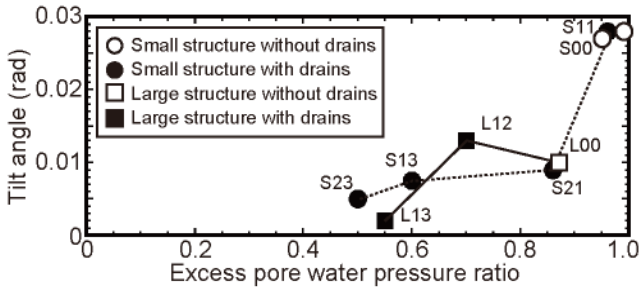

Figure 7 Relation of excess pore water pressure ratio with tilting angle

3.4 Estimation of safety factors against tilting

To estimate how the tilting and settlement of structures occur, equilibrium of load and moment acting on structures is examined. Figure 8 shows the failure conditions of a structure found on a non-liquefiable layer having a thickness of H, which overlies a liquefied layer with drainpipes. Assuming that only the shear force of the soil above the groundwater table can act against the weight of and the overturning moment from the structure in cases without drains but that the remaining effective stress in cases with drainpipes can resist the driving force and moment to some extent. The factor of safety with respect to vertical force equilibrium, F_{SW}, may be therefore given by:

$$F_{SW} = \frac{R_W}{L_W} \tag{1}$$

in which R_W is the resistant force from the ground and L_W is the entire weight of the structure, defined as:

$$R_W = 2\left(K\frac{H^2}{2}\gamma\tan\phi\right)(B+L) + \sum_{i=1}^{n}\int\sigma'_i dA \tag{2}$$

F_{s1}: Resultant force of shear stress in cross plan against shaking direction
F_{s2}: Resultant force of shear stress in horizontal plan against shaking direction
F_p: Resultant force of effective stress

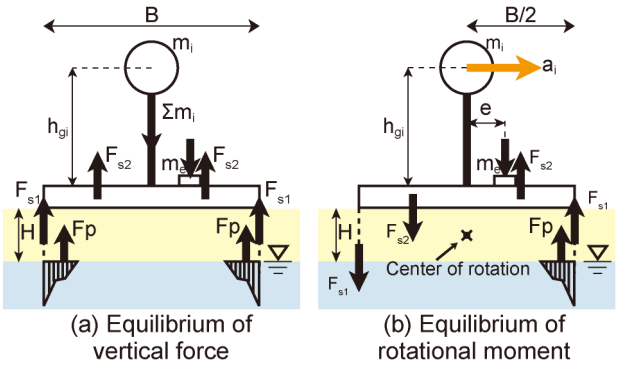

Figure 8 Equilibrium of vertical force and rotational moment

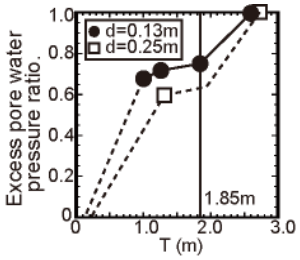

Figure 9 Excess pore water pressure ratio with distance from sensors

$$L_W = (m_1 + m_2 + m_e)g \tag{3}$$

in which K is the coefficient of earth pressure, γ is unit weight of non-liquefiable soil, H is the height of the surface layer above the groundwater table, ϕ is internal friction angle of the non-liquefied soil, B is the width of structure, L is the length of structure, n is the number of drainpipes, A is the area located within the effective radius of drains and below the footing, σ'_i is the effective stress of the soil within an effective radius of drains; and m_1, m_2 and m_e are masses of superstructure, foundation and additional eccentric mass added on the foundation, respectively; and g is gravity acceleration.

The safety factor with respect to moment equilibrium, F_{SM}, may be given by:

$$F_{SM} = \frac{R_M}{L_M} \tag{4}$$

in which R_M is the resistant moment, L_M is the overturning moment from structures, defined as:

$$R_M = \left(K\frac{H^2}{2}\gamma\tan\phi\right)\left(\frac{B}{2}+L\right)B + \sum_{i=1}^{n/2} l_i\int\sigma'_i dA \tag{5}$$

$$L_M = m_1 a_1 h_{g1} + m_2 a_2 h_{g2} + m_e g e \tag{6}$$

in which, l_i is a distance of drainpipes from the center, a_1 and a_2 are accelerations of superstructure and footing, h_{g1} and h_{g2} are heights of gravity of center of

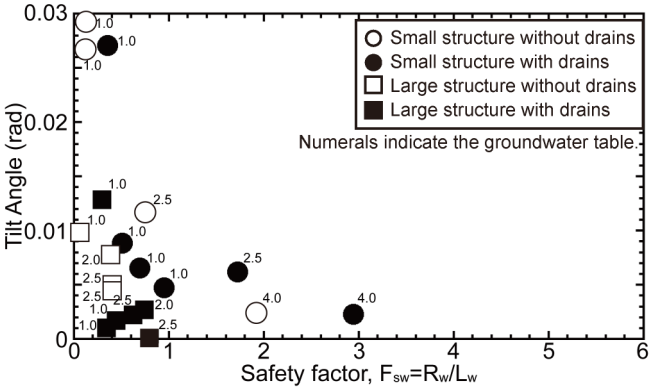

Figure 10 Relation of tilting angle with safety factor, F_{SW}

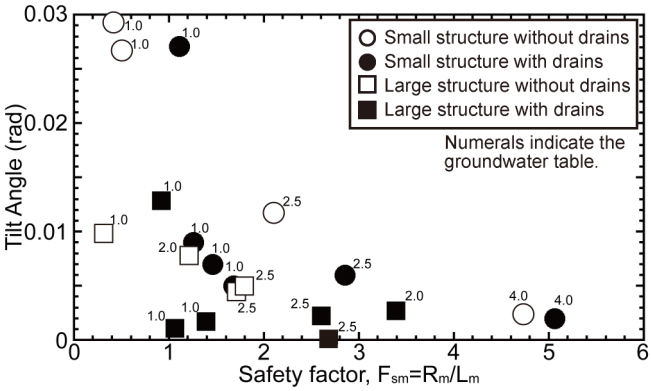

Figure 11 Relation of tilting angle with safety factor, F_{SM}

superstructure and footing, and *e* is eccentric distance of eccentric mass.

Figure 9 shows the maximum pore water pressure ratio plotted at the distance from the center of the nearest drainpipe. As expected, the pore water pressure ratio decreases with decreasing distance from the drainpipe. The trend is more significant for the drainpipes with a larger diameter. It is assumed that the effective radius is 1.85 m and the effective stresses within the effective radius are those shown in Figure 9.

Figure 10 shows the relationship between factor of safety factor with respect to force equilibrium and tilting angle of structures. The tilting angle of structures generally decreases with increases factor of safety; however, it seems that the trend is somewhat different depending the plan dimension of the footing. Figure 11 shows the relationship between factor of safety with respect to moment equilibrium and tilting angle of structures. Although F_{SM}=1 may not be a good boundary separating damaged from undamaged structures, there seems a fairly well defined trend in which the tilting angle of structures decreases with increasing factor of safety regardless of the plan dimension of foundations. This suggests that the dynamic overturning moment might have significant effects on the tilting angle of structures.

4. Conclusions

A series of centrifuge shaking table tests were conducted, in which drainpipes were installed around a house with its diameter and spacing as well as groundwater table being varied. On the basis of the result, the following conclusions may tentatively be made:

1) The absolute and relative settlements as well as tilting angle of structures can decrease with lowering groundwater table. When it is lowered at a depth of 4m, the absolute settlement approximately becomes equal to the ground settlement, but both relative settlement and tilting angle of structures become almost zero. This claims that dewatering could be an effective method for reducing liquefaction-induced damage to existing houses.

2) Although the absolute settlement of structures may not be reduced by drain method, both relative settlement and tilting angle of structures can decrease with increasing drainpipe diameter and with decreasing spacing between drainpipes. This suggests that the installation of drainpipes around a structure in an appropriate manner is promising.

3) The tilting angle of structures founded on liquefiable soils decreases with increasing factor of safety with respect to the moment equilibrium, in which both dewatering and drainage effects are taken into account. This suggests that the dynamic overturning moment might have significant effects on the tilting of structures founded on liquefiable soils.

Abstract: Suffusion is a potential risk for the long-term stability of the hydraulic structure, such as dams and levees. Suffusion is transport or migration of fine fractions inside the void of coarse skeleton. When suffusion occurs, the hydraulic and mechanical characteristics of soil are altered. In addition, suffusion has implications with valley fill in catchment topography as well as hydraulic structure. If the suffusion occurs and soil skeleton is intact in spite of fine fractions are eroded by seepage flow, the soil structure is probably unstable due to evolution of loose zone under phreatic surface. In this situation, soil structure is more vulnerable to large-scale earthquake.
For this reason, we performed a series of seepage tests on the small-scaled levees, followed by bearing capacity tests on levees. In this paper, extent of erosion-induced deterioration of shearing resistance of levee against external load is discussed through comparisons of bearing capacity at top of the slope before and after the suffusion. As a result, we noted out that suffusion has the potential to change the seismic stability of soil structure depending on the amount of eroded fine fraction and distribution of the fine fraction in the structure.

1. INTRODUCTION

The 2007 Noto Hanto Earthquake caused significant damages of fills built on catchment topography. In recent earthquakes, such as the 2011 off the Pacific coast of Tohoku Earthquake, in the mountain area, vulnerability of valley fills have been underscored. The reasons why fills damage concentrated on catchment topography are that the water table is typically high and major part of the fill is saturated. Moreover, the strong ground motion caused pore pressure increase, so that shear resistance of embankment decrease. However, poor quality fills, which are constantly high water table, are subject to suffusion, which is transport or migration of fine particles inside the void of coarse skeleton. This phenomenon is also expected one of the reason of collapse of fills. Foster and Spanngle (2000) reported that 46% of dams' failure or damage is related to internal erosion. Internal erosion (suffusion is one of the modes of the internal erosion) is one of the major causes of failure or damage of fill dams. Kenney and Lau (1985) developed index using grain size distribution appertains to internal stability of filter fill dam. Several elemental experiments result broadly confirmed this criterion by using well graded and gap-graded sand gravel soils (e.g. Skempton and Brogan 1994, Kokusho and Fujikura 2008). Skempton and Brogan (1994) also expressed internally unstable soils categorized by Kenny's criterion has significantly lower critical hydraulic gradient than well-known Terzaghi's theory. Kokusho and Fujikura (2008) approached how to determination of seepage failure mode by using Kenney's criterion and coefficient of uniformity Cu. Recent studies of suffusion have suggested the phenomenon is affected by fine fraction content, hydraulic gradient and confining pressure (Bendahmane *et al.* 2008, Moffat *et al.* 2011). Furthermore, much research are carried out about change of hydraulic characteristics of soil structure. Sterpi (2003) established an empirical equation governing internal erosion. Fujisawa *et al.* (2010), Cividini and Goida (2004), Cividini *et al.* (2009) simulated the internal erosion model through numerical analyses. However, these experimental and numerical approaches considered adsorption of erosion particle, but do not considered stability as exemplified by seismic performance of fills induced by internal erosion, such as suffusion.

If the suffusion occurs and soil skeleton is intact in spite of fine fractions are eroded by seepage flow, the soil structure is inferred unstable due to evolution of loose zone under phreatic surface. In this situation, soil structure is more vulnerable to large-scale earthquake. To address this issue, a series of seepage tests were conducted on the small-scaled levees, followed by bearing capacity tests on levees. In this paper, extent of erosion-induced deterioration of seismic performance of levee against external load is discussed through comparisons of bearing capacity at top of the slope before and after the suffusion.

2. EXPERIMENTAL DEVICE

2.1 Soil materials

To simplify the phenomenon, mixtures of fine and coarse fractions are used for the model slopes. Furthermore by using the cohesionless coarser soil than the prototype embankment material, phenomenon can also be macroscopically observed and occur in a short time. For this reason, the Silica No. 3 and Silica No.8 sands are used as model materials. The grain size distribution curves of each Silica sand and basic properties of the materials are summarized in Fig. 1 and Table 1. Silica No. 3 sand models soil skeleton, while Silica No.8 sand is used as the erodible fine particles, in the void of the coarse skeleton. Silica No. 8 sand is not categorized as fine fraction in the Japanese Industrial Standards. However, in this research, Silica No. 8 is considered as fine fraction because the grain size is relatively finer than Silica No. 3 sand that forms the soil skeleton. The chosen fine fractions of mixture are 10 %, 15 %. The grain size distribution curves of mixtures and basic properties of each mixtured material are shown in Fig. 2 and Table 2, respectively. According to Kenney's criterion which expresses internal stability of filter all the mixtures are internally unstable.

2.2 Experimental apparatus and procedure

Side view of the experimental system is schematically illustrated in Fig. 3. The steel box with inner dimensions of 450 mm (length) × 150 mm (width) × 350 mm (height). The embankment model is made in this box. The box has two tanks at both sides, named "water supply tank" and "drainage tank", respectively. Vertical sidewalls between the drainage tank and embankment model provide a metal gauze so that only water and fine fraction can flow through. By pouring the water in water supply tank, seepage flow in model ground could be realized. From the running off seepage water and sediment from toe of slope to drainage tank, the fine fraction was collected by sieve of size 0.075mm. Here, the effect of particles smaller than 0.075mm was not considered due to the very small amount. To prevent material separation during preparation of the model embankment, partially saturated soil is used. Water contents of model ground with fine fraction content of 10%, 15% area are 2%, 3%, respectively. The sand is compacted layer by layer with 20mm thickness. Then, the model ground is scraped off with a shaped frame and formed to be a 230.5mm high model embankment. The model embankment was composed of two areas, "Base zone" and "Slope zone". The Base zone is the 50mm-thick horizontal layer and the Slope zone is the embankment with the slope of 1 : 1.8. The target density is the minimum density of each mixture. Boundary condition at the upstream side is constant head

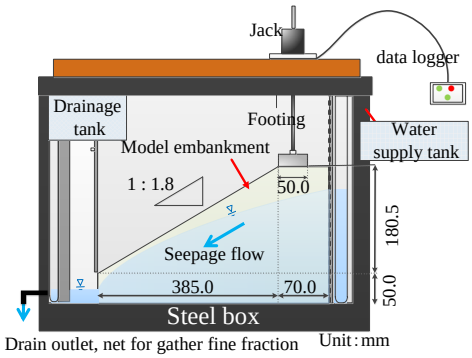

Figure 3 Side view of experimental model and Setting for bearing capacity test

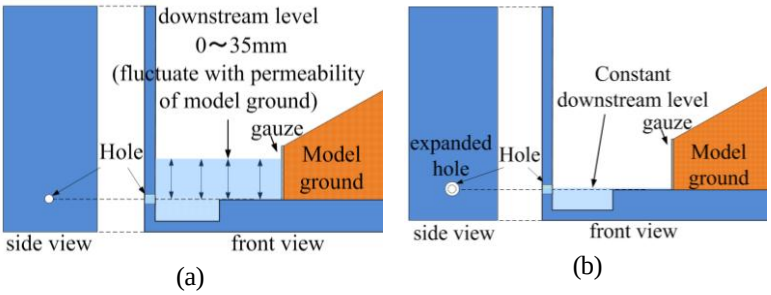

Figure 4 Boundary condition at the downstream site
(a) Type A (Case10%H-A), (b) Type B (Case10,15%H-B)

Table 3 Test cases

Case		Content of Silica sand No. 8 (%)	Boundary condition of toe of slope	Loading location	Loading speed (mm/min)	Dry density (g/cm^3)	Seepage time (min)

	20670					1.558	20670

(172mm). Boundary condition at the downstream side has two patterns: In Type A, the water level is set at a height of 35mm from the bottom, while it is set at the bottom in Type B. Since the size of the outlet for Type A is small, the water level can change (initial height is 0mm, maximum height, approximately, 35mm) if flow rate exceeds threshold value (approx.3000ml/min). Boundary condition at the downstream site of each type is schematically illustrated in Fig. 4.

In this study, three series of bearing capacity test on spatially-eroded soil structure by suffusion are conducted to discuss a destabilization of fill at each degradation stage after seepage test as shown in Table 3. For comparison, bearing capacity tests at initial state are also conducted. Within the scope of this study, at the beginning of the seepage test, position of the phreatic surface and unsaturated zone does not change much depending on the material used. Temporal position change of phreatic surface was estimated based on the visual observation using photographic images. During the loading test, seepage flow of the model ground has been kept constant.

Figure 3 also shows the schematic illustration of the case in which the installation location of model footing is top of slope and 20mm from the edge of a slope. The model footing made of duralumin (50mm in width, 150mm in breadth) whose bottom was roughened by attaching a sand paper is used. The loading device consists of a 50kN capacity actuator and an H-beam frame which is firmly bolted on the web of the steel box. Vertical load is measured by a load cell of 50kN capacity attached to the loading rod. The model footing is loaded at the rate of 62.5mm/min or 11.75mm/min until the failure occurs. A digital video camera in front of the side wall of the steel box is used for monitoring of the ground movement.

After the experiments, the grain size analyses for each part of model embankment were conducted to confirm position of distribution of fine fraction.

3. RESULT AND DISCUSSIONS

In Case 10%-A, 15.1% of the fine fraction was eroded by seepage test which was done before bearing capacity test on top of slope. On the other hand, in Cases 10%-B and, 15%-B, 5.3% and 5.4% of the fine fraction was eroded, respectively. The grain size analysis for each part of embankment after the experiments as shown in Table 4. The value of fine fraction content is relatively small in the upstream side (distance from the toe: 289-385 mm) due to

Table 4 Condition fine fraction content distribution before bearing capacity test

Case	Initial state	Distance from the slope toe (mm)			
		0-96	96-193	193-289	289-385
10%-A	9.94	7.69	10.82	10.46	5.22
10%-B	9.98	8.91	10.28	11.46	8.99
15%-B	15.03	12.91	16.03	16.01	11.93

no supply of fine particles from the upper stream side.

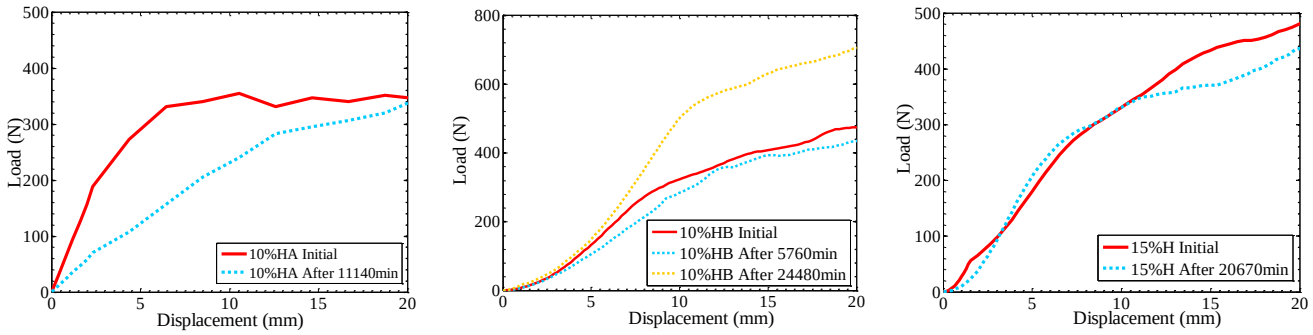

Figure 5 shows the load-displacement curves before and after the seepage tests for Cases 10%-A, 10%-B and Case 15%-B, respectively. In Case 10%-A where cross-sectional area of the drainage boundary becomes large with increase of flow rate, relatively large amount of fine fraction is internally washed out due to seepage flow. Owing to suffusion, failure mode of the slope is general shear failure and the peak appears in the load-settlement curve, while the slope exhibited local shear failure and no clear peak is seen in the curve after 10140 min (Fig. 5(a)). In the latter, 15 % of the fine fraction was eroded by seepage test. In the former, the slip surface appeared around the phreatic surface (Fig. 6(a)), while the large deformation zone was extended well below the phreatic surface due to the suffusion-induced strength reduction of the soil in the latter. As a result of the strength reduction of the soil, decrease in the bearing capacity was observed for the embankment with suffusion. This indirectly suggests decrease of seismic performance.

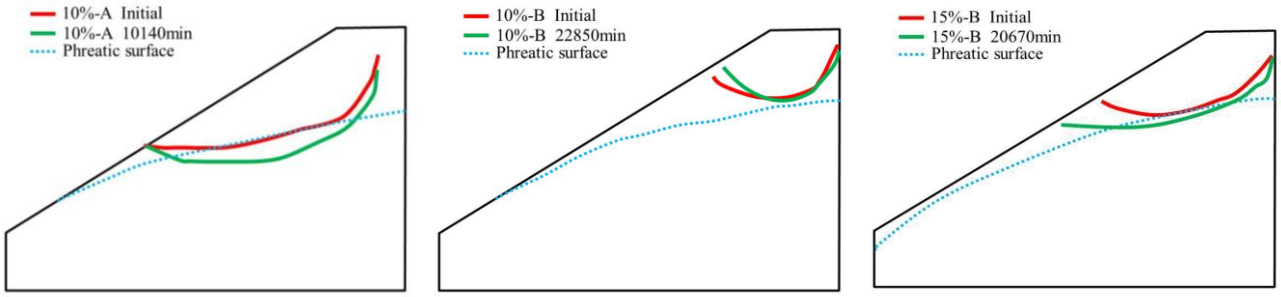
In Cases 10%-B and, 15%-B, amount of fine fraction loss is small due to the difference in the hydraulic boundary condition around the toe as shown in Fig. 4. In these cases, no clear difference in failure mode before and after suffusion is observed. Decrease in the bearing capacity is not observed after suffusion in these cases as shown in Fig. 5 (b) and 5 (c). Location of the slip surface are also observed little to change Fig. 6 (b) and 6 (c). The result of case of rinsed in water 24480 min in Fig. 5 (b) indicate larger bearing capacity than initial state. This fact indicates that the suffusion does not necessarily cause the strength reduction of the soil and the bearing capacity of the embankment. These can either increase or decrease depending on amount of eroded soil of the seepage flow, i.e., progress of the internal erosion.

4. CONCLUSIONS



In this paper, extent of erosion-induced deterioration of seismic performance of levee against external load is discussed through comparisons of bearing capacity at top of the slope before and after the suffusion.

By considering effects of amount of fine fraction and hydraulic boundary condition on soil erodibility, the suffusion-induced destabilization of the embankment is examined and the following conclusions are drawn:

(a) Case10%A-H (b) Case10%B-H (c) Case15%B-H

Figure 5 Result of bearing capacity tests

(a) Case10%A-H (b) Case10%B-H (c) Case15%B-H

Figure 6 Comparison slip surface between before and after the suffusion

Suffusion can change the stability (e.g. seismic performance) of soil structure depending on the amount of eroded fine fraction and distribution of the fine fraction in the structure. When relatively large amount of fine fraction is eroded, the soil structure can be destabilized. Note, these facts indicate that the suffusion does not necessarily cause the strength reduction. Therefore, this result needs to be tested one step further by conducting some parametric experiments.

Abstract: Correct determination of shear wave velocity is pivotal in reliable estimation of small strain shear modulus (G_{max}). Discussed herein is the determination of small strain shear modulus (G_{max}) in triaxial tests using disk type piezoelectric transducers. A laboratory investigation for the measurement of shear wave velocity was carried out to examine the effects of electromagnetic coupling (crosstalk), shape of input waveform, excitation frequency, and isotropic confining pressure on measurement of shear wave travel time. The evaluation showed that the distortion of shear wave signals caused by electromagnetic coupling between source and receiver can effectively be removed by proper grounding of transmitter and receiver disk transducers. Using sinusoidal input waveform and increasing the number of wavelengths between source and transmitter was observed to diminish near field effects and improve the reliability of shear wave travel time determination.

1. INTRODUCTION

The small strain shear modulus of soil, G_{max}, is a fundamental parameter in several static and dynamic analyses involving deformational calculations (Jardine, 1986; Richart et al., 1970). It provides valuable soil information relevant to various engineering applications including liquefaction assessment, foundations subjected to dynamic loading, and soil improvement control, etc. The value of G_{max} is commonly determined by well-established laboratory experimental techniques such as resonant column, and cyclic torsional shear tests. Besides, determination of G_{max} by using elastic wave propagation velocity in soil is gaining popularity due to its procedural simplicity. In such tests, an elastic shear wave generated by a piezoelectric transducer located at one end of a confined soil specimen is received by another piezoelectric transducer located at the other end of soil specimen. The travel time of elastic wave between the source and transmitter, t, and travel distance, L, are used to compute the wave propagation velocity defined as;

$$V = L/t \tag{1}$$

After determining the shear wave velocity by using the above mentioned expression, small strain shear modulus, G_{max}, can be determined by using the relationship from elastic continuum mechanics;

$$G_{max} = \rho V_S^2 \tag{2}$$

where, Vs is the shear wave velocity, and ρ is the total mass density of soil specimen.

The correct determination of shear wave velocity is therefore critical in reliable estimation of G_{max}. Although there is considerable agreement among researchers to use tip-to-tip distance between transmitter and receiver bender element for determination of Vs (Dyvik & Madshus, 1985; Leong et al., 2005; Viggiani & Atkinson, 1995); there is however no consensus on the shape of excitation waveform, and determination of first arrival of shear wave. The intent of this paper is to discuss the determination of correct shear wave arrival time by using a flat-shaped disk transducer. Ambiguities involved in the determination of correct arrival time due to electromagnetic coupling, shape of input waveform, and near-field effect are discussed hereinafter.

2. EXPERIMENTAL SETUP

Disk type piezoelectric ceramic plates manufactured by

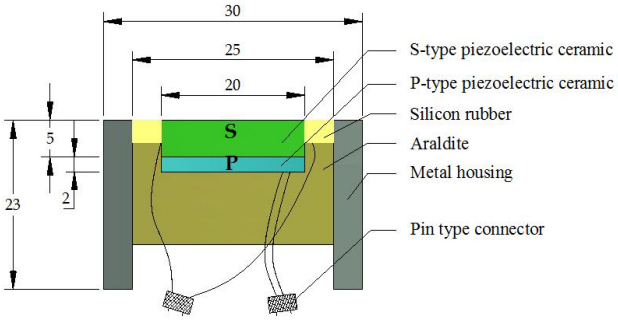

Figure 1: Schematic diagram of disk transducer.

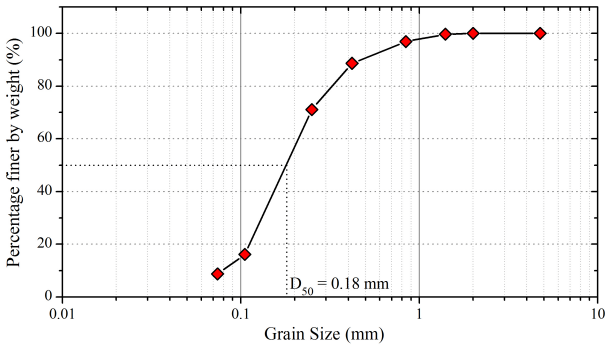

Figure 3: Edosaki sand – particle size analysis.

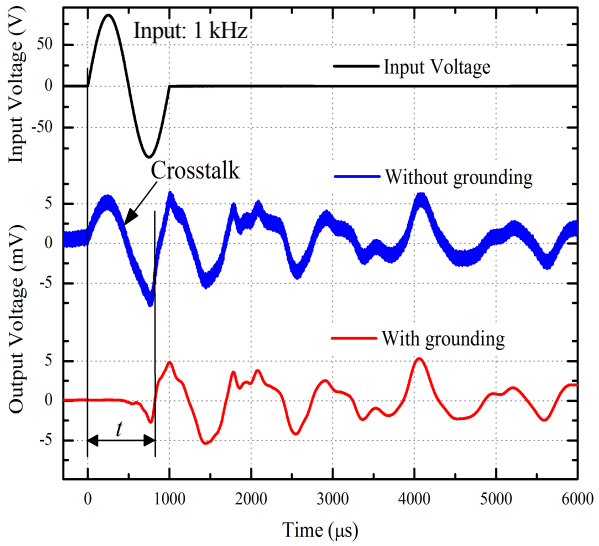

Figure 4: Crosstalk affecting shear wave receiver signals in Edosaki sand at isotropic confining stress of 150 kPa.

Fuji ceramics corp. were employed in this study. The ceramic disks ware 20 mm in diameter with a thickness of 2 mm and 5 mm for P and S type respectively. Both P and S type disks were bonded together with araldite (a two-component epoxy glue) and were encapsulated in a metal housing. Space in the top of metal housing was filled with silicon rubber to make the transducer more ductile and to allow easy movement of transducer. A thin layer of araldite was also coated on the surface of transducer to protect it against direct exposure of testing material and also to make it waterproof. Figure 1 shows schematic representation of disk transducer used for this study. The metal housing supporting the disk transducer was then fixed at the center of triaxial cell base pedestal by means of an O-ring.

The transmission system to excite the transmitter disk transducer consisted of function generator (Tektronix, AFG3022B) and power amplifier (NF Corp. model HSA4012). The function generator produced an excitation voltage of 4.5 *Vpp* (*Vpp = peak-to-peak voltage*) which was amplified to 90 *Vpp* by power amplifier and applied to the transmitter disk transducer. The excitation voltage was limited to 90 *Vpp* in order to avoid deterioration of piezoelectric elements due depolarization. The receiving system consists of a digital oscilloscope (HIOKI model 8860 with Hioki 8957 high resolution input module). The wave transmitted through the soil specimen was received at the top cap by receiver disk transducer which transferred the signal to oscilloscope to be digitally displayed. Input signal from the power amplifier was fed to the oscilloscope through a monitoring channel. The digital oscilloscope thus records both the input and output signals simultaneously. A schematic diagram of measurement system is show in Fig. 2.

3. MATERIALS AND METHODOLOGY

Test material used for this study was Edosaki sand (natural sand with around 10% fines). Particle size distribution of Edosaki sand is shown in Fig. 3; and Table 1 summarizes its basic material properties. A 70% saturated

triaxial specimen (*height = 150 mm, diameter = 75 mm*) was prepared at an initial relative density of 87%. Isotropic confining pressure was increased from an initial value of 15 kPa to 300 kPa at a rate of 0.4 kPa/min. During this stress increment shear wave velocity readings were taken at 50 kPa, 100 kPa, 200 kPa and 300 kPa respectively. Courtesy nondestructive nature of the test, on a single specimen, several elastic wave measurement readings can be taken by varying fundamental parameters like input waveform, excitation frequency, applied voltage, isotropic stress level, etc.

Table 1: Basic properties of Edosaki sand.

Property	*Value*
Specific gravity, Gs	2.639
Minimum void ratio, e_{min}	0.647
Maximum void ratio, e_{max}	1.160
Fines (%)	9
Maximum dry density (g/cm^3)	1.762
Optimum moisture content (%)	14.6

4. CROSSTALK AND GROUNDING

Electromagnetic coupling between source and receiver piezoelectric transducer causes the deterioration of output signal in the form of an early component which is quasi-simultaneous with the input signal. This electromagnetic coupling, which is often referred as "crosstalk", can be very important in conductive soils such as wet clays on seafloor sediments (J. Lee & Santamarina, 2005). Crosstalk significantly affects the determination of correct arrival time when testing with low input frequencies, which are often required while studying nearly saturated sands. In such cases, deterioration of signal due to crosstalk masks the actual arrival of received signal. Figure 4 shows crosstalk deterioration in shear wave signals obtained in 70% saturated Edosaki sand specimen at isotropic confining

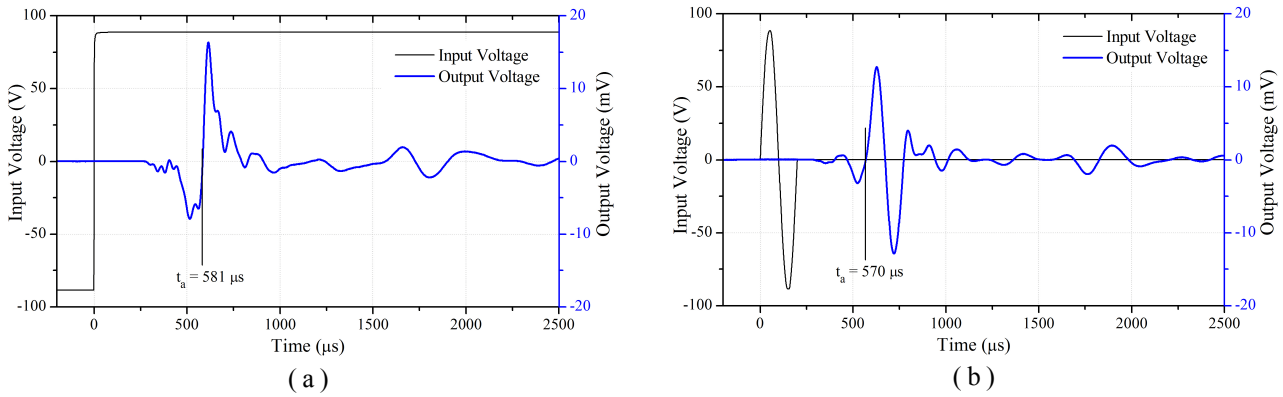

Figure 5: Effect of input waveform on receiver signals; (a) square pulse (b) sine pulse.

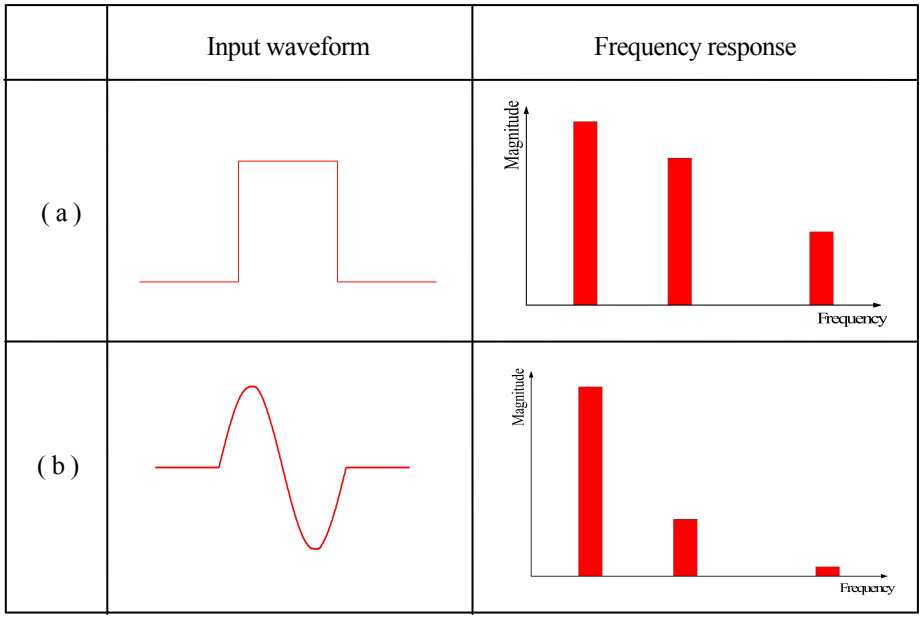

Figure 6: Frequency response of commonly used driving waveforms; (a) square pulse (b) sine pulse (after Blewett et al. (2000))

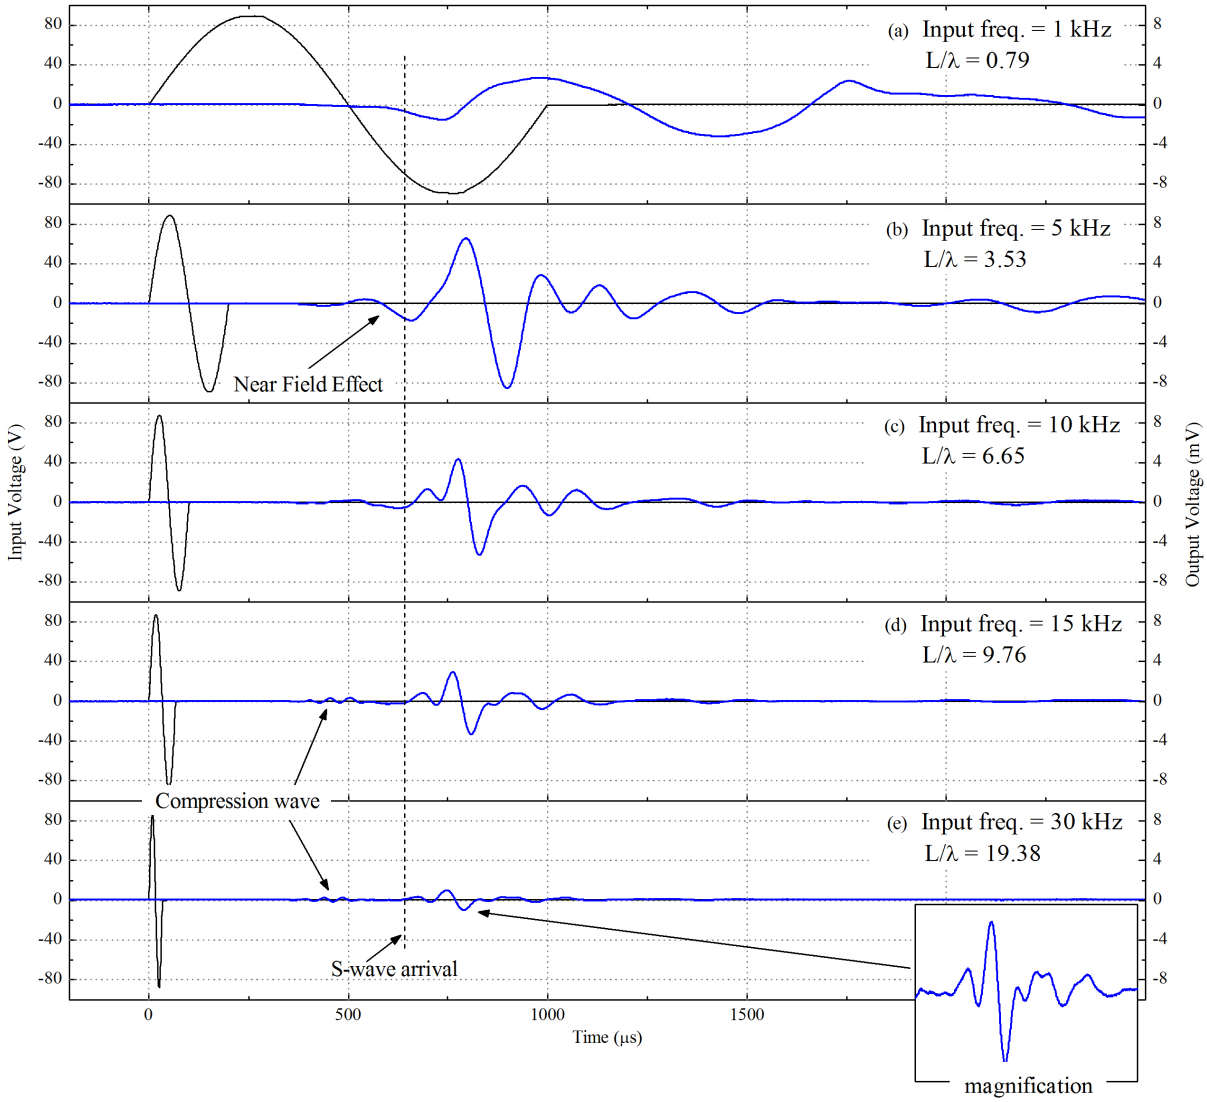

Figure 7: Effect of excitation frequency on shear wave receiver signals in Edosaki sand specimen at isotropic confining stress of 150 kPa; (a) f_{in} = 1 kHz; (b) f_{in} = 5 kHz; (c) f_{in} = 10 kHz; (d) f_{in} = 15 kHz; (e) f_{in} = 30 kHz.

pressure of 150 kPa. As the actual arrival point of received signal is masked by crosstalk, the first arrival would appear at a time later than the actual arrival time; consequently the computed wave velocity is lower than the actual value. Crosstalk in disk transducers is found to be removed by grounding the transmitter disk transducer. Received signal is also influenced by 50 Hz noise from commercial power supply, as can be observed from increased thickness of received signal in Fig. 4. Grounding the receiver disk transducer ensures removal of noise caused by commercial power supply. Both transmitter and receiver disk transducers are therefore, properly grounded in all subsequent tests conducted in this study.

5. INPUT WAVEFORM

Two types of input waveforms are commonly used by researchers; square (Bates, 1989; Dyvik & Madshus, 1985; Lohani et al., 1999; Rodríguez & Moreno-Carrizales, 2001), and sinusoidal (Blewett et al., 2000; C. J. Lee & Huang, 2007; Leong et al., 2005; Pennington et al., 2001; Viggiani & Atkinson, 1995). Response of both square and sinusoidal waves is evaluated in this study. Figure 5 shows receiver signals for square and sinusoidal wave in 70% saturated Edosaki sand specimen. In case of square input, more distortion was observed before the actual arrival causing greater ambiguity in determination of travel time (Fig. 5(a)). Also the received signal does not resemble the input signal; this observation is consistent with the observations made by Jovicic et al. (1996), Blewett et al. (2000), and Leong et al. (2005). High distortion for square wave input can be explained on the basis of large number of frequency components contained within it (Fig. 6(a)). Group velocity dispersion within the specimen leads to separation of different frequency components within the voltage-edge waveform. These propagate at different speeds, arriving at different times, and producing a severely distorted receiver waveform (Blewett et al., 2000). Conversely, sinusoidal wave input causes comparatively less distortion due to the presence of fewer frequency components (Fig. 6(b)).

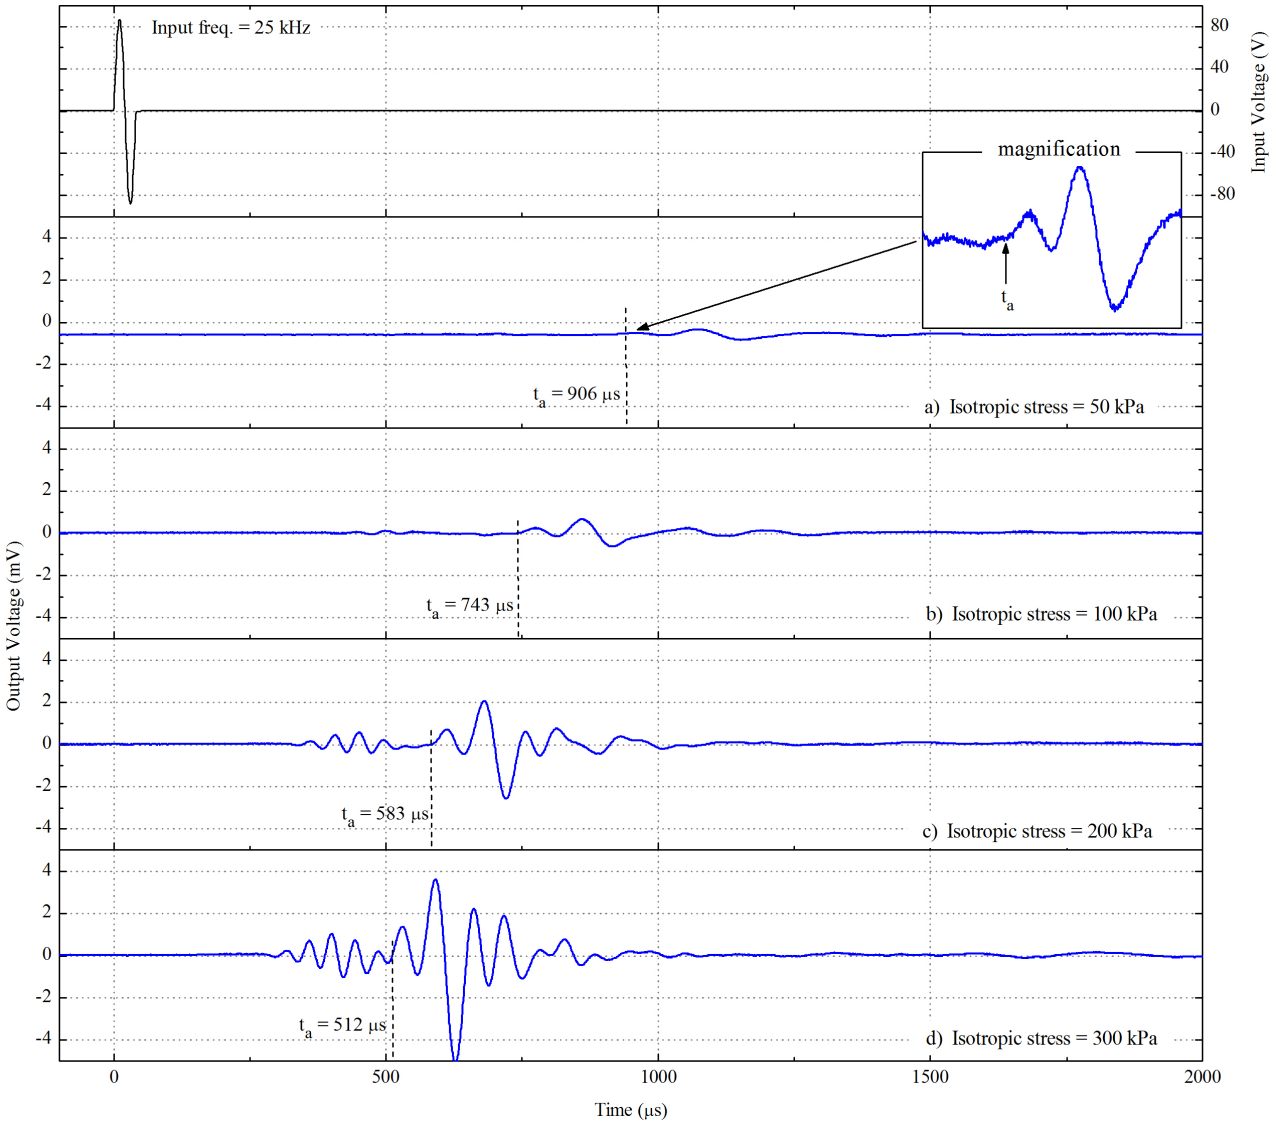

Figure 8: Effect of isotropic confining stress on shear wave receiver signals in Edosaki sand specimen; (a) Isotropic stress = 50 kPa; (b) Isotropic stress = 100 kPa; (c) Isotropic stress = 200 kPa; (d) Isotropic stress = 300 kPa.

Receiver signals for sinusoidal wave input resembled the input signal and less distortion observed at the beginning of signal, made travel time determination comparatively easy (Fig 5(b)). Sinusoidal input waveform is therefore, used for all subsequent tests in this study.

6. NEAR-FIELD EFFECT

During shear excitation, disk transducer, generates two P-wave side lobes parallel to its plane of vibration. These lobes are generated due to the compression effect associated with shear vibration. Difference in travel velocity prevents interference of shear and compression waves. However, test result of shear waves show some traces of distorted P-waves making the identification of first arrival ambiguous. Sanchez-Salinero et al. (1986) showed that the S-wave signal is always accompanied by propagation of another signal of opposite polarity travelling with the velocity of P-waves. This so-called "near-field" effect is quantified in terms of wave path length *(L)* to wavelength *(λ)* ratio. Inverting the polarity of input voltage does not help in removing near-field effect as by doing so the polarity of whole signal, including the near-field component is reversed (Mancuso & Vinale, 1988).

In this study, the effects of excitation frequency on shear wave receiver signals are evaluated by testing 70% saturated Edosaki sand triaxial specimen. Figure 7 shows typical test results of varying input frequency from 1 kHz to 30 kHz at isotropic confining pressure of 150 kPa. Maximum amplitude of shear wave signal is received at f_{in} = 5 kHz. J. Lee and Santamarina (2005) suggested that the excitation frequency of strongest signal gives the approximate resonant frequency of the system. The magnitude of near-field effect is found to decay considerably with increasing L/λ, i.e. number of wavelengths between transmitter and receiver (Fig. 7(a) to (e)). This observation is consistent with several other researchers including Sanchez-Salinero et al. (1986), Brignoli et al. (1996),

Arulnathan et al. (1998), and Leong et al. (2005), etc. Also, for sufficiently high excitation frequencies, the compression wave component can visibly be separated from shear wave as can be observed in Fig. 7 (d) and (e). However, increased wave attenuation (Fig. 7 (a) to (e)) and overshooting of signals (J. Lee & Santamarina, 2005; Wang et al., 2007) at high frequencies limits the maximum excitation frequency and hence the L/λ ratio.

Figure 8 shows the effect of stress level on received signals. A high excitation frequency of 25 kHz was used in order to minimize near-field effects. The number of particle contact points within the specimen increase with higher isotropic stress. It not only increases the shear wave velocity but also the amplitude of received signal. However, at higher isotropic stress the amplitude of compression wave component is also found to increase (Fig. 8 (c) & (d)). This strong compression wave component, having very low attenuation, thus interferes with shear wave signal, making it further difficult to distinguish the first arrival of shear wave (Fig. 8 (d)). Thus, a higher excitation frequency may not be a good choice at high confining pressures.

7. CONCLUSIONS

Accurate determination of shear wave velocity is essential for reliable evaluation of G_{max}. In this study, disk type piezoelectric transducers capable of measuring shear wave velocity in laboratory triaxial apparatus were fabricated. Ambiguities involved in the correct determination of shear wave travel time are discussed. The main conclusions drawn from this study are summarized in the following points;

- Electromagnetic coupling between source and receiver piezo-transducer, commonly known as crosstalk, was found to distort the shear wave receiver signals. Crosstalk could effectively be removed by grounding both transmitter and receiver piezoelectric transducers.
- Large number of frequency components contained within square excitation leads to exceedingly distorted receiver signals. Interpretation of first arrival and determination of shear wave travel time is considerably easy when sinusoidal excitation waveform is used.
- The S-wave signals are affected by near-field effects. Near-field effect diminishes with an increase in L/λ ratio, i.e. increasing excitation frequency.

Abstract: A large number of civil engineering structures were damaged due to liquefaction during huge recent earthquakes in Christchurch and need to be reconstructed. Prior to reconstruction, properties of soils in different areas should be identified and, based on behavior of underlying soils, appropriate foundation for structures should be designed. Cone Penetration Test (CPT) is one of the most common in-situ tests for soil characterization. However, this test is relatively expensive and needs skilled operator. Therefore, Swedish Weight Sounding (SWS) test has become popular for ground investigation as it does not occupy large space and it is simpler and faster compared to other methods. Nevertheless, using SWS has some disadvantages such as low accuracy of soil classification and rod friction is excluded in the test results. The Screw Driver Sounding (SDS) test developed in Japan is a new operating system for SWS consisting of a machine that drills a rod into the ground at different steps of loading while being rotated. This machine can continuously measure the required torque, load, speed of penetration and rod friction during the test, so can give a better overview of the soil profile along the depth of penetration. In this paper, based on the test conducted in Christchurch adjacent to a borehole and a CPT site, a comparison of the accuracy of soil classification based on CPT and on SDS method is discussed. The results confirm the advantages of SDS over the CPT method in terms of accuracy for soil classification.

1. INTRODUCTION

It is well understood that huge earthquakes can cause severe damage to civil engineering structures. Following the devastating earthquakes in Christchurch, a significant part of the structures was either destroyed or badly damaged and need to be reconstructed. A significant part of such damage was related to ground failures associated with liquefaction. Liquefaction is a phenomenon that occurs in saturated, sandy soils during earthquakes, which results in a loss of soil strength and bearing capacity. The city of Christchurch is situated on the east coast of the South Island of New Zealand, which borders the Pacific and Indian-Australian tectonic plates. Adequate knowledge of ground conditions is very important for analyses, design and construction of geotechnical systems. For preventing similar damages in the future, physical and mechanical properties of soils in different areas should be identified prior to reconstruction and based on the behavior of underlying soils, appropriate foundation for structures should be designed.

Recently, the use of in-situ soil testing has increased in geotechnical engineering practice. This is because of the rapid development of in-situ instruments, improved understanding of soil behavior and the subsequent realization of the limitations and inadequacies of some conventional laboratory testing (Eslami, 2006). Several in-situ tests obtain direct measurements of soil properties and geotechnical parameters (AASHTO, 1988). The most common tests include: standard penetration test (SPT), cone penetration test (CPT), Piezo-cone (CPTu), Swedish weight sounding (SWS), flat dilatometer (DMT), pressure meter test (PMT), and vane shear test (VST). Each test applies specific loading patterns to measure the corresponding soil response in an attempt to evaluate material characteristics, such as strength and/or stiffness (AASHTO, 1988).

In this study after a review of CPT, SPT and SWS, a new in-situ test called Screw Driver Sounding (SDS) method is introduced and the results of soil classification by this test in Christchurch is compared to CPT-based soil classification.

2. POPULAR IN-SITU TESTS FOR SOIL CLASSIFICATION

The Standard Penetration Test (SPT) is still the most popular in-situ test (Eslami, 2006). However, plenty of

problems and limitations exist for this test, with respect to performance, interpretation and repeatability. These are due to the uncertainty of the energy delivered to the rod, test procedures and operator-equipment effects. On the other hand, the Cone Penetration Test (CPT) is simple, fast, and it gives continuous records with respect to depth. The results are interpretable on both empirical and analytical basis and a variety of sensors can be incorporated by using a cone penetrometer (Eslami, 2006). However this test needs skilled operator to perform (AASHTO, 1988).

Swedish weight sounding (SWS) is another in-situ test that is popular in Japan and Nordic countries. It is estimated that about 20,000 SWS tests are carried out annually in Sweden alone (Broms and Flodin, 1988). The test has also been used in countries like Singapore, Algeria and some east European countries (Bergdahl et al., 1988). Also Habibi et al. (2006) reported the use of SWS in estimating the bearing capacity of foundation for some buildings in southern areas of Tehran, Iran. The key advantages of this test are that it is highly portable, low cost and, similar to CPT, provides a continuous profile of the soil. SWS consists of some pieces of weights (a 5kg clamp, two 10kg and three 25kg weights), a screw-shaped point, 22mm extension rods and a handle (or a motor) for rotating the rods (Habibi, 2006). Figure 1 shows a schematic view of the apparatus and its screw-shaped point.

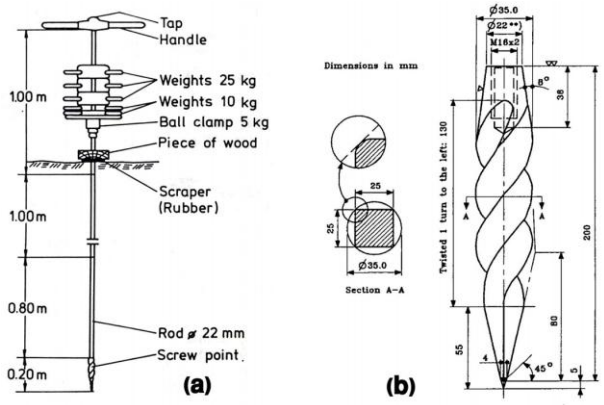

Figure 1 Swedish weight sounding equipment: (a) schematic view of apparatus (Bergdahl et al., 1977); (b) screw-shaped point (ENV19 97:3, 2000).

The penetration resistance of soil can be estimated ether by measuring the required load or the number of half-turns that the screw point is rotated to penetrate to a planned depth. When sounding is performed in soft soil, the penetration resistance is typically measured only through the weight required for penetration of the rods. This means that the weight is increased up to the weight which could penetrate the soil. The levels of static loading used in the test are 0, 5, 25, 50, 75 and 100kg. If the penetration does not occur with 100kg loading, the rod is rotated by using a handle. Although the SWS test is highly portable and simpler than other sounding tests, this test has some disadvantages such as low accuracy in classifying soils. As SWS is usually conducted without soil sampling, soil classification is estimated from the test results, local circumstances at the site and experience of operator. Furthermore, SWS cannot penetrate into very dense soils and the usual depth of penetration is limited to 10-15 m. The other problem associated with the SWS test is that the result is fairly influenced by rod friction, which may affect the measured results. Especially, in case where the soil contains gravel, the required load to penetrate, number of half-turns and consequently soil resistance from the SWS tends to be over-estimated as the rod friction becomes large.

3 SCREW DRIVER SOUNDING TEST

3.1 Background and test procedure

A new operation system for the SWS, the Screw Driver Sounding test, called as SDS, has been recently developed in Japan to minimize the disadvantages of the SWS as well as to incorporate a procedure to measure the rod friction. The machine originally used for the SWS test has been improved to be suitable for the SDS test. In the usual SWS test, there are two loading stages. In the first stage, a vertical load (W_{sw}) is applied to the rod in 4 incremental steps up to a load of 1kN. If the settlement of the rod does not reach 25cm depth, the rod is penetrated by rotating the rod into the soil in the second stage. In the SDS test, on the other hand, a static loading system is used and the number of load steps is increased to 7, while the rod is always rotated at a constant rate during the test. The step loads are 0.25, 0.38, 0.5, 0.63, 0.75, 0.88, 1kN in this order and the load is increased at every complete rotation of the rod. Measured items in the test are maximum torque (Max.*T*), average torque (Av.*T*), minimum torque of rod (Min.*T*), penetration length (*L*), penetration velocity (*V*) and number of rotations of rod (*N*). The data are measured at every complete rotation of the rod. In the SDS as well as the SWS, a set of loading is conducted at every 25cm for penetration and after each 25cm penetration, the rod is lifted up by a few centimeters and then rotated to measure the rod friction. Figure 2 shows the SDS machine during testing in Christchurch.

Figure 2 SDS machine during operation

3.2 Plasticity model for the SDS test

To clarify the interaction between the torque and the vertical force, a plasticity theory analogy model for the Swedish weight sounding by using the results of a SWS miniature test was proposed by Suemasa et al (2005). The summary of the model is described below for better understanding of the SDS result. Further details are provided by Suemasa et al (2005).

An incremental work done by torque and vertical force is given by

$$\delta E = \pi T \delta n_{ht} + W \delta s_t \tag{1}$$

where T is the required torque to rotate the screw point, W is the required vertical load, δn_{ht} is the number of incremental half turns and δs_t is the incremental settlement caused by the load. The penetration load, W_p, is defined as a the load by which the screw point is penetrated into ground without rotation. The incremental work is normalized by the penetration load as shown in equation 2.

$$\frac{\delta E}{W_p D} = \frac{\pi T}{W_p D}\delta n_{ht} + \frac{W}{W_p}\frac{\delta s_t}{D} = T_n \delta n_{ht} + W_n \frac{\delta s_t}{D} \tag{2}$$

In the above equation, D is diameter of the screw point, and T_n and W_n are the normalized T and W, respectively. From the observations of the test results, an elliptical yield locus centered on the origin is assumed in this model, i.e.

$$c_y T_n^2 + W_n^2 = 1 \tag{3}$$

where c_y is the coefficient of yield locus. A function of plastic displacement potential is also assumed to be elliptical, i.e.

$$c_p T_n^2 + W_n^2 = 1 \tag{4}$$

where c_p is a coefficient of plastic potential. If the associative flow rule is adopted, c_p must be equal to c_y. Differentiating this plastic potential function gives the displacement incremental vector as

$$N_{sw} D = \frac{\delta n_{ht}}{\delta s_t / D} = c_p \frac{\pi T}{W D} \tag{5}$$

where $N_{sw}D$ is the number of normalized half turns. From these results, it is found that each soil category has different values of c_p. Thus, by measuring the applied torque in SWS, soils can be classified by using the theory developed for SWS (Tanaka, 2012).

3.3 Estimation of rod friction

Due to the effects of rod friction during penetration, the measured load and torque for penetration are more than the required ones at screw point. The rod friction can be divided into a vertical component (W_f) and a horizontal component (T_f) as the rod is rotated and penetrated into the ground (Tanaka, 2012).

The applied load (W_a) and applied torque (T_a) by the SDS machine are defined as follows:

$$W_a = W_f + W \tag{6}$$

$$T_a = T_f + T \tag{7}$$

where W and T are load and torque at the screw point, respectively. The maximum shear stress acting on the rod surface is computed as,

$$\tau_{\max} = \frac{T_m}{2\pi r^2 \cdot L} \tag{8}$$

where T_m is the torque resisting the rod friction measured at the end of a loading set, r is a radius of the rod and L is a total penetrated length. Assuming that the direction of rotation velocity (V_θ) and of settlement velocity (V_z) are equal to those for horizontal shear stress (τ_θ) and vertical shear stress (τ_z) on rod surface, respectively, the formulas can be given as follows:

$$\tau_\theta = \tau_{\max}.\sin\theta \tag{9}$$

$$\tau_z = \tau_{\max}.\cos\theta \tag{10}$$

By substituting eq. (8) into eqs. (9) and (10), the vertical and the horizontal components of the rod friction are obtained as

$$\tau_f = 2\pi r^2 L \frac{v_\theta}{\sqrt{v_v^2 + v_\theta^2}} . \frac{T_m}{2\pi^2 L} \tag{11}$$

$$W_f = 2\pi r L \frac{v_v}{\sqrt{v_v^2 + v_\theta^2}} . \frac{T_m}{2\pi^2 L} \tag{12}$$

4. SOIL CLASSIFICATION USING SDS DATA IN JAPAN

Soils can be classified in different ways using SDS data. For instance, changes in measured torque which are caused by increasing the applied load are not equal for different types of soils. Per the classification proposed by Tanaka et al. (2012), the slope of the corrected torque against corrected load graph (dT/dW) tends to have a positive value for sand or loam, and a negative value or zero for clay and silt. Depending on the density and soil friction, the slope would change. Denser materials with more friction show higher value of dT/dW. For peat or organic soil, as well as other frictional soil, the corrected load is very small and the corrected torque increases as the corrected load increases. As these types of soils include plant roots and leaves that can be entangled at the screw point, the corrected torque has a tendency to increase. For tuff clay, the corrected torque tends to be constant or to decrease while the corrected load is increased. Tuff clay is compressible and shows brittle response in shear due to the many large gaps inside it. In the tuff clay, even with high SPT N value, it is thought that the corrected torque would be small due to the changes in soil fabric by the rotation of the screw point.

The slope of an approximate line obtained from the relationship between the number of normalized half turns ($N_{sw}D$) and normalized torque ($\pi T/WD$) is the coefficient of plastic potential (c_p). The relationship between c_p and dT/dW is shown in Figure 3 for different types of soils. The values of c_p for loam, loamy clay and tuff clay categorized as diluvial layer is more than 1 (Section A). On the other hand, for silt, this parameter changes between 0.3 and 1 (Section B). c_p for peat and organic soil is less than 0.3 (Section C). For diluvial layer, c_p is more than 1 and dT/dW is positive; c_p is less than 1 for alluvial layer and less than 0.3 for peat layer (Tanaka, 2012).

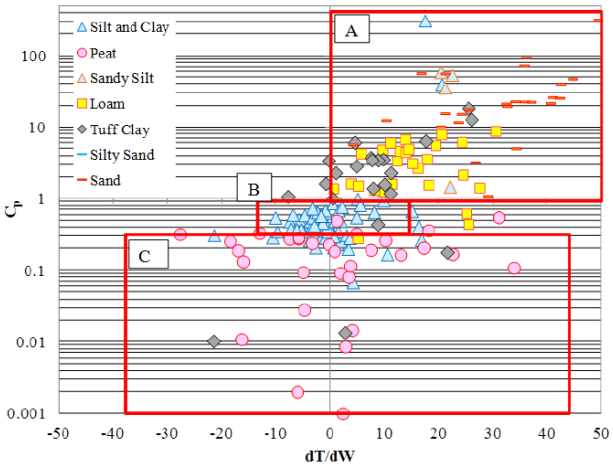

Figure 3. Relationship between c_p and dT/dW defining soil types (Tanaka, 2012).

5. SOIL CLASSIFICATION USING SDS DATA IN CHRISTCHURCH

A SDS test was conducted in Christchurch near a CPT site and borehole in order to make a comparison between the results of soil classification from these two tests. The selected site was located in Avonside Drive. This area liquefied during 2010 earthquake in Christchurch. Figure 4 shows the location of the selected site. The SDS test was conducted within a two meter distance from the CPT test and borehole. The borehole and CPT data was obtained from the Canterbury Geotechnical Database.

Figure 5 illustrates the CPT profile of the soil and the changes in SDS parameters along the depth. Based on Japanese data which has been presented in Section 3, soils can be classified by using dT/dW, average required torque and c_p. As shown in Figure 5, dT/dW is positive along the soil profile which means the soil is coarse-grained. From a depth of 1.0-2.75m, the average values of corrected torque and c_p are around 20 and 3, respectively; because of these low values, the soil in this region can be classified as sandy silt. Below 2.75m, the value of dT/dW gradually increases and this trend continues until 4m. Similarly, the average required torque for penetration increased from 35Nm to 45Nm, indicating an increase in soil friction or density. In

Figure 4 Location of test site in Christchurch.

this region, the value of c_p also gradual increased from 3 to 13. It can be predicted that between 2.75m and 4m, the percentage of fines in sand dropped or the soil becomes more frictional. From 4m to 5m, dT/dW increased gradually. The required torque for penetration in this part of the deposit was approximately 50Nm and average value for c_p was around 8. An increase in dT/dW in this section of the soil profile indicates a soil type with medium sand profile. There was a drop in dT/dW between 5 and 6 m referring to an increase in percentage of fines which reduced the friction of the soil. Below depth of 6m, an upward trend for dT/dW and c_p again continued, indicating a reduction in percentage of fines. Soil in this section of the profile can be classified as fine to medium sand.

The obtained soil classification from SDS is next compared to that obtained from CPT. For this purpose, the CPT soil behavior type classification used in this study is based on Robertson (1990) soil behavior type chart. Note that the CPT-based charts are for soil behaviour type (SBT), since the cone responds to the in-situ mechanical behavior of the soil and not directly to soil classification criteria based on grain-size distribution and soil plasticity. Robertson (1990) proposed using normalized (and dimensionless) cone parameters, Q_{t1}, F_r, and B_q, where

$$Q_{t1} = (q_t - \sigma_{vo})/\sigma'_{vo} \quad (13)$$

$$F_r = [f_s/(q_t - \sigma_{vo})]100\% \quad (14)$$

$$B_q = (u_2 - u_0)/(q_t - \sigma_{v0}) = \Delta u/(q_t - \sigma_{v0}) \quad (15)$$

where σ_{v0} is the in situ total vertical stress; σ'_{v0} is the in situ effective vertical stress; u_0 is the in situ equilibrium water pressure; u_2 is the pore pressure measured at cone shoulder; Δu is the excess penetration pore pressure and q_t is cone resistance corrected for pore water pressure on cone shoulder. In the original paper by Robertson (1990), the normalized cone resistance was defined using the term Q_t. The term Q_{t1} is used here to show that the cone resistance is the corrected cone resistance, and the stress exponent for stress normalization is 1.0.

Jefferies and Davies (1993) identified that a soil behavior type index, I_c, could represent the SBT in zones in the Q_{t1}–F_r

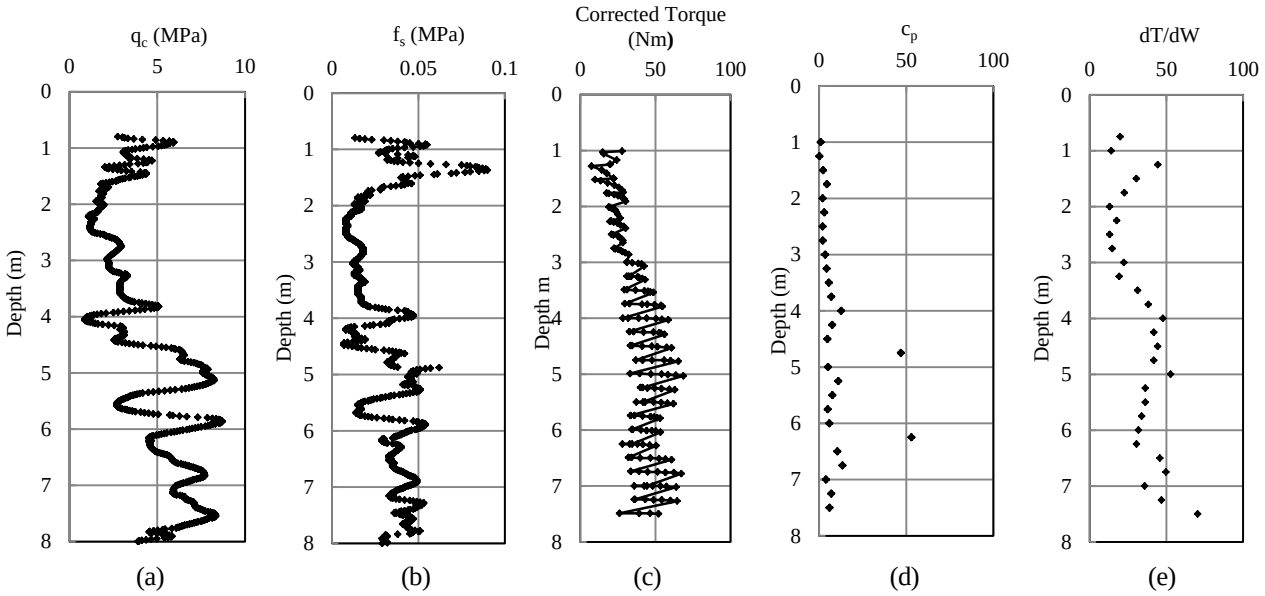

Figure 5 Variation with depth of: (a) cone resistance of CPT; (b) sleeve friction of CPT; (c) changes in corrected torque in SDS; (d) changes in c_p in SDS; (e) changes in *dT/dW* in SDS.

chart, where I_c is essentially the radius of concentric circles that define the boundaries of soil type. Robertson and Wride (1998) modified the definition of I_c to apply to the Robertson (1990) Q_{t1}–F_r chart as defined by,

$$I_c = [(3.47 - \log Q_{t1})^2 + (\log F_r + 1.22)^2]^{0.5} \qquad (16)$$

Contours of I_c on the Q_{t1}–F_r chart are shown in Fig. 6. The contours can be used to approximate the SBT boundaries. The chart identifies numbered areas that separate the soil types in twelve zones, as shown in table 1.

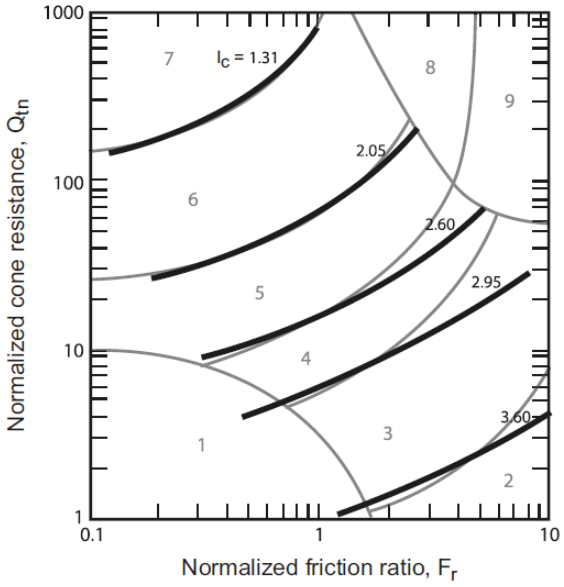

Figure 6 Contours of soil behavior type index, I_c (thick lines), on normalized SBTn Q_{t1}–F_r chart (SBT zones based on Robertson, 1990).

Table 1 Profiling chart for use in soil classification (Robertson 1990)

Zone	**Soil Behaviour Type (SBT)**
1	Sensitive fine-grained
2	Clay - organic soil
3	Clays: clay to silty clay
4	Silt mixtures: clayey silt & silty clay
5	Sand mixtures: silty sand to sandy silt
6	Sands: clean sands to silty sands
7	Dense sand to gravelly sand
8	Stiff sand to clayey sand
9	Stiff fine-grained

Table 2 shows the comparison of the results of soil classification using SDS, CPT and borehole. As seen from the table, the results obtained from SDS are very close to those indicated in the borehole description. Thus, even without sampling, SDS can classify soils with acceptable degree of accuracy.

It should be mentioned though that the SDS-based classification was formulated from a database of Japanese soils. Thus, more tests are currently being planned in New Zealand to increase the range of soil types in the database and to further refine/improve the proposed classification scheme. Moreover, it is planned to make use of the SDS parameters to identify regions of high liquefaction potential using the Christchurch experience as benchmark. Indeed, the

Table 2 Results of soil classification using SDS, CPT and borehole data

CPT Soil description	SDS Soil description	Borehole		Depth (cm)
		Strength/ Density	Soil description	
-	-	Loose	FILL: Fine sand, dry, poorly graded	0-80
Silty sand- Sandy silt	Sandy Silt	Soft	Sandy silt, Moist, low plasticity, sand is fine	80-275
Sand and Silty sand	Silty Sand	Loose	Fine sand with trace silt, wet, poorly graded	275-300
Silty sand-Sandy silt	Silty Sand	Soft	Sandy silt, moist, low plasticity, sand is fine	300-350
Silty sand-Sandy silt	Sand	Loose	Fine sand with trace silt, Wet, poorly graded	350-375
Sand and Silty sand	Sand			375-470
Sand and Silty sand	Sand	Loose	Fine to medium sand with trace silt, wet, well graded	470-525
Silty sand	Silty sand			525-600
Silty sand- Sand	Sand			600-750

SDS method has a very good potential in geotechnical in-situ investigation.

6. CONCLUSIONS

In this study, a comparison between the most common field tests was made and a new in-situ test, called Screw Driver Sounding (SDS) was introduced. Based on a large number of tests conducted in Japan, it was shown that soils can be classified using SDS parameters, such as c_p, average corrected torque and *dT/dW*. For a site located in Christchurch, SDS was performed and the results of soil classification using SDS parameters were compared with those obtained from a borehole and a CPT site located less than 2m. It was shown that both methods, i.e. SDS and CPT, give almost similar results, indicating that SDS provides accurate soil classification.

More tests are currently planned in New Zealand to refine the current method of soil classification. As a future research, it is planned to evaluate the liquefaction potential of sites based on SDS parameters.

Acknowledgments

The authors would like to acknowledge Nitto Seiko Company for providing the SDS machine and the Japan Home Shield (JHS) Company for providing assistance for this research. We also would like to acknowledge the Canterbury Geotechnical Database for providing the borehole data and CPT records in Christchurch, as well as the Christchurch City Council for providing access to the test site.

Abstract: The phenomenon that amount of internally eroded soil structures were prone to fail during Noto Peninsula Earthquake of Japan in 2007 draws the attention on the influence of seepage induced internal erosion on the cyclic resistance characteristics of the soil structures. Seepage induced internal erosion is defined as the gradual migration of fine particles in soils through the voids between the coarse particles. Gap-graded soil is vulnerable to internal erosion due to its deficiency in certain particle size. Internal erosion would cause the significant changes in void ratio, hydraulic conductivity and shear strength of soils. This paper concentrates on the influence of internal erosion on the cyclic resistance of gap-graded cohesionless soils by experimental investigations. A series of one-dimensional seepage tests are conducted inside of a newly developed triaxial cell, capable of applying constant rate seepage flow into soil specimens. Undrained cyclic shear tests are performed after seepage tests to evaluate the cyclic resistance change. It is noted that the internal erosion indicated by fine particle loss causes significant increase of hydraulic conductivity. The volumetric deformation of soil specimens is associated with the process of internal erosion. The cyclic resistance ratio is influenced by the internal erosion.

1. INTRODUCTION

Seepage-induced transfer of soil grains is observed widely both in natural soil deposits and in earth structures. Gap-graded soils, like sandy gravels or silty sands, are especially vulnerable to internal erosion due to its deficiency in certain particle size. The phenomenon that those zones of valleys, which may have been suffered from years of internal erosion, failed during Noto Peninsula Earthquake of Japan in 2007 raises the concern about the possible influence of internal erosion on the soil microstructure change and, consequently, the strength change. In literature, “internal erosion” refers to the phenomenon that small soil grains are eroded through the voids between the coarse grains by seepage flow. It develops chronically, usually accompanying with constant quantities of seepage flow over years.

The study on internal erosion originates from the phenomenon that base soil or filter, composed by those “poor graded” soils (i.e., gap-graded or coarse widely graded soils), could fail because of internal erosion of fine grains (Skempton and Brogan, 1994; Tomlinson and Vaid, 2000; Moffat and Fannin, 2006; among others). In those experimental investigations, various factors, such as the soil geometric characteristics, flow velocity, flow direction, hydraulic gradient and possible chemical reactions are taken into consideration. This phenomenon could be undertood from two perspectives: hydraulic mechanism and soil mechanics.

From hydraulic point of view, it is of significance to understand that (I) the factors governing the onset of internal erosion, (II) the amount of soil grains passing through the soil matrix and, correspondingly, (III) the variation of hydraulic parameters during internal erosion. The onset of internal erosion is governed by two constrains, geometrical constraint and hydro-mechanical constraint. Instinctively, geometrical constraint refers to the size of fines should be smaller than the size of voids in soil. Following the basic idea, many evaluation methods have been proposed to assess the internal stability of soil based on the grain size distribution (US Army Corps of Engineers, 1953; Istomina, 1957; Lubochkov, 1962, 1965; Kezdi, 1979; Kenney and Lau, 1985, 1986; Burenkova, 1993; Skempton and Brogan, 1994, among others). Kovacs (1981) defined the hydro-mechanical constraint as “the critical velocity or hydraulic gradient, above which the fine grains start to move”, which is found closely related with the effective stress level in soil. Skempton and Brogan (1994) firstly analyzed the influence of effective stress level on soil internal stability. A reduction factor was proposed to note that the soil internal stability will intrigue at a hydraulic gradient significantly lower than the anticipated from theory. Based on the results of series of permeameter tests, Moffat and Fannin (2011) demonstrated the effective stress level dependent hydraulic gradient characteristics and proposed the concept of a hydromechanical path in stress ~ gradient space. Li and Fannin (2012) proposed a linear

hydromechanical envelope in stress ~ gradient space. The envelope is governed by the proportion of effective stress in fines.

From soil mechanics point of view, the sand behavior is largely dependent on the friction along grain contacts. With the progress of soil erosion, the sand microstructure would suddenly change to another mode at certain hydraulic gradient, which is called "hydraulic gradient at failure" (Chang and Zhang, 2011). Correspondingly, the mechanical behavior of soil would greatly vary with this process. The study of the erosion dependent soil behavior is still on progress in literature. Wood *et al.* (2010) attempt to model the mechanical consequences of internal erosion by two-dimensional discrete element analysis. The simulation indicates that the erosion could intrigue the soil state change, from "dense" (below the critical state line) to "loose" (above the critical state line), with corresponding available strength lower than the critical state strength. Scholtès *et al.* (2010) consider the internal erosion as the progressive removal of the finest grains and conclude that the soil strength is strongly influenced by the erosion: the soil behavior changed from a dilatant to a contractant when extracting the fine grains. Those zones in the soil structure where internal erosion occurs would be more prone to fail. By the seepage tests in newly developed triaxial apparatus, Chang and Zhang (2011) prove that the mechanical behavior of tested specimens becomes contractive, which originally is dilative, after the loss of a significant amount of fine grains due to internal erosion.

The primary purpose of this paper is to experimentally show the influence of internal erosion on the cyclic behavior of gap-graded cohesionless soil. A multi-stage test procedure is applied to assess the condition necessary to trigger the internal erosion. The hydraulic conductivity change and volumetric strain of the tested soil specimen during seepage test are demonstrated. The cyclic resistance ratio change of the soil subjected to internal erosion is evaluated by a series of undrained cyclic tests.

2. TEST APPARATUS

The newly developed triaxial internal erosion apparatus could directly investigate not only the hydraulic characteristics of soils during onset and progress of internal erosion but also the mechanical behaviors subjected to internal erosion. It is applicable for testing non-cohesive soils. It mainly consists of a constant-flow-rate control unit, an automated triaxial system and eroded soil collection unit. In this apparatus, the hydraulic control is by constant-rate-of-flow. The unit is composed of a flow pump with the maximum flow rate of 1360mL/min for controlling flow rate through the specimen and a Differential Pressure Transducer (DPT) for measuring the pressure drop from the top to the bottom of tested specimens. The whole system allows independently synchronous control of the hydraulic condition and stress state of the tested specimens. The schematic illustration of the overall system is shown in Fig.1.

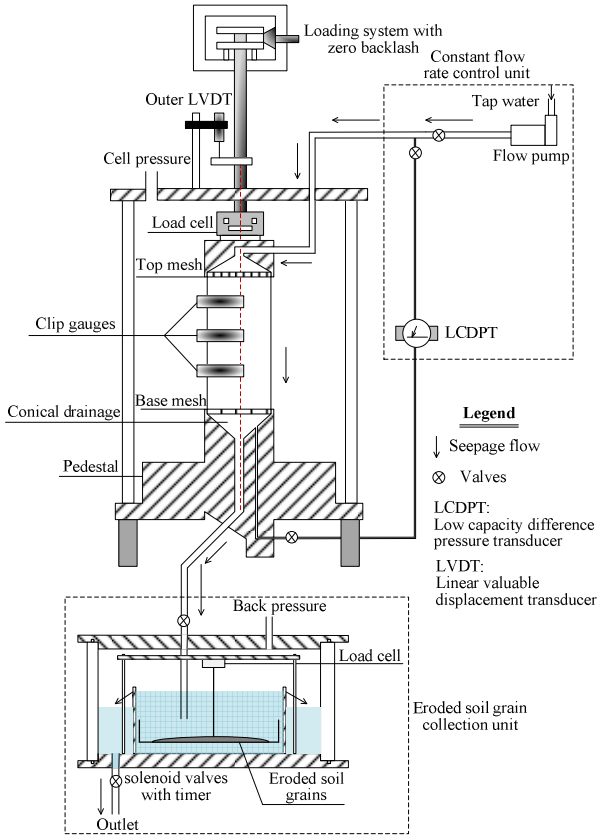

Figure 1 Schematic diagram of triaxial seepage test

3. TEST SPECIMENS

In this study, the tested specimens are the binary mixtures of two types of Silica sands (Silica No.3 and No.8) with different dominant grain sizes. With larger grain size, the Silica No.3 works as the soil skeleton in the mixtures while the fine Silica No.8 is the erodible fines. The mass fraction of Silica No.3 and No.8 in the mixture is determined considering the geometrical restriction: the volume of fines should be less than that of the voids between coarse grains. In this paper, the fine content of 35% is adopted. The grain size distribution and the physical properties of the mixture are shown in Fig.2.

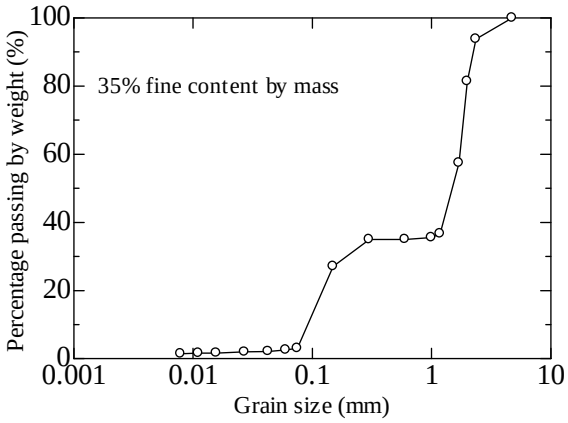

Figure 2 Grain size distribution curve of specimens

The tested specimen is 70mm in diameter and 150mm in height. The technics of moist tamping (Ladd, 1978) is implemented to prevent the segregation of the two different sized grains. The sample preparation procedures are as follows: determine the oven-dried weights of clean Silica No.3 and No.8 for a test according to the fine content and relative density. Thoroughly mix the soils with de-aerated water to make sure the distribution of fine grains in a specimen is uniform. Equally separate the wet mixture into 10 pieces and keep them in a zipped bag to equalize moisture at least 16 hours before use. The specimen is prepared layer by layer. Weigh the amount of material required for each layer, and place it into the mold by scoop. Each layer is compacted to the required density. The initial weight could not be directly checked after preparation. Therefore, the after-test oven-dry weight of the specimen together with the eroded soil weight should be checked.

4. SEEPAGE TEST & CYCLIC TEST

Those prepared soil specimens are firstly fully saturated (B>0.9) and then isotropically consolidated until mean effective stress reaches 50kPa. Depending on the test cases, Seepage tests are conducted while maintaining p'=50kPa (mean effective stress) and q=0kPa (deviatoric stress). After seepage test, the soil specimens are subjected to a cyclic shear stress in axial direction under the same effective stress as that of seepage test. The cyclic strength in terms of the cyclic resistance ratio (CRR) is defined as $\sigma_d/2\sigma_c'$ (σ_d: cyclic shear stress; σ_c': effective stress) that produces an axial strain of 5% in double amplitude in 20 cycles (N_c) of uniform load application. Three cyclic tests are performed with various values. The axial strain rate is set at 0.5%/min. Companion soil specimens at the same stress state without erosion are tested for the comparison purpose. A summary of the test cases is shown in Table 1.

5. TEST RESULTS & DISCUSSIONS

5.1 Seepage test results

In seepage test, the flow rate is increased gradually from 0 to 310mL/min. The measured hydraulic gradient is shown in Fig.3. Due to internal erosion, soil specimen would experience transferring of fines through the voids of coarse grains resulting in an increase of the void volume. Correspondingly, the hydraulic gradient would decrease. As is shown in Fig.3, at approximate 1500s, internal erosion initiates, indicated by the sudden decrease of hydraulic gradient. If Darcy's law is assumed to be applicable, it could be inferred that hydraulic conductivity of soil specimen increases due to internal erosion. Moreover, fines would be

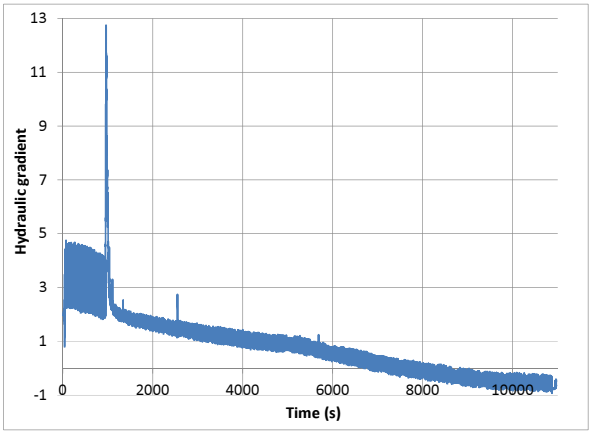

Figure3 Measured hydraulic gradient

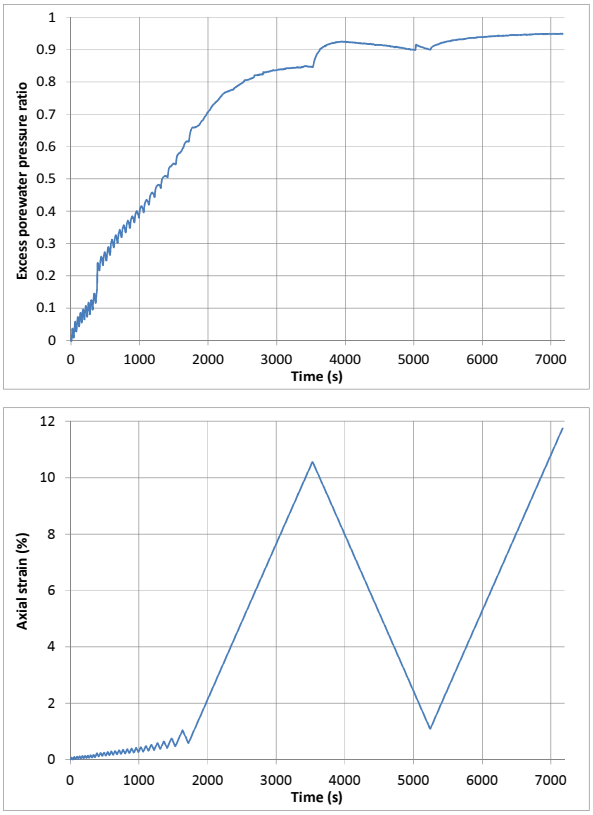

Figure 6 Pore pressure and Axial strain response of internally eroded soil specimen (CRR=0.12)

eroded away by the seepage flow, resulting in the increasing

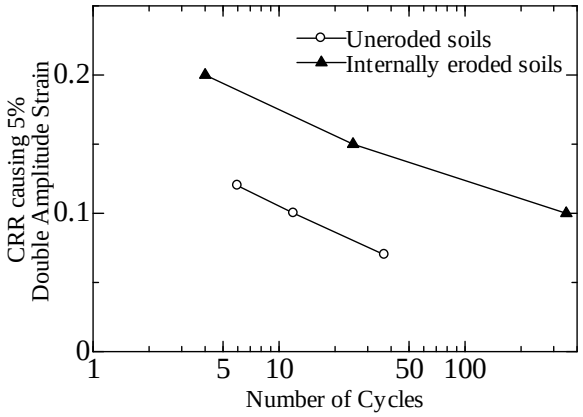

Figure 7 Cyclic Resistance of soil specimens

of volumetric strain of the tested specimen, as is shown in Fig.4. It can be observed that a dramatic change of soil volume occurs as soon as internal erosion initiates. With the progress of erosion, the volume change becomes moderate and reaches at a constant value. By weighing the mass of eroded soil grains, nearly half of the fines in soil specimens are eroded away.

5.2 Undrained cyclic test results

The typical pore pressure and axial strain response of the uneroded soil specimen under the cyclic resistance ratio of 0.12 are shown in Fig.5. That response of the internally eroded specimen under the same cyclic resistance ratio is shown in Fig.6. The test specimen without erosion shows liquefaction behavior of moderately loose sand. Pore pressure cumulates gradually at the early stage and reaches 0.9 of pore pressure ratio when liquefaction occurs. The axial strain increases linearly with the number of cycles which indicates that the soil specimen would produce a progressive or gradual failure. Fall *et al.* (1997) observed a similar behavior on gravels, which they referred as “ratchet” phenomenon. For the internally eroded soil specimen, pore pressure and axial strain response exhibit a similar behavior. Liquefaction occurs when pore pressure ratio is approximately 0.9. The axial strain increases with the number of cycles. A plot of cyclic resistance ratio versus number of cycles required to cause 5% double amplitude strain for uneroded and eroded soil respectively is shown in Fig.7. It indicates that the CRR causing 5% double amplitude strain in 20 cycles increases from 0.08 to 0.16 due to internal erosion.

6. CONCLUSIONS

Influence of internal erosion on soil cyclic behavior is experimentally studied through a series of triaxial seepage tests at designated stress state and undrained cyclic tests. By giving downward seepage flow to the gap-graded soil specimens, internally eroded soils are created. Undrained cyclic tests are performed on those internally eroded soils. The hydraulic conductivity of soils drastically increases with progress of the internal erosion. A large amount of fines would be eroded away with seepage flow. Soils would

greatly deform due to the loss of fines. The undrained cyclic test conducted on the eroded soils indicates that due to internal erosion CRR causing 5% double amplitude strain in 20 cycles would increase.

Abstract: In order to examine a relationships between damages of railway structures by earthquake and seismic intensity, the damage survey data of railway structures in the 2004 Niigata-ken Chuetsu earthquake and the 2007 Niigata-ken Chuetsu-oki earthquake are collected and compiled. Damage rates of different railway structures(earth structures, bridges, tunnels) are calculated at each JMA seismic intensity level. The results indicate that (1) the damaged embankments are found at the JMA seismic intensity 5- or larger, (2) the damaged bridges and tunnels are found at the JMA seismic intensity 5+ or larger, and (3) damage rates of all the structural types become higher with increase of the JMA seismic intensity.

1. INTRODUCTION

Better understanding of a relationship between damages of railway structures by earthquake and seismic intensity is needed for the optimized decision method of train operation control after an earthquake . If railway structures are damaged by earthquake and the train enters the damaged point, the train might be derailed. Therefore, if observations of ground motion in the wayside seismometers are larger than a certain level, train operation is suspended and the track is inspected. Suspended train operation by earthquake will affect the social activities. It is required to reduce unnecessary control. Therefore, it is important to know exactly relationships between damage to railway structures and seismic intensity, and to set reasonable criteria of train operation control after an earthquake.

Criteria of train operation control after an earthquake is determined based on the case histories of damage to railway structures by past earthquakes. Previous studies show that railway structures in the area where the JMA seismic intensity is larger than 5+ are damaged (Suzuki et al. 2003, Itoh and Taya 2006). However, damage rates for each the JMA seismic intensity level are unclear.

For damage assessment, Saitama prefecture and Tokyo metropolis constructed seismic seismic vulnerability functions based on the damage survey data in the 1978 Miyagi-ken-oki earthquake and the 1995 Hyogo-ken Nambu earthquake, respectively. These vulnerability functions, however, is applicable only in limited intensity levels, because these vulnerability functions were made based on earthquake damage survey data of a single earthquake. Takahama and Midorikawa constructed vulnerability functions that can be applied in the range of the JMA seismic intensity 4 to 7 based on the damage survey data in the 1978 Miyagi-ken-oki earthquake, the 1995 Hyogo-ken Nanbu earthquake, and the 2004 Niigata-ken Chuetsu Earthquake.

Railway structures can be classified into earth structures, bridges, and tunnels. It is thought that seismic capacity is different for each structural type. However, previous studies do not show relationships between railway structure damage and JMA seismic intensity for different structural types.

In this paper, we propose damage rates of different railway structural types at each the JMA seismic intensity level based on the 2004 Niigata-ken Chuetsu earthquake and the 2007 Niigata-ken Chuetsu-oki earthquake.

2. FLOW OF THIS STUDY

Fig.1 shows the flow of this study. To calculate damage rate of different railway structural types at each the JMA seismic intensity level, "the total length (or total number) of each JMA seismic intensity level" and "the number of damage of each JMA seismic intensity level" (divided into structural types) are needed. First, the total lengths of different structural types are measured for all lines surveyed. Tunnels and bridges are counted. Next, to grasp the number of damage of each structural type, damage survey data of railway structures in the 2 earthquakes are collected and compiled.

To calculate damage rates at each the JMA seismic intensity level, it is necessary to estimate the seismic

intensity at each point along the lines. In this study, spatial distributions of the JMA seismic intensity in 2 earthquakes are estimated based on seismometer data of JR, JMA, local government, JH, and K-Net.

The total numbers of different structural types and the total numbers of damaged structures at each the JMA seismic intensity level are grasped. Damage rates of different structural types at each the JMA seismic intensity level are calculated.

3. CONPILING DAMAGE SURVEY DATA OF RAILWAY STRUCTURES

Fig.2 shows all lines surveyed (6 lines, approximately 500 km). It is difficult to count earth structures. Therefore, the total length of earth structures is measured. It is easy to count tunnels and bridges. Therefore, the total numbers of tunnels and bridges are counted.

To measure the total length of earth structures, “the 100m points” are set for every 100m along lines. The structural type of each 100m point is picked up from the map symbol using “cyberjapan” by GSI. The numbers of 100m point of each structural type are counted. The total length of earth structures is calculated dividing the total number of 100m point of earth structures by 10.

Earth structures can be classified into "Embankments", "Cuttings", and "Natural ground or Lower embankments". The symbols of railway structure on “cyberjapan” are classified into tunnels, bridges, embankments, cuttings, and station yards. If the symbol on the 100m point means embankments or cuttings, the structural type is interpreted as the symbol. If the symbol on the 100m point is nothing, the structural type is interpreted as natural ground or lower embankments. Table 1 shows the total lengths of each structural type.

The total number of tunnels is found by counting the symbols on “cyberjapan”.The total number of bridges is found by counting the point crossing railway and road, or river. Table 2 shows the numbers of tunnels and bridges

Latitude and Longitude of a point can be picked up by clicking on the “cyberjapan”. Then latitude and longitude of each 100m point is picked up at the same time picking up the structural type. When estimating the JMA seismic intensity of each 100m point, latitude and longitude of the 100m point are required.

Damage survey data, such as kilometer post, structure name, and detail of damage, are described in the articles by the JR East. The number of damaged structures of each structural type is counted referring to these data. Damages which do not affect obviously trains are excluded. Table 3 shows the numbers of damaged structures dividing into structural types in the 2004 Niigata-ken Chuetsu earthquake and the 2007 Niigata-ken Chuetsu-oki earthquake.

Tunnels	18	4

4. ESTIMATION OF THE JMA SEISMIC INTENSITY AT EACH POINT

Estimating the JMA seismic intensity for all lines surveyed including sections without damage is required. Then the spatial distributions of the JMA seismic intensity for all area surveyed are estimated from recorded values. The JMA seismic intensity of each 100m point is picked up from the estimated spatial distributions. The JMA seismic intensity of damaged point is referred from the JMA seismic intensity of nearest 100m point.

The method to estimate the spatial distribution of the JMA seismic intensity, same as Yamazaki et.al (1998) and Maruyama et.al (2008), is as follows: (1) the observed values on the ground surface are converted to the estimated values on the bedrock by applying amplification ratios (2) the spatial interpolation on the base rock level is carried out (3) the amplification ratio is again introduced and the spatial distribution of the estimated values on the ground surface is obtained (Fig. 3). Table 4 shows the calculation condition in this study. Fig.4 and fig.5 shows the result of the estimation of the spatial distribution of the JMA seismic intensity in the 2 earthquakes.

5. CALCULATION OF DAMAGE RATES OF DIFFERENT RAILWAY STRUCTURES AT EACH SEISMIC INTENSITY LEVEL

5.1 Calculation of damage rates of earth structures at each seismic intensity level

The number of damaged earth structures are divided by the section length of each the JMA seismic intensity level. Then the damage rates at each seismic intensity level (locations/km) are calculated (Fig6-9).

The damaged embankments are found at the JMA seismic intensity 5- or larger. The damage rate of the JMA seismic intensity 5- is only 0.01(locations/km). The damage rates are higher with increase of the JMA seismic intensity. The Trends are not significantly different in the 2 earthquakes. Comparing between three structural types, the damage rate of embankments are the highest in any the JMA seismic intensity level. The natural ground and lower embankment is next, the cuttings is lowest. This is consistent with the empirical knowledge that higher embankments are vulnerable.

5.2 Calculation of damage rates of bridges at each seismic intensity level

The number of damaged bridges are divided by the total number of bridges of each the JMA seismic intensity level. Then the damage rates at each the JMA seismic intensity level are calculated (Fig. 10).

Damaged bridges are found at the JMA seismic intensity 5+ or larger. Not more than the JMA seismic intensity 6+, damage rates become higher with increase of the JMA seismic intensity. The damage rate at the JMA

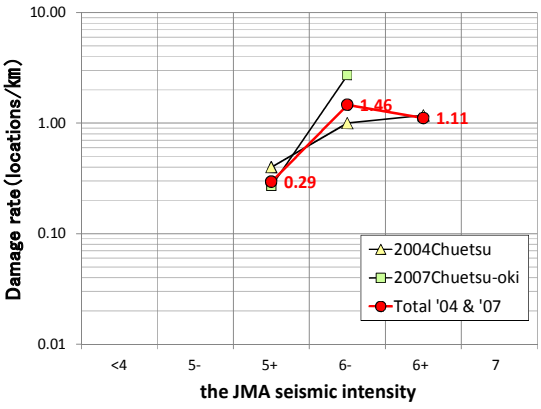

Fig. 8 The damage rate of each the JMA seismic intensity of cuttings

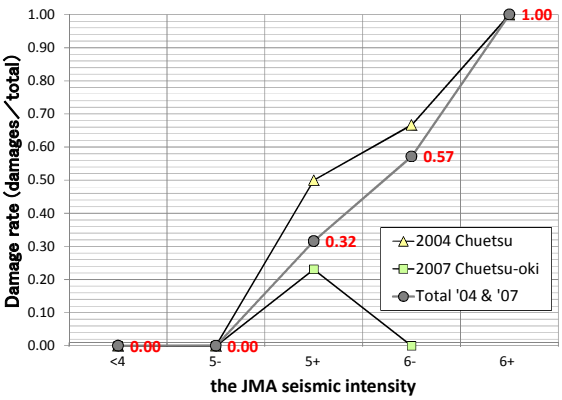

Fig. 11 The damage rate of each the JMA seismic intensity of tunnels

seismic intensity 6+ and 7 are comparable. Most of bridges in the area the JMA seismic intensity 7 are over-road bridges with short span. For this reason, it is thought that the damage rate at the JMA seismic intensity 7 is calculated lower.

5.3 Calculation of damage rates of tunnels at each seismic intensity level

The number of damaged tunnels are divided by the total number of tunnels of each the JMA seismic intensity level . Then the damage rates at each the JMA seismic intensity level are calculated (Fig. 11). The JMA seismic intensity of both entrance are compared. The JMA seismic intensity of the tunnel is applied the larger one.

Damaged tunnels are found at the JMA seismic intensity 5+ or larger. Damage rates become higher with increase of the JMA seismic intensity. All tunnels are damaged more or less at the JMA seismic intensity 6+.

Comparing between the 2 earthquakes, the damage rates of the JMA seismic intensity 6- are quite different. This is because the total number of tunnels at the JMA seismic intensity 6- in the 2007 Chuetsu-oki earthquake was only 2.

6. CONCLUSIONS

Damage survey data of railway structures in the 2004 Niigata-ken Chuetsu earthquake and the 2007 Niigata-ken Chuetsu-oki earthquake are collected and compiled. The damage rates of different structural types (earth structures, bridges, tunnels) at each the JMA seismic intensity level are calculated.

The results indicate that (1) the damaged embankments are found at the JMA seismic intensity 5- or larger, (2) the damaged bridges and tunnels are found at the JMA seismic intensity 5+ or larger, and (3) damage rates of all the structural types become higher with increase of the JMA seismic intensity.

The result will be available to optimize the decision method of train operation control after an earthquake.

Abstract: Storage tanks are critical lifelines that generally supply water or fuel. For this reason, it is very important that these structures remain undamaged or functional after an earthquake. However, previous investigations have demonstrated that strong earthquakes can cause severe damage or collapse of storage tanks. Theoretical studies by other researchers have shown that allowing the tank to uplift (separation of the tank base from the foundation) generally reduces the base shear and the base moment. This paper supplements and enhances the theoretical work performed by others. This paper reports on a series of experiments using a shake table of a model tank made of PVC containing water . A comparison of the seismic behaviour of a fixed base system (tank with anchorage) with a system free to uplift (tank without anchorage) is presented. The experiments were performed using stochastically simulated ground motions based on a Japanese design spectrum and two different tank aspect ratios (height/radius). Measurements were made of the stresses in the tank shell and the horizontal displacement of the top of the tank. Whereas the top displacement and the tank shell acceleration increased when uplift was allowed, axial compressive stresses decreased when the tank was able to uplift.

1. INTRODUCTION

Storage tanks are lifelines that store essential supplies such as potable water or fuel. For this reason, it is important that these structures remain operational after an earthquake. However, evidence in the literature (Haroun 1983, Manos and Clough 1985, Cooper 1997) has shown that large earthquakes can cause severe damage to storage tanks or even collapse in some cases (Figure 1). For these reasons, many studies have been carried out to investigate the seismic behaviour of storage tanks (Housner, 1957, Wozniak and Mitchell, 1978, Veletsos, 1984). A number of standards and design guides have been developed.

Figure 1 Steel tank collapsed during Darfield earthquake, New Zealand (2010)

Current standards for seismic design are based mainly on the spring-mounted masses analogy proposed by Housner (1957) (Figure 2). This model establishes that liquid storage tanks behave mainly in two vibration modes. The portion of the liquid contents which moves rigidly with the tank shell is known as the impulsive mass M_i. The portion of the contents which moves by developing a sloshing motion is called the convective mass M_c.

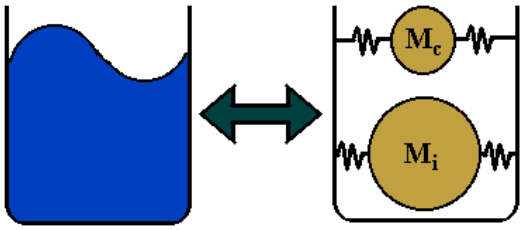

Figure 2 Spring-mounted masses analogy after Housner (1957)

A phenomenon that has been little studied is uplift of the base of the tank. Uplift is the physical separation of the tank base from the tank foundation. The first studies of liquid tanks assumed the structure to be fixed to the base. However, many storage tanks are not anchored to the base and thus these structures are able to uplift. Current design

guidelines for storage tanks (API650 2007, NZSEE 2009) give a conservative seismic design for unanchored tanks (Ormeño et al., 2012). These documents consider that uplift of structures has the potential to lead to structural collapse. Lack of investigation in this matter has established the belief that structural uplift is harmful for structures.

In the case of storage tanks, a few theoretical studies have been carried out concerning the uplift of the base plate. Ishida and Kobayashi (1988) and Malhotra and Veletsos (1994a) used small deflection beam theory to model the bottom plate of the tank and in this way they studied the behaviour of unanchored tanks. Malhotra (2000) utilised the moment-rotation relationship given by Malhotra and Veletsos (1994b) to carry out a simplified nonlinear analysis for performance-based seismic design of tanks. In the example presented by Malhotra (2000), the seismic forces were reduced by more than 70% from that of the equivalent fully anchored tank. Ormeño et al. (in print) investigated the effect of uplift on the displacement and acceleration of the tank shell. However, there is no experimental investigation about the effect of uplift on the tank shell stress which is the parameter that controls the design of this type of structure.

The objective of this work is to quantify the effect of uplift on storage tanks in terms of tank shell acceleration, of the top displacement of the tank and the axial stresses in the tank wall. The study entails the use of a PVC model tank that is subjected to earthquake motion on a shake table.

2. METHODOLOGY

2.1 Tank Model

A PVC tank is utilised to model a prototype steel tank (Figure 3). Two different aspect ratios (H/R: Liquid level to radius ratio) were studied. The properties of the model and prototype are shown in Table 1. Two different fixity conditions were tested, free base and fixed base. Figure 4 shows both cases. Dynamic properties were computed by using NZSEE (2009). Scale factors are shown in Table 2.

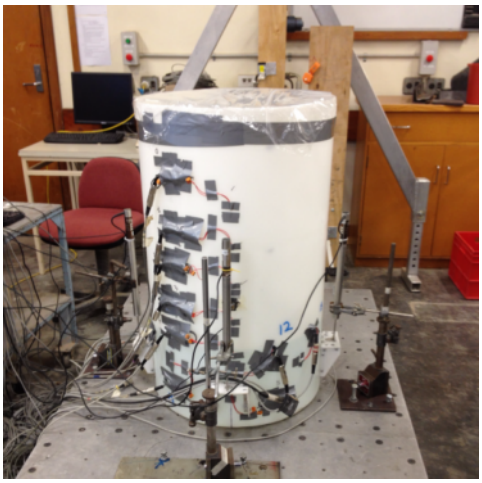

Figure 3 PVC tank model

Table 1 Dimensions and properties of tank model and prototype

	Model	Prototype
Material	PVC	Steel
Young's modulus (MPa)	$1.6*10^3$	$2.068*10^5$
Diameter (m)	0.50	10.00
Height (m) (#)	0.75	15.00
Wall and base thickness (mm)	4	10
Mass of the contents (kg) (#)	147	1178097

(#) These values correspond to an aspect ratio of 3

Table 2 Scale Factors

Dimension	Scale factor
Length	20
Mass (liquid content only)	8000
Time	4.64
Stiffness	369.5
Acceleration	0.93
Force	7440

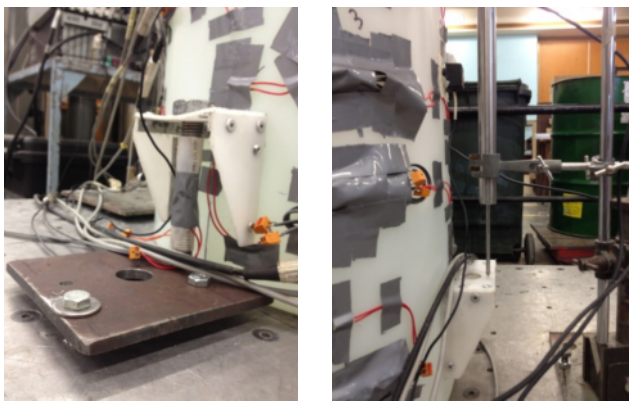

Figure 4 Fixed base case (left) and free base case (right)

2.2 Setup

Strain gauges were implemented on the tank wall to measure the axial distribution of stresses. A wire transducer was attached to the top of the tank to measure the horizontal displacement of the tank shell. An accelerometer was located at a height of 400 mm to measure the tank wall acceleration. Figure 5 shows the setup used.

2.3 Ground Motions

A set of 4 stochastically generated earthquake records based on the Kobe Japanese spectra were used in testing the tank model (Chouw and Hao, 2005). The similitude requirement was met by applying the scale factors shown in Table 2. Time-History of the Ground Motion 1 (GM1) is shown in Figure 6.

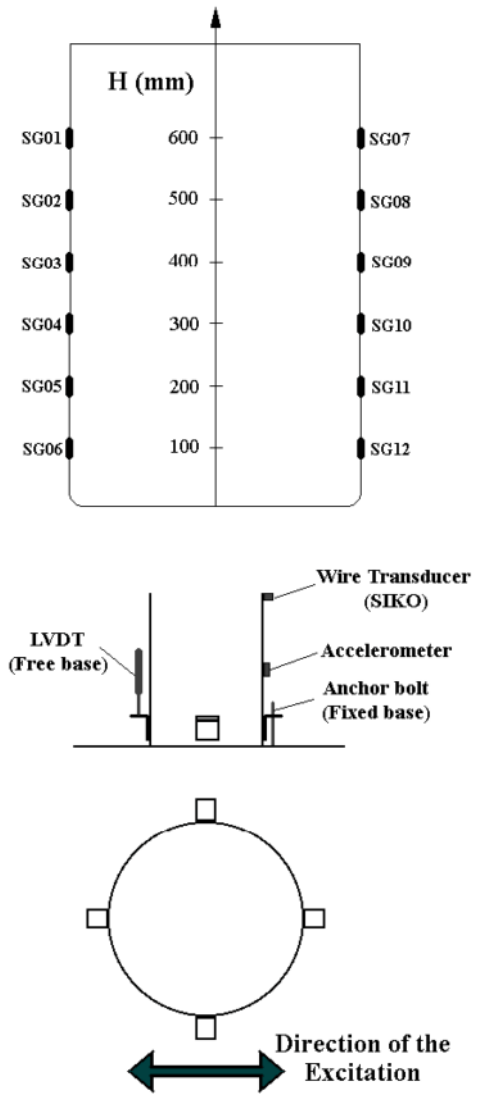

Figure 5 Experimental Setup. Strain Gauges distribution (top), locations of the devices utilised (centre) and plan view of the model (bottom).

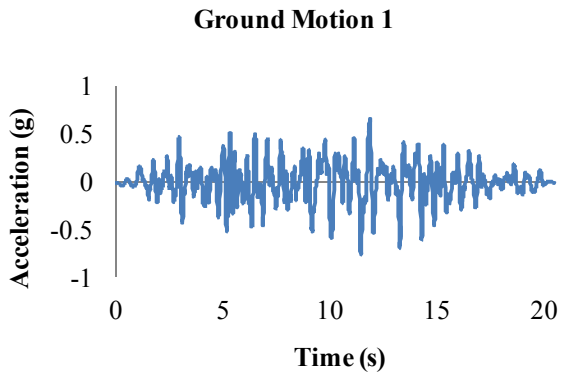

Figure 6 Ground Motion 1 (GM1)

3. RESULTS

Table 3 shows the ratio between the maximum displacement of the top of the tank shell for the free base condition to the one obtained for the fixed base condition. Table 4 shows the ratio between the maximum acceleration of the tank shell for the free base condition to the one obtained for the fixed base condition.

Table 3 Maximum top displacement ratio

Ground Motion	H/R=1	H/R=3
GM1	0.995	1.013
GM2	0.977	1.018
GM3	1.009	1.064
GM4	1.000	1.020

Table 4 Maximum tank shell acceleration ratio

Ground Motion	H/R=1	H/R=3
GM1	1.006	1.098
GM2	1.074	1.194
GM3	1.137	1.027
GM4	1.028	0.934

It is noticeable from the values shown in Tables 3 and 4 that higher values of displacement and acceleration are generally obtained for the free base case, i.e., maximum values of tank shell acceleration and top displacement are higher when the tank is able to uplift. This trend is observed in 13of 16 ratios shown in Tables 3 and 4.

However, the parameter that largely controls the design of liquid storage tanks is the stress in the tank shell. Figures 7 and 8 show the maximum axial compressive stress obtained for GM1 and for both aspect ratios.

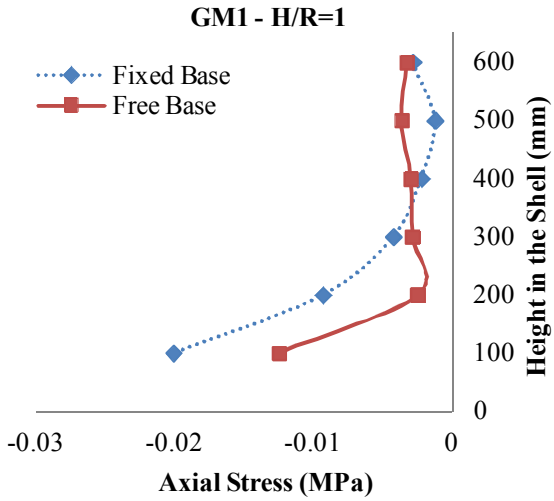

Figure 7 Maximum axial compressive stresses for Ground Motion 1 and H/R = 1

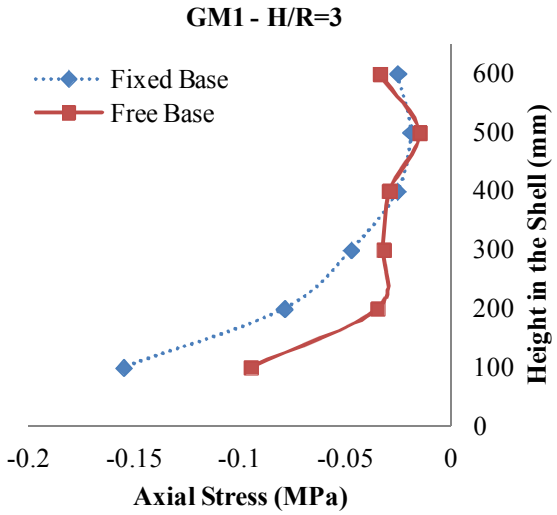

Figure 8 Maximum axial compressive stresses for Ground Motion 1 and H/R = 3

From Figures 7 and 8 it is noticeable that the axial compressive stresses decreased when the tank is able to uplift. To provide an overview of the effect of uplift on the axial compressive stresses, the bottom value (which is the maximum) will be considered. Table 5 shows the ratio between the maximum axial stress at the bottom of the tank wall for the free base condition to that obtained for the fixed base condition.

Table 5 Ratio of maximum axial compressive stress ratio

Ground Motion	H/R=1	H/R=3
GM1	0.622	0.612
GM2	0.713	0.751
GM3	0.599	0.740
GM4	0.553	0.802

It is noticeable from Table 5 that for all the cases analysed (4 ground motions and 2 aspect ratios) the maximum value of axial compressive stress in the tank shell decreased when the tank was able to uplift. The results obtained from Table 5 seem to contradict the results given by Tables 3 and 4. This apparent contradiction can be explained by analysing Figure 9. In Figure 9 the tank-liquid system for the free base case is modeled as a single degree of freedom (SDOF) system. Equation 1 defines the displacement of the SDOF system.

Among the terms shown in the right side of Equation 1, only the horizontal displacement due to the tank shell deformation, u, causes axial stresses in the tank shell. For this reason, the results shown in Tables 3, 4 and 5 are not contradictory, i.e., it is perfectly possible to obtain higher displacements (or accelerations) when the tank is able to uplift because the horizontal displacement (or acceleration) due to the rotation of base plate is included. This component has no role in the fixed base case. However, the axial compressive stress, which is the parameter that controls the design, decreases when the tank is able to uplift.

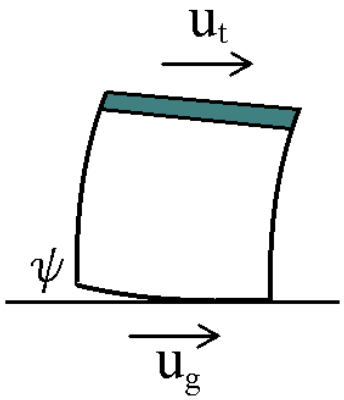

Figure 9 SDOF system for the free base condition

$$u_t = u_g + \Psi \cdot h + u \quad (1)$$

where: u_t = total displacement of the equivalent SDOF system;
u_g = ground displacement;
Ψ = base rotation due to uplift;
h = height of the equivalent SDOF system; and
u = displacement of the SDOF due to the tank shell deformation.

4. CONCLUSIONS

A series of experiments were carried out to determine the effect of base plate uplift on the axial compressive shell stresses in liquid storage tanks. The results showed that uplift has a beneficial effect on the axial compressive stresses in the tank shell. For the 4 ground motions and 2 aspect ratios utilised the maximum compressive stress decreased by approximately 20% to 40% when the tank was able to uplift. These results contradict the current design practice of unanchored tanks. Standards and design guides, API650 (2007) and NZSEE (2009), give a conservative procedure to compute the required tank shell thickness when the tank is able to uplift, considering that uplift has the potential to increase the axial stresses in the tank shell.

With respect to the values of maximum tank wall acceleration, these increased in 88% of the cases analysed when uplift was allowed. Similarly in 75% of the cases analysed the maximum top displacement was higher when the tank was placed on a free base than when the tank was on fixed base. At first sight these results seem to be contradictory to the results obtained for the axial stresses, but in fact, it is possible to get higher displacements and accelerations of the tank wall and lower induced wall stresses. The explanation of this feature of tank response is that it is only the component of the total displacement due to the tank wall deformation that causes stresses in the shell. The horizontal displacement due to the base plate uplift has no impact on the tank shell stresses.

Finally, it is recommended that the current standards and design guides be reviewed with respect to the procedures of design concerning the seismic design of storage tanks when uplift is included.

Abstract: In this paper, total behavior of The Greater Tehran gas distribution pipelines during seismic wave propagation is evaluated. By synchronizing and adjustment of distribution maps of the pipelines, ground conditions and seismic inputs, various different cases for evaluation are selected. These cases are analyzed by precise finite elements method. In the numerical evaluations, different pipe specifications including material, size, end conditions and bends, soil conditions and seismic wave attributes including peak ground acceleration, time history and directivity are considered. After comparison of the numerical results and simpler formulas, the basic criteria for damage assessment of the pipelines are created, which are used for network analysis. The results showed a relatively satisfying overall performance for the network; however, in several cases, some countermeasures for rehabilitation and improvement of the system reliability and safety are suggested and discussed.

1. INTRODUCTION

Pipelines are one of the most widespread lifelines in urban life, which have so many different usages in the contemporary days. Obviously gas distribution systems are among the most important types because of their purpose, yet vulnerability and high risks and consequences of the accidents and failures. This importance urges the stakeholders and decision makers to take all the significant natural and manmade hazards into the consideration for the risk management of these major lifelines.

Arguably the most significant and destructive natural hazards for the buried pipelines is the seismic activity, while this hazard can affect the structure in different ways as seismic transient wave, faulting, liquefaction, and landslide. Among all the mentioned effects of the earthquake, the seismic wave propagation is the phenomenon that occurs globally in a wide area; while the others are likely to happen locally in the vicinity of faults, problematic soils or the unstable slopes.

In this paper, the risk of gas distribution pipelines in the Greater Tehran area capital of Iran, during seismic wave propagation is subject of the study. The risk of this network was previously assessed for the liquefaction hazard by the authors (Nourzadeh et al. 2011-a, 2011-b), and this research is a continuation and follows the same procedure. In the previous research, it was proven that the gas distribution pipelines of Tehran has relatively low risk during the occurrence of liquefaction, and the only methodology suggested for boosting the performance of the network was planning several monitoring stations and implementation of a synchronized control and monitoring system, known as SCADA (supervisory control and data acquisition), to mitigate the risks of the network. In this research, first the seismicity of the area is reviewed, then several selected cases are analyzed numerically, of which the results are used to determine the network performance during the seismic wave propagation hazard.

2. SEISMICITY OF TEHRAN

The seismicity of Tehran Greater Area has been analyzed previously by different methodologies including deterministic seismic scenarios, and probabilistic seismic hazard analysis (PSHA). It is mostly advised to use the former assessments results in a risk assessment research (Klügel et al. 2006), while the latter leads to type of results mostly used in new designs. In this regard, the seismic scenarios of the area are used in the current research, which are described in the following.

The seismic scenarios are derived deterministically for causing the most destructive effect regardless of the probability of occurrence. In this method, different classes of the ground motions are considered in the area including historic and prehistoric earthquakes and also the maximum credible level of the shaking related to the known major faults. In the case of the Tehran Greater Area, the last strong ground motion happened back to more than 150 years ago, and the major active faults are shown in Figure 1.

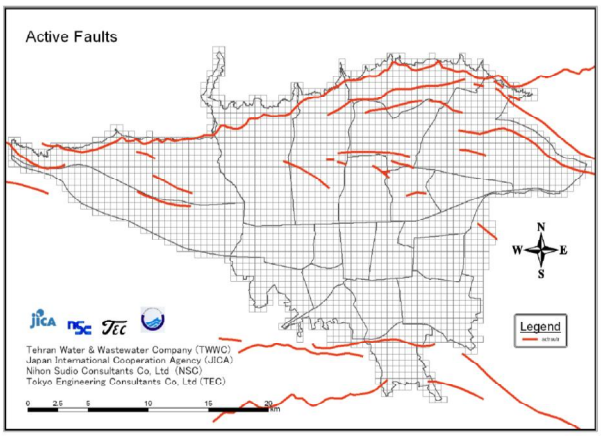

Figure 1 Major Active Faults in the Tehran Greater Area (after JICA, 2000)

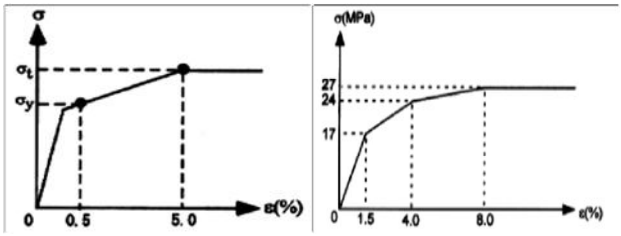
Four different scenarios were derived for the area in the previous studies based on three major active faults, namely Mosha, North Tehran and Ray Faults along with a floating fault model to take the hidden faults under the alluvial layers. The mechanism for most of these faults is strike slip as it was verified later (Ashtari et al. 2005), and the length of the faults exceed 68 km. The specifications of the faults and the resulted ground motions are shown in Table 1.

Table 1 Selected Significant Faults and Resulted Ground Motion Scenarios

	Mosha Fault	N. Tehran Fault	Ray Fault	Floating Fault
Length (km)	68	58	26	13
Width (km)	30	27	16	10
Depth (km)	0	0	5	5
Magnitude (M_w)	7.2	7.2	6.7	6.4
Max. PGA (g)	0.3	0.4	0.6	0.6

3. SEISMIC RESPONSE ANALYSIS OF GAS PIPELINES



3.1 Pipelines Specifications

The exact data on gas transmission and distribution pipelines in the Greater Tehran Area were gathered and used in the numerical simulations as shown in Table 2. Also the sizes and dimensions of the pipelines were gathered based on the construction manuals and standards, and considered respectively in the analyses.

Table 2 Specificaions of the Pipelines Network

	Main Transmission Network	Local Distribution Network
Internal Pressure	250 psi	60, 100 psi
Pipe Material	Steel: API 5L- Gr. B	Steel: API 5L- Gr. B
	Steel: API 5L- X 42	PE: HDPE 80, 100
Pipe Diameters	2- 48 inches	Steel: 2- 12 inches
		PE: 63- 160 mm
Burial Depth	1- 1.20 m	1- 1.20 m
Coating	Tar or 3 layered PE	Tar or 3 layered PE

As mentioned in the table above, the materials used in the pipeline network are steel and polyethylene (PE), so different numerical models for representing these materials were selected for the analysis. The mathematical models were selected to consider the nonlinear behavior of the pipe materials as shown in Figure 2.

(a) (b)

Figure 2 Material Models for (a) Steel Pipes, and (b) PE pipes (after Pezeshki et al, 2004)

3.2 Analytical Models

Based on the specification of the pipelines used in the gas distribution network in Tehran, different cases were selected for study to represent the overall response of the system. In this regard, 12 different pipes including 8 steel pipes (4 high pressure transmission pipes), and 4 different sizes of PE pipes were selected to be analyzed. The lengths of the continuous pipelines were selected as 700 and 1400 m for all cases, taking the findings and suggestion of the previous studies (JWWA, 1997, Lee et al. 2009) into the consideration.

Based on the soil distribution maps and properties of the dominant types in the greater Tehran area, 3 different soil types were selected as the surrounding soil model for the pipelines. The properties of soil types were selected as dense sand (DS) with internal friction angle (ϕ) of 35º, loose sand (LS) with ϕ of 25 º, and soft clay (SC) with cohesion (C) of 16.8 kPa. According to these assumptions, surrounding soil was modeled as nonlinear springs in three dimensions using

the basic formulation in the American codes (ALA, 2001).

The finite element model was generated using beam elements for the pipes, and three dimensional soil springs. The earthquake excitations were applied to the other end of the mentioned soil elements as displacement time-histories. For this analysis, time-histories of 3 major earthquakes of Tabas 1978, Northridge 1994, and Kobe 1995 were selected (data obtained from www.usgs.gov) and scaled to the selected PGAs for the analysis ranging from 0.3 to 0.65g. After generating design acceleration records, the time-histories were converted to the displacement records by the numerical integration in time, of which examples are shown in Figure 3 for scaling PGA of 0.65g.

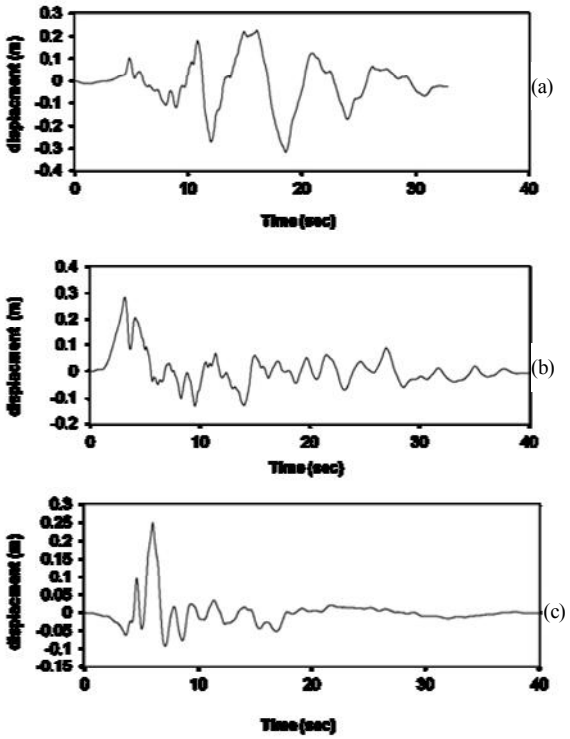


Figure 3 Displacement Time-histories of (a) Tabas, (b) Northridge, and (c) Kobe Earthquakes Scaled for 0.65g PGA

The earthquake excitations were assumed to act on the pipelines as the combined effect of surface and body (shear) waves. In this regard, the ground motions in 3 dimensions were applied to the pipelines with the incident angle of 0 and 45 degrees, and in both types the vertical component of the motion was scaled to 2/3 of the horizontal magnitude. The destructive effect of the seismic wave propagation on the pipeline is inducing differential displacements in the length as the result of phase delay of the received wave along the pipeline. Therefore the minimum seismic wave length of 100m was selected for the ground motions and the seismic inputs were assigned correspondingly.

3.3 Numerical Analysis and Results

The numerical simulations were conducted by the finite elements method using ABAQUS v6.10 software. In the analyses, the straight and bended (90º and 135º) pipelines with lengths of 700 and 1400m were discretized into 10m length beam models connected to 3D nonlinear soil springs at the nodes. Also the effect of soil and internal pressures were neglected in the analysis, as the effects are examined to be small (also in Lee et al. 2009).

The end conditions of the pipelines were assumed as combinations of fixed and pinned, however by a simple sensitivity analysis, it was found that the fixed-fixed assumption leads to more critical responses. The analyses started from the highest seismic action level (PGA of 0.65g), and continued until the pipelines are safe. The acceptance criteria for the pipeline safety were defined as strain levels under the allowable strains shown in Table 3. In the table, t and R refer to the thickness and radius of the pipes.

Table 3 Allowable Strains for Pipelines in Seismic Wave Propagation (ALA 2001, JGA 2000)

Failure Mode	Allowable Strain
Low-Cycle Fatigue, Buckling	0.175 t/R
Tension	3% for Steel Pipe
	20% for PE Pipes

Based on the described model assumptions, more than 340 FE analyses were conducted and the results were gathered in a database. The total behavior of the pipes were deterministically considered to be the most critical response during 3 time-histories, and therefore the overall results are shown in Table 4.

Table 4 Finite Elements Analysis Results for the Selected Cases

Pipe Mat.	Pipe Diameter	Bend Angle	Soil Type	PGA range	Response Level
Steel-Gr B	8" 12"	0	all	≥ 0.65 g	Major Damage
Steel-X42	12" to 30"	0	all	≥ 0.65 g	Major Damage
Steel-Gr B	4" to 12"	0	all	≥ 0.5 g	Moderate Damage
Steel-X42	12" to 30"	0	all	≥ 0.5 g	Moderate Damage

Pipe Mat.	Pipe Diameter	Bend Angle	Soil Type	PGA range	Response Level
Steel-Gr B	12”	90	all	≥ 0.65 g	Moderate Damage
Steel-X42	12” to 30”	90	all	≥ 0.65 g	Moderate Damage
Steel-Gr B	6” to 12”	45	all	≥ 0.6 g	Moderate Damage
Steel-X42	12	45	all	≥ 0.6 g	Moderate Damage
PE	all	all	all	≤ 0.65 g	Safe

In the table above, “Major Damage” is assumed the failure in tension, while “Moderate Damage” corresponds to the buckling and wrinkling failure in the pipes. As it is understood from the above mentioned results, the soil conditions do not play a major role in the response of the pipelines; also the PE pipes have shown very desirable behavior during this seismic action.

4. Damage Assessment of Gas Distribution Network

After response analysis of the buried pipelines during the selected seismic activities, the total network reliability and overall response should be assessed. In this regard, the damage distribution maps were produced in GIS environment. The final result of the analysis is shown in Figure 4.

In this map, the greater Tehran Area is divided into blocks and the PGA distribution corresponding each of the seismic scenarios were assigned. Comparing the PGA distributions, soil properties and pipeline network map gives the damage locations in the network as it is shown in the figure.

As it was shown in Table 4 and Figure 4, in some cases there will be a major damage in the gas distribution pipelines despite relatively satisfying performance of the system. It is also demonstrated that the main transmission pipelines will probably experience significant damages during the high seismic activities, which will lead to catastrophic events. Therefore it is essential to implement mitigation and retrofit plans for improving the performance of the network.

There are several mitigation and retrofit options for this matter as it is briefly discussed as following:

1- It is advised to use a central monitoring and spontaneous action station for automatic shut down of the system flow in case of disaster. This suggestion by the authors led to starting a preliminary SCADA system with an array of seismographs for real-time monitoring and immediate measures in the cases of earthquake occurrence for Tehran lifeline networks.

2- As the main transmission pipelines are believed to suffer the earthquake effects, it is suggested to implement secondary and alternative routes in north and south of the greater Tehran area to improve the redundancy in the system.

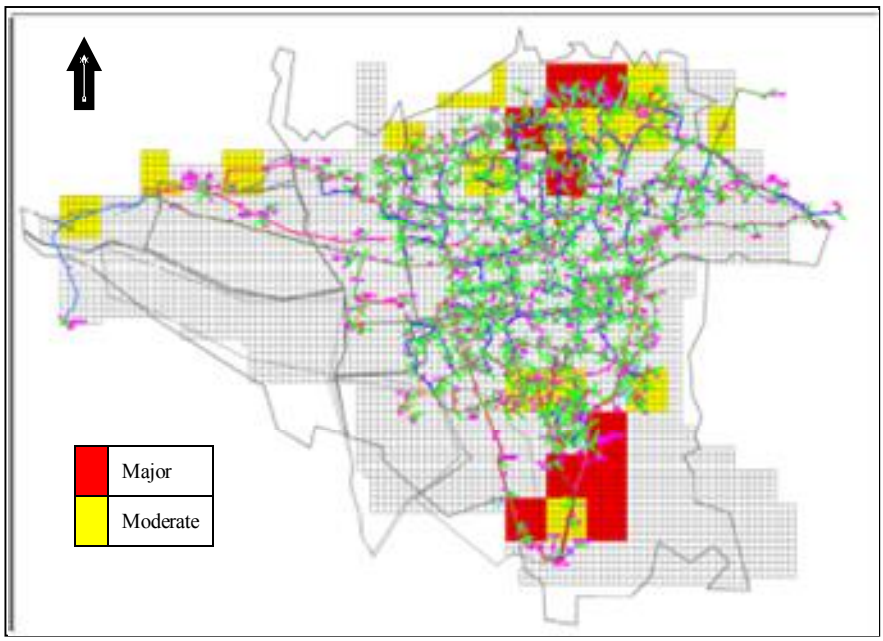

Figure 4 Damage Distribution Map in Tehran Gas Distribution Network

3- In all areas with moderate and major damage indexes, it was advised to use automatic shutoff valves for the pipelines to mitigate the secondary effects of the pipeline failures as the internal pressure of the pipelines are high, which could lead to probable explosions after the leakage.

4- It could be suggested to replace the vulnerable medium pressure pipelines with PE pipes in a long term plan, but in the short term the best mitigation plan could be using the monitoring systems and automatic shutoff valves.

5- It is advised to consider some emergency stations for field patrol and also post earthquake countermeasures in the highlighted areas.

5. CONCLUSIONS

In this paper, response of buried gas pipelines was analyzed during seismic wave propagation in the greater Tehran area in Iran. Using the fragility analyses of the individual structures, the overall performance and damage distribution in the system were derived and several mitigation and retrofit plans were discussed to boost the performance and mitigate the risk of the pipelines network during the seismic activity.

Abstract: Existing reinforced concrete buildings lacking details for ductile response during earthquake shaking represent a prevalent construction type in high seismic zones around the world. The poor seismic performance of these non-ductile concrete buildings is evident from recent earthquakes in Chile, New Zealand and Japan. Seismic rehabilitation of these existing buildings plays an important role in reducing urban seismic risk; however, with the massive inventory of existing concrete buildings and the high costs of seismic rehabilitation, it is necessary to start by identifying and retrofitting those buildings which are most vulnerable to collapse. Numerous sources of uncertainty complicate the ability to identify buildings which are vulnerable to collapse. For this reason, it is important to develop estimates of collapse probability to account for all significant sources of uncertainties. This paper will introduce the concept of collapse indicators, design and response parameters that are correlated with "elevated" collapse probability. The methodology for identifying collapse indicators is based on results of comprehensive collapse simulations. Appropriate collapse indicators and corresponding limits are evaluated by seeking trends between probability of collapse and collapse indicators. This paper will discuss significant challenges which pose a barrier to the assessment of collapse indicators that are applicable for the wide range of existing concrete buildings.

1. INTRODUCTION

In the mid-1990s new seismic rehabilitation guidelines (e.g. FEMA 273 [10]) were introduced to the world, providing the structural engineering profession with the first generation of 'performance-based' procedures for seismic assessment and rehabilitation design. These documents revolutionized the assessment of existing buildings by encouraging the use of nonlinear analysis, by enabling the engineer to select project-specific performance objectives, and perhaps most importantly, by recognizing that structural collapse was limited by both strength and deformation capacity. The past 15 years has seen modest improvements to this first-generation performance-based design procedure as FEMA 273 [10] has evolved into of ASCE/SEI 41 [3], including updated acceptance criteria for concrete components based on new experimental data [8]. However, the overall framework remains essentially deterministic and inconsistent conservatism in specified deformation capacities throughout the document may impact the reliability of the predicted performance of a building structure. Furthermore, the component-based assessment procedures (i.e. once one component is determined to have exceeded a performance level, the entire structure is deemed to have exceeded the performance level) ignore the ability of a structural system to redistribute loads as damage accumulates and will tend to lead to conservative assessments of collapse vulnerability. Seismic evaluation documents based on checklist assessments (e.g. ASCE/SEI 31 [2]) are also generally conservative to ensure dangerous buildings are not misdiagnosed. As currently formulated, ASCE/SEI 31 and ASCE/SEI 41 are not capable of reliably determining the relative collapse risk between different non-ductile concrete buildings. From a public policy standpoint, the ability to economically make this distinction across the large inventory of existing concrete buildings is a critical need and a necessary next step in the evolution of seismic rehabilitation documents.

ATC-76-5 [16] identified the following critical needs for addressing the collapse risk associated with older concrete construction:

- Improved procedures for identifying building systems vulnerable to collapse, including simple tools that do not require detailed analysis.
- Updated acceptance criteria for concrete components based on latest research results.
- Identification of cost-effective mitigation strategies to reduce collapse risk in existing concrete buildings.

To address the first critical need, ATC-76-5 proposed a methodology for identifying parameters, termed collapse indicators, correlated with an elevated probability of collapse based on results of comprehensive collapse simulations and estimation of collapse probabilities for prototypical concrete buildings. Ideally there should be a variety of collapse indicators, ranging from those appropriate for rapid

assessment to others used to identify collapse potential based on results of detailed nonlinear analysis. Collapse indicators for rapid assessment must be very simple parameters which can be established based on basic information available from a quick survey of the building or engineering drawings. Collapse indicators for detailed collapse prevention assessment can make use of the results from building analyses. This paper will demonstrate a methodology to identify collapse indicators and discuss challenges to be overcome in the identification of collapse indicators representative of a general inventory of buildings. The methodology discussed below was initially proposed as part of the ATC-76-5 project [16] funded by NIST, and will be further developed in ongoing projects (ATC-78 and ATC-95) funded by NIST and FEMA. This paper does not provide specific recommendations for collapse indicator limits, but instead focuses on the development of the methodology. The goal of the ongoing ATC projects is to refine the methodology and ultimately lead to simplified practical guidance for engineers on how to identify collapse vulnerable buildings based on limits for selected collapse indicators.

2. POTENTIAL COLLAPSE INDICATORS

The identification of collapse indicators appropriate for engineering practice, and establishing limits on these indicators, is best accomplished through detailed analytical studies such as those described in Section 3. However, before embarking on the analytical studies, it is essential to come up with a list of potential collapse indicators from which the recommended collapse indicators will be selected. Engineering judgment and experience with collapse analyses were used to select the preliminary list of potential collapse indicators below. It is anticipated that this list will evolve as further experience is gained from the analyses described in Section 3.

Ideally there should be a spectrum of collapse indicators, ranging from those appropriate for rapid assessment to others used to identify collapse potential based on results of detailed nonlinear analysis. Collapse indicators for rapid assessment must be very simple parameters which can be established from basic information available from a quick survey of the building or engineering drawings. Conversely, collapse indicators for detailed collapse prevention assessment can make use of the results from nonlinear analyses. It is proposed to categorize collapse indicators into two fundamental types:

Design parameter collapse indicators: These collapse indicators are determined based on design features of a concrete building, including reinforcement details, structural system layout, and relative strength and stiffness of members. These indicators can be further sub-categorized as "rapid assessment" (RA) or "engineering calculation" (EC) collapse indicators, where the former can be determined from a quick survey of the building or engineering drawings and the latter requires some calculation of capacities and demands based on engineering drawings. RA and EC collapse indicators will be useful for refining the seismic evaluation procedures in ASCE/SEI 31 [2].

Response parameter collapse indicators: These collapse indicators reflect the response of the structure based on results from building analysis (BA). Generally the most refined collapse indicators are expected to be derived from results of nonlinear analysis and provide system-level acceptance criteria for the Collapse Prevention performance level.

Table 1 provides a list of potential collapse indicators to be considered for investigation in the analytical studies discussed in Section 3. These collapse indicators have been grouped based on the classification described above, and further grouped as component or system-level parameters. Component Building Analysis indicators shown in Table 1 (BA – C#) can be interpreted as equivalent to component acceptance criteria in ASCE/SEI 41 [3]. It is anticipated that relationships may exist among the indicators, as vectors of indicators may be found to provide a better indication of collapse potential than any one indicator. For example, if the average minimum transverse reinforcement ratio (RA-C1) is less than a specific value and the column-to-floor area ratios (RA-S1) are greater than a specific value, then collapse potential is expected to be high.

3. COLLAPSE SIMULATION

In order to better understand and define the collapse potential for concrete buildings, model building prototypes are developed for nonlinear analyses using OpenSees [17]. These models, capable of capturing onset of structural collapse, enable the selection of collapse indicators having strong correlation with collapse potential. Using the prototypes, the Design Parameter collapse indicators listed above, including geometric and mass properties (e.g. plan dimensions, building height), can be varied to explore the effects on collapse probability. Sophisticated building prototype models allow explicit consideration of collapse probability considering both loss of vertical load carrying capability and lateral dynamic instability; uncertainty in modeling and ground motion are also accommodated.

Collapse of real buildings is highly dependent on the complex behavior and interaction among individual components. The analyses to refine the selection of collapse indicators utilize building models to explore characteristic behavior and the effects of parametric variations.

In contrast to ductile structural systems, non-ductile concrete buildings will typically experience gravity-load collapse resulting from loss of vertical load carrying capacity in critical components prior to experiencing a "side-sway" collapse resulting from degradation in lateral resistance [5]. The nonlinear building models used for this study incorporate elements capable of approximately capturing the loss of vertical load carrying capacity for critical gravity-load supporting components (e.g. columns [4,7] and slab-column connections [12]) and account for P-delta effects. It should be noted that these models provide a relatively simple representation of a very complex phenome-

Table 1: Examples of collapse indicators

Type of Collapse Indicator		System-level		Component-level	
Design Parameters	**Rapid Assessment (RA)** *Quantities that can be determined from a quick survey of the building or engineering drawings.*	*RA-S1.*	Maximum ratio of column-to-floor area ratios for two adjacent stories.	*RA-C1.*	Average minimum column transverse reinforcement ratio for each story.
		RA-S2.	Maximum ratio of horizontal dimension of the SFRS in adjacent stories.	*RA-C2.*	Minimum column aspect ratio.
		RA-S3.	Maximum ratio of in-plane offset of SFRS from one story to the next to the in-plane dimension of the SFRS	*RA-C3.*	Misalignment of stories in adjacent buildings.
		RA-S4.	Plan configuration (L or T shape versus rectangular)		
		RA-S5.	Minimum ratio of column area to wall area at each story**		
	Engineering Calculations (EC) *Quantities that require some calculation of capacities and demands based on engineering drawings, but do not require structural analysis results from computer modeling.*	*EC-S1.*	Maximum ratio of story stiffness for two adjacent stories	*EC-C1.*	Maximum ratio of plastic shear capacity ($2M_p/L$) to column shear strength, V_p/V_n .
		EC-S2.	Maximum ratio of story shear strength for two adjacent stories.	*EC-C2.*	Maximum axial load ratio for columns with $V_p/V_n > 0.7$.
		EC-S3.	Maximum ratio of eccentricity (distance from center of mass to center of rigidity or center of strength) to the dimension of the building perpendicular to the direction of motion.	*EC-C3.*	Maximum ratio of axial load to strength of transverse reinforcement (45 deg truss model).
		EC-S4.	Portion of story gravity loads supported by columns with ratio of plastic shear demand to shear capacity > 0.7.	*EC-C4.*	Maximum ratio of joint shear demand (from column bar force at yield) to joint shear capacity for exterior joints.
				EC-C5.	Maximum gravity shear ratio on slab-column connections.
Response Parameters	**Building Analysis (BA)** *Quantities for detailed collapse prevention assessment using the results from nonlinear building analyses.*	*BA-S1.*	Maximum degradation in base or story shear resistance.	*BA-C1.*	Maximum drift ratio.
		BA-S2.	Maximum fraction of columns at a story experiencing shear failures.	*BA-C2.*	Maximum ratio of deformation demands to ASCE/SEI 41 limits for columns, joints, slab-column connections and walls.
		BA-S3.	Maximum fraction of columns at a story experiencing axial failures.		
		BA-S4.	Minimum strength ratio (as defined in ASCE/SEI 41).		

* Collapse indicator notation: RA = Rapid Assessment; EC = Engineering Calculation; BA = Building Analysis; S=System; C = Component.

** May not result in collapse but could help prevent collapse if a mechanism forms.

Table 2: Four and seven story non-ductile RC frame structures

Num. of Stories	Num. of Bays	Story Height (m)	Bay Width (m)	Framing System	Period (s)
4[1]	3	3.96	7.62	Space	1.98
7[2]	8	4.12	5.72	Perimeter	1

[1] [14]; [2] [13]

non at the point of gravity-load failure, and hence, may lack some sophistication required to accurately capture the behavior of the building to the point of total collapse. In particular, given the lack of data available for validation, modeling of three dimensional gravity load redistribution through a slab floor system after gravity load failure of a single component should be considered approximate at best. Despite possible inaccuracies, the failure models provide good estimates of observed collapse behavior of simple 2D frames [6,9,20].

One significant challenge that must be overcome to undertake this analysis is the distinction between the "true" point of gravity-load collapse and non-convergence due to numerical instability of the model. In this study, collapse is detected based on a comparison of floor-level gravity load demands and capacities (adjusted at each time step to account for member damage and allow for load redistribution) [5,6,9]. The first point when floor-level vertical load demands exceed the total vertical load capacity at that floor is defined as gravity-load collapse for the building system. Non-convergence of the analysis prior to significant degradation in the capacity to resist gravity loads and not associated with large lateral displacements (side-sway collapse) will not be considered as collapse, and the results of such analysis will be omitted from the calculation of collapse probabilities.

The following sections briefly describe the scope for the analytical studies. First, the key elements of the numerical models are introduced. In this paper, four- [14] and seven-story [13] non-ductile reinforced concrete frame buildings located in Los Angeles, California, are used as example structures to illustrate the methodology. Next, the model and ground motion uncertainties are briefly explained. Finally, the two approaches used to establish limits on the collapse indicators (design and response parameters) are discussed.

3.1 Numerical Model

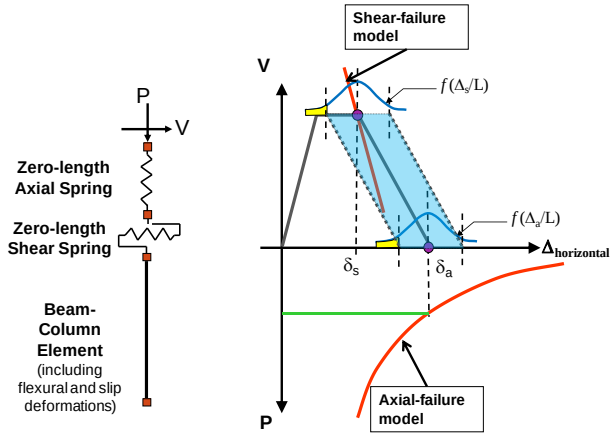
Two-dimensional finite element models are used to simulate the seismic response of the buildings using OpenSees [17]. A fixed-base model is used in the analysis; as a result soil-structure foundation interaction is neglected. The frame elements are modeled using the force-based beam–column model with distributed nonlinear fiber sections. The joints are modeled using the Alath and Kunnath model [1] which includes the pinching hysteric behaviour to account for the degradation usually seen in these non-ductile elements. Axial failure of joints is not considered in this example. The shear and axial response in the columns are modeled using the modified Limit State material model [4,7] recently implemented in OpenSees. Key characteristics of the structures are summarized in Table 2.

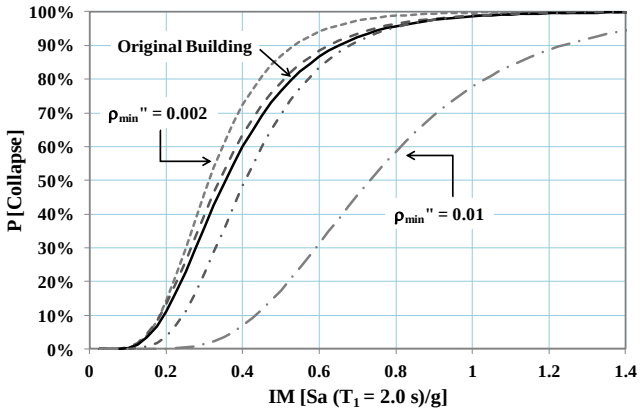
3.2 Record- to-record and model uncertainty

Performance-based earthquake engineering enables probabilistic prediction of structural response, incorporating key sources of uncertainty in the process. By using a suite of earthquake records, nonlinear dynamic analyses (via incremental dynamic analysis, IDA [19], and/or multiple stripe analysis, MSA [11]) directly incorporates information about variability in ground motions in the collapse performance assessment. However, nonlinear dynamic analysis alone does not account for how well the structural model represents the collapse behavior of the building; hence, model uncertainties should also be accounted for in the process of collapse simulation. These modeling uncertainties are especially important in predicting collapse, because of the high degree of empiricism and uncertainty in predicting deformation capacity and other critical parameters.

In this methodology the uncertainty for each random variable is explicitly considered in the analysis and reflected in the final probabilities of collapse. The random variables selected with the respective probability distribution should have the capability of capturing the major uncertainties inherent in non-ductile reinforced concrete frames. Uncertainty in the shear and axial failure models for non-ductile columns are considered as the main sources of model uncertainty for the example buildings. The shaded area shown in Fig. 1, presents the entire outcome of failure model variability considered for these non-ductile columns. The variability in the drift at column shear and axial load failure is represented by a lognormal distribution with a mean equivalent to the limit-state material failure models and a coefficient of variation of approximately 0.3 [9].

In addition to model variability, record to record variability is considered in the process. Accounting for record to record uncertainty is possible by selecting an appropriate suite of ground motions specific for the building site and the anticipated hazard level with a good fit to the conditional mean spectrum. Ten ground motions for each hazard level are considered using MSA in this example.





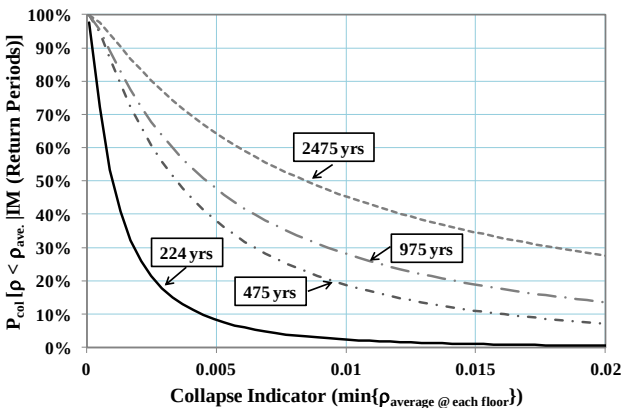


Fig. 1 Structural model uncertainty in shear and axial failure models [7]

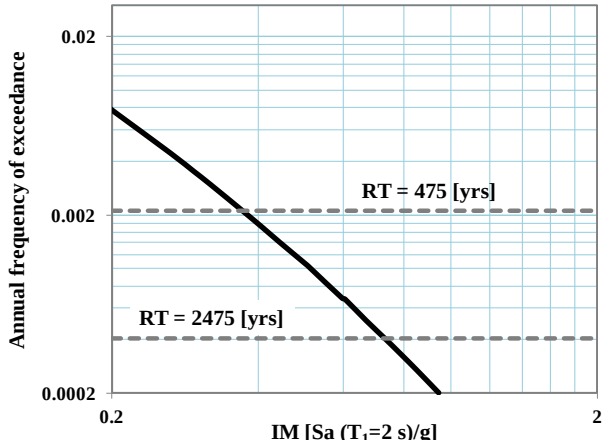
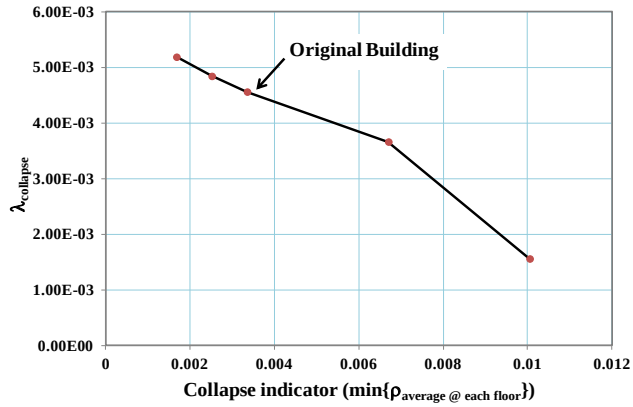
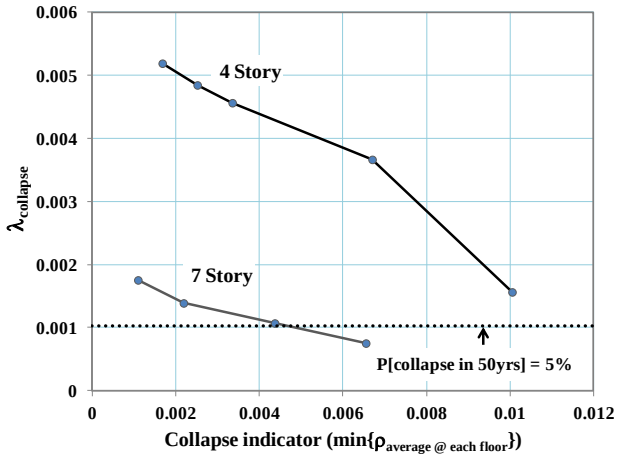
3.2 Assessment procedure for design parameters



The nonlinear models will be used to estimate the probability of collapse considering ground motion and model uncertainties. The procedure is to first build the complete nonlinear model of a building prototype and



(a) Develop collapse fragilities for a range of the selected collapse indicator (*e.g. RA-L1*)



(b) Develop collapse fragilities for a range of selected return periods (*e.g. 475 yrs, ...*)

(c) Estimate mean annual rate of collapse ($\lambda_{collapse}$) integrating the collapse fragility curves with the hazard curve

(d) Seek trends in $\lambda_{collapse}$ for changes in collapse indicator

(e) Repeat for "several" building prototypes and choose an appropriate risk and determine the range for the collapse indicator

Fig. 1 Procedure for establishing collapse indicator limits, design parameters

evaluate the building collapse fragility [5,6]. Two- and three-dimensional analytical models can be used. Then a selected collapse indicator parameter (e.g. RA-L1, average minimum column transverse reinforcement ratio) will be altered in the building model and the collapse fragility will be reassessed for each realization of the collapse indicator (Fig. 2.a). Fig. 2.a shows the variation of the collapse fragilities for the four-story example building with the average column transverse reinforcement ratio, RA-L1. As expected, collapse probability increases as the average column transverse reinforcement ratio decreases. The same figure can be represented by grouping the collapse fragility into different bins of hazard intensities as shown in Fig. 2.b. The variation of the collapse fragilities can be multiplied with the slope of the hazard curve shown in Fig. 2.c to estimate the mean annual frequency of collapse ($\lambda_{collapse}$) as a function of the design parameter (Fig. 2.d). The assessment illustrated in Fig. 2.a through Fig. 2.d can be repeated several times to access the sensitivity of the design parameters for several different building types (Fig. 2.e).

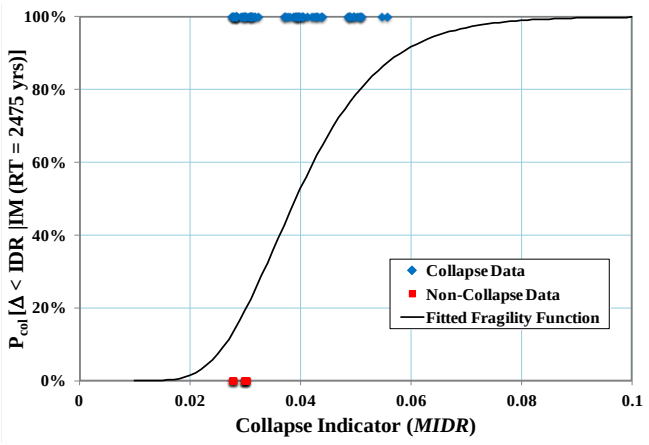
Limits on the collapse indicators can be selected based on a "suitable" mean annual frequency of collapse ($\lambda_{collapse}$) (Fig. 2.e). For instance, $\lambda_{collapse}$ could be selected to be consistent with the new risk-targeted ground motions used for new design [15], i.e. a uniform collapse risk of 1% in 50 years. To be consistent with current seismic rehabilitation practice and to encourage economical retrofits, it is reasonable to relax the target collapse risk compared to that used for new buildings; for example, a mean annual of frequency of collapse of 0.001, equivalent to a probability of collapse of 5% in 50 years. To achieve this selected risk level, Fig. 2.e indicates that the transverse reinforcement ratio should not be below, approximately 0.0043 and 0.012 for the seven- and four-story example buildings, respectively. It should be noted that an ideal collapse indicator would have only limited variation in the collapse indicator limit suggested by the different building types. The results shown in Fig. 2 suggest that transverse reinforcement ratio by itself may not be an ideal collapse indicator for frame buildings as the number of columns and stories also influence the results. Future research will consider how to determine appropriate limits for combinations of collapse indicators.

3.2 Assessment procedure for response parameters

As shown in Table 1, response parameters considered as collapse indicators could be related to the deformations (e.g. global/interstory drift ratios) or forces (e.g. minimum strength ratio) extracted from the nonlinear analysis. These response parameters are also referred as engineering demand parameters (EDPs). Since the performance level considered in this study is collapse prevention, the damage states are discrete and binary and it is assumed that the collapse observation is an ordinary Bernoulli random variable (i.e., a value of unity whenever the structure sustains collapse and zero in all other cases).

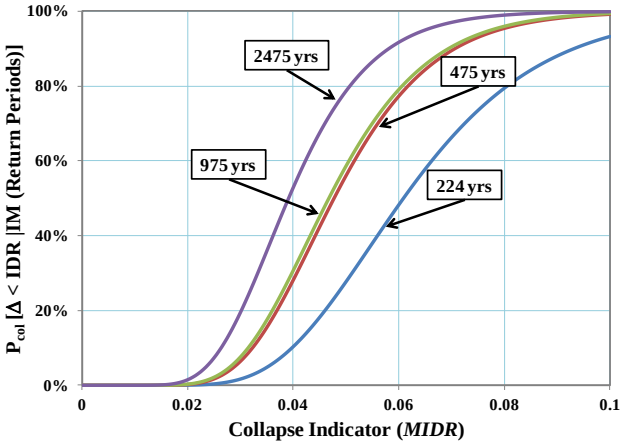
The variability in building responses can be accounted for using cumulative distribution functions (CDFs) to approximate the probability of each response parameter (e.g. maximum interstory drift ratio) occurring. For each building response (BR) and intensity measure (in this study the return period, RT, is used to represent the intensity measure), cumulative distribution functions are developed based on nonlinear dynamic analysis. The objective is to develop a CDF for the probability of collapse given BR and RT, P(Collapse| BR, RT). The probability of exceeding the collapse state conditioned on a particular building response and return period is modeled using a lognormal probability distribution, given by the following equation:

$$P(Collapse|\, BR, RT) = \Phi\left[\frac{Ln(BR) - Ln(\overline{BR})}{\sigma_{LnBR}}\right] \qquad (1)$$



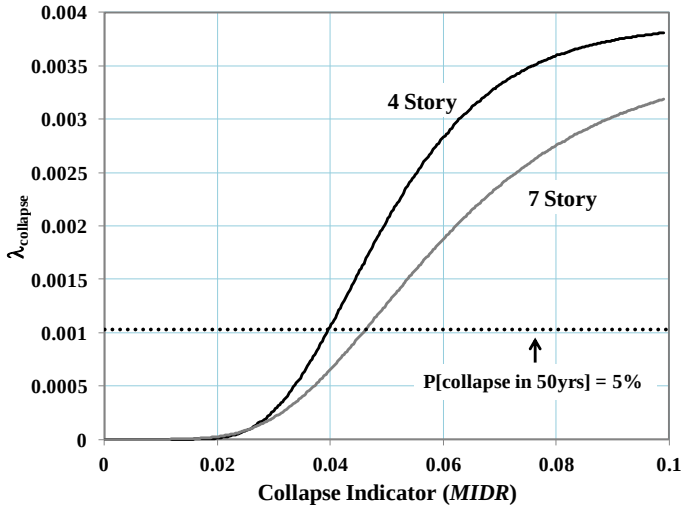
where P(Collapse| BR, RT) is the probability of achieving the collapse state, $\overline{BR}$ is the median of the BRs at which the probability of collapse is observed, and $\sigma_{\mathrm{Ln}BR}$ is the standard deviation of the natural logarithm of the BRs. As suggested by Ramirez [18] different methods could be used to determine the statistical parameters of the lognormal distribution for the CDF, for example, least square methods and the maximum likelihood method. The maximum likelihood method is used in this study to estimate the median ($\overline{BR}$) and standard deviation ($\sigma_{\mathrm{Ln}BR}$). CDFs for building prototypes are developed and related to a selected collapse indicator (e.g. BA-C1 - maximum drift ratio at collapse). Fig. 3.a shows a fitted curve of the response parameter. As shown in this figure, the results of the collapse indicator are either collapse or no collapse from response history analyses.

Using the methodology presented in the previous section, CDFs (Fig. 3.b) are multiplied with the slope of the hazard curve shown in Fig. 2.c to estimate the annual frequency of collapse ($\lambda_{collapse}$). Similar collapse fragilities would be determined for different building prototypes and trends in the probabilities of collapse are compared. Potential limits for the collapse indicator are estimated, similar to the design parameters, for a selected mean annual of frequency of collapse, such as 0.001. Using this limit, Fig. 3.c indicates the maximum interstory drift should not exceed 4.5% for the seven story building and 4% for the four story building.



4. SUMMARY AND FUTURE CHALLENGES

The risk associated with older non-ductile concrete buildings internationally is significant, and the development of improved technologies for mitigating that risk is a large and costly undertaking. Considering the limited funding available for seismic retrofit, to achieve a meaningful reduction in the collapse risk it is essential to be able to identify the very worst buildings and fix these first. A potential methodology for identifying collapse indicators based on results of comprehensive collapse simulations and estimation of collapse probabilities for a collection of building prototypes is described.



Although only demonstrated here for frames, the probabilities of collapse must be considered for a broad

(a) Determine *CDF* for prototype building

(b) Develop *CDF*s for range of selected return periods

(c) Repeat for "several" building prototypes and choose an appropriate risk and determine the range for the collapse indicator

Fig. 2 Procedure for establishing collapse indicator limits, response parameters

cross section of building types to ensure the selected limits for the collapse indicators are appropriate for the large varied inventory of existing buildings. Methodologies for selecting sample design (e.g. average column transverse reinforcement ratio) and response (e.g. maximum interstory drift ratio) parameter are explained. Limits on the collapse indicators can be selected based on a suitable mean annual frequency of collapse ($\lambda_{collapse}$). In this paper, $\lambda_{collapse}$ is selected based on a target collapse risk. An alternative to this method could be to compare $\lambda_{collapse}$ for the prototype buildings with the $\lambda_{collapse}$ of a "good" existing building, for which seismic rehabilitation is not required to achieve a collapse prevention performance level.

Additional research is required to establish limits for use in design practice and to improve the methodology to address the interaction of multiple collapse indicators. Ongoing studies funded by FEMA and NIST through the ATC-78 and ATC-95, respectively, are expected to result in specific guidance for practicing engineers based on some of the concepts presented in this paper.

Abstract: Low ductility wall buildings became part of the Peruvian construction boom of the first decade of the 21st century. Government promote under the Program named Mi Vivienda (My house in English), the construction of low rise buildings of 5 stories using walls with wire mesh reinforcement, provide part of a solution of the apartment deficit, with reasonable cost. However, the height of the buildings started to grow and grow, reaching 12 to 16 stories. In the design of this walls, provisions recommend the confinement of the corners of the walls, due the action of the walls ensemble will give a limited ductility under seismic behavior. In this paper the comparison of the action of perpendicular wall with a one plane wall is presented. Here experimental test has been performed by a cyclic loading test considering the action of a constant axial load of 40 kN, where the elastic stiffness of H shape wall is higher than one plane wall. Also resistant of the H shape wall increase, however ductility remains almost similar in both walls, due to the slip during the H wall test.

1. INTRODUCTION

Low ductility buildings appears at the middle of 1997 in Peru. As an initiative of Professor Galvez from graduate school of FIC-UNI, the promotion of the first multifamily building of four stories with the concept of replacing the masonry on a confines wall by a thin concrete wall reinforce with electrowelded wire mesh, will produce a compose material with similar better characteristics than the masonry. First experiments on this kind of wall where successfully developed at structural laboratory of CISMID-FIC-UNI (Zavala et. al 2003), considering a low stress concrete (100 kg/cm^2) a wall of 10 cm. thickness, 250 cm. height, 300 cm. length and reinforce on corners of 3 bars #3 with wall reinforce of Q91 wire mesh of 3 mm. diameter @ 10 cm. The result was a low ductility wall with low drift, even lower than the masonry limit (where Peruvian standards demands maximum drift of 1/200), with maximum drift near 1/400.

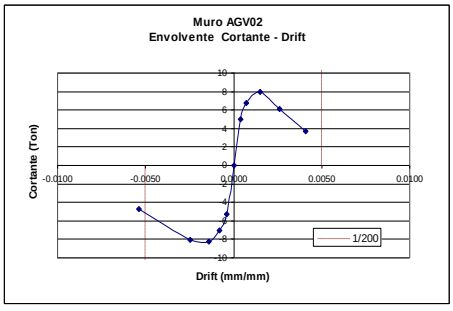

Figure 1: Behavior curve (Zavala et. al 1997)

This took the attention for the design of this kind of wall since the reinforce has upper yield point (65 to 70 ksi) than regular A60 bars (60 ksi), which is one of the reasons of the less ductility.

The Ministry of Housing invest in the research of the behavior of this kind of wall, so configuration variable and reinforce variable area presented(Zavala et. al 2003).

Since 1999 the use of this walls starts to grow on buildings projects. Government, through Ministry of Housing, promote under the Program named Mi Vivienda (My house in English), the construction of low rise buildings of 5 stories, provide part of a solution of the apartment deficit in the country, with reasonable cost.

However constructors started to grow in altitude the buildings to 8 stories, 12, stories and 16 stories, using the same reinforce, without research the behavior as a middle high building.

Therefore, on 2003 the Ministry of Housing introduce an recommendation for the design of low ductility walls on the Peruvian Concrete Standards.

The investigations of this kind of wall continue at UNI during the following years. On 2004 Medina and Zavala produce a research considering ideal conditions on material, construction process and standards. As an example a wall reinforce with normal concrete (210 kg/cm^2), 10 cm. thickness 250 cm. height, 300 cm. length and reinforce of 3 bars #4 with wall reinforce of QE257 wire mesh of 5.7 mm diameter @ 10 cm. gave results with a drift limit similar than confined masonry and upper stress.

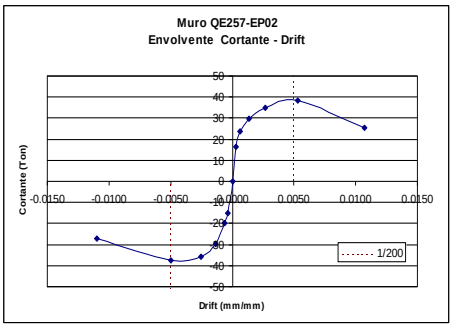

Figure 2:Behavior Curve Medina et. al 2004

Since 2004 investigation has been performed on in plane walls, however non investigation considering this kind of walls have been developed in Peru.

Under the SATREPS Peru - Japan joint research project and using the new jack system of capacity of 500 kN and 400 mm. stroke investigation of low ductility wall with the action of a perpendicular has been performed. In this paper preliminary results are presented showing the tendency of the contribution of the perpendicular wall to the in plane wall.

2. ABOUT THE EXPERIMENTAL TEST CONSIDERING PERPENDICULAR WALL ACTION

In order to investigate in experimentally the influence of the perpendicular wall on and H shape configuration against one plane wall, two experiments were performed: an experiment on a one plane wall, and an experiment with a perpendicular wall that produce an H shape wall.

2.1 About Test specimen

Both walls (one plane and H wall) will has the same dimensions: 2500 mm. length with 2600 mm. height and 100 mm. thickness. In the case of H wall, a flange with a total dimension (Bf) of 2500 mm. is incorporated to the one plane wall, in order to investigated it influence by the measured stresses.

The walls have a reinforce on the corners as confinement 3 bars #4. Wire mesh appears as reinforcement of the web and flange with electro welded mesh Q-158 (5.5 mm. diameter @ 0.15m As=1.58 cm2/m). Is common use of 600 mm. dowels between stories on buildings, but in the case of the specimens dowels are same growing from the footing base. Figure 3 presents the configuration of both specimens, one plane and H shape wall, notice that there is a horizontal border beam of 300 mm. by 300 mm. section on the top of each beam. Also foundation of 900 mm. by 300 mm. is on the bottom part of the specimen.

The construction process tried to replicate as near the real environment on the site area. So wire mesh from the footing was fixed with the wire mesh of the wall and three ductile bars #4 were placed on the corners of the specimens. Wood forms were used to encase the reinforcement and set the fluid mix of concrete inside to produce the concrete wall.

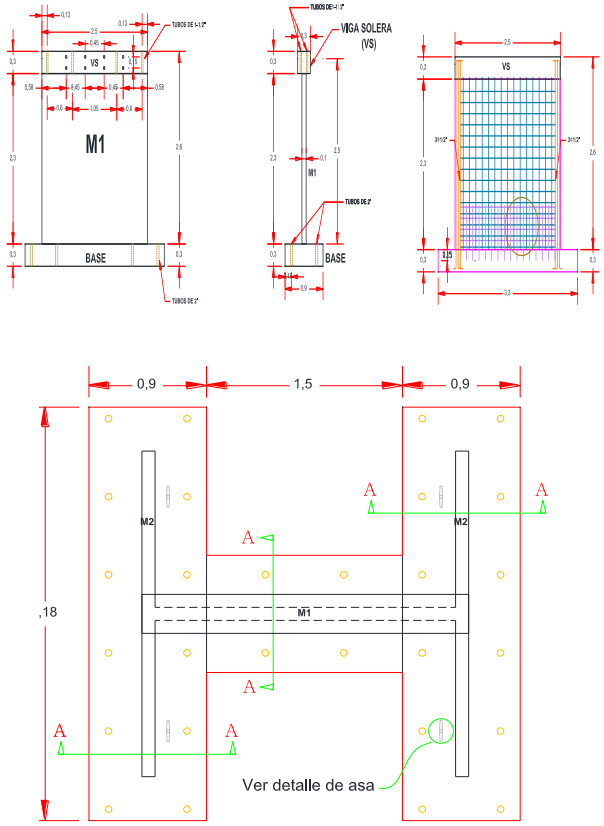

Figure 3: Test specimen configuration for H shape wall

On the top of each wall a loading beam is build to be use for setting of the loading steel frame. Figure 3 presents four stage of the constructions of the specimens.

2.2 About test performance

For the test execution 2 jacks and one actuator were used for the application of the loads. Axial load equivalent to 200 kN that approximately represents the load of four stories over the wall.

Figure 4: Test Setup on Plane and H walls.

During the execution of the test, this load will be applied at the beginning of the load process, and after reaching 200 kN, the load will remain constant during the whole test. To simulate the lateral action such a earthquake

movement, an increasing cyclic displacement will be applied to the specimen in order to start the movement of the wall and measure in each step the load.

For the measure of the displacements a set of transducer were placed to measure displacement in different locations on the walls. In the one plane wall and web wall (on H shape specimen), displacements transducers were set on the positions presented on Figure 5, here sensors on the body of the wall were setting on the diagonal, vertical and horizontal in order to reproduce the displacement on all directions. For the measure of the stress on points strain gauges were glued to the surface of the concrete and to the reinforce bars. All the sensors and gauges, were connected to an scanning box and data logger Tokyo Sokki TDS 530.

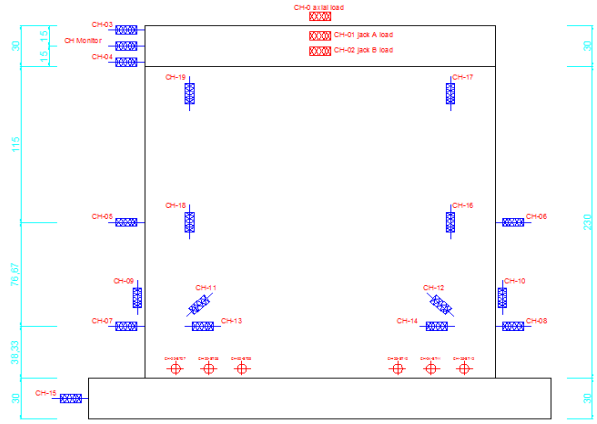

Figure 5: Displacement transducer setting

On Figure 4, the test setup of both specimens are presented. Here is possible to notice the difference on the setup due to need of application of the axial load and lateral load simultaneously in special in the case of the H shape wall were space is quite narrow to applied both loads. In the case of H shape wall the perpendicular wall (flange wall) has three lines of sensors in order to investigated the displacement on that positions and the dissipation of the stress. Also strain gages were set for the same purpose.

2.3 Test results

The cyclic displacement versus base shear on the experimented walls are presented on

Figure 6, where hysteresis curves of the development of each test are presented. It is possible to read that both specimens had almost the same level of maximum stress, but in different failure mode. The reason of this similitude of stress level is due to an slip on the foundation occurs after 4 mm displacement. In the case of the one plane wall, shear cracking appears on the base of the experiment. Then flexural cracks starts to appear on both borders elements, propagation horizontally. Finally diagonal cracks appear and a combination of shear failure with slip failure of the base, is the final failure pattern.

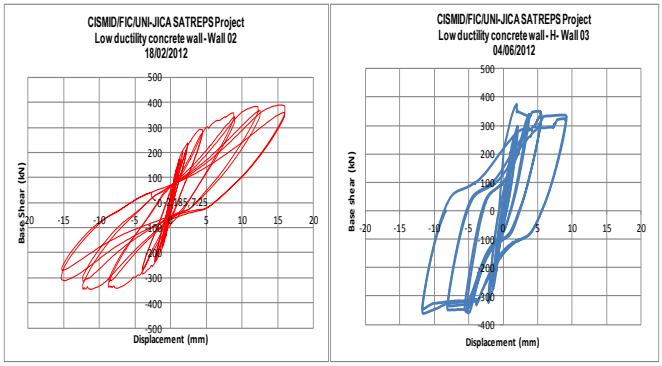

Figure 6: Hysteresis curves of one plane wall and H shape wall

Due to the slip of the specimen, we will consider the behavior of the H wall previous to the slip and compare the behavior curves of both specimens for this condition. The slip of the specimen occurred for 1/1600 drift, just after the cracking starts on the specimen. Figure 7 presents the behavior curve showing that both curves almost reached the same capacity. However, considering the first stage of the test, when drift is less than 1/1600, the behavior will introduce a difference on the resistant.

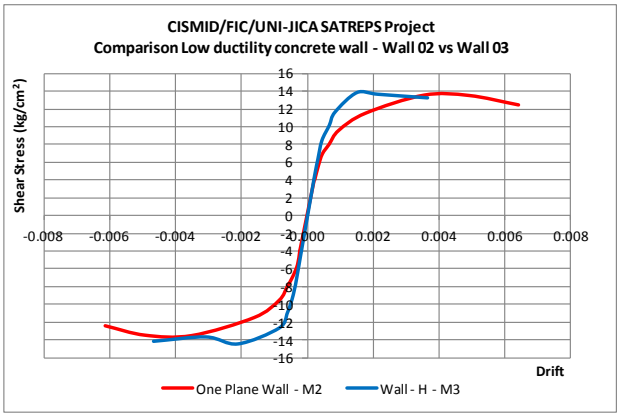

Figure 7: Behavior curves plane wall and H shape wall

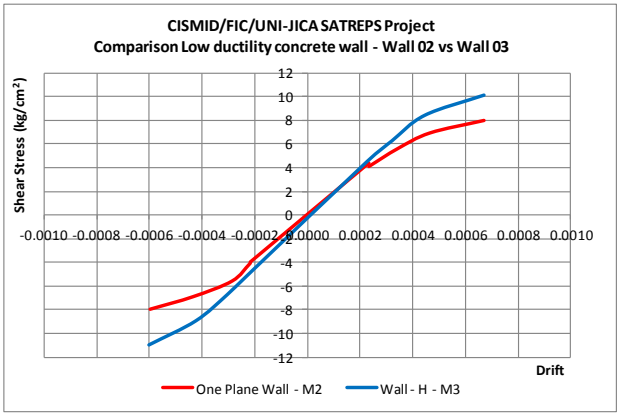

Figure 8: Behavior curves plane wall and H shape wall for drift less than 1/1600

On Figure 8 is presented the behavior curve prior the slip of the specimen. There is a notorious contribution of the perpendicular wall on the behavior.

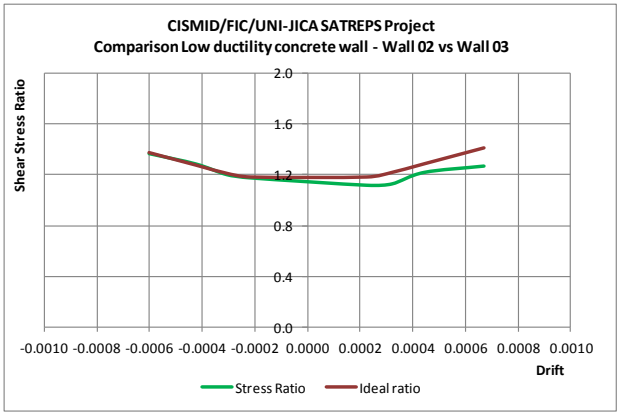

Figure 9: Stress ratio between H wall and plane wall

On green color is presented the shear stress ratio between the H wall and plane wall, that was compute from the test results. It is possible to the that when jack is pushing the curve shows a very defined ratio, however when jack is pull, the capacity of the system gave lower values. It is possible to recognize that ideal behavior on a simulation is given when jack is pushing the specimen. On red color in Figure 9, is presented ideal shear stress ratio for the wall. Here we can see that till behavior is elastic the ratio is about 1.18, so perpendicular wall action will increase 18% of shear stress capacity. After cracking of the specimen the increment became higher and reach a value of 1.40, so it means an increment of 40% in the shear resistance due to the perpendicular wall action.

A preliminary formula for the variation of the shear stress to evaluate the contribution of the perpendicular walls to the plane wall is the following:

$$\tau_H/\tau_{plane} = 552.98\gamma + 1.039 \qquad (1)$$

where τ_H/τ_{plane} is the shear stress ratio between the H wall with the plane wall and γ is the interstory drift.

3. CONCLUSIONS

Low ductility walls are an alternative to build middle rice buildings in Peru. Many research has been performed on plane walls however non research has been performed on this kind of wall to measure the perpendicular wall action. Therefore the present research present the first contribution in Peru for the knowledge of this action.

Two walls were investigate: one in plane and the other with H shape where the contribution of the flange to the in plane wall intend to be measure.

Unfortunately the H specimen slip occurs at 1/1600 drift during the test, after cracking occurs so test was completed showing similar results for the capacity of the walls.

Therefore, considering the behavior prior of the slip of the specimen shows a notorious difference between plane and H wall shear resistance.

This difference was evaluated in terms of ratio of both stresses for the same drift. Results shows that during elastic stage of the specimen, perpendicular walls contribute 18% to the shear resistance, but after cracking stress ratio increase till 40%. So the contribution of the perpendicular wall will be very important during the inelastic behavior of the wall

We need to continue the study in order to verify the spread of stress on perpendicular flange wall and web wall. We need to consider more study for the perpendicular action on the non linear behavior developing more test to prove the tendency of the preliminary formula (1) presented in this paper.

CFD ANALYSIS OF WIND PRESSURE ON THE COMPLEX HIGH-RISING STRUCTURE

Qiong Xing[1)],Jiang Qian [2)]

1) Phd Student, State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University, P. R. China
2) Professor, State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University, P. R. China
jqian@tongji.edu.cn *804119414@qq.com*

Abstract: The complex high-rising structures are more with increasing heights and more complicated shapes. Wind load is the control lateral load. Now wind tunnel test is an effective method of predicting the wind pressure distributions on the complex high-rising structures. But the similarity coefficients of the wind tunnel test can not be satisfied, and the model making and test conditions are limited. Having Shanghai TV tower as an engineering background, the CFD numerical model was built, and the surface roughness heights of the cylinders and spheres were determined. Numerical results are found to have good agreement with experimental results. On the basis, the influence of surface roughness on the wind pressure of the sphere and three cylinders was discussed. The results show that : when the surface roughness is not symmetrical, the symmetry of the wind pressure distribution on the sphere changes a little; when the surface roughness of the three cylinders are different, the phenomenon of drift flow around three cylinders still exists.

High-rising structures are used more widely, e.g. electricity, communication technology and office building. The high-rising structures are more with increasing height and more complex shape. Wind load is a dominant lateral fore, but Load code for the design of building structure only gives the shape coefficient with simple and regular shapes in the uniform flow. This can not be satisfied with the engineering practice need. Wind tunnel test is an effective method of predicting the wind pressure distributions on the complex high-rising structures, for the flow pattern is complicated. Li (1997) did the wind tunnel test of Shanghai TV tower, discussed the wind load distribution and lift coefficient of the middle and upper spheres, and analyzed interference effects of the cylinder group and spheres and internal interference effects of the cylinder group. Gu (2009) did the wind test of Guangzhou new TV tower. Guanzhou TV tower body is a peripheral framework composed of steel tubes, horizontal annular members, and spiral diagonals. A new experimental technique of dividing the entire tower into sections is proposed for the wind load distribution. But wind tunnel tests have many limitations. The models and working conditions are limited for some unsatisfied similarity coefficient, long periods and high cost. With the development of computational fluid dynamics, Numerical simulation is adopted in predicting wind loading distribution. Chen (2006) presented the details of the numerical simulations of Henan TV tower. Wind load distribution, shape coefficient and wind velocity distribution are in good agreement with experimental results. Shanghai TV tower as the engineering background, simulations were done to get the static wind distribution of the tower. The wind tunnel test results done by Li (1997) shows that the wind load distributions of cylinder groups and spheres are asymmetric under symmetrical incoming flow which is called “bias phenomenon”. The phenomenon has not given the explicit explanation. In this paper, simulations of Shanghai TV tower were done to get the preliminary explanation and calculation.

1. INTRODUCTION

Shanghai TV tower called the oriental pearl TV tower is located in Pudong Park surrounded by the Huangpu River. The wind environment of the tower is complicated. The members of Shanghai TV tower are simple, so it is easier to get the interference effects of members. Shanghai TV tower is 454 meters high. The main part of the tower is composed of three nine-meter columns and spheres with diameters of 45m and 50m. The tower is supported by three stanchions with slanting angle 58°. The tower pictures are shown in Fig. 1. The three big circular cylinders are in equilateral-triangular arrangements. Spacing between cylinders is varied from 2 to 3 cylinder diameters. The interference between the three cylinders and between the three cylinders and spheres is very strong and complex.

Figure 1 pictures of Shanghai TV tower

2. NUMERICAL METHOD

The Realizable k- ε model is adopted for simulations of the tower. Based on finite volume method, SIMPLE is a guess-and-correct procedure for decoupling and solution of the discretised equations.

Boundary conditions: At the inlet, the mean velocity is 30m/s as the wind tunnel test. The turbulent intensity at the inlet of the computational domain is specified as 5% for the turbulent intensity is relatively small at the uniform velocity inlet. The pressure-outlet condition is used at the outlet of the computational domain. Symmetric plane boundary condition is employed at the top and the sides of the computational domains. Wall function boundary conditions are used for the cylinders and ground.

Data processing: the pressure coefficient of the tower is specified as (Bencai Huang, 2008) :

$$Cp = \frac{P - P_{\infty}}{\frac{1}{2} r V_{\infty}^{2}} \qquad (1)$$

Where P is the wind loading pressure; P_{∞} is the aerostatic pressure; r is the air density; V_{∞} is the inlet velocity.

3. SIMULATION OF THE TOWER SURFACE ROUGHNESS

3.1 Simulation of Cylinder Surface Roughness

The inlet conditions, Reynolds number and the surface roughness are the key factors in flows around circular cylinders (Emil Simiu et al., 1978). In real structures, the circular cylinders and spheres are in the super-critical regime. In numerical simulations, the surface roughness is the determined factor to get the cylinders and spheres in the super-critical regime, for the diameters of cylinders and spheres and the inlet velocity is already known.

In numerical simulations of the cylinder and sphere surface roughness, the turbulent model, boundary conditions and data handling were used as mentioned above. In this way, the surface roughness could be adopted in the numerical simulation of the tower.

In numerical simulations, diameters of cylinders and spheres are used as the ones in the tower. The diameter of the cylinder is 9m, and 270m in height. The diameter of the sphere is 50m. According to the wind tunnel test of the single circular cylinder (Huizhi Li, 2002), the surface roughness of cylinders determined by the wind tunnel test was adopted in numerical simulations. The non-dimensional roughness height (ratio of roughness height and the diameter) is 1.5×10-4. Given the similar coefficient of wind tunnel tests, the surface roughness height of cylinders is 0.00135m (full scale) (Bert Blocken et al.,2007). The numerical simulated model is shown in Fig. 2.

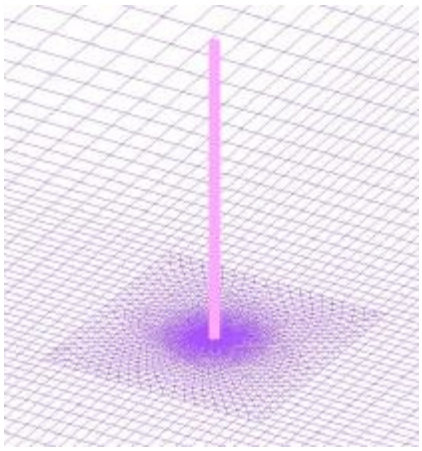

Figure 2 Numerical model of one cylinder

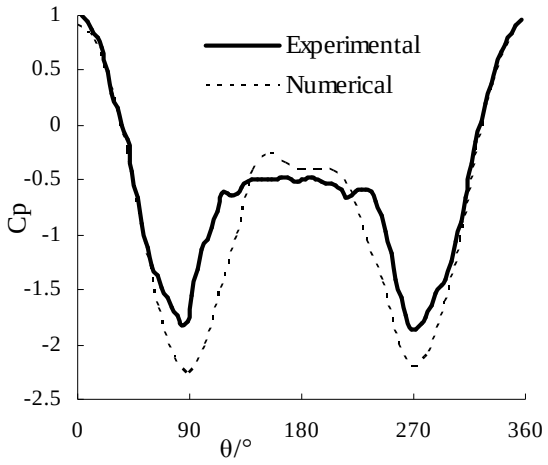

Figure 3 Comparison of numerical results and wind tunnel test results of one cylinder

To avoid three dimensional effects (Guochao Chen et al.,2011), results of the mid-section are adopted for comparison with the wind tunnel test results of one single cylinder (Huizhi Li,1997). Fig. 3 describes the comparison. The results show good agreement with experiments on the windward cylinder surface. The maximum Cp on the windward surface is 1. On the leeward surface ($90^\circ < \theta < 270^\circ$), the minimum Cp appears. The experiment result is near to -2. The numerical result is -2.26 within the experimental accuracy. The separation occurs approximately at 110° in experiment and 130° in simulations. On the leeward surface, there is a regime mean pressure coefficient is nearly uniform. The profiles of experiments and simulations are in the same trend. As mentioned above, the cylinder surface roughness satisfies the numerical simulation need of flow around cylinders in the super-critical regime.

3.2 Simulation of the Sphere Surface Roughness

In the wind tunnel test, the sphere model was made of wood covered by wire mesh (Huizhi Li,1997). There is not detailed data of the sphere surface roughness or the diameter of the wire in relative literatures. The surface roughness of spheres is an important factor in wind loading distribution of the tower. According to the diameters of wire and similar coefficient used in wind tunnel test, several roughness heights of the sphere were tested in numerical simulations. The roughness height of the sphere ranges from 0.04m to 0.2m. Fig. 5 reports the wind loading distributions of the sphere with different roughness heights.

As shown in Fig. 5, on the windward sphere surface, the wind load distributions of the sphere with different roughness heights are almost the same. The maximum Cp value is near to 1. The minimum mean pressure occurs at 90°. The separation point shifts from 110° to 130°. The absolute value of the minimum mean pressure decreases with increase of roughness height. The minimum mean pressure ranges from -1.085 to -0.849. On the leeward surface, the pressure coefficient decreases from 0.08 to -0.159 with increase of the surface roughness height. The sphere with roughness heights ranging from 0.04m to 0.2m is in the super-critical regime. The wind load distributions of the sphere with roughness heights ranging from 0.04m to 0.2m change slightly. All this indicates the wind loading distribution of the sphere is insensitive to surface roughness.

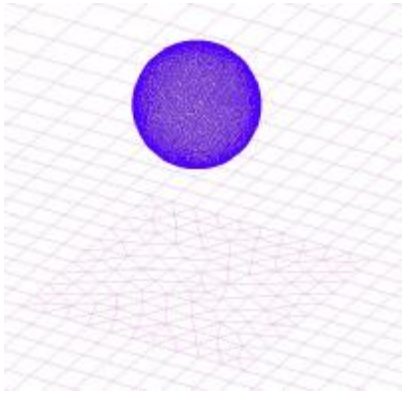

Figure 4 Numerical model of the sphere

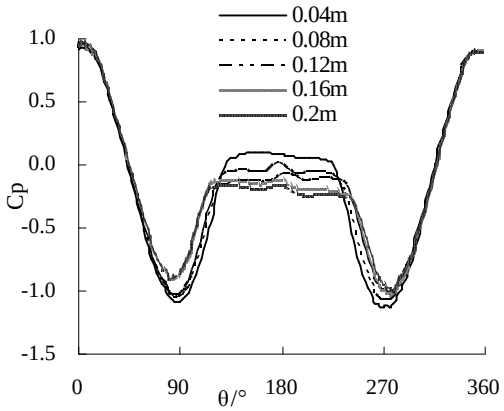

Figure 5 Pressure coefficient distribution of sphere with different roughness heights

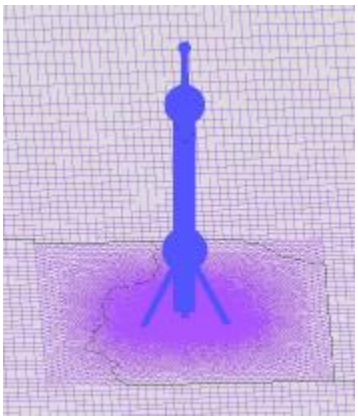

4. SIMULATION OF SHANGHAI TV TOWER

4.1Geometric Model

The structures above the space module are relatively small and their effect on wind load is negligible. So the structures above the space module are not included in the geometric model to reduce mesh amount and the computing time. In order to study interference effects of three cylinders, the small beams between the cylinders are omitted.

(a) Computational grid of the tower

(b) Computational grid of the vicinity of the tower

Figure 6 Mesh of numerical model of the tower

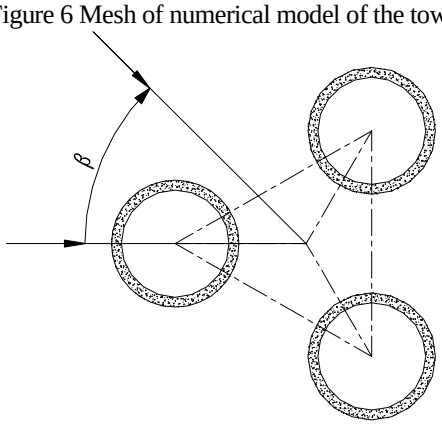

Figure 7 Schematic showing of the wind direction

4.2 Numerical Simulation Model

The computational domain is 2240m×4520m×1000m, in the span wise direction, the stream wise direction and normal to the ground wall. The tower is placed at 1/3 of the domain upstream. The tower is placed in a 320m×320m×500m rectangular sub domain(Guochao Chen et al.,2011). In the areas close to the tower, fine tetrahedral elements were used, whereas coarse hexahedron elements were used far away from the tower, as shown in Fig. 6. This handling can improve the computational accuracy and reduce the amount of mesh. The turbulent model, boundary conditions and data handling were used as the above. The cylinder surface roughness height is 0.00135m and the sphere surface roughness height ranges from 0.04m to 0.2m. The final surface roughness height is 0.1m according to comparison with the experimental results.

4.3Computing Conditions and Aata Handling

The calculating wind directions are 0° ,15° ,30° ,45° ,60° . Schematic showing of the wind direction is shown in Fig. 7. Fig. 7 shows 0° wind angle of attack.

4.4 Analysis of Computation Results

4.4.1 Analysis of Wind Load Distribution of the Spheres

In wind direction angle of 60, the wind loading distributions of the diameter surface at 75m in height and at 262.5m in height are compared with the experiment results done by Li(1997), as shown in Fig. 8 and Fig. 9.

On the windward and leeward surface of the lower sphere, the numerical results show good agreements with experiments. The maximum pressure coefficient reaches 1 on the windward surface. The pressure coefficients of the leeward surface range from -0.25 to 0.35. The minimum pressure coefficient reaches -1.12 and occurs at 90° approximately in numerical simulation and at 80° in the wind tunnel test. The separation point occurs at 110° in wind tunnel test and 130° in numerical simulation. The mean pressure distribution of the sphere is symmetric, and in contrast, the experiment result is not symmetric. There is deviation between the experimental and numerical results in the lateral direction on the windward surface.

On the windward surface, the numerical results fit better with experiments. The maximum pressure coefficient reaches 1 on the windward surface. The minimum pressure coefficient is nearly -0.9 in wind tunnel tests and -1.09 in numerical simulation and occurs at nearly 90° . On the leeward surface, the pressure coefficients of numerical results range from -0.2 to -0.26, and of the wind tunnel test results are nearly -0.45. But the numerical and experimental results are nearly in the same trend.

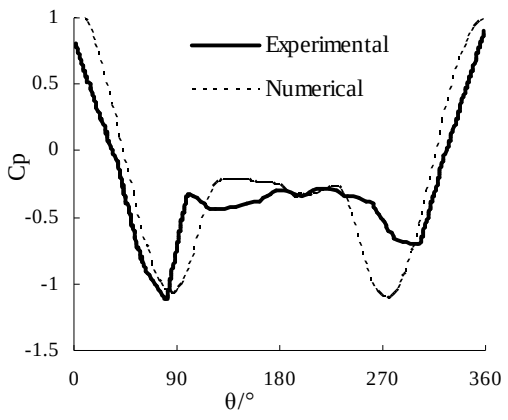

Figure 8 Pressure coefficient distribution of the sphere below

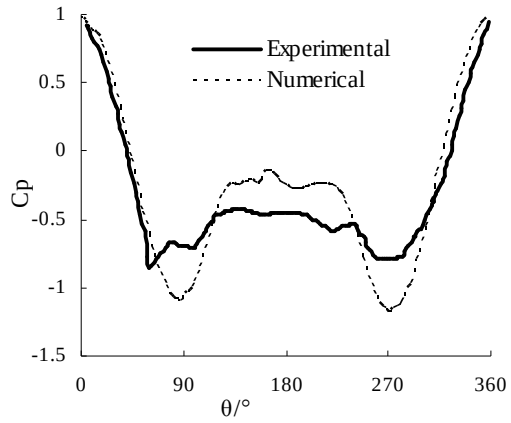

Figure 9 Pressure coefficient distribution of the sphere above

4.4.2 Analysis of Wind Load Distribution of the Cylinders

The mid-sections of the three cylinders are influenced little by the upper and lower spheres. Fig. 10, Fig. 11 and Fig. 12 report the wind loading distributions of the cylinders with cylinder 1 front and cylinder. As shown in Fig. 10, the maximum pressure coefficient is 0.9 and the minimum pressure coefficient is -3.37. The experimental minimum pressure coefficient is in the range of -2 to -2.5. The numerical wind loading distributions show good agreements with experiments in the same trend, except a little difference at 90° .

For cylinder 2 and cylinder 3, the wind loading distribution fits better with experiments on the windward surface and the difference between the numerical and experimental results is obvious on the windward surface. The wind loading distribution of the cylinder changes with different Reynolds numbers and different surface roughness heights. The minimum pressure coefficient ranges from -1.5 to -3. This can be concluded by literature (Huizhi li,1997; Zhifu Gu et al.,2001). The numerical results of cylinder 2 and cylinder 3 are within the range of -1.5 to -3. The numerical results are accepted according to relative literatures.

The numerical results show good agreements with experiments with the same trend. CFD numerical simulation can be a method of predicting wind load distribution of high-rising structures.

5. SURFACE ROUGHNESS INFLUENCES ON WIND LOAD DISTRIBUTION OF THE TOWER

5.1 Influence on Symmetry of the Wind Loading Distribution of the Sphere

The wind load distribution of a single sphere should be symmetric in symmetric flow. As shown in Fig. 5, the wind load distributions of spheres with different surface roughness heights are symmetric. In contrast, Fig.7 and Fig. 8 show the asymmetric wind loading distribution of the sphere in symmetric flow. This is inconsistent with empirical speculation. Some literatures predicted that the asymmetric wind load distribution of the sphere was probably related to the asymmetric surface roughness height and asymmetric interference of the cylinders. The numerical simulation model of the sphere with asymmetric surface roughness was made in FLUENT to study the asymmetric surface roughness influence. In numerical simulations, a part of the sphere surface is with 0.1m roughness height, and the left is with 0.08m, 0.12m, and 0.16m, respectively. Fig. 13 reports comparison of wind load distributions of the sphere with asymmetric and symmetric surface roughness. The profiles of wind load distribution of spheres with different surface roughness are almost the same, except a little discrepancy on the leeward surface. The profiles are symmetric as a whole. This means the asymmetric surface roughness has little influence on the wind loading distribution of the sphere. Finally, it is suggested that future studies can focus on the factors of the asymmetric wind loading distribution of the sphere.

5.2 Influences on Symmetry of the Wind Loading Distribution of the Group of the Cylinders

The wind loading distributions of the three cylinders are not symmetric in symmetric flow. The unsteady bias phenomenon is found in experiments and numerical simulations done by Gu (2001), K.Lam(1988), S. G. Pouryoussefi(2011) and Yan(2010), et al. Literatures did not give the explicit explanation of the bias phenomenon so far. Some literature predicted that the bias phenomenon was related to the surface roughness. The numerical simulation model of the cylinder under three different working conditions was built to study surface roughness influence. Working condition 1, the surface roughness height of three cylinder is all 0.00135m. Working condition 2, the surface roughness heights of cylinder 1, cylinder 2 and cylinder 3 are 0.00135m, 0.0018m and 0.0018m, respectively. Working condition 3, the surface roughness heights of cylinder 1, cylinder 2, and cylinder 3 are 0.00135m, 0.0018m and 0.0027m, respectively. Fig. 14, Fig. 15 and Fig. 16 report the comparison of wind distribution of the three cylinders under three working conditions.

The distributions of the three cylinders are almost the same under working condition 2 and 3. The separation point shifts toward 10°. The pressure coefficient at 90° under working condition 2 and 3 is 0.5 bigger than the one under working condition 1. The pressure coefficient at 270° under working condition 2 and 3 is 0.9 smaller than the one under working condition 1. The asymmetry of wind load distribution of cylinder 3 is improved under working condition 3. It suggested the bias phenomenon still exists when the three cylinders are with different roughness heights but the bias extent decreases. Further study of the bias phenomenon needed to be done.

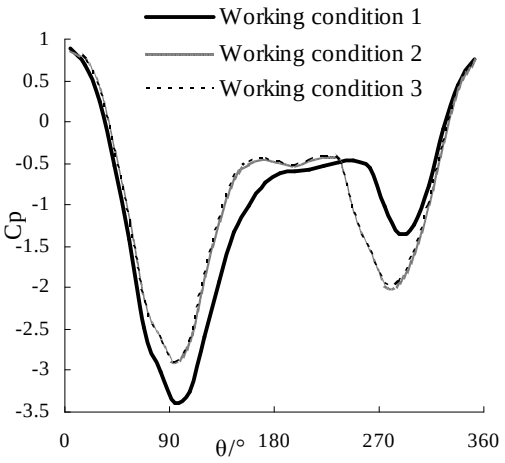

Figure 14 Pressure coefficient distributions of cylinder 1 under three working conditions

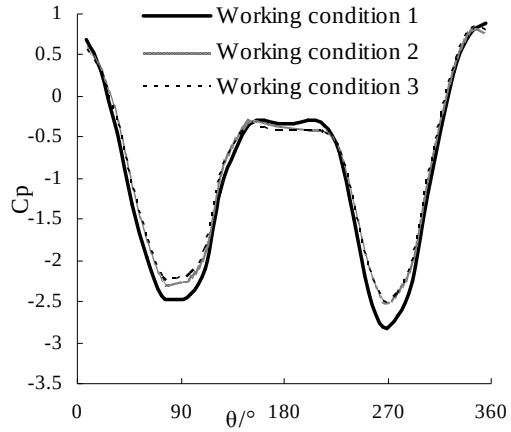

Figure15 Pressure coefficient distribution of cylinder 2 under three working conditions

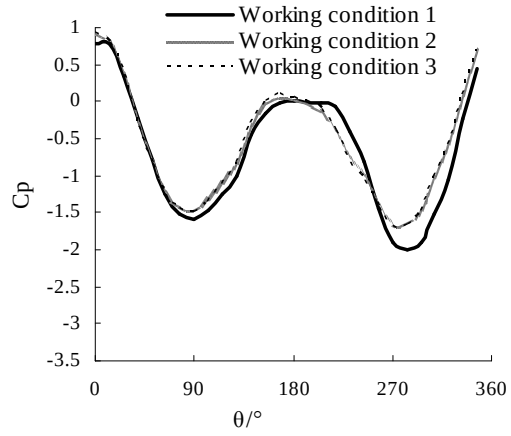

Figure 16 Pressure coefficient distribution of cylinder 3 under three working conditions

6. CONCLUSIONS

The main results may be summarized as follows:

(1) In comparison with the experimental and numerical loading distribution of the upper and lower spheres and the group of three cylinders, the numerical results show good agreements with experiments on the windward surface. Small differences are found between numerical and experimental results on the leeward surface within experimental error. CFD numerical simulation can be an effective method of predicting wind load distribution of high-rising structures.

(2) The surface roughness plays an important part in turbulent flow around spheres and cylinders. According to experimental and empirical surface roughness heights, the spheres and cylinders are in the sup-critical regime. The wind loading distribution of the sphere changes slightly in a specific range of surface roughness heights.

(3) In comparison of the wind load distributions of the sphere with symmetric and asymmetric surface roughness, the symmetry of the wind load distribution of the sphere changes a little in a specific range of surface roughness heights.

(4) Bias phenomenon still exists among the three cylinders when the surface roughness of the cylinders changes, but the extent of the bias decreases.

DYNAMIC ANALYSIS OF EXISTING NON-CONFORMING CONCRETE GYMNASIA WITH STEEL ROOF

Tetsuya Ohmura[1] and Shizuo Hayashi[2]

1) Associate Professor, Engineering Faculty, Tokyo City University, Japan
2) Professor, Materials and Structures Laboratory, Tokyo Institute of Technology, Japan
tohmura@tcu.ac.jp, hayashi.s.ac@m.titech.ac.jp

Abstract: Numerous gymnasiums were damaged at the 2011 Tōhoku earthquake and tsunami. Much of them were built before the Japanese building standard was revised. There are many gymnasiums besides Tohoku region and they should be strengthened to prepare to a large earthquake which might occur in the near future. However, it is often hard to strengthen them, because they have concrete posts to support their steel roof. Some of them were retrofitted by buttresses in the past, while the conventional method using buttresses needed much space to construct it and have a cost problem. We suggested a new retrofit method for them based on our dynamic analyses results.

1. INTRODUCTION

The Japanese building standards act was revised in 1981 based on experience gained from past earthquake disasters. However, there are still numerous school buildings and gymnasia built before 1981 that lack sufficient seismic performance. The seismic strengthening of these buildings has been promoted but there are many problems preventing it, including the cost and time required for the work. Advanced seismic strengthening methods have been expected to minimize the construction expense and to shorten the construction period.

When the Japanese building standard act was revised in 1981, not only the allowable stress design method for DBE but also the limit design method considered plastic hinges mechanism for MCE were shown. So buildings built before the revised were designed based on the former method, and there are a lot of existing non-conforming buildings which had the low control level of the work and the quality. The Hanshin Awaji earthquake of 1995 increased public awareness of the lack of sufficient seismic performance for existing non-conforming buildings. The law promoting the strengthening of buildings was enforced in that year, and numerous existing nonconforming buildings have been strengthened.

Public school buildings are often put to practical use as evacuation locations and earthquake resilience footholds, and seismic assessments and strengthening have been performed for concrete school buildings and steel gymnasia with the goal of ensuring the safety of students. Thus, the ratio of buildings with sufficient seismic performance has been steeply increased.

Generally, the codes by The Japanese Building Disaster Prevention Association (BDPA) are used for the seismic assessment and strengthening of concrete buildings. On the other hand, various strengthening methods that consider construction conditions have been developed and used in different social backgrounds.

In addition, school gymnasia have been done seismic assessment and strengthened based on codes by BDPA and the education ministry. If it is determined that steel gymnasia or combined concrete and steel gymnasia lack sufficient seismic performance, they should generally be strengthened by the addition of braces in the longitudinal direction and knee braces in the span direction.

However, to strengthen the two-story concrete school gymnasia with steel roofs shown in Figures 1 to 3, it would be easier to be strengthened in the longitudinal direction because they contain moment frames with shear walls, whereas being strengthened in the span direction would be harder because they contain concrete posts.

Figure 4 shows a sample of seismic strengthening for an independent concrete post. Their seismic performance depends on their ultimate moment strength of the bottom column or the rotation strength of the base, because they should be a cantilever during an earthquake. A strengthening method that involves the construction of a buttress after a pile and base were constructed was often used for buildings that lack base rotation strength. This strengthening method requires some room around the building and a longer construction period, which tends to increase the construction cost.

Although the above mentioned strengthening would be needed if the lack of sufficient seismic performance of an

independent concrete post was found after being assessed based on the codes, a longitudinal concrete girder has actually expected to be effective for an independent concrete post. Thus, there have been no heavily damaged or overturned independent concrete posts in past disasters.

In this study, three-dimensional static nonlinear analyses for two-story concrete gymnasia with steel roofs were performed and the hysteretic characteristics of each member were determined. Then, three-dimensional time history response analyses were performed in the span direction. The effect of longitudinal concrete girders was examined. The ultimate moment strength of these girders was increased, and the seismic performance of the building was studied. These results could be used as the basic data for a design to strengthen concrete gymnasia.

2. BUILDING

The building for our analyses is shown in Figure 1 to 3 as mentioned before. It has a stage in the west, an entrance in the east, an arena for basketball in the center. There are some gallery at the second floor level consist of some cantilever slab from the longitudinal concrete girders at the second floor.

Longitudinal concrete girders were also used at the roof level. The roof, which consisted of steel girders and horizontal braces, was supported at the top of independent concrete posts, but the lateral force at the roof could not be transferred via horizontal braces because of a lack of strength.

There are some concrete walls with opening in the longitudinal direction at the first floor and a moment frame in the second floor, as shown Figure 2. The seismic index of structure in their seismic assessment based on the BDPA was 1.12 at the first floor, and 0.87 at the second floor.

The stiffness and strength values in frames X1 to X2 and X7 to X8 were higher because there are many concrete walls around the stage in the west and the entrance in the east. The seismic index of the structure was 2.05. On the other hand, the stiffness of the independent concrete posts in frames X3 to X6 was lower and the seismic index of the structure was 0.47 because they were cantilever posts.

The independent concrete posts were located 6 meter apart in X3 to X6, the span in the Y direction was approximately 20 m, and the height of the eaves was approximately 9 m. Figures 5 and 6 show the statistics for the span and eave heights. This statistics included 26 gymnasia with the same structure.

The painted plot in the Figure means the gymnasia for our analyses. Independent concrete posts were located 5.0 to 7.5 m apart, the spans in the Y direction were 17.5 to 31.0 m, and the eave heights were 7.2 to 10.0 m in the statistics. The span and eave heights of the gymnasia in our analyses were typical.

Figure 7 shows component of the gymnasia. The depth in the span direction of the independent concrete post was 700mm, and the width was 600mm. 18 rebar D22 (#7) was located at the first floor, and rebar was decreased at the second floor.

The hoop diameter and interval were 9 mm and 100 mm, respectively. The widths of the girders were 350 mm at the second floor and 300 mm at the roof level. Their depth was 600mm. The compressive concrete strength was 32 N/mm^2, and the yield strength of the rebar was 343 N/mm^2.

3. ANALYSIS

Push over analysis was performed using 3 dimensional non-linear analyses at first. Next, their hysteretic characters of columns, posts, shear walls and girders were respectively determined by the modified Takeda model. Then three dimensional time history dynamic analyses were performed.

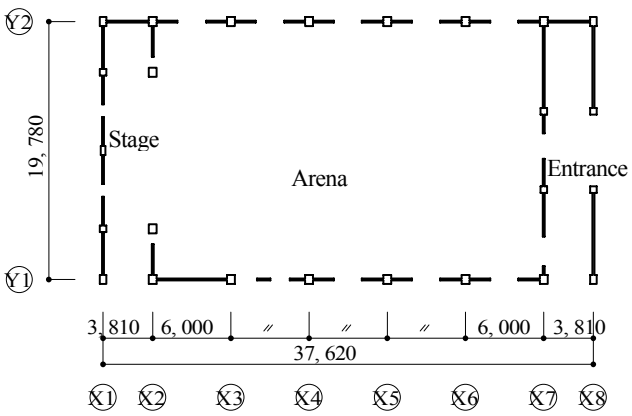

Figure 1 Plan (unit mm)

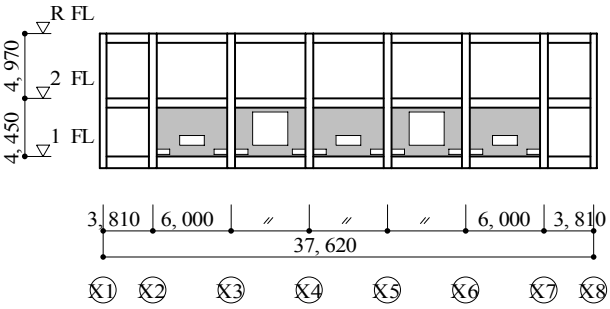

Figure 2 Y2 frame Elevation (unit mm)

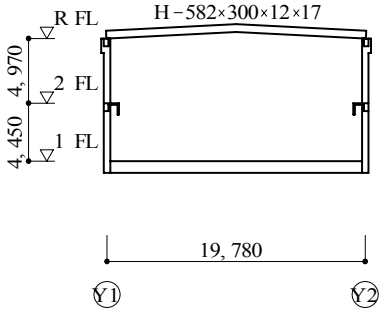

Figure 3 X4 to 6 frame Elevation (unit mm)

3.1 Modeling

Figure 8 shows models of the columns and girders. The model of the girder used two moment springs to consider cracking at both ends, along with a shear spring. The in-plane and out-of-plane moments were considered, but they were independent of each other. The combined moment effect was ignored.

It was assumed that the only rebar at the corner of the section was effective for the out-of-plane moment strength of the girders. The bending shape at the end of the hoop was 90°, but the effect of it was ignored.

The model of the columns has multi-springs at the both ends considered cracking and a shear spring.

The rotation strength of the base is considered, and they are modeled as the moment strength of the foundation girder.

As mentioned above, the horizontal braces at the roof could not transfer the lateral force of the roof, and the displacements of the independent concrete posts were different respectively.

The static earthquake load is determined by Ai in the Japanese building standard act. Masses were located at the second floor and roof level in our dynamic analyses, as shown in Figure 8.

Pin supports are located under the foundations, and the vertical and horizontal displacements of the foundations are ignored. Pushover analyses were stopped when any drift angle reached to 4%.

Figure 9 shows the ultimate moment strength of the longitudinal concrete girder in each run. Four runs were performed. Run #1 was performed for the original model for the existing gymnasia, and runs #2, #3, and #4 were performed for models with girders that have 9, 13, and 41 times the moment strength.

3.2 Earthquake motion input

Figure 10 shows the acceleration response spectra for the earthquake motion input. Five earthquake motions were input in the horizontal direction in the span direction. Their phases for the target spectra by BRI were based on El Centro NS (1940), Hachinohe NS (1968), JMA Kobe NS (1995), Taft EW (1952), and an artificial earthquake wave (BCJ-L2).

The target spectra were the acceleration response spectra, BRI-L2, which are represented by the horizontal motion normalized response spectra times the response equivalent ratio of the damping.

4. PUSH OVER ANALYSIS RESULTS

4.1 Hysteresis curve

Figure 11 and 12 show the hysteresis curve of the original model #1. Only frame Y2 are focused, because

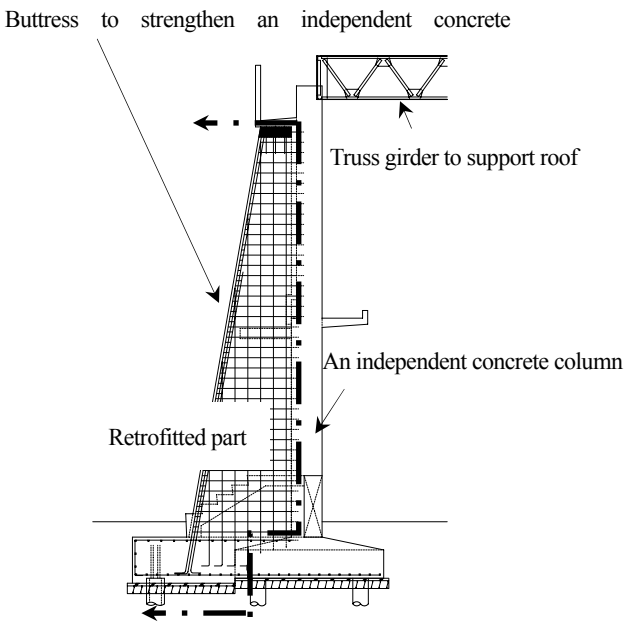

Figure 4 A detail of buttress

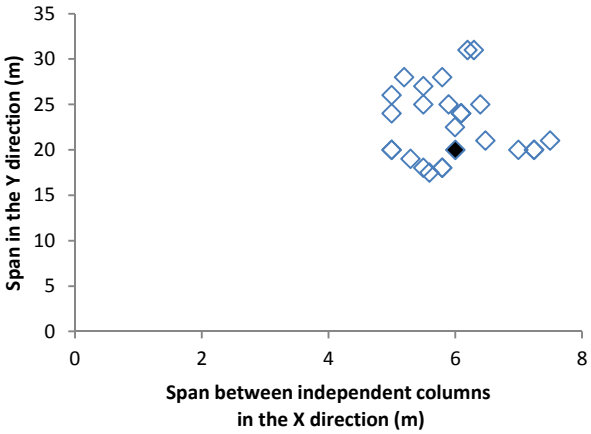

Figure 5 Statistics of span

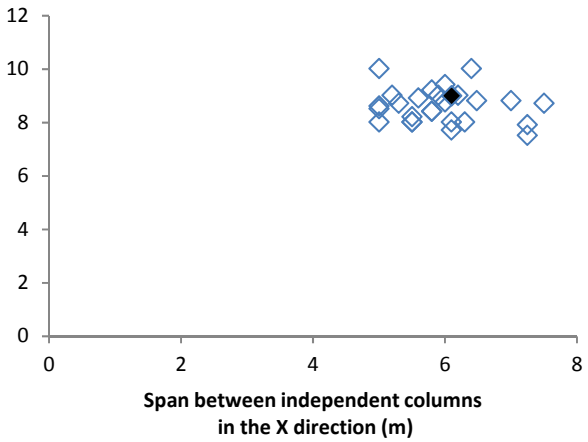

Figure 6 Statistics of eaves

the model is approximately symmetric.

Frames X1 to X2 with concrete walls are stiffer and have higher lateral strengths than frames X3 to X4 with the independent posts. The pushover analyses were stopped after a collapse mechanism was formed at frames X3 to X6 with the independent concrete posts and reached a sufficient drift angle.

The stiffness of frames X3 to X4 declined after a drift angle of about 0.3% at the second floor and at about 0.2% at the first floor, and a collapse mechanism formed at about 1.3% at the second floor and at about 1.1% at the first floor. Then, the lateral force was about 50 kN at the second floor and about 90 kN at the first floor.

The drift angle of frame X1 to X2 at the final step is about 3.1×10^{-3}% at the second floor and about 2.3×10^{-3}% at the first floor, and there is no stiffness reduction. They have high stiffness and strength because of concrete walls.

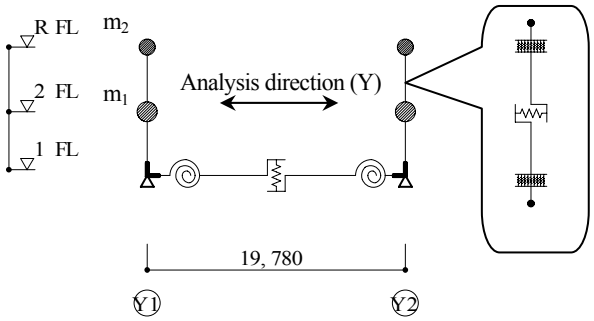

Figure 8 Column and girder model

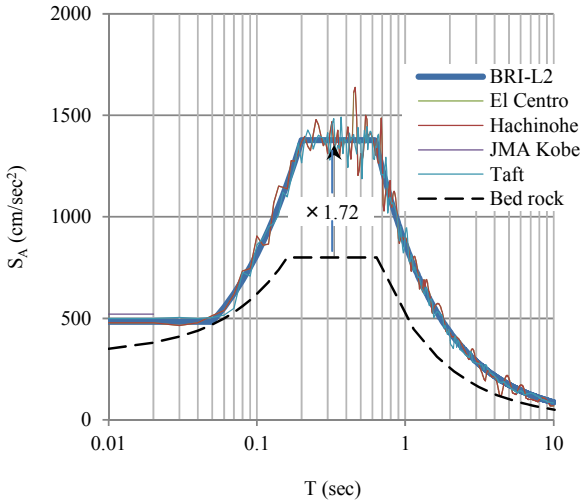

Figure 10 Acceleration response spectra

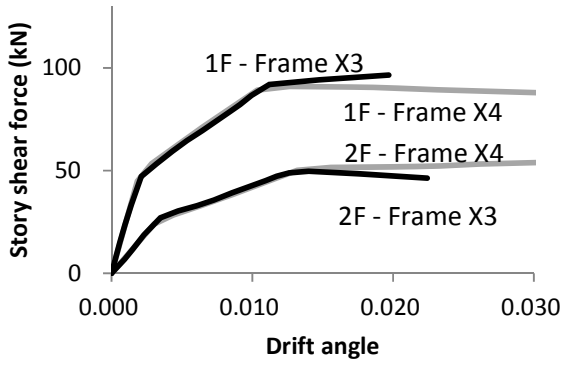

Figure 11 Hysteresis curve

4.2 Moment and hinge diagram

Figure13 shows a moment and collapse mechanism diagram for the original model #1. The moment diagram of the independent concrete posts in frame X3 to X6 is the same as that of a cantilever.

The out-of-plane moment at the longitudinal concrete girders occurred at the second floor and roof level. This means the longitudinal concrete girders were effective for the independent concrete posts with the application of a lateral load.

The moment diagram of the longitudinal concrete girder was the same as that of a long span girder that has both ends fixed. Moment hinges were formed at the center and at both ends of the girder. The independent concrete posts resist for lateral load as a cantilever supported by longitudinal concrete girders.

5. TIME HISTORY RESPONSE ANALYSIS RESULTS

The three dimensional static analysis was performed in the section 4, their skeleton curves for the dynamic analysis were determined based on the modified Takeda model. Then, three-dimensional time history response analyses were performed in the span direction, and analysis results were discussed.

5.1 Maximum response shear force and coefficient

Figure 14 and 15 show maximum response shear force and shear coefficient of the original model #1. They represented analysis results of the elastic model and the non-linear model. The solid and dash line mean the first floor and the second floor.

The analysis results for the five earthquake waves were different respectively, but the analysis results for frame X4 were approximately the same as those for frame X5. The analysis results for frame Y2 were focused upon because frames Y1 and Y2 were approximately symmetric and the analysis results for their independent concrete posts were approximately the same.

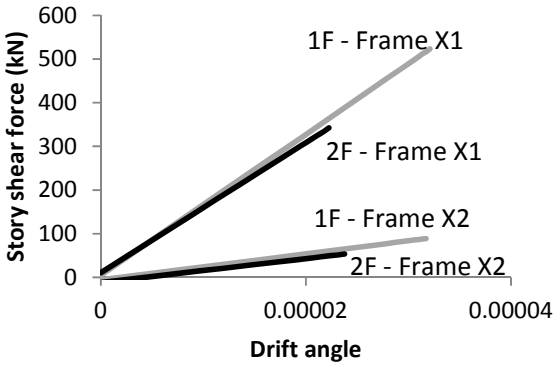

Figure 12 Hysteresis curve

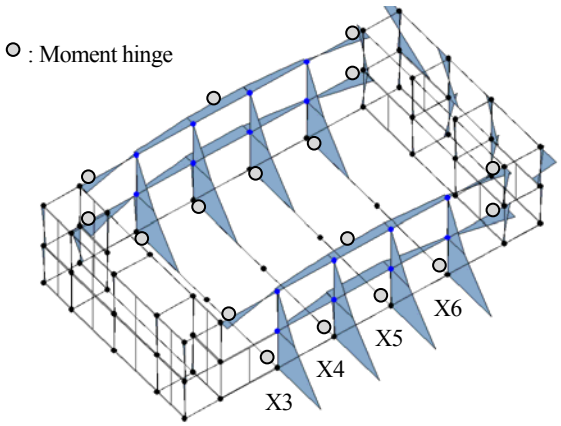

Figure 13 Moment and hinge diagram

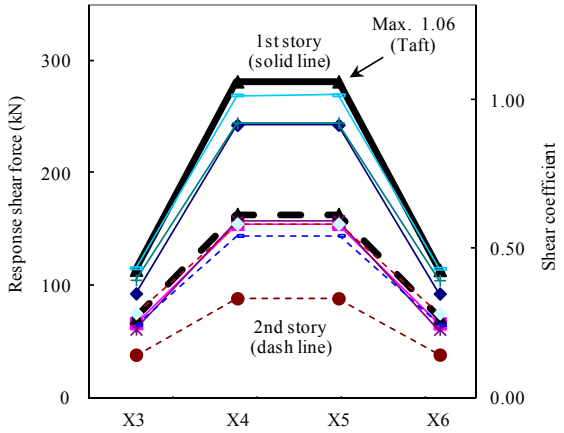

Figure 14 Response shear force (Y2 frame, elastic model)

(The original model)

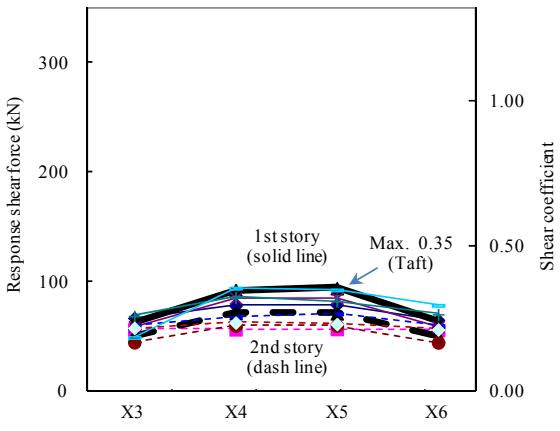

Figure 15 Response shear force (Y2 frame, non-linear model)

Maximum response shear coefficients of the elastic and non-linear models are 1.06 and 0.35. Maximum response shear coefficient is declined, because of plasticity of the frames.

Figure 16 shows the maximum response shear force and coefficient of model #3, where the out-of-plane moment strength of the longitudinal concrete girders was increased by 13 times. The maximum response shear coefficient of 0.36 was increased to 0.46 because the lateral strength of the independent concrete posts depended on the out-of-plane moment strength of the longitudinal concrete girders.

5.2 Maximum response inter story displacement and drift angle

Figure 17 shows maximum response displacement and drift angle at the roof floor. They were 220 mm and 2.3%.

Figure 18 shows maximum response displacement and drift angle of the model #3 which had 13 times the out of plane moment strength of the longitudinal concrete girders to the original model #1..

The maximum response displacement was decline to 81mm.

5.3 Effect of longitudinal girders for seismic performance

Maximum response shear coefficient was increased and maximum response displacement was declined in case out of plane moment strength of the longitudinal concrete girders was increased.

The method of seismic strengthening that the out of plane moment strength of the longitudinal concrete girders was increased was effective.

Figure 19 shows the relationship between the magnified ratio of the out of plane moment strength of the longitudinal

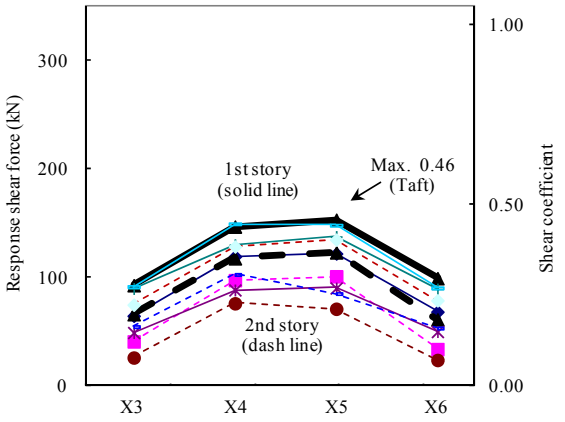

Figure 16 Response shear force (Y2 frame, non-linear model)

(Girder yield moment increased by 13 times to the original

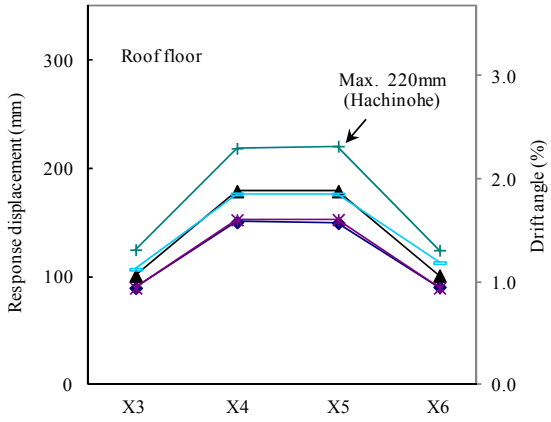

Figure 17 Response displacement (Y2 frame, non-linear model)

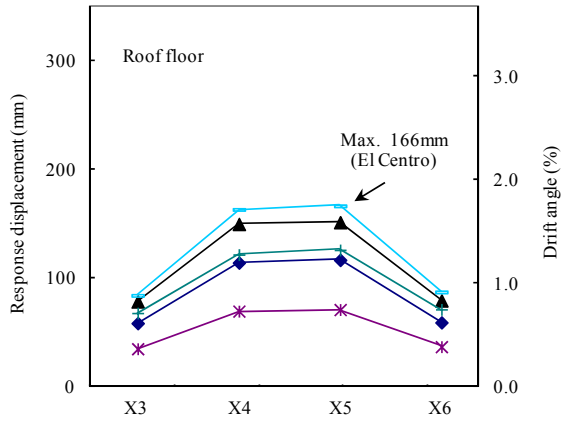

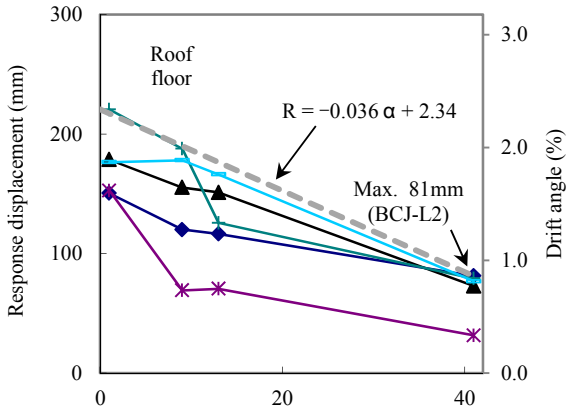

Figure 18 Response diplacement (Y2 frame, non-linear model)

(Girder yield moment increased by 13 times to the original

Magnification to ultimate momnet strength of girders

Figure 19 Relationship between magnification and drift angle

concrete girder and maximum response drift angle. The increment of the magnified ratio made maximum response drift angle decreased.

Maximum response drift angle could be calculated by using equation (1)

$$R = -0.036 \cdot \alpha + 2.34 \cdots\cdots\cdots\cdots (1)$$

where,

α = the magnified ratio of the out of plane moment strength of the longitudinal concrete girder

R = maximum response drift angle

6. CONCLUSION

1. An existing non-conforming gymnasium which had typical spans and eaves heights was modeled. The three dimensional static analysis results showed the effect of the longitudinal concrete girders for seismic performance, because moment hinges were formed at along them in the out of plane direction.
2. The three-dimensional time history response analyses results showed that the maximum response shear coefficient was 1.06 in the elastic model and 0.35 in the non-linear model.
3. The maximum response displacement was declined following increase of the out-of-plane moment strength of the longitudinal concrete girders.
4. The regression equation to calculate the maximum response drift angle using magnification ratio of longitudinal concrete girders.

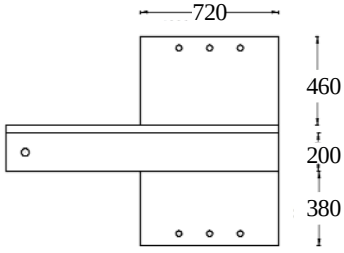
Abstract: This paper presents an investigation on the seismic behavior of T-beam-wide-column joints. First, a practical fiber-reinforced polymer (FRP) retrofit was proposed to enhance the lateral load capacity of such joints, and tests were carried out on both nun-retrofitted and retrofitted specimens. The applied retrofit increased the yield load by 18 to 28 percent and the ultimate capacity by 3 to 7 percent; however, enhancement in ductility was not observed. A finite element model using ABAQUS was next formulated and verified the behavior of the test specimens. The numerical model was then used to examine the effectiveness of an enhanced FRP retrofit scheme, which was found to increase the lateral load capacity of the joints by 47 to 70 percent, with ductile post-peak behavior.

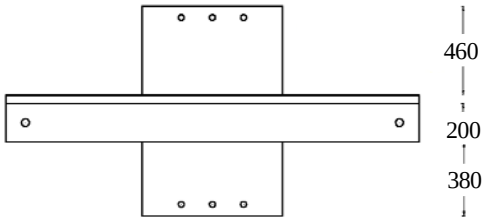
1. INTRODUCTION

Beam-column joints play an important role in the seismic response of building structures. In major cities in Asia, many buildings are gravity-load designed and they may be susceptible to the damaging effect of far-field earthquakes (Tan et al. 2012). In Singapore, in particular, columns in residential buildings often have a cross-section with a larger aspect ratio. As a result, beam-column joints are typically in the form of a T-beam wide column joint.



The behaviour of gravity-load designed T-beam-wide column joints under cyclic loading is not well understood. A study was therefore carried out to examine the lateral load capacity of T-beam-wide column joints. Both interior and exterior joints with and without FRP retrofit were tested. The results were used to verify a finite element model that was developed using ABAQUS (Dassault Systemes Simulia Corp., 2010) to predict the joint behaviour. An enhanced retrofit scheme was then established based on the test results of the retrofitted joints, and the verified model.

2. TEST PROGRAM



Exterior and interior T-beam-wide column joints were selected from the first/second stories of a 15-storey residential building. The first storey height is typically about 25% longer than upper storeys. The joints are designed without seismic provisions to BS8110 (BSI 1985) which resulted in the longitudinal reinforcement at the bottom of the beam being about half of that at the top. The transverse steel ratio in the column was 0.2%, and consisted of mild steel links with characteristic yield strength of 250 MPa. Longitudinal steel ratio in the column was 2.4%, and comprised high strength steel bars having characteristic yield strength of 460 MPa. No transverse reinforcement was provided in the joint region.

2.1 Test Specimens

The test specimens were two-fifth scaled models of the prototype joints, and the dimensions are shown in Figure 1.

(a) Exterior joint

(b) Interior joint

Figure 1 Dimensions of test specimens (*in mm*)

In total, four joint specimens were prepared and tested. They are labelled EU, ER, IU and IR, as shown in Table 1, with E denoting an exterior joint and I an interior joint.

The symbols U and R indicated unretrofitted and retrofitted specimens, respectively. In each specimen, the column segment has a height of 1040 mm, with a length of 460 mm above the top face of the T-beam and 380 mm below the soffit of the beam. It has a cross-section measuring 720 mm by 120 mm. The T-beam has a flange width of 400 mm, flange thickness of 40 mm, web width of 120 mm and overall depth of 240 mm. The beam protrudes a length of 600 mm on one or both sides of the column in the direction of the longer section dimension.

Table 1 Description of joint specimens

Designation	Type	Condition	f_c'(MPa)*
EU	Exterioir	Un-retrofitted	29.2
ER	Exterior	Retrofitted	21.3
IU	Interior	Un-retrofitted	27.4
IR	Interior	Retrofitted	27.7

*concrete compressive strength at day of testing joint, based on average of three cylinders

All joint specimens have similar arrangement of steel reinforcement as shown for an interior joint in Figure 2. The column had sixteen 13 mm diameter (deformed) bars as longitudinal reinforcement, and 6 mm diameter (smooth) closed links at 90 mm spacing as transverse reinforcement. The flange of the beam had 6 mm diameter (deformed) bars at 130 mm spacing in two orthogonal directions at the top acting as negative reinforcement. The beam was further reinforced with four 10 mm diameter (deformed) longitudinal bars at the top and two 10 mm diameter (deformed) bars at the bottom, with 6 mm diameter (smooth) closed links at 90 mm spacing as transverse reinforcement.

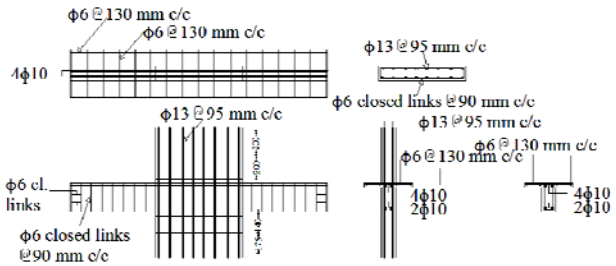


Figure 2 Steel reinforcement details

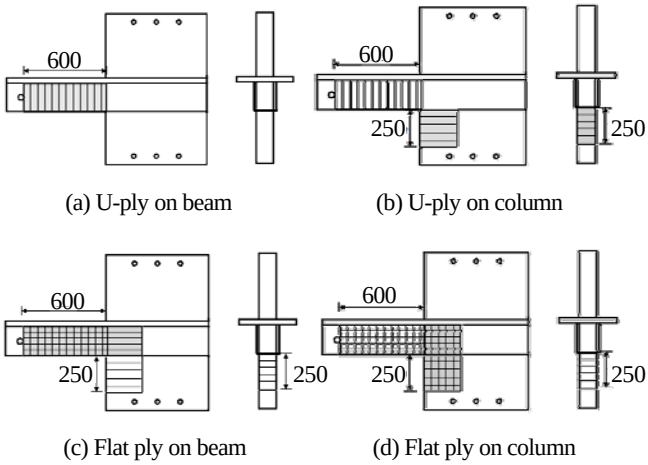
The concrete had a target cylinder compressive strength of 25 MPa at 28 days. Ordinary Portland cement, natural sand (fine aggregate), crushed granite of 10 mm maximum size (coarse aggregate) and water were mixed in ratio of 1: 3.08: 3.14: 0.79 by weight. The cement content was 289 kg/m^3.



The average yield strengths for 6 mm (smooth), 6 mm (deformed), 10 mm (deformed) and 13 mm (deformed) bars were 245, 375, 482 and 528 MPa, respectively.

Carbon FRP sheets were used to retrofit the joint specimens. They had a design thickness of 0.176 mm/ply and a fibre weight of 300 g/m^2, with an elastic modulus of 240 GPa, tensile strength of 3800 MPa and elongation at rupture of 1.55%, according to the manufacturer's specifications. A three-part resin with the main component, hardener, and powder, mixed in the portional of 2 : 1 : 2 by weight was to bond the FRP sheets.

2.2 Fabrication of Joint Specimens

The reinforcement cage was assembled and concrete cast. Holes were provided at the ends of the beam and column components (see Figure 1) to facilitate the passing of through bolts to simulate pin connection during testing of joints. The specimens were stripped off the mould 24 hours after casting, and then placed under wet gunny sacks for at least 28 days. After that, the specimens were left inside the laboratory.

FRP sheets were applied only on the part below the flange of the beam to simulate actual condition. The surface of the specimen was first grinded to remove dust, grease, disintegrated materials and other bond inhibiting materials. Then, resin was applied on the required surface using a roller, followed by installation of the carbon FRP sheets. Figure 3 illustrates the procedure in which the FRP sheets were applied for Specimen ER. The same FRP system was applied to Specimen IR. After the installation of the FRP system, the joint specimens were left in the laboratory for a week before testing.

Figure 3 FRP retrofit of joint specimen

2.3 Test Set-up, Instrumentation and Procedure

The joint specimens were tested with the column in an upright position, as shown in Figure 4. The column pin support was considered as the point of contraflexure for the bottom column, while the centre of actuator was considered as the point of contraflexure for the top column. The beam ends were connected to the test floor by means of C-channels on each side, with high strength G 8.8 bolts forming the pin and roller joints.

Axial load was applied on un-retrofitted exterior joint specimen, that is, EU, only, using prestressing strands that were tensioned between stiffened plates mounted at the top and bottom of the column.

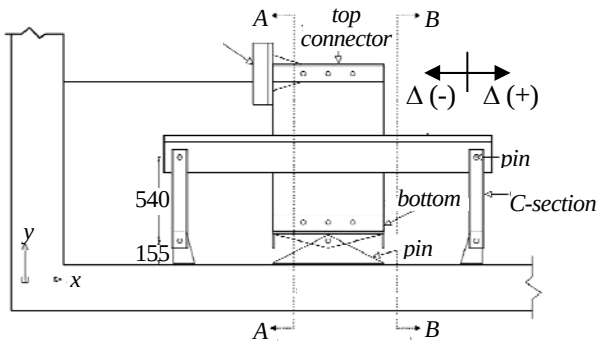

Figure 4 Test set-up (*dimensions in mm*)

The axial load ratio was 0.10. It was however found that the axial load ratio up to 0.5 (Ahmed 2013) has little effect on the response of the joint to lateral loading. Consequently, axial load was not applied to the remaining three specimens.

Each test specimen was instrumented with strain gauges to monitor strains in concrete, steel and FRP sheets in the vicinity of the joint. Linear variable displacement transducers (LVDTs) were used to measure the lateral displacement at top and bottom of the column segment as well as ends of beam segments, and vertical and horizontal displacements at the beam-column interfaces.

The un-retrofitted specimens, EU and IU, were tested under static pushover loading, for which the rate of loading was 0.02 mm/min throughout. On the other hand, the FRP retrofitted specimens, ER and IR, were tested under cyclic loading with the loading cycles shown in Figure 5.

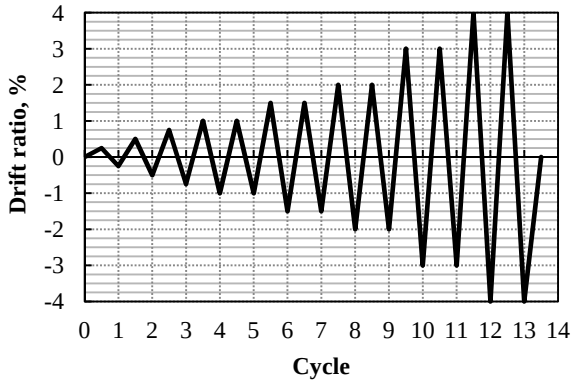

Figure 5 Loading cycles for retrofitted specimens

The rate of loading for the FRP retrofitted specimens was 0.01 mm/s for the first three cycles with maximum drift ratios of 0.25%, 0.50% and 0.75%, respectively. The drift ratio was defined as the lateral displacement of the top relative to the bottom of the specimen, divided by the specimen height. From the fourth cycle onwards, the loading rate was 0.02 mm/s.

The loading was paused after every full cycle to locate the regions of FRP debonding and rupture and the crack pattern. The test was stopped after the load had dropped 20% below the peak value.

3. TEST RESULTS AND DISCUSSION

Figure 6(a) shows the observed load versus lateral displacement at the top of specimen (corresponds to point of contraflexure in the upper column) for exterior joints, while Figure 6(b) shows the same for interior joints.

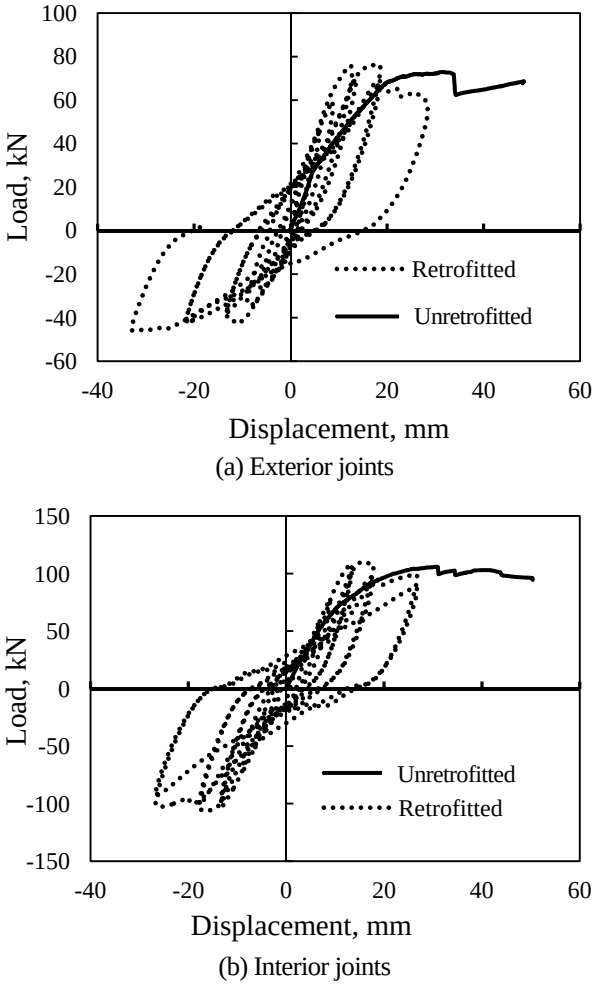

Figure 6 Load-lateral displacement relations

3.1 Unretrofitted Joints

The exterior joint [Figure 6(a)] experienced first flexural cracking at the top of the slabs at a load of 25.2 kN and a displacement of 4.3 mm. Inclined shear cracks began to form from the bottom of slabs at a load of 40.1 kN and discplacement of 8.8 mm.

The cracks subsequently propagated towards the beam-column joint and first yielding of longitudinal steel occurred in the top beam bars under tension at a load of 64.3 kN and displacement of 18.1 mm. Concrete began to crush at about 68.6 kN and 19.6 mm. Due to crushing and spalling of concrete, failure occurred at 72.4 kN and a displacement of 33.1 mm. Finally, the slab was completely cracked under tension near the beam-column joint. Thus, most of the damage occurred in the beam near the beam-column joint, resulting in shear-compression failure of the beam. There was negligible damage in the column or

the joint although some inclined cracks formed at the joint.

Similar behaviour was observed for the interior joint. Flexural cracks first appeared at the top of the slabs, load of 25.8 kN and a lateral displacement of 3.22 mm. Cracks began to form from the bottom of the beam on one side of the beam column joint at 37.1 kN and a displacement of 4.77 mm. At 46.1 kN and 6 mm, these cracks had propogate4d to the bottom of the slabs and subsequently towards the joint region.

Yielding of steel reinforcement first occurred at bottom of the beam near the joint at 80.1 kN and 13.1 mm, then on top of the beam on the other side of the joint at 94.8 kN and 18.9 mm. Concrete began to crush at the bottom of the beam near the beam-column joint at about 98.2 kN and 21.1 mm, and failure finally occurred at 105.9 kN at a lateral displacement of 30.8 mm.

Most of the damage was found in the beam near the beam-column joint. There was negligible damage on the column or the joint although some diagonal cracks formed in the joint. Shear compression failure was observed in the beam on one side and flexural tension failure on the other side of the joint.

3.2 FRP-Retrofitted Joints

Both FRP retrofitted exterior and interior joints were tested under cyclic loading (refer Figures 4 and 5). The push direction is referred as the positive (+) direction and the pull direction as the negative (-) direction.

The retrofitted exterior joint ER experienced first flexural cracking in the slabs during the second cycle at a load of 24.1 kN and a lateral displacement at the top of the specimen of 3.1 mm [Figure 6(a)]. These cracks propagate with subsequent cycles. There was however no significant stiffness degradation up to the third cycle.

The longitudinal bars at the bottom of the beam first yielded at the 4^{th} cycle under a load of 40.1 kN and a displacement of -9.25 mm. Rupture of FRP sheets happed in the 5^{th} cycle at 42.9 kN and -11.2 mm. The specimen maintained its strength under positive loading throughout the next two cycles but lost stiffness and began to experience a drop in load-carrying capacity in the negative direction.

Next, yielding of the top longitudinal bars of the beam occurred in the push direction of the 7^{th} cycle, at 75.8 kN and +12.4 mm. The maximum lateral load capacity was attained with concrete crushing at 76.3 kN and +17.9 mm in the same cycle.

The test was terminated after 10^{th} cycle due to extensive damage of the specimen. Most of the damage again occurred near the beam column joint. Some shear cracks which initiated in the non-retrofitted regions, formed at the top and bottom of the columns and in the joint. FRP debonding was also observed in the beam and the joint, mainly due to compressive forces, but also partly due to poor bond between the FRP sheets and concrete in the joint region.

The retrofitted interior joint exhibited first flexural cracking at the top of the beam flange during the second cycle at 24.3 kN and +2.8 mm. Although the crack propagated subsequently, there was no stiffness degradation up to the 5^{th} cycle.

Yielding of the bottom longitudinal bars in the beam bottom occurred on both sides of the joint during the 6^{th} cycle, at 102.7 kN and +13.4 mm, and 97.3 kN and -12.3 mm. The maximum lateral load capacity was reached in the 7^{th} cycle due to rupture of FRP sheets on both sides of the joint followed by concrete crushing, at 108.1 kN and +18.2 mm, and 105.6 kN and -17.1 mm. The flanges on both side of the joint were found to be completely cracked across. The test was terminated after 10^{th} cycle due to extensive damage of the specimen.

Similar to the retrofitted exterior joint, most of the damage occurred near the beam-column connection, and some diagonal cracks formed at the top and bottom of the columns and in the joint. FRP debonding was also observed in the beam and the joint.

3.3 Effectiveness of Applied Retrofit

Figure 6(a) compares the lateral load response of un-retrofitted and etrofitted exterior joint, while Figure 6(b) shows the comparison for interior joints. The behaviour of retrofitted joint was similar to that of the un-retrofitted joint in the first cycle up to 30 kN for exterior joints, and 45 kN for interior joints, at which cracking occurred in the un-retrofitted joints. However, due to earlier cracking and subsequent yielding, the un-retrofitted joints exhibited more ductile behaviour at failure.

The displacement ductility, defined as the ratio of the lateral displacement at concrete crushing of the critical section to that at first yield of steel reinforcement, was 1.83 for the un-retrofitted exterior joint EU, and 2.35 for the un-retrofitted interior joint IU.

For FRP-retrofitted exterior joint ER, the failure mode was actually more brittle with debonding followed by concrete crushing while being loaded in positive direction and FRP rupture while being loaded in negative direction. The strength increase was only 5% and the displacement ductility was 1.44. It should however be noted that the concrete strength was much lower than that for the un-retrofitted joint (see Table 1). Also, the applied retrofit had delayed the yielding of steel reinforcement, with the first yield load increased by 18%, compared to the un-retrofitted joint, and hence a lower displacement ductility.

Similarly, for the FRP-retrofitted interior joint IR, the failure mode was more brittle with debonding followed by concrete crushing and FRP rupture. The first yield load was increased by 28% while the maximum load by only 2%. The displacement ductility was 1.36.

The retrofit technique investigated herein resulted in a higher first yield load but not so much the ultimate load capacity and tthe displacement ductility. A finite element model was thus formulated and verified using these test results, and subsequently used to propose an enhanced practical FRP retrofit method for the joints which would lead to increased ultimate strength while maintaining adequate displacement ductility of the joints.

4. FINITE ELEMENT ANALYSIS

A finite element analysis of the tested joints under lateral load was carried out using ABAQUS (DSSC. 2010). Steel reinforcing bars were modelled as one-directional strain elements with elastic-perfectly plastic properties in both tension and compression. Concrete was modelled by 8-node solid brick elements, and Concrete Damaged Plasticity Model was used to simulate the behaviour of concrete. Bond-slip and dowel action were modelled by considering "tension stiffening" effect in concrete. Further details are given in the reference (Aziz 2012).

FRP reinforcement was modelled using 3-D, four node shell elements. The elements were superimposed on the solid brick elements, and perfect bond between the FRP reinforcement and concrete elements was assumed. The FRP material is assumed to be linearly elastic. In-plane stress-based failure theory was used to specify failure of the FRP material, assuming that all the compressive stresses were taken by the saturant.

4.1 Verification of Finite Element Analysis

Figures 7(a) to (d) compare the observed lateral load response with the predictions of the FE analysis. The predicted ultimate load capacities were within 5% of the observed values. However, the predicted displacements were 6 to 10 mm smaller that the observed displacements, due to some slippage at the connections.

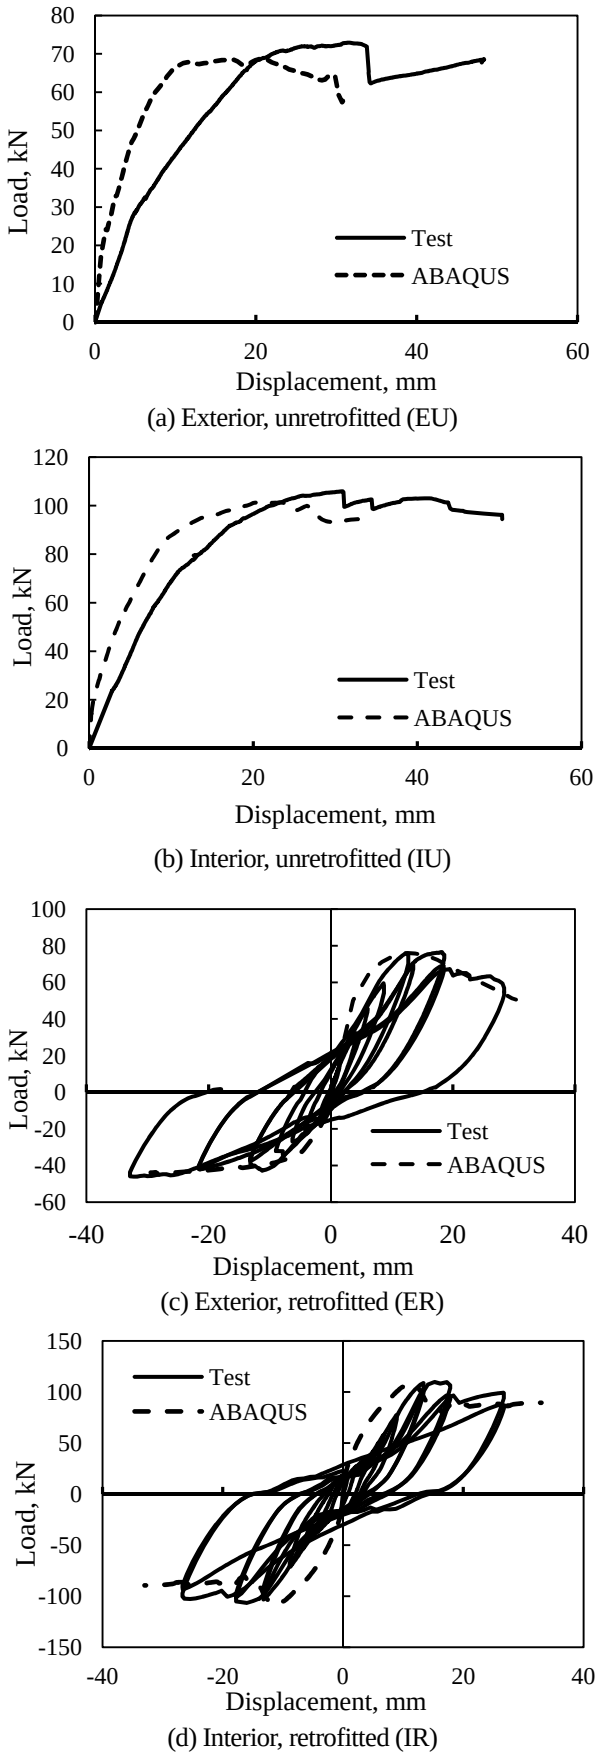
In general, the ABAQUS model was found to predict the increase in yield load and ultimate load capacity as observed in the tests. It also predicted a loss in displacement capacity due to FRP retrofit as observed in the tests. It can also be seen that failure of the FRP retrofitted exterior joint specimen by concrete crushing was more gradual than the retrofitted interior joint due to rupture of FRP reinforcement. The finite element analysis further indicated a strain greater than 0.004 at the location of FRP rupture, which agreed with recorded gauge readings.

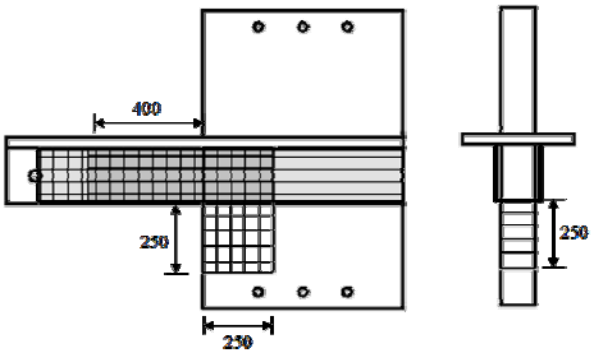
4.2 Suggestion for Enhanced Retrofit Scheme

Based on the test results and comparison with finite element analysis, and using the same modeling technique, the effect of various ply lengths and thicknesses on the joint performance was investigated. An enhanced retrofit scheme was established and shown in Figure 8.

For the exterior joint, a long flat FRP ply going around the end of the column instead of a flat ply ending 250 mm inside the joint is proposed. Additionally, a second flat ply extending from 200 mm before the pin connection (contraflexure point) in the beam to 250 mm inside the joint is applied. The additional plies are meant to improve the bond anchorage of the FRP sheets. They will help distribute the yielding of steel reinforcement over the length of the beam, thus providing better ductility.

A similar scheme is proposed for interior joints, in which two flat plys are provided across the whole width of the joint.





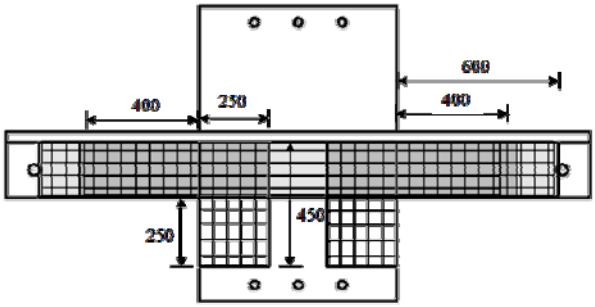


Figure 7 Comparison of FEA results with tests

(a) Exterior joint

(b) Interior joint

Figure 8 Enhanced retrofit scheme

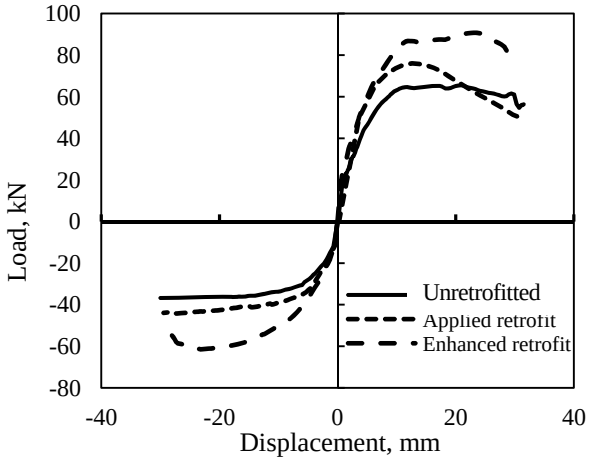

Figure 9 compares the load-displacement curves for the retrofitted joints under lateral loading using the original (applied) and suggested (enhanced) schemes with the un-retrofitted joint, based on the finite element analysis. The concrete strength was assumed the same and equal to that of the un-retrofitted joint shown in Table 1.

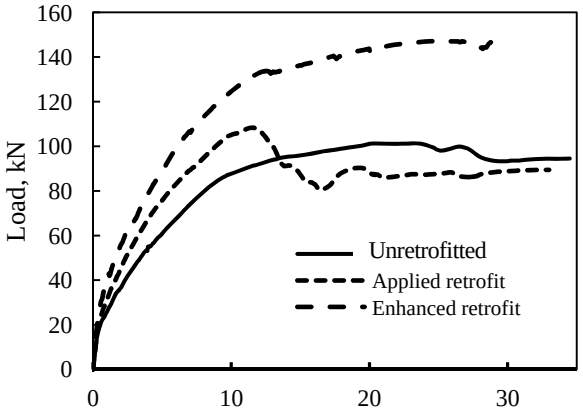
While the applied retrofit for exterior joint resulted in 17% increase in ultimate strength with respect to the unretrofitted joint in the positive loading direction, the enhanced retrofit scheme led to a strength increase of about 40%, and the capacity is maintained up to the ultimate displacement, that is similar to the un-retrofitted joint. In the negative loading direction, the applied retrofit resulted in 17% increase in ultimate strength whereas the enhanced retrofit increased the strength by about 70%.



For the interior joint, enhanced retrofit resulted in about 47% increase in the ultimate strength compared to 7% increase for the applied retrofit. The capacity was also maintained up to the ultimate displacement that is close to that of the un-retrofitted joint.

5. CONCLUSIONS

The tests showed that the T-beam-wide-column joints do not suffer much damage in the joint region under lateral loading. They were found to fail by flexural tension and shear-compression in the beam at the joint interface.

(a) Exterior joints

(b) Interior joints

Figure 9 FEA of unretrofitted and retrofitted joints

The experimentally investigated FRP retrofit scheme delayed the yield of steel reinforcement, and increased the lateral load capacity marginally. By adopting an enhanced FRP technique established from finite element analysis that was verified with the test results, it was shown that the lateral load capacity could be increased substantially without reduction in ductility of the joint.

Abstract: The paper presents the seismic performance of 10-story reinforced concrete buildings with various structural configurations in Bangkok area. The nonlinear dynamic analyses were conducted according to the guideline provided in ATC-40. The influence of the foundation configurations and structural systems on the seismic performance was evaluated. The simplified and refined analytical models for various foundation configurations were developed and compared. Nonlinear pile foundations were modeled using the load-transforms method for vertical displacement and p-y curves for horizontal movement. The analytical results revealed that the foundation configuration and structural system had significant effects on the seismic responses and performance. The refined analytical model with soil-structure interaction could provide realistic estimate of the structural responses under earthquake excitation and was crucial to be used in the analysis for the buildings with a flexible foundation system.

1. INTRODUCTION

Awareness for a seismic risk in Bangkok area due to remote-distance earthquakes from the active faults on the northern and western regions of the country has raised a concern on the safety and performance of old reinforced concrete buildings built before the release of the seismic design regulations in Thailand. These buildings were designed to mainly resist gravity and wind loads. Several structural configurations were generally used depending on the functional requirements. Some residential buildings were constructed using slab on ground without tie beam on the 1st floor level to reduce loads on foundation and provided a parking space. Without tie beams or structural members to provide a diaphragm action at the base, the buildings would have a flexible foundation system for lateral loads. Additionally, many of these buildings were designed using bored pile with deep pile tip to increase in the load capacity per pile and had only one pile per footing. These flexible base conditions caused the buildings to be vulnerable to the seismic excitations.

The paper was therefore aimed to evaluate the seismic performance of typical reinforced concrete buildings with various structural configurations. The effect of foundation flexibility on base shear, natural frequency, and seismic performance was examined using nonlinear static pushover analysis.

2. NONLINEAR STATIC PUSHOVER ANALYSIS

Nonlinear static pushover analysis can be used for the performance analysis of new and existing buildings. It is an efficient analysis method to trace the structural responses from the elastic range, though yielding and cracking, up to complete failure. Pushover analysis can be described as the method applying lateral loads in a pattern that represent the relative inertia forces at each floor level. A building is pushed laterally under lateral loads until a target displacement is obtained. The target displacement used in the analysis can be the displacement corresponding to the one expected for design earthquake or the displacement causing collapse mechanisms. Generally, both force distribution and target displacement are based on the assumption that the response is controlled by a fundamental mode throughout the analysis (Pinho et. al., 2007). Although the assumption is incorrect, the analysis results obtained from this simplification have been shown to provide rather good estimates of seismic performance (Krawinkler and Seneviratna, 1998).

By utilizing the analysis, the sequence of yielding and failure can be traced. The strength degradation or reduction in stiffness of members for each increment of lateral loads is monitored during the analysis and used to update the analytical model for the next incremental load. Nonlinear behaviors of structural members are commonly considered using a plastic hinge concept which the degradation is concentrated at critical locations. Figure 1 presents a general shape of the flexural plastic hinge provided in ATC-40. By combining many step loads, the relationship between base shear and top roof displacement or a capacity curve can be developed. The curve generally exhibits saw tooth characteristic corresponding to overall strength degradation. The capacity curve is then used to compare with the seismic demand required by a specific earthquake to obtain the

performance point of the structure.

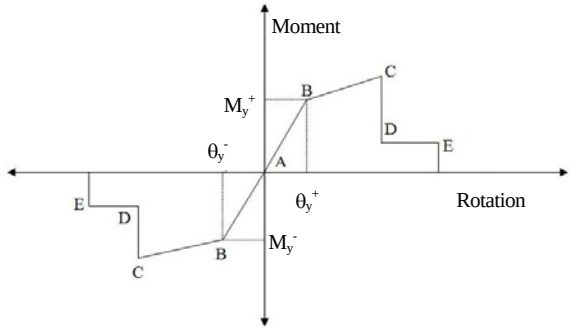

Figure 1 Relationship between Moment and Rotation of Flexural Plastic Hinge (ATC-40)

3. FOUNDATION MODELING

Buildings are commonly supported by pile foundations in areas with soft soil condition. During an earthquake excitation, these foundations provide restraints for vertical and lateral movements at the base of the structures. Sufficient load carrying capacity of the foundations is therefore required to prevent an excessive displacement and instability of the structures. The relationship between the resistant load in pile and vertical movement can be modeled using the load transfer approach (Seed and Reese, 1957). With this simplification approach, piles can be modeled as a series of elements with nonlinear springs, as presented in Figure 2, to represent the interaction between friction force on pile's surface and settlement, called T-Z spring, and the relationship between the resisting force at pile tip and settlement, call Q-Z spring. Based on this concept, several spring models are available in the literatures, including Vijayvergiya (1977), McVay (1989), Pando (2003), API (2000), and FHWA (2010).

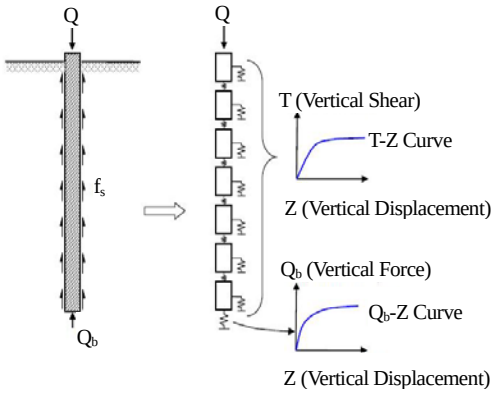

Figure 2 Load Transfer Approach for Vertical Movement of Pile

In this study, the most suitable model was selected based on a comparison of the available proposed models and the experimental results of static pile load tests for driven and bored piles of fourteen construction projects in Bangkok area. The comparative study revealed that the model proposed by Vijayvergiya (1977) gave the best estimate of the pile responses. The relationships between the friction on pile surface (f_s) and settlement (z) for clay and sand can be expressed as:

$$f_s = f_{s,\max} \cdot \left(2 \cdot \sqrt{\frac{z}{z_c}} - \frac{z}{z_c} \right) \quad (for \quad z \le z_c) \tag{1}$$

$$f_s = f_{s,\max} \quad (for \quad z \ge z_c) \tag{2}$$

Where z_c is the movement required to mobilize $f_{s,\max}$.

The relationships between bearing resistant (q) at pile tip and settlement (z) can be expressed as:

$$q = \left(\frac{z}{z_c} \right)^{\frac{1}{3}} \cdot q_{\max} \quad (for \quad z \le z_c) \tag{3}$$

$$q = q_{\max} \quad (for \quad z \ge z_c) \tag{4}$$

Where z_c is the movement required to mobilize $q_{\max}$.

Piles resisting lateral loads can be modeled as an elastic beam on elastic foundation. The interaction of soil and pile can be represented by elastic springs on the front and back of the pile being considered, as shown in Figure 3. The relationship between spring force and lateral displacement can be presented using p-y curve. Based on the available p-y curves in the literatures and a comparative study with the experimental results of fifteen lateral pile load tests, the models proposed by Matlock (1970), Reese and Welch (1975), and Reese et. al. (1974) were used in this study for soft clay, stiff clay and sand, respectively.

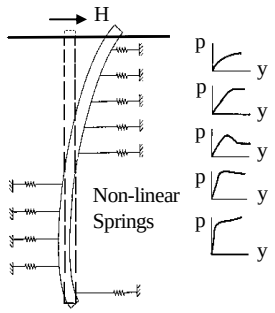

Figure 3 p-y Curve for Lateral Movement of Pile

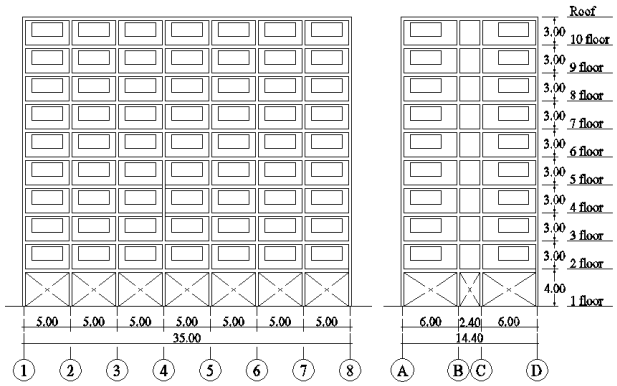
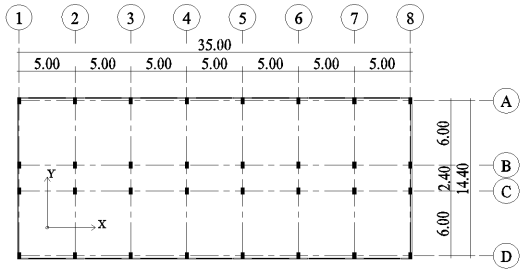
Pile group effect can be included in the analysis by means of P-multiplier. The p-y curve of single pile is adjusted by multiplying with a reduction factor to account for a pile group effect. The P-Multipliers for a pile group with spacing between piles of 3 times of a pile diameter were equal to 0.80, 0.55 and 0.45 for the front, second and third rows, respectively (Rollins, 2006).



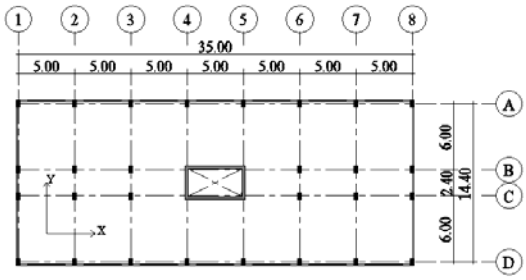
4. STRUCTURE MODEL

The seismic responses and performance of typical 10-story reinforced concrete buildings with various foundation configurations and structural systems were examined. Table 1 presents the variation of foundation configurations and structural systems included in this study. All buildings were designed for gravity loads with concrete compressive strength of 24 MPa and yield strength of 400 MPa for reinforcing steel. Two structural systems, namely Building Type A and Building Type B, were the buildings with beam-column structure and slab-column-shear wall structure, respectively, as presented in Figure 4.



For each Building Type, several structural systems at the 1st floor level were considered, including precast slab on ground beam, flat slab, and slab on ground without tie beam. With the specified design live load of 200 kg/m^2, typical dimensions of reinforced concrete members were equal to 0.35x0.60 m for column, 0.25x0.50 m for beam, and 0.175-m thickness for flat slab. Two foundation configurations included a fixed-base condition and nonlinear soil-pile systems with soil properties corresponding to typical soil layers in Bangkok area, as presented in Figure 5. For the foundation systems with bored piles, the bored piles of size 0.6-m in diameter and 0.8-m in diameter were used for the exterior and interior columns, respectively. With these pile sizes, one bored pile had sufficient capacity to resist gravity loads and was assigned for each column. In the case of driven pile, the pile sizes of I-0.30x0.30 m and I-0.35x0.35 m were employed. According to the applied gravity loads, four driven piles were used for each footing. By comparing the analysis results of the buildings with similar structural systems at the 1st floor level but having different pile types, the effect of number of piles per footing on the seismic responses could be examined.

Table 1 Structural Configuration of Building Models



Building Type	Structural System at First Floor	Foundation	Pile Type
A1	-	Fixed Base	-

Figure 4 Building Configurations

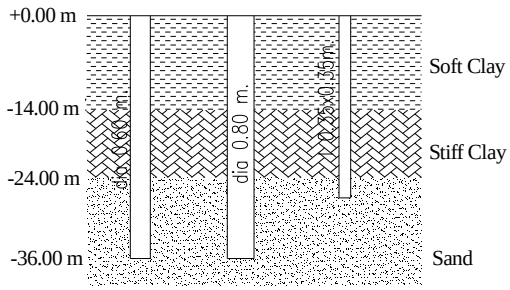

Figure 5 Soil Layer and Pile Depth

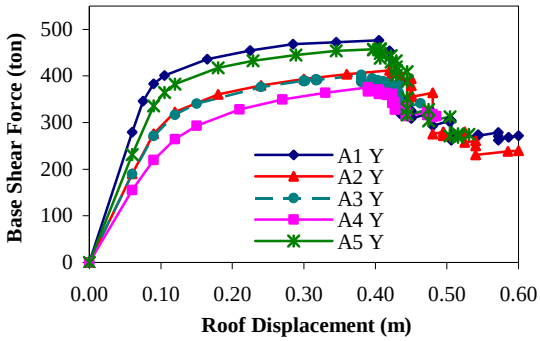
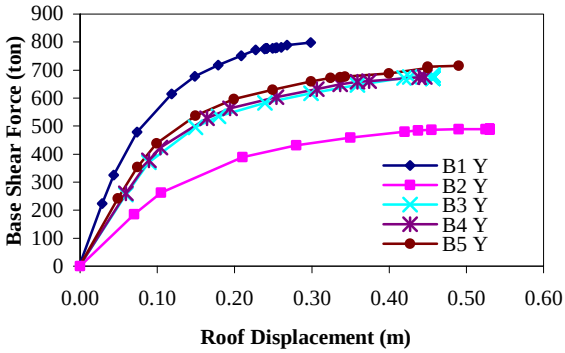
Three-dimensional finite element models were developed for each structural configuration using the commercial finite element software SAP 2000. Beams and columns were modeled using line elements having linear elastic properties along the length with nonlinear hinges to represent the nonlinear flexural behavior of beams and both

axial and flexural behaviors of columns. The nonlinear hinges in beams and columns were modeled as lumped plasticity at the start and end of each element and assigned according to the guidelines provided in FEMA-356. The diaphragm action of flat slab at the 1st floor level for Building A3 and B3 was modeled using elastic linear shell elements. An interaction between internal forces and nonlinear behavior of shear wall under earthquake was incorporated in the model using available nonlinear shell elements. Piles were modeled by line elements with nonlinear T-Z and Q-Z springs to represent the resisting force for vertical displacement and nonlinear p-y springs for lateral displacement.



5. ANALYSIS RESULTS

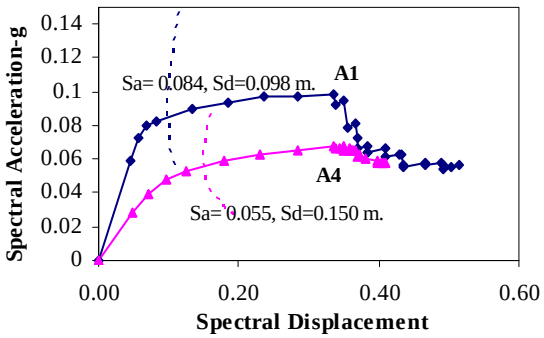
Nonlinear static pushover analysis was conducted to evaluate the effect of foundation configurations and structural systems on the seismic performance of the buildings. The soil-structure interaction of each building was investigated and presented in terms of dynamic characteristics and a relationship between base shear force and roof lateral displacement. The performance level of buildings was determined using the design earthquake provided by the Uniform Building Code (1997).



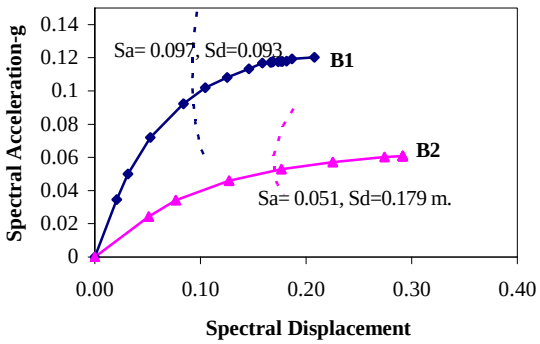
5.1 Pushover Curve

A nonlinear static pushover analysis was performed using three-dimensional finite element models. The seismic performances of the buildings in both X- and Y-directions were evaluated. The capacity curves were plotted between base shear and top roof displacement, as presented in Figure 6. The analysis results revealed that the building models with the consideration of soil-structure interaction had the capacity to resist lateral load of 5-25 percent lower than the fixed-base model for Building Type A and 10-40 percent lower than the fixed-base model for Building Type B. Building Type A failed in shear mode with inflection points located on the 2nd to 4th floors, while Building Type B failed in flexural mode. The failure mechanisms were different, depending on the foundation system. In the elastic range, the relationship between roof displacement and base shear was linear. With an increase in lateral force, beams on the 2nd to 4th floors started to yield and then the structural failure progressed to the columns on the 1st floor level.

The acceleration-displacement response spectra (ADRS) were plotted using the capacity curves obtained from the pushover analysis, as presented in Figure 7. The capacity spectra were compared with the demand spectra given by the Uniform Building Code (1997) for seismic Zone 1. An intersection between the capacity and demand spectra represented the performance point, where the capacity of structure matched the demand given by the earthquake force. The analysis results indicated that the structural responses of all buildings at the performance point were in a nonlinear region.



a) Building Type A



b) Building Type B

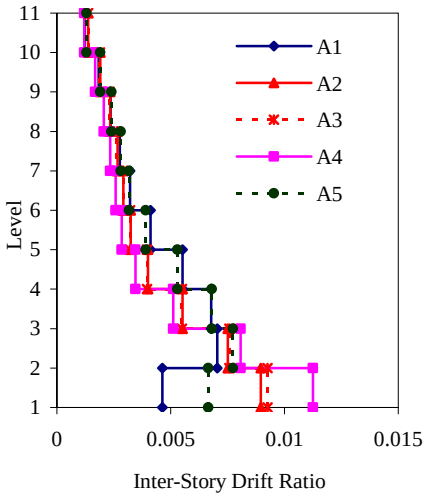
Figure 6 Capacity Curves in Y-Direction

a) Building Type A

b) Building Type B

Figure 7 Acceleration-Displacement Response Spectra

5.1 Dynamic Characteristics



A comparison of the natural periods of buildings with various foundation configurations and structural systems is presented in Table 2. The natural periods were obtained from modal analysis of the finite element models. For the same structural systems, the natural period increased considerably when the flexibility conditions at the 1st floor level were included in the model. The buildings with flexile structural conditions at the 1st floor level had natural periods of 15-42 percent and 25-70 percent longer than the ones with a fixed based condition for Building Type A and Type B, respectively. The buildings with flat slab at the 1st floor level (A3 and B3) were found to have the natural period relatively close to the ones with precast slab on ground beam (A2 and B4).

The base shear and top roof displacement corresponding to the design earthquake of UBC (1997) were determined and are presented in Table 2. The analysis results indicated that the buildings with flexible foundations had lower base shear but higher lateral displacement than the building with a fixed base. The base shear forces in the buildings with a fixed base (A1 and B1) were 33-56 percent greater than the buildings with a very flexible base condition (A4 and B2). These higher values of shear force resulted in a greater amount of reinforcement required for the earthquake resistance design. Additionally, a number of piles per footing were found to affect the natural period and base shear at the performance point. When a group of piles was employed, the natural period and base shear of the buildings without tie beams (A5 and B5) were relatively close to the buildings with a fix base condition.

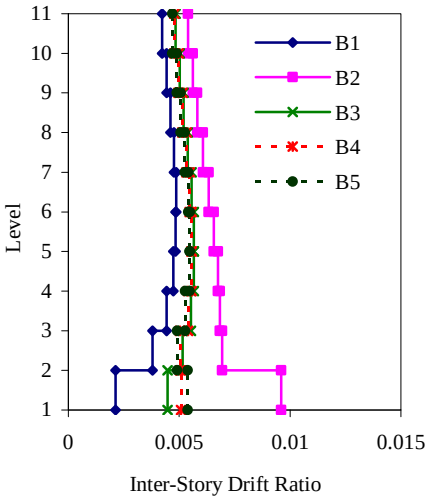


Table 2 Dynamic Characteristics and Seismic Responses for Various Structural Configurations

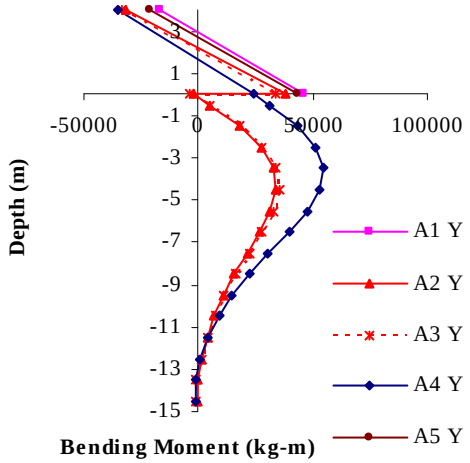
Building Type	Natural Period (second)	Base Shear (ton)	Lateral Displacement (cm)	Percentage of Base Shear in Shear Wall
A1	1.75	412	12.30	-
A2	2.21	348	16.00	-
A3	2.22	345	16.20	-
A4	2.49	310	17.80	-
A5	1.98	395	14.10	-
B1	1.82	643	13.20	81.42
B2	3.11	412	24.40	46.07
B3	2.38	536	18.00	88.34
B4	2.35	542	17.70	71.77
B5	2.29	565	17.30	49.73

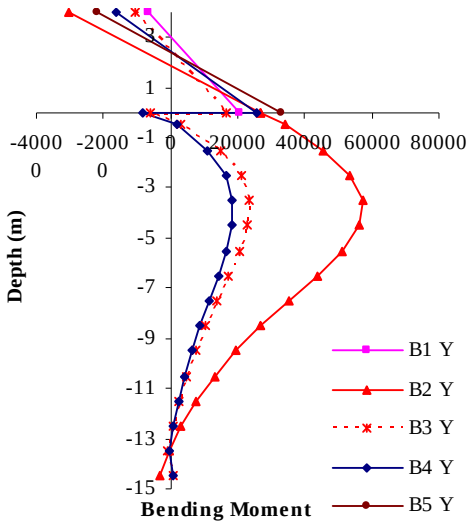
The lateral roof displacements of Buildings Type A with flexible base conditions were in a range of 14.1 to 17.8 cm, which were greater than the displacement of 12.3 cm obtained from the building with a fixed base condition. Similarly, the lateral roof displacements of Building Type B with flexible base conditions were varied from 17.3 to 24.4 cm and greater than the displacement of 13.2 cm given by the building with a fixed base condition. Figure 8 shows the inter-story drift along Y direction. The Building Type A1 and B1 with a fixed base condition had maximum inter-story drift of 0.46 and 0.22, respectively. These inter-story drifts were found to increase significantly as the flexibility condition at the base was considered. The maximum inter-story drifts of building with flexible base were in a range of 0.58-1.14 percent for Building Type A and 0.55-0.96 for Building Type B. It should be noted that buildings that had slab on ground without tie beam had the inter-story drift greater than the allowable limit for immediate occupancy performance level of 1 percent. However, all buildings had the maximum drift less than the limit of 2 percent for the life safety performance level.

a) Building Type A



b) Building Type B

Figure 8 Inter-Story Drift along Y-Direction



5.2 Internal Force Distribution

The effect of foundation flexibility on the distribution of shear force in the structures was investigated. The building models with a fixed base condition provided base

shear forces greater than the building models with flexible base conditions. The base shear forces were decreased by 25-35 percent when slab on ground without tie beam was used, instead of a fixed base condition. For Building Type B with shear wall, the distribution of base shear in columns and wall considerably depended on flexibility at the base. Most of the shear force was resisted by shear wall when a fixed base condition was assumed. However, the distribution of base shear in shear wall was decreased by 10-44 percent, when a soil-structure interaction was considered in the models.

a) Building Type A

b) Building Type B

Figure 9 Bending Moments in Column at 1st Floor Level and in Pile

Figure 9 presents the variation of bending moment in column at the 1st floor level and in pile for Building Type A and Type B. Shear and bending moment forces were varied depending on the structural configurations. The buildings with high flexural stiffness at the 1st floor level had a high value of bending moment at the pile cap. For the buildings with a flexible base condition, the maximum bending moment in pile was located at the depth approximately equal to five times of a pile diameter.

6. CONCLUSION

The effect of foundation flexibility and structural system on the seismic responses and performance of typical 10-story reinforced concrete buildings in Bangkok area was examined using nonlinear static pushover analysis. Nonlinear material property and nonlinear soil-structure interaction were considered. Based on the analysis results, the following conclusions were drawn:

1. The seismic responses and performance of the buildings were affected by a number of piles per footing and structural system at the 1st floor level.

2. The model with a fixed based condition overestimated the overall lateral stiffness of the buildings with flexible bases, resulting in relatively low values of natural period and roof displacement. This could lead to an overestimated design base shear and underestimated inter-story drift at the performance point.

3. The distribution of internal forces in structural members and piles was influenced by the flexibility at the base and foundation.

4. The refined analytical model with soil-structure interaction was essential to be used in the analysis for the buildings with a flexible foundation system.

Abstract: Through the Great East Japan Earthquake, port facilities have been strongly recognized as transportation base for emergent supply in order to provide assistance for rehabilitation of disaster-affected areas. A practical method to evaluate residual structural capacity of damaged port facilities is required to establish to judge whether the facilities can be used for emergent purpose such as transportation base or not. This paper deals with residual structural capacity of reinforced concrete (RC) superstructure of pile-supported open-type wharf damaged by earthquake actions. In the experiment, reversed cyclic horizontal loading was conducted on 1/4 scaled models of pile-supported open-type wharf in order to cause different levels of damage in steel pipe piles. Thereafter, bending loading tests were carried out on superstructures of the damaged models to investigate the failure process and the residual load carrying capacities of RC superstructure of pile-supported wharf damaged by earthquake actions. The result of the bending loading tests on damaged RC superstructures can be utilized as a reference for judging whether RC superstructure can be used for emergent purpose after earthquake.

1. INTRODUCTION

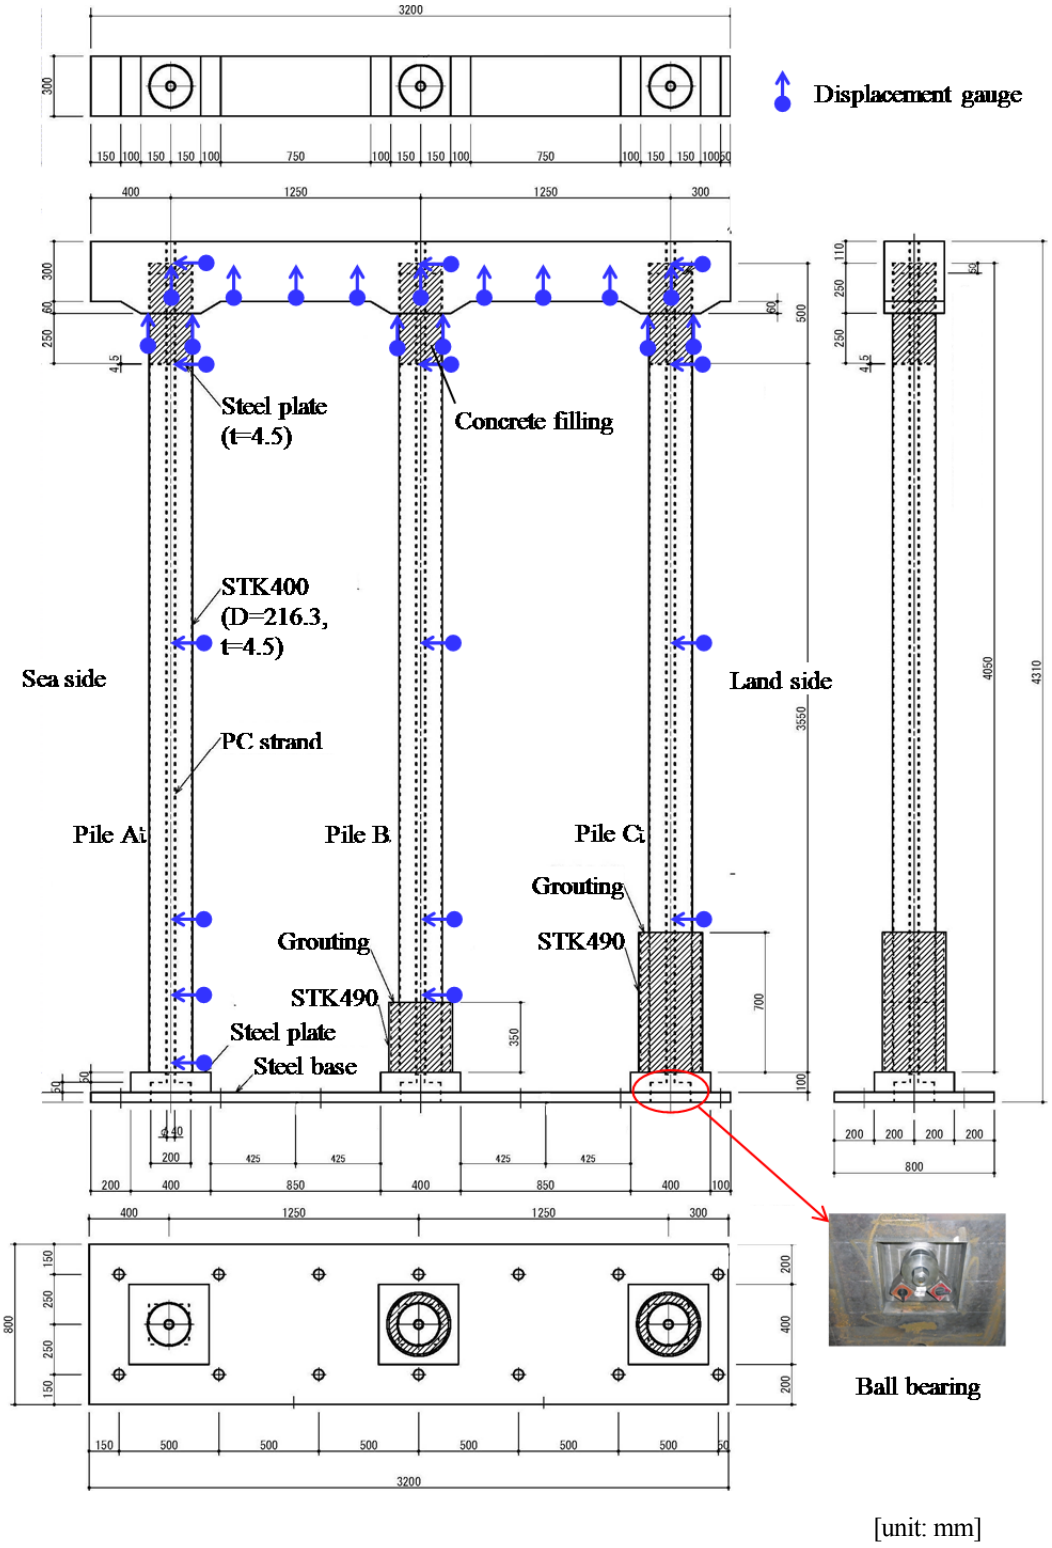
Among berthing facilities in port areas, a pile-supported pier structure is superior to other types of structures, such as a gravity type quaywall, from the viewpoint of seismic performance. Therefore, there are only few examples of structural damage in pier structures due to earthquake so far. One of the examples was reported that a pier at Kobe Port was damaged due to Great Hanshin Awaji Earthquake, 1995 (Inatomi et al. 1997). In this example, it was considered that steel pipe piles were buckled by increased soil pressures due to liquefaction, not by seismic motion itself (Minami et al. 1997). Also, considerable damages were not observed in pier structures even after Great East Japan Earthquake, 2011 (Takahashi et al. 2011), indicating their high performance against seismic motions.

On the other hand, through the experiences of Great East Japan Earthquake, it was strongly recognized that port facilities are very important for urgent restoration of disaster-affected areas after the earthquake. It is because port facilities can be used as transportation base for urgent materials and rescue activities.

In the present design of port facilities (The Ports and Harbours Association of Japan. 2007), partial damages are allowed against seismic actions in order to obtain rational cross-sections of structural members. The limit state against the L1 seismic motion is yielding of steel pipe piles and cross-section failure of reinforced concrete (RC) superstructure, and the limit state against the L2 seismic motion is designated by the number and position of plasticity of steel pipe piles. However, in case that structural components of pier are damaged due to earthquake, there is no method to judge whether the damaged pier can be used and to judge whether usage restriction is necessary. Hence, it is essential to establish residual performance evaluation methods of pile-supported pier structures damaged by earthquake in order to assist the disaster-affected areas, as well as those for other type berthing facilities.

There are lots of research works on structural behavior of pile-supported pier structures during earthquake (Yokota et al. 1999). However, most of the research focused on elastic and plastic behavior and residual capacity of steel pipe piles, while no research was conducted on residual performance of RC superstructure of damaged pier. The RC superstructure directly supports vertical loads of cargos and vehicles on the apron, so that it is important to appropriately evaluate residual structural capacity of RC superstructure of damaged pier to judge the possibility of usual or restricted use. Furthermore, in evaluation of residual structural capacity of damaged RC superstructure on site, it is also required to establish urgent inspection system after earthquake.

In this paper, the relationship between damage state and residual structural capacity of RC superstructure of



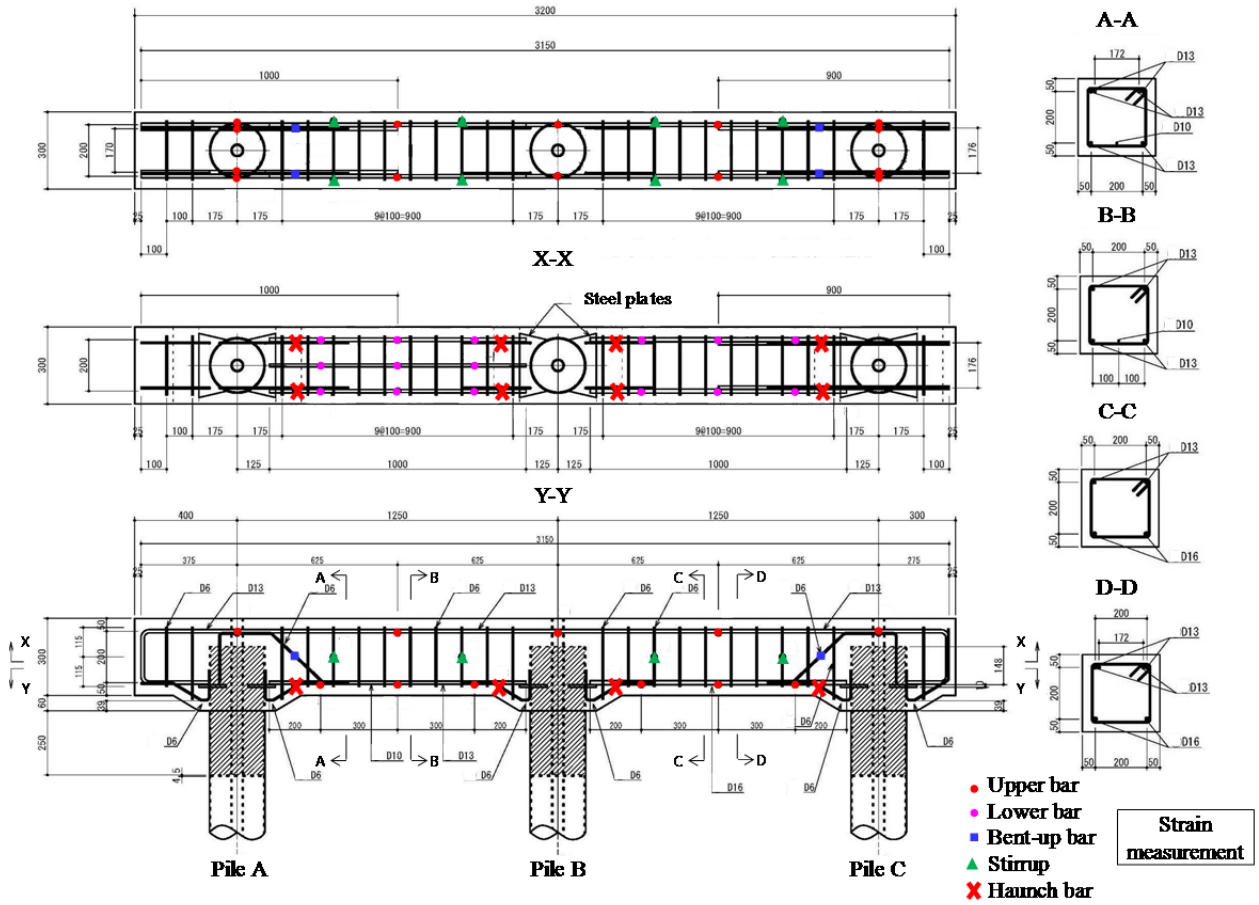


Figure 1 Test Model

pile-supported pier structures damaged by seismic motion was experimentally investigated as a first step of series of research works. In the experiment, models of pile-supported pier structures were damaged by reversed cyclic horizontal loading, and bending loading tests on damaged RC superstructures were conducted to examine the residual structural capacity of concrete members. By changing the degree of damage caused by reversed cyclic horizontal loading on each model of pier structure, the relationship between the degree of overall damage of pier structure and residual structural capacity of RC superstructure was made clear.

[unit: mm]

Figure 2 Steel Bars Arrangement of RC Superstructure

2. EXPERIMENTAL OUTLINE

2.1 Test Model

Figure 1 shows the shape and dimensions of 1/4 models of a pier structure. The original pier structure was a typical pile-supported open-type wharf in Japan, of which front water depth was -10m. The model consisted of one reinforced concrete beam and 3 steel pipe piles. Pile A was located in the sea side, and Pile C was in the land side. Below the fixed points of piles under the seabed, larger steel pipes were set around the piles and grouting was made between them to simulate the design supporting condition of piles under the seabed. Similar to the actual pier, concrete was fulfilled into the top of steel pipe piles in order to rigidly connect between piles and superstructure.

Figure 2 shows the steel bars arrangement of RC superstructure. The steel bars arrangement was decided so that the ratios of bending capacity and shear capacity of RC superstructure to the plastic moment of steel pipe piles were almost the same as those of the original pier structure. Main bars were welded to steel plates connected to steel pipe piles at the heads.

Mechanical properties of concrete, grout, steel pipe piles and steel bars are listed in Table 1. The yield strain of

steel pipe piles was assumed to be 2000μ.

The positions of measurement of displacement and strain during loading are also indicated in Figure 1 and Figure 2.

Photo 1 Bending Loading Test

2.2 Loading Method

Figure 3 illustrates the method of reversed cyclic horizontal loading on the model, simulating seismic motions. To fix the model to a load-bearing wall, steel pipe piles were welded to steel plate and base, which was rigidly connected to the load-bearing wall by PC bars. PC strands were inserted into inside of piles to apply axial forces to the piles simulating the design dead load and surcharge. During the loading, the axial forces were monitored by load cells, and adjusted to be the designated values by using hydraulic jacks. The designated axial forces were 10% of the yield load in compression of the piles for Pile A and Pile C, and 5% for Pile B. Horizontal forces simulating seismic motions were applied by a hydraulic jack connected to the load-bearing wall. The horizontal loading was conducted based on the fundamental horizontal displacement, δ_y, which was defined as the displacement when the maximum strain in steel pipe piles reached the yielding in the first horizontal loading. Figure 4 shows the loading step for each test model. In Model 1, the loading was continued up to $4\delta_y$ after the peak, while the loading in Model 2 and Model 3 was finished at the peak load, $3\delta_y$, and the yielding of steel pipe pile, $1\delta_y$, respectively. By the horizontal loading, the test models were damaged at different degrees.

After the horizontal loading, bending loading tests on the damaged RC superstructures of the test models were conducted in order to investigate the relationship between the degree of overall damage of pier structure and residual structural capacity of RC superstructure. In the bending loading test, steel rigid columns were installed onto a load-bearing floor so as to set a hydraulic jack for the bending loading to RC superstructure, as shown in Figure 5. The width of loading plate inserted between the superstructure and the jack was 100mm. The axial forces to the steel pipe piles were kept to be applied to the same values as the horizontal loading. The hydraulic jack for the horizontal loading was released from the test model in order not to restrain the superstructure from the load-bearing wall. The bending loading test was conducted on the beam between Pile B and Pile C (Beam BC), and then the beam between Pile A and Pile B (Beam AB). The view of the bending loading test is shown in Photo 1.

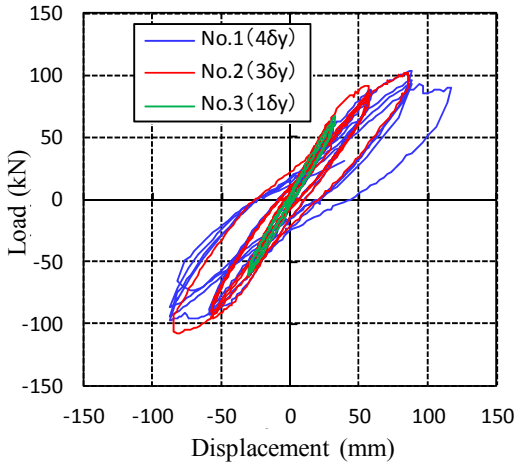

Figure 6 Result of Reversed Cyclic Horizontal Loading

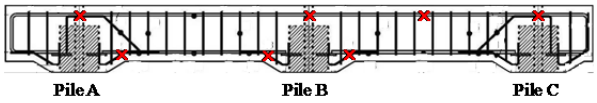
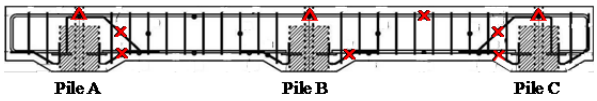
3. RESULTS AND DISCUSSION



3.1 Damage Process of Pile-supported Pier Structure During Earthquake

Figure 6 shows the relationship between the horizontal load and the horizontal displacement of RC superstructure during the reversed cyclic horizontal loading on the test models. The fundamental horizontal displacement was 29mm for Model 1, 28mm for Model 2, and 30mm for Model 3, respectively.



In Model 1, the horizontal load reached the peak of 103.7kN at the loading step of $3\delta_y$. After the peak, the horizontal loads were decreased gradually, and the ultimate state was reached at the loading step of $4\delta_y$, due to breakage of welded part between Pile A and the steel base. The damage process observed in Model 2 and Model 3 was similar to that in Model 1.

With increase in the damage degree of the model as a whole, damage in the RC superstructure was progressed as follows: Figure 7 shows the positions of yielding of steel bars in RC superstructure of Model 1 and Model 2 during the reversed cyclic horizontal loading. In Model 3, yielding of steel bars was not apparently detected during the loading. From this figure, it was found that steel bars near the pile heads were yielded in cased that the pier structure suffered from the maximum horizontal load, $3\delta_y$.

Figure 8 shows crack patterns observed in side surface and bottom surface of RC superstructure of test models after the reversed cyclic horizontal loading. The number of cracks around the midspan of the beam was small, and the width was narrow. Cracks were concentrated near the pile heads, and spalling of concrete cover was observed in Model 1 and Model 2. In comparison between Model 1 and Model 2, more cracks occurred near the head of Pile B in Model 1. This coincided with the state of yielding of steel bars mentioned above. Focusing on Model 3, many cracks occurred near the head of Pile C, even though the maximum experienced horizontal displacement was $1\delta_y$. It was because

(c) Model 2, Side Surface

(d) Model 2, Bottom Surface

(e) Model 3, Side Surface

(f) Model 3, Bottom Surface

Figure 8 Crack Patterns

Pile C was located on landside, being the shortest. Based on the test result, the damage process of RC superstructure was summarized as follows: many cracks first occurred near the pile head on landside, and then the pile head on seaside was damaged. Finally, cracks near the pile head in between became dominant after the maximum horizontal capacity of pier structure was reached. This tendency was similar to the previous research result (Yokota et al. 1999).

From the test result, it can be said that the degree of overall damage of pier structure is able to be qualitatively evaluated by checking crack patterns of RC superstructure at urgent inspection after earthquake. However, in actual conditions, it might be necessary to consider influence of

(f) Model 3, Bottom Surface

Figure 11 Crack Patterns after Bending Loading Tests on RC Superstructure

materials deterioration such as steel bar corrosion on structural behavior of RC superstructure, necessitating further research works in the future.

3.2 Result of Bending Loading Tests on Damaged RC Superstructures

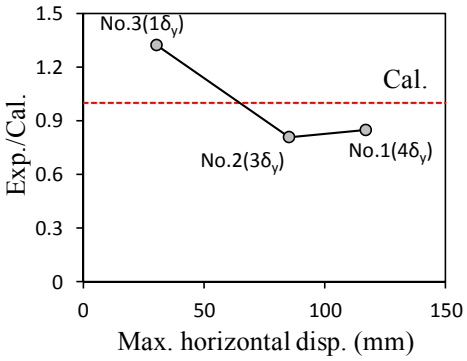

Figure 9 shows the relationship between load and midspan deflection during the bending loading tests on Beam BC. Model 3 had the largest residual structural capacity of RC superstructure, since the model was not heavily damaged due to the preceding reversed cyclic horizontal loading, that is, the experienced maximum horizontal displacement was $1\delta_y$. The residual structural capacities of RC superstructure of Model 1 and Model 2 were almost the same, because both the models suffered from the maximum horizontal capacity of pier structure.

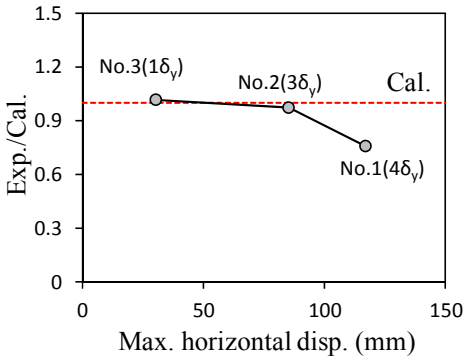
Figure 10 shows the load-deflection relationship obtained from the bending loading tests on Beam AB, which was conducted after the test on Beam BC. The residual structural capacities of Beam AB were smaller than those of Beam BC, since damage due to the preceding bending loading on Beam BC affected structural behavior of Beam AB. In particular, the constraint conditions at the head of Pile B were different between Beam BC and Beam AB. Focusing on the influence of the degree of overall damage on residual structural capacity of RC superstructure, Model 3 had the largest capacity among three models, similar to the tendency observed in Beam BC.



Crack patterns of RC superstructure after the bending loading tests on Beam BC and Beam AB are illustrated in Figure 11. The red lines in the figure indicate dominant cracks occurring during the bending loading tests, which caused the ultimate failure of beams. The failure mode of the beams was shear failure after yielding of steel bar in concrete in all the cases. The heavier the degree of overall damage of pier structure, the less the number of bending cracks and the number of cracks near the pile head. On the contrary, crack widths were larger in case of RC superstructure with heavier damage due to the preceding loading.

3.3 Residual Structural Capacity of Damaged RC Superstructure of Pile-supported Pier Structure

In judging whether RC superstructure can be used for emergency purpose after earthquake and whether the

(a) Beam BC

(b) Beam AB

Figure 12 Residual Structural Capacity of Damaged RC Superstructure of Pile-supported Open-type Wharf

restriction is necessary for temporary use, information about residual structural performance of RC superstructure damaged by seismic motions is surely required. Based on the test result of the bending loading tests on damaged RC superstructure, the following method can be proposed to roughly evaluate the residual structural capacity of RC superstructure damaged by seismic actions. Since all the beams failed in shear, shear capacity of concrete beam was focused on. The ratios of the maximum load obtained from the bending loading tests on concrete beams to their shear capacities calculated according to Japanese standard specifications (Japan Society of Civil Engineers. 2007) were introduced to evaluate the residual structural capacity. Figure 12 shows the relationships between the capacity ratio and the experienced maximum horizontal displacement during the reversed cyclic horizontal loading, which expresses the degree of overall damage of pier structure during earthquakes. From this figure, even though the pier structure suffered from heavy damage such as $4\delta_y$, residual structural capacity of RC superstructure was more than 70% of sound one.

4. SUMMARY

In this study, residual structural capacity of RC superstructure of pile-supported open-type wharf damaged by seismic motions was investigated through the experimental approach. The result will be useful to judge whether the structure can be used for emergency purpose after the earthquake. Also, it can be one of the references to examine if usage restriction or urgent repair is necessary or not.

This study is the first step of series of wide-ranged research projects, leaving lots of issues to be solved. From now on, a system for urgent restoration of port facilities after earthquake should be established by conducting intensive researches regarding evaluation methods of residual structural performance of damaged facilities, judgment criteria for temporary use, urgent repair technique for damaged facilities.

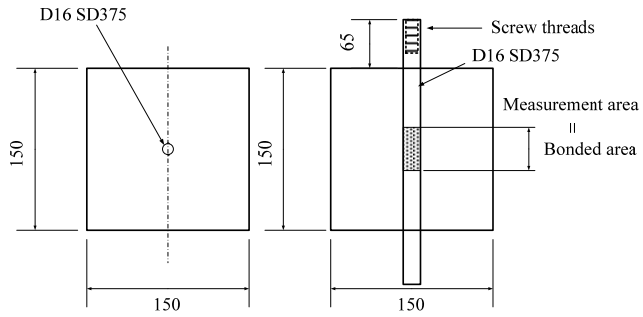
STUDY ON BOND PROPERTY OF CORRODED REINFORCING BAR UNDER CYCLIC LOADING

Tomohiro Miki [1] and Takuya Shiomi[2]

1) Associate Professor, Department of Civil Engineering, Kobe University, Japan
2) Graduate Student, Department of Civil Engineering, Kobe University, Japan
mikitomo@port.kobe-u.ac.jp, 116t124t@stu.kobe-u.ac.jp

Abstract: Cyclic loading during an earthquake affects on the bond behavior between reinforcing bar and concrete. The final goal of this study is to investigate the effect of corrosion on the bond behavior between reinforcing bar and concrete subject to cyclic loading. First, accelerated corrosion tests were carried out for the reinforced concrete specimens and positive and negative cycle loading tests were performed for all the specimens. The results of loading tests indicate that the maximum bond stress of corroded specimens in which more than 2% of cross-sectional loss of reinforcing bar is observed is larger than that of non-corroded specimens. In the pre-peak behavior, the initial stiffness of bond stress-slip relationship becomes larger as the corrosion proceeds, and the specimens without corrosion cracks show small influence due to the corrosion under cyclic loading.

1. INTRODUCTION



An appropriate maintenance management system has been required with the deteriorated of existing reinforced concrete (RC) structures. For the rational operation in the maintenance of the structures, it is required to evaluate the residual mechanical performance of the deteriorated structures appropriately. In the analysis for these structures, not only the material deterioration itself but also the interaction between concrete and steel reinforcing bar should be considered. In this point of view, the bond property is very important. One of the problems in the bond property of RC structures is corrosion of reinforcing bar. The bond stress due to the significant expansion pressure by the corrosion products decreases when the steel corrosion occurs in the RC structures (Fang, 2006). Herein, the bond property between the reinforcing bar and concrete is greatly affected by cyclic loading during an earthquake (Morita and Kaku, 1975). The final goal of this research framework is to comprehend the bond property between reinforcing bar corrosion and concrete under cyclic loading experimentally.

2. TEST PROGRAMS

2.1 Specimens

The schematic diagram of the specimen is shown in Figure 1 and the specified mix of concrete used is shown in Table 1 (Shiomi and Miki, 2012). The size of the specimen is a cube of 150 × 150 × 150 mm, and the D16 reinforcing bar is arranged at the center of the square section. The test program consisted in a total number of 16 RC specimens. To avoid the disorder of bond condition on the concrete edge, the bond in 55mm from the concrete edge side was removed by wrapping the vinyl tape around the reinforcing bar. The measurement area was in the range of 40 mm at the center. Only this area was located at the corrosion area of the corrosion specimen. In this study, a concrete with a designed compressive strength of 30 N/mm^2 was obtained. Maximum size of coarse aggregate was 20 mm. Early-strength Portland cement was used with an air entraining agent (Pozzolith No.70) in the concrete mixes.

The experimental case is shown in Table 2. The experimental parameters were the bond length of bonded area, the degree of corrosion and the level of cyclic. In the degree of corrosion of the corrosion specimen, the ratio of cross-sectional loss of reinforcing bar was the range 0% (un-corroded specimen) and between 0.9% and 6.3%. The level of cyclic was subjected to three types of once, three and ten times. Still, the way of loading is explained later.

2.2 Accelerated Corrosion Tests

In this study, accelerated corrosion tests were performed to corrode the reinforcing bar of the corroded specimen within a short time. The schematic diagram of the electrolytic corrosion test is shown Figure 2. To corrode only the bonded area, the reinforcing bar in the concrete was covered with a vinyl tape excluding 40 mm of the center in the measurement area and the reinforcing bar of the portion outside the specimen was coated by epoxy resin. The specimen was soaked in electrolytic solution (5% sodium chloride, NaCl by the weight of water). The reinforcing bar was set as an anode and the stainless plate was as a cathode. Then the amount of corrosion was managed by weld time.

After loading tests, reinforcing bar was taken from the demolished RC specimens. To remove the corrosion product on the reinforcing bar, the bars were immersed in the 10% solution of diammonium hydrogen citrate at room temperature for 1 day. After removing the corrosion products, reinforcing bars were divided into samples with the length of 40mm. In order to evaluate the corrosion level of reinforcing bar the ratio of cross-sectional loss is used. The corrosion ratio is defined as a ratio of the weight-loss of corroded reinforcing bar from its initial weight to that of non-corroded reinforcing bar and calculated by using Eq. (1).

$$C = \frac{\Delta w}{w} \times 100 \quad (1)$$

where, Δw: weight difference between the samples of non-corroded and corroded reinforcing bars (g/mm), w: weight of non-corroded reinforcing bar (g/mm)

2.3 Loading Tests

The positive and negative cyclic loading tests were performed for all pullout specimens. A servo motor drive screw type loading machine was used for loading test. The screw was carved for the edge of the loading side exposure reinforcing bar of the pullout specimen, and it was connected with the crossing head of the loading machine. The schematic diagram of the loading test setup is shown in Figure 3.

Load and slip displacement in the direction to pulling out is defined as positive, while that in the opposite direction is defined as negative. The loading speed was set as 1.5mm/min and controlled at the cross head of the testing machine. The loading tests were performed by setting the controlled displacement acting at reinforcing bar; the test machine displacement at the cross head. The slip displacements of the reinforcing bar to be reversed the loading direction were set to be 0.02 mm, 0.2 mm, 0.5 mm, 1.0 mm, 2.0 mm and 3.0 mm, respectively.

(c) No.15 (Corrosion 6.3%)

Figure 4 Corroded Reinforcing Bars

3. TEST RESULTS AND DISCUSSION

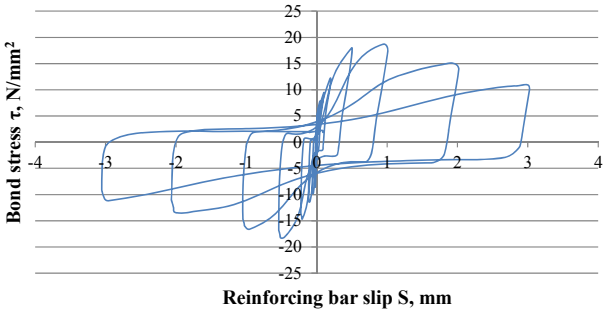
3.1 Accelerated Corrosion Tests

The amount of cross-sectional loss of reinforcing bar is summarized in Table 2. Various amount of corrosion can be seen as this table. The photos of corroded reinforcing bar after electrolytic accelerated corrosion test are shown in Figure.4. The corrosion condition of reinforcing bar in the bonded area indicates that the cross sectional loss due to corrosion is concentrated around rib in the reinforcing bar. This is because the corrosion action became active due to bleeding water that stands around rib. It is found that the reinforcing bars in No.14 and No.15 specimens had pitting corrosion at around the rib.

3.2 Results of Loading Tests

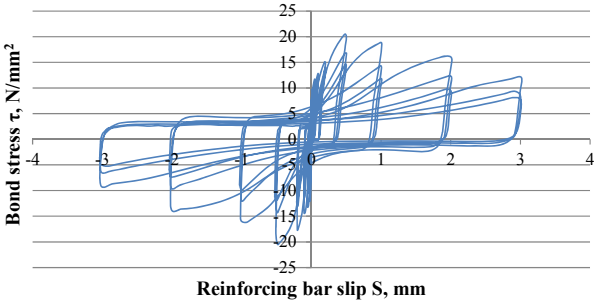
3.2.1 Bond Stress-Reinforcing Bar Slip Relationships

The relationships between the bond stress and slip of reinforcing bar of No.9, No.13 and No.19 specimens are shown in Figure 5, respectively. Here the bond stress τ and the reinforcing bar slip S can be calculated by using following equations.



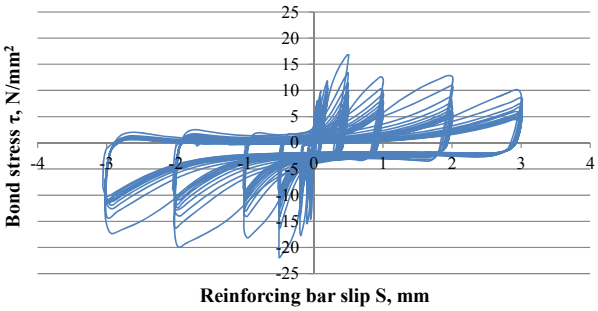
$$\tau = \frac{P}{\pi\, Dl} \qquad (2)$$

where, τ: bond stress, P: the axial tension acting reinforcing bar (N), D: the diameter of reinforcing bar (D16: D = 15.9 mm), l: the measurement area (Corrosion area in case of corrosion specimens =40mm)



$$S = ① - \left(\frac{② + ③}{2}\right) \qquad (3)$$

where, S: the reinforcing bar slip (mm), ①～③: the displacement measured by displacement gage ①～③ (mm) as shown in Figure 6.



For the bond stress in the vertical axis in Figure 5, an upward load (the direction of pulling) was defined as positive while downward load (the direction of compressing) was defined as negative. As for the slip of reinforcing bar in the cross axis in the figure, the displacement of upward was defined as positive, while that of downward was defined as negative. Values of ② and ③ during loading was significantly small compared with displacement of ①.

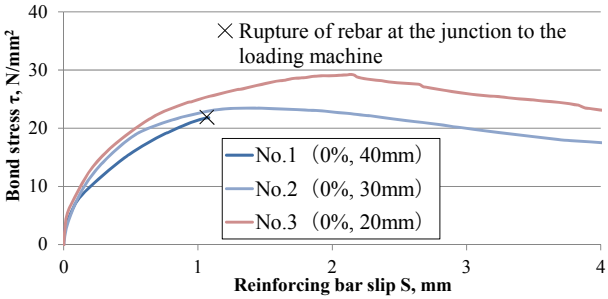

Figure 7 Bonded Surface of Concrete after Loading Test

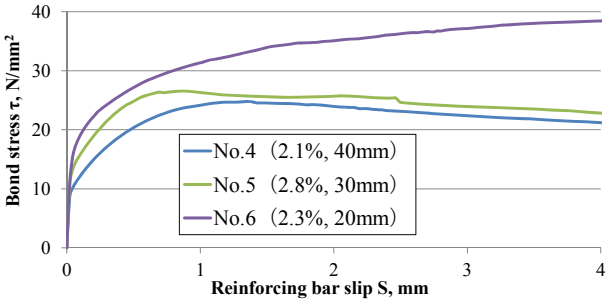
3.2.2 Bonded Surface of Concrete after Loading Tests



After loading tests, the specimens were demolished and the measurement area was visually observed. The photos of the concrete surface are shown Figure 7. The surface of the bonded concrete in the specimens subjected to more than three loading cycles seems to be smooth. The concrete among between adjoining transverse ribs of reinforcing bar resisted the slip deformation, and the fracture surface of concrete was finally formed as connecting at a tip of transverse rib to the adjoining rib.

3.2.3 Influence of Bonded Length of Reinforcing Bar

Figure 8 shows envelope curves of the bond stress-slip of reinforcing bar under monotonic loading. In these specimens the bonded length of the reinforcing bar which corresponds to the corrosion area of the rebar was changed in the range from 20 mm to 40 mm. The bonded lengths of 20 mm, 30 mm and 40 mm which are 1.3, 1.8 and 2.2 times the diameter of the D16 rebar, respectively are significantly shorter than a development length of the deformed bar that is used in the test. Although the maximum bond stress of the specimen of 20 mm bonded length was largest among these specimens in the both cases of sound and corroded reinforcing bar, the difference of these bond stress-slip of the rebar relationships seems to be not significant. Therefore, the following discussion is focused on the bond stress-slip relationships of the specimens in which the bonded length of rebar is set to be 40 mm.

(a) Corrosion Ratio: 0%

(b) Corrosion Ratio: around 2.5%

Figure 8 Envelope Curves of Bond Stress-Reinforcing Bar Slip Relationship under Monotonic Loading

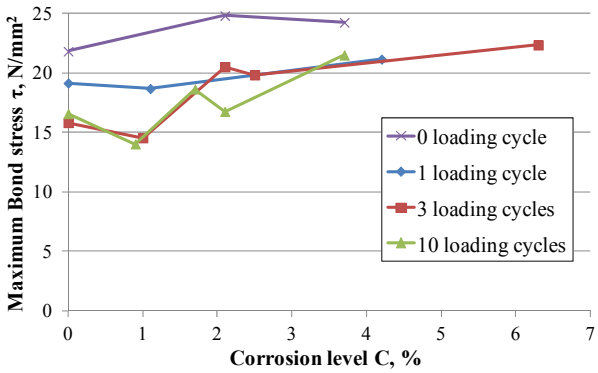


Figure 9 Maximum Bond Stress with Different Corrosion Levels and Loading Cycles

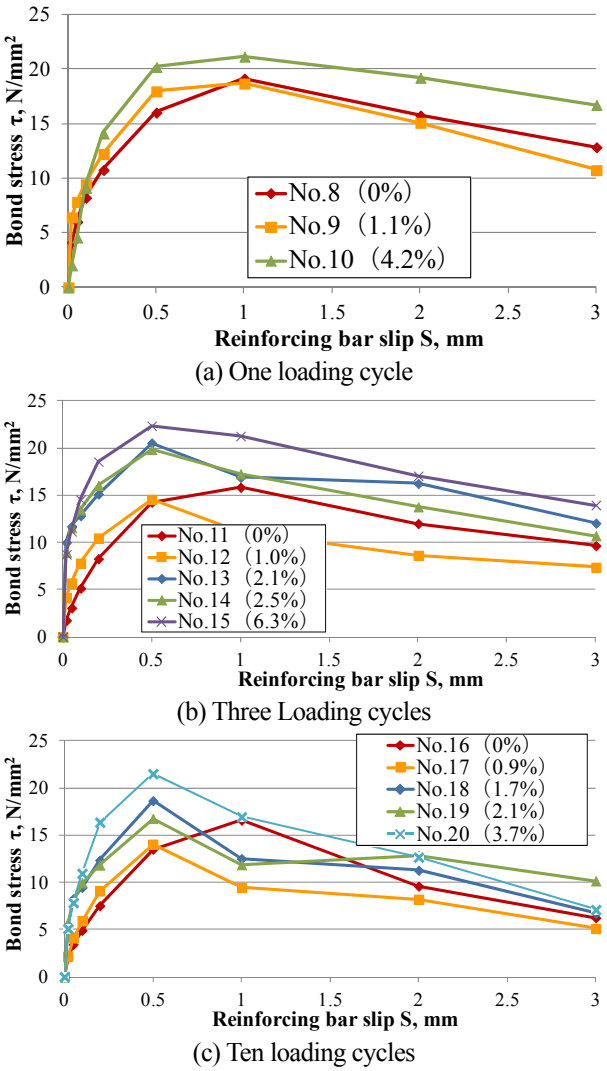
3.2.4 Influence of Corrosion Level of Reinforcing Bar

The relationships between the corrosion level and the maximum bond stress of specimen subjected to the monotonic or cyclic loading are shown in Figure 9. The results in the figure indicates that the maximum bond stresses of the specimens for more than around 2% cross-sectional loss due to the corrosion were larger than that of non-corroded specimens. This is because of an expansion pressure due to the corrosion products and the bond stress increases by the reaction force of surrounding concrete.



On the other hand, the maximum bond stress generally decreases when corrosion level greatly increases since the crack in the concrete along with a rebar occurs due to the expansion pressure of significant corrosion products. It should be noted that there is no crack in the specimen after the accelerated corrosion test was carried out in which the

corrosion level was set as until around 6% in this study.

Figure 10 shows the envelope curves of the relationship between the bond stress and slip of reinforcing bar under cyclic loading. The bond-slip relations under each loading cycle can be compared in these figures. The results indicate that the initial stiffness in the bond stress-slip relationship increases as the increase in the corrosion ratio. On the other hand, the post peak behavior in the bond stress-slip curve is similar in the each case although the maximum bond stress increases when the corrosion proceeds.

3.2.5 Influence of Number of Loading Cycles

The envelope curves of the bond stress-slip of reinforcing bar relationship are shown in Figure 11. The parameter compared with in the figures is the difference in the number of cyclic loading. The experimental results show that the bond stress becomes smaller as the increase in the loading cycles at all the corrosion level. The specimen subjected to cyclic loading of more than three times indicates that the maximum bond stress reaches at 0.5 mm of the slip. This behavior is caused by the bond deterioration under cyclic loading due to the concrete cracking along with the reinforcing bar and smoothed the bonded surface of the concrete as previously shown in Figure 7. It can be found that the decrease in the bond stress in the post peak is significantly observed in the specimen of around 4% of the corrosion.

(d) Corrosion Ratio: around 4%

Figure 11 Envelope Curves of Bond Stress-Reinforcing Bar Slip Relationship at Each Corrosion Ratio

3.2.6 Bond Stress Deterioration during Loading Cycles at Constant Slip Displacement of Reinforcing Bar

A decrease ratio of bond stress during loading cycles at the constant slip displacement of 0.02 mm, 0.5 mm and 2.0 mm are shown in Figure 12, respectively. Here, the decrease ratio of bond stress is defined by using Eq. (4) as follows,

$$\alpha_{i-N} = \frac{\tau_{i-N}}{\tau_{i-1}} \qquad (4)$$

where, $\tau_{i\text{-}N}$: the bond stress at the slip i mm and the N^{th} cycles, $\tau_{i\text{-}1}$: the bond stress at the slip i mm and the first cycle, i: the slip displacement of reinforcing bar at free end (i = 0.02, 0.5 and 2.0 mm), N: the number of load cycles (N = 1, 2···10, during 10 times loading cycles)

When a constant slip displacement is applied, the change of the bond stress as increase in the number of cycles can be confirmed from Figure 12. The experiment shows that the bond stress in the No.16 specimen decreases at 0.02 mm of the slip of rebar as shown in Figure 12(a) while the bond stress of corroded specimens remains constant. The bond stress in the No.16 specimen decreases to around 70% of initial value during loading cycles. It is also found that the bond of corroded specimens doesn't deteriorate when the slip of rebar is relatively small.

At the slip displacement of 0.5 mm, the bond stress of No.16 decrease to 55% of the bond stress at this slip displacement during 10 times cycles while the bond stress of corroded specimens significantly decreases to 30-40% of the peak stress at this slip displacement. In the post-peak range in which the slip of rebar reaches at 2.0 mm, the decrease ratio of all specimens indicates similar. Consequently, specimens without corrosion crack have a little influenced of the corrosion even when the number of cycles is increased.

4. CONCLUTIONS

The cyclic loading tests were performed for all pullout specimens where a D16 reinforcing bar was embedded in the concrete. In the experiment the bonded length of rebar was set as within 20 mm to 40 mm and the corrosion level was evaluated by the ratio of cross-sectional loss which ranged between 0.9% and 6.3%. The conclusions obtained in present study are as follows;

(1) The maximum bond stress of the corroded specimens in which the cross-sectional loss of rebar is more than around 2% becomes larger than that of non-corroded specimens.

(2) In the pre-peak behavior where the slip of rebar is less than 0.5 mm, the initial stiffness in the bond stress-rebar slip relationship increases as the increase in the corrosion ratio.

(3) The specimen subjected to cyclic loading of more than three times but less than ten indicates that the maximum bond stress is reached at 0.5 mm of the slip of rebar.

(4) At the slip displacement in which the peak bond stress is reached, the bond stress of the non-corroded specimen decreases 55% of the initial value during 10 times cycles while the bond stress of corroded specimens significantly decreases to 30-40% of the peak stress. On the other hand, in the post peak where the slip of rebar reaches 2.0 mm the decrease in the bond stress indicates similar to that of the non-corroded specimen, consequently, specimens without corrosion cracks have a little influence of the corrosion even when the number of cycles is increased.

Abstract: To investigate strengthening methods for anchorage part of rebars damaged by corrosion, beam type bond test apparatus representing anchorage part of RC beams was prepared and pull out tests of anchorage part of rebars damaged by corrosion strengthened by restraint force and FRP sheets were conducted. As a result of the experiment, non-strengthened specimen failed in bond splitting failure, however, failure mode of the strengthened specimens shifted to rebar yielding and their pull out strength recovered to the level of the non-damaged specimen. In addition, loading tests of corroded RC beam whose anchorage parts were strengthened by restraint force and FRP sheets were carried out. As a result, failure mode shifted from anchorage failure to flexural failure and load carrying capacity significantly increased.

1. INTRODUCTION

Recently, the number of deteriorated reinforced concrete (RC) structures due to corrosion of steel rebars has been increasing in many countries. Degradation of mechanical performance of RC structures due to corrosion of steel rebars is one of the seismic risks in urban societies. The rebars in the beams of RC structures may suffer corrosion throughout the length or may partially corrode localized portions such as mid span, shear span and anchorage part. If the corroded rebars with insufficient anchorage strength is subjected to a tensile force near the supports of beams, the anchorage failure occurs and the load carrying capacity significantly decreases. Hence, to prevent the anchorage failure of corroded RC beams, development of repairing and strengthening method for anchorage portion is immediately needed.

In order to recover or improve the load capacity of RC structures, strengthening of whole beam is not economical as it requires huge amounts of time, labor and materials. So, the more realistic countermeasure to prevent anchorage failure is to repair and strengthen only the anchorage portion. Many studies have been conducted to deal with the mechanical properties of the corroded RC beams (Matsuo et al. 2004, Tsunoda et al. 2007). However, the study on the RC beams with corroded anchorage part and its strengthening methods has not been investigated yet. Hence, this study focuses on the strengthening of the corroded anchorage part which highly influences the mechanical performance of the RC beams.

To investigate the mechanical characteristics of corroded rebars in the anchorage part of RC beams and to develop the strengthening methods of anchorage part, corroded specimens which represent the anchorage part of RC beams were prepared and pull-out tests of corroded rebars were conducted on non-strengthened and strengthened specimens. In addition, the loading tests of corroded RC beams strengthened in anchorage part of rebars were also conducted. In this study, three different strengthening methods by using transverse reinforcement, restraint force and continuous fiber sheet were investigated.

2. EXPERIMENTAL PROGRAM

2.1 Outline of the specimens

This study consists of two series of experiments. Series 1 is the pull-out tests of corroded rebars, and series 2 is the loading tests of RC beams. In series 1, a beam-type bond testing apparatus shown in Figure 1 was used to represent the anchorage part of a beam. Pull out force was applied to the rebars in terms of bending moment acting between loading and supporting points. The outline of the testing part is shown in Figure 2. Unbonded part of 65 mm in length was provided at the end of loading part and the bond length was 350 mm. Steel rebars were deformed bars with nominal diameter of 15.9 mm and Table 1 shows the mechanical properties of the rebar.

In series 2, in order to simulate the structures with corroded rebars throughout the span and partially

corroded rebars at the anchorage part, six RC beam specimens having corrosion throughout the rebars, i.e. whole part corroded beam (series 2-1) and three RC beam specimens having corrosion at anchorage part (series 2-2) were prepared. Figures 3 and 4 show the outline and the cross sectional view of series 2, respectively. Table 1 shows the mechanical properties of rebars. Table 2 shows the specifications of the RC beams. Concrete of design compressive strength 30 N/mm^2 was used and the mix proportion of concrete is shown in Table 3. Shear reinforcements were provided in only series 2-2 and in order to assume the failure of test span, larger amount of stirrups was provided in the other span.

The shear capacity V_u of RC beams was calculated by adding the shear carried by concrete which was assumed to be the same as shear capacity of RC beams without stirrups and stirrups (Niwa et al. 1987), and is given by,

$$V_u = V_c + V_s \tag{1}$$

$$V_c = 0.2 \cdot \sqrt[1/3]{f_c'} \cdot \sqrt[1/4]{\frac{1000}{d}} \cdot \sqrt[1/3]{p_w} \cdot \left(0.75 + 1.4\frac{d}{a}\right) \cdot b_w d \tag{2}$$

$$V_s = A_w f_{wy} (z/s) \tag{3}$$

where, V_c is shear carried by concrete (kN), V_s is shear carried by stirrups (kN), f_c' is compressive strength of concrete (N/mm^2), d is effective depth (mm), p_w is

longitudinal reinforcement ratio (%), A_s is cross sectional area of longitudinal rebars (mm^2), b_w is width of the beam (mm), s is spacing of stirrups (mm), A_w is total cross sectional area of stirrups in the range of s (mm^2), f_{wy} is yield strength of stirrups (N/mm^2), z is moment arm length (mm).

2.2 Steel corrosion acceleration method

Following the procedure given by Tsunoda et al. (2007), electric corrosion tests were conducted to corrode steel rebars. The outlines of the electric corrosion test in each series are shown in Figure 5. In this method, the steel rebars and the stainless steel plate were set to anode and cathode. In series 1 and series 2-1, about 20 mm in height from the bottom of the specimen was soaked in 3% NaCl solution and corrosion was induced in the whole part of steel rebars. In series 2-2, water level of 3% NaCl solution was below the bottom of the specimen. To induce corrosion in the steel rebars at the anchorage part, the bottom of the anchorage part of the beam was connected to 3% NaCl solution through a sponge (Figure 5(c)). The corrosion degree in each specimen was controlled by using accumulated current given by the product of an electric current and time. The target corrosion degree in all specimens of series 1 was 10%.

2.3 Experimental cases

Table 4 lists the experimental cases of both series. In series 1, a non-corroded control specimen N was prepared to compare the difference of bond behavior between corroded and non-corroded specimens. Three different strengthening methods using transverse reinforcement, restraint force and continuous fiber sheet were implemented to strengthen the specimens. The arrangement of transverse reinforcements is shown in Figure 6. Closed stirrups of steel rebars with nominal diameter of 9.53 mm were provided as the transverse reinforcement. Restraint force was introduced by using four PC bars and two steel plates as shown in Figure 7. High elasticity carbon fiber sheet and glass fiber sheet were wrapped in the specimens as

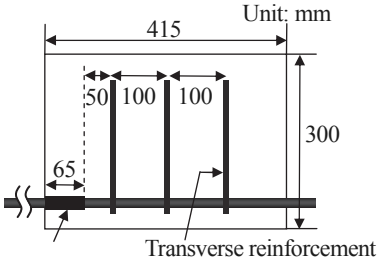

Fig. 6 Arrangement of transverse reinforcements

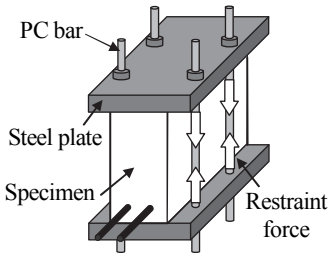

Fig. 7 Method to introduce restraint force

Table 5 Material properties of fiber sheet

Sheet	Thickness (mm)	Tensile strength (N/mm^2)	Elastic modulus (kN/mm^2)
Carbon	0.143	1900	640
Glass	0.118	1500	73

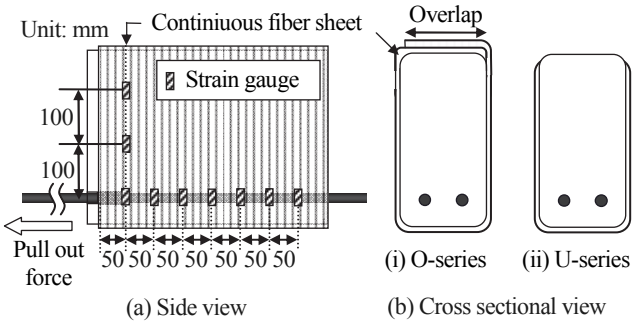

Fig. 8 Continuous fiber sheet and location of strain gauges

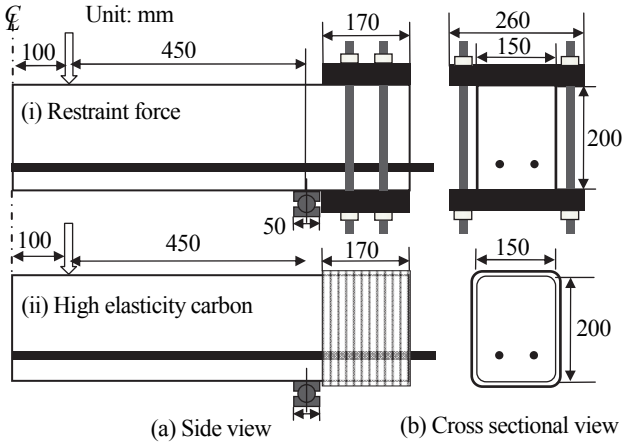

Fig. 9 Outline of strengthened specimens

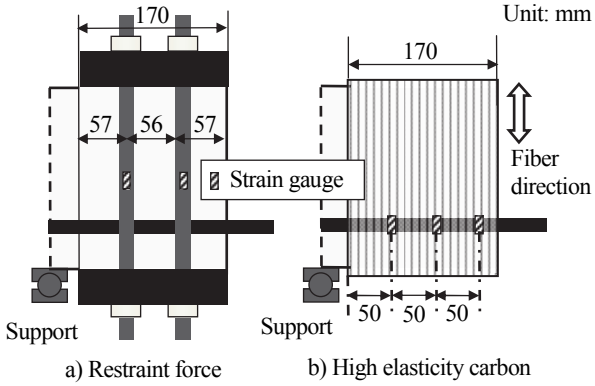

Fig. 10 Details of strengthened parts

shown in Figure 8. The corners of the specimen were chamfered before wrapping the fiber sheet. Table 5 shows the material properties of each continuous fiber sheet. The fiber sheets were wrapped in two different ways. The first way was to wrap all around (O-series), and the other way was to wrap the specimen in only sides and bottom (U-series) as shown in Figure 8(b).

In series 2, before investigating the strengthening effect of RC beams, non-strengthened specimens were prepared to compare the mechanical characteristic to RC beams having steel corrosion at whole part and anchorage part. The parameter of non-strengthened specimens was the corrosion degree. Similarly, the specimens strengthened by the restraint force and high elasticity carbon fiber sheet were prepared. The corrosion degree in both strengthened specimen was 16%. Strengthening was introduced only at the anchorage part of RC beams in series 2-1. The outline of strengthened specimen is shown in Figure 9. The each strengthening method was introduced in the same process as in series 1. Restraint force was introduced by using four PC bars and two steel plates. During the application of restraint force, strain in each PC bars were monitored to confirm the equal tensile forces in all PC bars (Figure 10(a)). To avoid the disturbance to the support plates, strengthening length was set to 170 mm, which was 30 mm shorter than anchorage part.

2.4 Instrumentations and loading method

In series 1, the slip of rebars at the location where the pull out force is applied was measured by using the attachment equipment shown in Figure 11. The attachment equipment was connected to the longitudinal rebars through a 15 mm square duct of depth equal to cover concrete (Figure 12). The duct was created in the sides of the beams during casting. Thus, the measured displacement of the aluminum plate in attachment equipment provides the slip of rebars. To measure the strain in unbonded portion of rebar, one strain gauge was attached at the point 100 mm away from the testing part (Figure 2(a)). In the specimens strengthened by fiber sheet, installation of π-gauges and visual observation cannot confirm the crack propagation and widening in concrete as fiber sheet is wrapped on surface of specimen. Thus, in order to evaluate the crack propagation and widening, strain gauges were attached to the surface of fiber sheet at 50 mm interval as shown in Figure 8.

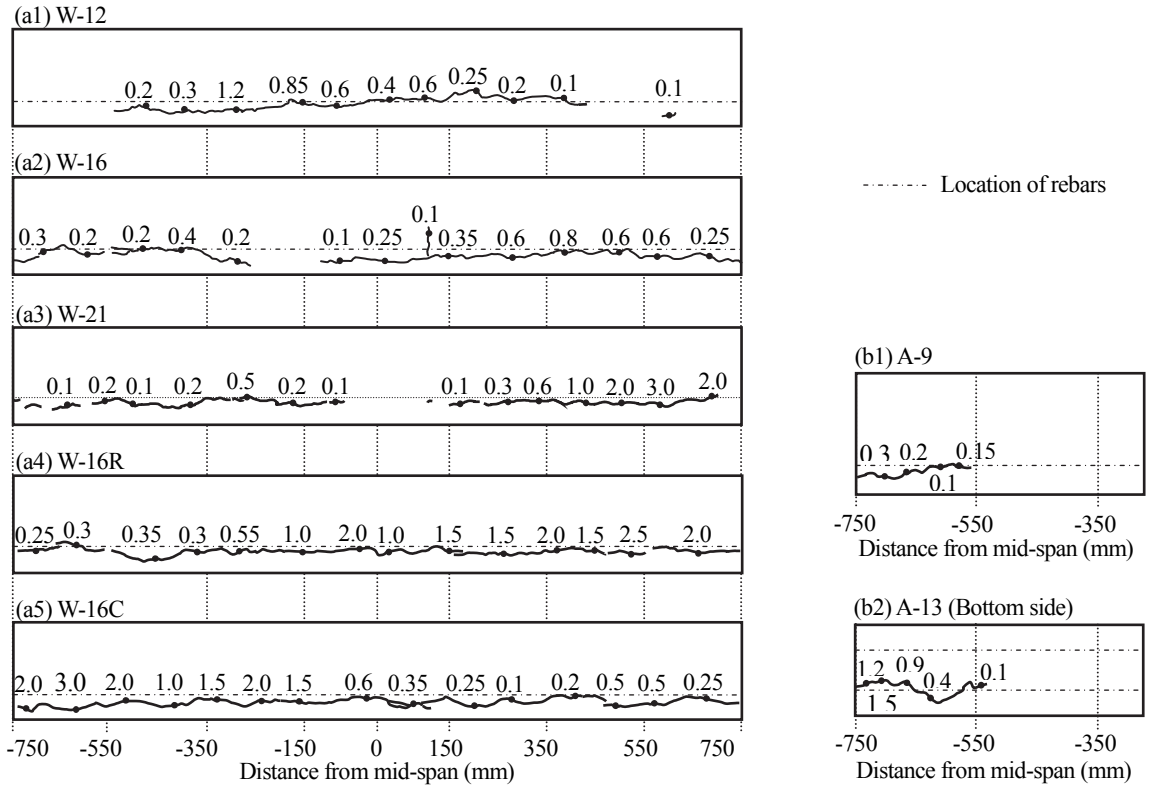

Fig. 11 Corrosion crack conditions

In series 2, mid-span and support displacement were measured by using displacement transducer and the strain in rebars at the mid-span of non-corroded specimens W-0 and A-0 was measured by strain gauges. Also, strain gauges were attached to the stirrups in the specimens of series 2-2. Strain gauges were also attached to the surface of fiber sheet at 50 mm interval as shown in Figure 10.

For loading tests in both series, four-point bending tests were conducted. Teflon sheets sandwiching the grease were inserted between the specimen and the supports to prevent the horizontal friction.

3. RESULTS OF ELECTRIC CORROSION TESTS

3.1 Corrosion crack condition

Figures 11 shows the location of corrosion cracks in all the specimens of series 2. In all series, some corrosion cracks caused by the steel corrosion acceleration test propagated along the longitudinal rebars on the surface of specimens. The values in the figure represent the crack width in mm and the bold ones represent the maximum corrosion crack width. The corrosion crack width tended to increase with increase of accumulated current in all the cases except in specimen W-16 (Table 4 and Figure 11(a)).

3.2 Steel damage condition

After the loading test, rebars were taken out from the specimens and the rust on the rebars were removed using wire brushes. The cleaned rebars were soaked in 10% diammonium hydrogen citrate for two days at 60 degrees Celsius to clean up the remaining corrosion products following to the recommendation by JCI (2004)[4]. Then, the rebars in series 1 and 2-1 were cut into pieces with 50 mm length. In series 2-2, the rebars at the anchorage part was cut to 200 mm length and 100 mm long rebar was taken from the portion beyond the anchorage part.

To evaluate the amount of steel corrosion, the mass reduction ratio C was calculated and is given by,

$$C = (w_0 - w_c)/w_0 \times 100 \quad (4)$$

where, w_0 is the mass per unit length of an original rebar (g/cm), w_c is the mass per unit length of a corroded rebar (g/cm).

The corrosion degree of rebars was defined as the average value of C at each section of two rebars. Table 4 shows the results of corrosion degree. In series 2-2, the corrosion in rebars at 100 mm from supporting point of the specimen A-9 and A-13 were 2.8% and 3.1%, respectively and the corrosion degree in the rebars beyond 100 mm away from the supporting point was almost 0%.

4. RESULTS OF PULL OUT TESTS OF ANCHORAGE SPECIMENS (SERIES 1)

4.1 Result of the maximum pull out force

Table 4 shows the results of the loading test, where the maximum pull out force (P_{max}) was calculated by using the strain in the unbonded part of the rebars. When the specimen failed in the bond splitting, the pull out force was calculated by multiplying a cross sectional area and the elastic modulus of a rebar to the measured strain. However, when the measured strain exceeded the yielding strain, the pull out force was calculated by multiplying a cross sectional area of a rebar to the yield strength. The corroded specimen C11 failed in the bond splitting at 60% of the maximum pull out force of the non-corroded specimen N. It shows that the anchorage strength decreased due to the steel corrosion. The maximum pull out force of all the strengthened specimens was almost same as that of the specimen N. Hence, the effectiveness of the applied strengthening methods to recover the anchorage strength was confirmed.

4.2 Result of slip and strain of FRP sheet

Figure 12 shows the change of slip measured by the attachment equipment. In this figure, the specimen C14T which was strengthened by transverse reinforcements is not shown because the slip could not be measured. Here, value of slip under 14, 28, 42, 56, 60 and 64 kN of pull out force are shown. The bond between rebars and concrete decreased due to corrosion, consequently, the slip of the corroded specimen C11 was larger compared to that of non-corroded specimen even though the pull out force was small. The slip of all the strengthened specimens decreased compared to the specimen C11. This shows the application of each strengthening method prevented corroded rebars from pulling out.

Figure 13 shows the strain distribution of each fiber sheet when the pull out force was 14, 28, 42, 56, 64, 67 kN and peak load. Positive value means tensile strain. In all specimens strengthened by fiber sheet, the strain at distant point from the point of the pull out force increased with the increase in the pull out force. It indicates that the tensile force acted in the sheet because cracks along the rebars were widened. Since the elastic modulus and thickness of carbon fiber sheet were larger, the strain in the specimens strengthened by high elasticity carbon fiber sheet was larger than that of the specimens strengthened by glass fiber sheet. Therefore carbon fiber sheet was more effective to prevent cracks from widening. Moreover, comparing specimens having different wrapping way, the strain in the specimens which had larger corrosion degree was larger than that of the specimen having smaller corrosion degree. In this experiment, two strain gauges were also attached at 100 mm interval in height direction as shown in Figure 8, however, measured strain in these gauges were very small in all the specimens. Also, the corrosion degree of the specimen C13C-U and C13G-U was 3% larger than that of the specimen C8C-O and C8G-O. Hence, it can be said that the tensile force acted on the fiber sheet was affected by corrosion degree but not by the wrapping way of fiber sheets.

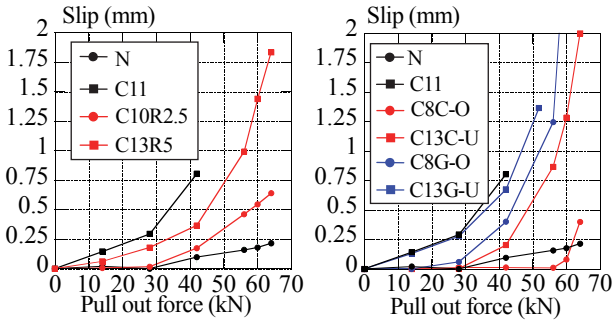

Fig. 12 Slip at the point of pull out force

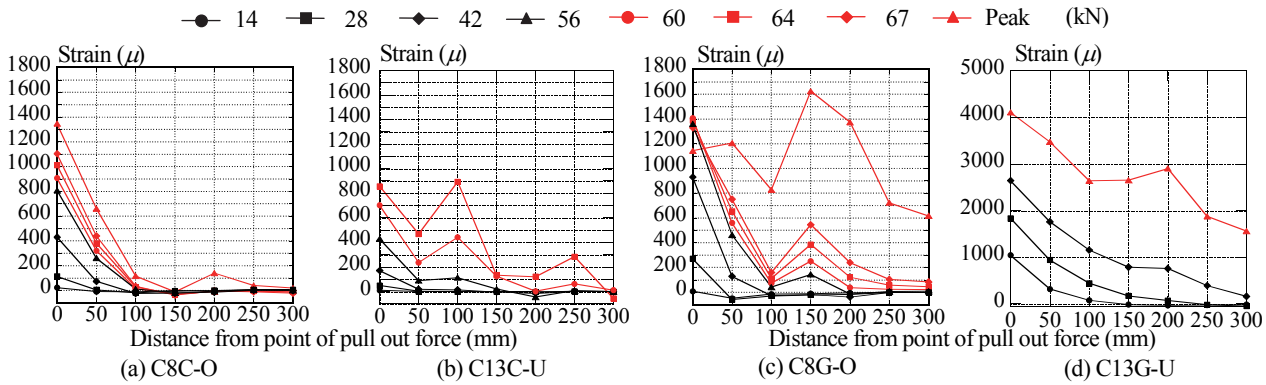
5. RESULTS OF LOADING TESTS OF RC BEAMS (SERIES 2)

5.1 Failure mode and the peak load

The compressive strength of concrete, the calculated shear capacity of RC beam (P_{cal}), the observed peak load P_{max} and the failure mode are tabulated in Table 4. P_{cal} was calculated considering no



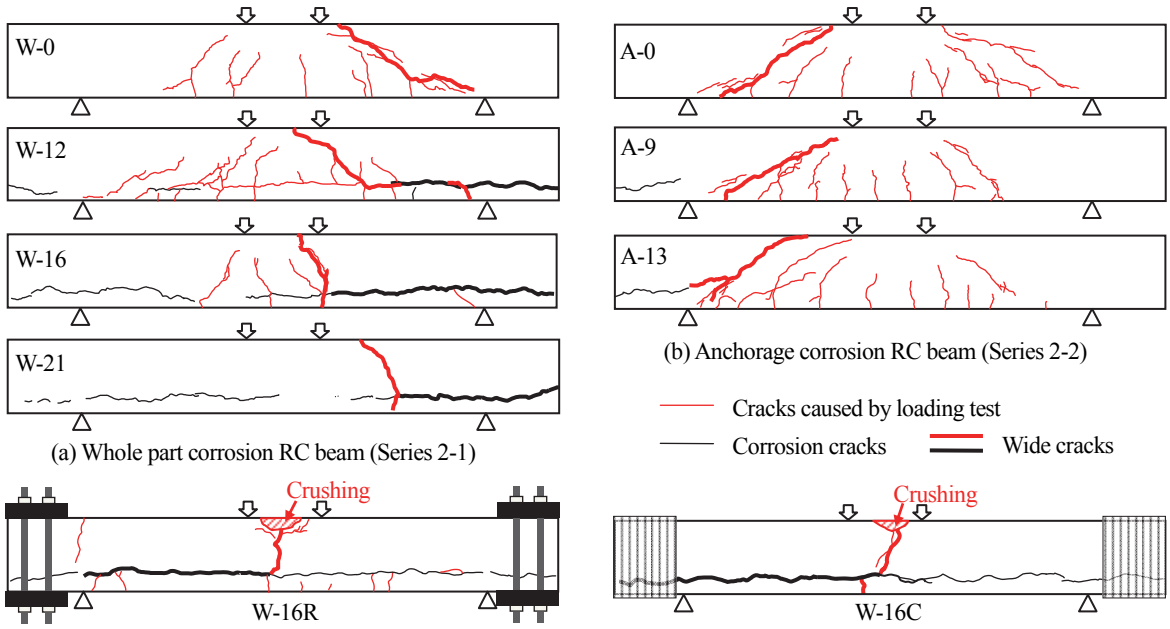


Fig. 13 Strain distribution in fiber sheet

(b) Anchorage corrosion RC beam (Series 2-2)

(c) Strengthened RC beam (Series 2-1)

Fig. 14 Crack conditions at the maximum load

corrosion in the rebars.

(1) Non-strengthened RC beams (Series 2-1 and 2-2)

Figures 14(a) and (b) show the crack pattern in non-strengthened beams at the peak load. In the non-corroded specimen W-0 and A-0, diagonal cracks occurred and propagated from loading point to support and finally failed in shear. The shear capacity of corroded specimen W-12 increased by 37% compared to W-0 because of formation of arch action caused by the corrosion of longitudinal rebars[3]. In all the corroded specimen of series 2-1, the corrosion of the rebars deteriorated the bond between concrete and rebars leading to the anchorage failure. Moreover, the peak load decreased with the increase of corrosion degree. In particular, the corroded specimen W-21 in which corrosion degree was more than 20% failed in anchorage before flexural cracks occurred and the peak load was about 30% of non-corroded specimen W-0.

In series 2-2, the corroded specimen A-9 failed in shear similar to the non-corroded specimen A-0. Because the anchorage strength of rebars did not decrease much when corrosion degree was 9% and pull out capacity was enough not to be failed in anchorage. The corroded specimen A-13 failed in anchorage and the maximum load decreased 13% compared to non-corroded specimen A-0. The pull out force acted on the rebars of anchorage exceeded the pull out capacity when corrosion degree reached to 13%.

(2) Strengthened RC beams (Series 2-2)

In corroded specimens W-16R and W-16C strengthened by restraint force and high elasticity carbon fiber sheet, flexural cracks dominated and finally failed in flexure due to crushing of concrete in compression zone at the mid span as shown in Figure 14(c). The corrosion cracks inside the span gradually widened with increasing the load level. However, in the specimen W-16R, the cracks at the anchorage portion did not widened even though the load reached to the peak. It shows that the application of restraint force can prevent the cracks from widening.

Compared to the corroded specimen W-16, the maximum load of strengthened specimens W-16R and W-16C decreased by 6.6% and 12.8%, respectively in spite of strengthening. These behaviors seemed to be related to the corrosion crack width. The maximum corrosion crack width in the specimen W-16 was 0.8 mm. Whereas, those of the specimens W-16R and W-16C were 2.5 mm and 3.0 mm, respectively (Figure 11(a)). It is reported that the bond is affected more by the corrosion crack width along the longitudinal rebars than by the corrosion degree[1]. Hence, there is a possibility that load capacity of the specimen W-16R and W-16C before strengthening was close to the specimen W-21 in which maximum corrosion crack was 3.0 mm rather than the specimen W-16. Since the peak load of the strengthened specimens W-16R and W-16C was almost three times as much as that of W-21, it can be confirmed that the applied strengthening methods have significant effect on the load capacity of corroded RC beams.

5.2 Load-displacement curves

(1) Non-strengthened RC beams (Series 2-1 and 2-2)

Figure 15 shows the load-displacement curves of all the non-strengthened RC beams. In the specimen W-0, a diagonal crack occurred when the load was 62 kN and the load slightly decreased. Then, the load increased again. Finally, at the peak load (71.7 kN), the

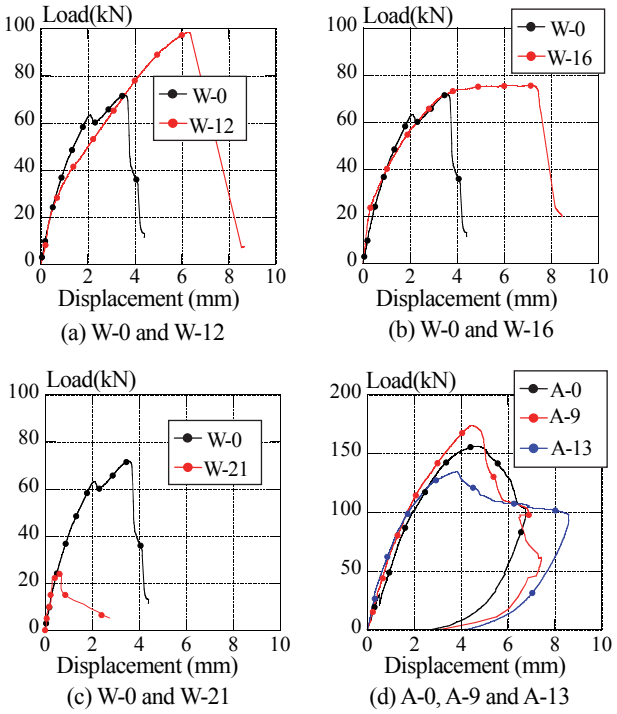

Fig. 15 Load-displacement curves (Non-strengthened specimens)

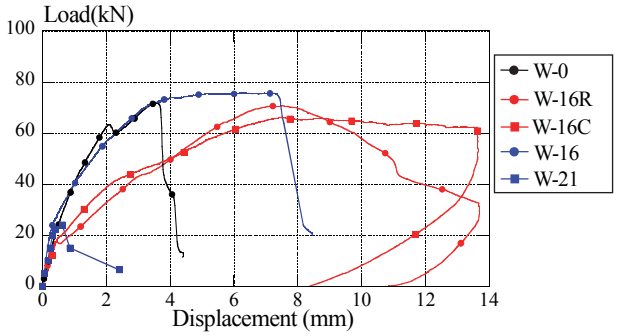

Fig. 16 Load-displacement curves (Strengthened specimens)

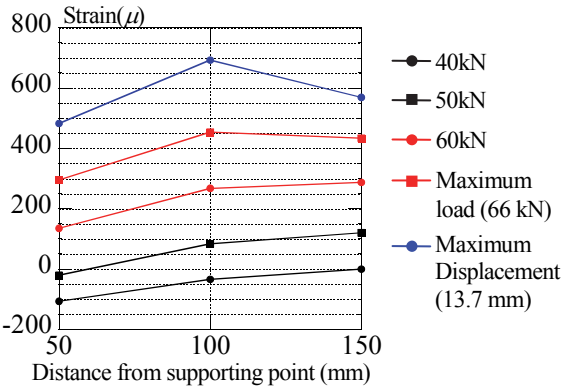

Fig. 17 Strain distribution of fiber sheet (W-16C)

diagonal crack widely opened and the load decreased rapidly. In the specimens W-12 and W-16 which failed in anchorage, a rapid drop of the load was confirmed after failure. In particular, in the specimen W-12 which had the largest pull out force among the corroded specimens, the load suddenly dropped from the peak load (98.5 kN) to 7.2 kN exhibiting the brittle failure.

In all cases of series 2-2, the load increased after a diagonal crack occurred because of the presence of stirrups. Finally, the stirrups yielded and the diagonal tension failure occurred in the specimen A-0 and A-9. The specimen A-13 failed in anchorage before all stirrups yielded.

(2) Strengthened RC beams (Series 2-2)

Figure 16 shows the load displacement curves of two strengthened specimens along with those of the specimens W-0, W-16 and W-21 to compare the response of strengthened and non-strengthened specimens. After the load reached to about 20 kN, stiffness of two strengthened specimen gradually decreased compared to the other non-strengthened specimens. In the specimen W-16R, after the peak load, the load gradually decreased. In contrary, the load suddenly dropped after the peak load in the specimens W-0 and W-16. In the specimen W-16C, the load did not decrease much after the peak load. Flexural failure is supposed to occur because crushing of concrete in compression zone at mid span was observed at 10 mm of displacement.

Compared to the specimen W-21 in which the maximum corrosion crack width was almost same as that in two strengthened specimens, the peak load and the deformation performance of the specimen W-16R and W-16C were improved substantially. On the other hand, compared to the non-corroded specimen W-0, the stiffness of two strengthened specimens decreased significantly. Although the load capacity was recovered by strengthening, the stiffness was not recovered when strengthening was applied only to the anchorage portion.

5.3 Strain of FRP sheet

In order to evaluate the crack propagation and widening of cracks, strain gauges were attached in the fiber direction of the fiber sheets (Figure 10(b)). Figure 17 shows the strain distribution in high elasticity carbon fiber sheet when load was 40, 50, 60 kN, the peak load (66 kN), and the maximum displacement (13.7 mm). Positive value means tensile strain.

When the load was 40 kN and 50 kN, due to the compressive force acted on concrete from the vertical support reaction, compressive strain was observed particularly at the point 50 mm from the support. On increasing load, the crack widened and tensile force acted on the fiber sheet to resist widening of cracks, that resulted tensile strain in all the strain gauges. After the peak load, the strain also became larger until the maximum displacement. Moreover, the strain at the 50 mm from the supporting point was the smallest among the three gauges throughout the loading test. The support reaction was dominant at that point because the location of strain gauge was the nearest from the support.

6. CONCLUSIONS

1) The anchorage part specimen in which mass reduction ratio was 11% failed in bond splitting with 38% reduction in pull out strength. However, pull out strength recovered to the level of non-corroded specimen after restraint force and continuous fiber sheet were provided. By applying these methods, mechanical performance of anchorage parts of rebars having corrosion can be improved.
2) The anchorage part specimen strengthened by high elasticity carbon fiber sheet in which elastic modulus and thickness were comparatively larger prevented cracks from widening than that strengthened by glass fiber sheet. Strengthening effect of the continuous fiber sheet wrapped in U-shape (only sides and bottom) was almost same as that wrapped to whole section. Strengthening effect of continuous fiber sheet on anchorage parts of rebars is not affected by the wrapping way but stiffness of the sheet.
3) Shear capacity of the RC beam specimen having corrosion in whole part of longitudinal rebars increased due to the arch action when mass reduction ratio was about 12%. However, anchorage failure occurred and load capacity decreased when mass reduction ratio was more than 16%. Load capacity of RC beams having corrosion in whole part of longitudinal rebars decreases when the amount of corrosion exceeds certain degree.
4) In RC beams having corrosion only in the anchorage part of longitudinal rebars, pull out force starts to act on the rebars in anchorage part after the formation of a diagonal crack. The specimen with mass reduction ratio of 13% failed in anchorage and the load capacity decreased. Reduction of load capacity and failure mode are supposed to be determined by magnitude of the pull out force at the anchorage as well as the corrosion degree.
5) By providing restraint force or continuous fiber sheet, failure mode shifted from anchorage failure to flexural failure and load capacity significantly increased compared to the specimen in which width of the corrosion cracks was the same. However, member stiffness was smaller than that of the non-corroded specimen. By strengthening anchorage parts of rebars, load capacity of RC beams can be improved. In order to save cost and time, strengthening of only anchorage parts is supposed to be effective for maintaining safety of structures.

**)sjhwang@ntu.edu.tw*

Abstract: School buildings of all types of construction were seriously damaged by the 921 Chi-Chi Earthquake. Seismic evaluation and retrofit of these numerous vulnerable school buildings is an important societal issue to be resolved. The National Center for Research on Earthquake Engineering (NCREE) assisted the Ministry of Education with the arrangement of the program to accelerate the retrofit and rebuilding of elementary school, junior high school, senior high school and vocational school buildings, as part of the Economic Recovery Act. Currently, the program plans to spend 18.27 billion NTD between 2009 and 2012, and has proceeded with the seismic evaluation and retrofit of school buildings in Taiwan. In addition, NCREE established a School Project Office for this program to ensure that the work will be carried out in the most economic and effective manner. The purpose of the office is to provide administrative and technical supports, and to hold training programs and workshops for school administrators and professional engineers. A three-stage strategy for screening with existing school buildings also has been proposed by NCREE for execution of this program.

1. INTRODUCTION

Taiwan is located on the circum-pacific seismic zone. Earthquakes are common experiences for people in Taiwan. There were lots of heavy earthquakes happened and often caused schools to be destroyed seriously in the past years. In 1999, the Chi-Chi Earthquake caused nearly half of the school buildings in the central area of Taiwan to collapse or damage seriously. As many as 656 primary and secondary school buildings were damaged in that earthquake. This disaster told us the seismic capacities of existing school buildings in Taiwan are probably not sufficient. Significant casualties and property losses could be resulted from the collapse of these school buildings under strong earthquakes. Furthermore, school buildings might have to be assigned as emergency shelters immediately after a severe earthquake. To avoid casualties in the future earthquakes is the most important job in Taiwan. To retrofit these bad seismic performance school buildings is one solution to reduce the probable casualties.

The global economy went into a slump in 2008 as the impact of the international financial crisis spread. The whole economy has been heavily affected by this turn of events, and the unemployment rate has risen swiftly. On December 30 in 2008, the government announced that it will directly inject NT$858.5 billion to rescue Taiwan's economy over the next four years. The project involves 20 key public works projects and 64 special investment plans, and aims to achieve 6 major objectives. A total of NT$500 billion will be invested under the project. The focus of the policy will be on expanding public works projects, promoting major private investment projects, and fostering developing of industries that display a high degree of competitiveness. One of these projects is about the retrofitting or reconstruction of school buildings which is superintended by the Ministry of Education. Before the retrofitting the seismic capacity of school buildings should be evaluated with a reliable method. A three-stage strategy for screening with existing school buildings (Fig.1) was proposed by NCREE. These three stages are simple survey, preliminary evaluation and detailed evaluation. Simple survey is conducted by school administration while preliminary and detailed evaluations by professional engineers.

After a stage is completed, a summary report is submitted through internet to NCREE where a data base is established (Hwang, 2008). Based on the statistical analysis result from the data base, decision on seismic upgrading of school buildings can be made by the executives. Moreover, it is a good reference for the engineering community. Through the processes of preliminary evaluation, detailed evaluation, retrofit design and retrofit implementation, seismic upgrading of school buildings will be completed.

2. SEISMIC DEFICIENCY OF PUBLIC SCHOOL IN TAIWAN

Most school buildings in Taiwan were designed based upon the standard floor plan developed in 1966. Typically there is a corridor outside of the classrooms. The floor or roof above the corridor is often cantilevered without columns, and classrooms have been configured side by side in a row. Based on the damage statistics, a lack of seismic

resistance appears to be a common problem in the existing school buildings in Taiwan. Some of the major characteristics of seismic deficiency in school buildings are: (1) lack of integral planning; (2) collapse along corridor; (3) effect of short columns; (4) imbedded pipelines; and (5) lack of transverse reinforcement.

2.1 Lack of integral planning

In Taiwan, a large number of old buildings in elementary and secondary schools appear lacking of an integral planning in advance (Chung, 2000). Instead, many old school buildings have been constructed and later on expanded in a patchy way. It was due to the population growth in the school district and the rising of multifarious branches of teaching, the number of existing classrooms was no longer enough. Hence the school authorities had strived for funding from year to year. When the budget allowed, new classrooms were added to the existing ones in the horizontal or vertical directions at different times in order to solve the problems of under-supply of classrooms. If the new classrooms were added horizontally, the structural system of the old school building could be spoiled. If the new classrooms were built on top of the old ones, seismic and gravity load demands on the old classrooms would be significantly increased. The new classrooms expanded in the horizontal direction are rather closely adjacent, if it is not connected, to the old ones so as to maintain the continuity of activity space for pupils and teachers. Having constructed at different times, the old and the new classrooms could be different in height, weight or stiffness. Thus, the two structures may possess different fundamental vibration periods. When an earthquake occurred, the old and new classrooms would vibrate not in-phase. Under this circumstance, if the adjacent seismic gaps were not wide enough, those classrooms could have pounded each other. The pounding could cause the complete failure and collapse of columns in the adjacent building.

2.2 Collapse along corridor

Most school buildings in Taiwan were designed based upon the standard floor plan developed in 1966. According to the standard floor plan, classrooms have been configured side by side in a row. Typically there is a corridor outside of the classrooms. The floor or roof above the corridor is often cantilevered without columns. Transverse to the corridor, classrooms are typically partitioned by using brick walls which are continuous in the gravity direction. However, along the direction of the corridor, doors and windows have been constructed for entrance and natural light. Only small amount of walls could be continuous. The noted cantilevered corridor may be convenient for students' activities on the first floor. Thus, it often leaves only 2 reinforced concrete frames along the corridor direction. Unfortunately, these two frames typically consist of short columns. These short columns are resulted from the concrete or brick windowsill constructed between the columns. The adverse effects of the short column on the seismic performance of RC frame structures will be highlighted later in this article. Based on the worldwide observations on school building damages, there is strong evidence that school buildings tend to collapse along the corridor. There seems no case recorded that school buildings collapse transverse to the corridor direction.

2.3 Effect of short columns

In order to gain lighting and ventilation, the two exterior sides of the classrooms have been built with windows and doors. At the upper portion of the columns, it is often constrained by concrete or brick lintel above the window. At the lower portion of the columns, it is typically constrained by the noted infill below the windowsill. Thus, the effective length of the column has been significantly shortened. During an earthquake, the shear demand on the shortened column is therefore greatly increased. Unfortunately, these columns have been constructed with poor concrete and without sufficient shear reinforcement. Consequently, the columns have been found frequently failed in the shear mode, with X-shape cracks commonly observed. As a matter of fact, if a seismic gap had been cut between the column and the infill, the effective length of the column would not be shortened. In this manner, a more desirable flexural failure mode could be achieved. The seismic gap could be filled with compressible but watertight material.

2.4 Imbedded pipelines

Utility lines, including water supply, drainage and electricity have been embedded inside the columns. Consequently, the effective area of the columns is substantially reduced. The cross-sectional area of the columns is typically about 25 to 30 cm square. After a 5-cm diameter minimum drainage pipe is embedded, the column cross-sectional area is greatly reduced. The strength of the column has been evidently reduced and was never carefully taken into account. It is obvious that a complete separate space for running the utility lines is needed.

2.5 Lack of transverse reinforcement

The spacing of column transverse steel reinforcement in many old buildings has been found exceeding 20 cm. Transverse steel reinforcement is essential in confining core concrete, prolonging buckling of longitudinal reinforcement and prohibiting shear failure. The lack of lateral reinforcement should help to explain why the school building columns have often been failed in a brittle shear failure mode. The ductility of this kind of columns can be effectively enhanced by seismic retrofit using steel or carbon fiber jacketing.

3. STRATEGY AND STATISTICS OF SEISMIC UPGRADING

3.1 Three-stage strategy for screening

In order to effectively tackle the seismic deficiency problems for school buildings in Taiwan, three stages have

been proposed for screening, including simple survey (Chung, 2005), preliminary evaluation (Chung, 2004) and detailed evaluation (Chung, 2008). The simple survey is conducted by school administrators. In a simple survey, a chart has been developed for collecting school data and building data. School data include street address of the school, the number and the identification of school buildings. Building data include the number of stories, the year of design or construction, condition of the building, floor dimension, number of columns and the cross-sectional dimension of the typical column in each frame, number of walls and the cross-sectional dimension of the typical wall in each frame. After the survey chart is filled, data entries are submitted through internet. Before the extensive simple survey was launched across all school districts, workshop has been held to train school administrators responsible for conducting the survey.

The second stage of screening, preliminary evaluation is conducted by professionals. In a preliminary evaluation, a chart has been developed for the professionals to carry out the evaluation. In addition to the identification of the school and the building, the data include design ground acceleration, number of stories, floor area above the first story, cross-sectional areas of columns, reinforced-concrete walls, four-side and three-side bounded brick walls, and conditions of the building.

The third stage of screening is the detailed evaluation conducted by professional engineers. The push-over method using commercial computer program such as ETABS has been adopted in Taiwan. Seismic retrofit design is conducted by professional engineers. Four seismic retrofit techniques for school buildings have been verified experimentally in NCREE. It includes reinforced concrete jacketing of columns, steel jacketing of columns, wing walls addition adjacent to columns and composite columns addition to partition brick walls. The proposed strategy of seismic evaluation and retrofit of these school buildings has been accepted and implemented by the Ministry of Education. It has been recommended by NCREE research team that detailed evaluation and retrofit design of a school building be conducted by the same professional engineer so that the responsibility can be clearly defined. Moreover, it is also suggested that the detailed evaluation and retrofit design must be reviewed by a panel so that the engineering work quality can be guaranteed. In the final stage of retrofit construction, inspection has been prescribed.

The seismic performance of school buildings can be evaluated from its seismic capacity to demand ratio. The seismic capacity of the school buildings is computed by superimposing the shear strength of various vertical members such as walls and columns. The seismic demand is determined from the weight and location of school buildings. The seismic performance is further modified according to the conditions of the buildings. Simple survey has been conducted by school administrators such as director of general affairs, section chief of general services, or teacher with knowledge on civil engineering or building maintenance. The information of the survey has been submitted to the computer server in NCREE through internet.

3.2 Statistics of seismic database for school buildings in Taiwan

In Taiwan, there are 3,497 elementary and junior high schools. Among them, 3,419 schools (about 98%) completed the simple survey and submitted school data and building data to NCREE. The data base possesses data for 12,650 school buildings and the data for 11,060 school buildings (about 87%) are valid.

According to the statistics analysis, the means of the length and depth for the floor plans of school buildings are 52.9m and 11.5m, respectively. The mean of the number of stories for school buildings is 2.8. The mean of the floor area of the first floor for school buildings is 616m^2. The mean of the spans along the corridor for school buildings is 4.0m. The mean of the ratio of column area to floor area for school buildings is 57.0cm^2/m^2. The seismic design codes of buildings were revised in 1982 and 1997. 39% of school buildings were built before 1982, 41% between 1982 and 1997, 15% after 1997 and 5% unknown. 80% of the school buildings scored with fundamental seismic performance less than 80, 18% between 80 and 100, 38% above 100. After consideration of the conditions for the school buildings through modification factor, 55% of the school buildings scored with seismic performance indices less than 80, 16% between 80 and 100, 29% above 100.

4. ACTIVITIES IN SEISMIC UPGRADING PROJECT

The School buildings of all types of construction were seriously damaged by the 921 Chi-Chi earthquake. Soon after, NCREE started to develop technologies for seismic evaluation and retrofit. As a result of the achievements of laboratory and in-situ experiments, NCREE developed several seismic technologies, including a simple survey method, a preliminary evaluation process, a detailed evaluation process, and a retrofit design method. NCREE then used these research results in their "Technology Handbook for Seismic Evaluation and Retrofit of School Buildings (Chung, 2008)." By holding training programs and workshops, NCREE provides professional training in those technologies to school administrators and professional engineers in Taiwan.

During the past several years, NCREE assisted the Ministry of Education with establishing a seismic database for the assessment and retrofit of school buildings, and with collecting basic information as well as the results of the evaluation and retrofitting for all school buildings in Taiwan. By establishing the actual seismic capacity of all school buildings in Taiwan, this internet database has become the foundation of the plan for their seismic capacity improvement. In addition, NCREE assisted the Ministry of Education with the arrangement of the program to accelerate the retrofit and rebuilding of elementary school, junior high

school, senior high school and vocational school buildings, as part of the Economic Recovery Act. Currently, the program plans to spend 18.27 billion NTD between 2009 and 2012 (Table 1), and has proceeded with the seismic evaluation and retrofit of elementary school, junior high school, senior high school and vocational school buildings in Taiwan (Table 2). In addition, NCREE established a School Project Office for this program to ensure that the work will be carried out in the most economic and effective manner. The purpose of the office is to provide administrative and technical support, and to hold training programs and workshops for school administrators and professional engineers.

To date, NCREE held 37 training programs in 2009, including preliminary evaluations, detailed evaluations, retrofit designs and review committee conferences (with 2,666 people participating). NCREE also held 15 training workshops, authored and produced a technology handbook, developed a seismic evaluation method (Capacity Spectrum Method) and developed seismic rehabilitation method for school buildings, in cooperation with 1,246 professionals. Finally, NCREE assisted the Ministry of Education with conducting 1413 peer reviews of retrofit designs, with 453 school buildings passing the final reviews. Of these, 100 buildings have completed their retrofit. Additionally, three observation/evaluation workshops held in Wan-Fang elementary school and Da-Tong elementary school by NCREE showcased the advantages of retrofit implementation.

5. CONCLUSIONS

In Taiwan, the Ministry of Education has launched a project on upgrading the seismic performance from 2009 to 2012. A three-stage strategy for screening with existing school buildings has been proposed by NCREE. These three stages are simple survey, preliminary evaluation and detailed evaluation. Preliminary evaluation of school buildings is conducted in sequence according to the seismic performance indices of school buildings from simple survey. Detailed evaluation of school buildings is carried out in sequence according to the seismic performance indices of school buildings from preliminary evaluation. Retrofit design and implementation of school buildings are executed in sequence according to the capacity and demand ratios from detailed evaluation. In this project, thousands of school buildings will be beneficial through the processes of preliminary evaluation, detailed evaluation, retrofit design and retrofit implementation to compete against the next seismic hazard.

Abstract: Soft-first-story structures such as pilotis buildings are known as vulnerable structures against earthquakes. In this paper, a simple scheme for reducing the structural damage of such buildings is proposed, and its effectiveness is experimentally examined through substructure pseudo-dynamic tests. In the proposed method, low yield strength steel devices are applied as elasto-plastic damper on the first story of the buildings. The six stories single-span pilotis model with or without steel damper were provided for the test. The behavior of the two side columns at the first story and the steel damper are tested experimentally. The substructure pseudo-dynamic tests are successfully performed to investigate the elasto-plastic behavior of the damper and the reinforced concrete columns placed on the soft-first-story, as well as the total structural performance. The experimental results indicate that the seismic damage of pilotis buildings can be reduced since the steel dampers work effectively as expected. Especially, the steel dampers provide good performance during the largest ground motion and followed large aftershocks. The maximum response displacement has a stronger correlation with maximum momentary input energy than the amount of total input energy, because of the characteristics of the elasto-plastic behavior of reinforce concrete structure during earthquake.

1. INTRODUCTION

Soft-first-stories structures such as pilotis buildings are vulnerable structure against earthquake. Especially, in Kobe earthquake 1995, some pilotis buildings designed with current design codes as well as many old buildings had suffered the serious structural damages. Most of those damages were concentrated on the first story due to the change in lateral stiffness and strength compared to the upper portion of the structures. One of the ways to reduce the seismic damage of such structures is to increase column section on the first story in order to improve their stiffness discontinuity. However this has also constructive problem causing discontinuity of main bars of columns. Another way is to dissipate seismic response energy of the soft-first-story using dynamic damper taking advantage of concentration on structural deformation on the soft-first-story.

A simple scheme for reducing the structural damage of such pilotis buildings using low yield strength steel devices as elasto-plastic damper set on the first story is proposed in this paper. Detailed response of such buildings should be discussed based on precise elasto-plastic behavior of steel dampers. Especially, the shape of hysteresis loop of steel damper including fatigue behavior is important. A full size test seems to be almost impossible; therefore we conceived a scaled model and substructure pseudo-dynamic testing method for the purpose. In this study, the six stories pilotis reinforced concrete (RC) frames were experimentally tested in order to examine the effectiveness in reducing the structural damage using steel damper. Two sets of structural models were compared with each other through substructure pseudo-dynamic tests.

2. OUTLINES OF TESTS

Figure 1 shows outlines of the building model in this study. That is the six stories single span pilotis frame and also one-directional in-plane loading in transverse direction is taken into account. Its transverse span is 9,000mm. The height of the first story is 3,500mm and the height of the upper floors is all assumed to be 3,100mm. The steel damper is set between the lower and the upper beam on the first story of this frame, where the damper support member is assumed to be rigid so that deformation or stiffness of the support member can be neglected.

In substructure pseudo-dynamic test, a model structure is divided into two portions. One is actual specimen which is tested experimentally so that elasto-plastic behavior of the critical portion of the structure is realistically represented. The behavior of another portion, which would not critically affect on the total response of the structure, is numerically calculated in conventional elasto-plastic computational method. Substructure pseudo-dynamic test is developed on a basis of pseudo-dynamic test, which is an experimental

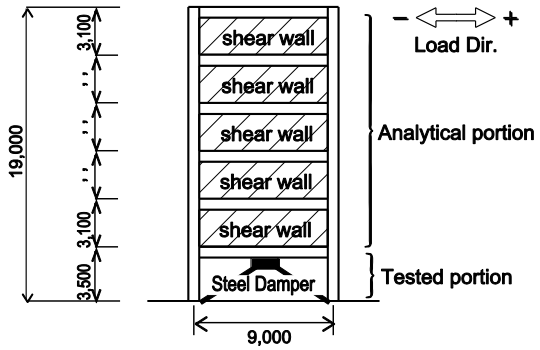

Figure 1 Outlines of model frame

technique for simulating a seismic response of the structural component. In these tests, two side columns and one steel damper on the first floor are the tested portion, which are replaced into three specimens. Figure 2 shows the diagram of pseudo-dynamic testing system which was developed in our laboratory. The system consists of the main management part (Main PC), data acquisition part and hydraulic pump control part. The main management part controls the total system and executes the numerical analysis during the tests. The main PC sends command signals such as the target displacement assigned for each tested portions to the hydraulic pump control unit so that the target displacement can be reached. Then the measured information such as the restoring forces and moments of the tested portion is sent back to Main PC together with analytical results of numerical models to calculate the total structural behavior. The loading conditions for the tested portion, the deformations, axial loads and rotational angles of beam-column connections are calculated step by step prior to the next step loading. Thus, the loading is carried out with accuracy of 1/100 mm using servo-controlled hydraulic jacks. Also loads in the two directions, that is, horizontal and axial loads, as well as rotational moment at the column top, are measured simultaneously.

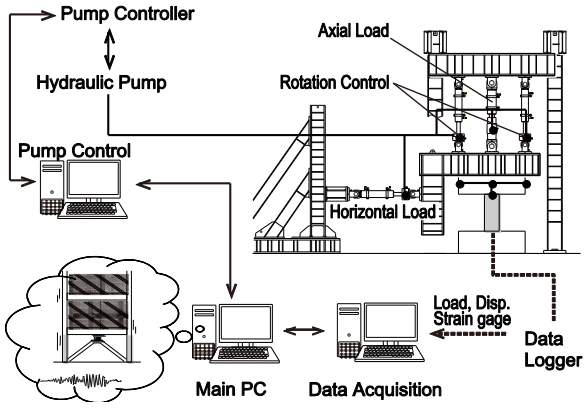

Figure 2 Schematic diagram of testing system

The integration method using the operator-splitting (OS) method was applied in these tests. This method has been used in many substructure pseudo-dynamic experiments, and made it possible to calculate seismic response under the interaction between the specimen and the whole frame [Nakashima et al. 1990]. The formulations of this method are follows:

$$Ma_{n+1} + Cv_{n+1} + K^I d_{n+1} + K^E_{n+1} d_{n+1} = P_{n+1} \quad (1)$$

$$\tilde{d}_{n+1} = d_n + v_n \Delta t + a_n \left(\Delta t/2\right)^2 \quad (2)$$

$$d_{n+1} = \tilde{d}_{n+1} + a_{n+1} \left(\Delta t/2\right)^2 \quad (3)$$

$$v_{n+1} = v_n + \left(a_n + a_{n+1}\right) \left(\Delta t/2\right) \quad (4)$$

Here, K^I and K^E_{n+1} are the linear and non-linear stiffness matrices, M and C are mass and viscous damping matrices, $\tilde{d}$ and d are predictor and corrector displacement vectors, v and a are velocity and acceleration vectors, and Δt is the integration time interval, respectively.

The characteristic of this method is to divide the stiffness of the whole structure into a linear and a non-linear stiffness. For the non-linear tested part, the explicit predictor-corrector method is used.

The Newmark's β method, the linear stiffness integration method, is also applied to take account of the non-linear portion of the whole structure. When the linear stiffness is much larger than the non-linear stiffness, the integration method is unconditionally stable. In this work, the equations were transformed into the incremental equations. It was confirmed that even when the incremental form equations were applied, the condition where the linear stiffness is larger than the non-linear tangent stiffness, provides that the integration method gives stable solutions.

The procedures of the substructure pseudo-dynamic tests in this study are as follows:

1. By using the integration method (OS method), the target predictor displacement $\tilde{d}$ at the next step is calculated. The Main PC (as shown in Figure 2) is used in this calculation.
2. The main PC sends the target displacement (horizontal displacement and rotational angle at the top of the column and steel damper) to the PCs for Pump Control of each specimen (two RC columns and the steel damper).
3. Until the current displacement reaches the target value, the specimens are loaded by the four jacks (one jack, in the case of damper) under the control.
4. The restoring forces (horizontal load and moment at the top of the column) are measured when the displacements reach the target value by the load cells attached to the jacks, and the values are fed back to the Main PC.

5. After the restoring forces are fed back to the Main PC, it sends a command to the PC for Data Acquisitions.
6. After the data acquisition is completed, procedure 1 is performed using the data on the restoring force and input acceleration.

In this study, two RC specimens and one steel damper on the first floor were tested. Therefore two kinds of test loading systems were prepared. Here, each specimen must be loaded simultaneously with up-per portion (analytical part) as a part of the frame. Therefore four static hydraulic jacks (in the case of damper, one jack) were installed to each column specimen so that loading with three degree of freedom (in the case of damper, single degree of freedom) could be performed. In the case of RC column, the central jack in the vertical direction had a loading capacity of 2,000kN and the force capacity of the other two vertical jacks and one horizontal jack were 500kN. The force capacity of horizontal jack set for damper was 500kN.

Specimens of RC columns are shown in Figure 3. The dimension of the column was 300 x 300 mm in section and 1,050mm in clear height, which was 3/8 scale of the building model. The main reinforcements were deformed 13mm bars, which had averaged yield strength of 377 N/mm^2. The shear reinforcements were deformed 6mm high strength bars, which had averaged strength of 1,100N/mm^2. The compressive strength of the concrete was 38.8 N/mm^2.

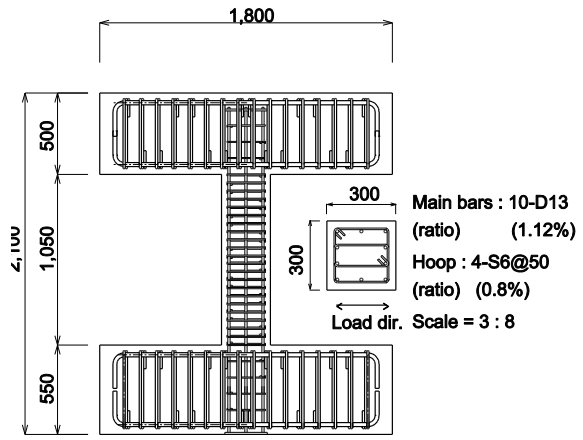

Figure 3 Details of the RC column

The steel damper was designed so that about 10% of the damping factor for the building model can be achieved. Figure 4 shows details of the low yield steel damper. The steel damper was panel shapes and its dimension was 262mm squared and 6mm thickness. In the case of damper portion, full-scale model was prepared to provide realistic elasto-plastic hysteresis behavior. The low yield strength steel had the average yield strength of 154 N/mm^2.

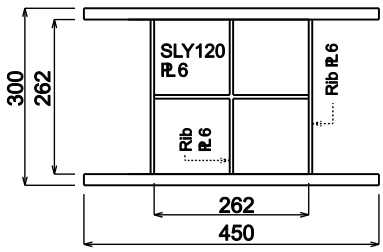

Figure 4 Details of the low yield steel damper

Two series of substructure pseudo-dynamic tests have been conducted. One is for pilotis frame with the steel damper set on the soft-first-story. The other one is only pilotis frame without the steel damper to confirm the damper effect. In these tests, the integration time interval was 0.01s. The Rayleigh damping was applied and the viscous damping ratio was set at 3%. Simulated earthquake ground motions as shown in Figure 5 have been used. The simulated motions are based on the phase characteristics of the El Centro 1940. And the target spectral characteristic is based on the design spectrum specified in the Japanese building design code. Both series of the tests, with damper or without damper, have been divided into 3 steps, which are from weak elastic response (RUN1) to the strong plastic level (RUN3). After RUN3 (the maximum level tests), the second step level test have been carried out again as RUN4 in order to discuss the aftershock response.

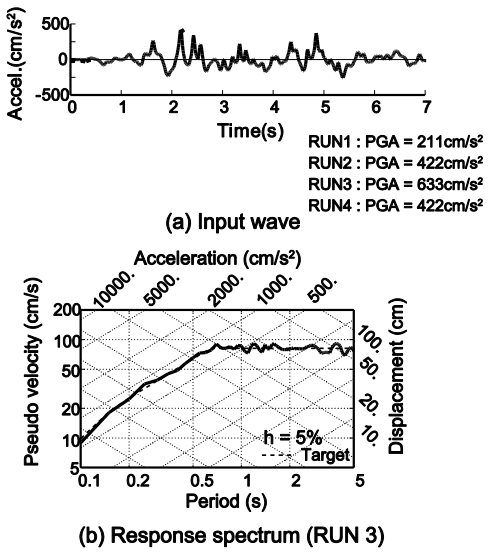

Figure 5 Input ground motion

3. TESTS RESULTS

Figure 6 shows base shear versus story drift hysteresis loops obtained through the tests. Figure 7 shows the shear force versus deformation relationships of tested members during RUN3. In these figures, upper show the case of bared

pilotis frame without damper and bottom show the case with damper. It can be seen that damper set on the soft-first-story worked enough and indicated good performance for the pilotis frame, especially in larger level excitation.

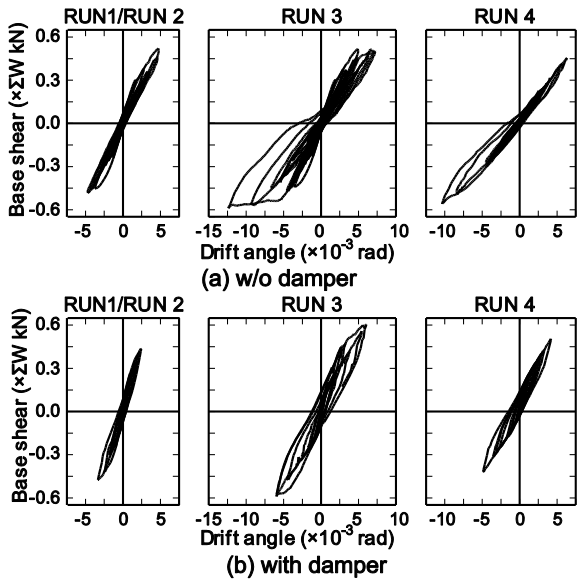

Figure 6 Base shear – drift angle relationships

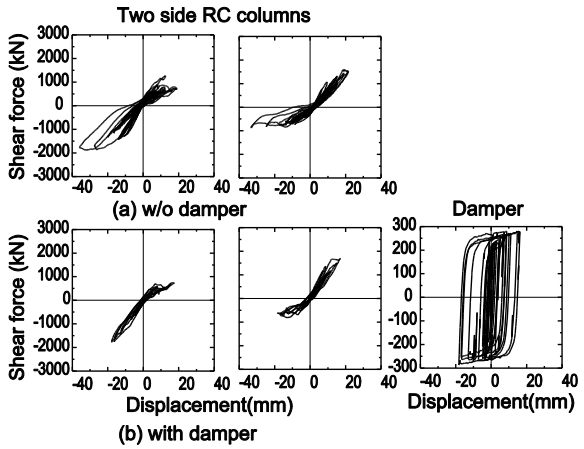

Figure 7 Shear force – deformation relationships of tested members during RUN3

During RUN1, both models (with or without damper) showed almost elastic behavior. In the case of model without damper, some main bars yielded at the bottom of RC column during RUN2. Then in the following loading RUN3, all of reinforcements yielded and story drift angle reached about 1/80. Contrarily, the model with damper, some of main bars yielded during RUN3, its maximum displacement remained within the half of the model without damper. During RUN4, which represents the behavior in aftershock, both models showed larger response than RUN 2; however the model with damper had much less displacement than the model without damper.

The maximum lateral load distributions in both tests are shown in Figure 8. Re-cent studies [e.g. Yong 1999] suggest that in pilotis structures, the maximum lateral load on each floor would be uniformly distributed, because most of displacement tends to concentrate on the first story due to the change in lateral stiffness and strength on the floor. In this research, also the maximum lateral load distribution is same as the recent research results even if the damper is set into the soft-first-story.

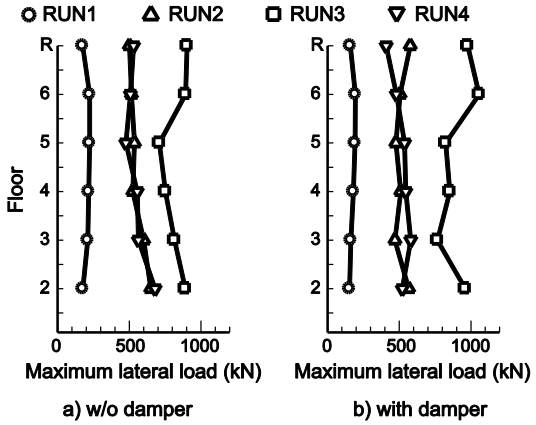

Figure 8 Maximum lateral load distributions in both tests

4. ENERGY RESPONSE

To discuss energy response during earthquake is helpful in designing building structure. In this study, seismic response energy of soft-first-story frame is discussed based on results of substructure pseudo-dynamic tests. Total input energy *EI* and momentary input energy ΔE are discussed dividing input energy into hysteretic energy dissipation (lateral and axial direction) of RC columns at the soft-first-story and the upper portion (shear wall), viscous damping and energy dissipation of damper set on the first story. Here, momentary input energy means increment of input energy, which is defined as seismic energy inputted during a half cycle of response [Inoue *et al.*1998]. Figure 9 shows time histories of displacement and seismic energy response ΔE and *EI* during RUN3, which is the maximum level loading of the tests.

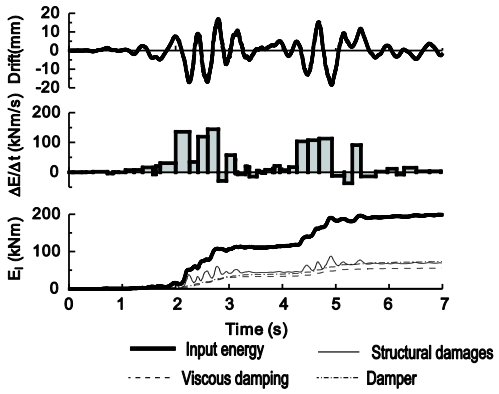

Figure 9 Time history of energy response during RUN3 (the model with damper)

It can be seen that ΔE is large when displacement is increased in both tests. Figure 10 shows relationships between the maximum momentary input energy ΔE_{max} and the maximum story drift of first story. It suggests that ΔE_{max} reflects a kind of intensity of energy input, related with the maximum response displacement which is developed during transient responses.

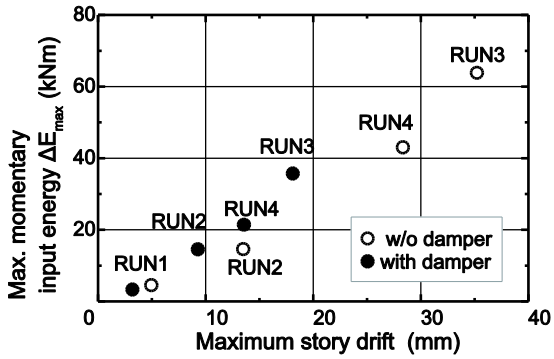

Figure 10 Maximum moment input energy – maximum story drift relationships

Table 1 and 2 show the each ratio of dissipated energy to seismic input in each step of tests. The model without damper, dissipated energy due to RC columns damages are about 40 to 50% of all the input energy, and the viscous damping energy is about 30 to 40%. This tendency is observed in all the step of input level.

Table 1 Energy dissipation ratio (total input)

(a) w/o damper

	CH	CA	U	D	V
RUN 1	64%	4%	5%	N/A	37%
RUN 2	45%	6%	9%	N/A	40%
RUN 3	49%	6%	6%	N/A	39%
RUN 4	42%	6%	5%	N/A	47%

(b) with damper

	CH	CA	U	D	V
RUN 1	26%	4%	7%	38%	25%
RUN 2	25%	2%	6%	43%	24%
RUN 3	27%	3%	5%	37%	28%
RUN 4	17%	4%	5%	47%	27%

CH : Column damage (Horizontal)
CA: Column damage (Axial)
U: Upper wall damage
D: Damper dissipation
V: Viscous damping

Table 2 Energy dissipation ratio of ΔE_{max}

(a) w/o damper

	CH	CA	U	D	V
RUN 1	63%	11%	10%	N/A	16%
RUN 2	65%	0%	0%	N/A	35%
RUN 3	70%	6%	5%	N/A	19%
RUN 4	61%	7%	8%	N/A	24%

(b) with damper

	CH	CA	U	D	V
RUN 1	56%	8%	9%	18%	9%
RUN 2	45%	5%	12%	19%	19%
RUN 3	58%	9%	9%	14%	10%
RUN 4	53%	9%	7%	20%	11%

CH : Column damage (Horizontal)
CA: Column damage (Axial)
U: Upper wall damage
D: Damper dissipation
V: Viscous damping

In the case with damper, the energy dissipation of steel damper is so large (about 40%). And as a result, the energy dissipation due to column damages and viscous damping are less than cases without damper. Especially, the energy dissipation ratio during RUN4 shows that the steel damper worked enough even for comparatively large aftershocks.

5. CONCLUSIONS

Substructure pseudo-dynamic tests are successfully performed to investigate the dynamic behavior of the damper and the reinforced concrete columns placed on the soft-first-story, as well as the total structural performance. Experimental results indicate that the seismic damage of pilotis buildings can be reduced since the steel dampers work effectively as expected. Especially, the steel dampers provide good performance during the largest ground motion and followed large aftershocks. The maximum response displacement has a stronger correlation with maximum momentary input energy ΔE_{max} than the amount of total input energy, because of the characteristics of the elasto-plastic behavior of RC structure during earthquake.

EARTHQUAKE-RESISTANT DESIGN OF LIGHTLY-REINFORCED AND LOW-RISE CONCRETE WALLS

Julian Carrillo

Assistant Professor, Department of Civil Engineering, Universidad Militar Nueva Granada, Colombia
wjcarrillo@gmail.com

Abstract: Low-rise housing units made of reinforced concrete walls are a common type of construction in many Latin American countries. These walls are often 100 mm thick with concrete compressive strengths of 15 to 20 MPa, and require a minimum or lower amount of web reinforcement. Existing requirements in current codes are not directly applicable and led to excessive costs. To study the seismic behavior of thin, lightly-reinforced and low-rise concrete walls and to develop a guideline for design of typical housing, an extensive research program was carried out. The experimental program included 39 quasi-static and shaking table tests of walls with different height-to-length ratios (0.5, 1.0 and 2.0) and walls with openings. Variables studied were the type of concrete (normalweight, lightweight and self-consolidating), web steel ratio (0%, 0.125% and 0.25%) and the type of web reinforcement (deformed bars and welded-wire mesh). Using a performance-based seismic design approach, recommendations for predicting the shear strength, displacement capacity, as well as acceptance limits of the structural response, are proposed. Taking into account the practical approach of the recommendations, they provide a robust tool for designers and code-developers to assess the adequacy of current design procedures and to promote a safe and economic housing.

1. INTRODUCTION

Over the last ten years, in order to satisfy housing demand, the number of new housing units in several Latin America countries, such as Mexico, Peru and Chile, has increased considerably. A significant portion of these housing units is one to two stories high and has been constructed with reinforced concrete (RC) walls. Because of the typical large wall-to-floor area ratio of these housing units, seismic force and displacement demands are, most of the times, relatively low. This phenomenon has prompted housing developers to use walls with low concrete compressive strengths (between 15 and 20 MPa) and small thickness (100 mm). For these cases, the minimum wall reinforcement prescribed by the American Concrete Institute's Building Code (ACI 318-11), appears to be excessive for controlling wall diagonal tension cracking. The use of thin walls, web reinforcement in ratios smaller than the minimum code-prescribed values, and web shear reinforcement made of welded-wire mesh are also the consequence of the hasty construction and cost-cutting practiced by developers in order to be competitive in the housing market.

Aimed at studying the seismic behavior of lightly reinforced, thin concrete walls and developing guides for the analysis and design of low-rise housing, a large research program was carried out. The experimental program comprised 39 quasi-static and dynamic loading tests of walls with different height-to-length ratios (0.5, 1.0 and 2.0) and door and window openings, three web steel ratio (0%, 0.125% and 0.25%), three types of concrete (normalweight, lightweight and self-consolidating) and two types of web shear reinforcement (deformed bars and welded-wire mesh).

The aim of this paper is to report on the development of a backbone model for typical RC walls, as well as to discuss and introduce acceptance limits of structural response as they relate to the expected wall damage. A performance-based seismic design (PBSD) approach was considered so that suitable limit states could be taken into account. Acceptance limits were derived for different damage levels (performance levels), within a PBSD framework. Selected performance indicators were allowable story drift ratios and residual cracking. Allowable story drift ratio is a common performance indicator in structural design. Residual cracking was expressed in terms of residual crack width and residual damage index.

2. EXPERIMENTAL PROGRAM

The experimental program comprised testing of 39 isolated cantilever walls. Main characteristics and failure modes of the 39 wall specimens are presented in Table 1.

2.1 Variables Studied

Variables studied were those obtained from current design and construction practice for low-rise housing in Latin America. A detailed description of the experimental program may be found elsewhere (Carrillo and Alcocer, 2013, 2012a-d). The following variables were studied:

Table 1 Main Characteristics of Wall Specimens

Type of testing	Wall	Type of concrete	f_c MPa	Type of web reinforcement	f_y MPa	$\rho_h = \rho_v$ %	t_w mm	h_w mm	l_w mm	h_w/l_w	Failure mode **

D = deformed bar, W = welded-wire mesh, * wall with openings, ** DT = diagonal tension, DC = diagonal compression, SL = sliding.

Height-to-length ratio: walls with height-to-length ratio (h_w/l_w) equal to 0.5, 1.0 and 2.0, and walls with openings (door and window openings) were tested. Full-scale wall thickness, t_w, and clear height, h_w, were 100 mm and 2.4 m, respectively. Then, to achieve the height-to-length ratio, length of walls was varied.

Concrete type: normalweight (N), lightweight (L) and self-consolidating (S) concrete were included in the test series. Nominal concrete compressive strength, f_c', was 15 MPa for all types of concrete. Ranges of measured mechanical properties of concrete for the 39 specimens are presented in Table 2.

Table 2 Mechanical Properties of Concrete

Property	Normal-weight, N	Light-weight, L	Self-consolidating, S
Compressive strength, f_c, MPa	16.0 - 24.7	10.8 - 26.0	22.0 - 27.1
Modulus of elasticity, E_c, MPa	8430 - 14750	6700 - 10790	8900 - 11780
Tensile splitting strength, f_t, MPa	1.55 - 2.20	1.14 - 1.76	1.58 - 1.98
Flexural strength, f_r, MPa	2.32 - 3.75	1.43 - 3.29	2.27 - 2.48
Specific dry weight, γ, kN/m^3)	18.8 - 20.3	15.2 - 18.3	18.9

Web steel ratio: 100% of ρ_{min} (0.25%), 50% of ρ_{min} (0.125%), 0% of ρ_{min} = without reinforcement (for reference only) were used. Minimum web steel ratio (ρ_{min}) was that prescribed by ACI 318-11. Web reinforcement was placed in a single layer at wall mid-thickness and same ratios of horizontal and vertical reinforcement ($\rho_h = \rho_v$) were used.

Type of web reinforcement: deformed bars (D) and welded-wire mesh made of small-gage wires (W) were used. Nominal yield strength of bars and wire reinforcement, f_y, was 412 MPa (for mild steel) and 491 MPa (for cold-drawn wires), respectively. Ranges of measured mechanical properties of steel reinforcement for the 39 specimens are presented in Table 3. In the cold-drawn wire reinforcement used in this study, the loading branch between onset of yielding and maximum deformation capacity (at fracture) was much shorter than that of mild-steel reinforcement. The behavior of wire reinforcement was characterized by fracture of material with a slight increment of strain (see the Elongation row in Table 3).

Table 3 Mechanical Properties of Steel Reinforcement

Location in the wall	Boundary: deformed bar	Web: deformed bar, D	Web: welded-wire, W
Type	Mild	Mild	Cold-drawn
Yield strength, f_y, MPa	411 - 456	435 - 447	605 - 630
Ultimate strength, f_{su}, MPa	656 - 721	659 - 672	687 - 700
Elongation, %	9.1 - 16.0	10.1 - 11.0	1.4 - 1.9

Boundary elements: because of their aspect ratio, the behavior of the RC walls tested was expected to be controlled by shear deformations. Therefore they were likely to exhibit a brittle failure mode governed by shear demands. Since the aim of this program was to study the shear behavior of the walls, the longitudinal boundary reinforcement was purposely designed and detailed to prevent flexural failure prior to achieving a shear failure. Thickness of boundary elements was equal to web thickness. Typical geometry and reinforcement layout of some of the full-scale wall specimens are shown in Figure 1.

2.2 Test Setups

Quasi-static (monotonic and reversed-cyclic) and dynamic (shaking table) testing series were included. In quasi-static testing, loading protocol consisted of a series of increasing amplitude cycles. For each increment, two cycles at same amplitude were applied (Sánchez, 2010). Owing to limitations in the payload capacity of the shaking table equipment, lightly-reduced scale models were designed and built for shaking table testing. During dynamic testing, models were subjected to a series of base excitations represented by earthquake records associated to three limit states (Carrillo and Alcocer, 2012b).

An axial compressive stress of 0.25 MPa was applied on top of the walls and was kept constant during testing. This value corresponded to an average axial stress in the first floor walls of a two-story prototype house.

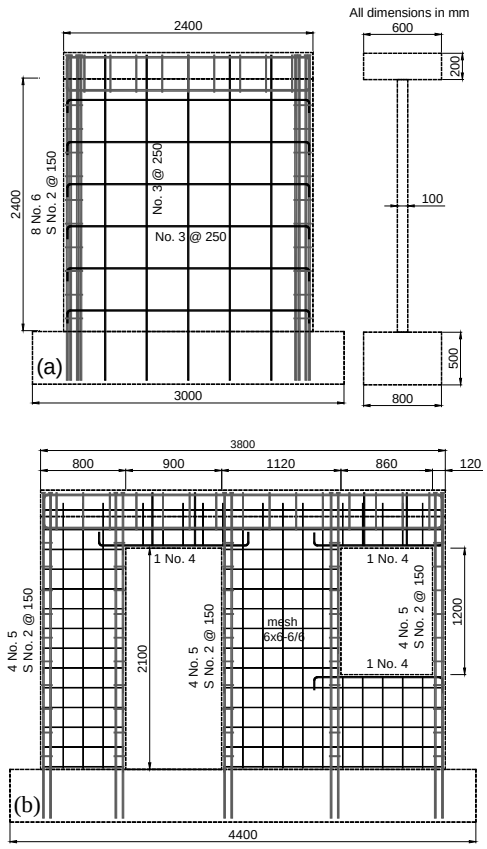

Figure 1 Geometry and Reinforcement Layout of Some Wall Specimens: (a) h_w/l_w = 1.0, 100% of ρ_{min} and Using Deformed Bars; (b) Wall with Openings, 50% of ρ_{min} and Welded-Wire Mesh.

2.3 Failure Modes

For evaluating the observed wall behavior, three failure modes were defined: (i) when yielding of the majority of the web shear reinforcement and no web crushing of concrete was observed, a diagonal tension failure (DT) was defined; (ii) when yielding of some steel bars or wires, and noticeable web crushing and spalling of concrete was observed, a diagonal compression failure (DC) was defined, and, (iii) when yielding of the majority of the web steel reinforcement and noticeable web crushing of concrete was observed, a mixed failure mode (DT-DC) was defined. Test results indicated that the contribution of wall sliding to the whole deformation was negligible for all tests. Therefore, wall sliding at the base (SL) was not purposely included.

Walls reinforced with 50% of the minimum code prescribed web steel reinforcement ratio and using deformed bars or welded-wire mesh, exhibited DT failure. Failure mode was governed by web inclined cracking of concrete at approximately 45° and yielding of most of web shear reinforcement prior to severe strength and stiffness decay. In walls reinforced with welded-wire mesh, fracture of wires after plastic yielding of web shear reinforcement was observed. Failure was brittle because of the limited elongation capacity of the wire mesh itself (see Table 3). In

contrast, walls reinforced using deformed bars and the minimum web steel ratio, exhibited DT-DC failure. Typical final crack patterns of walls during shaking table testing are shown in Figure 2.

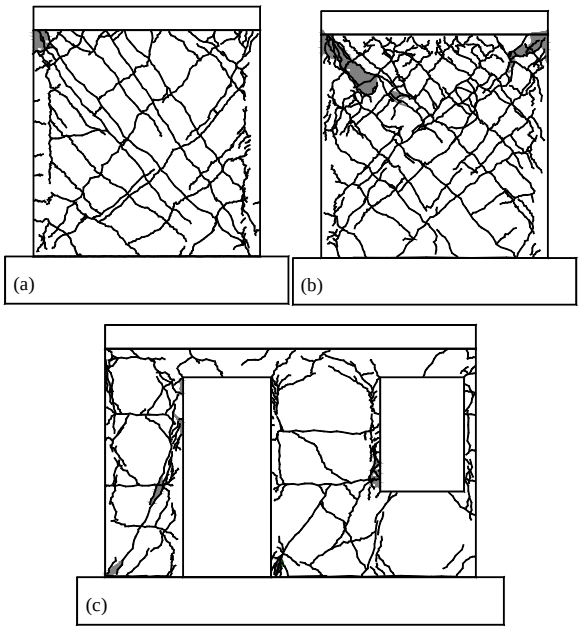

Figure 2 Typical Final Crack Patterns: (a) Wall with h_w/l_w = 1.0, 50% of ρ_{min} and Using Welded-Wire mesh (DT Failure), (b) Wall with h_w/l_w = 1.0, 100% of ρ_{min} and Using Deformed Bars (DT-DC Failure), (c) Wall with Openings, 50% of ρ_{min} and Using Welded-Wire Mesh (DT Failure).

3. BACKBONE MODEL

Most seismic codes, including the American Concrete Institute's ACI 318-11, rely mainly on conventional force-based limit states (i.e. ultimate limit state) and on serviceability limit state, but they do not include an explicit relationship between displacement demand and capacity. In contrast, modern design procedures set more emphasis to the deformation capacity of a system. For example, Performance Based Seismic Design (PBSD) requires the explicit consideration of lateral displacement as a performance indicator, besides verifying the structural design through an essentially force-based procedure (Priestley 2000). PBSD has been applied to systems failing under flexural mode, but its implementation for systems under shear failure is still limited. According to a literature review (Carrillo and Alcocer, 2013), to date there is no methodology for performance-based design of low-rise RC walls failing in shear. One of the main obstacles hindering the implementation of PBSD in these cases is the absence of suitable models for predicting the load-displacement curve of elements failing in shear.

Several analytical models have been proposed for predicting the peak shear strength. Nevertheless, due to the particularities of the RC walls in low-rise housing, most of the design recommendations and equations in the existing models are not directly applicable. In general, the main limitations are: (i) previous models have been developed on the basis of a much wider range of parameters controlling the shear behavior of walls; in contrast, in typical low-rise housing, parameters vary in a narrower range (low concrete strength, thin walls, low axial stress, low steel ratios); (ii) the behavior of walls with web shear reinforcement made of welded-wire mesh is not explicitly included in previous models; in the walls tested in this study, the low strain capacity (elongation) of the cold-drawn wire reinforcement, which significantly reduces the displacement capacity of walls, is a key parameter for PBSD; (iii) previous models have been calibrated on the basis of results observed from quasi-static tests only, that is, loading rate effects, low-cycle fatigue, cumulative parameters (Carrillo and Alcocer 2012d), and the dynamic effect of the vertical axial stress on the wall shear strength have been excluded, and finally, (iv) some previous models are not readily practical and versatile for design purposes.

3.1 Limit States

From the shape of the envelope of measured hysteresis of specimens described in Table 3, it was decided that a tri-linear backbone model was suitable for describing the performance of walls for low-rise housing (Carrillo and Alcocer, 2012a). The backbone model for PBSD is shown in Figure 3. The model is described using parameters associated to three limit states: diagonal shear cracking (V_{cr}, R_{cr}), peak shear strength (V_{max}, R_{max}) and ultimate deformation capacity (V_u, R_u).

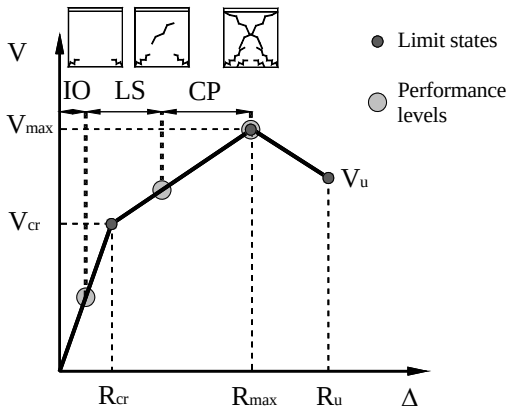

Figure 3 Backbone Model

Diagonal cracking limit state is attained when the initial inclined web cracking is observed. Strength limit state corresponds to peak shear strength. Ultimate deformation capacity limit state is associated to any of the two following scenarios: when a 20% drop to the peak shear strength is reached or when web shear reinforcement made of welded-wire mesh fractures. In the specimens studied, the first scenario occurred in walls reinforced with deformed bars; the second scenario was observed in walls with web shear reinforcement made of welded-wire mesh.

3.2 Objectives and Levels of Performance

A performance objective is the description of an acceptable damage level (performance level) of a structure when it is subjected to an earthquake motion associated to a specific intensity (hazard level). In a PBSD context, performance levels are introduced as limiting values of performance indicators that can be measured in the structural response (Guljas and Sigmund, 2006). When performance levels are established, associated limiting values (performance indicators) became the acceptance criteria whose compliance ought to be verified during subsequent design stages.

Following the procedure recommended in Vision 2000 (SEAOC, 1995), three performance levels were selected in this study: immediate occupancy (IO), life safety (LS) and collapse prevention (CP). Performance levels and corresponding damage stages of walls for low-rise housing are shown descriptively in Figure 3.

3.3 Shear Strength Capacity

Eq. (1) is proposed for estimating the peak shear strength of the RC walls used in typical low-rise housing. The functional form of the equation is similar to that of current design methodologies. The equation was proposed by Carrillo and Alcocer (2013) and was calibrated using the 39 isolated walls described in the experimental program (Table 1). Eq. (1) assumes that shear strength is made up by the contribution of concrete, V_c, plus that of the web steel reinforcement, V_s.

$$V_{\max} = V_c + V_s = [\alpha_1 \sqrt{f_c'} + \eta_h \rho_h f_{yh}] A_w \leq \alpha_2 \sqrt{f_c'} A_w \quad (1)$$

where α_1 and α_2 are coefficients defining the relative contribution of the concrete to diagonal tension and diagonal compression strength, respectively. Such contributions are calculated using Eqs. (2) and (3), respectively.

$$\alpha_1 = 0.21 - 0.02\left(\frac{M}{V l_w}\right) \text{ (MPa)} \quad (2)$$

$$\alpha_2 = 0.40 \text{ (MPa)} \quad (3)$$

where M/Vl_w is the ratio between bending moment and shear force times wall length. In Eq. (1), f_c' is the specified concrete compressive strength, ρ_h is the horizontal web steel ratio, f_{yh} is the yield strength of the horizontal web shear reinforcement, and η_h represents the efficiency of ρ_h and should be calculated using Eq. (4). Eq. (1) was calibrated on the basis of the gross area of a concrete wall section, A_w, that is, wall thickness (t_w) times wall length (l_w).

$$\eta_h = 0.8 \quad \text{For deformed bars} \quad (4a)$$

$$\eta_h = 0.7 \quad \text{For welded-wire mesh} \quad (4b)$$

Shear strength at distributed diagonal web cracking corresponds essentially to the shear force at which the principal tension stress of concrete is reached. Thus, it is assumed that V_{cr} is similar to the contribution of concrete to shear strength, then:

$$V_{cr} = V_c = \alpha_1 \sqrt{f_c'} A_w \quad (5)$$

As mentioned earlier, the ultimate deformation capacity limit state is associated with a 20% drop in the peak strength, or to the fracture of web shear reinforcement made of welded-wire mesh. For the former case:

$$V_u = 0.8 V_{\max} \quad (6)$$

3.4 Displacement Capacity

The equations for calculating displacement parameters were developed in terms of drift ratio (as a percentage), as it is a very common performance indicator used in code-based design. Drift ratio, R, was obtained by dividing the relative displacement measured at mid-thickness of the top slab by the height at which the displacement was measured (h). The proposed relationships are based on a model in which the total displacement is calculated as the sum of contributions related to flexure and shear. The contribution of wall sliding at the base was omitted because the sliding displacements measured during the tests were minimal (Carrillo and Alcocer, 2012b).

On the basis of observed trends from experimental results, and considering the findings of similar studies, it was assumed that the displacement associated with diagonal cracking was independent of the ratio and type of web steel reinforcement. Thus, using the diagonal cracking shear strength (V_{cr}), calculated via Eq. (5), and the cracked initial stiffness (K_{cr}), Eq. (7) is proposed for calculating R_{cr}.

$$R_{cr}(\%) = \left(\frac{V_{cr}}{K_{cr}}\right)\frac{100}{h} \quad (7)$$

where K_{cr} includes both shear and flexural deformations. According to Ghobarah (2004), realistic drift calculations should be made using a reduced gross inertia due to the properties of the cracking section. For walls tested in cantilever, K_{cr} is calculated from conventional theory of materials using Eq. (8).

$$K_{cr} = \left(\frac{h^3}{c_1 3 E_c I_g} + \frac{h}{c_2 G_c A_c}\right)^{-1} \quad (8)$$

where A_c is the shear area of the wall cross section (A_w/1.2), E_c is the modulus of elasticity of concrete, I_g is the moment of inertia of gross concrete section about the centroidal axis, G_c is the shear modulus of concrete and, c_1 and c_2 are factors for including cracking of concrete prior to the reinforcement yielding. Carrillo and Alcocer (2012b) have recommended the use of $c_1 = c_2 = 0.5$ for the practical seismic design of walls used in typical low-rise housing.

Eqs. (9) and (10) are proposed for estimating R_{max} and R_u. The equations were derived from observed trends and

iterative nonlinear regression analyses. Constants a_1, a_2, b_1, b_2, c_1 and d_1 depend on the type of web shear reinforcement. The proposed values for these constants are presented in Table 4.

$$R_{\max}(\%) = \frac{V_{\max}}{t_w\sqrt{f_c'}}\frac{1}{a_1}e^{b_1(M/Vl_w)} \quad \text{For deformed bars} \qquad (9a)$$

$$R_{\max}(\%) = \frac{V_{\max}}{t_w\sqrt{f_c'}}\frac{1}{a_2}\left(\frac{M}{Vl_w}\right)^{b_2} \quad \text{For welded-wire mesh} \qquad (9b)$$

Table 4 Constants for Calculating Drift Capacity

At peak shear strength, $R_{\max}$		At ultimate, R_u
Deformed bars (MPa)	Welded-wire mesh (MPa)	Deformed bars (MPa)
$a_1 = 5200$	$a_2 = 1450$	$c_1 = 3650$
$b_1 = 1.30$	$b_2 = 1.60$	$d_1 = 1.35$

Because of the brittleness of the failure mode observed in walls reinforced with welded-wire mesh, R_u was considered to be equal to R_{max} (Equation 10a). Like R_{cr}, R_{max} and R_u include the contributions of both shear and flexural deformations.

$$R_u(\%) = \frac{V_{\max}}{t_w\sqrt{f_c'}}\frac{1}{c_1}e^{d_1(M/Vl_w)} \quad \text{For deformed bars} \qquad (10a)$$

$$R_u(\%) = R_{\max}(\%) \quad \text{For welded-wire mesh} \qquad (10b)$$

4. PERFORMANCE LEVELS

Definition of comprehensive and realistic quantitative acceptance limits that are associated to well-known damage stages has been the subject of research and discussion. Considering that PBSD has been mainly applied to systems failing under flexure, most studies include performance indicators for walls exhibiting a ductile failure mode. According to Ghobarah (2004), available story drift limits are conservative for ductile structures, but may be unsafe for non-ductile structures.

To evaluate seismic damage of concrete walls in low-rise housing, whose response is governed by shear deformations, performance indicators related to story drift ratio (R_{allow}) and residual cracking were used (Carrillo and Alcocer, 2012c). Residual cracking was, in turn, analyzed in terms of residual crack width (w_{res}) and a residual damage index (I_{cracks}). For establishing the limiting values of selected performance levels, the following was considered: (i) for low-income population, housing unit is the main patrimony; therefore, housing rehabilitation should be economical and easily attainable, especially for IO and LS performance levels; (ii) consistent with the latter, safety levels of walls failing in shear, associated to threshold values of performance indicators should be higher than those used for medium- and high-rise concrete buildings dominated by flexural deformations; and (iii) response measured during testing indicated that strength and stiffness degradation of concrete walls was rapid as soon as peak shear strength was reached (Carrillo and Alcocer, 2012d); therefore, drift values close to those at peak shear strength should not be permitted for PBSD of low-cost housing.

Based on technical and economic facts, the immediate occupancy (IO), life safety (LS) and collapse prevention (CP) performance levels for low-rise concrete housing are related to initial inclined web cracking, to extension of web inclined cracks to wall edges without penetration into boundary elements, and to wall peak shear strength, respectively. Expected damage for the three performance levels is described in more detail in Table 5. The prescribed damage stages roughly corresponded to design strengths of 25%, 75% and 100% of the peak shear strength for IO, LS and CP performance levels, respectively. Note that CP performance level was defined to that at peak shear strength, that is, strength degradation was purposely excluded for the reasons explained above.

Table 5 Performance Indicators

Performance level	Expected damage	Indicator	Type of web shear reinforcement		
			Deformed bars	Welded-wire mesh	Wall without reinforcement
IO	*Minor damage:* - Flexural cracking at the boundary elements and minor web inclined cracks.	R_{allow}	0.15 Safety level = 1.8 *CV* = 17.0 %	0.10 Safety level = 2.3 *CV* = 27.2 %	0.05 Safety level = 5.6 *CV* = 16.5 %
		w_{res}, mm	0.10	0.08	0.05
		I_{cracks}, %	---	---	---
LS	*Moderate damage:* - Extension of web inclined cracks to the wall edges without penetration into the boundary elements.	R_{allow}	0.40 Safety level = 1.9 *CV* = 17.8 %	0.25 Safety level = 2.1 *CV* = 24.6 %	0.10 Safety level = 4.9 *CV* = 34.1 %
		w_{res}, mm	0.50	0.20	0.07
		I_{cracks}, %	0.10	0.04	---
CP	*Significant damage:* - Noticeable web diagonal cracking and/or yielding of some web steel bars/wires. - Moderate web crushing of concrete and damage around openings.	R_{allow}	0.65 Safety level = 2.4 *CV* = 32.9 %	0.35 Safety level = 1.3 *CV* = 24.8 %	0.15 Safety level = 5.4 *CV* = 21.7 %
		w_{res}, mm	2.50	0.40	0.10
		I_{cracks}, %	0.30	0.08	---

Typical residual crack patterns associated to performance levels of walls reinforced with 100% of ρ_{min} and using web shear reinforcement made of deformed bars, as well as of walls reinforced with 50% of ρ_{min} and using welded-wire mesh are shown in Figure 4.

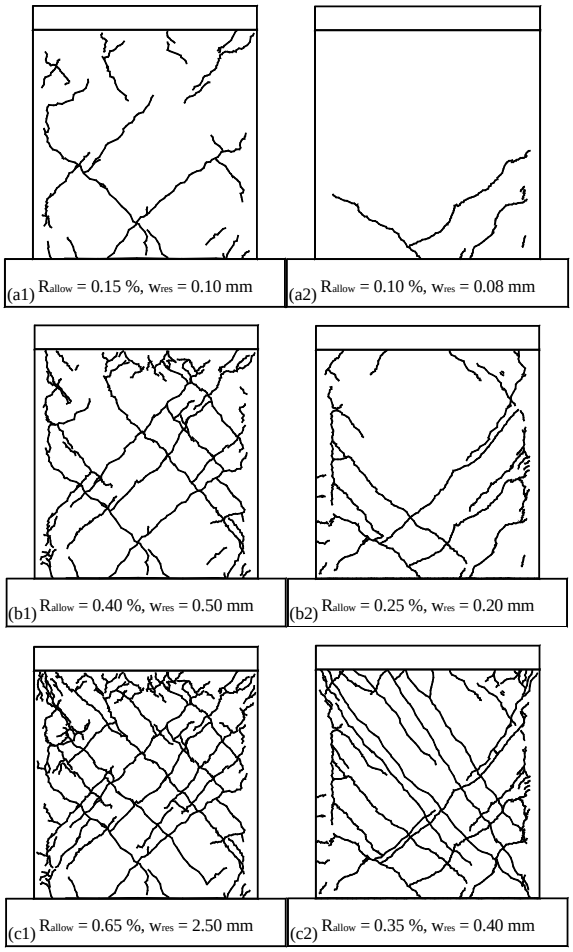

Figure 4 Residual Cracking Stage for Walls Reinforced with 100% of ρ_{min} and Using Deformed Bars: (a1) IO, (b1) LS and (c1) CP; and with 50% of ρ_{min} and Using Welded-Wire Mesh: (a2) IO, (b2) LS and (c2) CP.

Acceptance limits in terms of allowable story drift ratios (R_{allow}) and residual crack width (w_{res}) are indicated in Figure 4. Considering that some crack propagation was observed while maintaining the peak load during intervals of quasi-static testing protocol (Carrillo and Alcocer, 2012d), the expected damage level and limiting values of residual cracking were described and defined exclusively from damage observed during shaking table testing of concrete walls.

Although the final damage level of walls (Figure 2) was significantly larger than that associated to the CP performance level (Figure 4), walls reinforced with 50% of ρ_{min} and web shear reinforcement made of welded-wire mesh were suitably rehabilitated using jacketing made of steel fiber reinforced concrete. In general terms, the observed and measured performance of rehabilitated walls was satisfactory because strength and displacement capacities measured in the original walls were adequately restored. Further information may be found elsewhere (Avila et al., 2011).

4.1 Allowable Story Drift Ratios

Similarly to findings reported by Ghobarah (2004), Duffey et al. (1994) stated that allowable story drift limits specified by most seismic codes are generally unconservative for concrete walls with low aspect ratio with characteristics similar to those investigated herein, because such code-based drift limits are likely more directed toward medium- and high-rise structures than for low-rise shear walls.

Allowable drift ratios were determined from hysteresis curves measured during shaking table and quasi-static tests of RC walls. Typical measured hysteresis curves for walls with web shear reinforcement made of deformed bars and with web steel ratio equivalent to 50% and 100% of the minimum web steel ratio prescribed by ACI 318-11 are shown in Figures 5 and 6, respectively. Similar results for walls with web shear reinforcement made of welded-wire mesh are presented in Figure 7. In the graphs, limits proposed for IO, LS and CP performance levels are also indicated. Results for walls with h_w/l_w ratios equal to 0.5, 1.0 and 2.0 are included in these figures. The hysteresis curves were expressed in terms of the normalized shear strength (V/V_{normal}), shear stress (in the right-hand ordinate axis), and lateral drift ratio expressed in percentage. Shear strength predicted using equations proposed as a result of this program (Carrillo and Alcocer, 2013), V_{normal}, was utilized to normalize the measured lateral force, V. Calculated shear strength was computed using as-built wall dimensions and measured mechanical properties of materials (see Tables 1, 2 and 3). The mode of failure is also indicated in the graphs.

Analyzing trends for determining R_{allow}, it was evident that the type of web shear reinforcement and the h_w/l_w ratio (or M/Vl_w ratio) were the main factors affecting R_{allow}. For example, for walls with h_w/l_w = 2.0 it would be feasible to define story drift limiting values higher than those for walls with h_w/l_w = 0.5 or 1.0 (Figures 5 to 7). However, for code purposes, it is unwise to propose R_{allow} values that depend on h_w/l_w or M/Vl_w ratios. This statement is based on the fact that, at the same story, all walls are subjected to practically the same value of story drift demand. With regards to the type of concrete used, significant differences among walls made of normalweight, lightweight and self-consolidating concrete were not observed.

As it was indicated above, one of the objectives of this research program was to develop analysis and design guidelines for RC low-rise housing. From the results of this program, it was apparent that shear strength of walls reinforced with 50% of ρ_{min} was comparable to that of walls reinforced with 100% of ρ_{min}. It was also found that minimum web reinforcement is overly conservative for controlling diagonal tension cracking, especially for structures located in low seismic hazard zones.

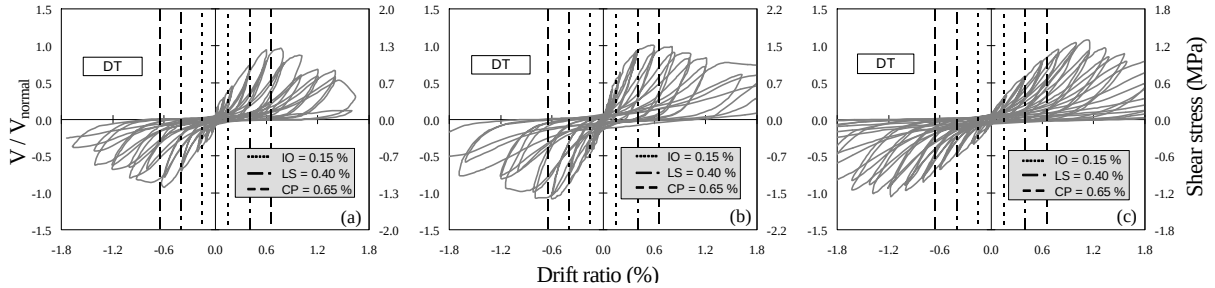

Figure 5 Hysteresis Curves and Allowable Story Drift Ratios for Walls Reinforced with 50% of ρ_{min} and Using Deformed Bars: (a) h_w/l_w = 0.5 (Normalweight), (b) h_w/l_w = 1.0 (Lightweight) and (c) h_w/l_w = 2.0 (Normalweight Concrete).

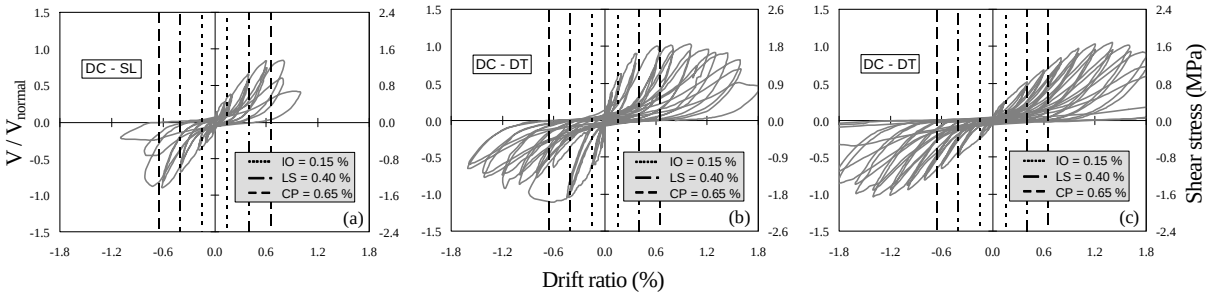

Figure 6 Hysteresis Curves and Allowable Story Drift Ratios for Walls Reinforced with 100% of ρ_{min} and Using Deformed Bars: (a) h_w/l_w = 0.5 (Normalweight), (b) h_w/l_w = 1.0 (Normalweight) and (c) h_w/l_w = 2.0 (Normalweight Concrete).

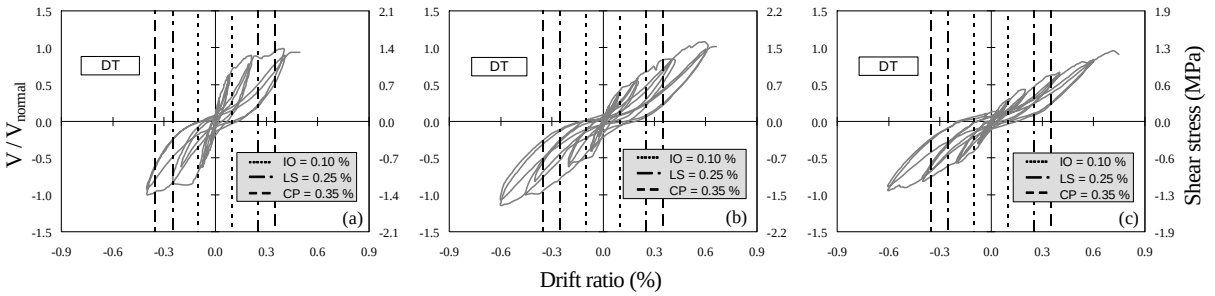

Figure 7 Hysteresis Curves and Allowable Story Drift Ratios for Walls Reinforced with 50% of ρ_{min} and Using Welded-Wire Mesh: (a) h_w/l_w = 0.5 (Normalweight), (b) h_w/l_w = 1.0 (Lightweight) and (c) h_w/l_w = 2.0 (Normalweight Concrete).

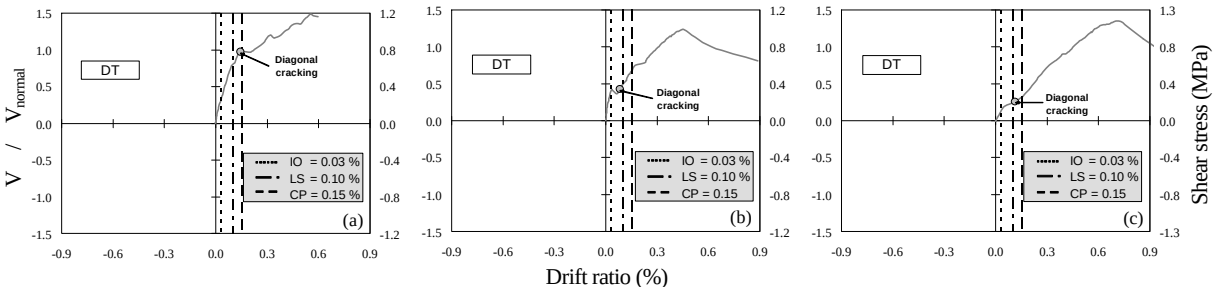

Figure 8. Hysteresis Curves and Allowable Story Drift Ratios for Walls without Web Shear Reinforcement (h_w/l_w = 1.0): (a) Normalweight, (b) Lightweight and (c) Self-Consolidating Concrete.

For the design methodology, three zones were identified. For low-hazard zones, walls without web shear reinforcement are allowed. For medium-hazard, walls with 50% of ρ_{min} can be used. For high seismic hazard zones, 100% of ρ_{min} should be used. For the low seismic hazard zone, shrinkage cracking should be controlled. Also, more stringent drift ratios for limiting inclined cracking of concrete should be applied. For this case, performance levels are related to the same damage stages defined for walls with web shear reinforcement made of welded-wire mesh and

deformed bars. Expected damage for the three performance levels are shown in Table 5. The envelopes curves for walls without web reinforcement are shown in Figure 8. In the graphs, the limits proposed for IO, LS and CP performance levels are indicated. Prescribed damages stages roughly corresponded to design strengths of 15%, 40% and 50% of the peak shear strength, for IO, LS and CP performance levels, respectively.

Based on measured hysteresis curves, proposed allowable story drift limits and description of the expected damage for the three performance levels are presented in Table 5. The maximum crack width measured after unloading, w_{res}, is also indicated in the table. As it was mentioned earlier, proposed values only depended on the type of web shear reinforcement. A single value for walls with web shear reinforcement made of deformed bars was established because differences in behavior between walls with 100% and 50% of ρ_{min} were not significant (Figures 6 and 7). The corresponding damage stages of the walls are shown in Figure 4.

Limiting values of allowable story drift ratio (R_{allow}) specified by seismic codes are not necessarily associated to the maximum capacity of structural elements or systems. These limiting values are typically associated to prescribed safety levels so that they can be used in practical structural engineering design. The safety level of an allowable drift ratio value for a particular performance level was calculated as the ratio between the measured drift capacity at a defined limit state and the measured drift ratio of the performance level (Carrillo and Alcocer, 2012c). Mean values and coefficients of variation (mean–*CV*) of the safety levels of allowable drift ratios for IO, LS and CP performance levels of walls are presented in Table 5. It was considered that a safety level of 2 was appropriate for seismic design of reinforced walls. For unreinforced walls, a safety level of 6 was selected as a target value.

Safety levels are dependent on the steel reinforcement ratio and characteristics of web shear reinforcement. For instance, safety levels were higher for walls with web shear reinforcement made of welded wire mesh than those for walls with deformed bars. An exception was observed for the CP performance level of walls with web shear reinforcement made of welded-wire mesh because displacement capacity at failure of these walls was almost equal to displacement capacity at peak shear strength. In addition, for walls where web shear reinforcement was not used, safety levels are roughly three times higher than those of walls with web shear reinforcement. In all cases, variation of safety levels was high (around 20%). This can be explained by the fact that results from tests of walls having different h_w/l_w ratios were used.

4.2 Residual Cracking

Limiting values of residual cracking (w_{res}, I_{cracks}) associated to the defined limiting values of story drift ratios were established using the damage observed during shaking table tests of RC walls. In this research, index I_{cracks} was calculated using Eq. (1).

$$I_{cracks} = \frac{\sum (l_{crack} \times w_{crack})}{A_{facade}} \times 100 \qquad (11)$$

where l_{crack} and w_{crack} are the length and maximum width of a residual crack measured at the end of an earthquake record, and A_{facade} is the wall surface area on one side. The maximum value of w_{crack} was also calculated and was labeled as w_{res}. For each wall tested, the relationship between w_{res}, or I_{cracks}, and maximum story drift measured during testing stages was plotted and evaluated in Figure 9. It was noted that the rate of increase of residual cracking was not significantly influenced by the type and amount of web shear reinforcement.

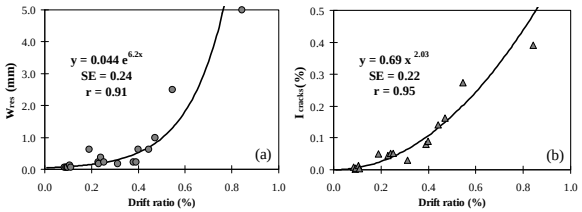

Figure 9 Residual Cracking: (a) Measured Residual Crack Width, (b) Residual Damage Index.

Also shown in Figure 9 are curves obtained from nonlinear regression. In this study, two commonly used measures of "goodness-of-fit" of results of nonlinear regression analyses were computed: the correlation coefficient (r) and the standard error of the residuals (SE). Fitted curves showed a very good agreement with test data, i.e. r is close to 1.0 and SE is around 20%. Applying the equations developed, for a story drift ratio equal to 0.5%, w_{res} and I_{cracks} are equal to 0.98 mm and 0.17%, respectively. For instance, for a RC wall with h_w/l_w = 1.0 and h_w = 2.4 m, the total area of residual cracks is roughly equal to 9800 mm^2 (2400 mm × 2400 mm × 0.17%), and thus, the total length of cracks with a crack width equal to 0.98 mm is roughly equal to 10 m (9800 mm^2 / 0.98 mm). In this way, the length of cracks to be repaired can be estimated. To determine the limiting values of w_{res} and I_{cracks}, equations of nonlinear regression analysis depicted in Figure 9 were used. Results are also included in Table 5.

5. DISCUSSION

5.1 Scope and Evaluation of the Recommendations

Up to date, PBSD has been applied basically to systems with a prevailing failure mode under flexure; thus, its implementation for systems failing by shear is still limited. This is the case of RC walls failing under shear. One of the main obstacles hindering the implementation of PBSD is the absence of suitable models for predicting the load-displacement curve, as well as of the lack of appropriate acceptance limits. Analysis of test data and experimental programs revealed that walls with the characteristics of those studied herein had not been tested

extensively.

In this study, a backbone model for estimating the load-displacement curve of the RC walls and acceptance limits in terms of story drift ration and residual cracking in typical low-rise housing were developed. The variables included were obtained from the design and construction practices of low-rise economic housing in several Latin American countries. The recommendations have also been calibrated on the basis of results observed from quasi-static and dynamic tests. The latter are considered a more suitable testing method as shake table testing includes the dynamic effects experienced by real structures when subjected to actual earthquake loads, i.e. loading rate effects, low-cycle fatigue, and cumulative parameters (Carrillo and Alcocer, 2012d).

5.2 Limitations

The applicability of the recommendations is limited to walls with the characteristics of typical RC walls in one- and two-story economic housing, i.e. prismatic walls with $M/Vl_w \leq 2.0$ and walls with door and window openings, thickness of boundary elements equal to web thickness, response governed by shear deformations, a specified concrete compressive strength that varies between 15 MPa and 25 MPa, axial stress that is less than 0.03 f_c', a web steel ratio smaller than or equal to 0.25%, wall web reinforcement made of deformed bars or welded-wire mesh, and same amounts of horizontal and vertical web reinforcement. Normalweight ($19 \leq \gamma \leq 21$ kN/m3), lightweight ($15 \leq \gamma \leq 19$ kN/m^3) and self-consolidating ($19 \leq \gamma \leq 21$ kN/m^3) concrete was used in the experimental program.

6. CONCLUSIONS

In order to improve design methods toward safer and more economical housing, a backbone model and acceptance limits for PBSD were developed. The semi-empirical model included three different limit states (diagonal cracking, peak strength and ultimate deformation capacity) and is intended to capture the average response from the experiments. Limit states include prediction of shear strength and displacement capacity. The proposed model has been developed to be included in design guidelines. Due to this feature, the proposed model may be implemented in conventional force-based design, as well as in PBSD. For PBSD, the tri-linear backbone model may be used for estimating the global load-displacement capacity curve of the housing in order to be compared to acceptance limits at selected performance levels.

Within a performance-based seismic design framework, and due to the lack of acceptance limits of performance indicators for shear-dominated walls, a series of acceptance limits were also developed. Selected acceptance limits were story drift ratios, residual crack width and residual damage index. These limits were developed for immediate occupancy, life safety and collapse prevention performance levels. Because of the inherent brittle nature of the mode of failure of walls tested, acceptance limits were purposely developed to be conservative, i.e. limits are smaller than those measured at peak strength. These values provide an adequate level of safety against rapid deterioration of stiffness and strength after reaching peak lateral load capacity.

The outcome of this research could contribute to the development of more accurate models and guidelines for improving current provisions. By adopting the recommendations proposed herein, safer and more economical housing may be designed. More economical housing also has the indirect benefit of facilitating the reduction of housing deficits.

Abstract: An object of this study is to evaluate strength of confined masonry walls. Eleven confined masonry wall specimens were tested under cyclic lateral load in the previous study. The walls were constructed with brick and joint mortal and no reinforcements in the walls. Two reinforced concrete columns of both side confined the wall. In this paper, results of these specimens were classified into three failure modes and two transition mode those were shear failure, slipping failure, flexural failure, and those combinations. And strengths of the specimens could be roughly estimated by calculations of flexural strength and cracking strength. However, brick strength isn't used in these calculations nevertheless cracks were observed on bricks. Therefore, two kind of shear-loading tests were conducted to verify the cracking strength formula. One is shear-loading test of prism specimen consisted with brick and mortar. The other is shear-loading test of brick in order to obtain strength when the brick cracks.

1. INTRODUCTION

Confined masonry buildings are commonly constructed in many countries. In these structures, masonry walls are confined with reinforced concrete columns and beams. Because of these low-cost buildings, various constructing methods, problem of skill level, and so on, a simple evaluation method for strength of the confined masonry wall is desirable.

An objective of this study is to propose simple and logical evaluation method for strength of the confined masonry wall without opening. Eleven one-story and one-span specimens of confined masonry walls were tested under cyclic lateral load in previous studies (Toge et al. 2006, Sakaitani et al. 2008, Hayashi et al. 2009, Sugai et al. 2010, Murai et al. 2011, Tanabe et al. 2012). In this paper, failure modes of these specimens are classified firstly. Next, strengths of test results are compared with calculations of strengths for the failure modes. Then, two kind of shear-loading tests were conducted to verify the cracking strength formula. One is shear-loading test of prism specimen consisted with brick and mortar. The other is shear-loading test of brick.

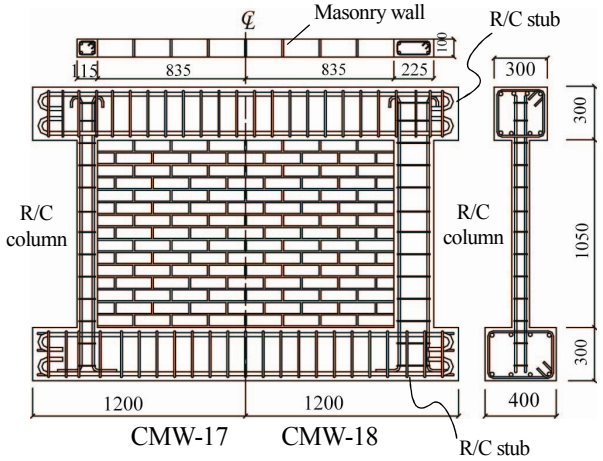

Figure 1 Details of Specimens

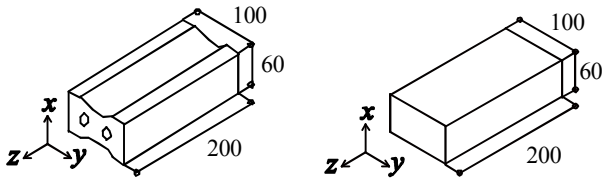
2. CYCLIC LOADING TEST OF CONFINED MASONRY WALLS

2.1 Outlines of Experiments



Eleven confined masonry wall specimens without opening were prepared in the previous studies. Figure 1 shows detail of two of these specimens. The specimen was one-story and one-span wall. The wall was confined with two reinforced concrete columns, hereafter R/C columns, at both sides. The specimens were modeled ground-story in three-story building, and were half scale. Therefore, the specimen of masonry wall with R/C columns was fixed by two R/C stub beams at top and bottom.

Table 1 shows list of the eleven specimens. Primary parameters were strength of joint mortar, brick, and longitudinal bars in column. The bricks were gardening bricks at retail in Japan, and had hole or no hole as shown in Figure 2. Compressive strengths of the bricks are shown in Table 1, and its loading direction is shown in Figure 2. The

F_{mor}: target compressive strength of joint mortar, f_{br}': brick compressive strength, f_{mor}': compressive strength of mortar cylinder, f_c': compressive strength of concrete cylinder, σ_y: yield stress of reinforcing bar.

Special brick Cuboid brick

Figure 2 Dimension of Bricks

bricks were cut in 100mm of length on x-directional compression test. Target compressive strengths of joint mortar, F_{mor}, were 10 and 30 N/mm^2. Mortar compressive strengths, f_{mor}', are also shown in Table 1 those are given by compression tests of mortar cylinders. The mortar cylinders have 50mm in diameter and 100mm in height.

Figure 3 shows a loading setup. The bottom stub was fixed, and a lateral load and a vertical load were applied through universal joints. The specimen was subjected to static cyclic load. The vertical load was transferred through steel plates those were placed between a steel beam and the top stub above the columns. The vertical load shown in Table 1, which acts on the specimen as axial force, kept constant during the test. Lateral displacement at the top stub, δ in Figure 3, was measured by displacement transducers. Rotation of the specimen, hereinafter R, is equal to δ/H, which H is equal to 1050 mm of clear span.

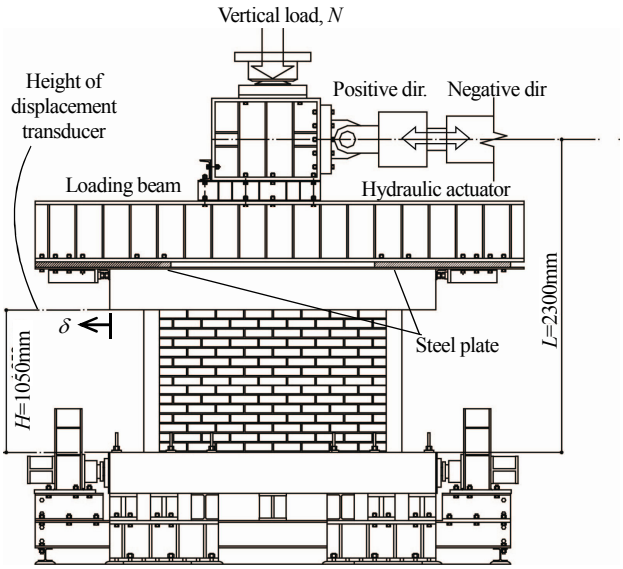

Figure 3 Loading Setup

2.2 Test Results and Failure Mode

Figure 4 shows representative test results, which are lateral load - rotation curves and damages after the loading. As shown in this figure, test results were classified into three failure mode and two transition mode; shear failure mode, flexural failure mode, slipping failure mode, flexural failure mode after slipping, and slipping failure mode after flexural yielding.

Performances of those failure modes are as follows. The shear failure mode: it could be observed diagonal cracks extending, and then shear resistance declined brittlely. The flexural failure mode: the wall yielded in flexure due to yielding of longitudinal bars in the column, and showed ductile behavior. The slipping failure mode: the wall failed due to cracking in joint mortar. Bricks also cracked at compression part in the wall, but major crack could be observed in the joint mortar. The flexural failure mode after slipping: first peak of shear resistance occurred by cracking in the joint mortar, and then second peak was due to yielding of the longitudinal bars in the column. The slipping failure mode after flexural yielding: first peak of shear resistance was due to yielding of longitudinal bars in column, and then the resistance declined because of cracks in the joint mortar.

3. EVALUATION OF STNREGTH

3.1 Concept of Evaluation

In this paper, a design concept is assumed that the confined masonry wall resists earthquake by its strength, and ductility of the wall isn't taken into account. The strength of

confined masonry wall is evaluated by cracking strength in the wall because cracks in masonry wall must weaken resistance against lateral force in out-of-plane direction. And a flexural strength is adopted for evaluation in case of short reinforcements in columns.

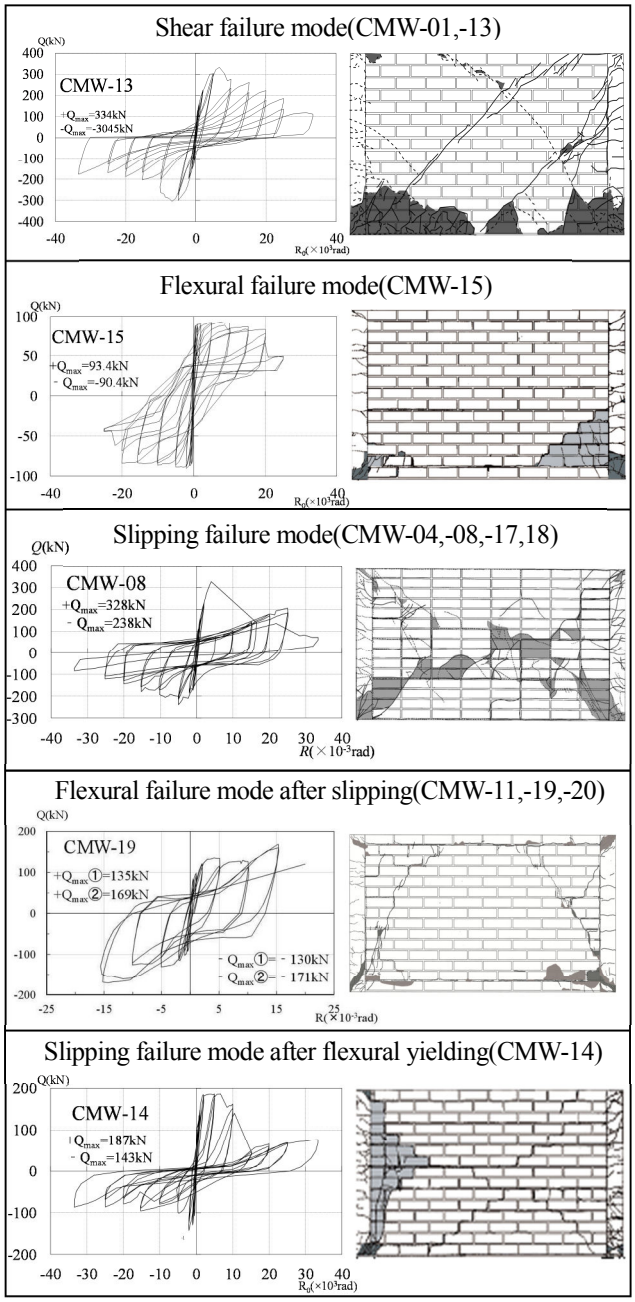

Figure 4 Failure Mode

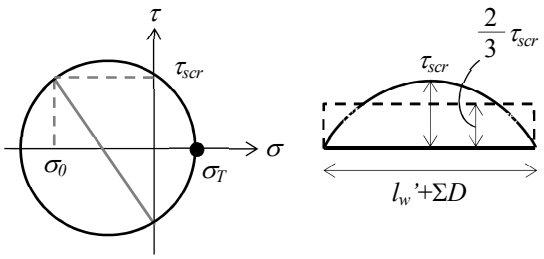

Figure 5 Stress in Horizontal Section of wall

3.2 Cracking Strength

A shear cracking strength for R/C shear wall written in AIJ guideline (Architectural Institute of Japan 1999), which is the following equation, is applied to the cracking strength of masonry wall in this paper.

$$V_C = \frac{t_w l_w}{\chi_w}\tau_{scr} \tag{1}$$

$$\text{where } \chi_w = \frac{3(1+u)\left\{1-u^2\left(1-\frac{t_w}{b}\right)\right\}}{4\left\{1-u^3\left(1-\frac{t_w}{b}\right)\right\}} \tag{2}$$

$$u = \frac{l'_w}{l'_w+\sum D} \tag{3}$$

$$\tau_{scr} = \sqrt{\sigma_T^2 + \sigma_T\sigma_0} \tag{4}$$

t_w: thickness of a wall panel;
l_w: distance between centers of boundary columns;
σ_0: axial stress per unit area;
σ_T: concrete tensile strength ($0.33\sqrt{\sigma_B}$ can be used.);
σ_B: concrete compressive strength;
b: width of columns;
D: depth of columns;
l'_w: clear span of a wall panel.

This strength is decided by assuming the maximum principal stress in concrete reach the tensile strength of concrete as shown in Figure 5. An object of this formula is a shear wall having larger width of column than wall thickness. In this paper, the confined masonry walls have the same column width as wall thickness. The following equation can be given from Eq. (1) by assuming conditions that concrete strength is replaced by mortar strength, and b is equal to t_w.

$$V_{cr} = \frac{2}{3}t_w(l'_w + \sum D)\tau_{cr} \tag{5}$$

$$\tau_{cr} = \sqrt{\sigma_{mT}^2 + \sigma_{mT}\sigma_0} \tag{6}$$

t_w: thickness of wall;
D: depth of columns;
l'_w: clear span of a wall panel;
σ_o: axial stress per unit area
σ_{mT}: mortar tensile strength ($0.33\sqrt{f_{mor}}$ can be used.)
f_{mor}: mortar compressive strength

As shown in Eq.(5), this model is given by assuming parabola shear stress distribution shown in Figure 5.

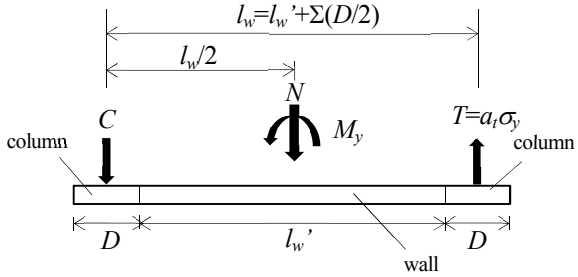

Figure 6 Section of Bottom End

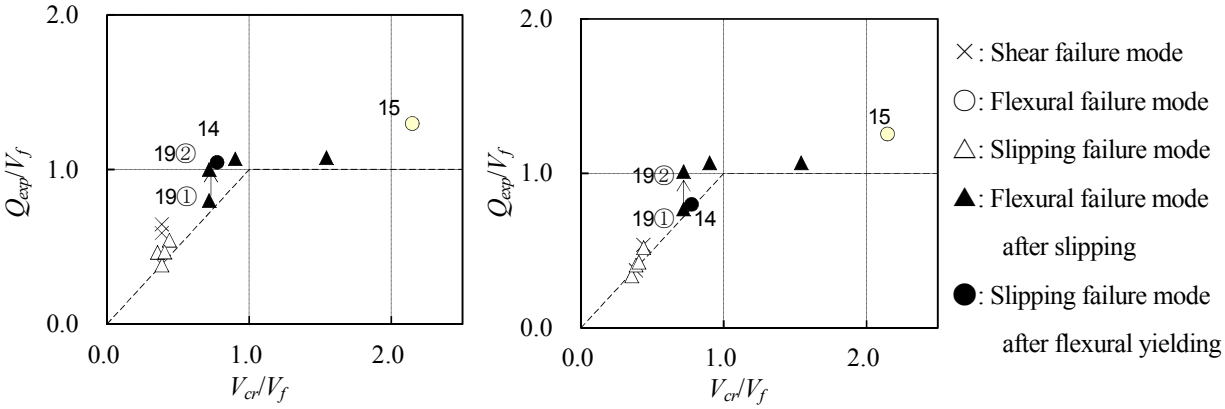

Figure 7 Comparison between Test Results and Calculations of Strength of Confined Masonry Wall Specimens

3.3 Flexural Strength

The flexural strength of confined masonry wall is based on a flexural strength of R/C shear wall (Architectural Institute of Japan 1990), as follows.

$$M_y = l_w(a_t\sigma_y + 0.5N) \quad (7)$$

$$V_f = M_y/L \quad (8)$$

a_t: gross sectional area of longitudinal bars in tensile column;
σ_y: yield strength of reinforcing bars;
D: depth of columns;
l_w: distance between centers of boundary columns;
N: axial force;
L: shear span of a wall.

Above equation is assumed a stress distribution at a bottom end of the wall as shown in Figure 6. This formula has no effects of vertical reinforcements in wall because the specimens have no reinforcements in wall. The effects of reinforcements in wall must be examined separately.

3.4 Comparison between Test Results and Calculation

Figure 7 shows comparison between test results and calculation of strength. A left figure shows comparison of positive side of loading, and a right one is negative side. Q_{exp} expresses the maximum shear load in the test, only the first peak of shear load of CMW-19 is also drown together. V_{cr} and V_f are calculations of cracking strength and flexural strength, respectively. The V_{cr} is calculated with a condition σ_o=0 by assuming columns support all the axial force. A vertial axis is Q_{exp}/V_f, and a horizontal axis is V_{cr}/V_f. In this graph, a point is plotted near to Q_{exp}/V_f=1 or Q_{exp}/V_f=V_{cr}/V_f if the test result is close to the flexural strength or the cracking strength, respectively.

As shown in Figure 7, the calculations of strengths show good agreement with the maximum shear force and the failure mode of test results. A tendency can be seen that the specimen fail in shear or slipping when V_{cr}/V_f is less than 1.0, and fail in flexure when V_{cr}/V_f is greater than 1.0.

The specimen CMW-14, as shown in Figure 4, yielded in flexure under positive side loading, and the maximum load under negative side loading was lower than that of positive side. The CMW-14 was classified into slipping failure mode after flexural yielding. As shown in Figure 7, the maximum loads under positive and negative side loadings of CMW-14 almost agreed with V_f and V_{cr}, respectively. The maximum load of CMW-15 was greater than V_f, because, according to strain gages, work hardening of longitudinal bars in tensile column was observed. CMW-19 showed two peaks of load as shown in Figure 4, which was classified into the flexural failure mode after slipping. The first and second peaks of load of the CMW-19 agreed with V_{cr} and V_f, respectively.

As results of the comparison, the strength of specimens can be roughly evaluated by V_{cr} and V_f, and the failure mode is distinguishable by comparing V_{cr} and V_f,. However, some problems remain in this method. In this paper, the following problems are aimed; V_{cr} doesn't evaluate two types of cracking those are crack in joint mortar and crack through brick and mortar; brick strength isn't included in this method; a cracking criterion of masonry wall that is composite material wall doesn't solved. In order to examine these problems, two kinds of shear-loading tests were conducted.

4. SHEAR-LOADING TESTS OF PRISMS AND BRICKS

4.1 Objectives of Shear-loading Tests

Two types of cracking are aimed those are crack in joint mortar and crack through brick and mortar. In order to examine cracking criteria of masonry wall, material properties of brick and mortar are needed at least. In this study, two kinds of shear-loading tests were conducted. One is shear-loading test of prism specimen consisted with brick and mortar whose object is to be occurred the two types of cracking. The other is shear-loading test of brick. The test is conducted to obtain strength when the brick cracks. Tensile strength of mortar can be obtained by a splitting test of cylinder, and compression tests of mortar cylinder and brick give those compressive strengths.

EM10-I EM30-I

Figure 11 Photo after the Tests

4.2 Prism Specimens and Test Results

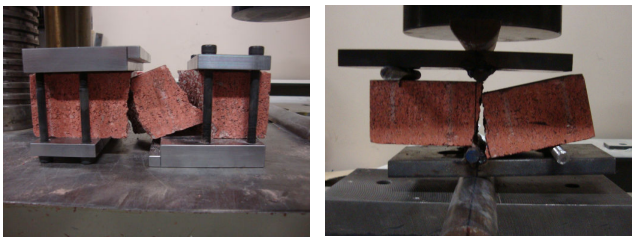

Figure 8 shows the prism specimen that is consisted with three pieces of brick, joint mortar, and stub concrete. The specimen had breaking joint, and was constructed as the joint is placed at center of the prism. Table 2 shows list of the specimens and those material properties. A parameter of this test is mortar strength, which target strengths are 10 and 30 N/mm^2. Two production lots of bricks were used in this test. The shear-loading tests in which the first and second lots of bricks were used, were called phase I and II, respectively, as shown in Table 2. Strength of the stub concrete is about 40 N/mm^2. Three specimens were prepared per four combination of mortar and brick strengths, and totally twelve prism specimens were tested.

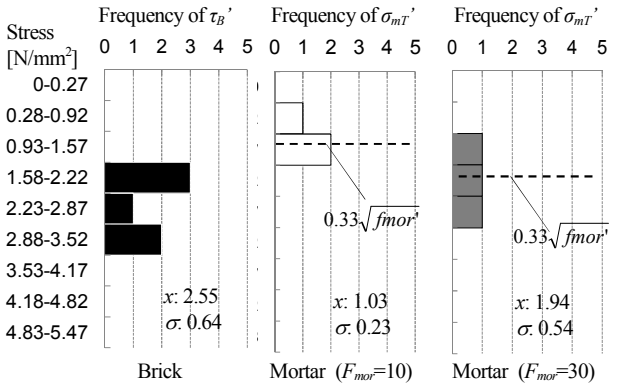
Figure 9 shows loading setup. The prism specimen was fixed on loading beam with four PC bars. The specimen was subjected to shear, bending, and axial force by vertical load and tension in the PC bars. The PC bars have load cells, and were adjusted as tension in the bars was equal to zero before loading. Shear force and axial force transmit from the loading beams to steel blocks, concrete stubs, and masonry part. Bending moment is equal to zero at section A-A' shown

Type A Type B Stress in Brick

Figure 12 Detail of Shear-Loading Test of Brick

Type A Type B

Figure 13 Photos after Shear-Loading Tests



in Figure 8, and shear stress at the center is largest in the section A-A'. Therefore, target of this test is crack in middle part shown in Figure 8. As shown in Figure 10, normal stress and shearing stress on the section A-A' are assumed as values given by dividing axial force and shear force by sectional area at A-A', respectively. The axial force and shear force are equal to the total tension in PC bars and the vertical load, respectively. The normal stress and shearing stress when a crack occurs at middle part of prism, is named σ_{exp} and τ_{exp} in this paper.

Figure 10 also shows Mohr's stress circle with σ_{exp} and τ_{exp}. The maximum principal stress, σ_{1exp}, can be given from a test result. In Eq. (5), the strength is decided by assuming the maximum principal stress reach the tensile strength of mortar. In order to examine this assumption, σ_{1exp} is compared with mortar tensile strength and brick strength associated with crack.

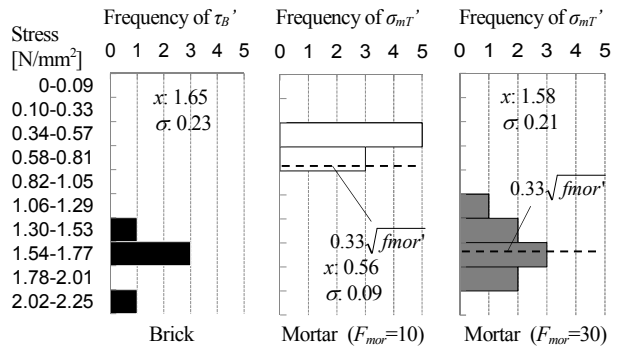


Figure 11 shows photos after the tests. All the specimens failed immediately after cracking. Therefore it can be considered that the maximum load was equal to load of cracking. As shown in Figure 11, at the middle parts of the specimens, crack was in joint mortar of EM10-I, and went through brick and joint of EM30-I. The results could be obtained that different strength of joint mortar caused different cracks in the masonry prisms. Table 2 also shows test results. In a column of "crack at middle part" in this table, "joint" and "brick and joint" means that a crack passed through almost on the center, and "brick" means that a crack was a little distant from the center. σ_{1exp} is the maximum principle stress mentioned above.

4.3 Shear-Loading Test of Brick and Test Results

As shown in Figure 12, two types of shear-loading

Phase I (EM10: $_{mean}\sigma_{1exp}$=1.47, EM30: $_{mean}\sigma_{1exp}$ =1.66)

Phase II (EM10: $_{mean}\sigma_{1exp}$=1.50, EM30: $_{mean}\sigma_{1exp}$ =1.63)

Figure 14 Strengths of Brick and Mortar

system of brick were tried. The both types were aimed that bricks failed with single crack plane at the center. The Ohno system of anti-symmetric bending, which was published in 1956 in Japan, was applied to the type B. Figure 13 shows test results of the both types. The type A wasn't good system because the brick failed with two cracks. It was supposed that bending caused the crack distant from the center. Regarding the type B, the brick failed with single crack plane. Therefore, the type B was adopted in this study. τ_B' is a value given by dividing the maximum load by sectional area of a brick as shown in Figure 12.

4.4 Considerations

Figure 14 is histograms of the test results, whose vertical axis is strength and horizontal axis is frequency.

Table 3 τ_B' and σ_{mT} of CMW speimens

Failure mode	Specimens	V_{cr}/V_f	Stress[N/mm^2] 0 1 2 3 4 5 6
Shear failure mode	CMW-01	0.39	○ ▲
	CMW-13	0.44	○ ▲
Flexural failure mode	CMW-15	2.15	○ ▲
Slipping failure mode	CMW-04	0.44	○ ▲
	CMW-08	0.36	○ ▲
	CMW-17	0.39	○ ▲
	CMW-18	0.41	○ ▲
Flexural failure mode affter slipping	CMW-11	1.54	○
	CMW-19	0.72	○ ▲
	CMW-20	0.90	○ ▲
Slipping failure mode after flexural yielding	CMW-14	0.77	○ ▲

○: $0.33\sqrt{fmor'}$ ▲: τ_B'

Interval of the vertical axis is equal to a standard deviation of τ_B' that is the test result of shear-loading test of brick, and mean of τ_B' is at the center of interval. Results of splitting test of mortar cylinder, σ_{mT}', are shown together. The mortar cylinders for splitting test had 100mm in diameter and 200mm in height. A broken line is $0.33\sqrt{f'_{mor}}$, which is adopted in Eq. (5) as mortar tensile strength. In Figure 14, x is a mean value, and σ is a standard deviation of each data. $_{mean}\sigma_{1exp}$ is the mean of σ_{1exp} shown in Table 2, which is the results of shear-loading tests of prism specimens.

As shown in Figure14, because τ_B and σ_{mT}' have wide variation in those results, it is difficult to conclude a cracking criterion of masonry wall in this paper. However, the following tendencies can be seen: σ_{1exp} is obtained between τ_B' and σ_{mT}'; σ_{1exp} of the specimen cracked in joint is close to σ_{mT}'; σ_{1exp} of the specimen cracked through brick and joint is close to τ_B'. In this study, two types of cracking couldn't be distinguished by comparing between τ_B' and σ_{mT}'.

4.5 Shear-Loading Test of Brick used in Confined Masonry Wall Specimens

Shear-loading tests were conducted with bricks those were used in the confined masonry wall specimens shown in Table 1. Table 3 shows comparison between τ_B' and σ_{mT}. The τ_B' is an average of shear-loading test results of bricks, and the σ_{mT} is equal to $0.33\sqrt{f_{mor}'}$, which was calculated with mortar compressive strength f_{mor}'. As shown in Figure 7, Eq. (5) showed good agreement with the test results, though brick strength wasn't used in Eq. (5). As shown in Table 3, τ_B' are close to mortar tensile strength in the specimens of shear failure mode and slipping failure mode. Therefore, in spite of no brick strength in Eq. (5), it is supposed that the cracking strength gave good agreement with the test results of loading test of the confined masonry wall specimens. Regarding the failure mode of the confined masonry wall specimens, in spite of difference between τ_B' and σ_{mT}, the specimens can be classified into flexural failure mode if V_{cr}/V_f is larger than 1.0.

5. CONCLUSIONS

In this paper, failure modes of eleven confined masonry wall specimens were classified into three failure modes and two transition modes those were shear failure, slipping failure, flexural failure, and those combination. And strengths of the specimens could be roughly estimated by calculations of flexural strength and cracking strength. Two kinds of shear-loading tests with a prism specimen and a brick were conducted in order to verify the cracking strength. In the shear-loading test of brick, strength τ_B' could be obtained when the brick failed with single crack plane. As results of the shear-loading tests of prism specimens, the maximum principal stresses in the specimens with crack in joint mortar and crack through brick and mortar, are close to mortar tensile strength and τ_B', respectively. And as results of the shear-loading tests of bricks those were used in the confined masonry wall specimens, τ_B' are close to mortar tensile strength on the specimens of shear failure mode and slipping failure mode. Therefore, in spite of no brick strength in the cracking strength formula, the cracking strength gave good agreement with the test results of loading test of the confined masonry wall specimens.

Abstract: The lattice model is the method which can easily demonstrate the load-displacement relationship of reinforced concrete (RC) beams. This model functioned by both the arch action and the truss action can calculate the load-capacity, and indicates the bearing mechanism of loads. The existing discretized method of lattice model shows the non-linearity by changes in both areas of arch and compressive truss elements. However, this method cannot decide the areas of these elements for beams with small shear-span effective ratio. In this research, we consolidated the development of damages caused by many factors to the areas of all elements, and proposed all process as a method for the calculation of load-capacity of RC beams by lattice model arranged by experiment results.

1. INTRODUCTION

The design code in the field of civil engineering (JSCE 2007) describes some calculation equation such as: the design shear capacity (V_{yd}), the shear compression capacity (V_{dd}), the web compression capacity (V_{wcd}). The failure mode of the RC beams was classified as above three types; and equations was described according to the assumption of the load bearing mechanism. According to the verification system, these calculation equation need to calculate the shear capacity of beam with small differences among V_{yd}, V_{dd}, and V_{wcd}, because a failure phenomenon changes gradually according to its specification. However, each equation consists of contributions by concrete and by stirrups has been developed separately. This history made the differences among V_{yd}, V_{dd}, and V_{wcd} large. Figure 1 shows the calculation of V_{yd} and V_{dd} of RC beams with high dense stirrups as a function of a/d. There is not crossing point between curves of V_{yd} and V_{dd}. The gap between curves of V_{yd} and V_{dd} was caused by, such as the accuracy of the equations. In addition, the value of V_{yd} is corresponding to the yield of stirrups, on the other hands; the value of V_{dd} is corresponding to the maximum load. Therefore, with considering failure type, the calculation method which does not depend on failure type will solve the problem of the gap.

One of the methods for demonstrating the load-bearing capacity as well as load-displacement relationship is the lattice model. The lattice model can express the load-bearing mechanism easily and clearly. The previous study (Niwa et al. 1995) develops the lattice model for slender RC beams with changing the cross-section area and stress-strain relationship of each strut. The cross-section area was decided by calculating the minimum potential energy. According to the trial for the RC beam with smaller a/d by authors, however, the cross-section area was not decided by the method.

The objective of this study is to develop the discretization method for RC beam including the range of smaller a/d. By fixing the stress-strain relationship applied to each strut, the cross-section area of each strut was controlled according to the experimental results. Then, the contribution of each strut changing by specimen design was discussed.

2. CONTRIBUTION OF ARCH AND TRUSS MEMBERS BASED ON CROSS-SECTION AREA

2.1 Concept of Anlayses

Figure 2 describes the lattice model used in this study. The model discretizes RC beams as the flexural compression

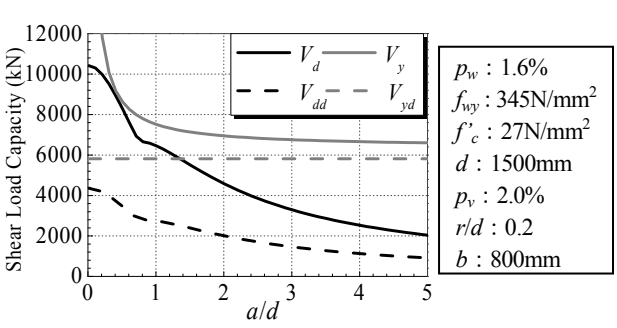

Figure 1 Continuity between V_{yd} and V_{dd} as a Function of a/d

member, flexural tension member, diagonal compression member, diagonal tension member, arch member, horizontal member for longitudinal rebar, and vertical member for stirrups. The previous study (Niwa et al. 1995) decreases the strength of concrete for compression member with considering to the lateral strain of concrete proposed by Collins. The propagation of damage by increment of loading was expressed by changing the stress-strain relationship. On the other hands, this study considered the propagation of damage by controlling the cross-section area of each strut according to the experimental results. This section focuses on t-value corresponding to the ratio of area between arch and truss members.

2.2 Analytical Method

This paper referred RC beam having a/d=0.5, 2.0 (Tanimura et al. 2004). This paper discretized these specimens as Figures 2, 3. The stress-strain relationship is used as follows: bilinear-type for rebars, parabola involving compressive fracture energy for concrete in compression, one-forth model for concrete in tension, and Okamura-Maekawa model involving the effect of bond between rebar and concrete for flexural tension members.

2.3 Analytical Results

Figures 4 and 5 compare the load-displacement relationships of specimen No.31 and No.3 (Tanimura et al. 2004) as a function of t-value. Four t-value were used as 0.2, 0.4, 0.6, and 0.8. These figures indicate that maximum load was increased with the increase in t-value. The calculation result seems to be corresponding to the experimental value when t=0.8 at No.31, and t=0.4 at No.3. Table 1 tabulates the vertical component of load carried by each member at maximum load. The table indicates the same load generating the diagonal member in both model with different a/d, but the contribution by arch and stirrup member. Even so, the load started to be decreased when the arch member reached its peak. This result implies that the contribution of arch member increased with the decrease in a/d. On the other hands, the cross-section area of the arch needs some enough when a/d become larger, resulting in t=0.8 at a/d =2.0, and t=0.4 at a/d =0.5.

3. LATTICE MODEL DISCUSSED BY THE EXPERIMENTAL RESULTS

3.1 Analytical Concept

This section decides the cross-section area of each member according to the experimental results, and discusses the contribution of each member.

3.2 Analytical Method

The stress-strain relationship used in this section was corresponding to the chapter 2. The cross-section area of diagonal compressive member, diagonal tension member, and arch member was decided according to the experimental data (Tanimura et al. 2004), of which specimen has p_w of 0.21, 0.48, 0.84%, and a/d of 1.5. Table 2 summarizes the

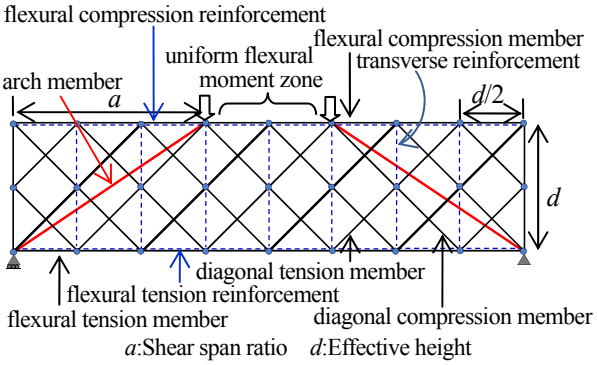

Figure 2 Concept of Lattice Model (a/d=1.5)

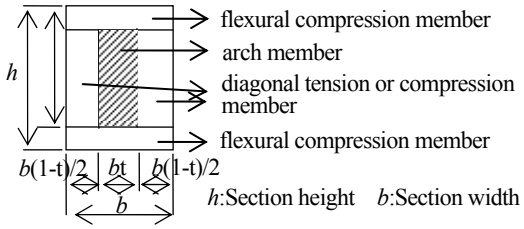

Figure 3 Section of Lattice Model

method for setting the cross-section area of each member, and Table 3 compares the experimental value referred for this study and analysis data. The stiffness of the shear force-displacement curve decreased after a diagonal crack was observed. The cross-section area of the diagonal tensile member was adjusted to obtain the first bending point of load-displacement curves obtained by the specimen and the lattice model.

The stiffness as well as cross-section area of the diagonal compression member will affect the load carried by stirrups. The cross-section area of the diagonal compression member was decided by fitting the load carried by stirrups in the specimen with that in the lattice model. This means the average stress $\sigma_{s.ave}$ of all stirrups in the shear span was identical. Figure 6 shows the relationship between the average stress by stirrups and shear force. Even some of the stirrups were yielded, $\sigma_{s.ave}$ become smaller with the increase in p_w (Table 2).

Finally, the cross-section area of the arch member was decided when the maximum load of the specimen and the lattice model were identical. The height of flexural compression member was fixed as 200 mm, and the cross-section area of the other member was decided as the previous study (Niwa et al. 1995).

3.3 Analytical Results

Figures 7 show the shear force-displacement relationship. According to 3.2, the lattice model can demonstrate the load-displacement curve as well as the load bearing capacity.

Figure 8 the cross-section area of arch, compression, and tension members as a function of p_w. The cross-section areas of arch and compression members were increased with the increase in p_w. The previous study (Tanimura et al. 2004) reported that the localized compressive failure zone was increased by the lateral force, which was also affected by the arrangement of stirrups. This is one of the reasons the increment of cross-section area of arch member. On the other hands, there was no tendency in the diagonal tension member by p_w because the member was set as expressing the diagonal cracking.

Figure 9 shows the hysteresis of force carried by each member in No.12, which was calculated at the cross-section identified by dash-line in Figure 1. The diagonal tension member did not carry when the displacement reached 2 mm. The summation of load carried by the arch and the diagonal

tension members was corresponding to the shear carried by concrete (V_c) in slender RC beams (JSCE 2007). On the other hands, the summation of both in this study, of which a/d being smaller, was increased with the increase in the displacement.

4. CONCLUSIONS

This study developed the lattice model, which demonstrated the load carrying mechanism by changing the cross-section area of each member. In the range of this study, the cross-section member of arch, diagonal tension members were increased with the increased in p_w. The developed model demonstrated the load-displacement relationship in pre-peak region.

THREE-DIMENSIONAL NONLINEAR BEAM-TRUSS MODEL FOR NON-PLANAR REINFORCED CONCRETE WALLS

Yuan Lu[1] and Marios Panagiotou[2]

1) Graduate Student Researcher, Dept. of Civil and Environmental Engineering, University of California at Berkeley, Berkeley, CA, USA
2) Assistant Professor, Dept. of Civil and Environmental Engineering, University of California at Berkeley, Berkeley, CA, USA

Abstract: This paper presents a three-dimensional (3D) nonlinear cyclic model which uses a coarse grid of beam and truss elements in order to capture the behavior of non-planar reinforced concrete walls including shear-flexure interaction and diagonal crushing failure. 3D nonlinear Euler-Bernoulli fiber-section frame elements are used to represent steel and concrete in the vertical direction, nonlinear trusses are used to represent the steel and concrete in the horizontal direction, and nonlinear biaxial trusses are used to represent the diagonal field of concrete in compression. The model represents the effects of shear- flexure interaction by accounting for strains in the horizontal direction and the biaxial effects, the effect of normal tension strain on the compressive strength of concrete, of the concrete diagonals. The model is validated by comparing the experimentally measured and numerically computed response of three reinforced concrete wall specimens which have T-, C-, and I-shape sections, respectively; the response of the latter two specimen are characterized by crushing of the concrete in the diagonal direction. The overall force-deformation and local strain responses are presented.

1. INTRODUCTION

Reinforced concrete (RC) walls are one of the most common elements used in structures to resist loads and develop deformations expected during earthquake excitation. The computation of their nonlinear cyclic response is of significant interest to both practicing engineers and researchers. This task is particularly challenging for non-planar RC walls, which are commonly used in medium- and high-rise construction, when subjected to uni-axial or multi-axial loading representative of earthquake excitation. The computation of the response of non-planar RC walls can be even more challenging when it is significantly affected by flexure shear interaction (FSI). Here, FSI is described as the combination and coupling of axial, flexural, and shear load on structural elements, resulting in a multi-axial stress-strain state and coupling of nonlinearities that affect the behavior of concrete in compression. The FSI may significantly affect the cyclic behavior of RC non-planar walls in terms of strength, stiffness, deformation capacity, softening response, and strains developed in steel and concrete.

Nonlinear modeling approaches for non-planar RC walls may be divided into five main categories: (i) fiber-section beam-column element (termed beam elements in this paper) models; (ii) wide column models known also as equivalent frame models; (iii) truss or lattice models; (iv) models with beams and trusses; and (v) finite element (FE) models using either plane stress or solid elements.

Fiber-section beam models (sometimes called "stick" models) typically use a linear shear force – deformation and torsional moment – twist angle relationship (Mazars et al. 2006, Orakcal and Wallace 2006), and have been altered to consider the inelastic behavior of the transverse steel reinforcement and represent FSI using equilibrium, specific assumptions for the shear strain field, and bi-axial concrete material laws (Petrangeli 1999, Petrangeli et al. 1999, Martinelli 2008). However, these models use the plane-sections-remain-plane assumption of beam theory, which can significantly differ from the section response of non-planar walls in reality.

Beyer et al. (2008b) presented a nonlinear equivalent frame model using nonlinear Euler-Bernoulli (no shear deformation) fiber-section vertical beam elements and rigid horizontal beam elements connected with linear shear and torsional springs. This model did not account for the inelastic response of steel in the horizontal direction as well as for the bi-axial behavior of the concrete diagonals.

Three-dimensional truss models (also called lattice models) have been used to model hollow square RC columns (Miki and Niwa 2004) but have not been used to model any non-planar wall or hollow section member that experienced diagonal concrete crushing.

Barbosa (2011) presented a 3D model for planar RC walls consisting of Euler-Bernoulli fiber-section beams that represented the boundary elements of the walls, and nonlinear truss elements to model the concrete and steel in the horizontal direction and the inner regions of the walls in the vertical direction. Nonlinear concrete trusses were used in the diagonal direction and elastic beams were used in parallel with vertical elements for out-of-plane stiffness.

Nonlinear cyclic 3D FE models using plane stress elements or solid (block) elements that use smeared crack

and/or plasticity models have been developed and used to analyze the cyclic behavior of RC non-planar walls or RC components with hollow sections (Sittipunt and Wood, 1993; Ile and Reynouard, 2000; El-Tawil et al. 2002; Palermo and Vecchio 2002; Maekawa 2003; Hassan and El-Tawil 2003; Balkaya and Kalkan 2004; Ile and Reynouard 2005; Kotronis et. al. 2005). Three-dimensional FE models using only plane-stress elements do not model the out-of-plane flexural rigidity of segments comprising a non-planar wall. The complexity and computational effort required in nonlinear 3D FE modeling using solid elements increases significantly compared to 2D models.

This paper describes a nonlinear beam-truss modeling approach for non-planar RC walls subjected to cyclic uni-axial or multi-axial loading that requires moderate computational effort. The main objective of the proposed model is to compute the post-cracking 3D behavior of non-planar RC walls, considering FSI and mesh-size effects. The model, which uses a nonlinear truss element developed herein, applies a bi-axial material model for concrete in the diagonal direction, as well as existing nonlinear truss and Euler-Bernoulli fiber-section beam elements. The model accounts for the effect of normal tensile strain on the stress-strain relationship of concrete in compression [as reported by Vecchio and Collins (1986)], but also incorporates mesh-size effects as proposed by Panagiotou et al. (2012) for planar walls in 2D. Compared to the beam-truss model of Barbosa (2011), the model developed herein features different placement of beam and truss elements, and also accounts for the instantaneous bi-axial effects in the behavior of concrete in the diagonal direction in compression. Compared to the beam-truss model presented in the report by Lu and Panagiotou (2012), the model presented in this paper uses nonlinear truss elements in parallel to the horizontal linear beam elements in the horizontal directions.

To test the efficacy of the model, the experimentally measured and computed response of three case studies were considered: (i) a wall with a T-shape section subjected to uni-axial cyclic loading with significant contribution of the flange to the response; (ii) a U-shape section wall subjected to multi-axial cyclic loading, which failed by crushing of concrete in the diagonal direction; and (iii) an I-shape section wall subjected to uni-axial loading, which failed with diagonal crushing of the web. The global responses in terms of lateral force-lateral displacement as well as the more localized strain responses are presented.

2. BEAM-TRUSS MODELING APPROACH

Consider the T-section wall shown in Figure 1(a) where its length along the *X*- and *Y*-axis is L_X and L_Y, respectively. The thickness of the rectangular-section segments of the wall parallel to the *X*- and *Y*-axes is t_X and t_Y, respectively. The height of the wall is *H*. Figure 1(b) shows the model of this wall, which consists of four type of elements: (1) nonlinear fiber-section Euler-Bernoulli beam elements – called nonlinear beam elements herein – in the vertical direction (*Z*-axis); (2) nonlinear truss elements in the two horizontal directions (along *X*- and *Y*-axes); (3) linear Euler-Bernoulli beam elements – called herein linear beam elements – in parallel to the truss elements in the horizontal directions; and (4) nonlinear truss elements in the diagonals of the panels formed by the horizontal and vertical elements.

The points where at least one vertical and one horizontal element intersect with a diagonal truss comprise

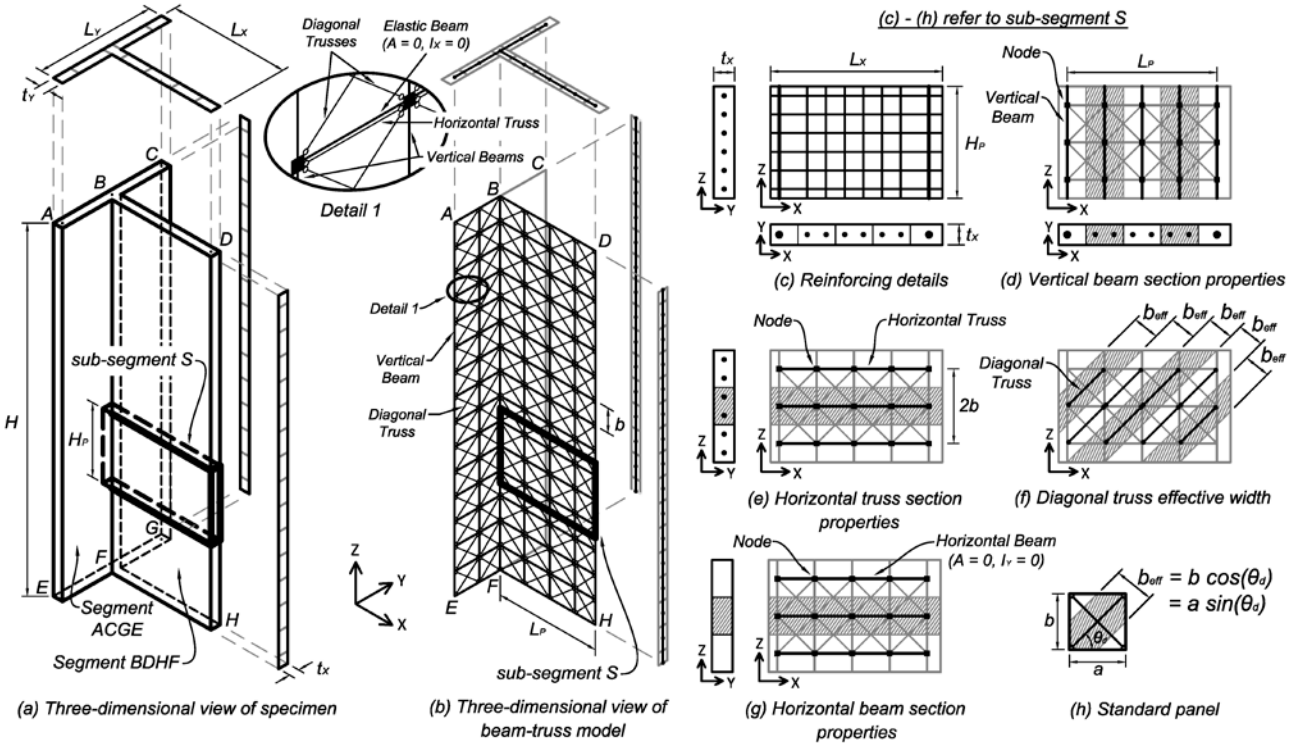

Figure 1. Schematic description of the beam-truss model approach for a T-shape section wall.

the nodes of the model, shown in Figure 1(d) and (e). Each node has six degrees of freedom (DOFs), with all DOFs fixed at the base. Nine lines of vertical beam elements were used (five in each of the two segments of the T-wall) and line BF was common for the two segments. Fifteen lines of horizontal trusses and linear beams were used along the height of the wall. As an example of the determination of section properties, considered sub-segment S of segment ACGE of the wall [see Figure 1(a)], the reinforcing details of which are shown in Figure 1(c). The vertical beam elements and horizontal truss elements model the concrete and steel included in the section areas each element represents. Figures 1(d) and (e) show the section properties (area of concrete, area and layout of steel) of each of the vertical beams and horizontal trusses, respectively. For the vertical nonlinear beam elements, a fiber-section with 24 fibers in a 6 × 4 grid is used to represent the concrete and a single fiber to represent each reinforcing steel bar. The linear beam elements in the horizontal directions [shown in Figure 1(g)] have flexural rigidity E_cI_Z (to model the out-of-plane stiffness of the segments of the wall), zero axial rigidity, and zero in-plane flexural rigidity. Gross section properties are used to calculate I_Z. Both the vertical nonlinear fiber-section beams and horizontal linear beams, have torsional rigidity GJ equal to 10% of the gross section torsional rigidity, GJ_g. E_c is the initial concrete modulus and $G = 0.38E_c$, the concrete shear modulus.

In addition to the vertical and horizontal elements, concrete truss elements were used for all diagonals to model the compressive field of concrete in the corresponding direction. The angle of the diagonals with respect to the horizontal elements is θ_d [see Figure 1(h)]. In this study, θ_d ranged between 40° and 50°, and the effect of the truss angle was investigated in Case Study 3 presented below. The area of each diagonal is the product of the effective width b_{eff} [see Figure 1(f)] and the thickness of the panel t_X. The effective width of the diagonal is $b_{eff} = a \sin(\theta_d)$, where a is the length of the panel [see Figure 1(h)].

3. MATERIAL CONSTITUTIVE STRESS-STRAIN RELATIONSHIPS

3.1 Concrete Model for Vertical and Horizontal Elements

The stress-strain relation of concrete used in the vertical beam and horizontal truss elements is shown in Figure 2, where f_c' is the peak compressive strength of unconfined concrete occurring at strain ε_o = 2%. The compressive stress-strain relation up to f_c' is based on the Fujii concrete model (Hoshikuma et al. 1997):

$$f(\varepsilon)=\begin{cases} E_c\varepsilon + 0.5\cdot\left(\dfrac{f_c' - E_c\varepsilon_o}{\varepsilon_o}\right)\cdot\varepsilon^2 & \varepsilon \le \varepsilon_o \\ \left(\dfrac{f_c' - f_{cc}}{(\varepsilon_o - \varepsilon_{co})^3}\right)\cdot(\varepsilon-\varepsilon_{co})^3 + f_{cc} & \varepsilon_o < \varepsilon \le \varepsilon_{co} \end{cases} \quad (1)$$

The initial concrete modulus was $E_c = 5000$ sqrt(f_c') (MPa). For unconfined concrete, after reaching f_c', the compressive stress decreased linearly to zero at strain ε_u. The value of ε_u accounted for mesh-size effects base on the notion of concrete fracture energy in compression (Bazant and Planas 1998), with $\varepsilon_u = (1 - \Lambda)\,\varepsilon_o + (L_R/L)(0.2\% + \Lambda\,\varepsilon_o)$ where L is the length of the truss element or the length corresponding to each integration point of the beam element (Coleman and Spacone 2001), L_R = 600 mm is the reference length considered in this study, and $\Lambda = f_c'/[0.5\,(E_c\varepsilon_o + f_c')]$, a factor that considers the effect of unloading on the concrete fracture energy in compression. For $L = L_R$, ε_u = 0.4%. See Bazant and Planas (1998), Coleman and Spacone (2001), Panagiotou et al. (2012), Lu and Panagiotou (2012) for additional discussion on how the degrading branches of material constitutive laws account for mesh-size effects in FE, fiber-section beam, truss models, and beam-truss models respectively.

For confined concrete, the peak compressive stress f_{cc} occurring at strain ε_{co}, and the strain ε_{cs} at which softening initiates was calculated based on Mander et al. (1988). The stress-strain relation of confined concrete is described in Equation 1and was the same as the unconfined during loading up to f_c'. The confined concrete stress remains constant and equal to f_{cc} for strains between ε_{co} and ε_{cs}. For strains larger than ε_{cs}, the stress softens linearly to zero at a strain ε_{cu}. Accounting for mesh size effects $\varepsilon_{cu} = (1 - \Lambda)\,\varepsilon_{cs} + (L_R/L)(0.2\% + \Lambda\,\varepsilon_{cs})$, where $\Lambda = f_{cc}/[0.5\,(E_c\varepsilon_{cs} + f_{cc})]$. For L_R = 600 mm, $\varepsilon_{cu} = \varepsilon_{cs} + 0.2\%$.

The concrete tension stress-strain relationship during loading is linear with tangent modulus E_c until it reaches the tensile strength of concrete $f_t = 0.33$ sqrt(f_c') in MPa. After this point, the concrete softens [see Stevens et al. (1991)]:

$$f = f_t \cdot [(1-M)e^{-\lambda_r(\varepsilon-\varepsilon_{cr})} + M] \quad (1)$$

where the parameter $M = C_t\rho_l / d_b$, λ_t = 540 / sqrt(M), and C_t = 75mm, ρ_l is the steel ratio in the direction parallel to the axis of the beam element, and d_b the diameter of the rebar of interest.

Upon unloading from a compressive strain, the tangent

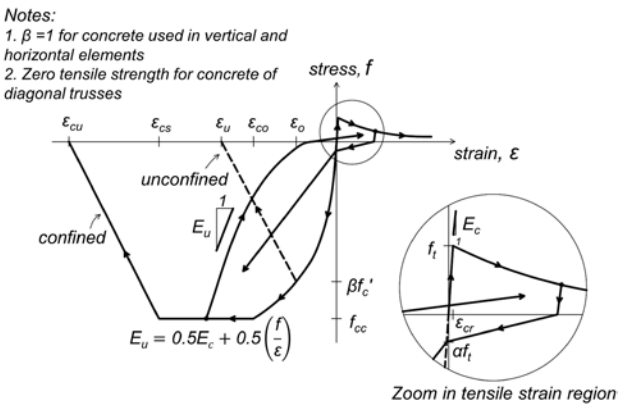

Figure 2. Stress-strain relationship of concrete material models

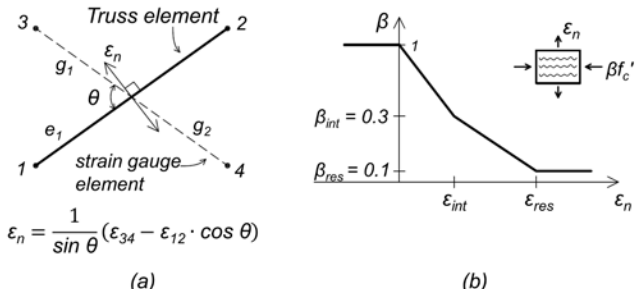

Figure 4. (a) Truss element accounting for biaxial effects in the compressive stress-strain behavior of concrete. (b) Relation between concrete compressive stress reduction factor, β, and normal strain, ε_n.

modulus is $E_u = 0.5\,E_c + 0.5(f/\varepsilon)$ until reaching zero stress, then reloads linearly to the point with the largest tensile strain that occurred before. The unloading from a tensile strain is linear with a tangent modulus E_c until reaching zero stress. After this, the material loads in compression and targets a stress equal to $\alpha \cdot f_t$ at zero strain with $\alpha = 0.5$. Thereafter, the material loads linearly to the point where the peak compressive strain occurs. In the case where the stress of this target point is less than $\alpha \cdot f_t$, the material reloads directly to the point where peak compressive strain occurred without passing through the point with stress $\alpha \cdot f_t$ at zero strain.

3.2 Concrete Model for Diagonal Truss Elements

The concrete material model used for the truss elements has two differences compared to that used for the vertical and horizontal elements: it has zero tensile strength and accounts for the bi-axial strain field on the concrete compressive behavior as described by Vecchio and Collins (1986). Thus, the compressive stress-strain behavior is dependent on the strain, ε_n, normal to the axis of the truss element. For truss element e_1 extending from node 1 to node 2 [shown in Figure 3(a)], ε_n is computed using the zero-stiffness gauge element extending from the mid-length of the element to nodes 3 and 4, g_1 and g_2, respectively. The instantaneous compressive stress of element e_1 is multiplied by the factor β determined from the instantaneous normal strain ε_n, which is the average of the strain measured with the gauge elements g_1 and g_2. The angle θ is the angle formed between the undeformed truss and the gauge elements; values of θ close to 90° are suggested. When $\varepsilon_n > 0$, the relationship between β and ε_n is tri-linear, as shown in Figure 3(b). otherwise $\beta = 1$. For this study, the relation between β and ε_n depends on the length of the gauge elements, as first proposed by Panagiotou et al. (2012). Here, $\varepsilon_{int} = (600 / L_g)\cdot 1\%$ and $\varepsilon_{res} = (600 / L_g)\cdot 2.5\%$, where L_g is the total length of gauge elements g_1 and g_2, as shown in Figure 3(a). In this paper, $\beta_{int} = 0.3$ is used, and the sensitivity of computed response to the value of β_{int} was investigated in Case Study 3 presented below. For the truss elements, the same equations described in the previous section are used to determine ε_u and ε_{cu}, with L being the length of the truss element (Panagiotou et al. 2012).

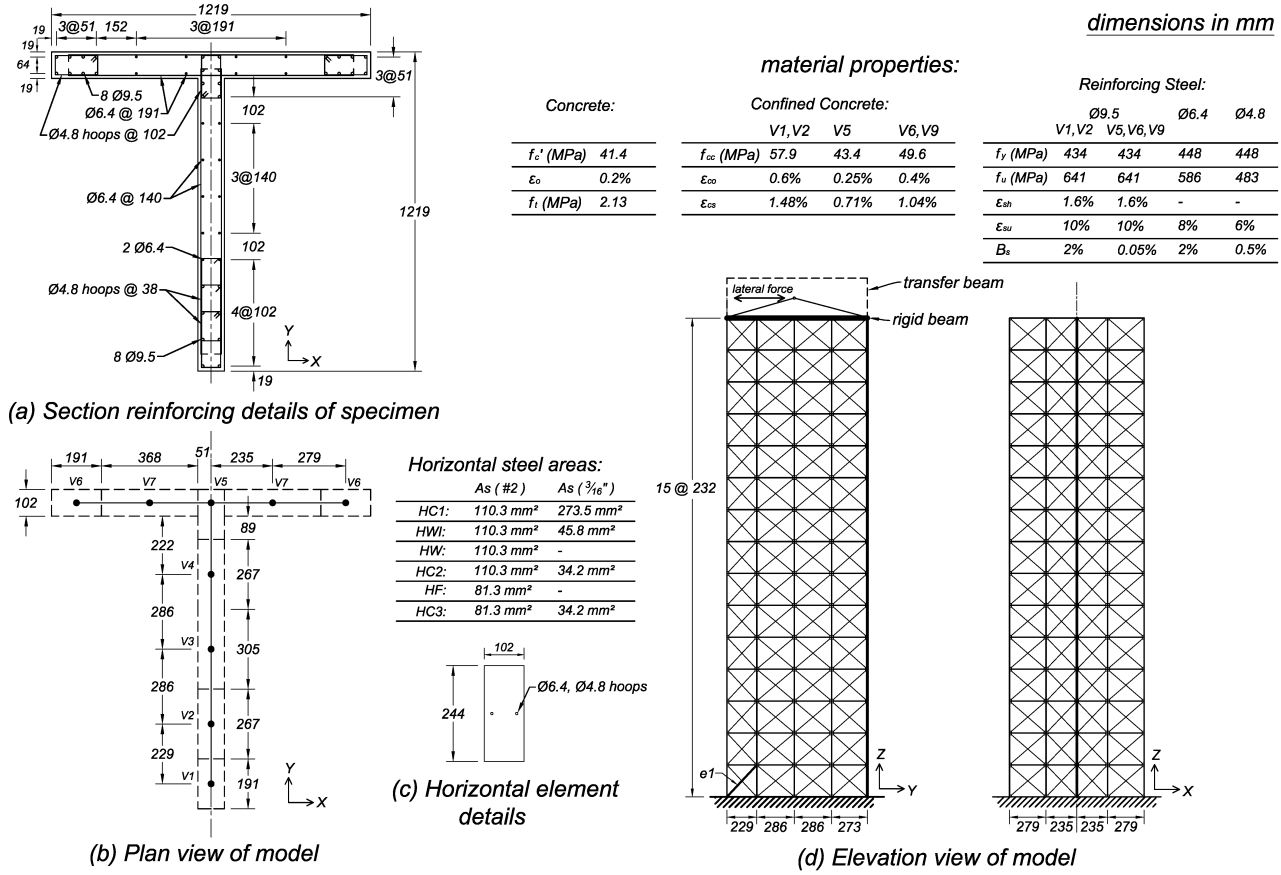

Figure 3. Case study 1 – TW2: Description of the specimen and TW2-9 beam-truss model.

3.3 Reinforcing Steel Model

The Giuffré-Menegotto-Pinto model (GMP) was used to model the reinforcing steel. The initial elastic modulus was E_c = 200 GPa, the yield strength was f_y, and the post-yield hardening ratio was B_s. Values of B_s used in the different bars of the three case studies are given in Figures 4, 8, and 9, respectively. These values were determined based on steel coupon monotonic tension test results reported in each case study. The values of B_s were calibrated for the regions of the walls where peak strains were computed so that the maximum computed stress at peak computed strain matched the stress at the same strain in the experimental coupon-test results. The parameters controlling the transition between the elastic to plastic branches (Filippou et al. 1983) were as follows: R_0 = 20, cR_1 = 0.925, and cR_2 = 0.15 with 5% isotropic strain hardening in compression only (a_1 = 5%). The effects of geometric nonlinearity (bar buckling) and bond slip between reinforcing steel and concrete as well as of strain penetration in the base anchorage blocks were not considered in this study.

4. MODEL VALIDATION

4.1 Case Study 1: Thomsen and Wallace (1995, 2004) – Specimen TW2

In this case study, a T-shape section RC wall - called TW2 - was considered (see Figure 4). The shear span ratio was M / VL_w = 3, where M is the bending moment at the base of the wall, V the base shear force, and L_w the length of the wall in the direction of loading. The length of both the web and the flange of this wall was 1219 mm. The axial load ratio of the wall was $N / f_c'A_g = 0.074$, where N is the vertical load applied at the centroid of the section and A_g is the gross T-shape section area. The vertical load remained constant during all cycles. The loads were applied through a steel beam that was placed at the top of the web in the direction of loading. The average longitudinal steel ratio ρ_l was 1.2% and the transverse steel ratio ρ_t in the web equal to 0.44%. Boundary elements were used at both ends of the web and the flange.

Figure 5(a) shows the experimentally measured lateral force versus lateral displacement response of TW2. Positive displacement is the direction in which the flange is in compression, and negative displacement is the direction in which the flange is in tension. The specimen was tested up to drift ratio Θ = 2.5%. The drift ratio is defined as Δ /H, where Δ is the lateral displacement, and H is the height where the lateral load is applied. The specimen experienced lateral strength degradation during the second and third cycles, at peak drift ratio Θ = 2.5% in the negative direction due to out-of-plane buckling of the confined core of the boundary region at the end of the web. Figure 6 shows the profile of experimentally measured (using strain gauges attached on the reinforcing steel bars 51 mm from the base of the wall) steel tensile strains along the flange for the negative direction of loading where the flange was in tension. The profiles were uniform for Θ = 1%, while larger strains were concentrated near the mid-length of the flange for Θ = 2% and 2.5%.

Two beam-truss models (BTM) were developed for this case study. The first BTM, shown in Figure 4, was termed TW2-9. As shown in Figure 4(b), the BTM TW2-9 had nine nodes at its base with θ_g ranging from 40° to 47°. Details for the concrete and steel section areas in the vertical, horizontal,

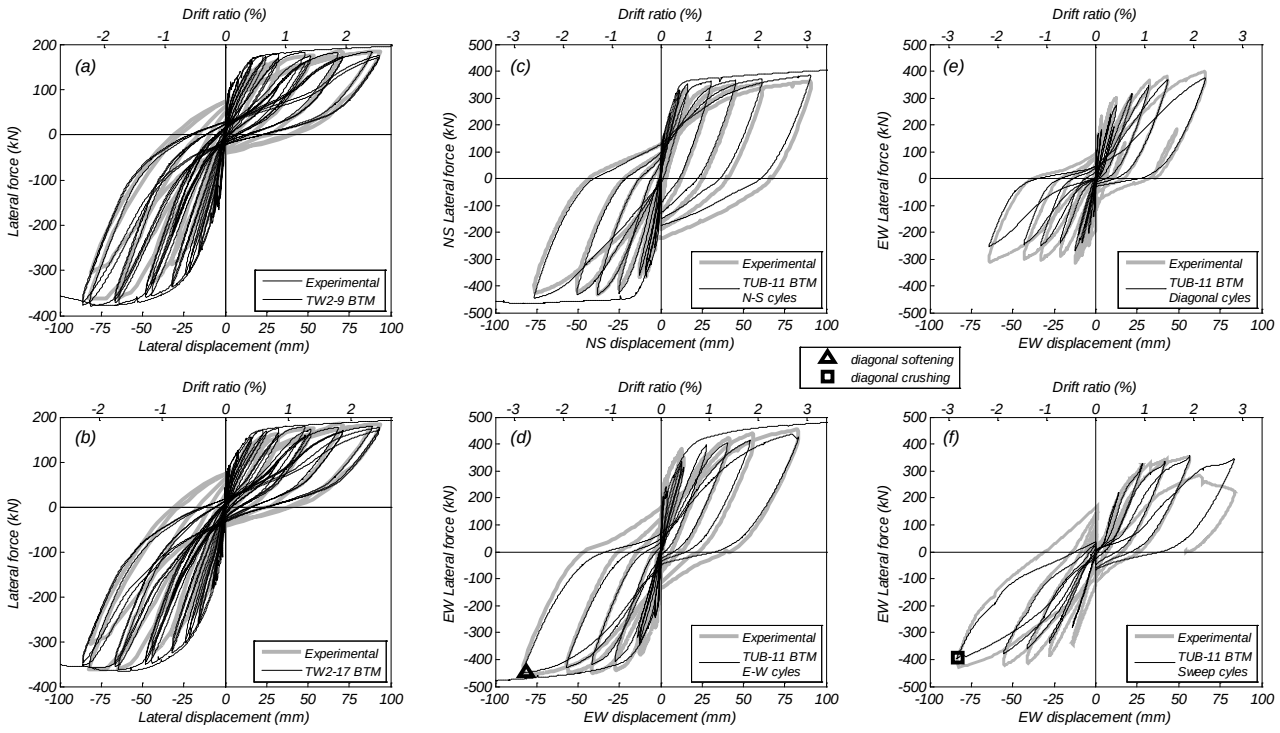

Figure 5. Results of BTMs for Case Studies 1 and 2: (a) TW2-9, (b) TW2-17; (c) TUB-11 N-S direction, (d) TUB-11 E-W direction, (e) TUB-11 diagonal cycle for the E-W direction, (f) TUB-11 sweep cycle for the E-W direction.

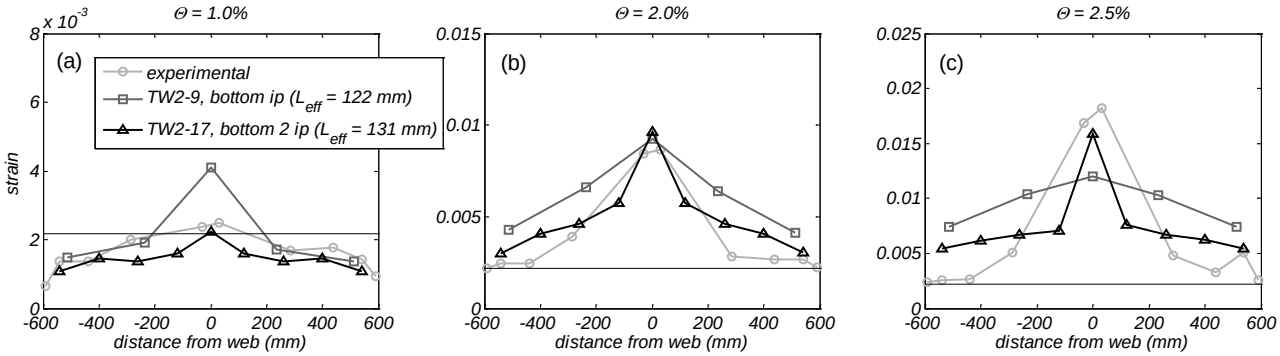

Figure 6. Case study 1 – TW2: Comparison of measured and computed tensile strains of the reinforcing steel along the base of the flange for drift ratios: (a) 1.0%; (b) 2.0%; (c) 2.5%.

and diagonal elements are presented in Lu and Panagiotou (2012). The second BTM was termed TW2-17, with two times finer mesh than TW2-9 [see Lu and Panagiotou (2012) for more details on this model]. The BTMs TW2-9 and TW2-17 had 881 and 2857 DOFs, respectively, and required 36 and 190 minutes, respectively, to run the cyclic analysis consisting of 3565 mm of total applied displacement.

Figure 5(a) compares the experimentally measured and numerically computed response using the TW2-9 model. The numerical model computed the force-displacement response satisfactorily. For both directions the computed peak lateral strength was in excellent agreement with the experimentally measured response. The computed lateral strength at Θ = 1.0% was 1.17 times the experimentally measured response. For drift ratios larger than 1.5%, the computed lateral strength did not exceed 1.09 times the experimentally measured. This model did not account for buckling of the sections, which was the predominant mode of failure of this wall. The peak diagonal compressive strain of the web computed for negative displacement was 0.14%, measured in element e_1, shown in Figure 4(d). This was in good agreement with the observed response in the experiment where no crushing of the diagonal compression field was observed. Model TW2-17 computed a similar force-displacement cyclic response to that computed by TW2-9 [see Figure 5(b)], resulting in a computed lateral strength that was 1.14 times the measured strength at 1.0% drift ratio.

Using models TW2-9 and TW2-17, Figure 6 compares the experimentally measured and numerically computed steel tensile strain profiles along the flange near its base. The numerically computed strains shown are the strain of the bottom integration points of the bottom elements of the flange of TW2-9 and the average computed strains of the two integration points of the bottom elements of the flange of TW2-17. These computed values correspond to a smeared strain over a length 122 mm and 131 mm, respectively. For 2.0% and 2.5% drift, model TW2-9 computed a smoother strain profile than that measured; however, using this model, the computed strain for Θ = 2.5% at the mid-length of the flange was 0.66 times the experimentally measured strain. Overall, the computed strains using model TW2-17 (two times finer mesh than TW2-9) was in very good agreement, with the experimentally measured strains; the computed strain values at the mid-length of the flange were between 0.85 and 1.15 times the experimentally measured strains, and computed strain at mid-length of the flange was 1.15 times the experimentally measured strain for Θ = 2.5%. This comparison demonstrates the effect that the level of mesh refinement can have on the magnitude of computed strains.

4.2 Case Study 2: Beyer et al. (2008a) – Specimen TUB

The test specimen of Case Study 2 – called TUB – was a U-shape section wall with M / VL_w = 2.8 in the E-W direction and 2.6 in the N-S direction, see Figure 7. The axial load ratio was $N / f_c'A_g$ = 0.04. The load remained constant during the cyclic load reversals and was applied through a steel beam parallel to the E-W direction passing from the centroid of the section. To apply the lateral load, a collar was used at the top of the wall. One actuator was used in the E-W direction and two in the N-S direction. The reinforcing steel ratios ρ_l and ρ_t were equal to 1.0% and 0.45%, respectively. Boundary elements were used at the ends of each of the three segments of the wall. At each level of lateral displacement, the specimen was tested with one cycle in each of the E-W, N-S, and diagonal (SW - NE) directions as well as a sweep cycle. The force-displacement responses were plotted separately in each of the E-W and N-S directions for each cycle and are shown in Figure 5(c) to (f). The specimen failed due to crushing of concrete compression diagonals at about 260 mm from the base of the segment of the wall parallel to the E-W direction during the sweep cycle at peak drift ratio Θ = 3%. The peak lateral force in the E-W direction was $5.4A_w\text{sqrt}(f_c')$, where A_w is the total cross-sectional area of segment of the wall parallel to the EW direction, and f_c' in psi. This is only 54% of the peak shear force that ACI (2011) allows.

Figure 7 shows the beam-truss model – termed TUB-11 – which had eleven lines of vertical elements in total and with θ_g ranging from 41° to 44°. The collar was also modeled with a BTM [see Figure 7(e)], and elastic linear beam was used to model the steel spreader beam, see Figure 7(b). The BTM TUB-11 had 924 DOFs and required 99 minutes to run the cyclic analysis consisting of 4095 mm of total displacement.

For the N-S and E-W cycles, the computed response using TUB-11 was in excellent agreement with the measured response, see Figure 5(c) and (d) respectively. The model

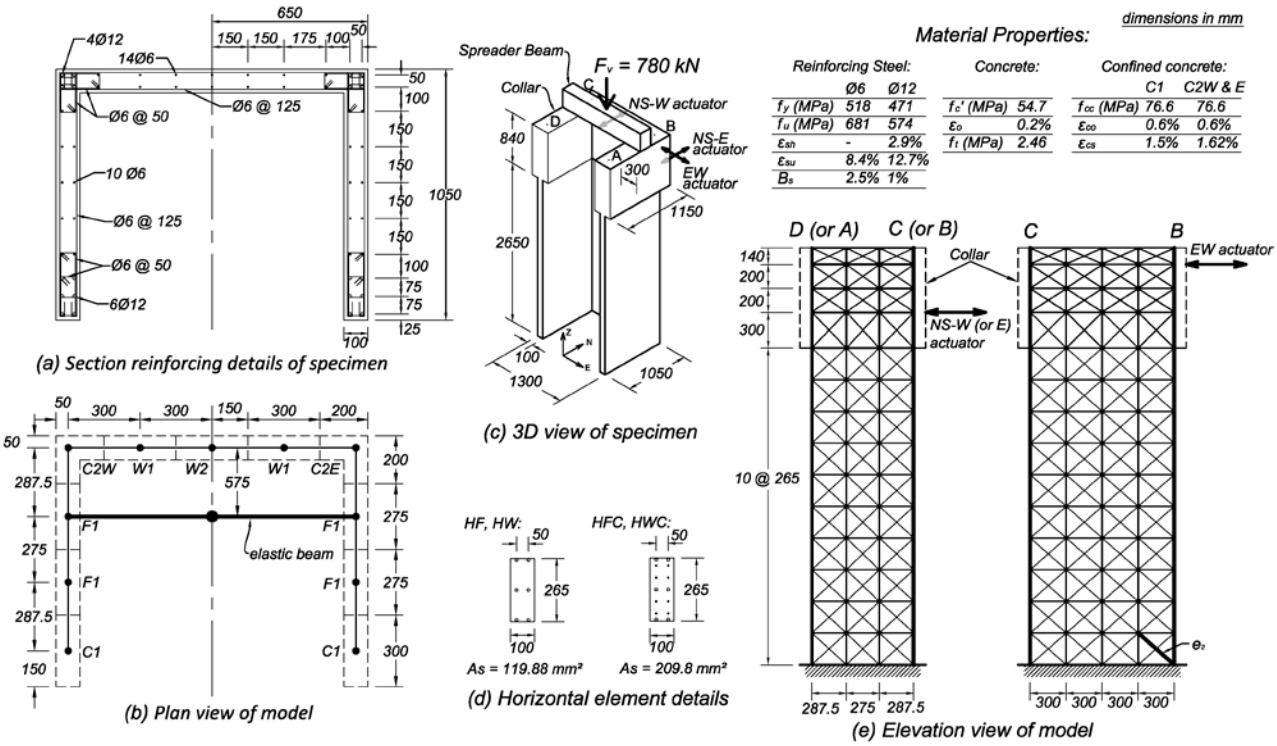

Figure 7. Case study 2 – TUB: Description of specimen and the TUB-11 beam-truss model.

computed a peak lateral force that is 1.06 and 0.98 times the experimentally measured peak lateral force for the N-S and E-W cycles, respectively. In the diagonal and sweep cycles, the computed peak lateral forces in the E-W direction were 0.94 and 0.92 times the experimentally measured, respectively, see Figure 5(e) and (f). The cyclic computed response in all directions considered was in very good agreement with the experimentally measured for all cycles. In very good agreement with the experimentally observed diagonal crushing, the model computed crushing of the concrete 265 mm from the base at element e_2, see Figure 7(e), in the segment of the wall parallel to the EW direction during the sweep cycle at drift ratio Θ = 3.0%.

4.3 Case Study 3: Oesterle et al. (1976) – Specimen F1

Case Study 3 considered the I-shape section wall with M / VL_w = 2.4, which is shown in Figure 8. The two parallel segments of this wall (termed flanges) were 914 mm long, while the third segment perpendicular to them (termed the web) was 1905 mm long. The specimen was subjected to uni-axial load reversals in the direction of the web. A 203-mm-thick slab was cast at the top of the specimen. No axial load was applied on the specimen. The lateral load was applied at 4572 mm from the base of the wall. The flanges were very heavily reinforced with longitudinal steel ratio of 3.8%, while the corresponding ratio for the web was 0.28%. The transverse steel ratio was 0.65% both in the web and the flange. Figure 9 shows the experimentally measured force-displacement response of F1. The specimen was tested up to Θ = 2.2% with 3 cycles at each level of displacement. Spalling in the diagonal direction was first observed during the second cycle at 1.1% peak drift ratio. The specimen experienced significant loss of the lateral strength during the first cycle of 2.2% drift ratio due to crushing of concrete of the web in the diagonal direction at 300 mm from the base of the wall. The peak lateral strength of this specimen was $8.6A_w\text{sqrt}(f_c')$, where A_w is the section area of the web.

Two numerical BTMs were developed. The first BTM - termed F1-11-45 - is shown in Figure 8; it had eleven lines of vertical beams, see Figure 8(b), with horizontal elements every 298 mm and θ_g ranging from 44° to 46°. The top slab of the BTM was modeled with elastic linear beam elements. The second BTM - termed F1-11-50 - also had 11 lines of vertical beams but had horizontal elements every 373 mm, resulting in θ_g around 50°. The BTMs F1-11-45 and F1-11-50 had 991 and 793 DOFs, respectively, requiring 45 minutes (each) to run the cyclic analysis of 2722 mm of total displacement.

Figure 9(a) compares the experimentally measured and numerically computed response using F1-11-45 model. The computed response was in very good agreement with the experimental response in terms of peak strength and the general hysteretic response up to the point where major strength degradation was computed, with the computed peak strength being 0.95 times the experimentally measured strength. In good agreement with the experimentally observed response, the model computed diagonal crushing of concrete [in the diagonal truss element, e_3, at the base of the web, as shown in Figure 8(c)] followed by a strength degradation of 0.5 times the computed peak strength at 2.0% drift in the first cycle with peak drift ratio Θ = 2.2%; this was in fair agreement with the experimental response, where crushing occurred at -2.0% drift during the same cycle. The point of crushing was very sensitive to the relation between β and ε_n: the same BTM F1-11-45 using β_{int} = 0.3, 0.4, and 0.5 computed crushing in the diagonal direction at 2.0%,

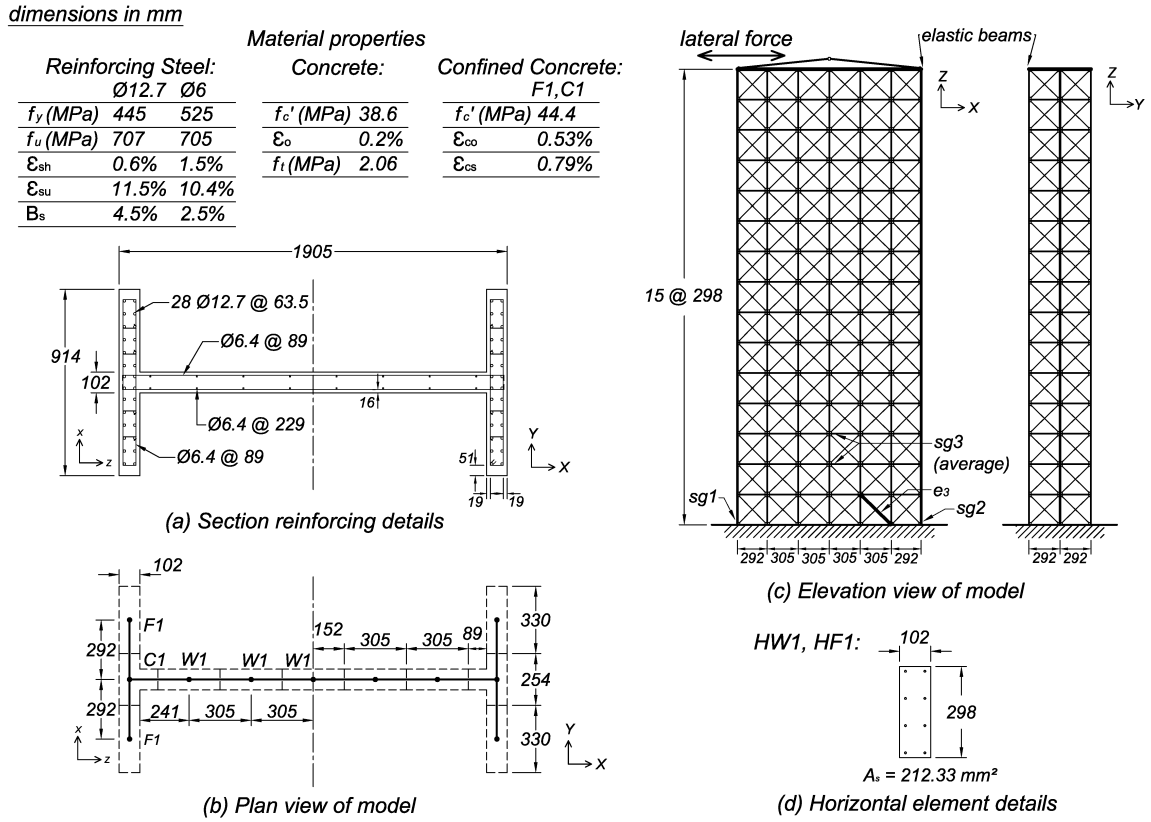

Figure 8. Case study 3 – F1: Description of specimen and the F1-11-45 beam-truss model.

2.2%, and -1.6% drift, respectively, of the first cycle with peak drift ratio Θ = 2.2% [see Figures 10(a) and (b)], with the computed response with β_{int} = 0.5 to be closer to the experimentally measured response. As shown in Figure 9(b), the value of β_{int} had practically no effect on the part of the computed response before the initiation of softening in the diagonal direction.

F1-11-50 computed a peak strength that was 0.95 times that computed by F1-11-45 and computed crushing of concrete in the diagonal direction at Θ = 1.3% during the first cycle with peak drift ratio of 2.2%, see Figure 9(c). After the first crushing of the diagonal trusses, the computed strength of this model dropped to 0.38 times the peak strength. Similar observations that the increase of the angle of the diagonals resulted in initiation of strength degradation and crushing of concrete in the diagonal direction at smaller displacement level were made in the 2D model of Panagiotou et al. (2012).

Figure 10 shows the experimentally measured response using strain gauges attached on the steel rebars and computed strains versus lateral force. The response was plotted up to the first cycle of Θ = 2.2% (where experimentally measured strain data exist). The locations of the strain gauges are shown in Figure 8(c). The strains computed from this model were in very good agreement with the measured longitudinal and transverse strains at the base for the cycles with peak drift ratio up to and including 1.1%, with less agreement (for one of the three locations considered) in the cycle with peak drift ratio equal to 2.2%. For the third cycle at Θ = 1.1%, the maximum computed strains at the locations of *sg1*, *sg2*, and *sg3* were 0.77, 0.81, and 1.12 times the measured strains, respectively. For the

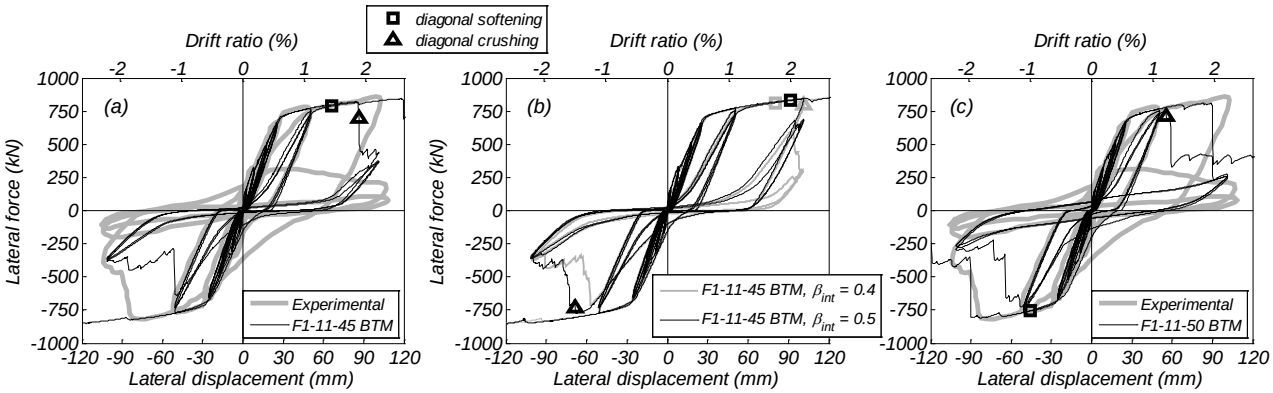

Figure 9. Results of BTMs for Case Study 3: (a) F1-11-45 (β_{int}=0.3), (b) F1-11-45 (β_{int} = 0.4 and 0.5) (c) F1-11-50 (β_{int}=0.3).

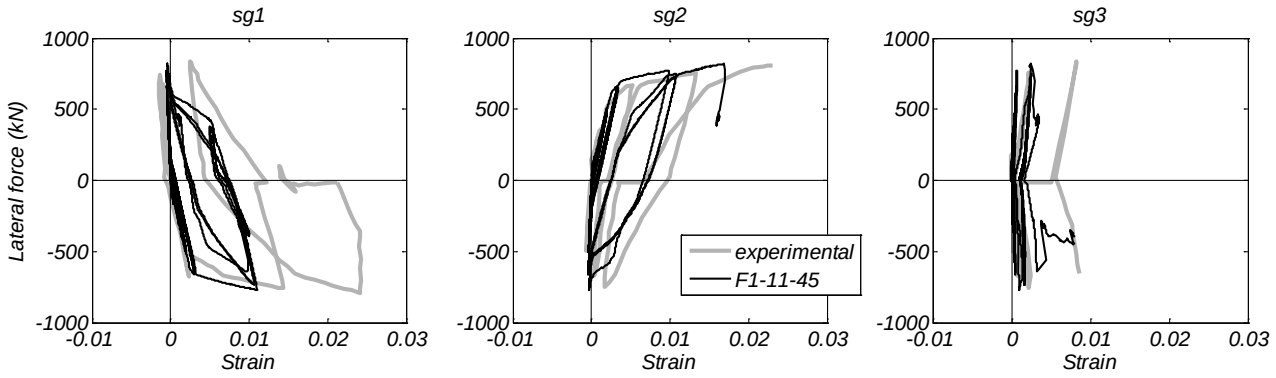

Figure 10. Case Study 3: Comparison of measured and computed lateral force vs. strain using BTM model F1-11-45. The locations of strain gauges are shown in Figure 8.

first cycle at Θ = 2.2%, where the diagonal web crushing occurred, the maximum computed strains at the locations of *sg1*, *sg2*, and *sg3* were 0.45, 0.74, and 1.07 times the measured strains, respectively. The length corresponding to the integration point used for the computed strains were 149 mm for *sg1* and *sg2*, and 153 mm for *sg3*.

5. CONCLUSIONS

This paper described a three-dimensional (3D) beam-truss model (BTM) for non-planar reinforced concrete walls. The model used nonlinear fiber-section Euler-Bernoulli beam elements in the vertical direction and nonlinear truss elements in the horizontal direction to represent concrete and reinforcing steel. Linear beams were used in parallel with the horizontal truss elements to model the out-of-plane flexural rigidity of the wall segments. Nonlinear truss elements were used to represent the diagonal field of concrete in compression. The model represents the effects of flexure-shear interaction by computing the stresses and strains of steel and concrete in the vertical, horizontal, and diagonal directions, and by accounting for the effect of normal tensile strain on the compressive behavior of the concrete in the diagonal direction. The model accounted for mesh-size effects by considering the strength degrading branches of the concrete stress-strain material models dependent on the length of the elements.

The efficacy of the model was investigated comparing the computed response using the BTM with the experimentally measured response of three non-planar RC walls subjected to cyclic loading having a T- U-, and I-shape section, respectively. The experimentally observed failure mode of the latter two walls was due to diagonal web crushing. The response of the three walls using existing nonlinear fiber-section Euler-Bernoulli beam models was also computed. The following conclusions were drawn:

1. The beam-truss models computed very satisfactorily the post-cracking cyclic force-displacement response of the three specimens. The computed peak lateral strength was between 0.92 and 1.1 times the experimentally measured for all three case studies. In very good agreement with the experimentally measured response, the model computed crushing of concrete diagonals of the U- and I-shape section walls of Case Studies 2 and 3, respectively, for cycles with maximum drift ratios equal to 3% and 2.2%, respectively.

2. Models TW2-17 and F1-11-45 computed strain histories that were in good agreement with the experimentally measured response for all the cycles (apart from one location of F1-11-45 during the last cycle of the response). The authors believe that the computation of strains (local response) is more sensitive to model parameters than the overall force-displacement response; the lower level of accuracy in the computation of strains is assumed to be due to a combination of the following reasons: (a) the strains computed were averaged over a specific length while the experimentally measured were local strains of the steel (no experimentally measured data using displacement transducers were available); (b) the formulation of the model was using constant-angle diagonals of width equal to b_{eff}; (c) the steel model used did not model the yield plateau and nonlinear hardening explicitly; and (d) the model did not account for the effects of bond slip and strain penetration of steel in the anchorage blocks.

3. For the T-shape section wall, the models TW2-9 and TW2-17 computed peak strength 1.05 and 1.01 times the experimentally measured for the direction of the response with flange in tension, respectively. The models computed the lateral strength at 1.0% drift to be 1.17 and 1.14 times the experimentally measured, respectively. The overestimation at 1% drift was assumed to be due to the overlap of areas of concrete in the vertical, horizontal, and diagonal elements of this model as well as due to the use of constant-angle diagonals of width equal to b_{eff}. Overestimation of strength and stiffness was also observed in the other two Case Studies, but it was negligible for drift ratios larger than 0.5%.

4. The effect of mesh refinement [considered in Case Study 1] was found to be negligible on the overall force–displacement response but was important for the magnitude of computed strains. The ratio of length of the vertical beams to the height of the wall was equal to 6.7%, and 3.6% in models TW2-9 and TW2-17, respectively. The latter resulted in much better agreement between computed and measured strains along the flange of the T-shape section wall.

5. The effect of the angles of the diagonals was investigated in Case Study 3. Models F1-11-45 and F1-11-50 had diagonal elements at 45^o and 50^o with respect

to the horizontals, respectively. F1-11-45 computed initiation of degradation at 2.0% drift ratio, which was in better agreement with the experimental data. As expected, the level of drift at which crushing of the diagonal concrete was computed was found to be sensitive to the relation of concrete compressive strength and normal tensile strain (values of β_{int} = 0.3 to 0.5 were considered in Case Study 3).

Abstract: An innovative technology for affordable earthquake-resistant houses consisted of movable interlocking blocks is introduced. It is anticipated that the mortar-free construction can facilitate more energy dissipation during an earthquake because of the relative movability at the block interface. As part of the development process, a mortar-free interlocking column with rope reinforcement is tested under harmonic and earthquake loadings to understand the dynamic response. The un-grouted ropes are post-tensioned with a magnitude of 200 N. A mass of 150 kg is placed at the top of the column to simulate the mass of diaphragm. To enhance the ductility and material damping of the whole structure, the novel interlocking blocks are made with coconut fibre reinforced concrete. The influence of rope reinforcement on the development of relative displacement, base shear, overturning moment and block uplift is investigated. The results confirm that the proposed construction technology has a potential for earthquake prone regions, especially in developing countries.

1. INTRODUCTION

Economical earthquake-resistant housing is desirable in seismically active rural areas of developing countries. These regions often suffer a significant loss of life during strong ground motion because of lack of seismic-resistant housing. To enable an efficient and cost-effective structural solution, a new concept of construction was investigated utilizing structures consisting of (i) newly developed interlocking blocks with relative movability at the block interface and (ii) coconut-fibre rope reinforcement. The interlocking blocks were prepared with coconut fibre reinforced concrete (CFRC). An up-to-date history of the interlocking blocks, developed by other researchers, is summarized in Ali et al. (2012). Most of these blocks are hollow (Anand and Ramamurthy, 2000 and 2003; Jaafar et al. 2006), some are solid (Nazar and Sinha, 2007) and curved (Dedek et al. 2012), and in few cases, with provisions of holes for reinforcement. These blocks can be prepared mechanically or manually, but in some cases, it requires very complicated moulds and manual casting. Usually, the material is concrete (Anand and Ramamurthy, 2000 and 2003; Jaafar et al., 2006); stabilized soil [Dedek et al., 2012; Smith, 2012] and with fly ash (Nazar and Sinha, 2007; Uygunoglu et al, 2012). The thickness of these blocks also varies, making them suitable either for load bearing, partition or cladding wall. Interlocking mechanism is provided either by horizontal, vertical or both interconnecting keys for in-plane and out-of-plane directions. The main purpose of these blocks is to make precise alignment and quick construction. It may be noted that the interlocking keys of hollow blocks alone are normally not sufficient to resist stresses of design load for an assembled wall in a structure due to elimination of mortar layers (Thanoon et al., 2004). This might be because of limited key projection. To overcome this problem, normal reinforced concrete is used at regular intervals in the holes provided in hollow blocks. This makes the structure a little bit expensive. In some cases, relatively lesser mortar (as compared to that required in normal brick masonry) is used with the interlocking blocks (Smith, 2010). Their main objective considered so far is an easy, fast and cost-effective construction mainly for resisting static loading. Therefore, other interlocking blocks, except Elvin and Uzoegbo's blocks, are not discussed here.

Elvin and Uzoegbo (2011) studied the response of a full-scale dry-stack masonry structure (3.9 m x 3.9 m x 2.76 m high) under the scaled earthquake and harmonic loadings. The structure was made of interlocking bricks and minimum steel reinforcement with a 2560 kg top mass to simulate the roof loading. It was observed that the bricks were shifted and damaged in the plane of the wall to such an extent that brick-sized gaps opened up. Many bricks were split, cracked, crushed or even misplaced. The cracking of plaster and spalling also occurred. Despite this severe damage, the test structure remained standing, successfully carrying the roof load. The energies of the earthquake and harmonic loadings

were dissipated through inter-brick friction and in some cases by brick cracking and crushing. The bricks were dry-stacked, which allowed them to move and, hence, dissipate energy. The ability of the test structure to withstand the applied earthquakes relied heavily on energy dissipation through inter-block friction. It should be noted that only horizontal ground motion was considered. If the vertical component of the ground accelerations was considered, the friction between the bricks may be reduced.

The following points are carefully noted from Elvin and Uzoegbo study: 1. use of minimum steel reinforcement in the structure; 2. blocks made of soil, which resulted in splitting and crushing of bricks during dynamic loading; 3. insufficient longitudinal interlocking key height and lack of transverse keys; and 4. earthquakes with vertical components may have an adverse effect on energy dissipation. These observations may indicate some of the shortcomings for achieving an efficient performance of the proposed mortar-free structures. By comparison, the interlocking blocks presented here have following characteristics: 1. there is no use of steel reinforcement, only coconut-fibre ropes are used in mortar-free structures; 2. blocks are made of CFRC, which avoids splitting and crushing of materials and also gives additional material damping; 3. sufficient interlocking key heights in both directions; and 4. earthquakes with vertical components are considered in the design of interlocking blocks as energy is dissipated through uplift (i.e. the relative movement at the interface).

To the best of the author's knowledge, the investigation of mortar-free construction without steel reinforcement for resisting earthquake loading has not been reported so far. The dynamic characteristics of mortar-free structures comprising the newly developed interlocking CFRC blocks are discussed in the following sections.

2. EXPERIMENTAL PROCEDURES

2.1 Preparation of blocks, foundation and column

As concluded in Ali et al. (2012), the optimized CFRC properties was obtained with a mix design ratio (cement: sand: aggregates: water) of 1:4:2:0.64, 5 cm long fibres and 1% fibre content by mass of concrete materials. Therefore, the same mix design is used for preparing blocks for the current study. For testing of CFRC mortar-free structures, a footing with a size of 1500 mm long, 600 mm wide and 200 mm deep was also prepared with CFRC (having a mix design ratio of 1:4:2 and 5 cm long fibres) but with a low fibre content (0.25%) because of the presence of steel reinforcement (ϕ10mm@100mmc/c in both directions at the bottom layer and ϕ5mm@100mmc/c in both directions at the top layer). The reason for using CFRC in the foundation was to observe the damage (if any) due to friction between the blocks and the foundation. Steel reinforcement was used so that the foundation could easily be shifted on and off the shake table; otherwise, steel reinforcement was not required. The holes were provided in the foundation for the insertion of the ropes (i.e. to anchor the ropes in the foundation) so that the same foundation could be used for all structures to be tested; otherwise, the holes in the foundation were not required. There was no damage to the foundation after all structures had been tested, however it had been planned to repair any damage from one test before the start of next. The depth of foundation would be governed by the rope tension (i.e. pullout load) generated during the dynamic loading. A groove (1200 mm long, 200 mm wide and 75 mm deep) was also provided in the foundation for holding the interlocking blocks. All specimens were cured for 28 days, then dried for 48 hours and finally whitewashed before testing to enable clear identification of cracks. Coconut fibre ropes of ~36 mm diameter were used as vertical reinforcement of the structures. The tensile strength of these ropes was 15.3 MPa, reported in Ali and Chow (2013). The mortar-free column with ropes is shown in Figure 1. The column consisted of a stack of 13 single standard blocks with an overall height of 1.92 m. A mass of 150 kg was placed at the top of the column to simulate the roof mass. A post-tension force of 200 N was applied in the ropes for the column with vertical reinforcement. The column was tested under harmonic and earthquake loadings. The column without ropes was also tested in a similar manner and reported in a separate paper. However, the outcome of the testing of column without ropes is briefly presented here to compare the results with that of column with ropes so that the influence of post-tensioned un-grouted ropes on the dynamic behavior can be clarified.

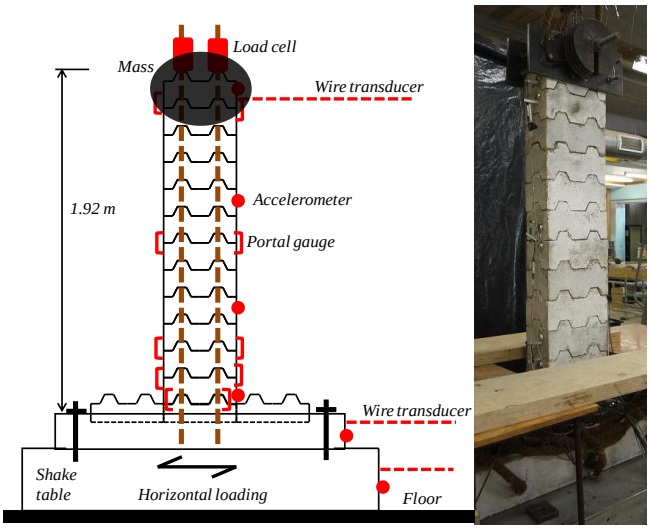

Figure 1: Instrumentation of mortar-free column with ropes, schematic (left) and actual (right).

2.2 Instrumentation

The experimental setup for the mortar-free column with ropes mounted on the shake table along with the details of the following instrumentation for measuring its response is shown in Figure 1:

(i) Six accelerometers along the structure height for determining induced accelerations (at shake table, at foundation, one each at blocks 2, 5, 9 and the top block of the structure)

(ii) Ten portal strain gauges for quantifying the block relative movement, i.e. uplift (five on left and five on right sides)
(iii) Three wire displacement transducers (one at the structure top, one on the foundation and one on the shake table)
(iv) Two load cells at the structure top for measuring the rope tension.

2.3 Testing

Using the shake table, the loadings employed on the structure were in the following sequence:

a. Harmonic loading with constant amplitude and varying frequencies passing through the fundamental frequency. Three levels of amplitudes (i.e. 5, 10 and 15 mm) were applied. Each of these amplitudes was applied with exciting frequencies ranged from 1 Hz to 2 Hz with an increment of 0.25 Hz. The corresponding peak table accelerations ranged from 0.02 g (for 5 mm and 1 Hz) to 0.24 g (for 15 mm and 2 Hz).
b. Earthquake loadings (Tabas 1978, Llolleo 1985, El Centro 1940, and Kobe 1995). These were applied from 0.05 g to 0.20 g with an increment of 0.05 g.
c. Harmonic loading with a constant frequency (1.5 Hz and varying amplitudes, beginning from 20 mm and increasing until structure failure. The selection of the constant frequency was based on the experience of test (a) as the structure at the selected frequency responded in resonance.

It is important to note that the structure was tested through the whole sequence of loading and the damage occurred at any stage was cumulative. The readings of the wire displacement transducers at the foundation and shake table confirmed that the shake table was capable of simulating the load accurately.

3. RESULTS AND ANALYSIS

3.1 Structural response under harmonic loading with constant amplitudes and a varying frequency

3.1.1 Fundamental frequency and damping ratios

The half bandwidth method was used to determine the damping ratio and the fundamental frequency in spite of the fact that the considered structure behaved nonlinearly. The applied ground motion, u_g, of 5 mm and the corresponding top displacement, u_t, time histories of the column without ropes are shown in Figure 2 for the exciting frequency of 1.5 Hz. The column response is divided into three phases: A. when the column started its vibration until it attained the steady-state condition, B. steady-state response of the column, and C. free vibrations of the column. The duration of phase A varied considerably for different amplitudes and frequencies. The steady-state response is used for the calculation of transmissibility TR_d and TR_a using displacement and acceleration readings, respectively. The damping ratio and the fundamental frequency calculated from the displacement and acceleration readings are close to each other. A comparison of TR_d vs f/f_n curves for all amplitudes of the harmonic loading is shown in Figure 3. f and f_n are the excitation frequency and the structural fundamental frequency, respectively. It may be noted that the curves become relatively flatter for high amplitude loading showing higher damping of the structure. As expected, the structure without ropes has more damping compared to the structure with rope (Figure 4). The structure with ropes have, as expected, a higher average fundamental frequency (1.57 Hz) compared to the structure without ropes (1.47 Hz).

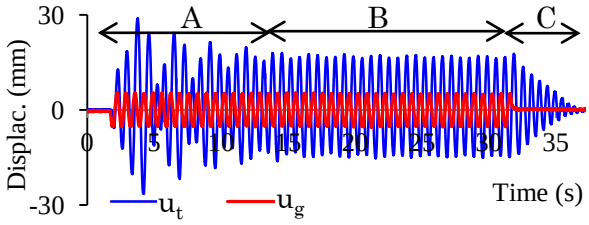

Figure 2: Displacement time history due to a harmonic loading of 5 mm and 1.5 Hz for column with ropes.

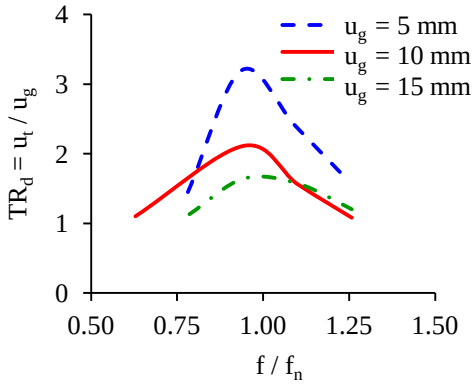

Figure 3: TR_d vs f/f_n curves due to harmonic loadings for column with ropes.

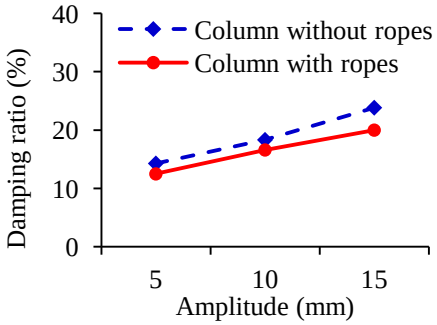

Figure 4: Comparison of the damping ratios from different amplitudes of harmonic loadings.

3.1.2 Base shear – displacement curves, energy dissipation and overturning moment

Base shear 'Q' is calculated as $\Sigma(m_i.\ddot{u}_i)$, where $\ddot{u}_i$ are the accelerations at the considered locations and m_i are the

contributing masses corresponding to $\ddot{u}_i$. The column mass is divided into the contributing masses in such a way that, along the structure height, the centre of each mass is close to $\ddot{u}_i$. The purpose of this approximate calculation of base shear is to obtain the base shear - displacement relationship. Displacement, u, is top in-plane relative horizontal displacement which is taken as the difference between the top displacement and the base displacement as measured by the wire displacement transducer. The base shear – displacement (Q-u) curves obtained from different frequencies under 10 mm harmonic loading are shown in Figure 5. The magnitudes of the base shear and the displacement are generally larger for the structure without ropes compared to the structure with ropes.

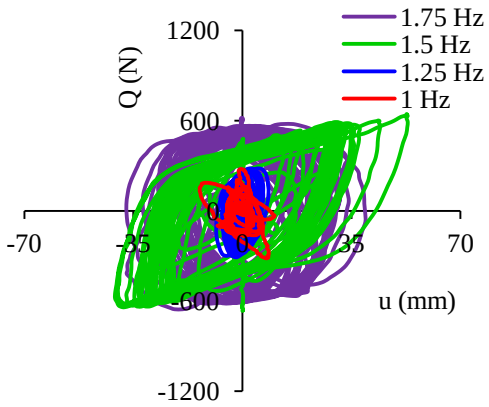

Figure 5: Q-u curves obtained from harmonic loadings for column with ropes.

The Q-u curves are further divided into the structure responses in the periods A, B and C, as defined in Figure 3, to highlight the behaviour during steady-state response. The area within one loop of a Q-u curve of the steady-state response is taken as the energy dissipated for whole system per cycle. Energy dissipation increased up to a frequency near the resonant frequency and then decreased (Figure 6). It also increased with increasing amplitude. The column without ropes had more energy dissipation compared to the column with ropes.

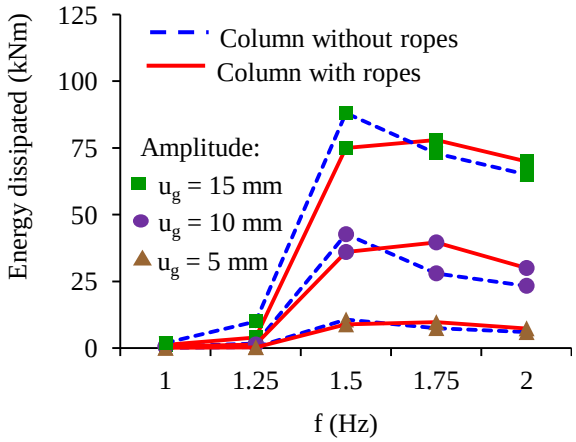

Figure 6: Comparison of energy dissipation due to harmonic loadings.

The maximum overturning moment of the structures is calculated by multiplying the maximum base shear with the height from the base of the groove in the foundation to the centre of the mass taken in the calculation of the base shear. The comparison of overturning moment for the structures is shown in Figure 7. The maximum overturning moment generally first increases up to a frequency near to the resonant frequency and then decreases with an increase in the exciting frequency. It also increased with an increasing input amplitude. The incremental trend in overturning moment is more non-linear at strong excitations compared to that due to the low excitations. Generally, the structures without ropes had a higher overturning moment compared to the structures with ropes because of larger top relative displacement in the former structure.

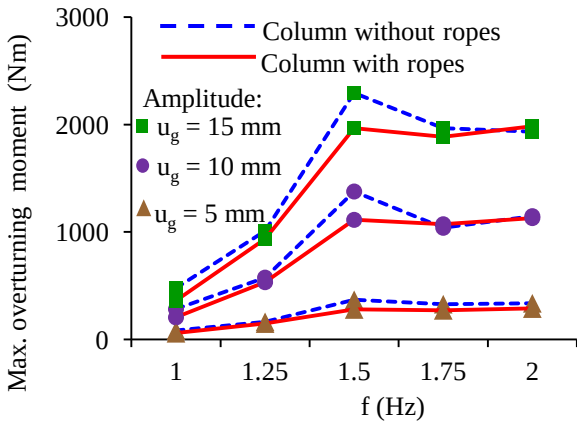

Figure 7: Comparison of overturning moment due to harmonic loadings.

3.1.3 Block uplift and rope tension

The mortar-free column allows vertical relative movement at the block interface during the applied harmonic loadings. The block uplifts along the column height during one cycle is shown in Figure 8. When the column deflected towards one side (say left side, as shown in the figure), uplifts are observed at the right side and the top relative displacement is to the left. Regarding the rope stresses, considerably more tension is observed in the right rope compared to the left rope. It may be noted that for a higher load, there will be some tension in the left ropes because of significant uplift at the right side. All these observations are reversed when the column is deflected to the other side (i.e. the right side). The magnitude of the uplift (at edges as shown in Figure 9) along the column height decreases from bottom to top, with the maximum uplift at the column base.

The uplifts between blocks 1 and 2 due to the 1.5 Hz and 10 mm harmonic loading are shown in Figure 9. The left and right uplifts occurred alternately. As expected, the time history of the rope tension corresponds to the development of uplift. The rope tension time history is presented in Figure 10. The tension in the left and right ropes also occurred alternately.

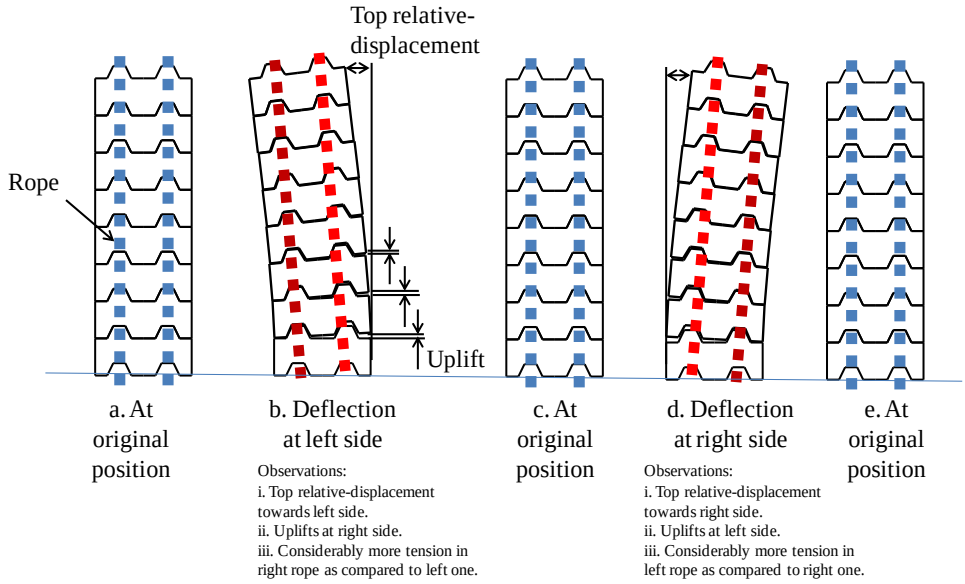

Figure 8: Observations during deflections under harmonic and earthquake loadings.
(Note: Foundation and top-mass are not shown for clarity)

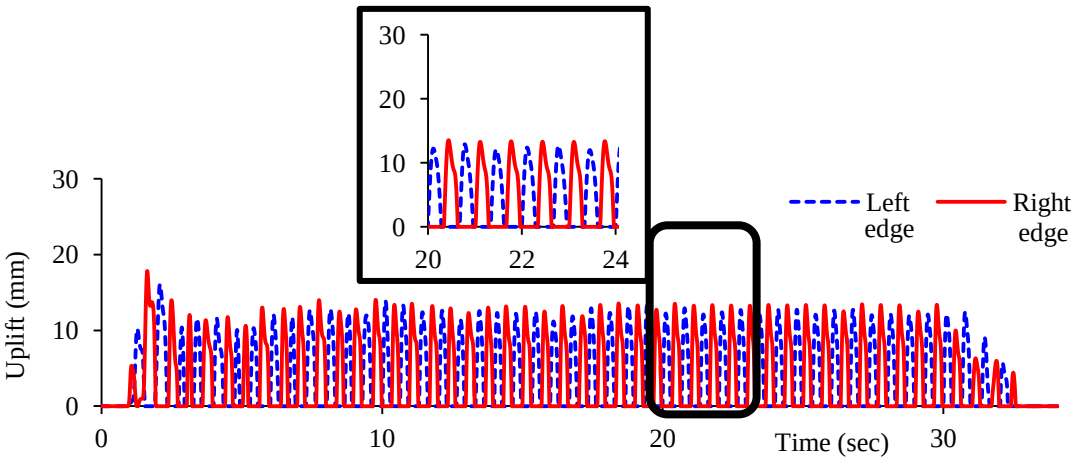

Figure 9: Maximum uplifts for 1.5 Hz and10 mm harmonic loading for column with ropes.

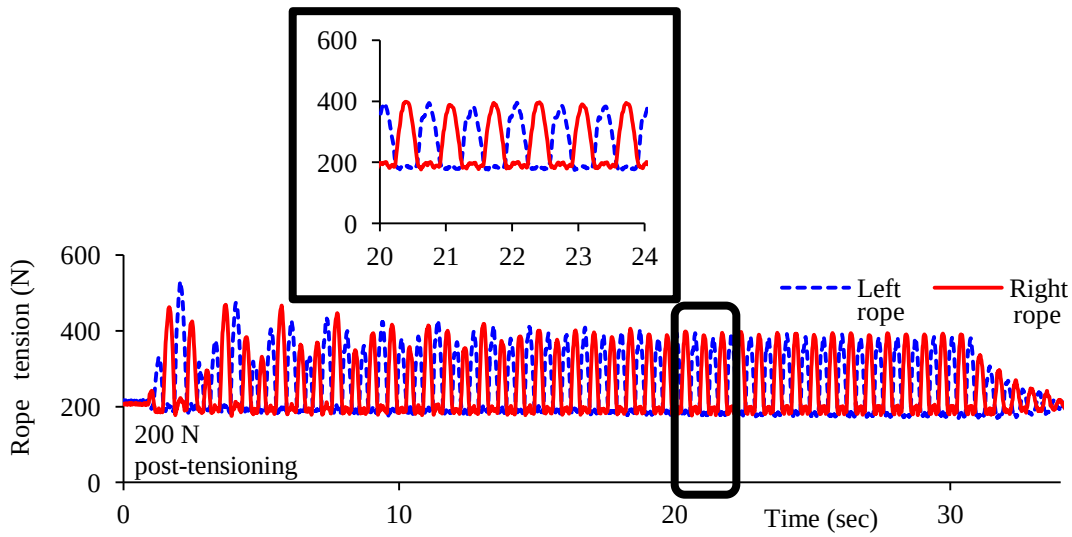

Figure 10: Rope tension – time history due to the 1.5 Hz and10 mm harmonic loading for column with ropes.

It is observed that the number of uplifts increased with a higher frequency. The maximum uplifts between blocks 1 and 2 at different frequencies under steady state of 10 mm harmonic loading are shown in Figure 11. The magnitude of uplift increased up to a frequency near to the resonant frequency and then decreased. As expected, the structure without ropes had more uplift compared to the structure with ropes. This has lead to a higher damping and consequently higher energy dissipation in the former structure.

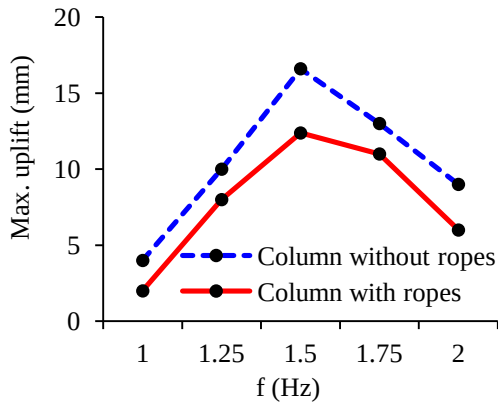

Figure 11: Comparison of maximum uplift due to harmonic loadings.

The relationship between the rope tension and relative displacement is presented in Figure 12. The number of times the ropes underwent tensioning increased as the frequency increased. The maximum rope tension during steady-state response with different amplitudes of harmonic loadings is shown in Figure 13. The magnitude of rope tension increased up to a frequency near to the resonant frequency and then it decreased. The tension developed in the rope was far less than the pull out load determined in a previous study (Ali and Chouw, 2013). This indicates that the ropes would not be pulled out due to the harmonic loadings considered if the ropes were embedded in the foundation. The rope tension was also less than the rope ultimate tensile load, ensuring no possibility of the rope breaking. As determined in Ali and Chouw (2013), a force of 1625 N is required to pull out ropes from a 100 mm deep foundation. The rope of 36 mm diameter is capable of taking a tensile load of 14 kN.

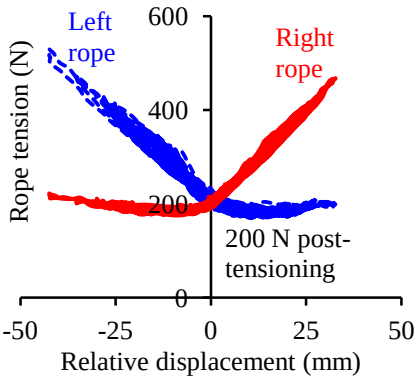

Figure 12: Rope tension – horizontal relative displacement.

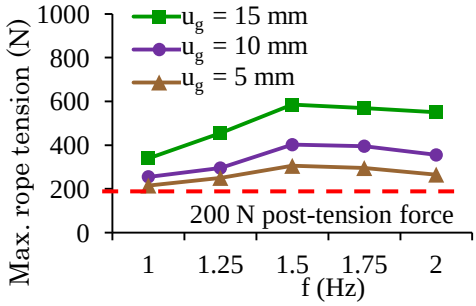

Figure 13: Maximum rope tension during steady-state response of the column with ropes to the harmonic loading.

3.2 Structural response under earthquake loadings

The considered earthquake loadings with the PGA scaled to 0.2 g are shown in Figure 14. The fundamental frequency of the column is marked in the enlarged view of the response spectrum (Figure 15) to enable an estimation of the impact of the load considered on column tested. It is noted that the response spectrum is for linear structures. For a structure with a fundamental frequency of 1.57 Hz, the response acceleration due to El Centro and Kobe earthquake loadings would be close (i.e. 0.40 g and 0.41 g, respectively), and the response acceleration (0.36 g) due to Llolleo earthquake loading would be larger than that (0.24 g) due to Tabas earthquake loading. However, the response of the considered mortar-free structures was expected to be nonlinear. It could be anticipated that the Kobe earthquake loading would be critical, followed by the EL Centro, Llolleo and Tabas earthquake loadings for the considered structures and that the increment in the considered response parameters (i.e. induced acceleration, base shear, overturning moment, block uplift and rope tension) would also be nonlinear. This is being observed in the considered parameters explained in the following sub-sections:

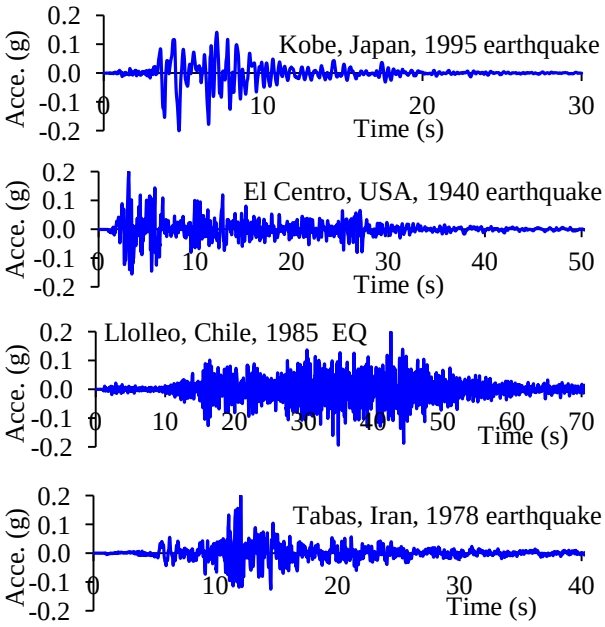

Figure 14: Earthquake loadings with PGA = 0.2 g.

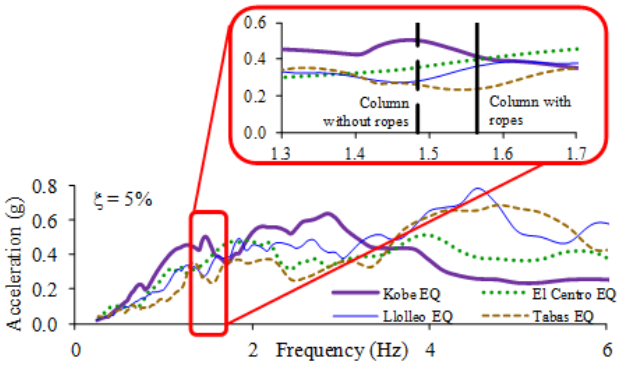

Figure 15: Response spectrum with marked fundamental frequencies of columns.

3.2.1 Induced accelerations

Induced vibrations were recorded using accelerometers attached along the height of the structure. The accelerations recorded at the blocks 2, 5, 9 and the column top (notated as $\ddot{u}_2$, $\ddot{u}_5$, $\ddot{u}_9$ and $\ddot{u}_t$, respectively) under the El Centro 1940 loading are shown in Figure 16. It can be observed that the maximum induced top acceleration was higher than the peak ground acceleration. The increase in the peak response accelerations at any considered location, due to the applied incremental peak ground acceleration, was nonlinear for the structures with and without ropes. The reason for this could be the variation of the inertial force within the column due to the applied ground motions.

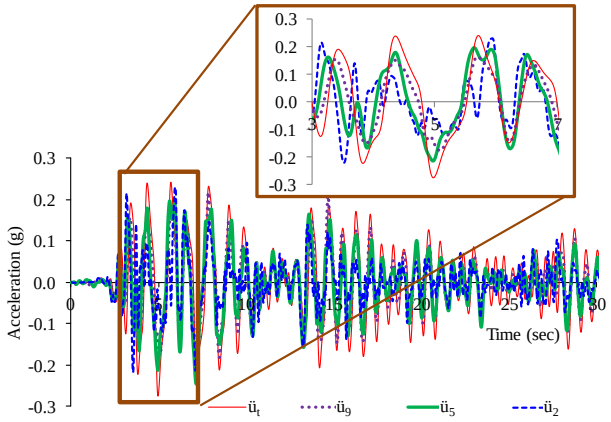

Figure 16: Induced accelerations in column with ropes.

3.2.2 Base shear – displacement curves and maximum overturning moments

Base shear, displacement and overturning moments were calculated in the same manner as those of the harmonic loading. The base shear – displacement curves are shown in Figures 17. It is observed that the structures without ropes have relatively wider hysteretic loops compared to the structures with ropes. This shows more energy dissipation for the former structures. The structure without ropes experience larger lateral displacement in comparison to the structure with ropes. The maximum overturning moment for column with ropes due to the earthquake loadings is shown in Figure 18. The maximum overturning moment is not proportional to the applied incremental earthquake loading. The Kobe earthquake loading generated the highest overturning moment followed by El Centro, Llolleo and Tabas loadings.

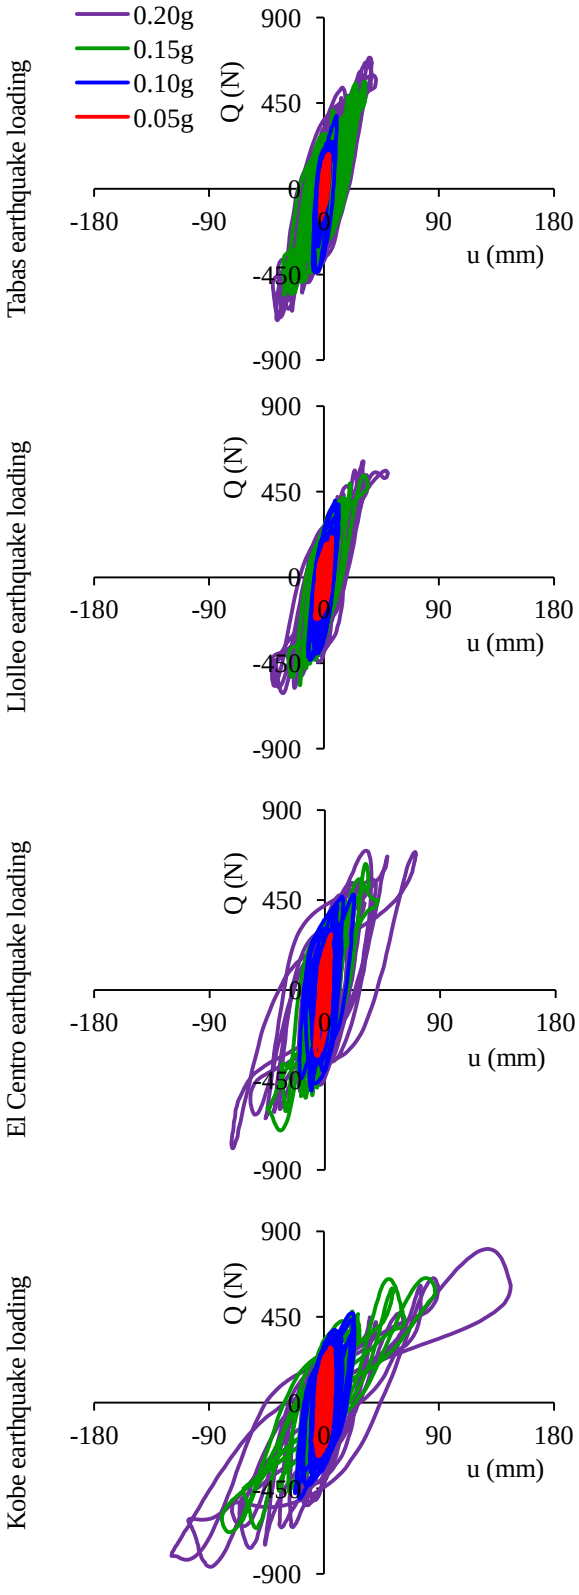

Figure 17: Q-u curves obtained from earthquake loadings for column with ropes.

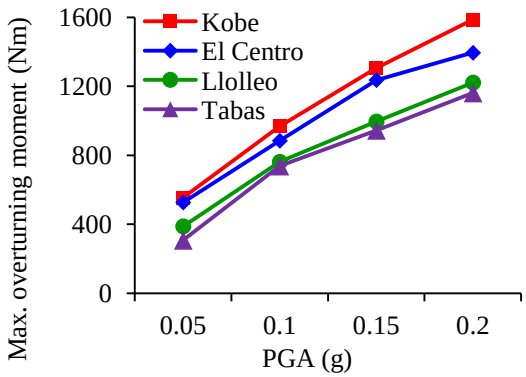

Figure 18: Comparison of overturning moments due to earthquake loadings for column with ropes.

3.2.3 Block uplift and rope tension

Left and right uplifts occurred alternately. As expected, more uplifts were observed in the structure without ropes than in the structure with ropes. The maximum block uplift due to the earthquake loadings is shown in Figure 19. The maximum block uplift is not proportional to the applied incremental earthquake loading. The reason for this could be the non-linear activation of inertial force along the column height. Kobe earthquake loading generated the largest uplift, followed by El Centro, Llolleo and Tabas earthquake loadings.

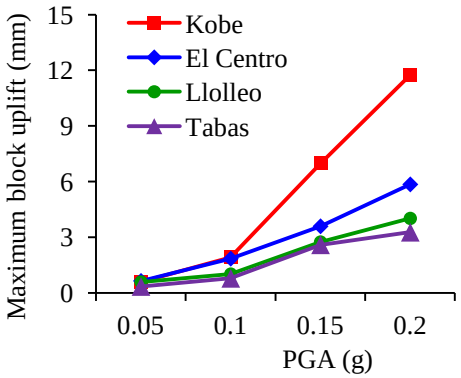

Figure 19: Comparison of uplifts due to earthquake loadings for column with ropes.

The rope tension due to 0.2g El Centro 1940 earthquake loading is shown in Figure 20. As expected, the left and right ropes were activated alternately. It can be observed that there was some magnitude of tension in one rope when the other was in full tension. This observation is already explained in Figure 8 (see stages b and d). The maximum rope tension due to the earthquake loadings is shown in Figure 21. Corresponding to the nonlinear uplift development along the column height, the maximum rope tension is also nonlinear. Kobe earthquake loading generated the highest tension, followed by El Centro, Llolleo and Tabas earthquake loadings.

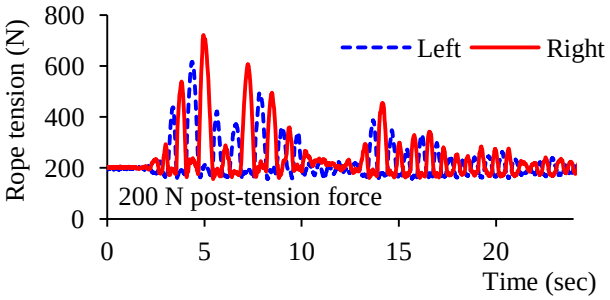

Figure 20: Rope tension due to 0.2g El Centro 1940 earthquake loading.

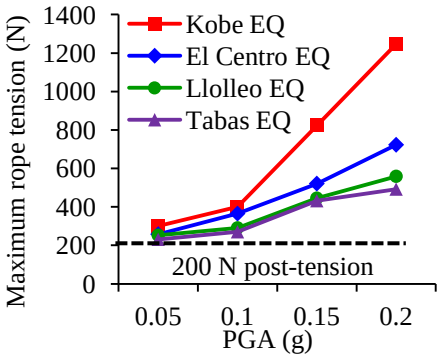

Figure 21: Maximum rope tension due to earthquake loadings.

3.3 Structural response under harmonic loading with constant frequency and varying amplitudes

As mentioned earlier, the structure was tested under successive loading, and any damage occurring at any stage was cumulative. No damage was observed even after all earthquake loadings had been applied. Finally, harmonic loadings with a constant frequency (1.5 Hz) and varying amplitudes (20, 30, 40, 50, 60 and 70 mm) were employed to introduce damage in the structure. As expected, the block uplifts and top relative displacements increased with increased input load. The columns without and with ropes failed during harmonic loading of 50 mm and 60 mm, respectively. The column failed in bending in the out-of-plane direction because one of the bottom interlocking keys cracked and partially shear off, causing instability in the structures. The column failure and damaged interlocking key of the block are shown in Figure 22. From the discussion of block testing (Ali et al., 2012), it was predicted that the main cause of structural failure would be the damage in one of the bottom interlocking keys of the block. It is recommended that a careful compaction in the bottom interlocking keys can result in higher capacity/strength of the block. The mechanically prepared blocks may also avoid such damage.

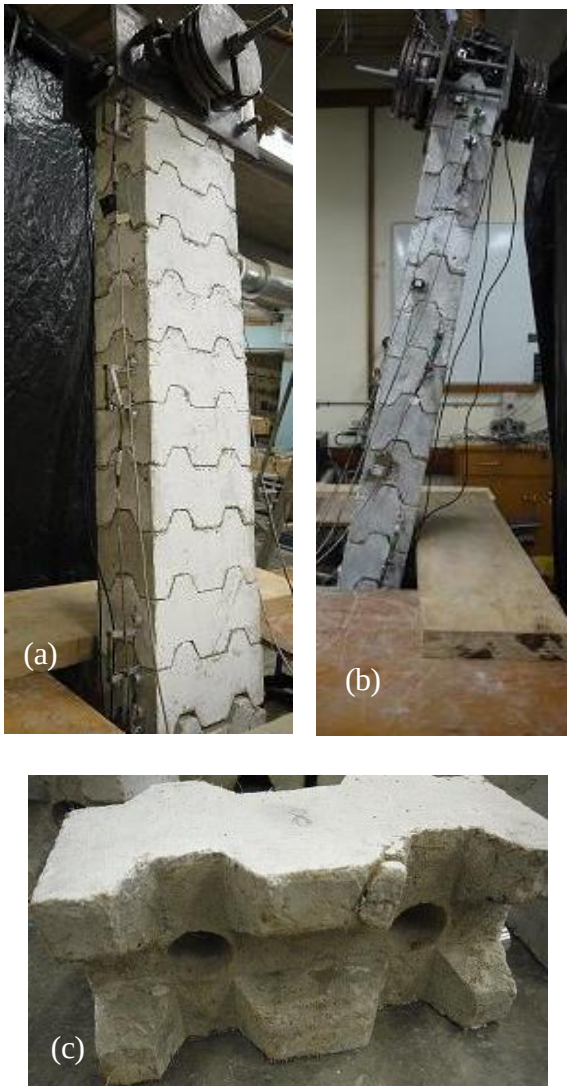

Figure 22: Typical column failure; (a) isometric view, (b) side view, and (c) damage in the bottom interlocking key.

3. CONCLUSIONS

A new approach to construct economical earthquake-resistant houses has been described. The mortar-free columns consisted of an innovative CFRC interlocking blocks. CFRC was prepared with a mix design ratio (cement: sand: aggregates: water) of 1:4:2:0.64, 5 cm long fibres and 1% fibre content by mass of concrete materials. Columns were tested without and with the coconut-fibre rope reinforcement. The un-grouted ropes were utilized as the vertical reinforcement to limit the lateral displacement of the columns. On the other hand, the column without ropes yielded a higher damping due to greater relative movement of the blocks compared to the column with ropes. There is a need to find a balance between the lateral displacement and damping so that the maximum benefit in terms of energy dissipation while avoiding structural collapse can be achieved. A mass of 150 kg was placed at the top of the columns to simulate a roof mass. The results presented in this paper can only be considered indicative, confirming that the proposed construction technology has the potential for a wide use in earthquake prone regions.

Even though the columns performed in a nonlinear manner, linear methods were employed to estimate the damping and the fundamental frequency. The following conclusions can be drawn from this investigation:

- As expected, the fundamental frequency and stiffness of the column with post-tension ropes were higher than those of the column without ropes. However, the difference was small because of low post-tension force (i.e. only 200 N).
- The damping of the column without ropes was higher than that of the column with ropes because the relative movements of the blocks in the former column were large compared to those of the latter column.
- The higher damping was observed for all columns when harmonic loading was employed with amplitude of 15 mm compared to amplitude of 5 mm.
- The energy dissipation in columns was high at a frequency close to proximity of the resonant frequency. The same trend was observed for the maximum overturning moment, uplift and rope tension.
- The column with ropes had smaller relative top displacements and block uplifts compared to the column without ropes.
- The base shear of the column with ropes was smaller than that of the column without ropes. This is due to smaller top relative displacements.
- During the harmonic and earthquake loading, the induced accelerations at the top of the columns were generally higher than the ground accelerations, while smaller accelerations were observed at the other locations considered.
- The maximum rope tension recorded in any shake table test was significantly smaller than the force required to pull the ropes out of a 100 mm embedment.
- The maximum rope tension generated due to any dynamic loading was also less than the tensile load of the rope by a very considerable margin.

This work was the first step towards exploring the behaviour of the deemed technology. Full-scale walls having a top mass (or a diaphragm) should be investigated for a better understanding of their seismic performance. The loss in post-tension stress of ropes over a long period should also be studied.

Abstract: The substantial strain capacity and crack control capacity of ECC makes it an ideal material for earthquake-resistant structural members. In this study, the effects of reducing shear reinforcing ratio in polypropylene fiber reinforced cementitious composites (PP-ECC) beams were investigated. A normal RC control beam was prepared with providing amount of shear reinforcements. Further, fibe specimens using PP-ECC were fabricated with monotonic reducing shear reinforcing ratio from the level of RC control beam to zero. And there was also another RC beam without shear reinforcement within shear span was prepared for comparison. Based on the experimental results obtained, it was found that PP-ECC beam with 71% reduction of shear reinforcements can still reach the shear carrying capacity of RC control beams.

1. INTRODUCTION

Polypropylene Fiber Reinforced Engineered Cementitious Composites (PP-ECC, referred herein after), as one kind of ECCs, exhibits multiple fine cracking, pseudo strain hardening behavior and high ductility under uniaxial tensile loading. It has higher tensile strength compared to normal concrete and has capability of reaching ultimate tensile strain between 1 and 5% under monotonic loading. Its pseudo strain-hardening behavior results from its unique multiple fine cracking mechanism, in which closely spaced fine cracks forms because of the bridging action of fibers (Maalej and Li, 1994; Li, 1998). Different from the normal concrete in mixture, ECCs generally use fine aggregates and relatively low volume fractions of short and random fibers (approximately 2 to 3%). Since the absence of coarse aggregate, the elastic modulus of ECC is comparatively lower than that of normal concrete while its compressive strength does not have significant difference from normal concrete.

So far, various types of fiber have been utilized to produce ECCs, including steel, carbon and polymer fibers (Li, 1998). Most structural and retrofit application of ECC reported in the literature use ultra-high molecular weight polyethylene (PE) and polyvinyl alcohol (PVA) fibers. Compared with widely used PVA fibers, polypropylene (PP) fiber is softer, lower cost and easier dispersing which results in better workability. In addition, because of hydrophobic and non-polar nature of PP fiber, PP-ECC has better durability in alkaline environment. In this research, a cementitious composite combined with fabricated polypropylene fibers with improved bond properties (**Figure 1**) that exhibits the pseudo strain hardening and multiple fine cracking of ECCs (Hirata et al., 2009) was used. The properties of PP fiber are shown in **Table 1**.

Although the steel reinforced ECC (R/ECC) structural members such as column and beam-column joints with reduction of shear reinforcements (Li and Fischer, 2002; Parra-Montesinos et al., 2005) has been confirmed in previous study, the shear behavior of ECC beam with reduction of shear reinforcements has not been completely clarified yet. Therefore, Shimuzu et al. (2004) have done several experimental programs on evaluating the shear behavior of PVA-ECC by conducting Ohno shear beam tests and uniaxial tensile tests. The shear strength of tested beams was predicted by employing truss-and-arch model with reduced tensile strength which was obtained from uniaxial tensile tests. However, Kabele et al. (2007) revealed that only a fraction of ECC's tensile strength and strain capacity might be utilized in shear elements due to possible damage of bridging fibers on sliding crack surfaces. Therefore, determining reduction factor for ECC tensile strength is the key to predict shear strength of beam precisely.

In this research, totaling five PP-ECC and two normal RC beams with various shear reinforcing ratios were tested to clarify shear behavior. The tensile properties of ECC was obtained from uniaxial tensile tests.

r_w is shear reinforcing ratio. s is the spacing of shear reinforcements. A_s is the total cross sectional area of longitudinal reinforcements. p_w is the longitudinal reinforcing ratio.

diameter of 25.4 mm and yield strength of 400 MPa was used in all beam specimens for longitudinal reinforcement in tension. The shear reinforcement was adopted deformed bar with nominal diameter of 6.35 mm and yield strength of 323 MPa. The round steel bar with diameter of 6 mm and yield strength of 277 MPa was used for longitudinal reinforcement in compression. The type and properties of all steel bars used in these seven beam specimens is summarized in **Table 2**.

2.2 PP-ECC and Concrete

PP-ECC material used in this research is a class of short-fiber, randomly distributed cementitious composites with 3% fiber volume fraction. The polypropylene fiber has a diameter of 36 μm and a length of 12 mm. The modulus of elasticity and tensile strength of this fiber are 5 GPa and 480 MPa, respectively. This fibrillated polypropylene fiber with rugged surface results in improvement of bond properties and exhibits the pseudo strain hardening and multiple fine cracking of ECC under tensile stress (Hirata et al., 2009). The mixture proportion of PP-ECC used in this study is shown in **Table 3**.

For the normal concrete beams, concrete with a design compressive strength of 27 MPa was used. Mixture components include 20 mm maximum size coarse aggregate, fine aggregate and high-early strength cement. **Table 4** gives the mixture proportion of normal concrete for control beam.

2.3 Test Specimens

Two different types of matrixes, totaling seven beams, including one control beam (RC-Ref), one RC beam without shear reinforcement within the shear span (RC-00) and five PP-ECC beams varying shear reinforcing ratio from the level of control beam to zero, summarized in **Table 5**, were tested by four-point loading method as shown in **Figure 2** The designations of these seven specimens are selected according to its matrix type and shear reinforcing ratio. 'RC' and 'RE' indicates that the matrix type of the specimen is 'Reinforced Concrete' or 'Reinforced ECC'. Except the case of control beam (RC-Ref), the latter digit in specimen designations indicates the shear reinforcing ratio, e.g. RE-24 means the specimen with shear reinforcing ratio of 0.24%

using steel reinforced ECC.

All beam specimens have the same cross-sectional dimension (150×300 mm), longitudinal reinforcements and shear span-depth ratio. The normal concrete beam, RC-Ref is designed following JSCE code, providing an amount of shear reinforcements (six stirrups in one shear span) which satisfied an under-reinforced condition, is used as a control beam. The beam specimen corresponding RC-Ref using PP-ECC, namely RE-42, having identical shear reinforcing ratio to normal concrete control beam RC-Ref, was also prepared for comparisons. The dimension and reinforcement details of these two beam specimens are as shown in **Figure 3**. To evaluate the shear behavior without shear reinforcements, another normal concrete beam specimen RC-00 without shear reinforcements was designed to compare shear capacity with beam specimen RE-00 with identical reinforcement but using matrix of PP-ECC. The dimension and reinforcement arrangement is shown in **Figure 4**. Whereas the rest three PP-ECC beam specimens, the shear reinforcing ratios vary from 0.30 to 0.12%, which means the shear reinforcements within one shear span decreases from four to one. All shear reinforcements were uniformly arranged distributed within the shear span as shown in **Figure 5**.

2.4 Test Setup and Procedure

The arrangement of test setup is shown in **Figure 2**. The beam was subjected to a four-point bending load. The distance of 200 mm between two loading points was fixed for all specimens. The shear span-depth ratio *a/d* for all specimens was 2.8. Two linear variable differential transformers (LVDTs) were used to monitor the deflection in the mid-span, and another two LVDTs were attached to the supporting points at two sides of specimen to measure the deformation. As for all steel reinforcements, two strain gauges were attached to two longitudinal reinforcements in tension. For every shear reinforcement within shear span, there were strain gauges attached at the region where diagonal crack was expected to occur. The locations of strain gauges are shown in **Figure 3**, **Figure 4** and **Figure 5**. All specimens were applied with a monotonic load up to failure.

3. TESTS RESULTS AND DISCUSSIONS

3.1 Load-Deflection Behaviors and Failure Modes

The experimental load versus mid-span deflection curves for all specimens involved in this study as well as their failed span at the ultimate stage are shown in **Figure 6** through **Figure 8**. The results of all specimens including material tests are summarized in **Table 6**. The shear carrying capacity by comparing ECC specimens with RC control beam is shown in **Figure 9**.

As for the steel reinforced concrete beam RC-Ref, the first crack appeared in the center span at a load of 54 kN, then inclined shear cracks were induced and propagated with increasing load. The ultimate load capacity of RC-Ref was

RE-00	104.38	8.19	32.8	3.71

*Tensile strength was obtained by split compression method. The rest were tested by direct tensile tests.
V_{exp} is the peak shear force taken by specimens during tests.

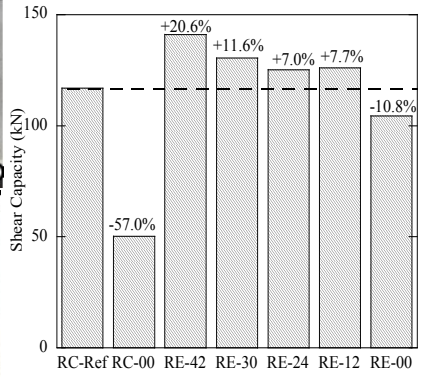

Figure 9 Shear Carrying Capacity Compared with RC-Ref

234.06 kN. After the peak load, the beam finally failed in crushing and spalling of the concrete in the compression zone of shear span closing to loading point. Flexural failure was prevented by providing sufficient longitudinal bars.

Beam RE-42 has an identical reinforcement layout to that of RC-Ref, except a different matrix, however, the ultimate load capacity was 20.6% higher than that of RC-Ref, achieved 282.18 kN. The first crack load of RE-42 is 86 kN, which is 32 kN greater than that of RC-Ref. Beyond the cracking load, the flexural stiffness decreased slightly but kept almost constant up to failure. Several diagonal cracks were developed in shear span, forming as extension of flexural cracks. These shear cracks bent following the compressive stress trajectory with increase of

load. Because of the lower shear span-depth ratio *a/d* (2.8 for all specimens), the beam flexural capacity cannot be fully developed, and then shear capacity dominates the ultimate load-carrying capacity. The failure of RE-42, similar to that of RC-Ref, was initiated by crushing of ECC at the top compression side of main shear crack.

RC-00 and RE-00 is a pair of counterpart beam specimens without shear reinforcements compared to the rest of specimens. RE-00 exhibits similar load-displacement behavior to that of RC-00 before diagonal cracking. Compared with commonly known brittle mode of shear failure such as occurred in RC-00, the shear failure of RE-00 was ductile. This is due to the bridging effect resulting from PP fiber. At the beginning, vertical flexural cracks firstly appeared at the tensile side of beam. When principle tensile stress within shear span exceeded the cracking strength of ECC, a diagonal crack propagated through the beam web. Instead of appearance of several wide cracks, numerous fine cracks developed in the ECC beams and spread throughout large area. The shear resistance of ECC beam was significantly increased by bridging force carried by fibers. The large deformation capacity was provided by multi fine cracking. The peak load of RE-00 was 208.76 kN, compared with that of equivalent concrete beam with shear reinforcements (RC-Ref) wherein the load and deflection capacity just decreased by 10.8% and 6%, respectively. However, if compared with another concrete beam without shear reinforcements (RC-00), the load and deflection capacity of RE-00 increased by 107.6% and 85.2%, respectively.

With various shear reinforcing ratios between the level of control beam and zero, RE-30, 24 and 12 are specimens failed in shear compression similar to that of RE-42. The stiffness of these three beams was found to be slightly higher than that of RE-00 but lower than that of RE-42. The peak load of RE-30, 24 and 12 were 261.12, 250.48 and 252.1 kN, respectively.

3.2 Cracking Pattern

Figure 10 presents the cracking pattern of all specimens at the peak load as well as critical crack developed after peak load as shown with red line. The strain of longitudinal rebars for five specimens in tension just reached yielding strain at their peak loads but soon decreased as increase of load. Meanwhile, the localized diagonal crack was gradually developed after the peak load and cracks in compression zone closing to loading points in shear span appeared.

As has been confirmed by previous research (Suryanto et al. 2010), in conventional reinforced concrete, any slide movement at a crack develops a significant degree of shear resistance because of the aggregate interlock and rough planes of crack. However, in ECC, while the crack opening is small, both crack-shear friction between crack surfaces and fiber bridging contribute to the shear transfer resistance. As the crack opening increases, the frictional resistance diminishes, while the contribution of fiber bridging remains, resulting in a significantly less shear resistance compared to normal concrete due to the absence of coarse aggregate. **Figure 11** shows significant crack slip observed after the peak load during the tests.

3.3 Proportion of Shear Resisting Forces

Considering the force acting at the diagonal crack in a ECC beam subjected to point loads (**Figure 2**), the shear force is resisted by shear carried by ECC (V_{ECC}) or concrete (V_c) and the shear carried by stirrups (V_s). As a result, the shear capacity of beam specimens (V) can be simplified by **Eq. 1** for ECC and **Eq. 2** for RC.

$$V = V_{ECC} + V_s \quad (1)$$

$$V = V_c + V_s \quad (2)$$

where, V_{ECC} is the shear carried by ECC for R/ECC specimens, V_c is the shear carried by concrete for RC beams

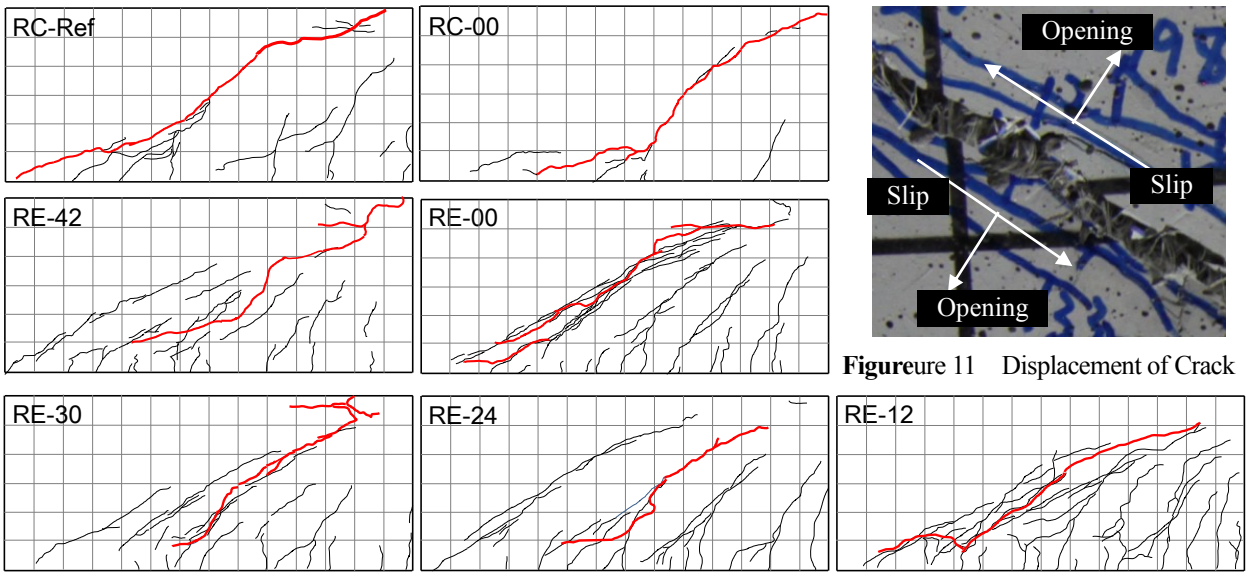

Figure 10 Cracking Pattern at the Peak Load

Figureure 11 Displacement of Crack

Table 7 Experimental Shear Carried by ECC/Concrete and Stirrups

Specimens	V_{exp} (kN)	V_{ECC}/V_c* (kN)	V_s (kN)	V_{ECC}/V_c (%)	V_s (%)
RC-Ref	117.03	49.99	67.04	43%	57%
RC-00	50.27	50.27	0	100%	0%
RE-42	141.09	100.17	40.92	71%	29%
RE-30	130.56	90.05	40.51	69%	31%
RE-24	125.24	86.39	38.85	69%	31%
RE-12	126.05	105.59	20.46	84%	16%
RE-00	104.38	104.38	0	100%	0%

V_{ECC}/V_c refers to the shear carried by ECC for ECC beam or concrete by RC beam.

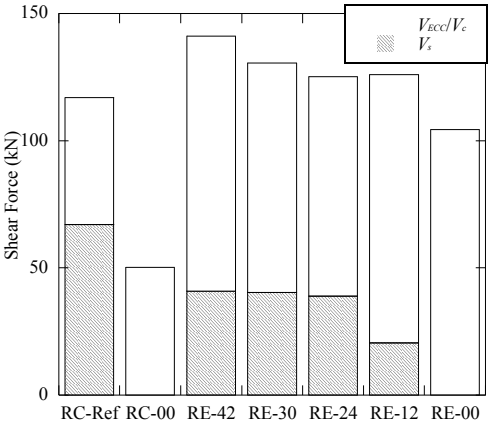

Figure 12 Shear Force Carried by ECC and Shear Reinforcements

and V_s is the shear carried by stirrups.

So far, since there are different simple models utilized for accounting for shear strength of ECC beam, V_{ECC}, shear carried by ECC has not been determined yet. The shear carried by stirrups (V_s) can be calculated from the strain of stirrups which diagonal crack crossed. The strain of stirrups was recorded by prepared strain gauges attaching on the stirrups during the tests. Thus, the shear carried by stirrups (V_s) can be formulated by **Eq. 3** and **Eq. 4**.

$$V_s = \sum \sigma_{si} \tag{3}$$

$$\sigma_{si} = \begin{cases} A_w E_s \varepsilon_s \left(\varepsilon_s < \varepsilon_y\right) \\ A_w f_{wy} \left(\varepsilon_s \geq \varepsilon_y\right) \end{cases} \tag{4}$$

where, σ_{si} is the stress of shear reinforcement crossing critical cracks at the peak load, A_w is cross sectional area of one shear reinforcement within s (mm^2), E_s is the elastic modulus of stirrups, ε_s is the stirrup strain recorded in the tests, ε_y is the yielding strain of shear reinforcements listed in **Table 2**, and f_{wy} is the yield stress of stirrups. As **Eq. 1** through **Eq. 4** presented above, the V_{ECC} and V_c can be calculated by **Eq. 5** and **Eq. 6**, respectively:

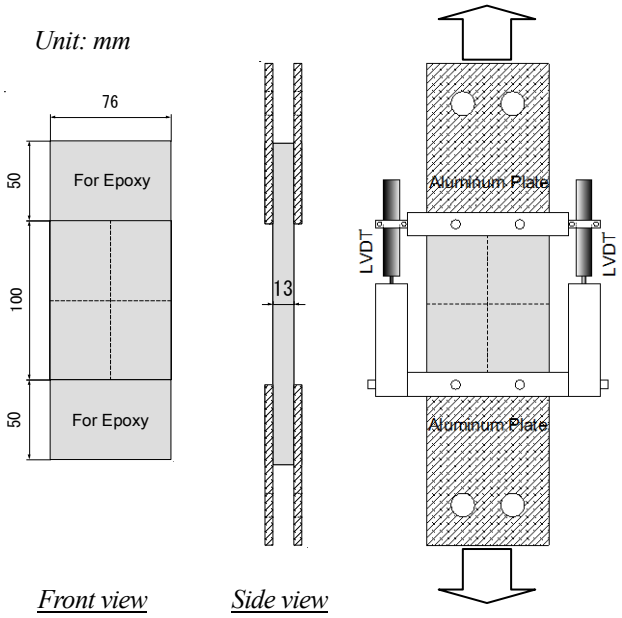
$$V_{ECC} = V_{exp} - V_s \tag{5}$$

$$V_c = V_{exp} - V_s \tag{6}$$

where, V_{exp} is the maximum shear force taken by specimens in experiments, V_{ECC}, V_c and V_s at the peak load were listed in **Table 7** and plotted in **Figure 12**.

4. UNIAXIAL TENSILE TESTS OF PP-ECC

4.1 Specimen and Test Method



Tensile properties of PP-ECC were also inspected by employing uniaxial tensile method. The specimens for uniaxial tensile tests were plates with cross sectional size of 76×13 mm, as shown in **Figure 13(a)**. The epoxy was used to glue both sides of plate specimens with aluminum plates which were used for setting specimen into test facility. Two LVDTs set parallel to axial direction at both sides, as shown in **Figure 13(b)**, were used to measure axial deformation. 0.1 mm/min was selected as the head speed of loading facility.

4.2 Test Results

Tensile stress vs. strain curves of three specimens are shown in **Figure 14**. The test result clearly shows typical pseudo strain hardening behavior of ECCs. From the beginning of tests, stress continued to increase until occurrence of the first crack. The stress suddenly decreased a little at the time when first crack occurred, whereas it continued to increase after the occurrence of first crack. As the loading continued, the increase and sudden drop of stress continued to happen. Meanwhile, more and more fine cracks were observed on the surface of specimen. At the strain around 3%, a localized crack gradually formed and the stress began to decrease slowly. If according to Shimizu et al. (2004)'s definition that ultimate strain is at the point where stress becomes half of maximum stress after peak stress, this test result shows that PP-ECC has strain capacity greater than 3%. The tensile strength is greater than 3 MPa.

5. EVALUATION OF SHEAR STRENGTH

Several researchers attempted to develop simplified model to evaluate shear strength of steel reinforced ECC structural member. Up to date, the truss-and-arch model recommended by AIJ for RC design of RC structural members, and modified truss model recommended by JSCE are utilized. In this study, the equation in Recommendations for Design and Construction of HPFRCC by JSCE (2008) was used to evaluate the shear strength. JSCE recommendations evaluate the shear strength of steel reinforced ECC beam based on a modified truss model for design of RC structural members. The equation incorporates three parts and the total shear carried by structural member is

(a) Dimension of specimen (b) Setup of tests

Figure 13 Uniaxial Tensile Tests of PP-ECC

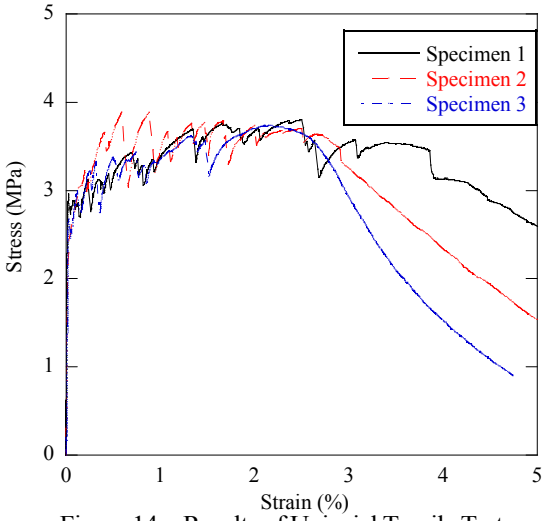


Figure 14 Results of Uniaxial Tensile Tests

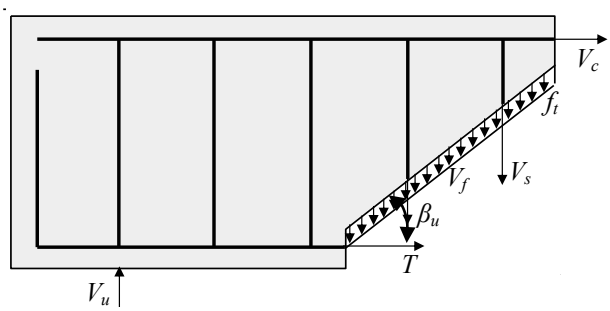

Figure 15 Shear Resistance Mechanism Defined by Modified Truss Model

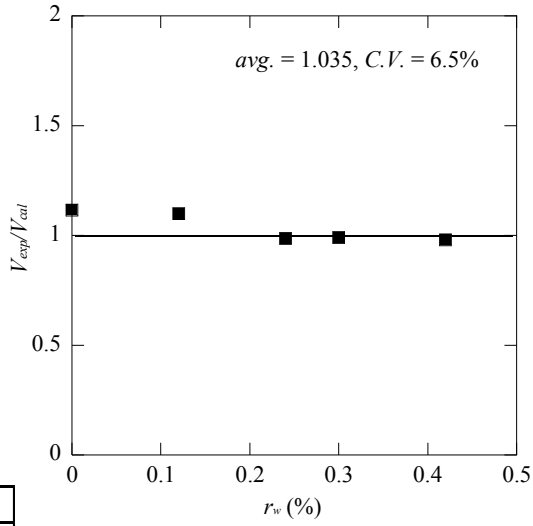

Figure 16 Comparison of Calculated Strength

Table 8 Results of v_t by Reverse Calculation

ID	RE-42	RE-30	RE-24	RE-12	RE-00
v_t	0.45	0.47	0.51	0.55	0.49

expressed by **Eq. 7** and shown in **Figure 15**.

$$V_{cal} = V_c + V_s + V_f \tag{7}$$

where, V_{cal} represents calculated total shear strength of ECC structural member, V_c, V_s and V_f represents shear carried by cement matrix, shear reinforcements and fiber, respectively. V_c is similar to the equation for RC structural members, but with a reduction factor of 0.7 due to the absence of coarse aggregate, which is expressed by **Eq. 8**.

$$V_c = 0.7 \times 0.20 \sqrt[3]{f'_c} \cdot \sqrt[4]{1/d} \cdot \sqrt[3]{100 p_w} \cdot b_w \cdot d \tag{8}$$

where, f'_c is compressive strength of ECC (N/mm^2), d is effective depth (mm), p_w is longitudinal reinforcing ratio and b_w is the web thickness (mm).

V_s is exactly the same as that for design of RC structures, which is presented by **Eq. 9**.

$$V_s = A_w f_{wy} \left(\sin\alpha_s + \cos\alpha_s\right) / s \cdot z \tag{9}$$

where, α_s is angle of shear reinforcements to the member axis, which is 90° in this study. s is the spacing of shear reinforcements and z is the distance from location of compressive stress resultant to centroid of tensile steel, taken as d/1.15.

V_f, the shear carried by fibers, is assumed to be uniformly distributed force in the vertical direction along the inclined crack due to the tensile property of ECC, which is presented by **Eq. 10**.

$$V_f = \left(f_t / \tan\beta_u\right) \cdot b_w \cdot z \tag{10}$$

where, f_t is the tensile strength of ECC (N/mm^2), β_u is the angle of diagonal crack surface to the member axis, taken

here as 45°.

However, according to the previous research, Kabele et al. (2007) revealed that only a fraction of ECC's tensile strength and strain capacity might be utilized in shear elements due to possible damage of bridging fibers on sliding crack surfaces. It is proposed that f_t with a reduced value will be adopted to evaluate the shear strength of these ECC specimens in this study. Therefore, the modified V_f can be expressed by **Eq. 11**.

$$V_f = \left(v_t \cdot f_t / \tan\beta_u\right) \cdot b_w \cdot z \qquad (11)$$

where, v_t is reduction factor for tensile strength of ECC. The value of v_t can be obtained by reverse calculation by using experimental results of specimens. The reverse calculation is shown in **Table 8**. Since there is no obvious tendency by factors, such as shear reinforcing ratio, tensile and compressive strength of ECC, and the average value for all specimens is 0.50, therefore, it was determined that v_t equal to 0.50 in this study. Then, according to **Eq. 8**, **Eq. 9** and **Eq. 11** presented above, the experimental value of maximum shear force in the beam tests is plotted with calculated shear strength given by **Eq. 7** in **Figure 16**. The average (*avg.*) and the coefficient of variation (*C.V.*) of the ratio of experimental to calculated value (V_{exp}/V_{cal}) are1.035 and 6.5%, respectively, which indicates that calculated results using v_t show good agreement with experimental results.

6. CONCLUSIONS

This paper describes the shear behavior of PP-ECC beam specimens with various shear reinforcing ratios by experimental investigation. Totaling seven beams, two normal steel reinforced concrete and five steel reinforced PP-ECC beams, were tested under static monotonic loading condition. In general, all beam specimens with the same longitudinal reinforcements and dimensions were failed in shear. However, PP-ECC beams had significantly large load-carrying capacity than do the counterpart RC beams. Especially the load-carrying capacity of PP-ECC beam without shear reinforcements within shear span almost achieved that of normal RC beam provide with an amount of shear reinforcements and was two times of that of RC beams without the shear reinforcements. Even the shear reinforcement was reduced from the level of control beam, the load-carrying capacity did not decreased significant, in particular three specimens with shear reinforcing ratio between level of control beam and zero, load-carrying capacity were not affected significantly by reduction of shear reinforcements, which is different from the case of RC.

The uniaxial tensile tests for PP-ECC were also performed to confirm the strain-hardening and multiple fine cracking behaviors, which are characteristics of ECC. Based on the test results, PP-ECC exhibited obvious strain-hardening and multiple fine cracking during the tests. The tensile strain capacity achieved 3% above and tensile strength was 3MPa above.

The evaluation method on shear strength of PP-ECC beams were proposed based on modified truss model by adding a tensile reduction factor. The calculated results show good agreement with experimental results.

Abstract: Including short fibers into concrete is one of the alternatives for improving seismic performance of concrete structures. The researches on fiber reinforced concrete (FRC) beams; however, has been focused mainly on steel fibers. In addition, the shear resisting mechanism of FRC beams has not yet been clarified. This paper aims to investigate the shear carried by steel and synthetic fibers of FRC beams with stirrups based on tension softening curves. FRC beams with various types of fibers, which were 30-mm steel, 60-mm steel, polypropylene, polyvinyl alcohol and polyethylene terephthalate fibers were tested. The shear carried by fibers was investigated from stress transferred across the crack and area of crack surface. The experimental results revealed that steel fibers could transfer more stress than synthetic fibers. However, synthetic fibers provided longer length and flatter angle of the diagonal crack, thereby increasing the area that stress can transfer. Finally, the evaluated shear carried by fibers based on tension softening curves showed good agreement with experimental results even types of fibers are varied.

1. INTRODUCTION

Fiber reinforced concrete (FRC) structures are superior to ordinary reinforced concrete (RC) structures because of their high shear strength coming from the bridging effect of fibers. Short fibers are proper to add in the structures to enhance the seismic performance. The use of fibers as shear reinforcement; however, has focused exclusively on steel fibers (Sharma 1986, Narayanan et al. 1987 and Kwak et al. 2002). Recently, synthetic fibers have become more attractive because of the effectiveness with which they improve shear strength (Li et al. 1992) and their relatively less cost when compared with that of steel fibers. Nevertheless, the influence of steel and synthetic fibers on the shear resisting mechanism of FRC beams with stirrups has not been completely understood. In the Japanese design guidelines for reinforced concrete piers with steel fibers (1999), steel fibers have been considered for the shear reinforcement of concrete structures. However, the design guidelines have not considered the post-cracking behavior of FRC beams in detail.

The method to evaluate the shear carried by steel fibers of FRC beams with stirrups was proposed by the authors (Jongvivatsakul et al. 2011). The tension softening curve—one of the parameters in fracture mechanics—was used to explain the post-cracking behavior of FRC beams. The stress transferred across the diagonal crack of the FRC beams was calculated using the relationship between the tension softening curve and crack surface displacement. The shear force carried by fibers was calculated. However, only 30-mm steel fibers were tested in the previous study. The proposed method has not been applied to various types of fibers yet.

The objective of this study is to investigate the shear carried by steel and synthetic fibers of FRC beams with stirrups by using tension softening curves. The shear resisting mechanism of five FRC beams with stirrups and various types of fibers (i.e. material type and length) was examined. In addition, the diagonal cracking behavior (i.e. the crack surface displacement, diagonal crack length and angle of diagonal cracks) and tensile stress transferred across the diagonal crack were discussed. The method to evaluate the shear carried by fibers using tension softening curves was verified to confirm the applicability of those curves in investigating the shear capacity of FRC beams with stirrups and various fibers.

2. EXPERIMENTAL PROGRAM

2.1 Specimens

A total of five specimens with different types of fibers were prepared and tested. The experimental cases are listed in Table 1. The specimens were named according to the type of fibers used in the beams. Figure 1 shows the dimension and reinforcing bar arrangement of a FRC beam. The shear span (a) was 700 mm and the effective depth (d) was 250 mm. The ratio of shear span to the effective depth (a/d) was 2.8. The longitudinal reinforcement ratio (p_w) was 2.7%. All specimens were controlled such that they would fail in the left shear span by providing fewer stirrups in the left shear span, as shown in Fig. 1. The stirrup ratio in the test span (r_w) was 0.30% in all specimens.

Table 1 Experimental Cases

Specimen	Material type of fiber	Fiber volume ρ_f (%)	Properties of fibers						p_w *4 (%)	f_y *5 (MPa)	r_w *6 (%)	f_{wy} *7 (MPa)	s *8 (mm)

Figure 2 Fibers

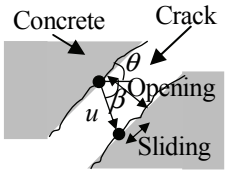

Figure 3 Definition of u

2.2 Material

The materials used in this study were high-early strength Portland cement, fine aggregates, coarse aggregates, and high-performance air-entraining (AE) water-reducing agent. Table 2 shows the mixture proportion for concrete.

Five types of fibers were incorporated into concrete, including steel fibers with lengths of 30 mm (SF30) and 60 mm (SF60), polypropylene fibers (PP), polyvinyl alcohol fibers (PVA) and polyethylene terephthalate fibers (PET). Pictures of the fibers are shown in Fig. 2 and their properties are summarized in Table 1. The volume fraction of fibers was equal to 1.0% of the full volume of the concrete in all specimens.

The longitudinal reinforcing bars were made of deformed steel having 25.4-mm nominal diameter. The stirrups made of deformed steel that was 6.35 mm in nominal diameter were arranged as the shear reinforcement. The yield strengths are listed in Table 1. Two round bars of 6-mm diameter were used as compression bars with yield strength of 304 MPa.

2.3 Loading Setup and Instrumentation

Specimens were subjected to a four-point bending with a simply-supported condition, as illustrated in Fig. 1. Steel plates were placed on the pin-hinge supports and loading points. Figure 1 shows the detailed loading arrangement along with the locations of loading points and strain gauges. The measuring parameters were the applied load, displacements of mid-span and supporting points using four transducers and the strain of the longitudinal steel bars and stirrups.

2.4 Measurement of Crack Surface Displacement and Diagonal Crack Length

Crack surface displacement (u) was measured from the image analysis system developed by Watanabe et al. (2009). Crack surface displacement (u) is defined as the total displacement of cracks in the direction of principal tensile strain (β), which is the direction of the crack's movement, as shown in Fig. 3. In order to analyze the images, red targets of 5-mm diameter were attached on the specimen surface with an interval of 20 mm. During the loading test, photographs of the specimen were captured for every 5 kN of shear force by using three digital cameras fixed on tripods. The image analysis system can investigate the coordinates of the red targets throughout the test span. As a result, the crack surface displacement can be calculated. Because the diagonal crack was expected to open rapidly

near the peak load, some photographs were captured near the peak load with short time intervals to capture the exact behavior at the peak.

Moreover, the length (L) and angle of the diagonal crack (θ) were measured from the visible diagonal crack at the peak load by using the software system, which supports analytical functions ranging from the image measurement to statistical data processing. Calibration was performed to define the length of one pixel in the image for converting the measurement data in pixels to actual lengths. In addition, the images captured for the measurements of crack surface displacements were used to measure crack length and the angle of diagonal cracks at the peak.

3. TENSION SOFTENING CURVES

The tension softening curves were used to investigate stress transferred across the diagonal crack of FRC beams. The curves were obtained from the bending tests of notched beams with a dimension of $100 \times 100 \times 400$ mm, following the standard of the Japan Concrete Institute (2003). Table 3 lists the compressive strength and fracture energy (G_F) of the concrete measured by notched beam tests. Using a least-squares data-fitting procedure, the shape of bilinear curves of the tension softening diagram can be obtained as shown in Table 3. The tension softening curves of five types of fiber reinforced concrete are shown in Fig. 4.

The tension softening behavior varied depending on the type of fibers. SF30 showed the highest peak stress. However, SF60 resisted the highest stress across the crack after $u \geq 0.12$ mm. It is because fiber length increased; thus, the bonding strength improved. At the identical crack opening displacement, steel fibers (SF30 and SF60) transferred higher stress than that by synthetic fibers (PP, PVA and PET) due to their high tensile strength and anchorage. There were two mechanisms in which the stress transferred between crack surfaces was lost. SF30, SF60 and PP failed in the pull-out mechanism, whereas PVA and PET exhibited both pull-out and cut-off mechanisms. Because the tensile strength of fibers was comparatively greater than their bond strength, pull-out failure occurred.

4. CALCULATION OF SHEAR FORCES

From the free body diagram of a part of the shear span of a FRC beam subjected to point load (Fig. 5), the shear capacity (V) of FRC beams can be considered as:

$$V = V_c + V_s + V_f \tag{1}$$

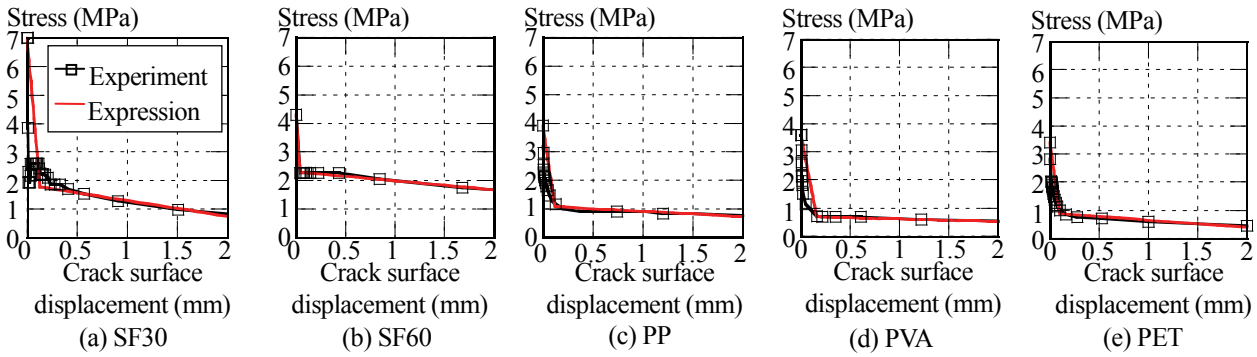

Figure 4 Tension Softening Curves

Table 3 Properties and Expression of Tension Softening Curves

Type	f_c' *1 (MPa)	f_t *2 (MPa)	G_F *3 (N/mm)	Expression
SF30	56.6	3.6	4.24	$\sigma = \begin{cases} 7.0 - 40.2u & \text{for } u < 0.13 \text{ mm} \\ 1.85 - 0.55u & \text{for } u \geq 0.13 \text{ mm} \end{cases}$
SF60	55.9	3.4	8.82	$\sigma = \begin{cases} 4.3 - 50.5u & \text{for } u < 0.04 \text{ mm} \\ 2.3 - 0.31u & \text{for } u \geq 0.04 \text{ mm} \end{cases}$
PP	58.8	3.9	3.02	$\sigma = \begin{cases} 3.9 - 23.5u & \text{for } u < 0.12 \text{ mm} \\ 1.1 - 0.18u & \text{for } u \geq 0.12 \text{ mm} \end{cases}$
PVA	59.9	3.6	2.34	$\sigma = \begin{cases} 3.6 - 18.2u & \text{for } u < 0.16 \text{ mm} \\ 0.7 - 0.09u & \text{for } u \geq 0.16 \text{ mm} \end{cases}$
PET	61.5	3.3	2.89	$\sigma = \begin{cases} 3.4 - 25.2u & \text{for } u < 0.10 \text{ mm} \\ 0.9 - 0.25u & \text{for } u \geq 0.10 \text{ mm} \end{cases}$

*1 compressive strength, *2 tensile strength and *3 fracture energy

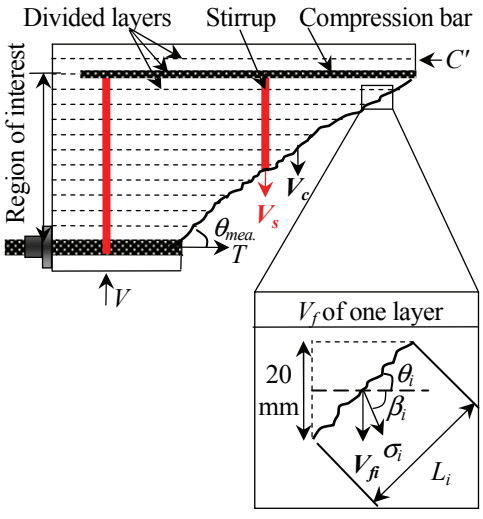

Figure 5 Free Body Diagram of a FRC Beam

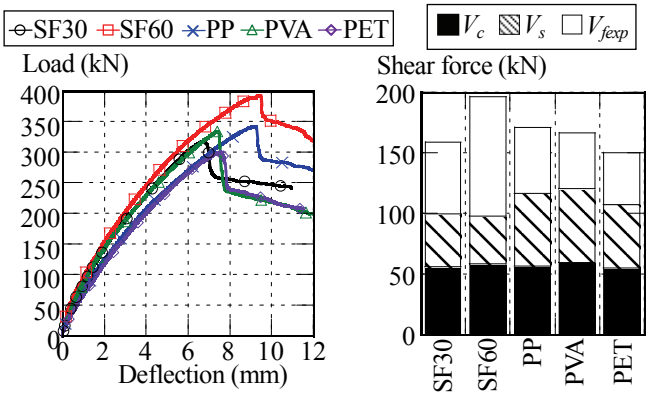

Figure 6 Load-Deflection Curves

Figure 7 Shear Contributions

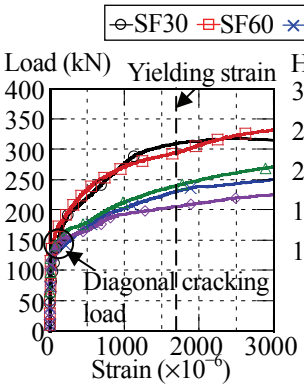

Figure 8 Stirrups Strain

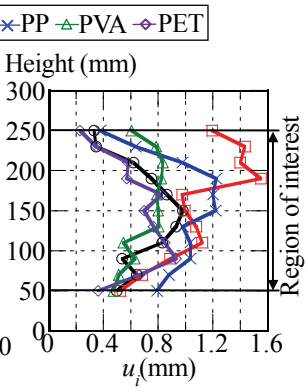

Figure 9 u_i at Peak Load

$$V_c = 0.2 \cdot \sqrt[3]{f_c'} \cdot \sqrt[4]{1000/d} \cdot \sqrt[3]{100 p_w} \cdot b_w \cdot d \quad (2)$$

$$V_s = A_w f_{wy} (z \cot\theta / s) \quad (3)$$

where V_c is shear capacity of members without stirrups (N), V_s is shear carried by stirrups (N), V_f is shear carried by fibers (N), f'_c is the compressive strength of the concrete (MPa), d is effective depth (mm), p_w is longitudinal reinforcement ratio, b_w is web thickness (mm), s is stirrup spacing (mm), A_w is the total cross-sectional area of stirrups provided in the range of s (mm^2), f_{wy} is the yield strength of stirrups (MPa), z is distance from the location of compressive stress resultant to the centroid of tension steel (z = 7d/8) (mm) and θ is angle between the diagonal crack and horizontal line measured from the observed diagonal crack (=$\theta_{mea.}$) (degree).

The experimental value of shear carried by fibers (V_{fexp}) can be obtained from Eq. (4).

$$V_{fexp} = V_{exp} - V_c - V_s \quad (4)$$

Furthermore, according to the JSCE design guidelines (1999), the shear capacity of FRC members can be predicted by using Eq. (5). Thus, the experimental value of κ(= κ_{exp}) can be calculated by Eq. (6). However, Eq. (5) was proposed only for steel fiber reinforced concrete members having 1.0–1.5% fiber out of full concrete volume.

$$V_{JSCE} = (1+\kappa) \cdot V_c + V_s \quad (5)$$

$$\kappa_{exp} = V_{fexp} / V_c \quad (6)$$

where V_{JSCE} is the predicted shear capacity from JSCE equation and κ is the coefficient representing the effect of fibers (κ= 1.0).

5. EXPERIMENTAL RESULTS AND DISCUSSIONS

5.1 Influence of Fiber Types on Shear Behavior

The relationship between the applied load and the mid-span deflection is presented in Fig. 6. The load-deflection response was linear prior to cracking. After the initiation of the first flexural cracking, the load-deflection response became nonlinear. Later, the diagonal crack was observed in the test span and it propagated to the loading point and support. In the pre-peak region, the propagation of the diagonal crack stopped and the inclination of the load-deflection curve decreased. Then, diagonal tension failure occurred and the concrete in the compression zone was crushed. The same behavior of the load-deflection response could be observed in all specimens.

Table 4 summarizes the concrete properties, information regarding diagonal cracks, calculated shear forces and shear forces obtained from the loading tests of FRC beams. Furthermore, Fig. 7 presents the shear contributions of concrete, stirrups and fibers. The shear capacity (V_{exp}) of SF60 was the highest among all specimens. The difference in V_c between each specimen was small because the compressive strength of the concrete did not significantly vary as shown in Fig. 7. On the other hand, V_s was different in each specimen due to the deviation in the angle of between diagonal crack and horizontal line, which was measured from the observed diagonal crack ($\theta_{mea.}$ in Fig. 5). The values of $\theta_{mea.}$ are given in Table 4. Steel fibers provided steeper angles of diagonal cracks than synthetic fibers. Figure 8 shows the average strain of stirrups in the test span. Stirrups in the test span were yielded before the ultimate load. Synthetic fibers (PP, PVA and PET) led the early yielding of stirrups before SF30 and SF60. Considering the shear carried by fibers from the experiment (V_{fexp}), V_{fexp} of SF60 was the greatest as observed in Fig. 7. The specimens including steel fibers showed higher V_{fexp} than synthetic fibers. In addition, V_{fexp} increased with the increase in fiber lengths from 30 to 60 mm. The κ_{exp} of SF30 and SF60 were greater than 1.0, which are the value recommended in the design guidelines (1999), whereas those of PP, PVA and PET were less than 1.0. In case that enough anchorage and bond are provided, steel fibers are the most effective to enhance the shear carried by fibers.

5.2 Crack Distribution Along the Depth of Diagonal Crack

In order to measure the crack surface displacement, the image analysis was performed. The specimens were divided

(7)).

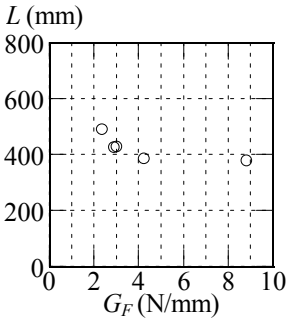

Figure 10 Effect of G_F on L

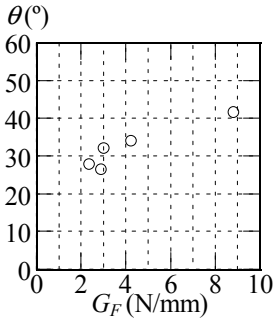

Figure 11 Effect of G_F on θ

into 15 layers. The pictures of specimens at the peak load were used to measure the information of diagonal crack of each layer (i.e. crack surface displacement (u_i), length of diagonal crack (L_i), angle of principal tensile strain (β_i) and angle of diagonal crack (θ_i)) (see Fig. 5). The region of interest for investigation of the shear carried by fibers is the part between location of compression bars and tensile reinforcing bars, where is 50-250 mm from the bottom of the specimens as indicated in Fig. 5. The region of interest is where fibers show their tensile performance.

The value of crack surface displacement (u_i) along the height of the diagonal crack is shown in Fig. 9. Generally, u_i was greater at approximately the middle height of specimens when compared with u_i at the top and the bottom of specimens because of the compression zone at the top of specimens and restraint by longitudinal reinforcing bars at the bottom part of the specimens. u_i differed depending on the types of fibers. u_i at the peak load was in the parabolic shape and was varied in the range from 0.2 to 1.55 mm as observed in Fig. 9. The average values of u_i in the region of interest (u) are listed in Table 4. SF60 had the widest u among all specimens.

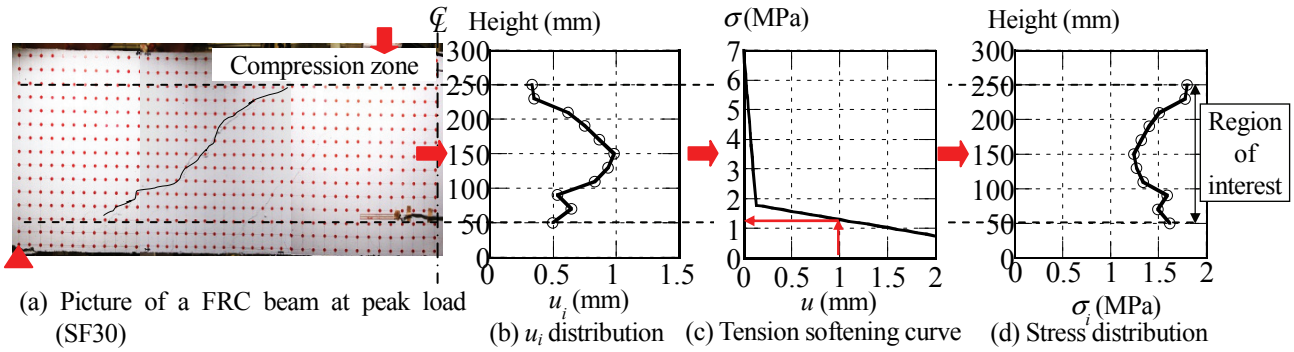
5.3 Diagonal Crack Length

The crack length (L) is the summation of L_i in the region of interest. The values of L are listed in Table 4. PP, PVA and PET provided longer L than those by specimens with steel fibers (SF30 and SF60), as shown in Table 4, because of the relatively flatter angle of diagonal cracks. In addition, there was a relation between L and G_F. L decreased with the increase in G_F as shown in Fig. 10. This tendency conforms to the effects of r_w and ρ_f on L as reported in the previous study by the authors (Jongvivatsakul et al. 2011). This implies that G_F can be one of the indicators for the efficiency of fibers as a shear reinforcement.

5.4 Angles of Principal Tensile Strain and Diagonal Crack

The angles of principal tensile strain (β_i) and diagonal crack (θ_i) of each layer were measured. Table 4 gives the average value of β_i in the region of interest (β). β did not change significantly among these specimens. On the other hand, by considering the average of θ_i (=θ), θ was varied from 26.5° to 41.6°. The specimens with higher G_F revealed steeper θ than those of low G_F (see Fig. 11).

6. SHEAR CARRIED BY FIBERS



6.1 Review of the Evaluation Method

The authors (Jongvivatsakul et al. 2011) have proposed a method for evaluating the shear carried by steel fibers by using tension softening curves. Tensile stress transferred across the diagonal crack (σ_i) can be converted from crack surface displacement (u_i) by using the relationship between tensile stress and crack opening displacement of the tension softening curves as shown in Fig. 12.

By considering the force acting at the diagonal crack in a FRC beam due to the effect of fibers (Fig. 5), the shear carried by fibers (V_{fcal}) is the summation of forces in the region of interest, where is the heights of 50-250 mm from the bottom of the specimens, and can be calculated from Eq. (7).

$$V_{fcal} = \sum_{i=1}^{n} \left(\sigma_i \cdot b_w \cdot L_i \cdot \cos\left(\beta_i + \theta_i - 90\right) \cdot \sin\beta_i \right) \qquad (7)$$

where n is the number of layers in the region of interest (n = 11), σ_i is the tensile stress of the layer i (MPa), L_i is the length of the diagonal crack of the layer i (mm), β_i is the angle of the principal tensile strain of layer i (degree) and θ_i is the angle of the diagonal crack of the layer i (degree).

(a) Picture of a FRC beam at peak load (SF30) (b) u_i distribution (c) Tension softening curve (d) Stress distribution

Figure 12 Investigation of Tensile Stress Transferred Across the Diagonal Crack

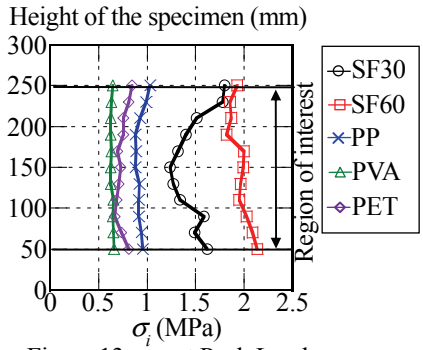


Figure 13 σ_i at Peak Load

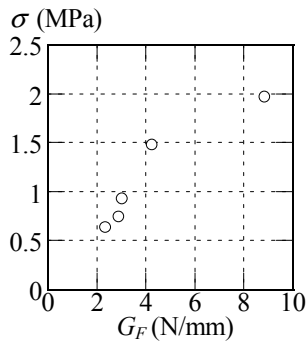

Figure 14 Effect of G_F on σ

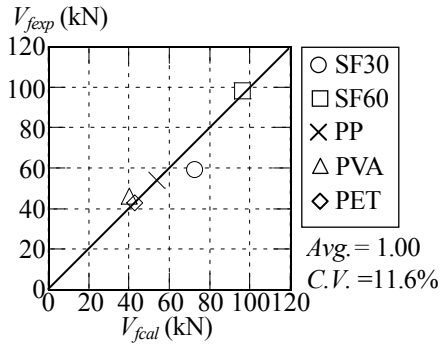

Figure 15 Comparison between V_{fexp} and V_{fcal}

This method was validated for evaluating the shear carried by steel fibers of FRC beams varying ρ_f, r_w and d with high accuracy. However, only steel fibers having length of 30 mm have been investigated in the previous research. It has not yet been extended to FRC beams with various types of fibers.

6.2 Calculated Shear Carried by Fibers

The tensile stress transferred across the diagonal crack at the peak load was evaluated from crack surface displacement and the relationship between the tension softening curves listed in Table 3. The results of stresses (σ_i) are shown in Fig. 13. The larger stress could be resisted to the top and bottom parts of the specimens because of the smaller u_i. Although u_i of the specimens was varied depending on the fiber types without the clear tendency, the value of σ_i was significantly different and a tendency was observed. It is because each fiber reinforced concrete transferred the different stress at the identical crack surface displacement as observed in tension softening curves. SF60 resisted the highest σ_i resulting in the largest V_{fexp}. Synthetic fibers resisted relatively low and uniform σ_i at the peak load due to their flat slope of the second branch of tension softening curves (i.e. when $u \geq 0.12$, 0.10 and 0.16 mm for PP, PVA and PET, respectively). The average value of σ_i in the region of interest (σ) is listed in Table 4. With the increase in G_F, σ increased as observed in Fig. 14.

Shear carried by the fibers (V_{fcal}) was calculated using Eq. (7) and was summarized in Table 4. Figure 15 shows the comparison between the experimental results and calculated values. The ratio of the mean of the experimental value to the calculated value of shear carried by fibers was 1.00 with a coefficient of variation (*C.V.*) of 11.6%. The proposed method can be used to evaluate shear carried by fibers of FRC beams. Moreover, this method can be used when the material types and lengths of fibers were varied because the tension softening curves can reflect the characteristic of each fiber.

7. CONCLUSIONS

(1) Shear capacity of FRC beams with steel fibers was greater than that of specimens having synthetic fibers. Steel fibers are the most effective to enhance the shear carried by fibers when there is enough fiber length and bonding strength due to high tensile strength of steel fibers.

(2) The specimen with 60-mm steel fibers provided the widest crack surface displacement at the peak load because of the effects of the fiber length and shape of ends. However, it was most effective for transferring stress across the crack because it resisted the highest stress in post-cracking behavior as indicated by the tension softening curve. Therefore, the post-cracking behavior in the curve is essential for investigating the shear resisting mechanism of FRC beams.

(3) Stress transferred across the diagonal crack and the angle of the diagonal crack increase with the increase in the fracture energy, while the length of diagonal crack becomes shorter. However, the angle of principal tensile strain was not varied in this study.

(4) The method to evaluate the shear contribution of fibers was presented. The calculated shear carried by fibers

showed a good agreement with experimental results, even for various material types and fiber lengths.

Abstract: Recently, the deterioration of prestressed concrete (PC) girders that leads to the ruptures of strands or tendons has become a concern in many countries. There are urgent needs of investigating as well as retrofitting the damaged members, particularly for seismic resistance, enhancement in strength, stiffness are required. This paper presents the experimental works of flexural strengthening for PC beams having ruptured strands using different amounts of externally bonded Carbon Fiber Reinforced Polymer (CFRP) sheets. The damaged PC beam had 50% of tensile prestressing strands were ruptured at middle of the span. Then, CFRP sheets were bonded to the tension surface for flexural strengthening with different amount of sheet layers. The flexural capacity of the strengthened beams was recovered up to 91.5% of the original PC beam. The increase in number of the bonded sheets resulted in the reduction of tensile stress carried by the remaining prestressing strands. The failure changed from debonding in the constant moment region to debonding from the end of the bonded sheets. The predicted flexural capacity based on ACI 440.2R guidelines tends to be overestimated when greater than three layers bonded because the failure modes were different from the predictions.

1. INTRODUCTION

Recently, the deterioration of prestressed concrete (PC) beams because of chloride attack, insufficient grout or external impacts that lead to the ruptures of strands or tendons has become a concern in many countries. These damages cause an excessive reduction of flexural capacity and decrease the stiffness of not only the damaged members but also the whole structures. As a result, the structures become high vulnerability to earthquakes. Hence, there are urgent needs of retrofitting the damaged members, particularly for seismic resistance, the improvement in the strength and member stiffness are required. The traditional strengthening methods (strand splices, external post-tensioning tendons or steel plate jackets), however, have drawbacks because they require large equipments, consume much time, labors. Moreover, the strengthening materials themselves may not be protected from future corrosion.

Meanwhile, the application of fiber reinforced polymers (FRPs) in structural repair and strengthening has been increased in the last decades. A various types of FRP materials (carbon fiber, glass fiber, aramid fiber, etc.,) have been commonly used in different types such as bars, sheets, laminates or meshes. While bars and grids are commonly used for substitute of internal steel bars in new structures, FRP sheets are applied for repair and strengthening of existing structures. Carbon fiber reinforced polymer (CFRP) sheets with the advantages of high strength to weight ratio, excellent corrosion resistance, ease and short time of construction have been adopted widely in strengthening of existing reinforced concrete (RC) members. To date, there have been many studies focusing on the application of CFRP sheets in flexural strengthening of RC beams. Besides, the provisions of the guidelines for design and construction of structural members strengthened by externally bonded FRP sheets in many countries like USA (ACI 440.2R-08) and Japan (JSCE recommendation 2002) prove the great contribution of those countries to broadening the application of a new strengthening method. Even though, there have been a few studies on the behaviors of damaged PC beams strengthened by externally bonded CFRP sheets. Moreover, because of difficulties in predicting the failure modes, the current design guidelines have not reflected all the factors; therefore, predicting the flexural strength of concrete members, particularly, PC members with ruptured strands externally bonded by FRP sheets has been still conservative.

Hence, this study aims to investigate the behaviors of PC beams having ruptured strands strengthened in flexure by externally bonded CFRP sheets. The object of strengthening was PC beams having 50% of strands ruptured. CFRP sheets were externally bonded to the bottom side of PC beams with different number of sheet layers. Furthermore, the experiment outcomes were compared with the predicted values based on the guideline of ACI (ACI 440.2R-08).

2. OUTLINE OF EXPERIMENTS

2.1 Details of PC beams

The details of the specimens are shown in Fig. 1. In the figure, CB denotes the control beam or undamaged beam. DB2 donotes the PC beams which had 50% of the prestressing strands were cut at middle of span. The specimens had a rectangular section of 150 mm wide and 300 mm high. The total length was 3.3 m while the beam span was 3.0 m. Four prestressing strands were arranged in two layers in tension zone. The prestressing strand had the nominal diameter of 10.8 mm, consisted of seven wires. The cross-section area of each strand was 70.08 mm^2. The prestressing strands were pre-tensioned with the initial stress of 1,075 N/mm^2. Two deformed bars diameter of 10 mm were set in compression zone. Also, the stirrups were provided to prevent shear failure. The stirrup spacing is shown in the figure.

For the damaged PC beams, to duplicate the rupture of prestressing strands, a portion of concrete with 100 mm long and 50 mm high was left at the middle of the span. Two of four strands were exposed at the bottom side span at this portion (section A-A, Fig. 1). The exposed prestressing strands, then, were cut using a steel cutting blade. In terms of strengthening, the concrete sections at the midspan were restored to the original rectangular shape by a high strength cementitous mortar.

2.2 Material properties

The mixing proportion of concrete is given in Table 1. The concrete was designed with the average 28-day cylinder compressive test of 55 N/mm^2. The tensile strength and yielding strength of prestressing strands were 1,894 N/mm^2 and 1,722 N/mm^2, respectively. The deformed bars used for stirrups and compression reinforcement had yielding strength of 370 N/mm^2. The design 28-day compressive strength of mortar was 50.2 N/mm^2.

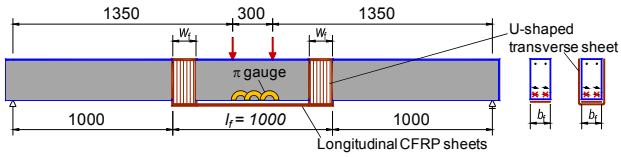

Figure 2 Layout of externally bonded CFRP sheets (Unit: mm)

2.3 Layout of externally bonded CFRP sheets

Table 2 lists the experimental cases. CB and DB2 were the reference cases, the other specimens were strengthened in flexure by attaching unidirectional CFRP sheets to the bottom face of the damaged PC beams. The attaching layout of CFRP sheets is illustrated in Fig. 2. The number of CFRP sheet layers was varied from one to five layers in the strengthened beams while the width and lengths of CFRP sheets were constant values of 125 mm and 1,000 mm respectively. Except DB2-100-1, the additional U-shaped transverse sheets were wrapped at the end of the longitudinal sheets in order to prevent the debonding of the longitudinal sheets. The name of specimen indicates the damaged beam - the length of the longitudinal CFRP sheets, presence of U-shaped anchorage sheets - number of CFRP sheet layers.

The CFRP sheet with the thickness of 0.111 mm was adopted in DB2-100-1. In the other specimens, CFRP sheets having the thickness of one layer of 0.333 mm were used.

CFRP sheets were bonded to concrete surface by wet-layup procedure. First, bottom faces of concrete were ground slightly to make them smooth. Then, a primer was

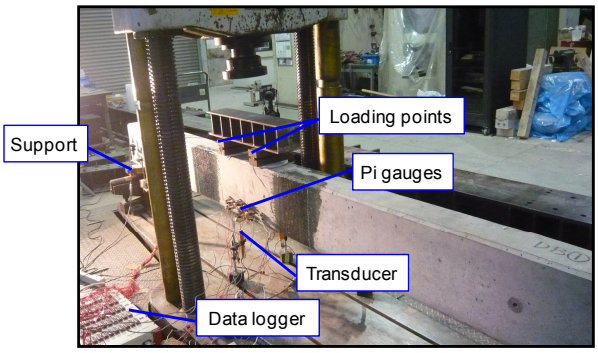

Figure 3 Instrument settings for loading test

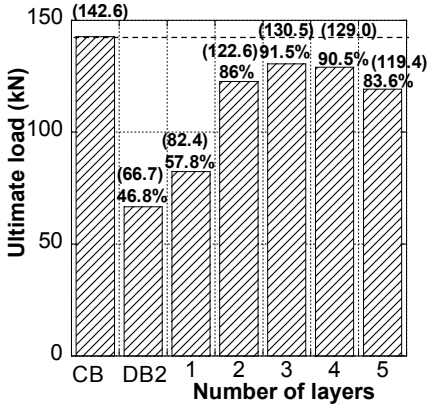
applied to the concrete surfaces. In the next stage, each layer of CFRP sheet was impregnated with an epoxy-resin to concrete surface. After all the layers of CFRP sheets were pasted, a finishing coat of the same epoxy resin was externally covered. The strengthened specimens were cured in the room temperature for at least seven days before the loading tests.

2.4 Loading method and measured items

The specimens were tested as simply supported beams with the effective span of 3,000 mm. Loads were applied at two points at a space of 150 mm on either side of the midspan (Fig. 3). Load was applied by a 1000 kN loading machine.



In Fig. 1, the solid rectangles present the locations of the strain gauges in the strands. The strain gauges were bonded to the strands before casting concrete. There were two measuring locations in uncut prestressing strands and six locations in the cut ones. The values of these strain gauges were monitored before, after cutting the strands and during the loading test. Besides, in order to measure the tensile strains in the surface of the bonded CFRP sheets, the strain gauges were attached along the sheets. In the top of concrete section, the gauges were attached to obtain the compressive strains at the midspan.

The linear variable differential transducers were used to monitor the vertical displacement of the specimens. Two transducers were set at the middle of the beam span, and the other two were located at each support. Moreover, the crack widths in the constant moment region were measured by π-gauges. The applied load and all measurements were recorded automatically through a data logger with the time interval of three seconds. The crack propagations during the loading were marked with the load levels.

3. EXPERIMENTAL RESULTS

3.1 Flexural capacity and stiffness

Figure 4 presents the effect of the number of layers of the bonded CFRP sheets on the ultimate load of the strengthened beams compared to CB and DB2. It can be seen clearly, the rupture of 50% of the prestressing strands at the middle of span led to a reduction in the flexural capacity of 53.2% in the damaged beam DB2. The ultimate loads was

( ) Experimental ultimate load, P_u.
% : P_u/P_u^{CB}

Figure 4 Comparison in ultimate loads

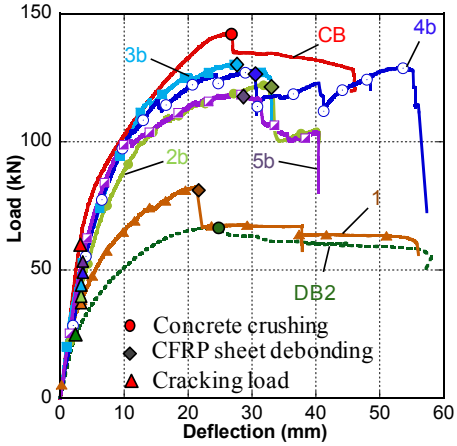


Figure 5 Load-deflection curves

recovered up to around 91.5% (130.5 kN) of CB in the beam strengthened by three layers. However, the ultimate load of the beams strengthened with four and five layers were not greater than that. The ultimate load of the beam strengthened by five layers slightly reduced in comparison to the load capacity of the beam strengthened with three layers. Likely, the debonding of CFRP sheets occurred earlier with the increase in the number of CFRP layers. Therefore, those CFRP sheets did not effectively utilize their full strength to the flexural capacity of the beams.

Figure 5 shows the relationship between the applied load and the deflection at midspan. As the slopes of the curves represent the flexural stiffness, the stiffness of the damaged beams DB2 decreased significantly compared to CB in post-cracking region. When CFRP sheets were bonded to the tension surface (DB2-100-1), the deflections in post-cracking region at same load levels was much smaller than that of DB2. Up to three layers bonded, the decrease in the midspan deflections was accompanied by the increase in number of CFRP sheet layers. Hence, the curves became steeper and get closer to that of CB. However, when the number of the sheets greater than three layers, the large difference in the stiffness between the strengthened and un-strengthened portions accelerated the widening of the cracks at the sheet ends. As a result, the beam stiffness was

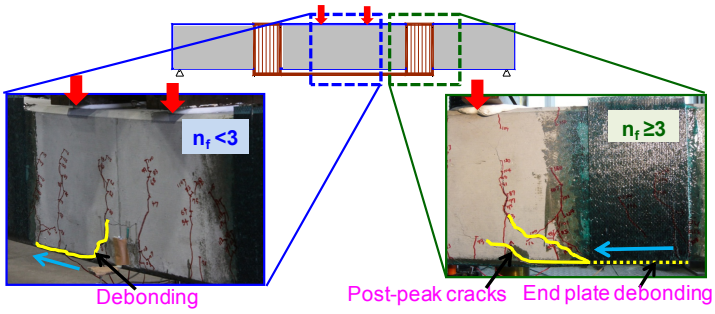

Figure 6 Failures occurred at different portions in strengthened beams

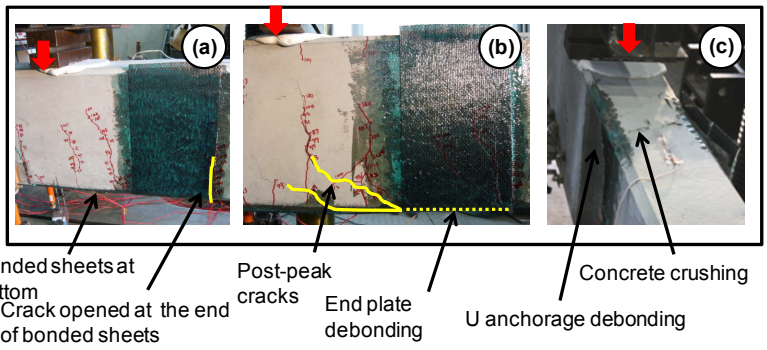

Figure 7 Typical failure of PC beams strengthened with greater than three layers

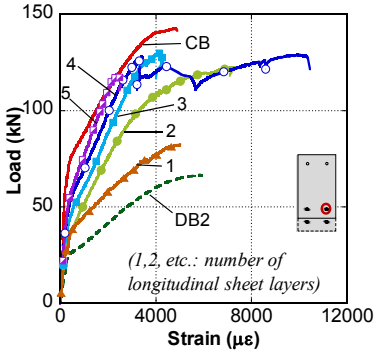

Figure 8 Load-tensile strain increment at midspan

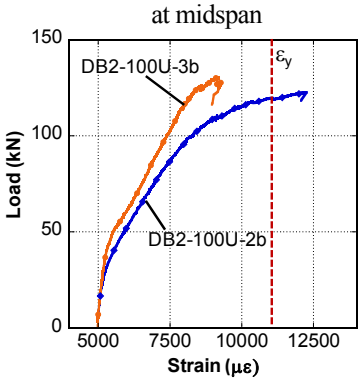

Figure 9 Strain development in strands

decreased, that led to a larger deformation in the beams strengthened with four and five layers.

3.2 Failures of composite sections

Figure 6 shows the failures occurred at different portions of the strengthened PC beams when the amount of CFRP sheets was increased. When the amount of the bonded sheets was less than three layers, the debonding of the bonded sheets was initiated from the flexural cracks in the constant moment region. However, in case the amount of the bonded sheets was greater than three layers, the sheets were debonded from the sheet ends. Likely, the critical sections in the strengthened PC beams were shifted from the constant moment region to the portion near the sheet ends when the amount of the bonded sheets was increased. Figure 7 details the general behaviors in the beams strengthened by more than two layers of CFRP sheets. At first, the flexural cracks were formed in the constant moment region. After that, as the gradual increase of the applied load, the cracks were formed in the shear span, in the portion from the loading points to the end of the bonded CFRP sheets. When the cracks at the ends of the bonded sheets opened (Fig. 7(a)), the beam stiffness was reduced. Consequently, although the deflection grew fast, the load carrying capacity increased slowly. Figure 7(b) shows the debonding of the longitudinal sheets in DB2-100U-4b. As can be seen, the debonding of the sheets was initiated from the sheet end, which propagated towards the loading point in the post-peak loading. As the debonding occurred from the sheet ends, the sections near the end of the sheets became more critical because the sheets terminated to carry the tensile stress. The debonding between the bonded CFRP sheets and concrete, then, was followed by the crushing of concrete at the top fiber of the section near the sheet end as shown in Fig. 7(c).

In general, the strengthened PC beams were failed by debonding of CFRP sheets. However, the failure behaviors were affected by the amount of the bonded CFRP sheets to the damaged PC beams.

3.3 Effects of amount of CFRP on tensile strains of internal prestressing strands and debonding mechanisms

Figure 8 illustrates the relationship of the applied load and the increment of the tensile strains at midspan of the uncut prestressing strands which is a circled in the section. It was apparent that the increase in tensile strains in the prestressing strands became smaller at the same load level when the number of CFRP layers was increased. The effect on the strain reduction in the remaining prestressing strands possibly resulted in the decrease of yielding load of strands. The evidence is given in Fig. 9. The tensile strain reached yielding strain (ε_y) when the beam was strengthened with two layers of CFRP sheets. Nevertheless, when the amount of CFRP sheets was increased to three layers, the tensile strain in the prestressing strands was still far to reach the yielding strain even the ultimate load was greater in case of three layers of the sheets were bonded.

Likely, the different failure behaviors (discussed in section 3.2) were influenced by this effect. When small amount of CFRP sheets bonded (e.g. two layers, Fig. 9), the strands yielded at the middle of the span. Hence, flexural cracks opened widely in the constant moment region and propagated around the mortar portion. This caused some displacements in vertical and horizontal directions at the interface between concrete and the bonded sheets. These

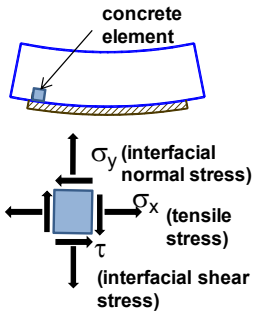

Figure 10 Stresses acting on concrete element near the interface

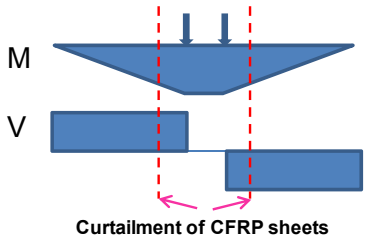

Figure 11 Moment and shear force diagram

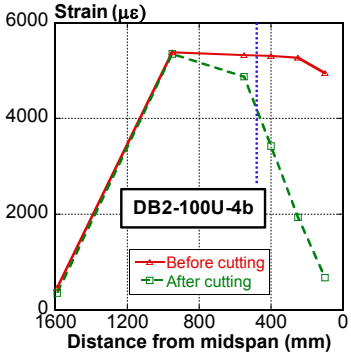

Figure 12 Strain losses in ruptured strands

displacements induced a shear and normal stresses at the crack mouth. When the principal stress at this location exceeded the bond strength, debonding started and propagated towards the sheet end. In this case, the debonding failure was generated from the cracks in the constant moment region. However, when a larger amount of CFRP sheets was bonded (e.g. three layers, Fig. 9), the tensile strain in the remaining strands did not reach yielding strain. Thus, the width of flexural cracks in the constant moment region remained small and the stresses did not rise at the middle of the span. Even though, debonding was started from the end of the bonded sheets because of high concentration of the interfacial stresses near the sheet ends.

Figure 10 introduces the stresses acting in a concrete element near the interface between concrete and bonded sheets, which are interfacial shear stress (τ), interfacial normal stress (σ_y), and the tensile stress (σ_x). The tensile stress at the bottom of concrete section is due to a bending moment at a considered section, while the interfacial stresses shows the high concentration at the end of the bonded sheets because the discontinuity in member rigidity. According to previous studies, the interfacial stresses are highly related to the distance between a support and the sheet end, elastic modulus and thickness of the bonded plate, elastic modulus of the adhesive layers and concrete compressive strength (Sayed-Ahmed et al. 2009 and Smith et al. 2001). If the combination of three stress components, the principal stress, exceeds the strength of the weakest element, the debonding occurs. As explained in the section 2.3, the lengths of the bonded CFRP sheets in the experiments were constant. Moreover, the curtailments of the bonded CFRP sheets were 350 mm shifted from the loading points, which located in the high moment and shear region (Fig. 11). In addition, Fig. 12 illustrates the typical behavior of the strain in the cut prestressing strand before and after it was cut. The horizontal axis shows the locations of the strain gauges while "zero" (0) corresponds to the midspan where the strands was cut. The vertical axis shows the measured values of the strain gauges. As can be seen, the strain dropped suddenly to approximately zero near the cutting point. For the gauges whose locations were further from the cutting point, the values of strain drops were gradually smaller. The curtailment of the bonded CFRP sheets is shown in the figure as the dot line. Clearly, the curtailment of the sheets was within the length in which the strains dropped.

Therefore, the debonding from the end of the bonded sheets in this study can be explained by the concentration of the stresses near the sheet ends. First, this referred to the increase in total thickness of the bonded CFRP sheets larger amount of sheet layers was used. Second, the curtailments of the bonded sheets located not only in high shear and moment regions but also within the length that strains in prestressing strands were lost, that led to the high tensile stress at the sheet ends. Moreover, it is certain that the behaviors of prestressing strands are highly related to the effective stress in the strands. Thus, the effects of prestressing stress level to debonding behavior in PC beams need to be further taken into account.

3.4 Comparison with the predicted load capacities based on the guidelines of ACI

The experimental results were compared with the calculated values based on the recent guideline of ACI (ACI 440.2R-08). In this guideline, the flexural section analysis was adopted and the flexural capacity was computed based on the stress and strain compatibility and equilibrium. For the PC beams strengthened with externally bonded FRP sheets, in case non-prestressed reinforcement is not provided, the flexural capacity consists of two components which are carried by prestressing strands and fiber sheets as shown in the below equation:

$$M_n = A_p f_{ps}\left(d_p - \frac{\beta_1 c}{2}\right) + \psi A_f f_{fe}\left(h - \frac{\beta_1 c}{2}\right) \quad (1)$$

Where:

A_p: area of prestressing steel
f_{ps}: stress in prestressing steel at beam failure
d_p: effective depth to centroid of prestressing steel
f_{fe}: stress in fiber sheet at beam failure
A_f: area of FRP sheets
h: height of beam section
c: distance from extreme compression fiber to neutral axis
β_1: ratio of depth of equivalent rectangular stress block to depth of the neutral axis
ψ: partial reduction factor, $\psi = 0.85$

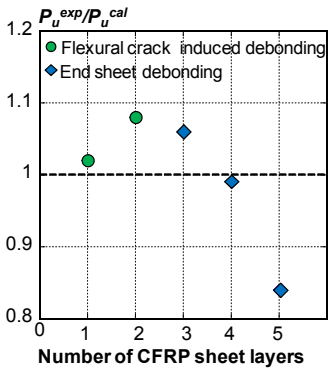

Figure 13 Comparison of ultimate loads between experimental and predicted values

The stress in fiber sheets at the beam failure (f_{fe}) in Eq. (1), is determined from the assumption of the failure modes. It takes the maximum strain in the FRP sheets at the sections computed from the case of whether crushing of concrete, debonding of FRP sheets or rupture of FRP sheets occurs. In the guideline, Eq. (2) is given to predict the effective strain of the bonded sheets in case the debonding of the bonded FRP sheets induced by an immediate cracks. In this equation, the debonding strain of the bonded sheets depends on compressive strength of concrete and properties of bonded sheets.

$$\varepsilon_{fd} = 0.418\sqrt{\frac{f'_c}{n_f E_f t_f}} \le 0.9\varepsilon_{fu} \qquad (2)$$

Where:
f'_c: *compressive strength of concrete (N/mm^2)*
n_f: *number of FRP layers*
E_f: *elastic modulus of FRP sheet (N/mm^2)*
t_f: *thickness of FRP sheet (mm)*
ε_{fu}: *ultimate strain of FRP sheet*

Figure 13 represents the comparison of the ultimate loads of the strengthened PC beams between experimental data and the calculations based on ACI guideline. In case the flexural cracks induced debonding occurred in the strengthened beams, the experimental results showed a good agreement with the calculation based on ACI. However, in case the debonding from the sheet ends occurred, even the reduction factor $\psi = 0.85$ was employed in the calculations, the calculated values tended to overestimated. This is because of the differences of failure modes when the amount of CFRP sheets were increased which have not been considered. The debonding from the sheet ends occurred in the experiments; however, there is no available method to to predict the flexural capacity of the strengthened beams failed in end sheet debonding in the recent guideline of ACI.

Moreover, as discussed previously, the failure behaviours of composite actions were influenced by not only the amount of the bonded sheets but also the location where the sheets are curtailed.

4. CONCLUSIONS

In this study, the effects of the externally bonded CFRP sheets on the pre-tensioned PC beams having strands ruptured were investigated in terms of flexural capacity, stiffness, strains in the remaining prestressing strainds and failure behaviors. Moreover, the failure mechnisms were explained, which was affected by the amount of the bonded sheets.

First, the strand ruptures in the PC beams lead to the reductions in both flexural capacity and member stiffness. The strengthening method in which CFRP sheets are bonded externally to tension surface of the damaged PC beams shows the effective performance in improvement of the flexural capacities, the stiffness in post-cracking region and decrease the stress carried by the remaining strands. The enhancement of the post-cracking stiffness and decrease of strains in strands are associated with the increase in number of CFRP sheet layers. The ultimate load was enhanced up to 91.5% of the ungamaged beam by bonding three layers of CFRP sheets.

Second, with the same sheet lengths provided, the failure modes tend to change from debonding induced by flexural cracks in the constant moment region to debonding from the sheet ends when the damaged PC beams are strengthened with larger amount of CFRP sheets. While the first failure mode results from the opening of the flexural cracks, the second one causes by the high concentration of stresses near the sheet ends. The concentration of stresses near the end of the bonded sheets is because of a larger amount of CFRP sheets bonded and the curtailment of the bonded sheets in a high shear and moment. Moreover, the lengths of CFRP sheets in this study did not cover the lengths in which the prestress in the prestressing strands were lost due to the ruptures. Hence, to utilize the strength of CFRP sheets with a large amount of CFRP sheets effectively, sufficient lengths of CFRP sheets need to be further investigated.

Finally, the recent guideline of ACI are insufficient to predict the debonding from the ends of the bonded sheets. Therefore, the calculated flexural capacities of the PC beams strengthened by externally bonded CFRP sheets tend to overestimate when this failure occurs.

Abstract: Shear failure in RC beams is well known as brittle nature. This failure can be prevented by the application of Ultra High Strength Fiber Reinforced Concrete (UFC). UFC provides highly advanced mechanical properties, such as high compressive strength as 150 MPa, high durability and high ductility. The use of UFC as a permanent formwork of RC structures is one of the alternatives to enhance the shear resistance and ductility of the structure. However, the available studies on the mechanical performance of RC beams using UFC permanent formwork is insufficient and the effect of shear span to effective depth (*a/d*) ratio has not been considered. The objective of this paper is to evaluate the shear capacity of RC beams using UFC permanent formwork considering the effect of *a/d.* The specimens were subjected to four-point bending. The experimental results indicated that UFC permanent formwork enhanced shear capacity of RC beams significantly. Moreover, failure mode changed depending on *a/d*. Finally, the shear carried by a UFC permanent formwork was investigated. Computational values showed good agreement with experimental values.

1. INTRODUCTION

The improvement of seismic performance of infrastructures is required, in order to mitigate the social damage and seismic risk. Prevention of shear failure in reinforced concrete (RC) members is one of the significant factors. Shear failure in RC members is well known as brittle nature. As methods for shear retrofitting and strengthening of RC members, cross-sectional restoration, steel plate attachment and FRP sheet attachment have been started to be used. However, these methods have some problems such as corrosion of steel plate and brittle failure of FRP material. This demand can be achieved by the utilization of developed Ultra High Strength Fiber Reinforced Concrete (UFC). UFC is an advanced cementitious material which has outstanding properties, such as more than 150 MPa compressive strength, high ductility and high durability.

The permanent formwork for RC structures is one of the applications of UFC. The definition for permanent formwork derived from CIRIA C558 is, the permanent formwork is a structural element of whatever material that is used to contain the placed concrete, mold it to the required dimensions and remain in place for the life of the structure (Wringley 2001). Shirai et al. (2008) reported application of UFC permanent formwork for repairing of Tedorigawa Bridge in Ishikawa prefecture, Japan. It shows that UFC formwork left in-place increased durability against chloride attacks, abrasion and impact wear. Moreover, The U-shaped UFC permanent formwork with shear keys and screws and bolts system which provided to fix the UFC permanent formwork to the inside RC was introduced by the authors (Wirojjanapirom et al., 2012). The results show that the shear capacity of RC beams using UFC U-shaped permanent formwork increased drastically. However, the available studies on the mechanical performance of RC beams using UFC permanent formwork is insufficient and the effect of shear span to effective depth (*a/d*) ratio has not been considered. Therefore, the objective of this paper is to evaluate the shear capacity of RC beams using UFC permanent formwork with considering the effect of *a/d.* The specimens were subjected to four-point bending. Shear capacities, crack patterns and failure mechanism were investigated.

2. EXPERIMENTAL PROGRAMS

2.1 Experimental Parameters and Specimens

To determine the effect of *a/d* on shear behavior of a RC beam with U-shaped UFC permanent formwork, the loading test of four specimens listed in Table 1 was conducted. Table 1 summarizes the testing variables and

specimen's name.

Figure 1 shows dimension, reinforcing steel bar arrangement and cross section of UFC20-K specimen. As constant variables for all specimens, effective depth, width, height and tension reinforcement ratio are d=220 mm, b=250 mm, h=300 mm and p_w =1.41%, respectively. In order to control a shear span of failure, a number of stirrups were provided in one span. Three specimens with different shear span. Effective depth of the beams was same, but the shear span was varied. The original specimen was UFC20-KB with a/d= 3.27. The a/d of UFC20-KB-ad1 and UFC20-KB-ad21 were 1.00 and 2.16, respectively. Figure 2 shows the dimension of UFC20-KB-ad21 and UFC20-KB-ad1 specimen. Specimens were subjected to a four-point bending with the load applied to both the UFC and RC at the same time. The applied load was measured. Mid-span deflection was measured by using transducers. Strain gauges were used for measuring the strain of tension steel bars at mid-span and concrete on the top fiber at mid of shear span. Moreover, four π-gauges were used to measure the diagonal crack opening width along the diagonal line between the loading point and support.

2.2 Materials

The self-compacting concrete was used in this experiment, and detail of mix proportion is summarized in Table 2. The materials used in the concrete mixes were high-early strength cement, lime stone powder, fine aggregates, coarse aggregates, viscosity improver and superplasticizer, which was high-performance air entrained (AE) water reducing agent. The designed compressive strength of 7-day age concrete was 35 MPa.

The steel short fibers with 0.2 mm diameter and 15 mm length were used for UFC. Mix proportion of UFC forms is shown in Table 3. The volume fraction of steel fibers in all specimens was 2.0%.

The longitudinal reinforcing bars used in this research were deformed steel bar with 21.6 mm nominal diameter. The yield strength was 1026 MPa. The deformed steel bar of 10 mm in diameter was arranged as compression reinforcement. The yield strength was 339 MPa.

Figure 4 Crack patterns

Table 4 shows the mechanical properties of concrete and UFC, and the result of loading tests. Figure 3 shows the relationships between the load and the mid-span deflection. Figure 4 shows the crack patterns of UFC20-KB-ad21, UFC20-KB-ad1 and UFC20-KB which the first two specimens failed in shear compression failure mode. After the loading test, UFC formwork was removed and diagonal crack of inside RC part was observed. The red lines in Fig. 4 represent the critical cracks.

In UFC20-KB specimen, flexural cracks on the UFC formwork appeared when the load was 82 kN. When the load reached to the peak (384 kN), the critical diagonal crack was propagated and widened, and the crushing of UFC under the loading point occurred as shown in Fig. 4(a1). Figure 4(a2) shows the diagonal crack of inside RC part. It seems that the diagonal crack of inside RC part occurred at the same location of that in the UFC permanent formwork.

In UFC20-KB-ad21 specimen, the diagonal crack on the UFC formwork initiated at 347.3 kN but the load was still increasing. Then, crushing of UFC under the loading point occurred at the peak load as shown in Fig. 4(b1). Figure 4(b2) shows the diagonal crack of inside RC part.

In UFC20-KB-ad1 specimen, the flexural crack on the UFC formwork initiated at 334.2 kN. After that, many cracks propagated in the direction from the support to the loading point with increasing in load as shown in Fig. 4(c1). After the loading test, the debonding failure of RC and UFC formwork and the crushing of inside RC part under the loading point were observed as shown in Fig. 4(c2).

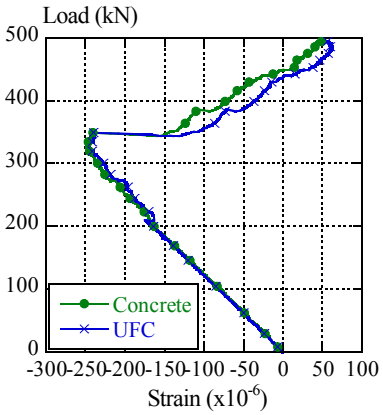

Figure 5 Load-strain at the upper surface (UFC20-KB-ad21)

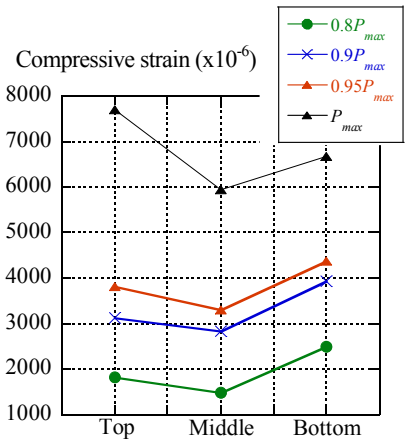

Figure 6 Maximun compressive strain of concrete

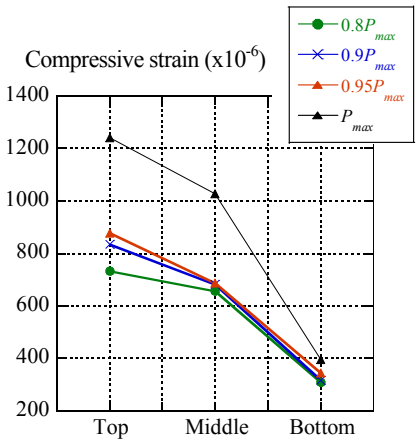

Figure 7 Maximun compressive strain of UFC

3.3 Effect of shear span to effective depth ratio (*a/d*)

For UFC20-KB, firstly, a diagonal crack initiated in RC part, however, failure did not occur because UFC on the sides of the RC part prevented the opening of the diagonal crack and the aggregate interlock in RC part remained. After that, as the load increased, the diagonal crack in RC part attempted to widen and UFC formwork was still resisting by forces, which were generated at the top and bottom of bolts and from the shear key interface. As a result, many cracks were observed on the UFC formwork as shown in Fig. 4(a1). Then, the main diagonal crack on UFC occurred at 70 percentage of peak load ($0.7P_{max}$) but load was still increasing, while the opening width of diagonal crack was increasing. Then, the load reached to peak and failure occurred.

For UFC20-KB-ad21, although a diagonal crack on UFC formwork initiated, the diagonal tension failure did not occur since UFC prevented widening of diagonal crack inside RC part. Consequently, the compressive stress acted above the diagonal crack. As a result, the top fiber strains of both UFC and concrete which measured at the top surface of mid of shear span were changed into the reverse direction as shown in Fig. 5. Here, the tensile strain is shown as positive, conversely, negative shows the compressive strain. The flexural tension stress occurred at the upper edge of both UFC and RC. After that, the load reached to the peak because of the crushing of UFC near the loading point as shown in Fig. 4(b1).

From the descriptions above, it can be said that when the *a/d* ratio changed from 3.27 to 2.16, the failure mode changed from the diagonal tension failure to the shear compression failure because of the compression stress acted above the diagonal crack and crushing of the UFC occurred near the loading point.

3.6 Compressive strain of concrete in the strut formation of UFC20-KB-ad1

UFC20-KB-ad1 also failed in the shear compression mode. The failure mechanism was examined by using the strains measured in the compressive strut of both concrete and UFC. The strains of concrete and UFC were measured by using the acrylic bars and concrete strain gauges, respectively. Figure 8(a) shows the arrangement of acrylic bars inside concrete. Concrete strain gauges were attached at the same position of those on acrylic bars. According to the method by Nakamura and Higai (1999), acrylic bars were fixed by making dents and set at the center of the cross section width in the direction of compressive stress flow from the loading point to the supporting point. Five acrylic bars were set at 17 mm intervals. Three strain gauges were attached on each acrylic bar, in order to measure the strain near the loading point, center of the compressive strut and the supporting point.

Figures 6 and 7 show the development of the maximum compressive strain of concrete near the loading point (Top), center of the strut (Middle) and near the supporting point (Bottom) of concrete and UFC, respectively. In both concrete and UFC, compressive strains increased drastically near the peak load because the compression struts were formed in both concrete and UFC formwork. Therefore, the compressive strains reached ultimate strain and crushing of concrete occurred. It should be noted that the distribution of compressive strain of both concrete and UFC seems to be different. This is because the compatibility between RC and UFC permanent formwork cannot be secured.

4. INVESTIGATION OF SHEAR CARRIED BY U-SHAPED UFC PERMANENT FORMWORK

4.1 Shear Carried by UFC Permanent Formwork Failed in Diagonal Tension

The shear carried by UFC permanent formwork failed in diagonal tension was investigated.

The shear carried by UFC formwork was calculated by subtracting the shear carried by concrete and stirrups from the total shear capacity obtained from the loading test as calculated from Eq. (1)

$$V_{UFC} = V_u - V_c - V_s \quad (1)$$

where, V_{UFC} is the shear carried by UFC formwork, V_c is the

Table 5 Shear carried by UFC formwork observed in the experiment and obtained in the calculation

Specimens	Thickness of UFC, t (mm)	Angle, θ (°)	tensile stress, σ_{UFC} (N/mm^2)	$V_{UFC\text{-}exp}$ $=V_{exp}$-V_c-V_s (kN)	$V_{UFC\text{-}cal}$ (kN)	Exp/Cal
UFC20-KB	20	22.1	3.8	127.3	118.8	1.07

shear carried by concrete, V_s is the shear carried by stirrups.

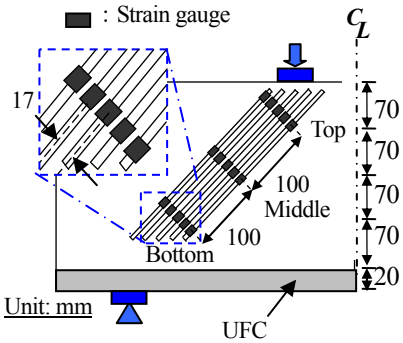
In this research, the shear carried by concrete was obtained by Eq. (2)

$$V_c = 0.2(f_c')^{1/3}(p_w)^{1/3}(\frac{1000}{d})^{1/4}(0.75+\frac{1.4}{a/d})b_w d \quad (2)$$

where, V_c is shear capacity of normal RC beam without stirrups (kN), f'_c is compressive strength of concrete (MPa) , p_w is tension reinforcement ratio (%), b_w is web thickness (mm) and d is effective depth (mm).

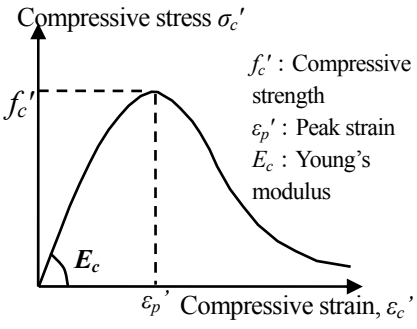
.

The shear carried by UFC formwork was computationally obtained based on a simplified shear carrying model. The crack length of permanent formwork and the angle of diagonal crack are represented by l and θ, respectively. Therefore, the shear carried by UFC formwork based on this model is given by Eq. (3).



$$V_{UFC} = \frac{2 \cdot t \cdot \sigma_{UFC} \cdot d}{\tan\theta} \quad (3)$$

where, t is the thickness of UFC permanent formwork, and d is effective depth.



The tensile stress (σ_{UFC}) was determined by the diagonal crack width measured by using π-gauge along the diagonal crack line from support to loading point and using the tension softening curve of UFC measured by Kakei et al. (Kakei et al. 2003).

4.2 Result of the Calculation

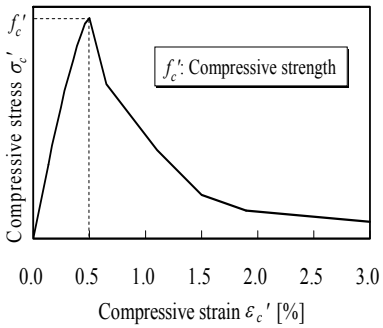


Table 5 summarizes the results of experimentally observed and computationally obtained shear carried by UFC formwork by Eq. (1) and Eq. (3), respectively. In all three specimens, the ratio of experimentally observed shear carried by UFC formwork to computationally obtained value shows good agreement. Thus, the model was able to give a reasonable result. This is because the diagonal crack on both

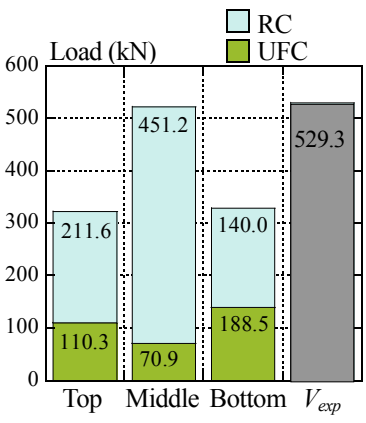

Figure 11 Comparison of calculation and experimental value of shear resisting force

UFC formwork and RC part was located to almost the same position, and also the diagonal crack width of UFC was measured.

4.3 Shear Carried by UFC Permanent Formwork Failed in Shear Compression

As mentioned, UFC20-KB-ad1 specimen failed in the shear compression failure mode. The shear carried by UFC permanent formwork failed in the shear compression failure mode is examined in this session.

Figure 8 presents the method for determining width of the compressive strut. The maximum strain point and both minimum strain points at $0.95P_{max}$ were connected by straight dashed lines as shown in Fig. 8 (b) and the width of compression strut was assumed to be the distance between the points where the strains equal to 0 as shown in Fig. 8 (b). Assuming that the strains of acrylic bars and concrete were the same and the stress state was assumed as uni-axial compression and the strain that measured on UFC was considered also in the same way. The compressive stress acting on the concrete was calculated by using the strain of acrylic bars, and the compressive stress of UFC was calculated by the strain measured by a strain gauge. From stress-strain model, the measured strains of both concrete and UFC were transformed to stress. For concrete, the stress-strain model proposed by Thorenfeldt et al. (1987) shown in Fig. 9(a) was used to calculate the compressive stress. For UFC, the stress-strain model of UFC based on the experimental results proposed by Kakei et al. (2003) shown in Fig. 9(b) was used to calculate the compression stress. Figure 10(a) and (b) show the compressive stress distributions of concrete and UFC permanent formwork, respectively. In concrete part, the strut width at the middle was wider than that near the loading point and near the support. It means that the stress concentrations were observed in both near loading and supporting points. This is because the constraint effect of UFC permanent formwork confined RC with screws and bolts.

4.3 Calculation of the compressive force

The stress distributions of both concrete and UFC were converted to the vertical component of the compressive force acting on the concrete strut and UFC strut by using Eq. (4) and (5).

$$F_{st} = D \times b_i \quad (4)$$

$$F' = F_{st} \times \sin\alpha \quad (5)$$

where, F_{st} is the compressive force acting on the concrete or UFC strut, D is the force per unit width under the compressive stress distribution curve, b_i is the width of cross section of concrete or both of UFC formwork thickness, F' is the vertical component of F_{st}, α is the angle of the strut with respect to the longitudinal axis of beams.

Figure 11 shows the comparison of the summation of calculated value F' from RC and UFC with the experimental shear capacity V_{exp}.

The summation of F' at the middle provided the good agreement with V_{exp}. However, the summation of F' underestimated V_{exp} at the top and bottom location. It is because the uni-axial stress-strain model (Thorenfeldt's model) was used while the compression strut of inside concrete was constrained by the UFC formwork with screws and bolts.

5. CONCLUSIONS

(1) Failure mode of RC beams using a UFC U-shaped permanent formwork changed depending on the shear span to effective depth ratio. Compression strut was formed in a UFC formwork in the case of *a/d* equal to 2.16 and 1.0.

(2) The shear carried by a UFC formwork in RC beams failed in the diagonal tension mode was investigated by assuming and using the tensile stress obtained from the tension softening curve. The computational values showed the good agreement with the experimental values.

(3) Compression forces of a UFC formwork and RC part in the specimen with *a/d* 1.0 calculated by using uni-axial stress-strain model did not show the good agreement near the screwed bolts. It indicated that the constraint effect of screwed bolts should be considered to evaluate the shear compressive capacity.

Abstract: High-performance fiber-reinforced cementitious composites (HPFRCC) are emerging materials that exhibit enhanced tensile behavior and ductility as compared to traditional concrete. Consequently, these materials are under investigation by researchers for use in a variety of structural components that are expected to dissipate energy during earthquakes. Developing an understanding of the bond created between HPFRCC materials and mild steel reinforcement is necessary to improve performance predicting tools and design guidelines for these novel materials. On-going research on characterizing the bond strength and bond-slip behavior of steel reinforcement in HPFRCC materials will be presented. Beam specimens with reinforcement splices were tested with varying amounts of cover and transverse steel to examine the bond characteristics of HPFRCC materials relative to ordinary concrete. Experiments completed thus far show that HPFRCC provides a confining effect that can substantially increase bond strength and bond-slip ductility. Future research on additional experiments of reinforced HPFRCC members will also be discussed.

1. INTRODUCTION

High-performance fiber-reinforced cementitious composites (HPFRCC) have been studied over the last two decades and proposed for a number of applications to improve the resilience of structures under earthquake loading. These materials exhibit a unique pseudo tensile strain hardening behavior that results in increased component ductility, energy dissipation and damage tolerance. Potential applications for HPFRCC materials include hinge regions for bridge piers (Rouse and Billington 2003), hybrid beam-column joints (Parra-Montesinos and Wight 2000), coupling beams (Lequesne et al. 2010) and many other related areas for increased structural performance under seismic demands.

In order to develop adequate design guidelines and performance predicting tools for HPFRCC materials, it is necessary to understand the bond that develops between HPFRCCs and steel reinforcement. Previous experimental studies on bond in HFPRCC materials have used the direct pull-out test and test results show a substantial increase in bond strength due to the mechanical properties of these materials (Chao et al. 2009). However, the pull-out test method is recognized as an inadequate method to fully characterize bond strength due to the simplified stress state (ACI Comittee 408 2003). Instead, a beam specimen with lap splices is the preferred experiment since a more realistic stress state can be obtained. Traditional strain softening fiber reinforced concrete (FRC) materials have been tested using beam splice specimens (Harajli et al. 2002), but there are no experimental results available, to date, on tensile strain hardening HPFRCC materials.

On-going research is being conducted by the authors to characterize bond between HPFRCC materials and steel reinforcement for future model development. In this paper, the results of experiments on beam specimens containing lap splices are presented for two different mixture types.

2. EXPERIMENTAL PROGRAM

2.1 Materials

Two cement based mixes were used to fabricate the specimens in this study; a normal weight concrete and an Engineered Cementitious Composite (ECC).

The normal weight concrete consisted of Type II/V Portland cement, water, fine aggregate and coarse aggregate. The fine aggregate had a fineness modulus of 3.1 and the coarse aggregate had a maximum size of 9.5 mm.

Engineered Cementitious Composites are one type of HPFRCC that do not use coarse aggregate. The ECC mix consisted of Type II/V Portland cement, Class F fly ash, silica sand, a viscosity modifying admixture, super-plasticizer and 2.0% by volume polyvinyl alcohol (PVA) fibers. The silica sand had a 0.13 mm particle size and the PVA fibers were 12 mm long. The proportions for 1 cubic meter of the concrete and ECC mixes are shown in

Table 1.

Table 1 Proportions for 1m^3 of Concrete and ECC Mixes

Mix	Binder		Water	Aggregate		Admixtures		PVA Fibers
	Cement (kg)	FA (kg)	(kg)	Fine (kg)	Coarse (kg)	SP (kg)	VMA (kg)	(kg)
Concrete	653	-	249	602	802	-	-	-
ECC	547	656	312	438	-	2.7	0.6	26

FA = Fly Ash; SP = Superplasticizer; VMA = Viscocity Modifying Agent

2.2 Specimen Design

As previously noted, beam specimens with lap splices were fabricated and tested in this study since they are considered the preferred specimen type for bond experiments. All specimens were designed to ensure that a bond failure would occur prior to yielding of the reinforcement. The specimens were designed in this manner so that the maximum bond stress could be measured.

The beams were 1473 mm in length and had a height of 229 mm. Shear stirrups, with a diameter of 10 mm, were placed in the maximum shear region and spaced at 89 mm to guarantee that the beams failed due to insufficient bond strength rather than shear.

Two steel longitudinal reinforcing bars with a diameter (d_b) of 16 mm were used throughout the cross section. At mid-span two bars were lap spliced to another another two bars as shown in Figure 1. Two of the bars were debonded for the remaining length of the beam using a thin wall PVC pipe so that reinforcement slip could be measured at the end of the beam. The reinforcement that was debonded was extended outside of the beam so that instrumentation to measure reinforcement slip could be installed. A splice length (L_s) of 10d_b (160 mm) was chosen to ensure that the specimens would fail due to bond rather than flexure.

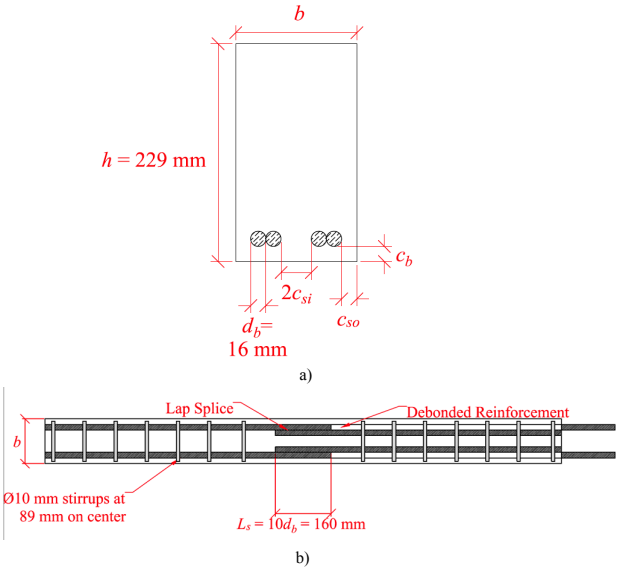

Figure 1 a) Specimen Cross Section within Splice Region b) Specimen Plan View

In addition to the mechanical properties of a material, there are two other important factors that affect bond behavior between steel reinforcement and a cementitious mix (Orangun et al. 1977). The first is the ratio of concrete cover to bar diameter (c/d_b), where the term "cover" refers to bottom cover (c_b), side cover (c_{so}) and cover between bars (c_{si}) as shown in Figure 1a. The second important factor is the presence of confinement (i.e., stirrups) in areas where bond is critical.

Four specimen types were designed with these factors in mind to examine how these two parameters (c/d_b ratio and presence of confinement) affected bond strength in HPFRCC materials. Specimens with two different cover to bar diameter ratios were studied, 1.0 and 1.5, and specimens with and without confinement in the splice region were tested for each mix type. The compressive strengths for ECC and concrete were 50 MPa and 45 MPa, respectively. The test matrix and compressive strengths of each material are outlined in Table 2.

Table 2 Test Matrix and Compressive Strengths

Specimen Name	Mix	b (mm)	c (mm)	c/d_b	Confinement	f'_c (MPa)
CON-1-UC	Concrete	127	16	1.0	-	45
CON-1-C	Concrete	127	16	1.0	2 #10	45
CON-1.5-UC	Concrete	159	24	1.5	-	45
CON-1.5-C	Concrete	159	24	1.5	1 #10	45
ECC-1-UC	ECC	127	16	1.0	-	50
ECC-1-C	ECC	127	16	1.0	2 #10	50
ECC-1.5-UC	ECC	159	24	1.5	-	50
ECC-1.5-C	ECC	159	24	1.5	1 #10	50

$c = c_b = c_{si} = c_{so}$

Confinement = number of stirrups in splice region

2.3 Test Setup and Procedure

The simply supported beams had a span length of 1372 mm and were loaded in four-point bending to create a constant moment region. A 245 kN universal testing machine applied force to a load distribution element, which then loaded the beam at the third points. The testing machine was set to displacement control at a rate of 0.5 mm/min. The test was paused at certain points during testing (i.e., just after first cracking, just before the expected bond failure load, after bond failure and at other intermittent points) to investigate and map crack patterns. All specimens were coated in a lime wash so that crack propagation could be easily identified. An overview of the test setup can be seen in Figure 2.

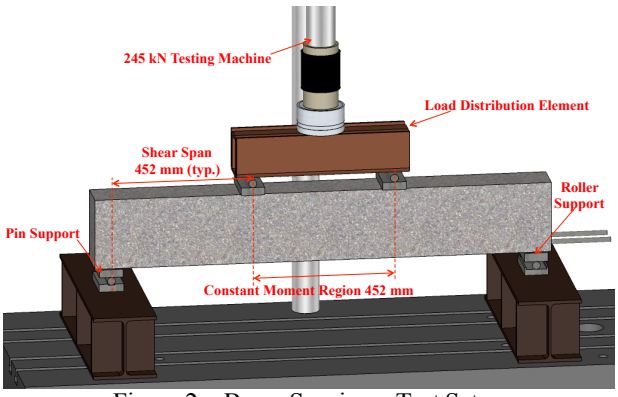

Figure 2 Beam Specimen Test Setup

Strain gages were installed to calculate bond stresses. The gages were placed on all four pieces of reinforcement 6 mm outside of the splice region. Linear variable

differential transducers (LVDTs) were positioned at mid-span to monitor vertical displacement.

LVDTs were also installed at the ends of the two reinforcing bars that were debonded. These LVDTs, shown in Figure 3, measured displacement (slip) of the reinforcement as the specimens were loaded.

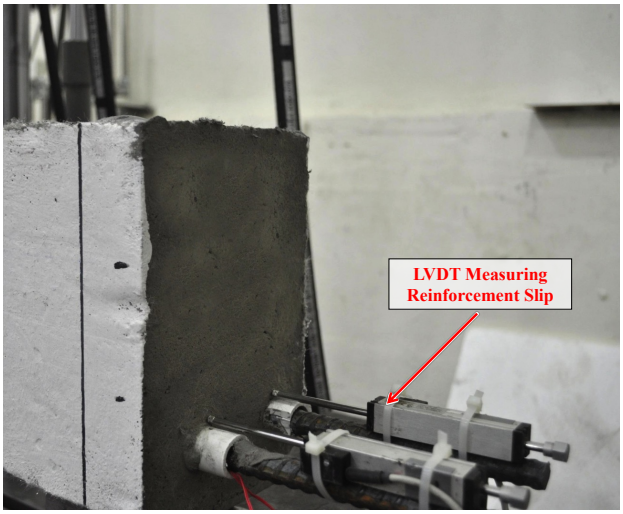

Figure 3 LVDTs Used for Slip Measurement

3. EXPERIMENTAL RESUTLS

3.1 Failure Mechanisms and Crack Propagation

Initial cracks were mapped after a change in stiffness was detected during testing. These first flexural cracks, shown in Figure 3, were well distributed throughout the constant moment region. ECC and concrete specimens both showed similar initial crack patterns within the constant moment region.

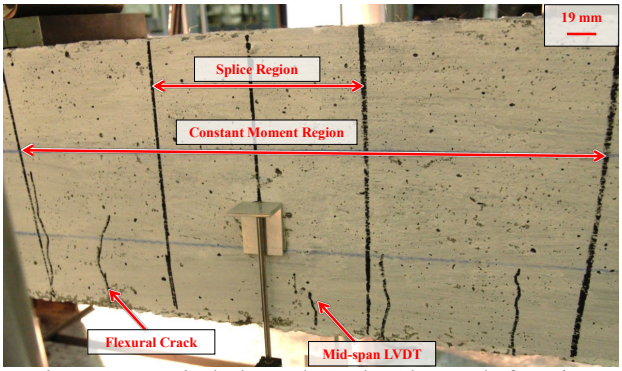

Figure 3 Typical Flexural Cracks Observed after First Cracking

A bond failure was observed when a drop in load carrying capacity occurred. The ECC specimens exhibited more distributed cracking; however, cracks localized in the splice region for both ECC and concrete specimens causing a bond failure. The bond cracks were observed on the vertical and bottom faces of the beams as shown in Figures 4 and 5, respectively.

While testing ECC-1.5-UC, a bond crack on the underside of the beam developed in the splice region. This crack then propagated towards a flexural crack outside of the splice region. As the experiment continued, the flexural crack widened and a portion of the beam began to separate out of plane as shown in Figure 6. It is important to note that this was the only specimen where this was observed.

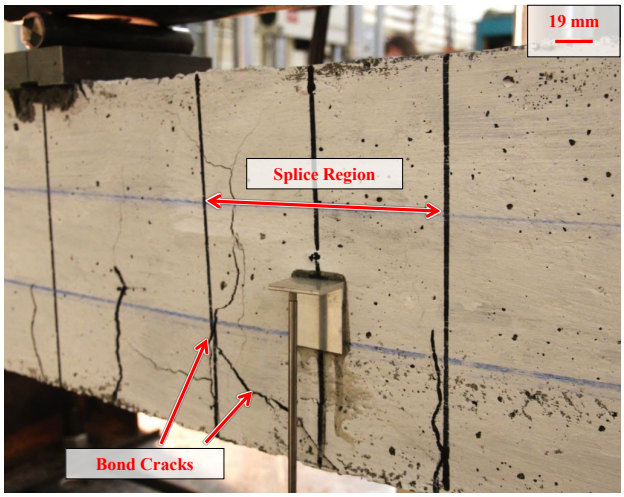

Figure 4 Typical Bond Cracks on Vertical Side of Beam

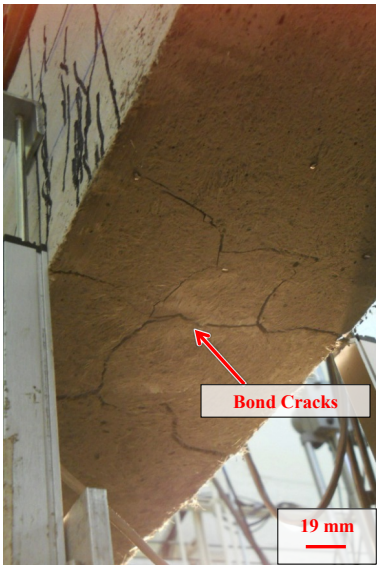

Figure 5 Typical Bond Cracks on Underside Side of Beam

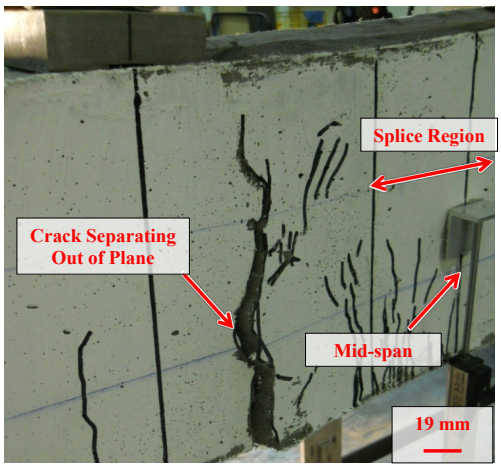

Figure 6 Separating Crack from ECC-1.5-UC

3.2 Bond Strength

Bond strength was calculated from the strain data collected during testing using Equation 1; where u is the bond stress, T_s is the tension force in the steel reinforcement, d_b is the diameter of the steel reinforcement, L_s is the splice length, A_b is the area of the reinforcement, E_s is the modulus of elasticity of the reinforcing steel and ε_s is the strain in the reinforcing steel. It should be noted that the average strain from the four gages was used.

$$u = \frac{T_s}{\pi d_b L_s} = \frac{A_b E_s \varepsilon_s}{\pi d_b L_s} \quad (1)$$

The peak bond strengths from all of the experiments are summarized in Table 3. The ECC specimens had higher maximum bond strengths than their concrete specimen counterparts. The increase in bond strength from ECC ranged from 22 to 64 percent.

There was an increase in bond strength by changing the c/d_b value from 1.0 to 1.5 for the concrete specimens, but little to no increase was observed for the ECC specimens. A substantial increase in bond strength was observed for the c/d_b value of 1.5 when confinement was added to the concrete specimens; however, there was little to no increase in bond strength by confinement otherwise.

Table 3 Maximum Bond Strengths in Concrete and ECC Specimens

Confinement	c/d_b	$u_{max,Concrete}$ (MPa)	$u_{max,ECC}$ (MPa)	Percent Increase
Unconfined	1.0	5.4	8.6	61%
Unconfined	1.5	5.8	8.3	42%
Confined	1.0	5.2	8.4	64%
Confined	1.5	7.0	8.5	22%

3.3 Bond-Slip Behavior

The bond stress vs. slip responses of the unconfined and confined specimens are shown in Figures 7 and 8. In general, the bond-slip curves have three distinct segmentss:

1. An initial branch where bond strength and reinforcement slip increase until the maximum bond stress is reached
2. A descending branch, after the maximum bond stress is reached where bond stress decreases as reinforcement slip increases
3. A final branch where bond stress remains relatively constant while reinforcement slip increases

Concerning the initial branch of the bond-slip curve, the ascending stiffness was similar for both materials. However, as noted in Section 3.2, the peak bond strengths for the ECC specimens were much higher.

After the maximum bond stress was reached, the bond strength of the ECC specimens decreased at a lower slip rate than the concrete specimens. When confinement was added to the concrete specimens, the descending portion of the bond-slip slip curve was less brittle than when confinement was not present. This was also true for the ECC specimens, but to a lesser degree.

The ECC residual bond strengths were substantially higher than the residual concrete bond strengths. Additionally the ratio of residual bond strength to maximum bond strength was higher for ECC specimens.

One important observation is that the residual bond strength of ECC-UC-1.5 was lower than that of ECC-UC-1.0. This was unexpected since bond strengths are expected to increase with increasing c/d_b ratios. However, one explanation for the decrease in residual strength is that the separating crack that developed in ECC-UC-1.5, as previously discussed in Section 3.1 and shown in Figure 6, resulted in a lower residual bond capacity. Additional specimens are planned to further investigate the distinct behavior of ECC-UC-1.5.

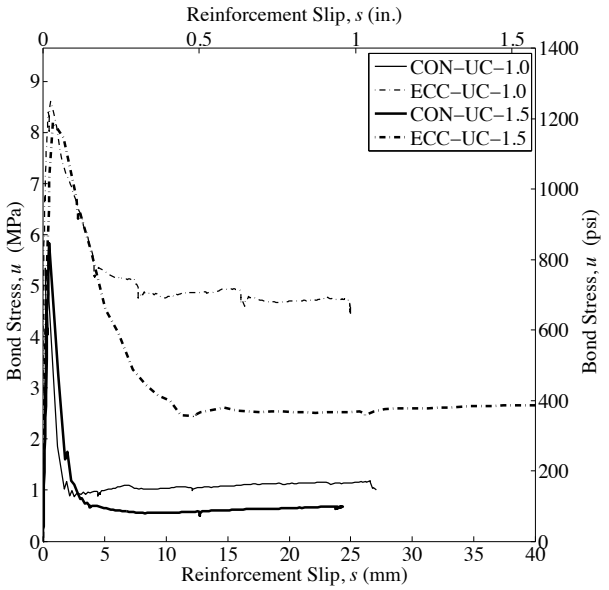

Figure 7 Bond Stress vs. Reinforcement Slip of Unconfined Specimens

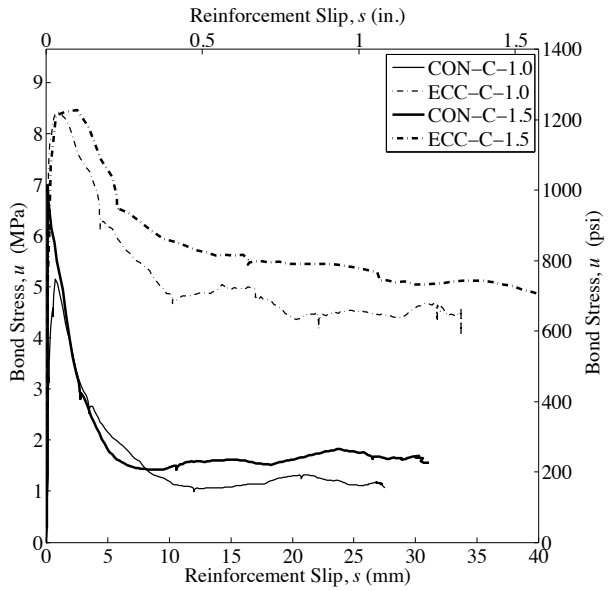

Figure 8 Bond Stress vs. Reinforcement Slip of Confined Specimens

4. CONCLUSIONS AND FUTURE WORK

4.1 Conclusions

Four variations of beam splice specimens were studied to examine the bond behavior in Engineered Cementitious Composites (ECC), one type of HPFRCC, as compared with traditional normal weight concrete. Eight beam specimens were tested in four-point bending with constant moment and shear regions. The parameters varied were cover to bar diameter ratios and amount of confinement in the splice region. Bond stresses were calculated from strain data, and reinforcement slip was measured using LVDTs attached to the reinforcement.

The ECC specimens had higher bond strengths than the concrete specimens in all of the experiments. Additionally, the concrete specimen failures were significantly more brittle since there was a more sudden drop in bond strength after the maximum bond stress was reached. Residual bond strengths were higher in ECC than concrete. Bond-slip data also showed that after the maximum bond strength was reached, bond strengths decreased at a lower slip rate for ECC than concrete.

4.2 Future Work

Additional specimens are being fabricated using two other HPFRCC mix types; a Hybrid Fiber Reinforced Concrete (HyFRC) which utilizes steel fibers and PVA fibers, and a High-Performance Fiber-Reinforced Concrete which uses steel fibers. These three mixes (ECC, HyFRC and HPFRC) represent a range of emerging materials that will help characterize bond in HPFRCCs.

Since the primary application of HPFRCC materials is for earthquake resistant construction, future experiments are planned to examine bond strength deterioration under cyclic loads. The results of these experiments will be used to develop theoretical bond-slip curves for different HPFRCC materials. These bond-slip curves will then be implemented in finite element programs to develop robust analytical models for HPFRCC materials.

Abstract: Reinforced concrete coupling beams with embedded structural steel sections are an alternative to diagonally-reinforced concrete coupling beams. Because prior testing has been conducted on relatively small steel sections, testing of large-scale specimens was conducted to validate analytical models used to determine the required embedment length. The test set-up included reversed-cyclic shear loading applied to the tip of a cantilevered coupling beam containing a structural steel section embedded into a concrete shear wall, which was simultaneously subjected to reversed-cyclic lateral loading to create alternating tension and compression fields across the embedment zone. To assess the degree of potential conservatism in the previously published embedment equations, tests were conducted on two composite coupling beams with varying embedment length, one beam with embedment length expected to result in good performance and a second beam with an embedment length of 75% of the first beam. Both test beams maintained shear coupling loads above 75% of the peak value up to a 6% rotation, although the beam with longer embedment displayed less strength degradation and less pinching.

1. INTRODUCTION

Reinforced concrete shear walls provide an efficient lateral system for resisting seismic and wind loads. Coupling beams connect adjacent colinear shear walls to create larger shear wall assemblages which more efficiently resist lateral loads. The coupling action of these beams reduces the overturning demand within individual wall piers, and imparts vertical forces to the walls via beam shear, thereby creating axial tension-compression couples between coupled wall piers. During significant seismic events, coupling beams are often the first elements to yield. For this reason, coupling beams act as fuses which dissipate earthquake energy through large inelastic rotations, and help control the magnitude and pattern of forces felt by the coupled walls.

ACI 318-11 code provisions require the use of diagonal reinforcement in reinforced concrete coupling beams when shear demand is high and length to depth ratio is low. Testing shows that beams constructed with this reinforcement maintain reliable strength during larger rotations (Naish et al, 2009). Such beams are frequently used in mid- and high-rise buildings in high seismic zones. Coupling beams are typically located between vertically stacked door or corridor openings, putting limitations on beam depth. The congestion associated with embedding diagonal reinforcement into boundary zones of reinforced concrete shear walls creates constructability challenges, thereby increasing construction time and cost.

The use of concrete-encased steel coupling beams provides a viable design alternative and potentially decreases congestion in the wall boundary zone. Embedded steel sections transfer coupling forces to shear walls through a bearing mechanism, which avoids the need for welded and bolted connections while benefiting from the ductility of properly-selected structural steel sections. Steel wide-flange sections encased in concrete are provided further stability against buckling, which results in increased beam ductility. The concrete encasement also provides fire-proofing for the steel beam.

2. BACKGROUND

2.1 Embedment Length

For reinforced concrete coupling beams with embedded steel sections, the strength of the beam-to-wall connection is dependent on the embedment length of the steel section. Adequate embedment length may be defined as the length necessary to create reliable transfer of forces from the beam to the wall without excessively damaging the wall. Mattock and Gaafar (1980) and Marcakis and Mitchell

(1982) developed load transfer models to determine the required embedment length. Although these embedment models govern the transfer of forces from unencased cantilevered steel sections to reinforced concrete columns, the mechanism is parallel to the transfer of forces from steel coupling beams to concrete shear walls.

The Marcakis and Mitchell (1980) and Mattock and Gaafar (1982) embedment models both assume a linear strain distribution in the embedment region, with a strain of ε_c = 0.003 at the outer face of the connection, as shown in Figure 1. A uniform magnitude stress block is used to approximate the bearing stress distribution at the front of the embedment region, while a parabolic stress-strain relationship (Hognestad, 1955) is used to determine the bearing stress distribution along the deeper portion. Based on the applied beam forces, equilibrium is achieved through iteration of the strain gradient. In lieu of iteration, simplifying assumptions were used to develop design equations. Because both embedment models were based on the same assumptions (leading to identical stress diagrams), use of the Marcakis and Mitchell (1980) and Mattock and Gaafar (1982) design equations yield nearly identical results.

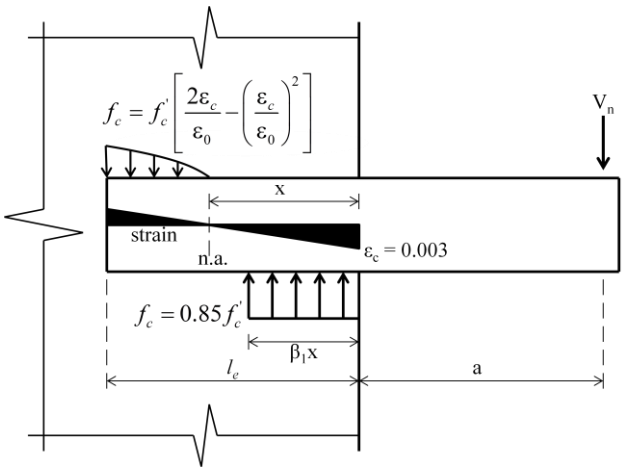

Figure 1. Embedment Model

Harries et al (2000) recommended that both the Marcakis and Mitchell (1980) and the Mattock and Gaafar (1982) embedment equations be modified to include the effects of concrete spalling at the face of the embedment. The Marcakis and Mitchell (1980) embedment equation modified to including spalling is as follows:

$$V_n = \frac{0.85 f_c' b(l_e - c)}{1 + 3.6\left(\frac{e}{(l_e - c)}\right)} \qquad (2.1)$$

where $e=a+(l_e - c)/2$. V_n is the ultimate beam load, a is the cantilever length, l_e is the embedment length, c is the distance of spalling, b is the effective width, and f'_c is the maximum compressive stress of concrete. The distance of spalling at the face of the connection is typically assumed to be equal to the depth of wall cover. During testing, Marcakis and Mitchell (1980) observed spalling of cover concrete to the outside of the column confining ties in the connection region, indicating load spreading to this effective width. The effective width, b, is thus taken as the width of the confined region, not to exceed 2.5 times the width of the embedded member.

The Mattock and Gaafar (1982) embedment equation modified to including spalling is as follows:

$$V_n = 4.5\sqrt{f_c'}\left(\frac{t}{b}\right)^{0.66} \beta_1 b(l_e - c)\left(\frac{0.58 - 0.22\beta_1}{0.88 + (a+c)/(l_e - c)}\right) \qquad (2.2)$$

where f'_c is in MPa, t is the wall thickness, b is the bearing width, equal to the flange width for wide-flange sections, and β_1 is the ACI stress block factor, defined as the ratio of the uniform stress block depth to the neutral axis depth.

Based on test results for shear-controlled concrete-encased steel coupling beams, Gong and Shahrooz (2001b) recommend computing the embedment length necessary to develop the full expected capacity of the composite coupling beam, including the effects of encasement on shear strength. Significant energy dissipation due to inelastic connection deformation occurred for members in which encasement was neglected when determining the member capacity for computing embedment length.

2.2 Embedment Detailing

As shown in Figure 2, the 2010 AISC *Seismic Provisions for Structural Steel Buildings* (referred to as the "2010 AISC Seismic Provisions" from this point forward) require the use of auxiliary transfer bars (welded to the beam flanges) and face bearing plates within the embedment zone

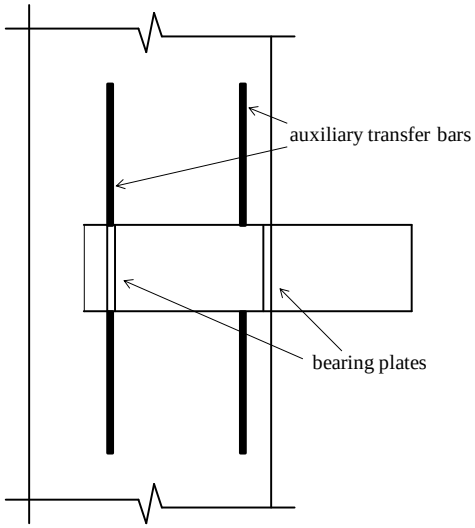

Figure 2. Embedment Detailing Requirements of 2010 AISC Seismic Provisions

of the embedded steel section. Transfer bars are required to be attached via welding to the top flange and bottom flange at the front and back of the member. A pair of web stiffener plates are required at the location of the back transfer bars, and a pair of face-bearing plates are required at the beam-wall interface.

The role of the auxiliary transfer bars is to aid in the transfer of load from the coupling beam to the shear wall. These bars are required to be developed into the shear wall, enabling the transfer of load via bond. The bearing plates also provide an additional force-transfer mechanism by allowing the formation of a diagonal strut between the two plates. These plates also act as web stiffeners, since the welded transfer bars create concentrated loads on the steel section.

3. TEST SET-UP AND SPECIMEN DESIGN

Because prior testing was often conducted on small-scale specimens (Gong and Shahrooz, 2001a; Gong and Shahrooz, 2001b), this research study strives to assess the reliability of the embedment equations at the largest scale possible based on laboratory constraints (determined to be ~one-half scale). Prior tests were often conducted for steel sections embedded into either uncracked (sometimes unstressed) walls or reaction blocks (Harries et al, 1993; Harries et al, 1997; Gong and Shahrooz, 2001a; Fortney, 2005). Because local stress/strain fields could impact the required length of embedment, the test was designed to include a wall subjected to lateral loading and overturning moment such that the wall strains/stresses at the embedment location represented realistic conditions, as shown in Figure 3.

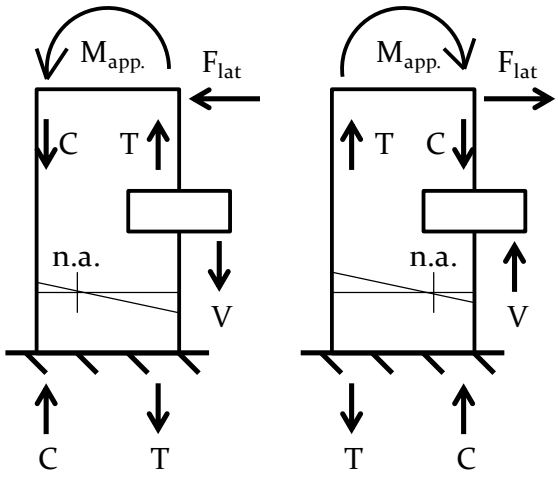

Figure 3. Wall Strains at Embedment Zone

The overall test set-up is shown in Figure 4. The test specimen included a reinforced concrete shear wall with two one-half-length composite coupling beams (one on each side of the wall), which were tested individually. The only difference between the two coupling beams was the embedment length. The point of load application represented the midpoint, which is also an inflection point, in a full-length coupling beam.

To generate wall overturning moment, two 1780-kN (max.) actuators with +/- 457 mm stroke were used to apply equal and opposite vertical loads. The wall lateral shear force (and additional moment) was applied by a 1335-kN (max.) actuator with +/- 305 mm stroke. To support the lateral reaction from the 300-kip actuator, reaction blocks were stacked, grouted at the interfaces, and post-tensioned to the laboratory strong-floor with 31.75 mm diameter high-strength Dywidag rods. The "top beam" in Figure 4 refers to a thickened portion at the top of the wall (poured continuously with the upper wall) constructed to facilitate anchorage to the loading beam. The top beam and footing were post-tensioned to the steel section at the top of the specimen and the laboratory strong floor, respectively.

3.1 Coupling Beams

Figure 5 shows cross-sections for the beams (same for both) and the shear wall. The embedded steel section was a (AISC) W12x96 (d = 322.6 mm, t_w = 14.0 mm, b_f = 309.9 mm, and t_f = 22.9 mm) with flanges trimmed to a width of 139.7 mm, which is an approximation of a one-half-scale (AISC) W24x250 (d = 668.0 mm, t_w = 26.4 mm, b_f = 335.3 mm, and t_f = 48.0 mm). The use of a built-up section for the embedded member was also considered in order to achieve precise scaling. However, due to differences in fabrication and material properties for wide flanges and built-up sections, the use of a built-up test section to represent a WF prototype section was deemed undesirable.

The aspect ratio of the test beams was 3.33, which is typical for office buildings in the U.S. Due to the high aspect ratio, the beams were flexure-controlled. Because the contribution of concrete shear strength was not essential to ensure flexure-critical behavior, coupling beam stirrups (6.35 mm dia. @ 76.2 mm spacing) were detailed as two U-bars rather than individual hoops for ease of constructability. Longitudinal bars (9.525 mm dia.), used as placeholders for shear reinforcement, were not developed in the shear wall, thereby contributing no flexural strength to the coupling beam to better control the moment transferred to the embedment region.

Because the beams were flexure-controlled, the maximum expected shear load was obtained by dividing the ultimate flexural capacity by the cantilever length (including wall spalling, i.e. wall cover). This approach assumes that the intended yield and failure mechanism is entirely within the beam rather than the connection, meaning that beam failure occurs at the face of the embedment rather than in the connection. Based on the maximum expected shear load, the required embedment length was determined using both the Marcakis and Mitchell (1980) and Mattock and Gaafar (1982) embedment equations corrected to include the effects of wall spalling per the recommendation of Harries et al (2000).

The 2010 AISC Seismic Provisions for Structural Steel Buildings supports the use of either an AISC-based or ACI-based approach to determine the flexural capacity of a concrete-encased steel coupling beam. When using the AISC-based approach, the ultimate flexural capacity of the beam is computed based on a fully plastic steel section and a uniform stress block for concrete in compression. The ACI-based approach requires strain compatibility of the cross-section. In this case the steel section was converted into an equivalent area of reinforcement and reinforced concrete beam analysis (strain compatibility fiber analysis) was performed using BIAX software (Wallace and Ibrahim, 1996) to determine the ultimate capacity. The steel properties of the A992 wide-flange used in all analyses were obtained from the test results of Liu et al (2007), which were used in the 2005 AISC Seismic Provisions. These test results provide a mean and standard deviation, as well as a maximum and minimum, for actual yield stress, F_y, and ultimate tensile stress, F_u, of structural steel wide flange sections tested under cyclic loading. For the AISC plastic analysis approach, values for both F_y and F_u were considered.

Both the AISC and ACI methods used to determine beam flexural capacity assume monotonic loading and the development of full composite action (i.e. no slip) between the concrete and steel. Since cyclic loading was applied and shear studs were not provided, these analysis methods were expected to over-predict the actual member capacity, which is conservative for computing minimum embedment lengths.

Based on the range of required embedment lengths obtained from the range of structural steel properties (Liu et al 2007) and the two analysis methods (AISC-based and ACI-based), shown in Table 1, a conservative embedment length of 813-mm was selected for the first coupling beam. An embedment length of 610-mm was selected for the second coupling beam, in order to assess the degree of conservatism inherent in the embedment equations and better understand the limitations of the connection. From this point forward, the beams with 813-mm and 610-mm embedment lengths are referred to as Beam 1 and Beam 2, respectively.

3.2 Shear Wall

Figure 5(b) shows the shear wall cross-section. ACI 318 Chapter 21 and Appendix A (strut-and-tie modeling) code provisions were used to guide the design of the shear wall. Within the embedment zone, bearing forces were assumed to transfer into wall vertical reinforcement. Because the bearing forces were computed to be larger for the section with shorter embedment length, local stresses in wall vertical boundary bars were expected to be larger than those associated with the longer embedment length. For this reason, 14#7 (22 mm dia.) wall verticals were used on the side with Beam 2, and 14#6 (19 mm dia.) wall verticals were used on the side with Beam 1. Horizontal and vertical web bars were selected to satisfy the ACI 318-11 code minimum.

An intermediate level of wall boundary confinement is representative of a mid-to-upper-level story for a high-rise reinforced concrete building in a zone of moderate to high seismic risk. Transverse reinforcement at the wall boundary was provided to satisfy provisions for an intermediate level of boundary confinement (often referred to as an "ordinary boundary element") per ACI 318-11 Section 21.9.6.5, which requires a 203.2 mm maximum spacing. Assuming 12.7 mm hoops and ties at 203.2 mm spacing for the prototype suggested 6.35 mm hoops and ties at 101.6 mm spacing.

ACI 21.9.6.5 also requires that $h_x \leq 355.6$ mm (per ACI 21.6.4.2 as mandated within ACI 21.9.6.5), which scaled to $h_x \leq 177.8$ mm. h_x is defined as the maximum center-to-center spacing of cross-ties or hoop legs. Two cross-ties were used for the test specimen in the short direction as shown in Figure 5; therefore, $h_x = 181.0$ mm for the 22.225 mm (dia.) verticals (deemed close enough to 177.8 mm). A central cross-tie was also needed in the long direction. Discontinuous 12.7 mm (dia.) vertical bars were used as placeholders for this cross-tie, but were not embedded into the footing or the concrete top beam in order to avoid adding wall flexural strength.

For horizontal and vertical web bars the code minimum reinforcing ratio is ρ=0.0025 per ACI 318-08 Section 21.9.2.1. At one-half-scale, 19.05 mm (dia.) @ 304.8 mm spacing (ρ=0.0031) scaled to 9.525 mm (dia.) @ 152.4 mm spacing (ρ=0.0031).

3.3 Embedment Detailing

Figure 6 and Figure 7 show the wall boundary detailing at the connection zone. Due to the presence of the embedded steel section, standard hoops and cross-ties could not be placed. In order to maintain wall boundary confinement through the depth of the embedded beam, pre-drilled holes through the web of the steel section allowed the use of threaded rods and steel plates to achieve the desired level of confinement.

Figure 6. Photo of Embedment Detail

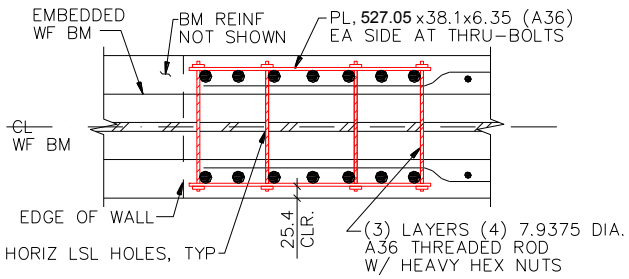

Figure 7. Drawing of Embedment Detail

Despite the detailing requirements of the 2010 AISC Seismic Provisions, auxiliary transfer bars and bearing plates (Figure 2) were not provided in the embedment zone. Transfer bars and bearing plates provide load transfer mechanisms in addition to bearing. This study is intended to assess the reliability of the embedment equations without the added benefit of additional load-transfer mechanisms.

4. TESTING PROTOCOL

The testing protocol is shown in Figure 8. The coupling beam actuator controlled the test. The three wall actuators were slaved to this actuator based on the force ratios shown in Figure 8. For Beam 1 the wall forces were large enough to exceed the wall cracking moment at the embedment zone. For Beam 2 the wall forces were 2.5 times larger than Beam 1 in order to approach wall yield at the embedment zone. Larger wall loads in combination with shorter embedment length were expected to create the more critical scenario for the coupling beam connection.

The calculated shear force at flexural yield, $V@M_y$, (based on BIAX strain compatibility fiber analysis using the average steel yield stress, F_y = 379 MPa, and the average steel ultimate stress, F_u = 502 MPa from Liu et al (2007)) for the composite coupling beam was computed to be 712 kN. Load-controlled cycles were performed at increments of $(V@M_y)/8$, $(V@M_y)/4$, $(V@M_y)/2$, and $3(V@M_y)/4$ (89 kN, 178 kN, 356 kN, and 534 kN). For the remainder of this paper the term "rotation" refers to the chord rotation of the cantilevered coupling beam, which was computed as the beam displacement at the point of load application divided by the 762 mm cantilevered length. Based on the observed stiffness at $3(V@M_y)/4$, the yield rotation was estimated and the test proceeded as displacement-controlled. For Beam 1 the yield rotation was estimated to be 1.67%, and subsequent cycles were carried out at rotations of 1.67%, 2.25%, 3.0%, 4.0%, 6.0%, 8.0%, 10.0%, and 13.0%. Despite very little strength degradation, the test was stopped at 13.0% rotation, which was deemed larger than any practical performance goal.

The difference in stiffness between the positive (upward) and negative (downward) loading direction was significant for Beam 2. Therefore, during load-controlled cycles, loading in the negative direction was carried out under displacement-control based on the actual displacement for the positive direction (which was load-controlled). Yield rotation in the positive direction was estimated to be 0.6%, and the displacement-controlled cycles were carried out at rotations of 0.67%, 1.0%, 1.5%, 2.0%, 3.0%, 4.0%, 6.0%, 8.0%, and 10.0%.

5. TEST RESULTS

5.1 Observed Damage

For both beam tests, damage concentrated primarily at the beam-wall interface. Figure 9 shows damage photos for both tests after the completion of loading cycles at 3% and 6% rotation. After 3% rotation Beam 1 showed significant cracking but minimal spalling at the interface. Comparatively, Beam 2 showed more spalling and wider cracking at the interface. After the cycles at 6% rotation, significant spalling was evident for both beams, with Beam 2 displaying more extensive spalling than Beam 1. Aside

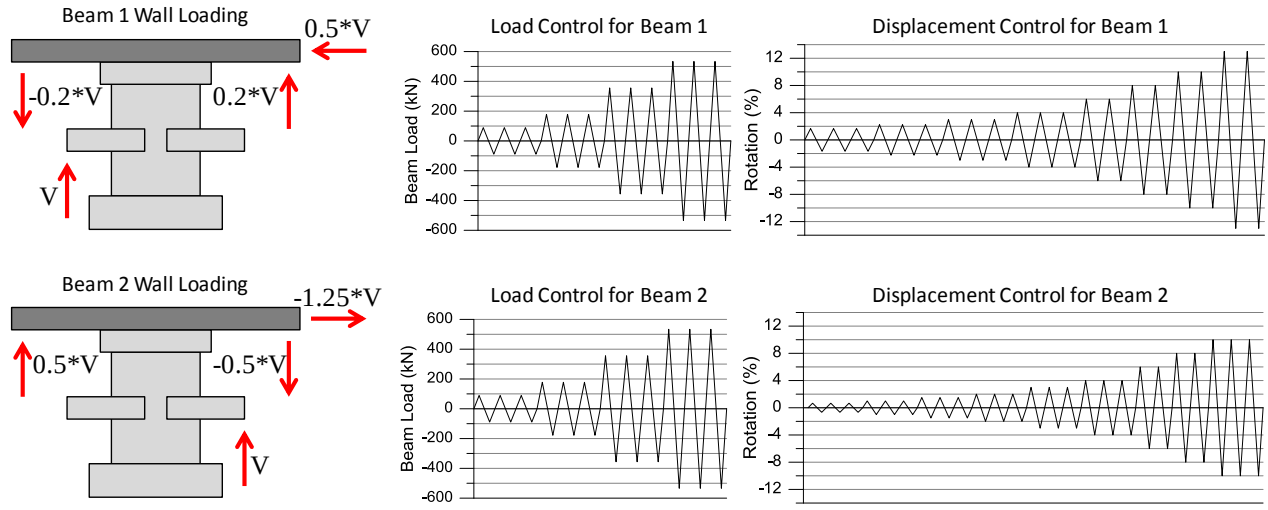

Figure 8. Testing Protocol

Beam 1 after 3% rotation *Beam 2 after 3% rotation* *Beam 1 after 6% rotation* *Beam 2 after 6% rotation*

Figure 9. Damage Photos

from the damage at the beam-wall interface, only minor hairline cracking was observed in the beam span for both tests. Cracking in the embedment region was evident during both tests, and was more extensive for Beam 2; however, there was no spalling in the embedment region during either test.

Although significant outward slip of the steel section was observed during the test, in actual structures, outward slip of the steel section is restrained at some level by a floor slab as well as embedment into an adjacent shear wall, which creates axial load on the coupling beam. Because axial load is dependent on structural lay-out, geometry, etc, it was not simulated for this test due to the lack of a specific prototype structure.

5.2 Load-Displacement

Figure 10 shows load-displacement plots for Beam 1 and Beam 2. Both plots display large ductility with minimal strength degradation. The plot for Beam 1 is symmetric, with very minimal strength degradation up to 13% rotation. The plot for Beam 2 displays more pinching, greater strength degradation, and noticeable asymmetry, including reduced capacity in the negative loading direction. The pinching is consistent with the formation of a gap between the steel flange and the concrete in the connection zone, which was observed during testing.

Although the Beam 2 embedment length was initially designed to be less than required, it is interesting to note that based on the observed capacity of the test beams and the as-tested concrete compressive strength of 51.0-MPa the minimum required embedment length computed for both the Marcakis and Mitchell (1980) and Mattock and Gaafar (1982) embedment equations is 584 mm, suggesting that the provided 610 mm embedment length for Beam 2 is adequate.

The asymmetry in the load-displacement plot for Beam 2 is attributable to the stress field created at the embedment zone due to wall loading. During positive (upward) beam loading, the wall loads created a vertical compression field in the embedment region, while a tension field was induced in the embedment region of the wall during negative (downward) beam loading. The Beam 2 connection was softer and also developed less capacity when in tension compared to compression. This effect appears less pronounced for Beam 1, due to lower-magnitude wall loading.

Throughout testing of Beam 1, a correction to the measured displacement was made to account for beam displacement due to wall rotation. This was also done for the early phases of Beam 2 testing; however, the data were not reliable and the idea of correcting for this was abandoned. Test data for Beam 1 were adjusted to neglect the correction in order to provide a direct comparison with Beam 2 test data in Figure 10. For this reason, the load-rotation plot for Beam 1 shows rotation levels that differ slightly from those used to control the test.

The performance of both coupling beams was favorable, characterized by minimal strength degradation at large ductility demands and observed damage concentration

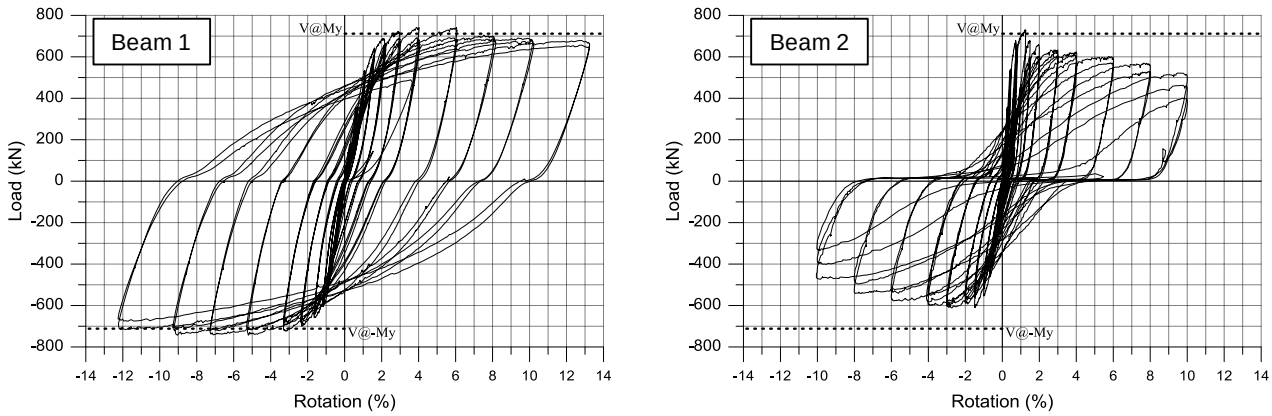

Figure 10. Load-Displacement

(indicative of plastic hinge formation) at the beam-wall interface. Favorable performance of these two members suggests that in this particular instance the embedment length was adequate to transfer the loads via bearing without the added benefit of additional force-transfer mechanisms. Changes to the 2010 AISC Seismic Provisions that would eliminate the need for face bearing plates and auxiliary transfer bars may be considered, although additional testing is needed to provide further evaluation.

5.3 Backbone Curves

Backbone curves are show in Figure 11. The backbone curves for the test data are comprised of load and displacement pairings at the peak of the first cycle of each loading increment. Note that the AISC Seismic Provisions do not explicitly provide backbone parameters. The backbones curves shown in Figure 11 were generated by combining AISC recommendations for stiffness, flexural capacity, and required ductility demand. To determine the initial stiffness for concrete-encased steel coupling beams, provisions H4.3.1 and H5.3.1 in the 2010 AISC Seismic Provisions refer to ACI 318-11 Chapter 10. Presumably this is a reference to ACI 318-11 Chapter 10 Section 10.10.4.1 which specifies an effective moment of inertia of $0.35I_g$ for beams, where I_g is the gross moment of inertia of the concrete section. Neither ASCE 41-06 nor FEMA 356 provide the rotational ductility parameters for steel coupling beams that are needed to generate backbone curves for modeling. However, section H5.5c of the seismic provisions indicates that steel coupling beams need not be designed to exceed a rotation of 0.08 radians (8.0%). The AISC backbone plots shown in Figure 11 were based on an initial stiffness of $0.35E_cI_g$ and a loss of all load-carrying capacity at 0.08 radians.

For the AISC backbone curves, the flexural capacity of the composite section was computed using a plastic analysis approach, including a uniform stress block for concrete in compression. This approach is supported by section H4.2.1 in the 2010 AISC Seismic Provisions. A plastic stress of F_y, the design yield stress of steel, was used. For the AISC expected capacity indicated in Figure 11, the plastic stress of structural steel was taken as R_y*F_y, where R_y is 1.1 for F_y = 345 MPa (50 ksi) in keeping with standard seismic design. The AISC backbone curves in Figure 11 considered fixity at the beam-wall interface as well as fixity within the connection, i.e. at $L_e/3$ from the beam-wall interface as suggested by Harries et al (2000) for modeling purposes. Moving the effective point of fixity to $L_e/3$ from the interface increases the effective cantilever length, thereby reducing the shear-carrying capacity of a flexure controlled-section.

Based on good agreement with test results, it appears reasonable to compute the design flexural capacity of composite coupling beams using the AISC approach. Referring again to Figure 11, the capacity of the AISC backbone curve matches well with the Beam 1 backbone. The AISC with fixity at $L_e/3$ backbone agrees well with the observed performance for Beam 2 negative (-), a case for which larger applied wall moment produced larger tension across the connection compared to Beam 1. Beam 2 positive (+) reaches a capacity that matches the AISC backbone but strength degrades to a residual capacity that better matches an AISC with fixity at $L_e/3$ backbone. The strength degradation is likely a result of the behavior in the negative loading direction, i.e. local yielding of vertical wall reinforcement allows the formation of gapping between the flange of the steel section and the surrounding concrete. Reliable strength for both positive and negative loading should be based on a fixity point at $L_e/3$ inside the beam-wall interface, whereas peak beam load for positive loading should be based on a fixity point at the depth of concrete spalling (wall edge minus concrete cover). More research is needed to further quantify the relationship between effective fixity and wall tension/compression across the connection.

Referring again to Figure 11, because the expected AISC capacity (including R_y) is slightly larger than the observed capacity for both beams in both loading directions, using the expected AISC capacity to determine the embedment length is slightly conservative and recommended for design. Note that for cases in which the beam capacity is reduced in the negative direction, the larger

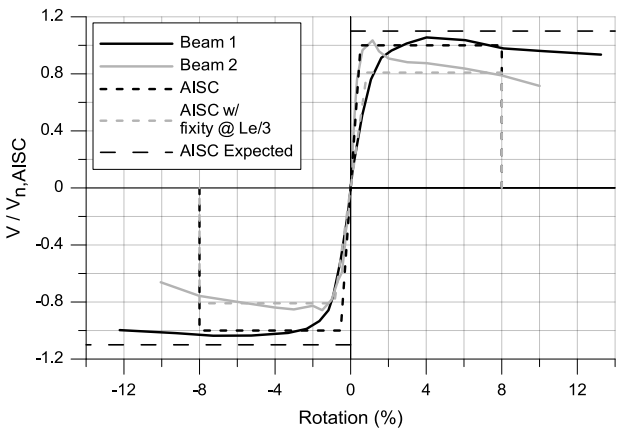

Figure 11. Backbone Curves

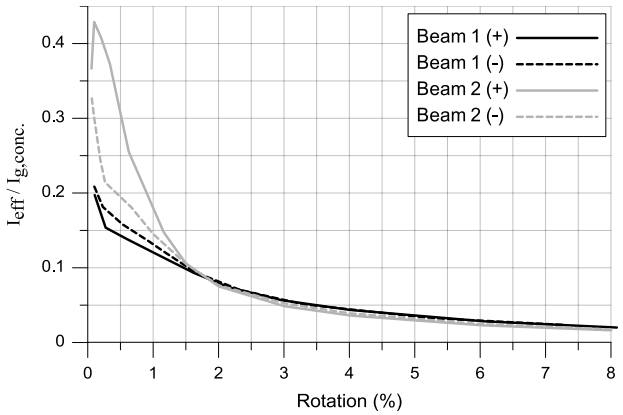

Figure 12. Effective Secant Stiffness

capacity in the positive direction governs the computation of the required minimum embedment length.

5.4 Effective Secant Stiffness

The effective secant stiffness was evaluated using the elastic stiffness relationship for a point load on a fixed-end cantilever, re-arranged to be expressed in terms of an effective moment of inertia, normalized by the gross moment of inertia. Figure 12 shows effective secant stiffness plots generated based on $E_cI_{g,conc.}$, where $I_{g,conc.}$ is the moment of inertia for the gross concrete section neglecting steel, and E_c is the elastic modulus of concrete. The plots in Figure 12 are based on data at the peak of the first cycle at each load/displacement increment. For comparative purposes, the absolute value of peak rotation is used, putting all data in the first quadrant.

Referring to Figure 12, there is minimal difference in the effective secant stiffness beyond rotations of about 1.5%. For rotations less than 1.5%, the difference between positive and negative stiffness values for Beam 2 is attributable to the embedment stresses in the wall, which produce compression for positive loading and tension for negative loading. The effective stiffness appears largest for Beam 2 loaded in the positive direction. Based on good agreement with the AISC backbone in Figure 11, using an initial stiffness of $0.35E_cI_{g,conc.}$ appears reasonable for Beam 2 positive (+). Referring to Figure 12, it appears reasonable to use an initial stiffness of $0.2E_cI_{g,conc.}$ for other cases, i.e. Beam 1 and Beam 2 negative (-). It also appears reasonable to use an initial stiffness of $0.35E_cI_{g,conc.}$ with fixity at $L_e/3$ (Figure 11) for cases with tension across the connection (i.e. in the negative loading direction).

Note that the larger negative stiffness for Beam 2 compared to Beam 1 may be somewhat misleading. Wall loading creates rotation that generates beam tip displacements that oppose the measured beam displacements reflected in Figure 12. Therefore, the relative cantilever displacement includes the measured displacement plus any additional opposing displacement due to wall rotation. Because the plot in Figure 12 does not reflect the effect of wall rotation, the stiffness values appear larger. Since the wall loads for Beam 2 were 2.5 times larger than for Beam 1, the effect is more pronounced for Beam 2. Due to local deformations in the embedment zone, obtaining reliable data for wall rotation was difficult; however, measured wall deformations were small compared to beam deformations, suggesting that the effect of wall rotation on beam tip displacements was relatively minor.

6. CONCLUSIONS

A testing program was undertaken to assess the performance of concrete-encased steel coupling beams embedded into reinforced concrete shear walls at large-scale and for realistic loading and boundary conditions. Moment and shear load were applied to the wall to generate stress/strain fields in the coupling beam embedment zones that were representative of conditions in actual structures; simultaneous reversed, cyclic loading was applied to the coupling beams. Two tests were conducted on structural steel wide-flange sections to investigate the role of embedment length and detailing on beam strength, stiffness, and deformation capacity. The embedment models proposed by Marcakis and Mitchell (1980) and Mattock and Gaafar (1982) were used to compute the required embedment length needed to transfer bearing forces from the beam to the wall. The embedment length for Beam 1 was selected to represent a conservative design, with longer embedment, whereas the embedment length for Beam 2 was selected to be a minimum value (75% of the value used for Beam 1). Wall loads were also varied, with the wall moment for the shorter embedment (Beam 2) approaching the wall yield moment in the embedment region, or approximately 2.5 times larger than the wall moment for Beam 1. Excellent performance was observed for Beam 1, with beam rotation capacity exceeding 10% with negligible strength loss. Damage at the beam-wall interface led to lower strength and deformation capacity for Beam 2, and also more pinching of the load-deformation response. Based on the study, the following conclusions were reached:

1) The design moment strength of concrete-encased steel coupling beams may be computed using a plastic section analysis in which the plastic steel stress is taken as the design yield stress, F_y, concrete in compression is modeled as a uniform stress block, and concrete tensile strength is neglected.
2) The effective point of fixity may be taken at the depth of wall spalling (i.e. wall cover) at the beam-wall interface for long embedment and lower applied wall moment (Beam 1). For Beam 2 (positive beam load), with shorter embedment and larger wall demands, the point of fixity varied between the depth of wall spalling (concrete cover) at yield to $L_e/3$ inside the beam-wall interface at 6% rotation. It appears that damage at the beam-wall interface for negative loading results in subsequent strength loss for positive loading. Therefore, reliable strength for both positive and negative loading over a range of plastic rotations typically expected for coupling beams (up to 6% rotation) should be based on a fixity point at $L_e/3$ inside the beam-wall interface, whereas peak beam load for positive loading should be based on a fixity point at the depth of concrete spalling (wall edge minus concrete cover). Two additional tests will be conducted to further assess these issues.
3) Embedment performance was adequate for both beam tests; therefore, either the Marcakis and Mitchell (1980) or Mattock and Gaafar (1982) embedment equations, modified to account for spalling as recommended by Harries et al (2000), may be used to compute the minimum required embedment length of the embedded steel section.

The embedment equation in the 2010 AISC Seismic Provisions is based on the Mattock and Gaafar (1982) embedment equation. Although Beam 2 was initially designed to examine behavior for an embedment length slightly less than required, the provided embedment length actually satisfied embedment equations based on the as-tested concrete compression strength and the observed beam capacity. For flexure-controlled sections, the expected shear force used to compute the minimum required embedment length may be determined based on the expected flexural capacity and effective point of fixity. The calculation for the expected flexural capacity differs from the calculation of the design flexural capacity in that the expected yield stress, R_y*F_y (with R_y taken as 1.1 for F_y = 345 MPa = 50 ksi), is used as the plastic stress.

4) The initial bending stiffness of a concrete-encased steel coupling beam depends on the stress/strain field across the connection. The effective bending stiffness was $0.35E_cI_{g,conc.}$ for Beam 2 positive (+), with the larger applied wall moment creating compression across the connection. The effective bending stiffness was $0.2E_cI_{g,conc.}$ for other cases, where $I_{g,conc.}$ is the moment of inertia computed for the gross concrete section.
5) The 2010 AISC Seismic Provisions require the use of auxiliary transfer bars welded to the flange of the embedded steel section and bearing plates welded near the end of the embedded steel section as well as at the beam-wall interface. The steel sections tested in this study did not use transfer bars and face-bearing plates; however, sufficient wall boundary vertical steel was provided to satisfy load paths for bearing forces. Test results indicated favorable performance for these members, suggesting that in this particular instance the embedment length was adequate to transfer the loads via bearing without the added benefit of additional force-transfer mechanisms. Changes to the 2010 AISC Seismic Provisions that would eliminate the need for face bearing plates and auxiliary transfer bars may be considered. More testing is needed to provide further evaluation.

Abstract: Seismic design philosophy emphasizes that structures should be able to deform under repeated cyclic loading yet not sustain severe damage and maintain structural stability. However, reinforced concrete structures built prior to the introduction of new seismic codes are susceptible to severe structural damage, particularly the columns. Poorly confined columns subject to cyclic loading have repeatedly demonstrated shear failure, resulting in reduced axial load carrying capacity and creating a discontinuous load path. It is believed that beam-slab subsystems, being an integral load transfer component in a structure, could help mitigate collapse by load redistribution in event of a support failure. This paper presents the results from tests conducted on two 1/3rd-scale pre-1960's designed beam-slab subsystems under simulated column removal at corner and center-edge column locations. Performance of the specimens was evaluated based on the load deflection relationship, post yield behavior, and observed damage to the specimen.

1. INTRODUCTION

1.1 Background

Reinforced Concrete (RC) slabs are an integral part of a structure and are required to transfer gravity loads to columns, shear walls, or beams. In modern design codes, e.g. ACI 318 (2011), slabs are designed to carry gravity and lateral loads through flexure and shear. Floor level slabs in buildings are particularly important service load carrying components and have been the focus of study by several researchers. Several studies (e.g. Hopkins and Park, 1971; Hung and Nawy, 1969; Park 1970 and 1971; Christiansen and Frederiksen, 1983; Guice et. al. 1989; Muthu et. al. 2006) have been performed to understand the behavior of slabs and the effect of membrane forces on the ultimate load carrying capacity. In particular prior efforts have compared experimental ultimate loads to predictions of Yield Line Theory (Johansen, 1962 and 1972). It has been suggested by researchers that the load enhancement realized via membrane effects could be used as a secondary load carrying mechanism to prevent progressive collapse after initial failure (e.g. Hawkins and Mitchell, 1979; Mitchell and Cook, 1984).

Owing to the importance of the beam-slab subsystem in mitigating structural failure, it is important to understand its performance under different loading scenarios. Several researchers have performed numerical and analytical studies on progressive collapse (e.g. Alashker et al., 2010; Alashker and El-Tawil, 2010 and 2011; Alashker et al. 2011; Mohamed, 2009; Bao et al., 2008; Sasani and Kropenlnicki, 2008; Sadek et al., 2011), however, only a few studies have been conducted on older RC structures (e.g. Sasani et al. 2007; Sasani and Sagiroglu, 2010; Sasani, 2008; Sasani et. al., 2011). Though these studies indicate the beam-slab subsystem demonstrates stable structural response under different support failure scenarios, they fail to investigate the role played by the beam-slab subsystem in mitigating structural collapse after initial support failure. To study and mitigate the collapse risk of older RC construction, it is necessary to understand the performance of this critical subsystem under a support failure scenario. It is envisioned that the large deflections and ensuing load redistribution that occur when a slabs support fails may help minimize the potential for system level failure under extreme seismic loading conditions.

1.2 Scope of Study

To understand and mitigate structural collapse of older construction, it is necessary to study the behavior of beam-slab subsystems designed based on older design codes. This paper describes the results obtained from an experimental investigation of two 1/3rd scale beam-slab subsystems under simulated support failure at different locations. The specimens were evaluated based on their load deflection behavior, post yield behavior and observed damage due to simulated column failure.

2. EXPERIMENT DETAILS

Two four panel (2x2 configuration) reinforced concrete specimens were constructed and tested under simulated column failure. Failure of three corner support location was

simulated on the first specimen, and failure of two center-edge columns were simulated on the second specimen.

2.1 Details of The Specimens

Specimen details were based on review of older construction typically found on the West coast of the United States and in consultation with a professional practice committee (2010). Each specimen was 6.45 m in both directions with supports at every 3.05 m. Spandrel beams, 7.62 cm x 30.48 cm (width x height), were present on two adjacent edges on specimen 1 and on one edge on specimen 2. Drop panels were provided at each support location as commonly observed in older construction. Both specimens were supported at nine support locations, i.e. a 3x3 support configuration, or a 2x2 panel configuration. Figure 1 (a) and (b) present a schematic of specimens 1 and 2, respectively and the corresponding test locations. Specimen 1 was tested at three corner support locations, namely (i) beam-beam corner, (ii) slab-slab corner, and (iii) beam-slab corner. Specimen 2 was tested at two center-edge support locations, namely (i) slab edge, and (ii) beam edge as shown in Figure 1 (b).

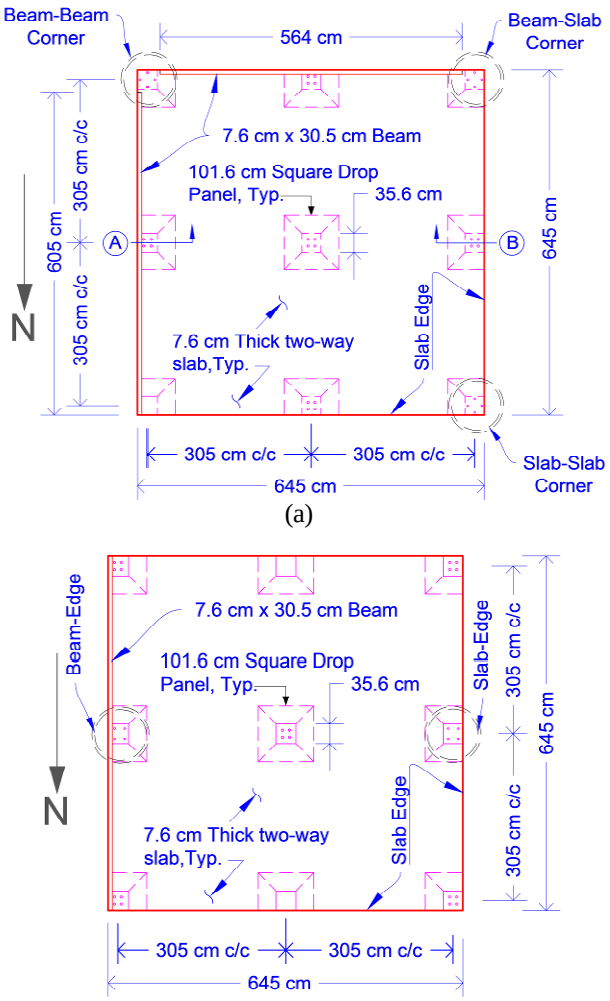

Figure 1 : Schematic of the test specimens, (a) plan view of specimen 1, and (b) plan view of specimen 2.

It is to be noted that in specimen 1, spandrel beams were curtailed, where present, near the test locations to facilitate mounting of actuators.

Both specimens were cast in place using a single pour of Type II concrete. Day of test uniaxial compressive strengths were 45.4 and 38.0 MPa for specimen 1 and 2, respectively. Reinforcement in the slab was provided using Grade 40 - M10 (9.52 mm diameter, 275 MPa) deformed bars and Grade 60 - M13 (12.7 mm diameter, 415 MPa) deformed bars were used for the spandrel beam longitudinal reinforcement. Grade 36 - M6 (6.3 mm diameter, 250 MPa) smooth rebar were used to provide shear stirrups on the spandrel beam at 12.7 cm spacing on center. Figures 2 and 3 provide a schematic of the slab and beam reinforcing in specimen 1, respectively.

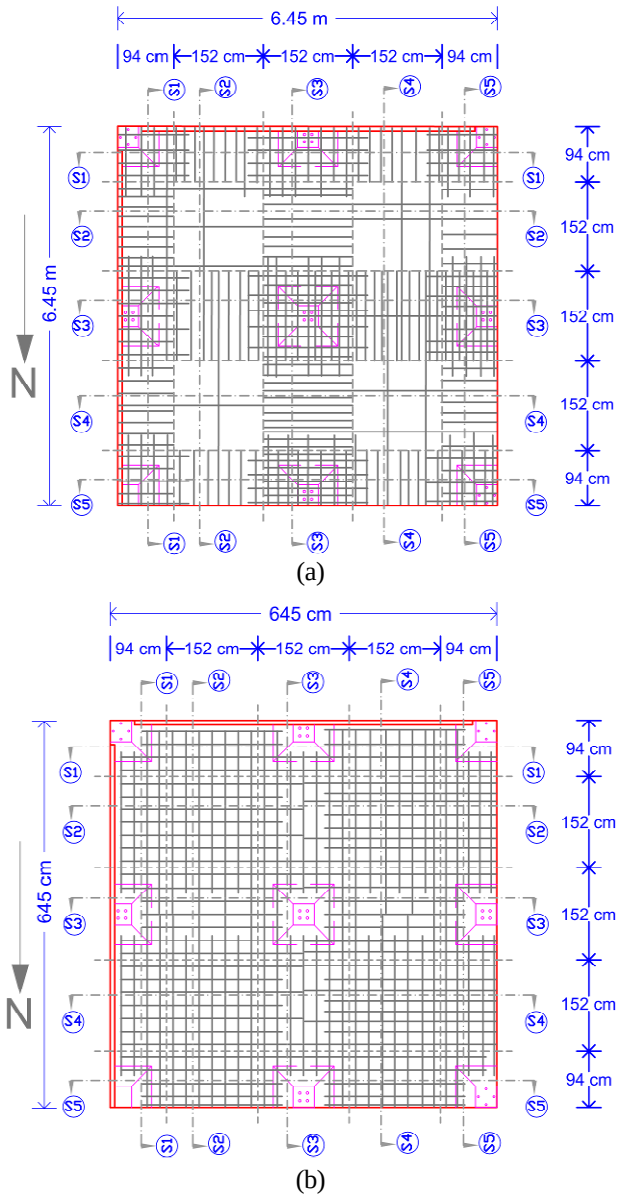

Figure 2 : Reinforcement detail of slab: (a) top rebar and (b) bottom rebar (refer to Table 1 for reinforcing ratios of top and bottom steel at cross sections S1-S5).

Other reinforcement details including, curtailment; rebar spacing; embedment details were provided based on ACI-318 (1956). A summary of slab reinforcing ratios is provided in Table 1.Reinforcing details in specimen 2 were similar to specimen 1. Additional details of the specimens may be found in test reports by Prasad and Hutchinson (2012).

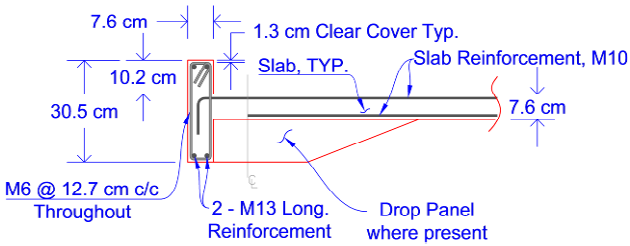

Figure 3 : Schematic of beam reinforcement detail.

Table 1: Summary of reinforcing steel ratios at different sections of specimen 1

	Top Reinforcing Ratio, ρ(%)	Bottom Reinforcing Ratio, ρ(%)
S1	0.51 - 0.66	0.51 - 0.59
S2	0.00 - 0.15	0.51 - 0.59
S3	0.51 - 0.88	0.51 - 0.59
S4	0.00 - 0.73	0.51 - 0.59
S5	0.51 - 0.66	0.51 - 0.59

2.2 Test Setup and Loading Protocol

Specimens were elevated above the reaction floor using concrete pedestals to provide sufficient clearance for load cell placement, inspection and push down. Figure 4 shows a schematic of the test setup for specimen 2.

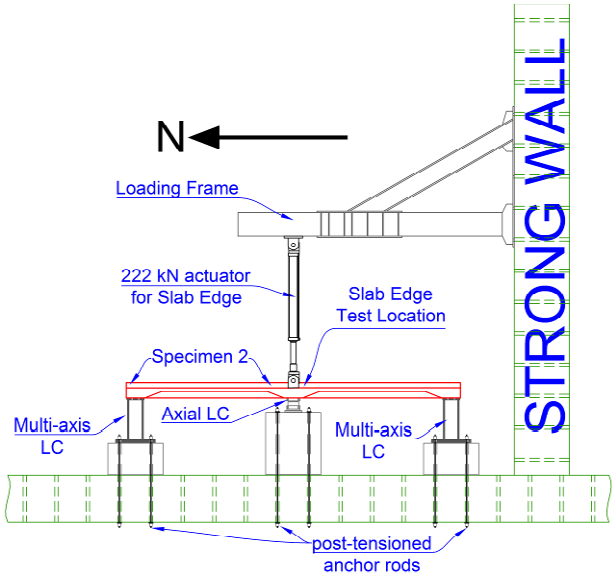

Figure 4 : Profile view of specimen 2 showing load cells at support locations and actuator for push down. Note: The axial load cell below the actuator was removed before the push test. (LC = load cell).

Both specimens were initially loaded under a uniform gravity load of 4.31 kN/m^2, which comprised of 3.35 kN/m^2 of uniform load to simulate prototype mass and 0.96 kN/m^2 to represent a uniform live load. This uniform gravity load was applied using concrete blocks, which were directly poured on specimen 1, and subsequently reused on specimen 2.

Specimens were tested under quasi-static push, in displacement control at the simulated column failure locations using a 222 kN actuator. Each location was tested one at a time with load cells in place at other push locations. After removal of the load cell at the test location and attachment of the actuator, specimen 1 was pushed (downward) to approximately 23 cm vertical displacement. Once the maximum displacement was attained, the actuator was retracted to zero load and detached from the specimen before moving it to the next test location. Figure 5 shows a photograph of the specimen with attached actuator before the test at the beam-beam corner location on specimen 1. A similar approach was used during the simulated support failure test locations on specimen 2. The slab edge was pushed monotonically to 26.7 cm before coming back to zero load, whereas the beam edge was pushed to a vertical deformation of 45.7 cm. It should be noted that once the test was complete at a given location, the respective load cell was unable to be moved back in place due to the accumulated large plastic deformation.

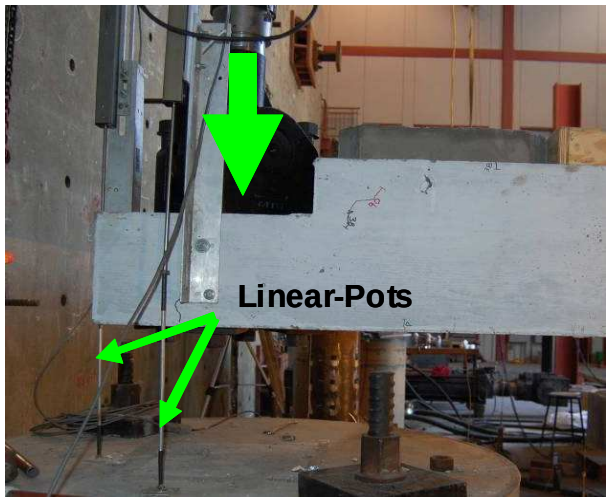

Figure 5 : Test setup at slab-edge push location on the second specimen before the test.

3. EXPERIMENTAL RESULTS

3.1 Load-Deflection Behavior

Figure 6 presents the vertical load deflection behavior at the three corner locations measured on specimen 1. Note that the negative load of approximately 8.9 kN at initial zero displacement is due to the self-weight of the specimen and the superimposed uniform loads.

The specimen was able to resist its largest vertical load at the beam-beam corner due to the presence of spandrel

beams on both edges adjacent to the simulated support failure test position. At this locations maximum load had an amplitude of 41.4 kN and occurred at a vertical displacement of 11.4 cm. It is to be noted that during the test at the beam-beam corner, the actuator inadvertently retracted back

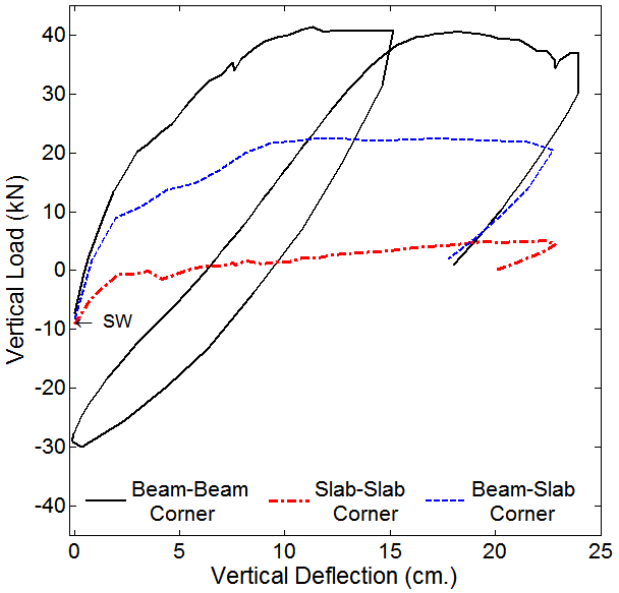

Figure 6 : Load deflection behavior at corner test locations on specimen 1 (SW = Self Weight)

to zero displacement due to error in actuator control, as a result a single recovery cycle is observed in the load-deflection response. At the beam-slab corner location, the specimen was able to achieve a maximum load of 22.7 kN at a vertical displacement of 10.2 cm. For both test locations, the beam-beam corner and the beam-slab corner, the specimen continued to deform plastically after initial yield with little strength degradation. During the test at the slab-slab corner on specimen 1, the maximum load was only 5.1 kN which was achieved at a displacement of 23 cm.

Specimen 2 was tested at two center-edge locations, namely the slab edge and the beam edge. Figure 7 presents the measured load-deflection behavior for specimen 2 at each of these simulated support failure locations. Similarly, initial negative loads at zero displacements are the initial reactions on the respective load cell at the test locations due to self-weight and superimposed uniform gravity loads. During the test at the slab edge, the specimen deformed approximately 12.5 mm under the gravity load itself. It was able to attain a maximum load of 40.9 kN at a vertical displacement of 27.3 cm. During the test at the beam edge, the specimen initially attained a large vertical load of nearly double that of the slab edge test location, with an amplitude of 74.2 kN at 6.35 cm vertical displacement. Beyond this, the vertical load abruptly decreased to 66.7 kN and remained nearly constant until a displacement of 12.7 cm. Subsequently, the specimen gained strength until a vertical displacement of approximately 31.8 cm where it attained its maximum vertical load of 83.6 kN. At approximately 32 cm vertical displacement, the drop panel at the test location

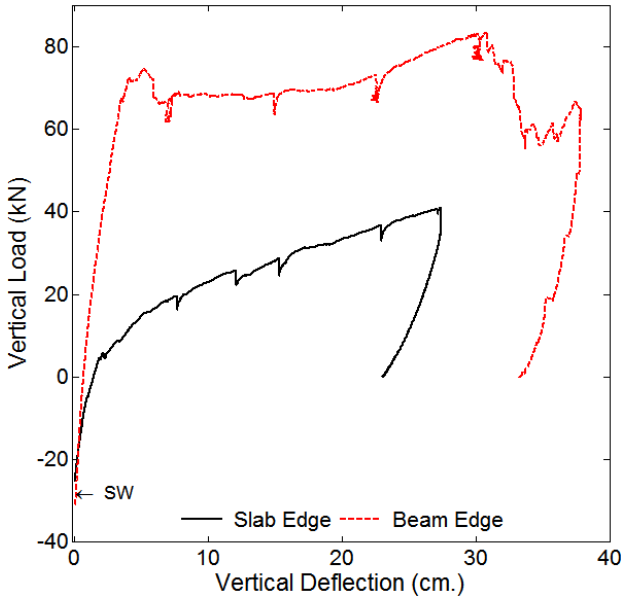

Figure 7 : Load deflection behavior at center-edge test locations on specimen 2 (SW = Self Weight)

failed in shear as shown in Figure 8, resulting in a dramatic reduced load capacity. Additional vertical displacement imposed on the specimen was mostly due to the rotation of the failed drop panel zone, which did not introduce significant vertical displacement on the beam itself. At the end of tests on specimen 2, significant plastic deformation was observed at both test locations.

Figure 8 : Shear failure at test location during the test at beam edge on specimen 2.

3.2 Observed Physical Damage

Figure 9 (a) and (b) present a schematic of observed damage on specimen 1 at the end of the simulated support failure tests. Tension cracks on the top follow the failure pattern as predicted by yield line theory. Although the yield lines were well defined along large cracks, the region of cracking was broad and spread over a width ranging from 10 to 18 times the thickness of the slab. Due to the smaller stiffness at the slab-slab edge, tension cracks on the top of the specimen were more tightly spaced as compared to the

other two sections where spandrel beams provide extra stiffness to the system.

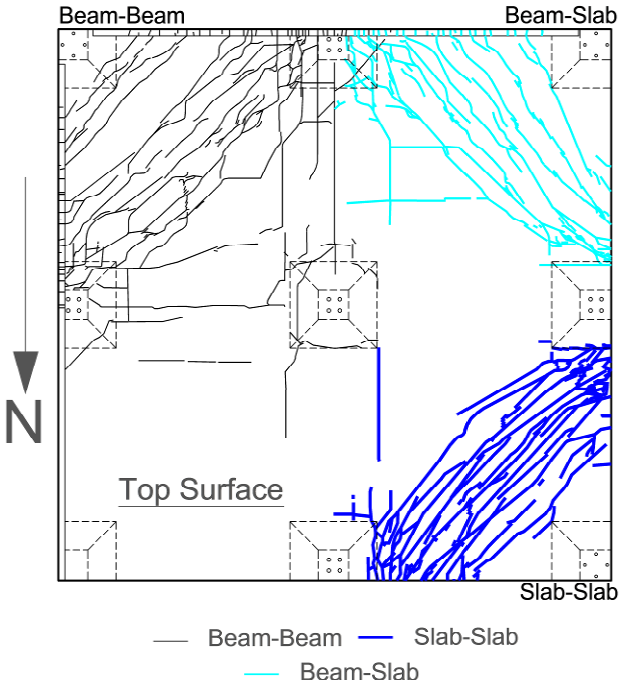

Figure 9 : Observed cracking at the end of each test on specimen 1 : (a) cracks on the top surface, and (b) cracks on the bottom surface and sides.

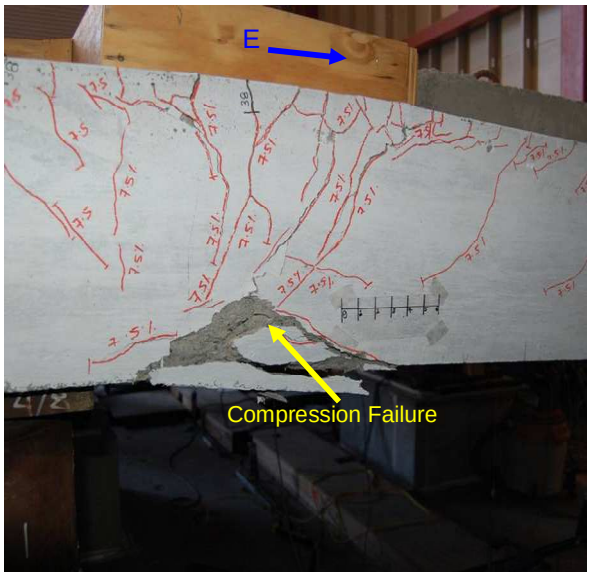
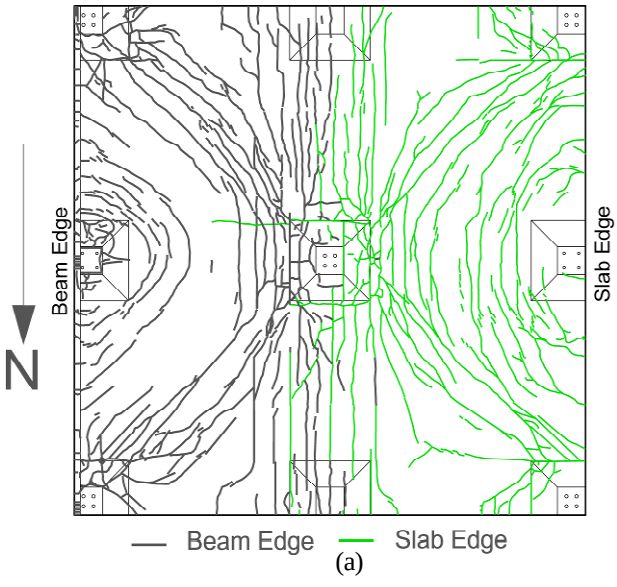
Cracks at the bottom of the specimen radiated outwards from the push location and were bounded by the yield lines that form along the adjacent support locations. Few cracks were observed inwards of the specimen due to the large membrane forces developing between supports in case of beam-beam and beam-slab corner.

A significant number of cracks were observed on the spandrel beams during the test at the beam-beam and beam-slab corner locations. Shear cracks formed near the push location, which transformed to flexure-shear cracks away from the push location. Near the adjacent supports, large flexure demand on the spandrel beam caused compression failure and rebar buckling at the bottom of the spandrel beams as shown in Figure 10.





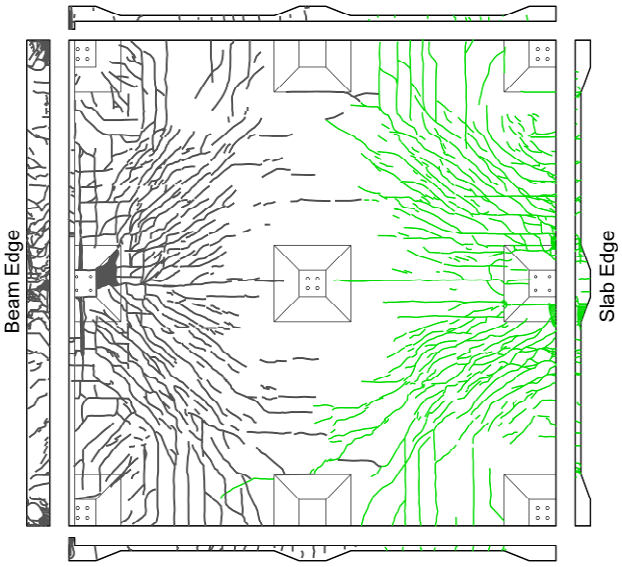


Figure 10 : Compression failure in EW spandrel beam near adjacent support at the end of test at beam-beam corner.

Figure 11 (a) and (b) presents a schematic of the damage observed on specimen 2 at the end of simulated support failure tests at slab edge and beam edge locations. Tension cracks on the top follow the predicted yield line patterns. However, region of cracking was broad and spread over a width of 35 to 50 times the slab thickness. Cracks on the top were more localized during the test at beam edge due to the increased stiffness compared to the cracking observed during the test at slab edge location. Large cracks were observed at adjacent corner support locations due to the large moment demands imposed at these locations.

(b)

Figure 11 : Observed cracking at the end of each test on specimen 2 : (a) cracks on the top surface, and (b) cracks on the bottom surface and sides.

Similar to specimen 1, cracks at the bottom radiated away from the push locations bounded by the yield lines on the top during the tests on specimen 2. Few cracks were observed inward of the specimen due to the large membrane forces that developed during each test.

Flexure and flexure-shear cracks were observed along the length of the beam and the slab edge during the tests. Flexure cracks were prominent near the adjacent corner supports and flexure shear cracks formed near the mid-span during each test. During the test at beam edge location, large moment and deflection demands at the ends of the spandrel beams caused rebar pullout hindering the beam from achieving is moment capacity, Figure 12. At the end of test at the beam edge location, large deflection and moment demands caused concrete spalling and beam rebar buckling at the test location as shown in Figure 13.

Figure 12 : Rebar pull out and concrete spalling at end of spandrel beam during the test at beam edge location.

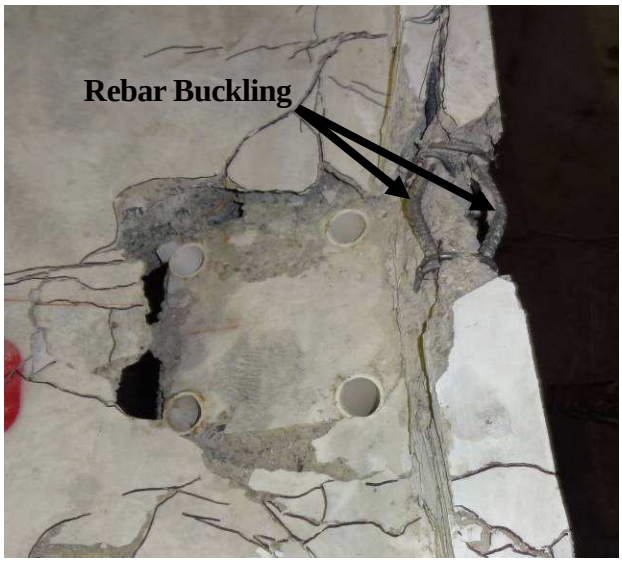

Figure 13 : Concrete spalling and rebar buckling at beam edge test location. Drop panel failure at the test location is also visible.

4. CONCLUSIONS

With advancements in understanding of seismic response of reinforced concrete (RC) structures over the past few decades, recent design codes have introduced several changes, including guidelines for reinforcement detailing to ensure safer structures under seismic events. Lack of these provisions in older codes renders some components of old buildings, such as columns for example, highly susceptible to shear failure. This in turn would result in a significant reduction in their axial load carrying capacity, compromising structure safety and increasing collapse risk. Being an integral part of a buildings load carrying mechanism, beam-slab subsystems have the potential to provide secondary load carrying capacity in the event of column failure. To study and mitigate the collapse risk in older construction, it is necessary to understand the performance of the beam-slab subsystem under support failure.

Simulated support removal tests were performed on two-1/3rd scale reinforced concrete beam-slab subsystems with details mimicked by pre-1960's construction. In total, three corner and two center-edge displacement-controlled push down tests were performed. For all column removal scenarios, the performance of the specimens was found to be satisfactory based on their maximum measured vertical load and stable post yield behavior. Test locations with spandrel beams were able to carry significantly larger loads compared to other locations due to large flexural strength of the beam. Although the failure pattern of each test conformed with predicted yield line theory, observed cracking was spread over a wide width. Severe damage was observed along the yield lines, with remainder of the slab experiencing little or no damage. Specimen edges were severely damaged at the end of each test with most severe damage observed during the test at the beam edge on specimen 2.

Abstract: A three-dimensional earthquake simulation test on a full-scale, four-story, prestressed concrete building was conducted using the E-Defense shaking table facility. The seismic force-resisting system of the test building comprised two post-tensioned (PT) frames in one direction and two unbonded PT precast walls in the other direction. The test building was subjected to several earthquake ground motions, ranging from serviceability level to near collapse. The behavior of the wall direction of the building under several ground motions is simulated using nonlinear response history analysis of practical structural engineering models, and the 2D simulation results are compared with the test results. Conducted numerical simulations are in good correlation with the test results for the important engineering parameters with some discrepancies.

1. INTRODUCTION

Past earthquakes have shown examples of unsatisfactory performance of buildings using reinforced concrete structural walls as the primary lateral force-resisting system. In the 1994 Northridge earthquake examples can be found where walls possessed too much overstrength, leading to unintended failure of collectors and floor systems, including precast and post-tensioned construction. In the 2010 Chile and 2011 Christchurch earthquakes, many structural wall buildings sustained severe damage. Although some differences in detailing practices exist between those countries and the U.S., the failure patterns raise concerns about how well conventionally reinforced structural walls in U.S. buildings will perform during the next earthquake. Past research efforts, including the PREcast Seismic Structural Systems (PRESSS) program (Priestley 1991) and subsequent studies, have explored alternative design approaches using post-tensioned (PT) precast structural walls to better control yielding mechanisms and promote self-centering behavior. These studies have provided excellent guidance on design and construction requirements, but examples of full-scale, three-dimensional dynamic tests to demonstrate behavior in realistic structural systems have been lacking. Such demonstrations are important to identify complex interactions that occur in complete building structures. Such demonstrations also are useful to serve as a vehicle for acceptance by the engineering community.

In December 2010, the National Research Institute for Earth Science and Disaster Prevention (NIED) in Japan conducted a three-dimensional earthquake simulation test on a full-scale, four-story building using the E-Defense shaking table. Design, instrumentation, preliminary numerical studies, and testing of the building were a collaboration among researchers from Japan and the U.S. The seismic force-resisting system of the test building comprised two bonded PT frames in one direction and two unbonded PT precast walls in the other direction. The building was designed using the latest code requirements and design recommendations available both in Japan and the U.S., including ACI ITG-5.2-09. The test building was subjected to several earthquake ground motions, ranging from serviceability level to near collapse.

Three-dimensional earthquake simulation testing of full-scale specimens is rare. Data from this test give a unique opportunity to understand the behavior of the unbonded PT walls and their interaction with other structural elements during an earthquake. In this study, the authors developed practical structural engineering models for the wall direction of the building. A comparison of the simulation and test results is done to assess the capability of currently available models to simulate the response of a real PT building under gradually increasing earthquakes.

2. OVERVIEW OF THE TEST

2.1 Test Specimen

The test specimen was a full-scale, four-story, post-tensioned precast concrete building. It had a rectangular plan (Figure 1), with dimensions 7.2 m in the Y (transverse) direction and 14.4 m in the X (longitudinal) direction. Height of each floor was 3 m, resulting in total building

height of 12 m. The lateral-load-resisting system in the Y direction was two precast unbonded PT shear walls and one bay unbonded PT center frame at B Axis. In the X direction the structural system consisted of two-bay bonded PT frames. All the structural elements were precast off-site and installed and post-tensioned on-site. Post-tensioning tendons of beams and columns in the X direction were bonded with grouting after installation. On the other hand, PT tendons of shear walls and beams in the Y direction were constructed to be unbonded from concrete.

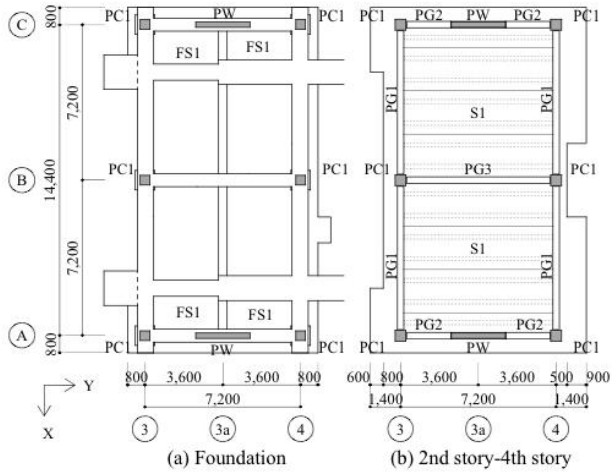

Figure 1 Plan View of the Specimen (Unit: mm)

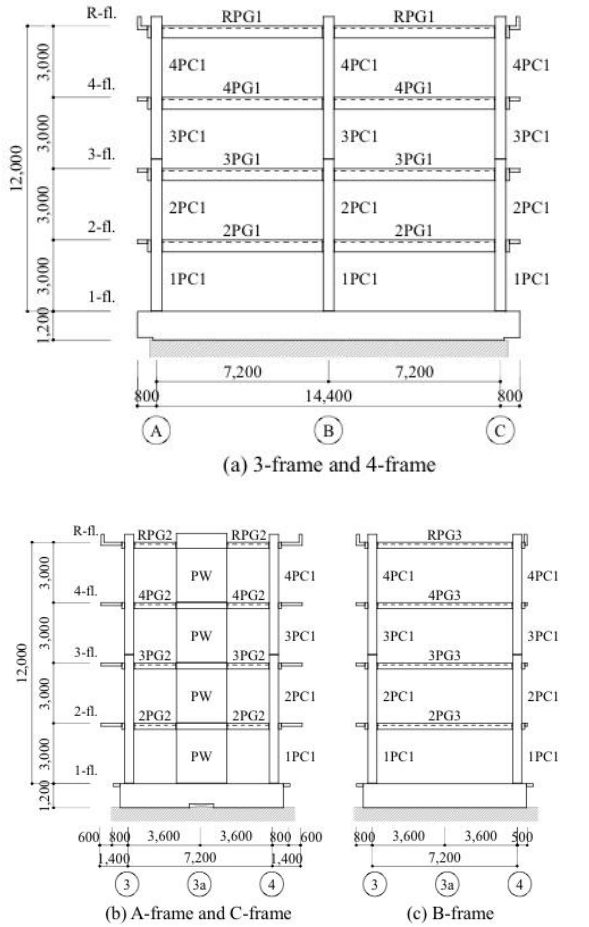

Figure 2 Elevation View of the Specimen (Unit: mm)

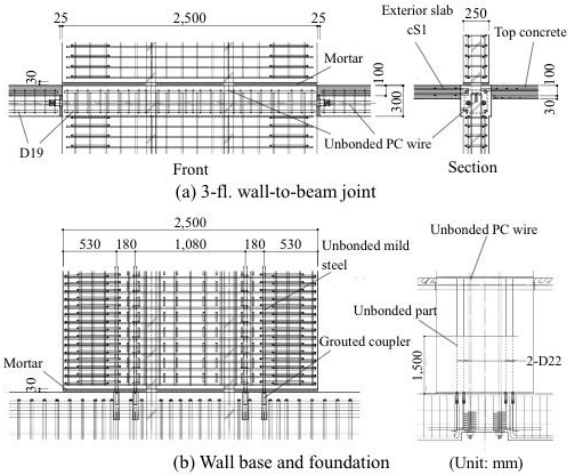
Shear walls had a rectangular cross section with a length of 2500 mm and a thickness of 250 mm. PT walls were 12 m high, and therefore had a slenderness ratio of H_w/l_w =4.8. Columns (PC1) had 450-mm square cross sections. Beams (PG2 & PG3) were partially precast, with the top 100 mm of the 300 mm by 300 mm section cast in place with the slab. The slab was 130 mm thick with the top 100 mm cast in place monolithically with the beams. The slab was supported by pretensioned joists with 1 m interval in the transverse direction. See Table 1 for additional details (Nagae et al. 2011).

Concrete design strength was 60 MPa for precast parts and 30 MPa for cast-in-place parts. The design strength of the grout mortar was 60 MPa. The first two floors of the north wall were constructed using FRCC (fiber reinforced cement composite). Nominal strength of the generic steel bar was 345 MPa. Transverse reinforcement of beams and walls in the Y direction was high strength steel bars with nominal strength of 785 MPa. Although columns were designed for required shear reinforcement by the Japanese Building Standard Law, the column core was not intentionally confined. PT rods of the columns were high strength steel with 1080 MPa design strength. PT strands used in walls and beams had design strength of 1600 MPa. Test results of the materials are shown in Table 3.

Reinforcement details of the PT walls and wall-to-beam joint details are shown in Figure 3. Eight D22 (22 mm diameter) steel energy dissipation bars were unbonded through the lower 1.5 m of the first story and connected to the foundation with mechanical couplers. Effective prestressing of the PT tendons was 0.6 times the yield strength for the walls and PG2 beams, and 0.8 times the yield strength for the other beams and columns.



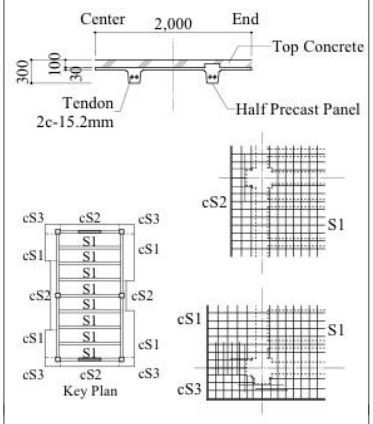


Figure 3 Reinforcement Details of Walls (Unit: mm)

The total weight of the specimen was 5592 kN. The weight of each floor was 996 kN for Roof, 813 kN for 3rd floor, 806 kN for 2nd floor, and 804 kN for the 1st floor.

2.2 Input Motions

Input ground motions were scaled JMA-Kobe and JR-Takatori records from 1995 Kobe earthquake. The motions were applied in two horizontal and vertical directions simultaneously. Firstly, JMA-Kobe motion was applied with wave amplitude scale factor of 10%, 25%, 50%, and 100%, respectively. Lastly, 40% and 60% JR-Takatori were applied. This paper considers the 25%, 50% and 100% excitations only. Figure 4 shows time records and acceleration response spectra of input motions.

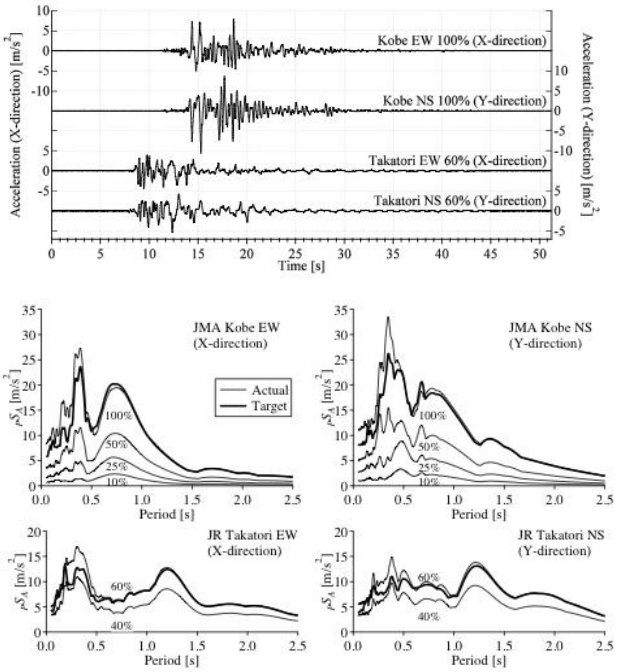

Figure 4 Time Records and Acceleration Response Spectra of the Input Motions

3. NUMERICAL SIMULATION

A three-dimensional numerical model of the Y direction of the specimen was implemented using the computer program Perform 3D (CSI). Figure 5 shows a 3D view of the model.

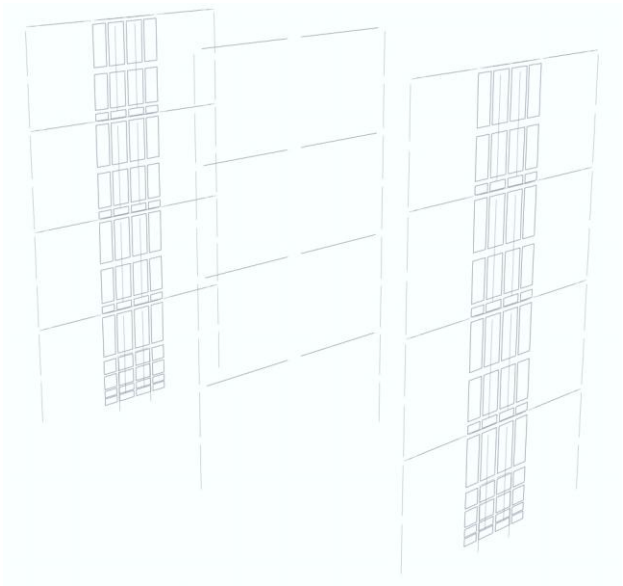

Figure 5 3D View of the Perform 3D model

3.1 Shear Wall Model

Structural walls were modeled using 4-noded "Shear Wall Elements" (CSI) with fiber cross sections. In this implementation, all interconnected planar wall segments at any level are assumed to remain plane when deformed. In the first story, where inelastic actions were expected to concentrate, shear wall elements were meshed so that each element had a height of $2b_w$ (b_w = wall thickness). This value is established from post-earthquake observations of the typical height of spalled regions. For the rest of the building, larger sized elements are used. Due to anticipated low shear demands, an elastic shear material was used for walls, with effective shear stiffness defined as $G_cA_w = 0.4E_cA_w$ /20 (PEER/ATC-72-1), in which G_c is shear modulus, E_c is Young's modulus of concrete (taken as $4700\sqrt{f_c'}$, MPa), and A_w is web area. Rocking behavior of wall segments is implemented for wall elements at each floor level. This behavior is achieved by inserting fiber sections at the interfaces having representative compressive behavior but zero tensile strength.

The constitutive material model for concrete is a trilinear idealization of material test results (Figure 6). The stress-strain relationship for confined concrete is implemented using the confinement model for high-strength concrete developed by Razvi & Saatcioglu (1999). Tension resistance of concrete is modeled except for the rocking sections.

Similarly, the reinforcing steel stress-strain relation was a simplified trilinear curve with a descending portion (Figure 7). The ultimate strain of reinforcing steel in tension was limited to 0.05 in consideration of cyclic fatigue (PEER/ATC-72-1). Behavior in compression was checked according to the ratio s/d_b (s = spacing of transverse

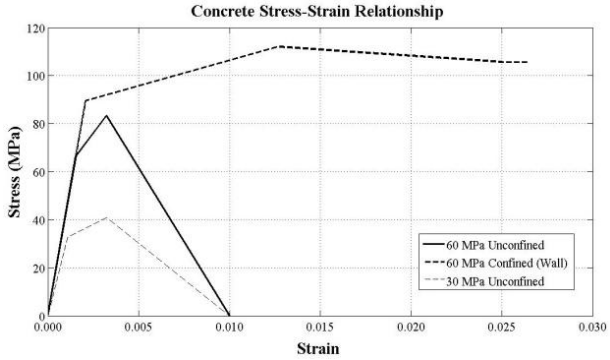

Figure 6 Concrete Stress-Strain Relation

reinforcement and d_b = diameter of longitudinal bar) in consideration of longitudinal bar buckling (Monti and Nuti, 1992). The adequately small s/d_b ratio is such that reinforcing bars are unlikely to buckle prematurely. The ultimate strain of reinforcing steel under compression nonetheless is limited to 0.02 because of potential buckling at large strains (PEER/ATC-72-1).

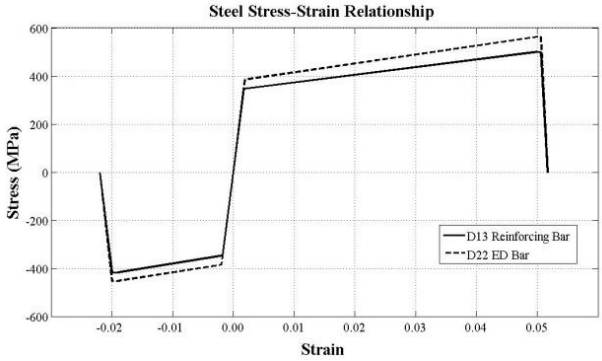

Figure 7 Reinforcing Bar Stress-Strain Relation

PT tendons and energy dissipation (ED) bars are modelled using truss elements with nonlinear material properties. Truss elements are connected to shear wall elements through rigid beams extending to locations of tendons and ED bars in the cross section. Lateral displacements of PT tendons are slaved to shear wall elements at each floor level, which is analogous to the effect of the tendon ducts. Truss elements representing the ED bars are modelled along the unbonded length of the bars. Bar slip (strain penetration) effects are considered for modelling of the ED bars. The ED bar trusses are extended below the top of the foundation to mimic the extra elongation caused by slip of the ED bars. Post-tensioning loads on tendons are applied as initial strains concurrently with gravity loads in analysis.

3.2 Beam and Column Models

Beams and columns are modelled using nonlinear beam-column elements with rigid end zones. Nonlinear fiber sections are assigned through the length of elements with distributed plasticity. Similar to the shear wall elements, a simplified trilinear curve with a descending portion is used to model concrete and steel materials. Due to adequate shear design of the members, an elastic shear material was used for beams and columns, with effective shear stiffness defined as $G_cA_w = 0.4E_cA_w$ (Elwood et al. 2007). Similar to rocking sections of wall elements, opening between precast elements is simulated by assigning a "rocking section" to beam element integration points closest to wall and columns). The aforementioned "rocking section" has the same cross section and fiber locations as at other integration points. However, materials assigned to this section are modified to have no tension resistance.

Upper portions of half-precast beams were cast monolithic with the slabs. Beam effective flange widths are calculated using ACI 318 equations. Unlike column elements, for which forces are resisted with fiber sections in both transverse directions, beam elements in Perform 3D use fiber sections only in the major bending axis. Bending stiffness of the minor bending axis is defined with effective bending stiffness $0.5E_cI_g$, in which I_g is gross section moment of inertia according to the minor bending axis.

Unbonded PT tendons of beams (PG2 & PG3) are modelled with parallel truss elements with nonlinear material properties. Their vertical displacements through beams and walls are slaved to parallel elements similar to modelling of ducts for walls. Similar to PT tendons of walls, post-tensioning loads on tendons are applied as initial strains. In contrast, bonded PT rods of columns (PC1) are included in the fiber cross-section. Post-tensioning loads on columns are approximated by applied point loads (in the same direction with gravity).

3.3 Miscellaneous Notes on the Numerical Model

Rayleigh damping is used for nonlinear response history analysis, with parameters set to produce 2 percent damping at periods $T_1/8$ and $1.25T_1$, where T_1 = 0.29 seconds. All analyses were in the Y direction; therefore, X-direction displacements of all nodes are restrained. After the application of gravity and prestressing loads, the model is excited with 25%, 50%, and 100% Kobe motions, respectively.

4. COMPARISON OF SIMULATION AND TEST RESULTS

Prior to application of earthquake motions, the test building was excited with white noise. Fundamental periods of the building were 0.29 s in the Y direction and 0.45 s in the X direction. Modal analysis of the numerical model resulted a fundamental period of 0.29 s in the Y direction.

Base shear versus roof drift ratio responses of the numerical model and test specimen under 25%, 50%, 100% Kobe excitations are shown in Figures 8, 10, and 12. Comparisons of roof drift ratio versus time responses of numerical model and test specimen are shown in Figures 9, 11, and 13. Flag-shaped hysteresis typical of unbonded post-tensioned concrete is apparent. The numerical model and test results are in very good agreement for important engineering parameters, such as stiffness, maximum base shear, and maximum roof drift. For all excitations, energy dissipated during the earthquake (area inside the hysteresis curve) is estimated with a good accuracy.

Although estimated maximum roof drift ratios are very close to the test results, phase shifts in roof drift ratio versus time are significant for some parts of the response. The roof drift ratio response history estimate for the 25% Kobe motion shifts out-of-phase after 19 s. The vibration period of the test specimen is increasing after 19 s, but the numerical model does not identify this increase in period.

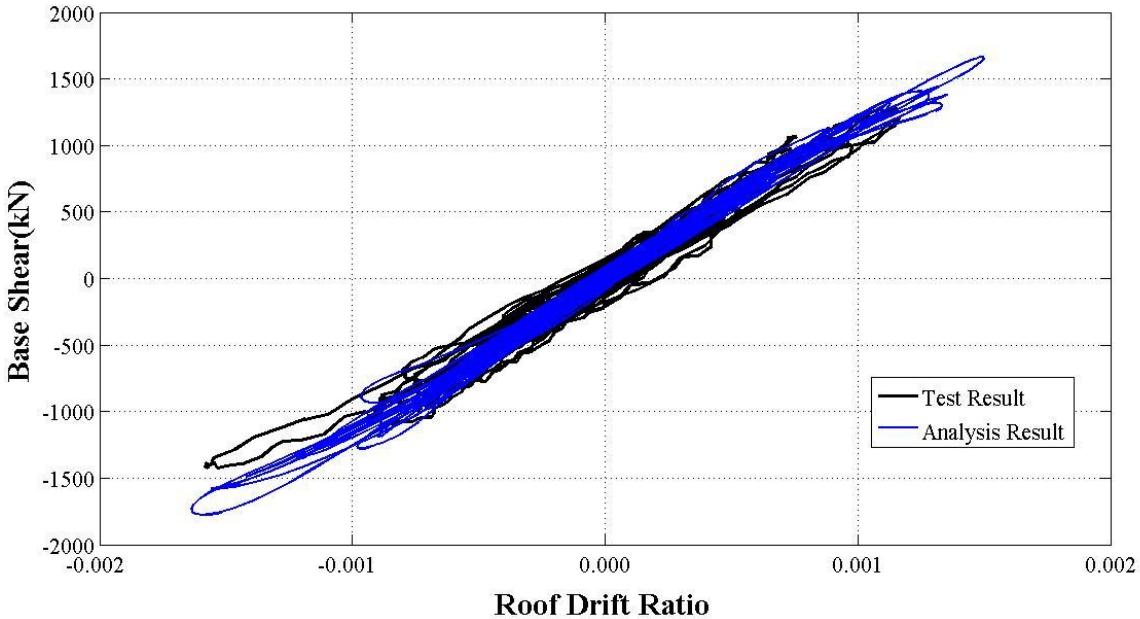

Figure 8 Base Shear-Roof Drift Ratio Comparison of Results for 25% Kobe Motion

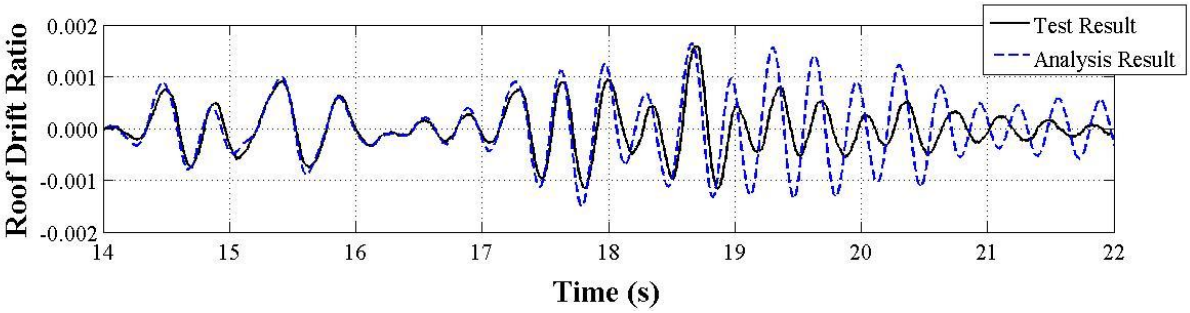

Figure 9 Roof Drift Ratio-Time Comparison of Results for 25% Kobe Motion

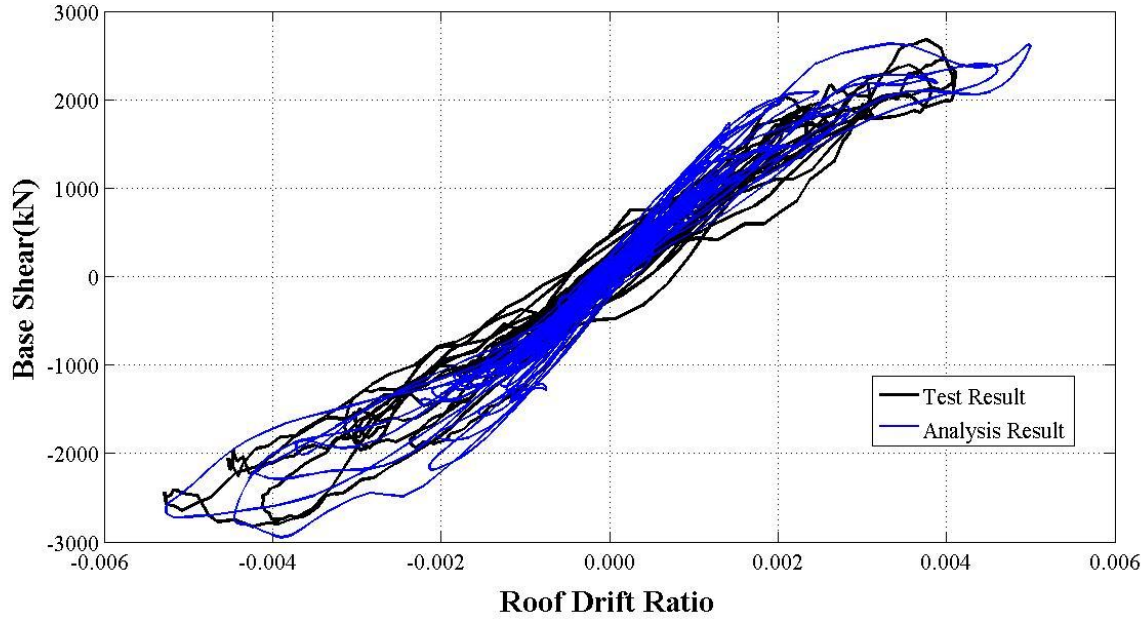

Figure 10 Base Shear-Roof Drift Ratio Comparison of Results for 50% Kobe Motion

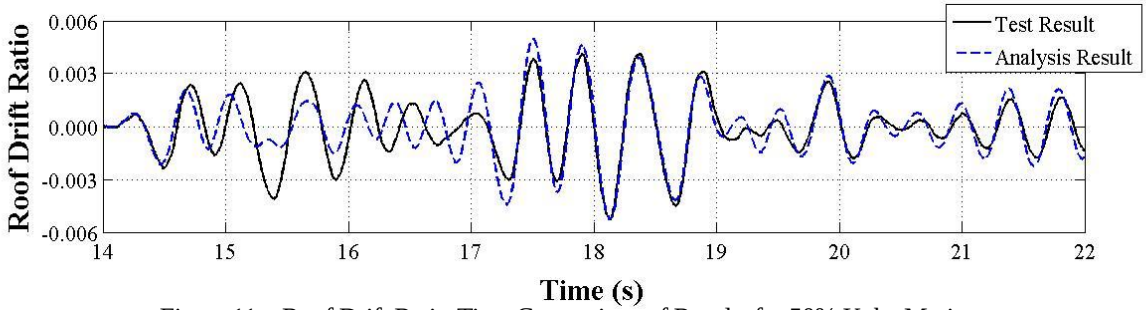

Figure 11 Roof Drift Ratio-Time Comparison of Results for 50% Kobe Motion

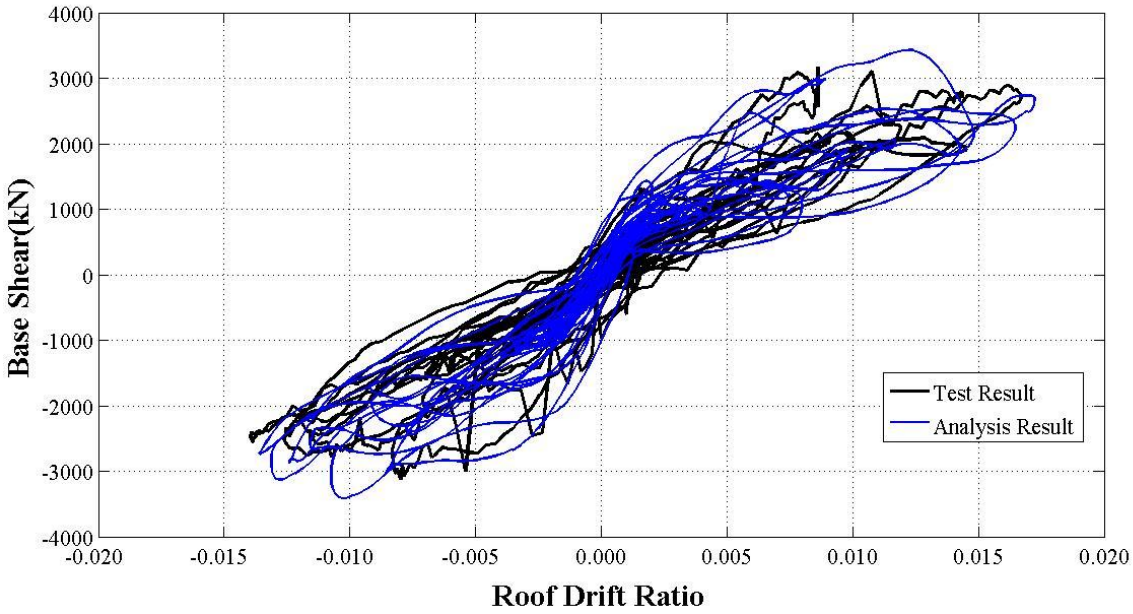

Figure 12 Base Shear-Roof Drift Ratio Comparison of Results for 100% Kobe Motion

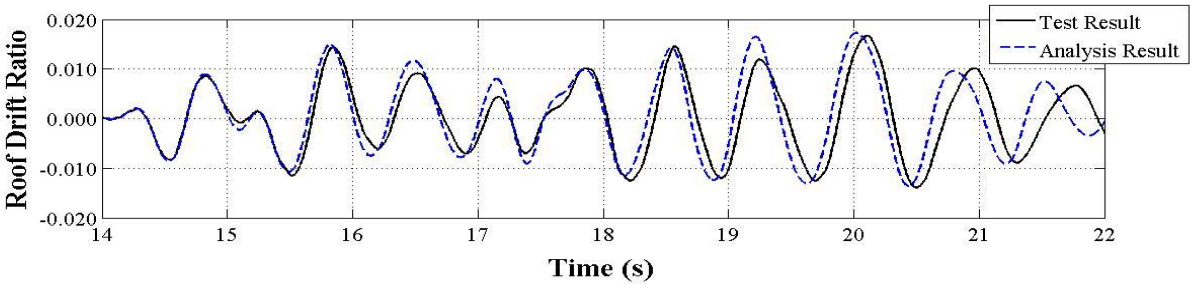

Figure 13 Roof Drift Ratio-Time Comparison of Results for 100% Kobe Motion

The calculated roof drift ratio history for the 100% motion also does not estimate the increase in vibration period after 21 s. Measured and calculated response decay near the end of the test match fairly closely for the 50% and 100% Kobe motion, suggesting the damping is modeled reasonably. For the 25% motion response, calculated response damps out more slowly than the test results.

5. CONCLUSIONS

A three-dimensional earthquake simulation test on a full-scale, four-story, prestressed concrete building is conducted using the E-Defense shaking table facility. The seismic force-resisting system of the test building comprised two post-tensioned (PT) frames in one direction and two unbonded PT precast walls in the other direction. The test building was subjected to several earthquake ground motions, ranging from serviceability level to near collapse. The wall direction (Y direction) of the building is modeled using the computer program Perform 3D, with emphasis on a model that would be practical for design-office implementation. This model is subjected to several base motions to explore the accuracy of the numerical model.

Important engineering parameters such as fundamental vibration period, stiffness, hysteresis shape, maximum base shear, and maximum roof drifts are adequately simulated using the numerical model. There are, however, some discrepancies in variation of these responses with time. These results indicate that, while further improvements may be desirable, the selected modelling approach is capable of producing seismic response estimates of sufficient accuracy to be used for detailed design of unbonded post-tensioned, precast structural wall systems.

Abstract: The probability of damage states with respect to a ground motion index is predicted through the seismic fragility curves. Using fragility curves, it is possible to estimate the vulnerability of structures to seismic hazard. In this study, an analytical approach was adopted to construct fragility curves for thin RC shear walls that are the vertical components of the lateral-force-resisting system to earthquakes typically used in Lima, Peru since 1998. The main characteristic of these walls is the use of electro-welded wire mesh as main reinforcement instead of conventional rebar. The thin RC shear walls were modeled based on the results of experiments. A series of non-linear dynamic response analyses was performed using strong motion records obtained in Lima, Peru and the damage ratios were estimated with respect to damage states. The fragility curves for the walls were constructed assuming that the damage ratios follow lognormal distributions. The fragility curves constructed in the present study are helpful for predicting the damage state of buildings composed of the thin RC walls especially in Lima, Peru.

1. INTRODUCTION

The study of seismic loss is a matter of research in many countries located in seismic-prone regions. Every study follows a similar flowchart during the process of loss estimation: estimation of intensity measures, structural responses, damage estimation, statistical analysis, construction of fragility curves and finally loss assessment. To evaluate the damage to structures, fragility curves are widely employed and developed for RC buildings (Jovanoska 2000), bridges (Karim and Yamazaki 2001), expressway embankments (Maruyama et al. 2010), and other types of structures (Chiou et al. 2011).

Withman (1973) defined the damage probability matrices, and the ATC Project (1985) also defined damage probability matrices for 78 categories of structures. Jaw and Hwang (1988) introduced the fragility curves, and Nocevski (1993) developed empirical and analytical fragility curves. Similar approaches to construct fragility curves are presented by Karim and Yamazaki (2001) and others.

During the 2010 Chile Maule earthquake, some buildings, which resist lateral seismic forces with thin walls, suffered from severe damage and in some cases collapsed (EERI 2010). In Lima City, many similar types of buildings have been built since 1998, and the number of these types of buildings has been increasing over the years. However, the last big earthquake that hit Lima city occurred in 1974. Therefore, it is difficult to know the actual behavior of these buildings during an earthquake and the loss associated with their fails.

The fragility curves can be developed based on analytical, empirical, expert's opinion and combinational approaches. The objective of this study is to develop analytical fragility curves based on numerical simulations and evaluate the influence of the use of electro-welded wire mesh as main reinforcement instead of conventional rebar for the thin RC shear walls. Fragility curves describe the conditional probability of a certain damage state for a given intensity of ground motion index and can be expressed as

$$P_{ik} = P\left[X \geq x_i \middle| Y = y_k\right] \quad (1)$$

where P_{ik} is the conditional probability of a certain damage level x_i for a given ground motion intensity y_k. X is the variable that reflects the damage state and Y is the variable that reflects the ground motion intensity.

The response characteristics of the thin RC shear walls were evaluated in the previous study (Quiroz et al. 2012). These walls were regarded as the prototype of those used in low-rise and mid-rise buildings in Lima, Peru. The numerical model of the wall is developed using a multi degree-of-freedom system and macro models that represent the overall behavior of the RC elements. A series of non-linear dynamic response analyses is carried out using Peruvian records. Regression analyses are performed to reveal the relationship between the damage ratios of the walls and the ground motion index to construct fragility curves. Finally, the influences on the fragility curves due to the type of material used as main reinforcement of the wall

are discussed and the probabilities of a certain damage state for three hazard levels areis estimated.

2. PROTOTYPES AND NUMERICAL MODEL

A thin RC shear wall was selected as a prototype of those used in low-rise and mid-rise in Lima, Perú. The dimensions of the prototypes were a height of 2400 mm (per floor), a length of 2650 mm and a thickness of 100 mm. The walls present the edge reinforcement consisted of conventional rebar. In the case of main reinforcement, two types of models are considered. The first wall is called MQE257EP and it presents electro-welded wire mesh, which is made of non-ductile material, as main reinforcement. The second wall is called MFIEN3EP and it presented conventional rebar as main reinforcement. A single layer of main reinforcement is used in both directions for both cases. Figure 1 shows a general view of the walls and Table 1 shows the distribution of reinforcement. The number of stories considered in the analysis is five.

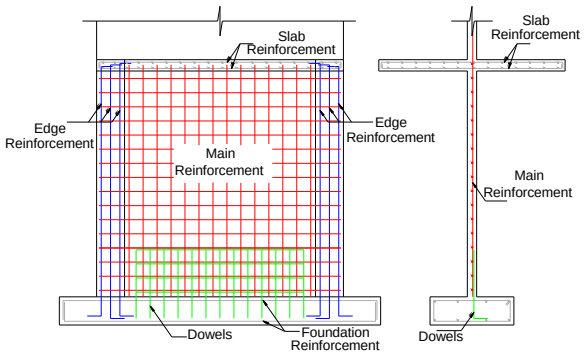

Figure 1 General characteristics of the specimens considered in the study

Table 1 Distribution of reinforcement in walls

Prototype	Main Reinforcement	ρ_h and ρ_v	Dowels	Edge Reinforcement
MQE257EP	QE257	0.257%	QE84/257	3 #4
MFIEN3EP	#3 @ 250	0.284%	#3 @ 250	

As can be observed from Table 1, the horizontal reinforcement ratio (ρ_h) and vertical reinforcement ratio (ρ_v) is almost similar for both walls. The wall MQE257 has the main reinforcement called QE257, which is formed by wires of 7 mm in the horizontal and vertical direction spaced at 150 mm. This wall has dowels which consists of a mesh QE84/257 formed by wires with a diameter of 4 mm in the horizontal direction and wires with a diameter of 6 mm in the vertical direction, both spaced at 150 mm. In case of the wall MFIEN3EP, the main reinforcement consists of corrugated bars with a diameter of 9.5 mm (#3) spaced at 250 mm in both directions. The dowels present a similar configuration as the wall MQE257 (#3 @ 250 mm) but they are distributed only in vertical direction.

The randomness of the structural characteristics is usually considered through the variation of the built-in materials properties, but in the present study, this effect has not been considered. Then, uncertainty in the capacity of the structural element was reduced by selecting material strengths based on the experiments and an appropriate inelastic model.

The compression strength of concrete was set to be 17.16 MPa that is typically used in these walls. The following properties were considered for the reinforcement based on the test (Quiroz et al. 2012). In case of the conventional reinforcement, the yielding stress was set to be 450 MPa with an associated strain of 0.002. As for the electro-welded wire mesh, the yield strain was 0.0035 with a yield stress of approximately 485 MPa. The main difference between these two types of reinforcement is the strain at the maximum strength. The strain of conventional reinforcement is 4.5 times larger than that of electro-welded wire mesh. Figure 2 shows a comparison of the two types of reinforcement.

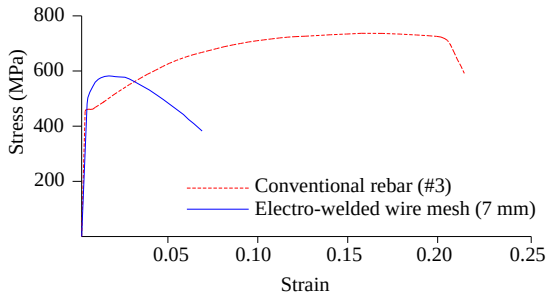

Figure 2 Schematic comparisons of conventional reinforcement and electro-welded wire mesh

The numerical model represents the effect of non-linearity of walls by modeling with the concentrated springs idealized by a trilinear backbone curve and hysteretic rules.

The definition of the bearing characteristics and their modeling of the hysteretic behavior of the cross-sections is of particular importance in defining damage under seismic motions. The bearing characteristics of a cross-section are given through the moment-curvature relationship. The three-parametric model proposed by Park et al. (1987), which is based on a tri-linear curve, was adopted to model the relationship. The three parameters α, β, and γ were estimated in the previous study (Quiroz et al. 2012).

To predict the hysteretic curve of the prototypes, the nonlinear behaviors of materials should be modeled numerically. In the case of concrete, unconfined concrete is assumed because the thickness of the walls is small and does not allow any type of confinement. The Kent and Park model was considered in this study (Kent and Park 1971). The tensile strength of concrete was neglected. The ultimate strain was set to be 0.0035 and the other parameters have been estimated using the expressions of Kent and Park (1971). For reinforcement, the uniaxial behavior of conventional reinforcement and electro-welded wire mesh is modeled by the trilinear model. The behavior is considered to be the same for compressive and tensile stresses.

3. DAMAGE LEVELS

To construct the seismic fragility curves, it is necessary to define structural damage levels. Many approaches have been used to define damage indices, e.g. one of those approaches considers three categories: non-cumulative, cumulative and combined damage indices. The structural parameters related to the categories mentioned before are the maximum deformation, hysteric behavior, and deformation/energy absorption. The first category has the advantage of simplicity in estimation process. Typical structural responses used in that category are drifts and displacement ductility ratios.

Because the damage to structure is related to local deformations, the drift can be used to show different damage states. The drift is calculated as the ratio between the relative displacement of a story and the height of the story. In the literature, it is possible to find many drift limits for walls. Farrar et al. (1993) proposed that the failure occurs with the drifts of 0.85 - 1.50% for low-rise walls with reinforcement ratio of smaller than 0.25%. Duffey et al. (1994) established that an 80% of reduction in ultimate capacity occurs at the drift of 1.34%, and a reduction of 50% occurs at the drift of 1.84% based on statistical analysis of their experimental results on light reinforced low-rise walls. Ghobarah (2004) stated that structural collapse of buildings with low-rise walls with low ductility can occurs at the drift of more than 0.80%.

For the present study, the maximum drift among at the all stories is considered as damage index and the definition of damage states by Ghobarah (2004) was employed because the drifts associated with the damage states are close to those observed during the experiments of Zavala (2004). Table 2 shows the definition of damage states proposed by Ghobarah based on the amount of drift.

Table 2 Definition of damage states with respect to the drift proposed by Ghobarah (2004)

State of damage	Drift limit (%)
No damage (ND)	0 – 0.1
Light (L)	0.1 – 0.2
Moderate (M)	0.2 – 0.4
Severe (S)	0.4 – 0.8
Collapse (C)	> 0.8

4. EARTHQUAKE GROUND MOTIONS

In order to consider the uncertainty of the ground motion, a way to overcome this is considering various records that reflect the seismicity of a specific place.

In the present study, a dataset of Peruvian records was used. This dataset consists of nineteen acceleration time histories recorded by Japan Peru Center for Earthquake Engineering and Disaster Mitigation, National University of Engineering, Peru (CISMID) and Geophysical Institute of Peru (IGP). The number of events is 14, and each record consists of the two horizontal components and one vertical component. The acceleration records of horizontal components are applied to the numerical models. All the records have been recorded in dense gravel soil, which represents the typical soil of Lima, and most of them consist of very high frequency contents. The dataset includes the ground motion record during the severe earthquake occurred in Lima after 1951. The magnitudes vary from 4 to 8. The magnitudes of the earthquake events are shown in Table 3. The origin of several of the records is associated withto the process of subduction between the Nazca and South American plates and presents a wide range of magnitudes and epicentral distances.

Table 3 Dataset of Peruvian ground motion records

Event	Year	M_W	M_S	M_L
Lima Eq.	1951	-	5.5	6
Ancash Eq. [1]	1970	-	7.8	-
Nov-71	1971	5.6	-	-
Jan-74	1974	6.5	6.6	-
Lima Eq. [1]	1974	-	7.6	-
Lima & Callao Eq. [1]	1966	8.1	8	-
Nov-74	1974	-	7.2	-
Mar-04	2004	-	-	5
Jul-04	2004	-	-	5.4
Mar-05	2005	-	-	5.7
Feb-06	2005			5.4
Lamas Eq.	2005	-	-	7
Pisco & Ica Eq.	2007	7.9	-	7
Callao Eq.	2008	5.3	-	5.3

In the Table 3, the superscript 1 indicates the records used to draw the inelastic design spectrum of the Seismic Peruvian standard E.030 (Ministry of Housing Peru 2003).

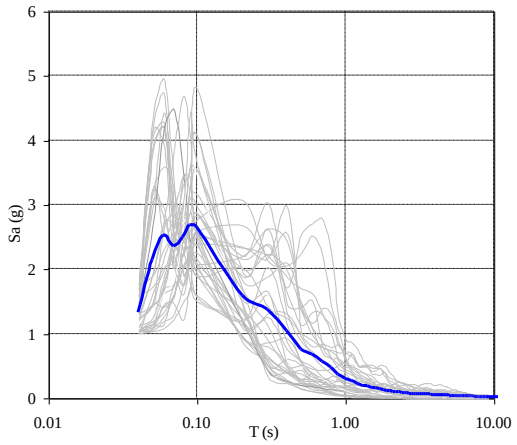

Figure 3 Acceleration response spectra (normalized to have PGA of 1g) with 5 percent damping ratio for Peruvian records

Figure 3 shows the acceleration response spectra for Peruvian earthquakes, which are normalized to have PGA of 1g, with the damping ratio of 5%. The mean amplitude is also shown with a thick line. Although the large variations in the spectral shape can be caused by many factors, such as

soil conditions and source-to-site distance, the mean amplitude of spectral shapes is different from event to event. Based on Figure 3, the ground motion records in Peru mainly consist of shorter period contents.

5. FRAGILITY CURVES

A difficult task in the analysis of structures is the determination of their structural response. IDARC2D (Reinhorn et al. 2009), a macro-element program, is used in the simulation of the structural response. IDARC2D has been extensively validated against laboratory testing of structural systems and components types, and it is used for the inelastic static and dynamic response analysis of RC structures.

The non-linear dynamic analysis is carried out using a combination of the Newmark-Beta integration method and the pseudo-force method. In the numerical analysis, the values for time increment step, damping value and damping type are 0.005 s, 5% and Rayleigh damping, respectively.

As is mentioned before, the fragility curves can be constructed with respect to different ground motion indices, e.g. PGA, PGV, AI, duration time, etc. In the present study, PGA was selected as the ground motion index because this parameter presented a better correlation with the drift than others. The damage ratio for each damage state under a certain excitation level is obtained. Base on these data, fragility curves for the walls are constructed assuming a lognormal distribution. This distribution was used by other researchers (Mehanny, and El Howary 2010).

The cumulative probability P_R of occurrence of the damage equal or higher than a damage state is given by

$$P_R = \Phi\left[\frac{\ln Y - \lambda}{\zeta}\right] \quad (2)$$

where Φ is the standard cumulative normal distribution, Y is the ground motion index (PGA), λ and ζ are the mean and standard deviation of ln Y. These two parameters of the distribution are obtained by the least-squares method on a lognormal probability paper.

The values of PGA for all records were scaled to have different excitation levels. Hence, the PGA for the records was scaled from 100 cm/s^2 to 1500 cm/s^2 with the interval of 100 cm/s^2. The scaled records were applied to the numerical model to obtain the damage index (maximum drift). Using the damage indices, the number of occurrence for each damage state was estimated under each excitation level. Finally, the damage ratio was obtained for every damage state. As an example, Figure 4 shows the number of occurrences of each damage state under different excitation levels for the wall MQE257EP and MFIEN3EP.

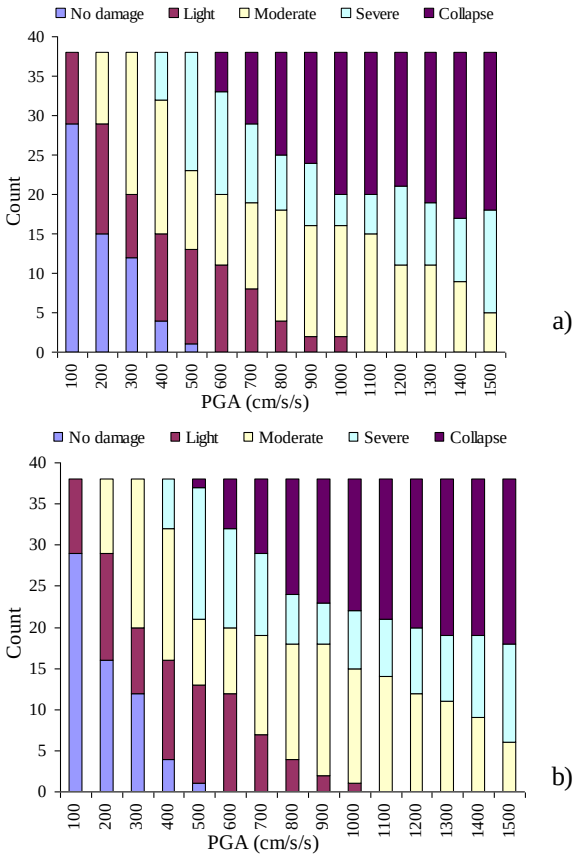

Figure 4 Number of occurrences of each damage state under the Peruvian records for the walls a) MQE257EP and b) MFIEN3EP

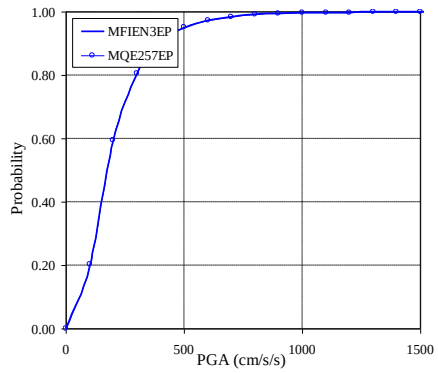
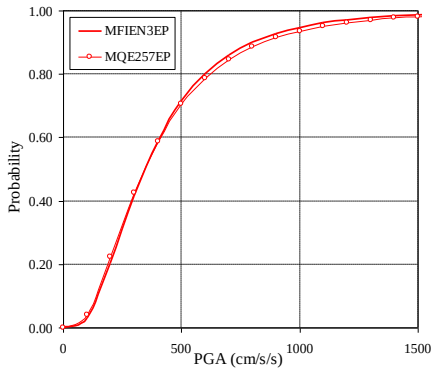
5.1 Influence of material used as main reinforcement

The use of electro-welded wire mesh as main reinforcement is a subject of controversy in the last years in Peru. From 1998 to 2004, many buildings were built whose lateral resistance system to earthquake consist of thin RC shear walls reinforced with electro-welded wire mesh as main reinforcement. For this reason, the influence of the use electro welded-wire mesh instead of conventional reinforcement as the main reinforcement in the fragility curves is evaluated.



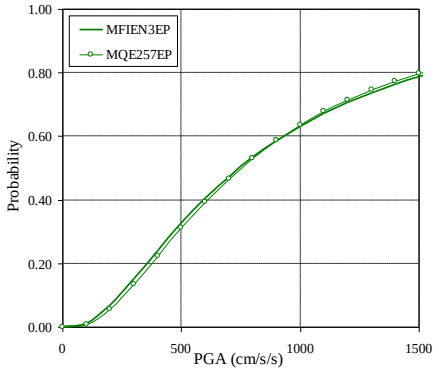
The fragility curves obtained for the walls MFIEN3EP and MQES57EP are presented. As can be observed, the amount of main reinforcement is almost the same for those walls but the material used in the every wall is different. Table 4 shows the parameters of fragility curves for thin RC shear walls.

Table 4 Parameters of fragility curves for the thin RC shear walls



Prototype	Damage state							
	D > Light		D > Moderate		D > Severe		D = Collapse	
	λ	ξ	λ	ξ	λ	ξ	λ	ξ
MQE257EP	5.14	0.65	5.83	0.70	6.62	0.83	7.13	0.82
MFIEN3EP	5.16	0.65	5.84	0.66	6.61	0.88	7.13	0.65

Figure 5 presents the fragility curves for the walls with respect to PGA considering Peruvian records for different damage states. As can be observed, the change in the



probability of exceeding a damage state with respect to the material used as main reinforcement is rather small. It is also observed that the slope of the curves gets steeper for first damage levels.

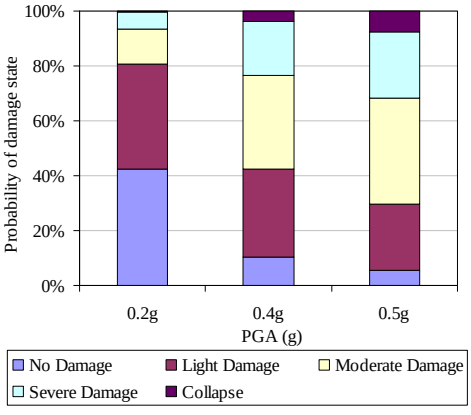
Figure 5 Comparison of the fragility curves for the walls MFIEN3EP and MQE257EP with a) light, b) moderate, c) severe and d) collapse damage states

5.2 Seismic performance

Finally, in order to evaluate the probability of being in each damage state, it is important to evaluate representative values of intensity. In the work of Silva (2008), the three levels of peak ground accelerations are presented (Table 5).

Table 5 Levels of hazard presented by Silva (2008)



Ground Motion	Return Period (Years)	PGA (g)
Frequent	50	0.2
Rare	475	0.4
Very rare	970	0.5

Based on the fragility curves presented before, the probability of being in each damage state at each specified hazard level is obtained. Table 6 shows the comparison for the walls MFIEN3EP and MQE257EP. Figure 6 shows the damage probabilities for PGA equal to 0.2g, 0.4g, and 0.5g for the same walls.

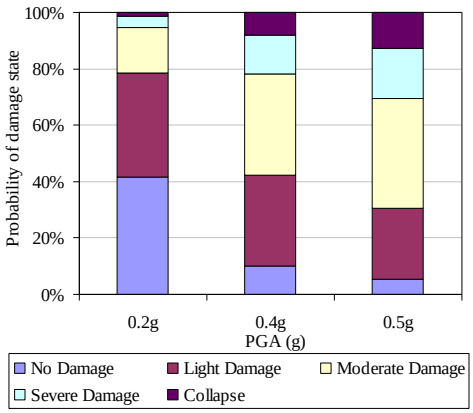


Table 6 Comparison of probability of each damage state for the three levels of seismic intensity

Damage State	PGA					
	MFIEN3EP			MQE257EP		
	0.2g	0.4g	0.5g	0.2g	0.4g	0.5g
No Damage	42.4%	10.3%	5.4%	41.7%	10.1%	5.3%
Light Damage	38.2%	32.0%	24.3%	36.8%	32.1%	25.1%
Moderate Damage	12.9%	34.3%	38.5%	16.2%	36.0%	39.1%
Severe Damage	6.3%	19.5%	24.1%	4.1%	13.9%	17.8%
Collapse	0.2%	3.9%	7.8%	1.2%	7.9%	12.7%

From Table 6, it is observed that in case of frequent earthquake, the damage is around 42% in no damage, 37% in light damage level and 14% in moderate damage for both walls. For a rare earthquake event, approximately 67% of the walls show light and moderate damage states and 10% of them without damage. In case of a very rare earthquake, approximately 63% of the wall MFIEN3EP and 57% of the wall MQE257EP show moderate and severe damage states. The probability of collapse is approximately 8% for the wall MFIEN3EP and 13% for the wall MQE257EP.

(a)

(b)

6. CONCLUSIONS

The use of fragility curves is a useful tool to estimate the structural damage in a certain type of structures due to the effect of future events. In the present study, the fragility curves for thin RC shear walls for low-rise and mid-rise buildings constructed in Lima is constructed thorough a series of numerical simulations. The PGA was selected as a seismic index, and the variation of the types of material used as main reinforcement were considered. The damage index is defined with respect to the drift, and it was classified into 4 damage states. The fragility curves presented in this study help to predict the damage that buildings composed of thin RC walls especially in Lima, Peru. From the analysis of the fragility curves obtained, the following conclusions can be drawn:

It was observed that the use of electro-welded wire mesh as main reinforcement gives similar damage probability compared with the wall consisted of the conventional reinforcement. This indicates that the use of electro-welded wire mesh is acceptable with the viewpoint of seismic resistance. The use of electro-welded wire mesh as main reinforcement can reduce the price of buildings.

The walls behave practically in moderate and light damage (94%) under the moderate earthquake. In case of the severe earthquake, the walls behave in severe and moderate damage (94% in average). The probability of collapse is approximately 6% in average for the both walls.

Abstract: A 1/2 scale model of a two-story self-centering reinforced concrete frame model was designed and tested on the shaking table in State Key Laboratory of Disaster Reduction in Civil Engineering at Tongji University to study the seismic performance of self-centering reinforced concrete frames. The interfaces in the joints can undergo compression but no tension by relaxing the constraints between structure and base or components. The forces for self-centering are provided by the post-tensioned prestressed reinforcement when the structure rocks under the earthquake. In this paper, the dynamic characteristics, displacement and joint responses of the model structure under different earthquake levels are discussed. The location and process of structural damage are summarized. The self-centering capability of the structure is analyzed. Test results indicate that the designed reinforced concrete frame has satisfying seismic performance and self-centering capacity subjected to earthquakes; self-centering structures can undergo large deformation with minor residual displacement after the earthquakes; more researches on energy dissipation members and the stiffness of columns and beams are expected.

1. INTRODUCTION

As an innovative branch of the seismic structural design, earthquake resilient structures have gained widespread concern in both academia and industry during the past few decades. This new system not only protects life safety by preventing structural failure in an earthquake, but also restores its structural function immediately after the earthquake (Lu *et al.* 2011). Earlier researches indicate that rocking of structure lowers the seismic excitation and ductility requirement of structures. Relaxing the constraints between structure and base or components, the interfaces in the joints can undergo compression but no tension. Post-tensioned prestressed reinforcement provides the forces for self-centering when the structure rocks under the earthquake (Zhou and Lu 2011). By controlling residual deformation of structures effectively, time and economic cost are saved. Little experimental research (Priestley 1991; Priestley and Tao 1993; El-Sheikh *et al.* 1999) on self-centering systems has been generated by far, most of which focused on steel frame structures (Christopoulos and Folz 2002; Garlock *et al.* 2007). Therefore, it is of significance to study the seismic performance of reinforced concrete self-centering structures.

This paper presents a 1/2 scale model of a self-centering reinforced concrete frame based on an one bay one span two stories prototype (Liu *et al.* 2012). It was designed and tested on the shaking table in State Key Laboratory of Disaster Reduction in Civil Engineering at Tongji University as the first shaking table test of large scale self-centering reinforced concrete structures in China. Focusing on the self-centering capability, the dynamic characteristics of the structure as well as the dynamic responses and damage under different levels of earthquakes are investigated. This provides the experimental basis for further study on self-centering reinforced concrete structures.

2. DISCRIPTION OF TEST

2.1 Model Design

In this experiment, a 1/2 scale model, with plan dimensions of 3.0 m × 1.5 m and a story height of 1.5 m was used. Columns were fixed in the base pits by prestressed strands. Rubber was placed in between the column and base. Top and seat angle connections were applied at the short beam and column joints. Prestressed strands were also used in the short beams. Figure 1 shows the plan and elevation of the model. Figure 2 shows a photograph of the test structure on the shaking table. The total height of the model including the base was 4.0 m while the weight was 13.0 t. The model was shaken in the short axis of the structure.

The model was fabricated under the similitude law (Lu *et al.* 2009; Zhou *et al.* 2006). Fine aggregate concrete with the characteristic strength of 40 MPa was used. HRB335 and HPB 235 were selected for the longitudinal reinforcement and stirrups, respectively. Two types of prestressed strands, Φ15.2 and Φ12.7 were adopted. The characteristic strength

of the angle steel was 345MPa. No slab was put on the floor. Two steel beams were hinged on the main beam to support the rigid mass above. Table 1 shows the similitude scale factors of the test model.

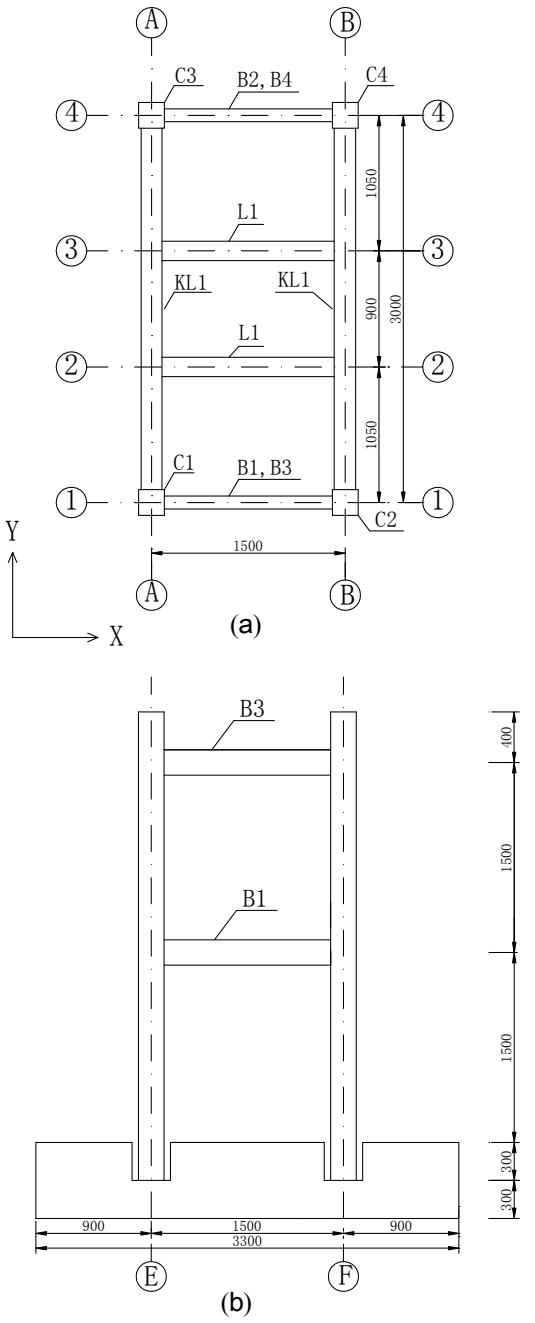

Figure 1 Plan and evalation view of test structure: (a) plan view, and (b) evalation view

Figure 3 shows the details of column base joints. Steel plates at the bottom of the columns were welded to the longitudinal bars. The interfaces between them and those in the base were separated. Rubber was placed in the interspace of columns and the base. Those construction measures were applied to prevent the local failures of concrete. The parameters of prestressed reinforcement in columns are shown in Table 2. The joints were expected to open at the interfaces under design excitation.

Table 1 Similitude scale factors

Parameter	Similitude scale factor	Parameter	Similitude scale factor
S_ε	1.000	S_M	0.125
S_σ	1.000	S_q	0.500

Column size	Prestressed reinforcement ratio	Prestressed strands	Prestressed force in each strand
200mmx200mm	0.69%	2Φ^{s}15.2	40kN

Figure 4 shows the details of beam-column joints in the direction of short dimension. Beams and columns were connected by prestressed strands. Steel plates were set at the end of beams and the sides of columns to prevent local failures. Top and seat angle connections were used to enhance the shear strength and stiffness of the joints. Meanwhile, they worked as energy dissipation devices after the joints opened. The joints were designed using the same criteria as the base joints. The parameters of prestressed reinforcement in beams are shown in Table 3.

Table 3 Parameters of prestressed reinforcement in beams

Beam size	Prestressed reinforcement ratio	Prestressed strands	Prestressed force in each strand
100mmx200mm	0.99%	2Φ^{s}12.7	40kN

2.2 Test Plan

Two historical ground motions were used for the shaking table tests, 1940 El Centro (NS) and 2008 Wenchuan waves. The model was subjected to two alternate series of excitation, (1) white noise tests to assess the damages after previous tests by evaluating the fundamental frequency of vibration, and (2) seismic tests to obtain the structural response under different levels of earthquake. The input ground motions were loaded at increments of peak acceleration by 0.05g starting from 0.05g. The maximum level test was the El Centro 0.60g test and the Wenchuan 0.80g test.

2.3 Sensors

Five types of sensors were used to record the response of the model: (a) four string potentiometers to measure the displacement of each storey; (b) eight linear variable differential transformers (LVDT) fixed on the beams ends and column bases to measure local displacement; (c) eight load cells to measure axial force of the prestressed strands in the beams (B1, B3) and columns (C1, C2); (d) eight accelerometers to measure horizontal and vertical floor accelerations; (e) four strain gauges to measure the strain of angle steel on C2.

3. TEST RESULTS

3.1 Dynamic Characteristics

Figure 5 shows the first and second frequency of vibration in the *X* direction estimated from each white noise test. The initial first frequency was 4 Hz. After the tests, the first frequency fell to 1.75 Hz. The change in frequency was mainly due to the damage of non-self-centering components and the yield of angle steel.

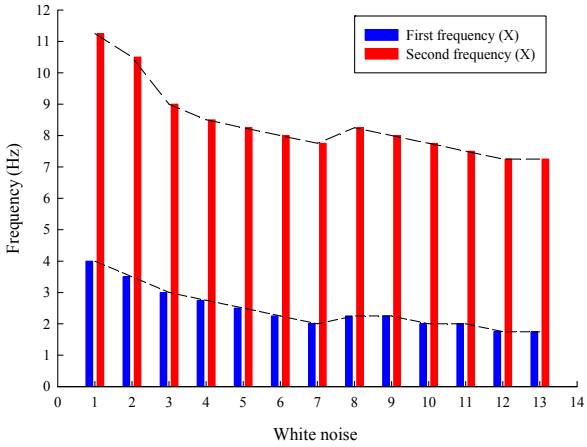

Figure 5 Change in frequency

3.2 Displacement Responses

Under seismic loads, the maximum floor displacement was 122.594mm for the first floor and 166.677mm for the second. Figure 6 shows the maximum inter-story drift ratio for each test. It reached 1/15 for the first floor and 1/26 for the second during the El Centro 0.60g test. The results demonstrate great ductility of the system.

Figure 7 shows the top floor displacement time history curve under the El Centro 0.60g test. The residual displacements were minimal respectively.

3.3 Joint Responses

The uplifts or openings are assumed to occur when the interfaces of self-centering joints reach a minimum gap of 1 mm. First, they were observed under the El Centro 0.20g test and the Wenchuan 0.30g test. When the El Centro 0.60g test

was loaded, the maximum uplift for column was 9.183 mm and the maximum opening for beam was 9.579 mm. Figure 8 shows the maximum uplift and opening under the El Centro 0.60g test. Figure 9 shows a picture of the uplift at the base and the opening at beam ends under the El Centro 0.40g test. Figure 10 shows the column uplift time history curve and beam opening time history curve under the El Centro 0.60 test.

The initial ratio of post-tentioning (PT) stress and yield stress were 0.16 and 0.23 for prestressed strands in columns and beams, respectively. The maximum stress of prestressed strands in columns were 473.185 MPa and 865.691 MPa for beams. The minimum stress of prestressed strands in columns were 248.829 MPa and 247.468 MPa for beams. These are shown in Figure 11. The prestressed strands were under linear elastic state across the test, providing the self-centering capability of the structure after the earthquake.

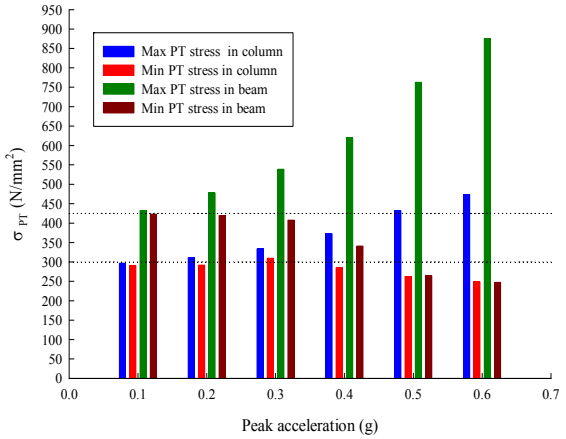

Figure 11 Maximum and minimum stress in prestressed strands under different earthquakes

The rubbers between the column and base were consistently elastic. Four strain gauges were used to measure the strains in the angle steel. The characteristic strength of the angle steel was 345MPa. The yielding strain is expected to be 1505με. As shown in Table 4, the angle steel was firstly considered yielded during the El Centro 0.25g test.

Table 4 Strain of the angle steel (με)

Test	B3T	B3B	B1T	B1B
El Centro 0.20g	1299	878	1112	1108
El Centro 0.25g	1725	1439	1740	1672

B1: beam B1; B3: beam B3; T: top; B: bottom.

4. CONCLUSIONS

This large-scale shaking table test validates that well designed self-centering reinforced concrete frame systems have satisfying seismic performance, especially under severe earthquakes. The structure with minimal residual displacement after the earthquake not only protects the lives and property but also saves great reconstruction time and cost. Below are the conclusions obtained from this study:

(1) The self-centering reinforced concrete frame has excellent seismic behavior. The tested model stayed elastic under excitation with maximum peak ground acceleration (PGA) of 0.20g. Small pieces of concrete cover fell down until the maximum PGA reached 0.45g. The structure kept in good condition without structural damage even after it went to 0.60g.

(2) The expected self-centering capacity was achieved in the test. The first uplift of columns and opening of beams happened at the El Centro 0.20g test. After the maximum PGA increased to 0.40g, the uplift of columns and opening of beams had been very obvious to observe. Large deformation of structure was obtained under the El Centro 0.60g test. However, no signal of collapse or structural damage appeared. The maximum uplift of columns reached 9.183mm while the maximum opening of beams 9.579mm. The structure went back to its initial position with negligible residual deformation.

(3) The major damage happened at the interfaces between angle steel and concrete. No damage was observed on the self-centering elements. The angle steel dissipated energy with large deformation as expected. It was noticed that yield of angle steel firstly happened at the El Centro 0.25g test, which could not be considered as a severe excitation. Higher strength of angle steel should be applied to achieve more ideal anticipation. However, rotational stiffness will also affect the self-centering capacity of structures.

(4) During the tests, bending deformation of both columns and beams were observed. To obtain better uplift and opening effect, columns and beams with higher stiffness should be selected.

Ongoing related studies involve numerical modeling and reliability analysis to characterize the self-centering reinforced concrete system. More research on energy dissipation devices and stiffness of elements is expected. It is hoped that an alternative of traditional seismic force resisting systems with better seismic performance and controllable post-quake repair could be provided.

Abstract: A laboratory test program was conducted at University of California - Berkeley to assess the response capabilities of large reinforced concrete special moment resisting frame (SMRF) beams. The size of the test beams is representative of modern high-rise construction in the seismically active west coast of the United States and is larger than was typical in the past practice. When the 2008 ACI 318 requirements for SMRF beams are applied to these large beams, the beam hoop spacing can be as great as 305 millimeters in the plastic hinge region. This raised a concern that such SMRF beams may not be able to meet the performance expectations during an earthquake and motivated the experimental study. In order to address the adequacy of the code hoop spacing requirements, the test program evaluated the response of two full-scale beam models tested under reversed-cyclic loading. In the first specimen, the transverse hoops were placed at a maximum spacing allowed by the 2008 Code. In the second, the hoop spacing was reduced to satisfy the updated 2011 Code requirements. The responses of the two specimens are discussed, especially noting differences in performance.

1. INTRODUCTION

Reinforced concrete special moment resisting frames (SMRFs) are commonly selected seismic load resisting systems in the United States. These systems, referred to as "special moment frames" in ACI 318 (ACI, 2011), are designed around the strong column-weak beam design philosophy whereby the majority of inelastic flexural deformations are intended to occur in the columns of the bottom of the first story and in the beams along the height of the building. The yielding of reinforcing steel and concrete cracking in the beams that occur in the plastic hinge regions are also the main source of energy dissipation in the reinforced concrete moment frames. Previous studies of generic reinforced concrete SMRF buildings (Visnjic et al., 2012) showed that mean rotation amplitudes of the beams along the building height were 2% for the design basis earthquake and 3% for the maximum considered earthquake levels. Therefore, for a structure subjected to multiple large displacement cycles at levels consistent with the building code design provisions, it is important that the beams are capable of sustaining deformation reversals in a stable manner and without significant loss of strength.

In taller buildings, SMRF beams can be as deep as 1200mm and are generally larger than what was used in the past practices. The provisions of the ACI 318 code prior to the 2011 edition when applied to such large beams could result in a maximum spacing of transverse reinforcement reaching 305mm in the plastic hinge region. This raised a question whether such beams would be able to realize the stable inelastic flexural behavior under large deformation cycles during seismic events. The concern motivated the undertaking of the experimental program to evaluate the response capabilities of large reinforced concrete SMRF beams satisfying the existing code requirements of 2008 ACI 318 (ACI, 2008). The findings prompted the reduction of the maximum allowed transverse hoop spacing to 152mm in the 2011 ACI 318 code and are presented in the subsequent sections.

2. EXPERIMENTAL PROGRAM

2.1 Beam Specimens

The experimental program included two 4115mm-long cantilever reinforced concrete beams anchored to a common reaction block (Figure 1). Both beams were 762mm wide and 1219mm deep (Figure 2) and were longitudinally reinforced with five No. 36 bars (d_b = 36mm) at both the top and bottom. Transverse reinforcement hoops consisted of three pieces: a stirrup with seismic hook, a crosstie at the top to close the hoop, and an additional vertical crosstie bracing the longitudinal bars along the top and bottom faces. Each piece was made of No. 16 bar. The crossties were alternated end for end along the length of the beam, as specified in the ACI 318 code. The beams also contained the longitudinal skin reinforcement made up of No. 15 bars.

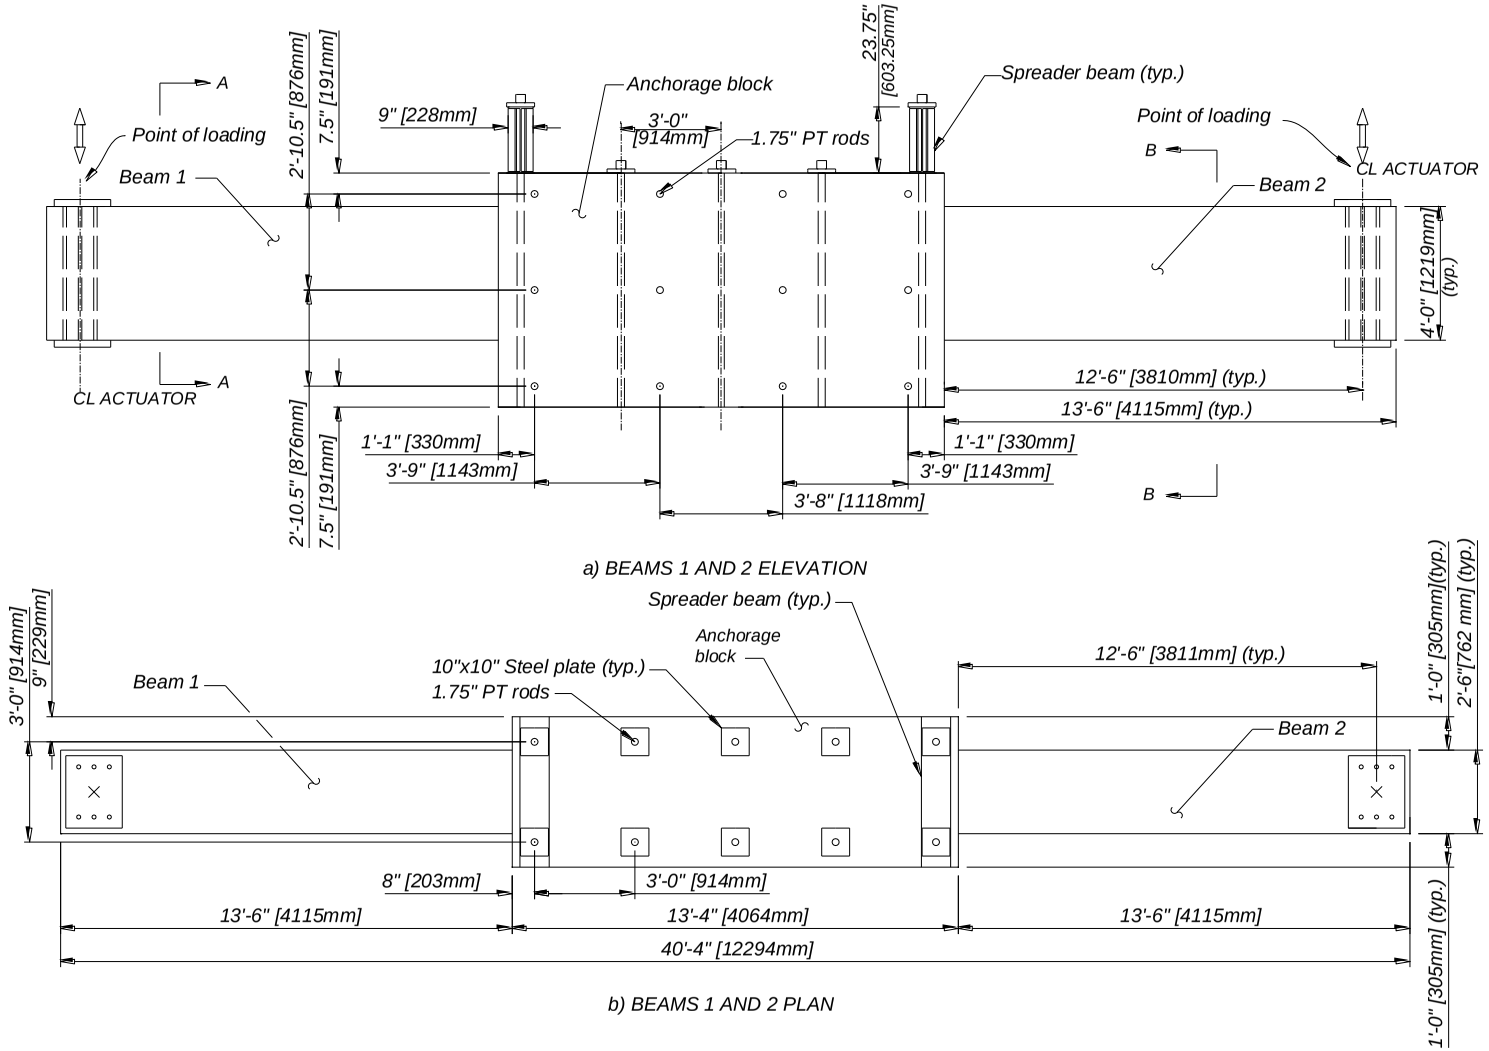

Figure 1 Laboratory Setup of Beams 1 and 2: (a) Elevation, and (b) Plan View

The only design parameter differing between the two beams was the spacing of the transverse hoops. Beam 1 hoops were spaced at s_h = 279mm to satisfy the provisions of the 2008 ACI 318 code. Beam 2 hoop spacing was reduced to s_h = 152mm and satisfies the current ACI 318 code provisions (ACI, 2011). This arrangement of beam hoops resulted in volumetric confinement ratios of ρ" = 0.31% and 0.57% for Beam 1 and Beam 2, respectively.

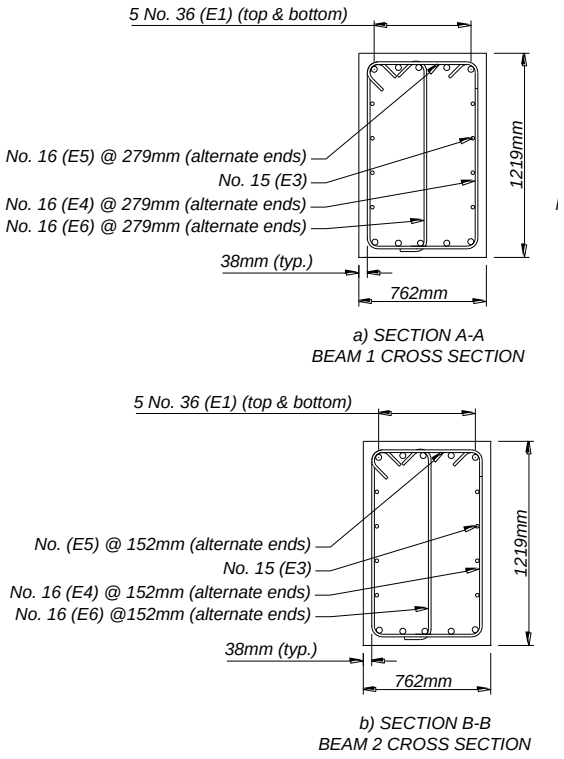

Figure 2 Cross Section of Beams 1 and 2

The specified compressive strength of normal weight concrete for the beams was f'_c = 34MPa. The concrete cylinders of sample from each batch used were tested on the day of the experiments for both beams. For Beam 1, the average compressive strength of concrete was 40.1MPa, while for Beam 2, it measured at 42.3 MPa.

ASTM A706 Grade 60 steel was used for the both the longitudinal No. 36 bars and transverse No. 16 bars with specified yield strength of f_y = 413MPa. Tension tests of three steel coupons constructed from No. 36 bars revealed the actual average yield strength to be f_y = 455 MPa with average maximum stress of f_u = 723 MPa. A well-defined yield plateau developed for the No. 36 specimens tested with the average strain at the onset of strain hardening equal to ε_{sh} = 1.2%. Average maximum measured stress in steel was f_u = 723 MPa. The coupons did not display a yield plateau. For the No. 16 bars, the average yield stress measured in three sample coupons was f_y = 503 MPa.

2.2 Loading Protocol

The beams were tested by imposing downward and upward displacement cycles simulating the effects of deformation reversals that occur during a major earthquake. Displacement history shown in Figure 3 was imposed by an actuator with a point of loading located 3810mm from the face of the anchorage block (Figure 1). Positive beam tip displacement and reaction forces correspond to downward beam deflection. A downward displacement and an upward displacement of equal amplitude followed with returning the beam tip to neutral position constitute a complete cycle. Cycles of equal amplitude were grouped into steps so that each new step contained cycles with different displacement amplitude from those in the preceding step. This is shown in Figure 3.

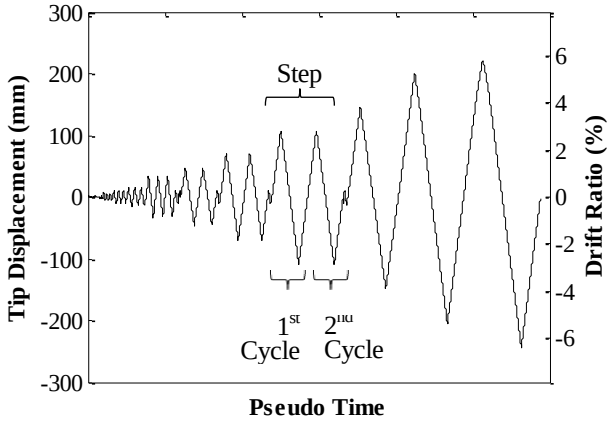

Figure 3 Loading Protocol for Beams 1 and 2

2.3 Instrumentation

The instrumentation of the test specimens included linear variable differential transformers (LVDTs) connected between steel rods that were embedded in the specimen along the top and bottom face of the beams. LVDTs were also placed between the bottom face of the beam at the point of loading and the strong floor to measure total beam deflection. In addition, strain gauges were attached to both the longitudinal bars and hoops at selected locations. During the testing of Beam 1, an error in data acquisition system resulted in permanent loss of measurements from few strain gauges and LVDTs, however, most important information could be gathered from the remaining instruments.

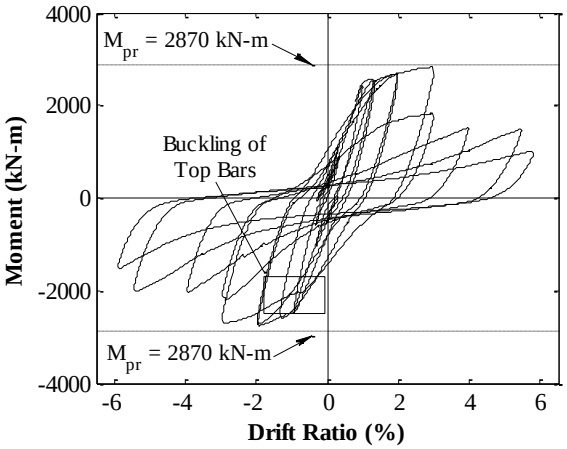
3. TEST RESULTS

3.1 Beam 1 Response Overview

Figure 4 shows the relation between the computed resisting moment and the measured beam drift ratio for Beam 1. The moment was calculated from the measured force applied at the beam tip and includes the self-weight of the beam. The initial deflection due to beam self-weight is deemed negligible and is not accounted for in the reported drift values. Cycles with amplitude lower than 0.28% are omitted from the graph for clarity.

Computed probable flexural strength M_{pr} = 2970 kN-m is also shown in Figure 4. This value was calculated in accordance with ACI 318 assuming the specified concrete compressive strength f'_c = 34 MPa and elasto-plastic steel stress-strain relation with maximum steel stress taken equal

to 1.25 times the specified yield stress, that is f_{pr} = 517 MPa. The M_{pr} calculation ignored the contribution of skin reinforcement, because the No.15 longitudinal bars were not fully developed into the anchorage. These bars, if accounted for, would result in 9% increase in M_{pr}. The peak measured moment was equaled to 2850 kN-m and was within 5% of the computed value.



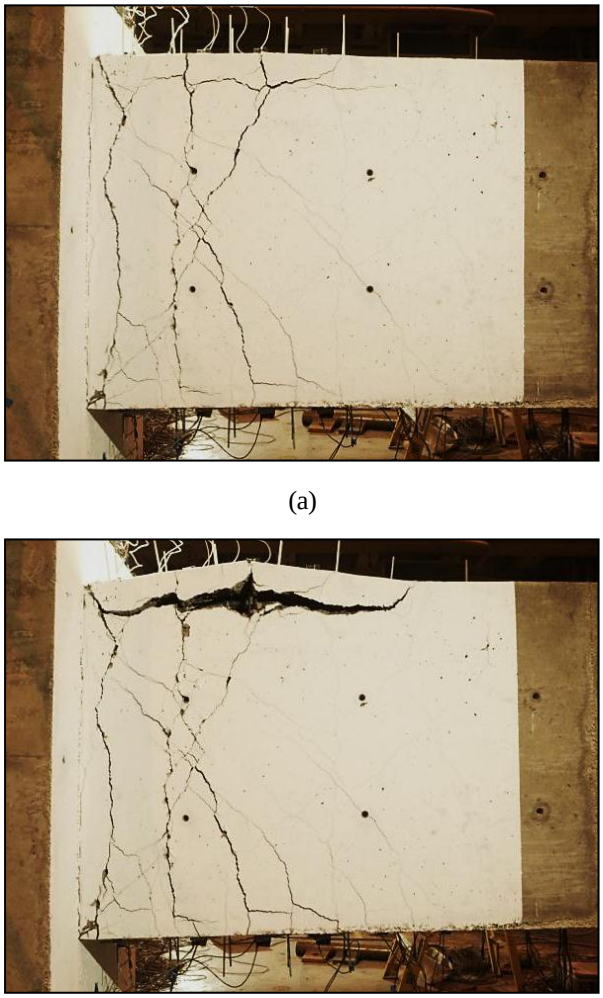


Figure 4 Moment-drift ratio history of Beam 1

The specimen displayed relatively stable response to load reversals with no apparent strength loss upon the completion of the cycles with 1.8% peak drift. During the first cycle with -2.7% peak drift, top longitudinal bars buckled, as shown in Figure 6, opening a "crack cave". This is also evident in the moment-drift ratio curve where a slight instantaneous drop in strength occurred (Figure 4). Buckling of longitudinal bars caused a 30% loss of flexural resistance during a second cycle with peak positive drift of 2.7% (Figure 4). During each subsequent cycle, Beam 1 showed progressive loss of stiffness and strength, with resistance of only 50% of the peak measured resistance during the last displacement cycle. Buckling also occurred in the bottom longitudinal bars, as can be seen in Figure 6(b).

Beam 1 developed large vertical cracks, attributable to flexure, which were spaced at about 250mm in the plastic hinge region. This is close to the spacing of the hoops and as can be seen in Figure 6(b), the locations of the cracks roughly coincide with the hoop locations. Diagonal cracks, attributable to shear, notably increased upon longitudinal bar buckling. The observed shear deformations contributed majorly to the total beam displacement in the last couple of cycles. In the last downward cycle with peak drift of 6.4%, Beam 1 exhibited signs of impending shear failure which can be observed in Figure 7, where the entire specimen moved in a translating mode.

(b)

Figure 6 Damage State of Beam 1during the First Cycle with Peak Drift Ratio θ = 2.7%: (a) Horizontal Cracks Indicating Onset of Top Longitudinal Bars Buckling (Instantaneous θ = -0.9%), and (b) Buckling of the Top Longitudinal Bars (Instantaneous θ = -2.7%)

3.2 Beam 2 Response Overview

The relationship between the computed resisting moment and the drift ratio for Beam 2 is plotted in Figure 8, with cycles of drift ratio amplitude lower than 0.28% omitted for clarity. Peak resisting moment for this specimen was 3148 kN-m, which was 10% higher than maximum resisting moment of Beam 1. Contrary to the first specimen (Beam 1), Beam 2 showed no evidence of significant strength loss upon completion of all cycles up to and including the peak drift ratio of 2.9%. Pinching of the moment-drift ratio curve became more pronounced in the second cycle with peak drift ratio of 2.9%. During this cycle horizontal cracks associated with initiation of bar buckling and top bar dowel action grew noticeably.

(b)

Figure 7 Beam 1 at the Maximum Positive Displacement Cycle (Instantaneous θ = 5.5%): (a) Overview, and (b) Plastic Hinge Region with Large Apparent Shear Deformation

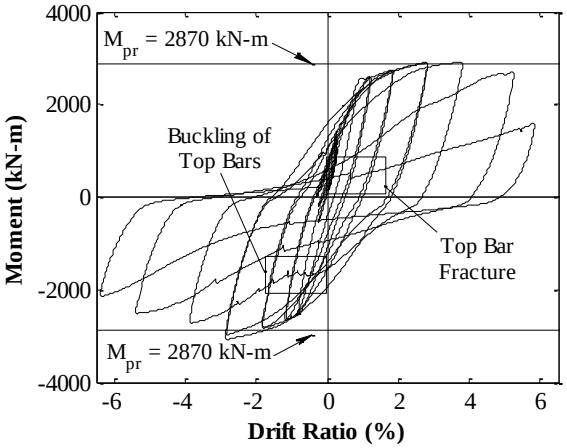

Figure 8 Moment-drift ratio history of Beam 2

Buckling of longitudinal bars in the top face became apparent during the upward displacement phase of cycle with peak θ = -3.9%, (Figure 9[a]). Instantaneous loss of strength can also be noted in the moment-drift curve due to the excessive buckling (Figure 8). Progressive reduction of resisting force followed during the subsequent cycles. Buckling of bottom longitudinal reinforcement became obvious during a cycle with a peak drift ratio of 5.3% (Figure 9[b]).

(a)

(b)

Figure 9 Beam 2 Plastic Hinge Region: (a) Buckling of the Top Longitudinal Reinforcement (Instantaneous θ = -3.9%), and (b) Buckling of the Bottom Longitudinal Reinforcement (Instantaneous drift ratio equal to peak cycle θ = 5.3%)

During the last loading cycle, corresponding to a 5.8% drift ratio, one of the top corner bars fractured at a beam drift ratio of 0.7%. This resulted in a sudden strength loss in the beam of approximately 38%. The peak resistance for this cycle was 43% lower than for the preceding downward cycle and 48% lower than the peak strength for loading in this direction. The condition of Beam 2 at the peak downward displacement is shown in Figure 10.

Figure 10 Overview of Beam 2 at the Maximum Positive Displacement (Instantaneous θ = 5.8%)

3.3 Shear Deformations

The relationship between the resisting shear and the shear deformation in the plastic hinge region of the two specimens is shown in Figure 11. For Beam 1, this relationship is plotted only for the cycles with peak drift ratio less than and including 1.8%, after which buckling occurred and measurements in the LVDTs were distorted. The peak measured shear force was 739 kN, corresponding to a nominal shear stress of 0.83 MPa, or $0.13\sqrt{f_c'}$ MPa using measured compressive strength. Although nominal shear strength V_n computed as defined in the ACI 318 was 1870 kN and more than twice the peak resisting shear value, significant deterioration of shear stiffness is notable as the cycles progress (Fig. 11). During the positive (downward) loading phase in the second cycle with peak drift θ = 1.8% shear deformations almost doubled from those measured in the preceding deformation cycle of the same drift amplitude. The shear stiffness deterioration is also evident in progressively larger pinching in the moment-drift ratio curves for the subsequent cycles of the same displacement amplitude (Fig. 4).

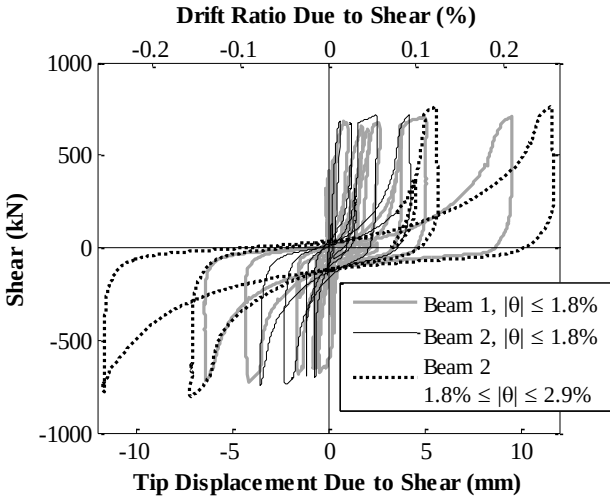

Figure 11 Measured Force vs. Shear Deformation Curve for Beams 1 & 2 and Cycles Preceding the Bar Buckling

The peak measured resisting force for Beam 2 was 805 kN, which corresponds to shear stress of $0.14\sqrt{f_c'}$ MPa, where f'_c is the measured compressive strength of concrete. The nominal shear capacity of Beam 2 computed according to ACI 318 was V_n = 2720 kN. Figure 11 shows the relationship between the resisting shear and shear deformation in the plastic region for Beam 2 for the cycles prior to the observed bar buckling. Shear stiffness degradation can be noted through the progression of cycles. Although Beam 2 was loaded to less than 30% of the computed nominal shear capacity, up to 10% of the total beam displacement was attributable to shear deformations. Beam 2 exhibited smaller shear deformations compared to Beam 1 at the cycles of equal displacement amplitude, which can be seen in Fig. 11. The solid gray and black lines depict approximate shear deformations for Beam 1 and Beam 2, respectively, up to a drift ratio of θ = 1.8%. During the last cycle with this drift ratio, approximate measured shear deformation in Beam 2 was roughly 50% of that measured during the equivalent cycle in Beam 1.

3.4 Measured Crack Widths

Both specimens developed large diagonal cracks associated with shear deformations and vertical cracks associated with flexural deformations. For Beam 2, crack widths were recorded at peak beam tip displacements for a first cycle in a step (refer to Section 2.3 and Figure 3 for definition) and upon completion of a step, that is, when the beam tip was brought back to zero displacement. Crack widths were not systematically recorded during the Beam 1 test; nevertheless, the measurements available provide a valuable insight in its response.

Figure 12 shows the diagonal (shear) crack widths measured at peak positive displacement of each leading cycle in a step. Crack widths in Beam 2 increase linearly with increasing drift ratio prior to cycle with θ = 1.8% amplitude. After this point, the cracks grow at an increased rate, though still in almost linear fashion. Few measurements recorded during Beam 1 test indicate that diagonal crack widths are roughly twice those of Beam 2 for drift ratios smaller than 2.7%. This is consistent with the shear deformation measurements (Figure 11) where Beam 1 displays twice the shear deformations of Beam 2. Largest recorded diagonal crack for Beam 1 was 25mm wide at 3.6% drift ratio, which is the instance when impending shear failure was initiated.

Vertical (flexural) crack width measurements are plotted as a function of peak drift ratio in Figure 13. The size of cracks increases approximately linearly with increasing peak drift ratio for Beam 2. The few measurements recorded for Beam 1 indicate similar trends, but slightly larger crack widths are recorded compared to those in Beam 2. Figure 13 also shows residual crack sizes for Beam 2 which can provide a measure of post-earthquake serviceability level and repairs required. Upon completing all of the cycles with drift ratio smaller than and including 3.9%, the largest residual crack measured on the Beam 2 was 15mm. It should be noted that the absolute largest residual crack was

recorded at the interface and it measured 20mm for this cycle.

3.5 Fixed-End Rotation

Rigid beam (fixed-end) rotation was measured by two pairs of LVDTs placed at the beam interface – two LVDTs were located at the top surface of each specimen and two were located at the bottom surface. The instruments were positioned to span a very short length (50mm) of the beam so as to minimize the flexural and shear deformation components in the measurement. Figure 14 shows the relationship between the fixed-end rotation and the total beam drift ratio for Beam 2. The curve is plotted only for the cycles prior to longitudinal bar buckling. As can be observed, fixed-end rotation contributes to roughly 40% of the total beam tip deflections for Beam 2. A 50% increase in fixed-end rotation is noted for the second cycle of 2.9% drift ratio, which is likely attributable to bond deterioration between the longitudinal reinforcement and surrounding concrete within the anchorage and the beam.

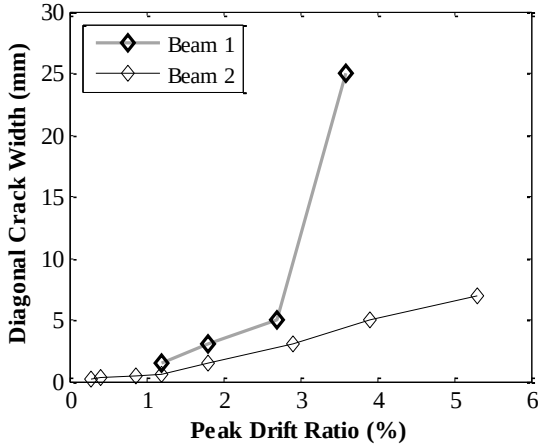

Figure 12 Diagonal Crack Width vs. Drift Ratio for Peak Positive Displacement of Each Cycle

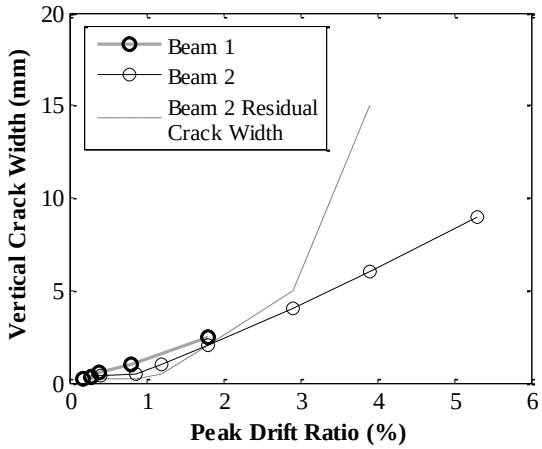

Figure 13 Vertical Crack Size vs. Drift Ratio for Peak Positive Displacement of Each Leading Cycle (Beams 1 & 2) and Residual Crack Size (Beam 2 Only)

Measurements from several instruments in Beam 1 were not acquired due to computer error during the experiment and as a result, only data from one of the top LVDTs measuring the deformation at the Beam 1 interface was recorded. Although this is not sufficient to compute the rigid beam rotations for Beam 1, the data available provide an approximate measurement of interface crack opening which offer an insight into level of fixed-end rotations of the specimen.

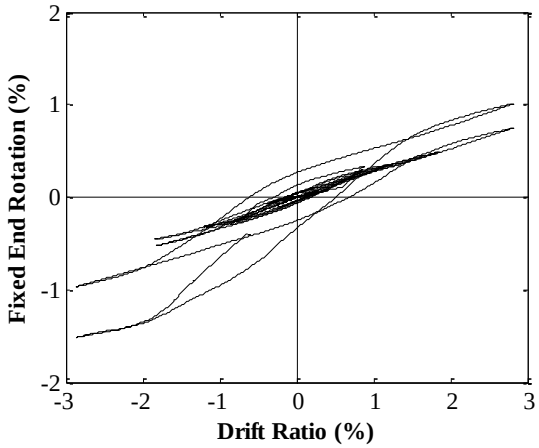

Figure 14 Fixed-End Rotation vs. Drift Ratio for Beam 2

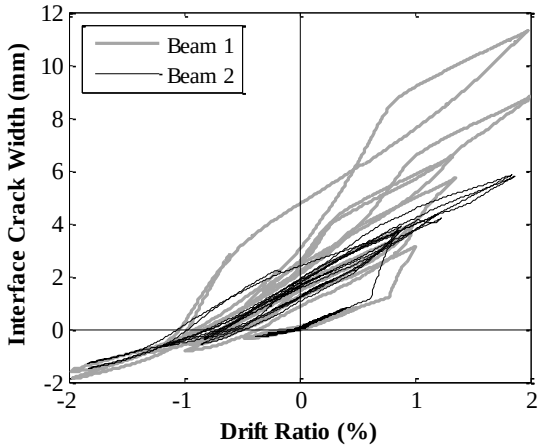

Figure 15 Elongation of LVDT Located at the Beam Interface with Reaction Block (Approximately Equal to Interface Crack Width) vs. Drift Ratio ($|\theta| \leq 2.9\%$)

The variation of the interface crack size with the beam drift ratio in Beam 1 is plotted in Figure 15 and compared to that of Beam 2, by plotting the data from the LVDT positioned at the corresponding location of Beam 2. Measurements from this instrument indicate approximately the same interface crack size when the top surface of beams where the instruments are located is in compression, that is, for the negative drift ratio.

During the cycles with positive drift ratio, interface cracks are similar for cycles with peak drift ratio less than roughly 0.7%. Beyond this point, interface crack size increases more quickly in Beam 1 (Fig. 15). At the maximum positive displacement of second cycle with peak drift ratio $\theta = 1.2\%$, interface crack in Beam 1 is roughly 1.5 times the size of interface crack of Beam 2. Crack widths at

the interface increase in both specimens during the following displacement cycle with θ =1.8% and Beam 1 again exhibits 50% larger interface crack. Upon displacing the beams to the same drift ratio for the second time (θ=1.8%) crack size in Beam 2 remains almost constant, while that of Beam 1 increases by another 30%. In other words, at the peak positive displacement for the second cycle with 1.8% drift ratio amplitude, Beam 1 interface crack was about 1.9 times the size of that in Beam 2. It may be plausible that same relationship holds for the rigid beam rotation attributable to slip between the two specimens, assuming the neutral axis depth at the same beam deflection does not differ significantly between the two specimens.

3.6 Plastic Hinge Elongation

Figure 16 shows the measured elongation in the plastic hinge region for the two specimens. The curve plotted corresponds to the elongation along the centerline of the beam, computed by averaging the elongations measured along the top and bottom face of the beams. This calculation excluded the contribution of bar slip at the interface with reaction block. Measurements of wire potentiometers beyond the point of longitudinal bar buckling were not considered. Interestingly, Beam 1 exhibited smaller growth for the cycles investigated. This may be due to larger contribution of fixed-end rotations for a given drift ratio, compared to Beam 2. Figure 16 indicates that upon completion of cycles with peak drift ratio of 2.9% the elongation of Beam 2 is 25mm.

A rule of thumb for estimating beam elongation is to multiply the beam drift ratio with half the height of the beam (e.g. Kabeyasawa et al., 2000). With this simple calculation, estimated beam elongation corresponding to drift ratios of 1.8% and 2.9% are 11mm and 17mm, respectively. The measurements reported in Figure 16 for the 1.8% drift ratio are almost identical to the estimated elongation. At the first cycle to 2.9% peak drift ratio, the measurements fall within 15% of the calculated value, while for the last cycle to 2.9% peak drift, the elongation measured is 50% higher than what was estimated by this rule of thumb.

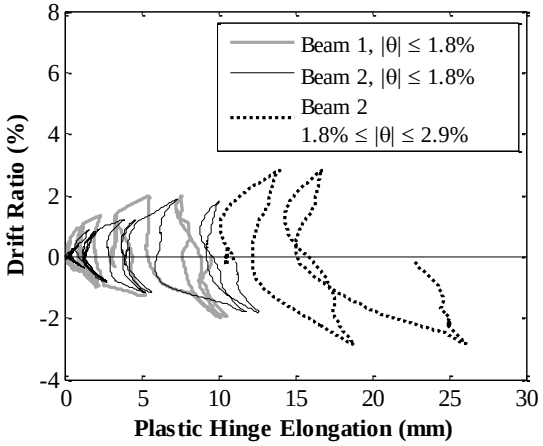

Figure 16 Axial Elongation of Plastic Hinge Region in Beams 1 and 2 Prior to Buckling of Longitudinal Steel

4. SUMMARY AND CONCLUSIONS

Two large reinforced concrete special moment resisting frame beams were tested in the laboratory program under reversed cyclic displacements of increasing amplitude (Section 2.2). Both beams had identical size (1219mm deep and 762mm wide), specified material properties, and size and arrangement of longitudinal reinforcement (Section 2.1). First specimen, Beam 1, contained No. 16 hoop sets spaced at 279mm (Figure 2[a]), corresponding to s_h/d_b = 7.8, and satisfying the requirements of ACI 318 (2008). The second specimen, Beam 2, contained hoops of identical components and reinforcement size as Beam 1, but spaced at 152mm (Figure 2[b]), which corresponds to s_h/d_b = 4.25. The transverse spacing of hoops in Beam 2 conforms to the provisions of ACI 318 (2011). The experimental investigation resulted in the following findings:

1. In both specimens, bar buckling of the longitudinal reinforcement was a primary source of damage initiation and progress. Longitudinal bar buckling initiated during a cycle with a peak drift ratio of 1.8% for Beam 1, while for Beam 2, bar buckling was delayed until the first cycle with a peak drift ratio of 2.9%.
2. Bars located at the top face were the first to buckle for both beams where the local concrete strength was expected to be the lowest, while longitudinal bars along the bottom face buckled in the subsequent cycles. A most likely cause of top bars buckling first, however, was the arrangement of the hoop components. In the absence of the top slab, the presence of the cap ties that closed the hoops at the top of the beam creates a weakness and this should be considered when detailing the transverse reinforcement in beams that are expected to deform into the inelastic range.
3. Beam 2 with reduced hoop spacing was capable of sustaining more displacement cycles and larger displacement amplitude than Beam 1. While Beam 1 lost 38% of its peak resistance during a second cycle to peak drift ratio of 2.7%, which occurred suddenly, Beam 2 strength loss was more gradual and did not occur until the cycles with peak drift ratio of 3.9%.
4. Although the beams had 2-3 times larger nominal shear capacity than the resisting shear induced during the tests, gradual degradation of shear stiffness was noted in both beams. Shear deformations in Beam 2 contributed to roughly 10% of the total beam displacement. Shear deformations measured in Beam 1 were roughly twice those in Beam 2 prior to cycles with longitudinal bar buckling. Larger shear deformations in Beam 1 were also evident from measured crack widths that were roughly twice those recorded in Beam 2. Apparent increase in shear deformations was exhibited during cycles after longitudinal bar buckling occurred, but the data was not quantified due to potential distortion of the instrument measurements.
5. Fixed-end rotations attributable to longitudinal bar slip constituted approximately 40% of the total beam displacement in Beam 2. Beam 1 rigid body rotation was not directly computed, however Beam 1 displayed larger interface crack widths than Beam 2, which indicates larger

fixed-end rotations.

6. During the displacement cycles that caused longitudinal bar yielding, plastic hinge zones of both specimens exhibited axial elongation of similar magnitudes. Beam 1 displayed slightly smaller elongation, possibly due to rigid body rotation contributing to a larger portion of the total beam displacement compared to Beam 2. Simple rule of thumb proves adequate for estimating beam elongation over most of the cycles prior to bar buckling.

Abstract: This study presents a performance-based design and assessment approach that captures a more realistic response of buildings when subjected to earthquakes and capable of incorporating target performance in the building design. The proposed method utilizes 3D nonlinear dynamic analysis of buildings with the objective of achieving predictable seismic performance and optimizes strengthening that translates to the owners' expectation. The frame model assumes that the nonlinear behavior of the structure is concentrated in plastic hinges, modeled as spring systems located at element ends. The building model is verified via agreement of elastic and nonlinear behavior with that obtained using conventional software. The ground acceleration data used in dynamic analyses is selected to be compatible with the design spectrum calculated at an assumed site. The method allows analysis of progressive collapse providing ease in the assessment of performance and identification of critical members of the building that needs retrofitting. This paper analyzes a building using the proposed method and shows that it is capable of simulating the building's nonlinear response and potential collapse mechanisms. Results show that the increase in member dimensions and/or the use of FRPs addresses the inadequacy and prevents the building to collapse.

1. INTRODUCTION

1.1. Background

In the past couple of years, several strong earthquakes occurred in countries such as Chile, Haiti, China, New Zealand, Japan, etc. that claimed thousands of lives and destroyed millions worth of infrastructure including ruptured roads, toppled bridges, and collapsed buildings. Similarly in the Philippines, a magnitude 6.9 earthquake shook Negros-Cebu area last February 2012 affecting about 64,000 families and causing major damages to roads, bridges, and buildings. The estimated cost of damage to the infrastructure was about 383 million pesos and 25% of it was on buildings. Reportedly, at least 15 thousand houses were either partially damaged or collapsed. Additionally, commercial buildings, government offices, schools, hospitals, malls, and churches were also damaged. The casualties reached at least 200 people, some of which were caused by collapsed concrete and debris. The local government advised a post-earthquake assessment to evaluate the extent of damage and urged to strengthen the existing structural policies as the buildings did not respond well to natural impacts (NDRRMC 2012). Thus, it is imperative to analyze the response of a building during earthquakes and predict its potential collapse mechanism.

This study proposes an approach that is capable of assessing and improving the structural response incorporating performance criteria when the building is subjected to seismic loads with the objective of optimizing safety. Performance based regulation often include performance criteria such as immediate occupancy, life safety and collapse prevention (Krawinkler 2004). Adopting this approach establishes a certain level of client-engineer agreement assuring compliance with the set criteria entailing to a more client oriented engineering as compared to the traditional approach.

Performance based approach in earthquake engineering emphasizes on the simulation of nonlinear response since earthquake loads often push the structure to its inelastic range. Moreover, nonlinear analysis is more reliable in capturing the material degradation or loss of strength thus providing a more realistic representation of structural response.

The proposed method of assessment uses an open-source program capable of performing 3D nonlinear dynamic analysis. This program is originally coded to simulate physically based rigid body systems and can correctly handle dynamics of rigid objects which includes motion, collision, interaction between object, etc. It was further developed to perform earthquake response analysis by introducing nonlinear links

(springs and dampers) with user-specified hysteresis rules.

1.2. Objective and Limitation

This study aims to analyze a residential house that is traditionally designed. The simulation of the house intends to identify the critical points or failing members and observe the potential collapse mechanism. This paper also aims to present the applicability of the method to strengthen the said building after the assessment via retrofitting assuming that the house is existing and redesigning if it is not yet constructed.

The study focuses on the collapse prevention of the building as its performance target. The analysis will only deal with the flexural behavior and failure of the structural members. It follows that the strengthening of the building will focus on the flexural capacities of the failing members.

1.3. Significance of the Study

Strengthening of identified critical members prior to earthquake is a necessary intervention to prevent damage to properties, personal injuries, and cost of repair. The end beneficiary of the study would be the owner of building since a thorough evaluation which gives them the knowledge on how strong their building is or how it would respond to earthquakes. Additionally, strengthening scheme will be prepared should they choose to implement in the future to improve their building and prevent potential collapse.

1.4. Related Study

Traditional design methodologies are being adopted in evaluating existing buildings. Using the strength based approach, the condition of the buildings are analyzed and checked if deficiencies are found. The deficiencies are determined by comparing members' capacity to the demands from the analysis. In seismic analysis, structural codes specify that the nonlinearity of elements should be considered. Current codes provide minimum provision for design with the objective of safeguarding against earthquake induced structural failures and loss of life, not to limit damage or maintain function (NSCP 2010). These current codes are being developed to eliminate a level of ambiguity particularly in quantifying damage states (UC Berkeley 2003).

Sung et al., (2006) used performance-based damage assessment on RC buildings. In general, performance-based earthquake assessment has the objective of determining the nonlinear performance of a building under different scales of strong earthquakes for safety and retrofitting considerations. They discussed several approaches for performance-based seismic evaluation provided by Applied Technology Council (ATC), Federal Emergency Management Agency (FEMA), etc. and extended these approaches to assess a low rise RC building through the results of pushover analysis and hysteresis relations.

Modelling Approaches

Giberson (1976) introduced nonlinear rotational springs at locations where bending moment reaches plasticity. Under earthquake loads, he used these springs at member ends assuming that inelastic deformation are concentrated at these locations and the middle part remain elastic. The spring stiffness properties were derived from the material properties and geometry of the member. This simple model is very viable to nonlinear analysis since any hysteresis relation can be assigned to the springs. The results using this method was found to be reasonable for a relatively low rise frame structure wherein the inflection points of the members does not deviate much from the middle.

Discrete element models overcome the variability of stiffness along member. This method sub-divides the member into several segments. Wen and Janssen (1965), presented discrete spring model in analyzing plane frame. It consists of segmented rigid elements connected by springs where flexibility is lumped as tributary basis where shorter segments are recommended in region of high bending moment.

Numerical approximations are expected to be more reliable as the number of segments or sub-elements increase. Most common numerical analysis method in structural analysis is the Finite Element Method (FEM). In FEM, the structure is represented by a finite number of elements connected by pre-selected number of nodal points. FEM's applicability in structures includes static, dynamic, linear and nonlinear analysis. In spite of its accuracy and wide range of application, it lacks the ability to deal with the separation between elements when subjected to large deformation since it assumes that the nodes connecting two or more elements have same displacements. Hence, it cannot simulate the potential collapse of the structure.

Meguro, K. and Tagel-Din, H. S. (2002) developed the Applied Element Method (AEM) to simulate highly nonlinear behaviour of structure under static and cyclic loadings. It discretizes the member into an assembly of elements connected by normal and shear springs which represent stresses and deformation. This method is capable of simulating large displacement, separation of elements and progressive collapse.

2. METHODOLOGY

The general procedure of the study is shown in the diagram in Figure 1 and is explained in the subsequent sections.

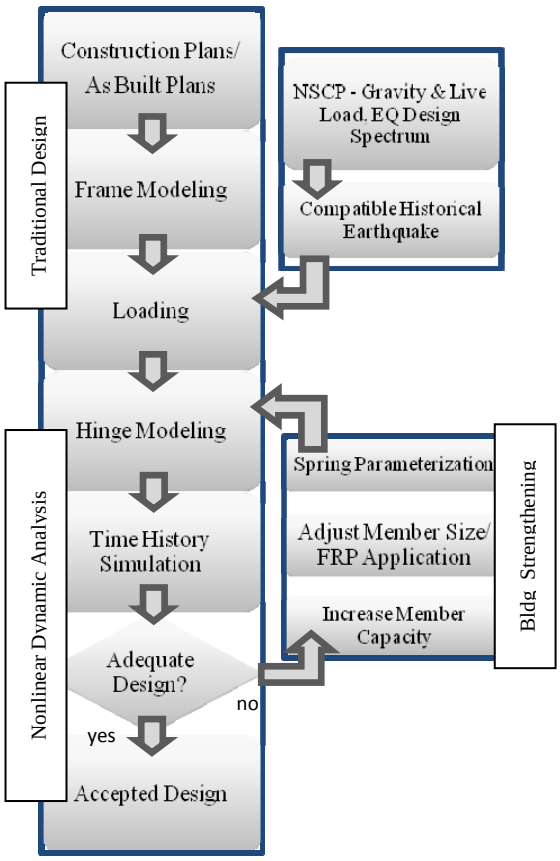

Figure 1. Conceptual Framework

2.1. Modelling

The building will be modeled as beam column space frame with inelastic hinges situated at end of each member to capture the concentration of plasticity of the material as shown in Figure 2

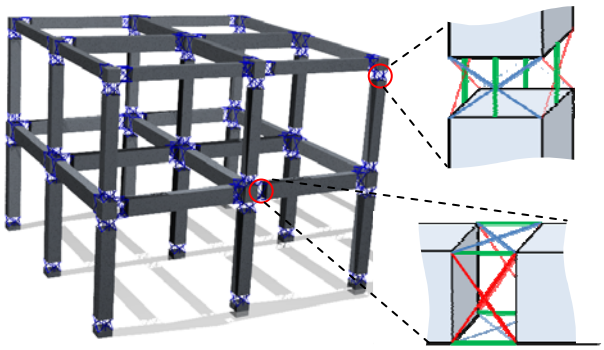

Figure 2. Proposed Building Model and Spring Configuration of Plastic Hinge at End of Beams and Columns

These hinges are modeled as a spring system capable of simulating the axial, shear, and flexural behavior of the members. The spring system configuration for beams consists of twelve springs which includes four parallel springs (axial spring in green) connected at each corner and two diagonal in-plane springs at each of the four sides of the beam (along the height and base of the member in red and in blue respectively.). On the other hand, spring configuration for columns is similar to that of beams but the four parallel springs are connected to the mid-edge of the member. This is to isolate the biaxial moment behavior of the column.

These spring configuration are optimally chosen to minimize the number of spring parameters to be determined in the succeeding section. Each spring has a load-deformation behaviour that may be elastic, elastoplastic, bilinear, tri-linear, etc.

2.2. Loading

Gravity and live loads are established using the information about the building and the minimum loads specified by the National Structural Code of the Philippines (NSCP).

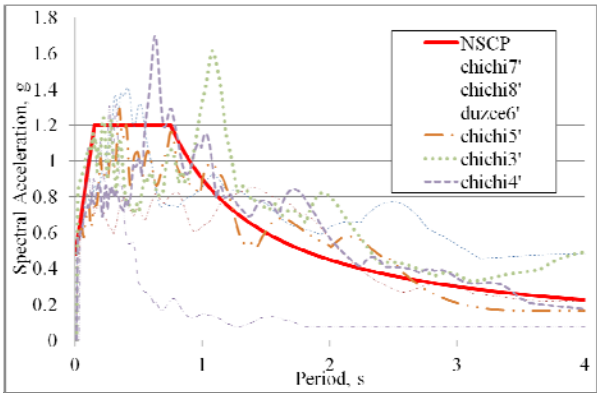

Figure 3. Selection of Design Spectrum-Compatible Earthquake Ground Motion used in Analyses

Earthquake loads are inputted as three dimension time histories and converted to inertial mass lateral loads. The selection of historical earthquake to be used is based on its compatibility with the design response spectrum provided by the NSCP using the data specific to the site, proximity to the fault line and soil conditions. In this research, the site is assumed to be on the University of the Philippines Diliman campus since it is relatively near the West Valley fault line which is a major fault found in Metro Manila. The response spectra of several earthquakes, namely 1995 Kobe, 1989 Loma Prieta, 1999 Chi chi, 1999 Duzce, 1979 Imperial valley, etc. (PEER 2010) were superimposed to the design spectra of the site. For brevity, only few earthquakes that is relatively close to the design spectra are shown on Figure 3. The repetition of Chichi earthquake in the figure corresponds to the data recorded from different stations. From this figure, it can be seen that chichi5 is a good representative of the design spectrum, hence, it will be used as the earthquake load in the succeeding time history analyses.

2.3. Spring Parameterization

Spring parameters are determined so that the resultant load-deformation curve is equivalent to the members' actual moment curvature depending on the section and reinforcements at the location of the hinge.

Beams

The assumptions in solving the spring parameters for beams are the following:

1. The load-deformation curve of the parallel (or longitudinal) springs under monotonic load is defined to be bilinear. Diagonal springs along the height is defined to be elastoplastic. Diagonal springs along the base are defined to be elastoplastic or elastic depending on the value ultimate point of deformation.
2. Actual beams' moment curvature relation is defined to be tri-linear having three critical stages namely, cracking point, yielding point, and ultimate point.
3. Deformation of the spring system is assumed to behave same as shown in Figure 4 when subjected to flexural loads.

Figure 4. Assumed Spring System Deformation under Flexure

4. Cracking of concrete of the actual beam is simulated by the simultaneous yielding of the parallel springs.
5. Yielding of the actual beam is dictated by the simultaneous yielding of the diagonal springs along the base.
6. Failure of the actual beam at ultimate point corresponds to the simultaneous failure of all springs.
7. Primary slope for the diagonal spring along the height depends on the vertical load to minimize static displacement.

Using these assumptions, all spring deformation parameters can be solved independently. Stiffness parameter can be also solved given the assumed loads transferred to the beam. The remaining unknown stiffness parameters are determined via system of linear equations by using the flexural deformation assumption (in Figure 4) and equating the sum of moments induced by each springs to the actual values of the flexural moment.

Columns

1. Similar to the beam, the load-deformation curve of the parallel springs along the base and height are defined to be bilinear but with different set of parameters. Diagonal springs along the base and height are both defined to be elatoplastic but also with different set of parameters.
2. Actual columns' moment curvature relation for both axis are defined to be tri-linear having three critical stages namely, cracking point, yielding point, and ultimate point.
3. Cracking of actual column to bending along x is dictated by the simultaneous yielding of the parallel springs along the base, thus
4. Cracking due to bending along y is controlled by the simultaneous yielding of the parallel springs along the height, thus
5. Yielding of actual column due to bending along x is simulated by the simultaneous yielding of the diagonal springs along the base.
6. Yielding of column due to bending along y is dictated by the simultaneous yielding of the diagonal springs along the height.
7. Failure of the actual column at ultimate point corresponds to the simultaneous failure of all springs.

Similar to the beam spring parameterization, all column springs' deformation parameters can be solved independently using the column assumptions in section 2.3(3)-(7) while the stiffness parameters are determined using summation of moments.

2.4. Time History Simulation and Building Assessment

The building model will be subjected to the earthquake load selected in section 2.2 in different directions to deal with the uncertainty of ground motion direction. It will be subjected to an incidence of 0°, 45°, 90°. This procedure will confirm the presence of critical member/s that can be used to check whether or not these members are the same as identified using static nonlinear pushover analysis.

After entering the building configuration data, i.e. node incidences, member connectivity, member dimension, rebar information, superimposed loads, and time history data, the program will internally solve for the displacement of each object at a time step as well as the strains induced per springs. The method will generate a graphical simulation showing the frame model being subjected to seismic loads for each direction. It will present a realistic shaking and readily observable interaction of members and structural response.

As the simulation progress, the state of the springs are identified for every critical points such as cracking, yielding and, flexure failure. The accumulation of yielding or failing springs within a joint will represent the state of the corresponding member. The sequence of failing members will be examined to identify the critical stages of the building's collapse mechanism. This procedure can also be used to efficiently isolate the members that need strengthening.

2.5. Retrofit/Redesign

Based on the assessment, the identified failing members are locally strengthened by adjusting the springs parameters. The amount of adjustment will be based on the increase in the actual members' capacity which correspond increase in member size and/or additional reinforcement which is applicable for newly designed building wherein the structural plans can still be revised. In case of an existing building, Carbon Fiber Reinforced Polymers (CFRP) will be used as the retrofit scheme to strengthen the members. The calculation will use CFRP specification in the will follow the provisions in ACI 440 (Guide for the Design and Construction of Externally Bonded FRP Systems for Strengthening Concrete Structures). The increase in capacity will be based on the amount of material used and its specification (FYFE Co. LLC. USA 2004). The enhanced building will then be simulated again to test whether the improvement is adequate and able to prevent collapse.

3. RESULTS AND DISCUSSION

3.1. Building and Moment Curvature

The building that will be used has 3 bays in *x* and *z* directions and has 3 levels. Column to column spacing is 3.5m and floor to floor height is 3m. All columns (C1) have 300x300mm section with 12-d16mm. Beams' specifications are summarized in the table below.

Table 1 Beam Schedule

Designation	Dimension	Top/Bottom Bars
B1 (2F Interior Beams)	300x400mm	6-d16mm/ 3-d16mm
B2 (2F Perimeter Beams) (Roof Interior Beams)	250x400mm	4-d16mm/ 3-d16mm
B3 (Roof Perimeter Beams)	200x300mm	3-d16mm/ 3-d16mm

The rendered model is shown in the Figure 2 illustrating the beams, columns, and the springs located at the ends of each members. The derived spring parameters for B1 and are shown in Figure 5 which follow the spring assumptions in section 2.3.

To check whether the spring system behaves like the member, its flexural response is calculated and is plotted with the actual section's moment-curvature diagram. Figure 6 illustrates moment-curvature relations of each spring, of the spring system, and of the actual section for the member B1. It can be seen here that response of the spring system agrees very well to that of the actual section. Also, the critical strain points on the moment curvature of the spring system coincides to the corresponding yield points of each springs as presented in section 2.3.

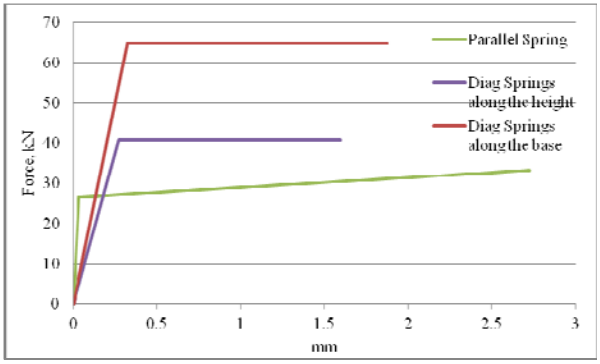

Figure 5. Sample Nonlinear Spring System Parameters of an RC Beam

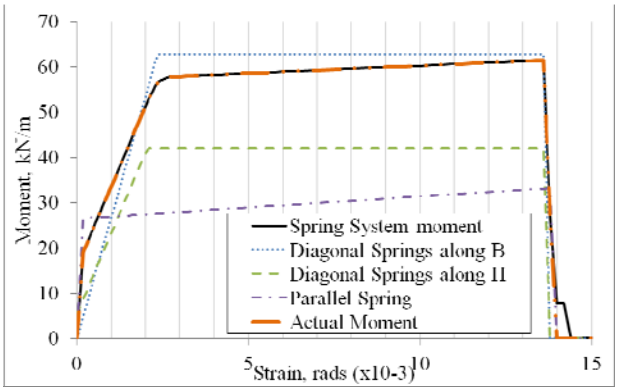

Figure 6. Agreement of Assumed and Computed Moment - Curvature Relations of a Plastic Hinge

3.2. Numerical Validation

1. Hysteresis Test

The observed hysteresis of the spring system generally follows the slopes of the curve envelope as the curvature increases. Figure 7 shows the general behavior of the spring system under increasing cyclic load. The figure also shows that the calculated moment curvature of the section (broken line) envelopes the hysteresis.

If unloading occurs before it reaches the cracking curvature point, it moves along the first slope hence behaving elastically. If the rotation reverses where the curvature is in between cracking point and ultimate (failing) point, the unloading slope is equivalent to the first slope and then followed by the second slope once it covers double the magnitude of the cracking point value. It will then follow the third slope when it attains a curvature magnitude equal to the yielding value from the unloading point. In cases where reloading takes place after unloading, the reloading slope will always track the first slope. If the reloading occurs before double the cracking point (along the first slope), it will traverse its existing path until it reaches its original unloading point. However, if reloading occurs after this point (along the second or third slope), it will not trace its existing path but will follow the first slope and then the second slope before reaching the unloading point. The spring system will follow this rule in any initial loading direction or in any load reversal.

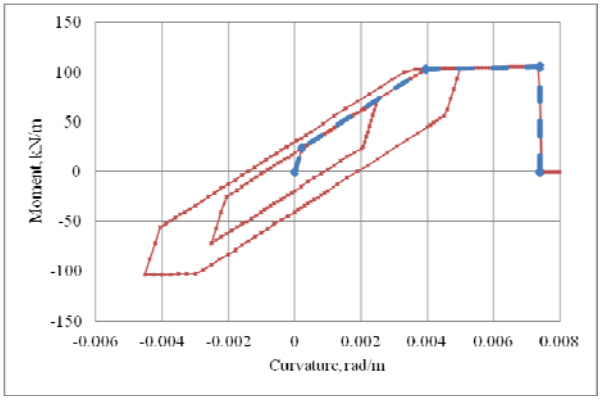

Figure 7. Hysteresis Behavior of a Plastic Hinge with assumed Nonlinear Spring Parameters

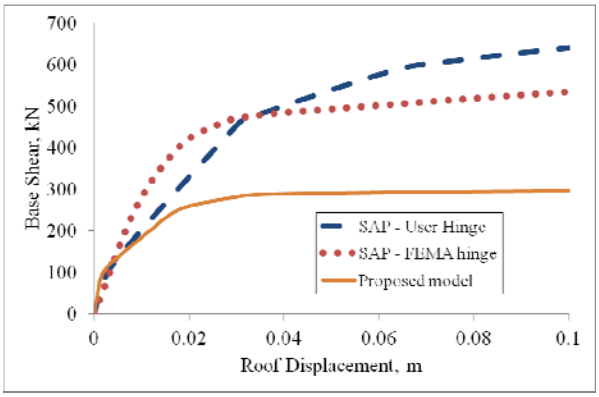

Figure 8. Comparison of Pushover Curves of Proposed Building Model and Corresponding SAP2000® models

2. Pushover Test

To evaluate the response model, a parallel runs are conducted by creating the same building configuration in SAP2000®. Two SAP2000® models are created differing only in the inelastic hinge properties, one has the default FEMA property and the other one has user-defined property same as in the proposed model. Push-over curves are derived for all models and is shown in Figure 8. It can be observed from the figure that in small displacements, the models are elastically behaving and relatively close to each other. The proposed model a steeper initial slope however it yields earlier. The figure shows that the strength of the proposed model is underestimated but the yield points for all models are relatively close. This may be due to the spring deformation assumptions made in section 2.3 where the diagonal springs contribute to the flexural resistance of the spring system. The steeper initial slope may be the effect of the rigidity of each member and the concentration of flexibility at the ends of the member, thus consistent to the general flexibility assumption.

3.3. Simulation Output

Simulating the model under 1999 Chi-chi earthquake in three incident directions, the program produced the output scenes shown in Figure 9. This figure shows the progression of the earthquake response with an incident angle of 45°. It can be observed here that springs start to yield 7 seconds after the earthquake started which coincides to the first significant increase in ground acceleration of Chi-chi time history data. This yielding of springs corresponds to the cracking and then steel yielding of the actual members. From here onwards, the number of yielding springs steadily rises and as the earthquake reaches its peak ground acceleration at about 10 seconds, the springs of the first floor columns begin to reach their ultimate deformation limit hence the failure of the columns. It can also be observe here the presence of yielding springs at the roof level due to amplified vibration causing larger forces at that level. On the 13th second, all springs connected to the first floor columns are at its ultimate point as they cannot resist lateral force anymore resulting to the full collapse of the building.

Shown in Figure 10 is a summarized chart of the number of elastic, yielding and failing springs colored as shades of green and red respectively describing the state of the springs at each floor per time-step as illustrated in Figure 9. The x-axis represents the number of springs, while the y-axis pertains to the beams and columns at a specific time frame. It can be seen here the formation of yield springs on beams and columns on all floors after 7 seconds. Failing springs are formed after the 10th second on the first floor columns and increases up until the full failure just before the 14th second. It was observed that the first columns that exhibited failure are the ones located at the mid and center columns followed by the failure of the corner columns.

For the cases of 0° and 90° earthquake incidence, no collapse is observed during the entire duration of the earthquake. But similar to the previous case, the yielding of springs starts on the 7th second. Also, there are failing springs formed at the first floor columns after the 10th second however it is not enough to generate a collapse.

3.4. Building Strengthening

1. Redesigning of Members

To address the failure of several members signified by the connected springs failure, the member dimension and/or the number of rebars is increased to adjust the springs' capacity. The adjusted columns are the ones identified from the previous section. Initially, the mid and center columns are adjusted from 300x300 mm to 350x350 mm while the corner columns are left unadjusted. This first trial also led to a full collapse. Continuing this iteration of redesigning, the final dimensions that attained a stable output is 400x400 mm for the mid and center columns and 350x350 mm for the edge columns.

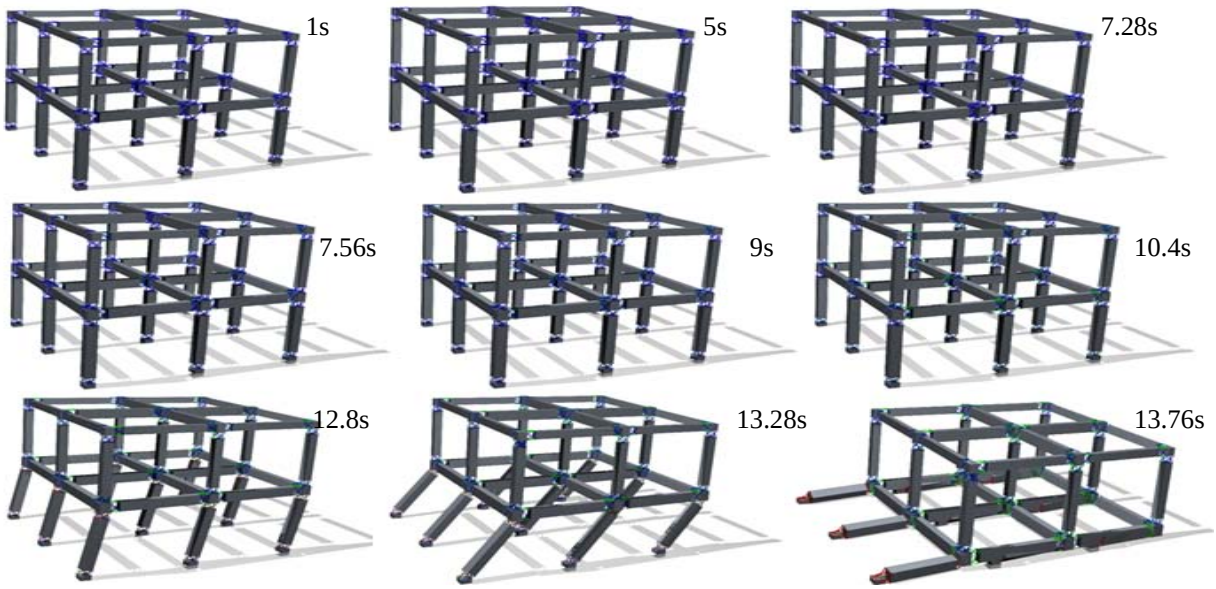

Figure 10. Progressive Collapse Sequence of a Two-Storey RC Building Subjected to 1999 Chi-chi Earthquake

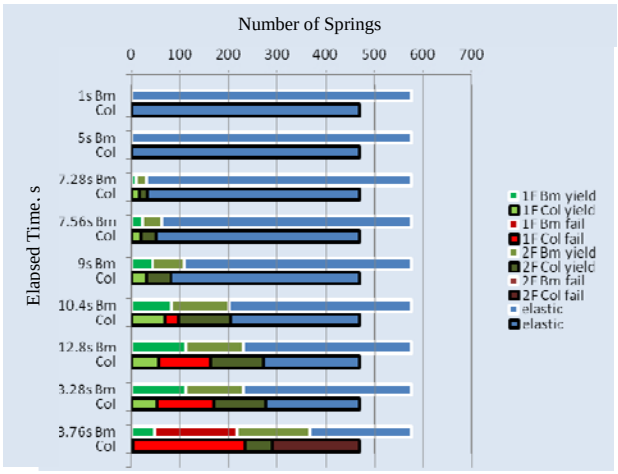

Figure 11. Progress of Yielding and Failure of Springs in Beams and Columns of Sample Building

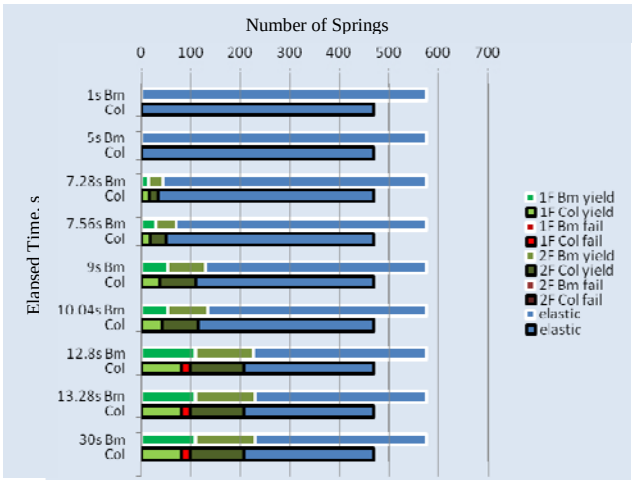

Figure 9. Progress of Yielding and Failure of Springs in Beams and Columns of Redesigned Building

Shown in Figure 11 is the state of springs of the improved building at the specified time frame. It can be seen here the significant decrease in the number of failing springs as compared to the original model. The presence of failing springs indicate the occurrence of damage on the member but insufficient to induce collapse even after 30 seconds of earthquake.

2. Retrofit by CFRP Application

Generally, the procedure of the design based on ACI 440 is similar to that of the reinforcing steel but with reduction factors to account for the material deterioration, bond-slip prevention between interface, and environment exposure. The assumptions used in the design is that there is a perfect bonding between different materials, shear deformation of the adhesive layer is neglected and it has linear elastic stress-strain relationship to failure. Figure 12 shows the computed capacities of an unreinforced section and sections with 1 to 5 plies of CFRP reinforcement.

To determine the amount of CFRP needed, the ultimate capacity of the composite section is derived from the improved final section calculated in the previous section. The calculated capacity of the 400x400 mm and 350x350 mm column is 178.9 kNm and 144.3 kNm respectively. The existing column will require 5 plies of CFRP to be equivalent to that of the 400x400 mm column while 3 plies are required to that of the 350x350 mm column. Each ply is 1 mm(0.04in) thick having a width equal to the width of the member. Therefore, the retrofitted columns will be 300x300 mm with 5 plies each face for the mid and center columns and 300x300 mm with 3 plies each face for the edge columns.

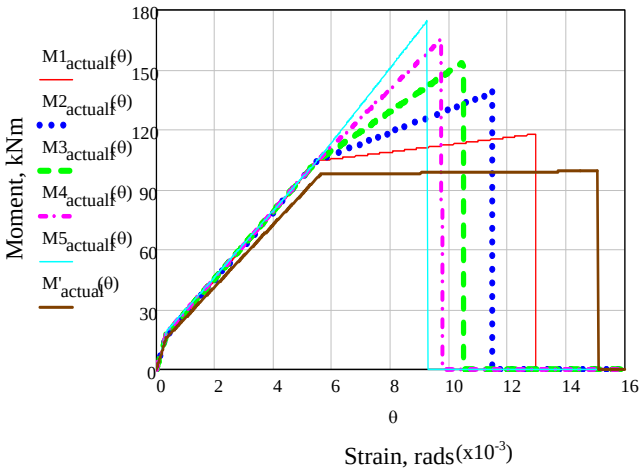

Figure 12. Improvement of Capacity of Beam Section with CFRP Reinforcement

4. CONCLUSION

The computed moment-curvature relation of the actual section is derived using the general concrete theories and this is the main basis of each of the spring parameters that makes up the member hinges. The calculated moment-curvature relation of the spring system is established to be virtually equivalent to that of the actual section. Also, this relation envelopes the hysteresis behavior of the spring system. The general behavior of the hysteresis traces the first slope at any point during unloading and/or reloading and then changes its slope once the deformation reaches its corresponding limit, namely the magnitude of the cracking and yielding curvature point. In small displacements, the test models in SAP2000® and in the proposed method are comparable in the elastic region. Push over curves substantiate the difference in lateral resistance and verify the effect of the spring system deformation assumptions. Also, the initial slope of push over curve derived from the proposed model demonstrates the distribution of the model's flexibility and shows the consistency using the one-component member model.

The time history analysis of the response confirms that the building model is inadequate when subjected to 1999 Chi-chi Earthquake and this earthquake load is chosen among others based on its compatibility with the design spectrum provided by the NSCP. The simulation proper for the 0° and 90° incident earthquake produce numerous members with yielding reinforcing steels indicated by the yielding of springs but no collapse is observed. However for the 45-degree incident case, full collapse is generated in 14 seconds of earthquake. The columns and beams exhibit yielding and failing as the ground acceleration increase significantly. The inadequacy is addressed by revising the member dimension or applying CFRP to increase the capacity of the section. The improved building requires 400x400 mm mid and center columns and 350x350 mm edge columns from the original 300x300 mm section. Using CFRP on the other hand, the composite section requires 5 and 3 plies per face of 1mm thick CFRP at the mid and center and edge columns, respectively.

Abstract: Connections between gravity framing (non-participating in resisting seismic forces) and the lateral force-resisting system need to be given considerations in building design. Studies of seismic behavior of the out-of-plane wall-to-beam joints are limited in literature. Furthermore, ACI 318 provisions with regard to seismic detailing of these joints are incomprehensive. The common practice is to provide a concealed column and/or a concealed beam where a gravity beam frames into a web of a structural wall. This research has a twofold objective. First, it is meant to assess the performance of these joints. Second, it will assess the impact of concealed columns on the overall performance of these joint. To accomplish these objectives, three half-scale reinforced concrete interior beam-wall joint specimens will be tested under quasi-static cyclic loading to simulate earthquakes. All test specimens have the same level of axial load, $0.2A_g$ f'c. These walls are designed to satisfy ACI 318 seismic provisions for structural walls loaded in the in-plane direction. These beams are designed as gravity members based on ACI 318 provisions.

1. INTRODUCTION

Where a beam frames into a web of a seismic structural wall (Fig. 1), it is common practice to provide a concealed column that has the wall width. Structural engineers consider that this addition would increase the wall's axial load capacity and the joint strength. The effect of these members on the performance of the joint and out-of-plane behavior of the wall needs further study. With a cursory review of literature with regards to reinforced concrete joints, it can be seen that the focus of the vast majority of research has been on the performance evaluation and design of beam-column joints and slab-column joints. Great advance has been made worldwide on their seismic design. Very little attention is given to the seismic performance of out-of-plane wall-beam joints. Furthermore, the ACI 318 seismic provisions are incomprehensive with regards to detailing of these joints. ACI 318 seismic provisions require members that are not designed as seismic force-resistant members to be designed and detailed for the demand imposed by the design displacement, which is inelastic displacement that the structure would experience during an earthquake. This implies that these joints should be designed to withstand forces imposed by the design displacement.

It appears that the only experimental studies done on out-of-plane beam-to-wall (or beam-wall like column) joints were conducted by Li et al (2002) and Li et al (2009). Li et al (2002) performed quasi-static tests on four full-scale non-seismically and limited seismically detailed joints. Two of the specimens were out-of-plane wall-like column-to-beam joints with column to beam width ratio of 3. They studied the influence of joint transverse reinforcement, lap splice of longitudinal beam and column reinforcement. Their test results showed that due to presence of limited joint transverse reinforcement, displacement ductility increased by nearly 50%. Also, the joint shear stress in these interior joints were $0.15f'_c$.

Li et al (2009) carried out experimental tests on six full-scale interior beam-to-wall-like columns and beam-to-wall joints. They investigated the impact of compressive axial load level on the overall performance of the joints. The results indicated that the axial load did not greatly influence the energy dissipation capacity, stiffness, and nominal shear in the joint but caused significant bond deterioration through the joint and, consequently, reduced lateral load capacity. Their test results also showed that these joints can withstand 2.0% drift ratio without significant strength and stiffness degradation.

Even though there have been some studies conducted on performance evaluation of non-ductile beam-column joints, the results may not reliably been considered since the joint strength deterioration is greatly influenced in relative thin walls due to bond slip (Kurose et al, 1988).

2. EXPERIMENTAL PROGRAM

2.1 Test Specimen Description

Three one-half scale interior out-of-plane wall-to-beam specimens, hereafter referred to as WB1, WB2, and WB3, are being constructed and will be tested under quasi-static cyclic loading. All the specimens have the same geometry but different wall sectional reinforcement and are subjected to the same level of axial compressive load, $0.2A_g f'c$. The length of the wall was controlled by the test setup space limits. The ratio of wall length to beam width is 3 for all test specimens. Each test specimen is a part of a structural wall system, where structural walls are used to resist earthquake induced lateral loads, with story height of 6' (1.83m) and span length of 10'-6" (3.2m)(Fig 2) to represent one-half scale connections of a building having 12' (3.658m) story height and 21' (6.40m) beam span length. Each test specimen consists of a 6" (152.4mm) thick, 24" (609.6mm) long, and 72" (1828.8mm) tall wall and 8"x13" (203.2x330.2mm) beams framing into the web of the wall. Fig. 2 shows the schematic illustrations of the specimens.

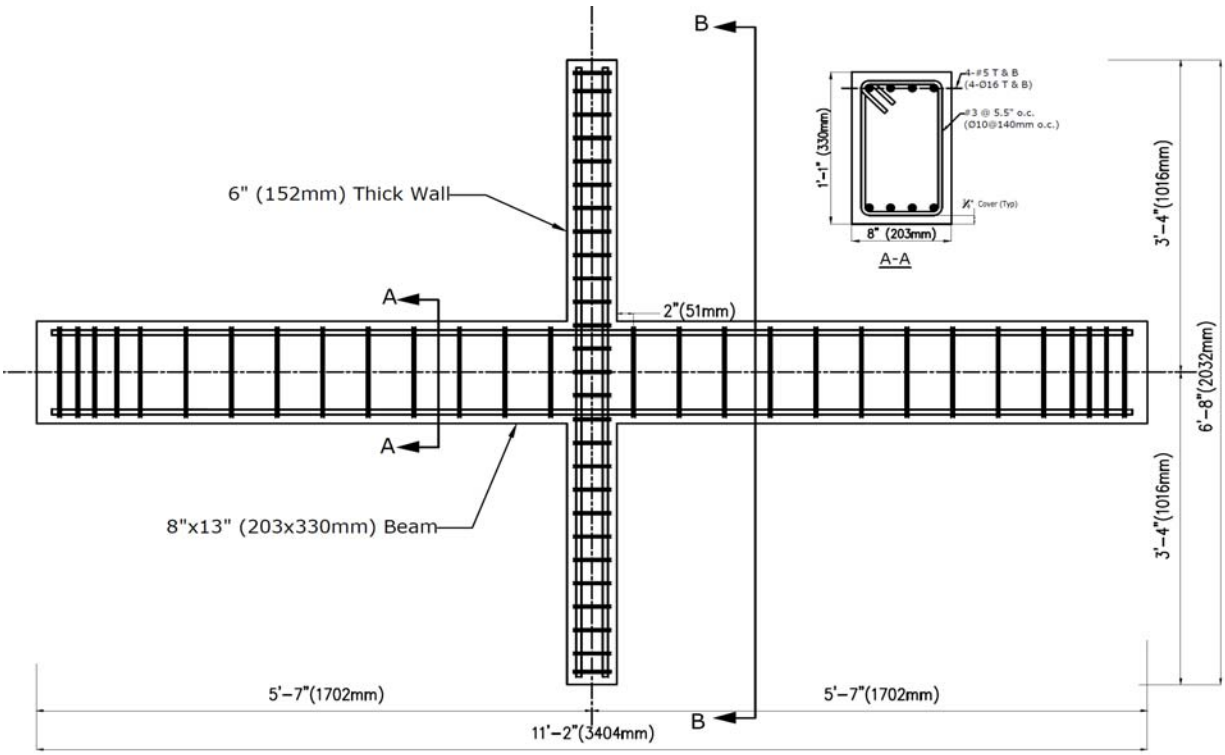

Fig.2- Test Specimens: WB1, WB2, and WB3

The first specimen, WB1, is a bare reference wall-beam connection, meaning that the joint is not strengthened with a concealed column. Furthermore, the joint has no lateral reinforcement except the wall horizontal reinforcement (Fig. 3). The second test specimen, WB2, is similar to WB1, except that a concealed column is made out of the web vertical bars, (Fig. 4). The concealed column is designed as gravity column to support the axial load with cross sectional dimension of 6"x7" (152.4x177.8mm). For WB3, in addition to the reinforcement provided in WB1, a concealed column is incorporated.

The walls were designed and detailed, in the in-plane direction, to satisfy the ACI 318 seismic provisions for structural walls. The wall web vertical reinforcement is the only parameter in the test specimens. All the test specimens have the same boundary elements in terms of both geometry and reinforcement. The first specimen, WB1, is a regular structural wall with two 6"x7" (152.4x177.8mm) boundary elements reinforced with 4-#5 (4-Ø16) bars each. The concrete in the boundary elements is confined using #3 (Ø10) seismic ties at 3" (76.2mm) on center. to satisfy requirements stipulated by ACI 318, as shown in Fig. 3. The web is reinforced horizontally and vertically using two curtains of #3 (Ø110) bars. Horizontal reinforcement is provided at 4.5" (114.3 mm) on center, resulted in a reinforcement ratio of 0.0081, whereas two bars are provided for vertical reinforcement per each face, yielding a reinforcement ratio of 0.0073. The web vertical bars are located outside the beam cage. Two horizontal wall bars pass through the joint core on each face of the wall, Fig 3. In WB2, the wall web vertical bars (4-#3 (4-Ø10)) are used as a concealed column passing through the joint core. The concealed column is transversely reinforced with #3 (Ø10) bars at 5" (127mm) on center with two ties located inside the joint. As for WB1, two of the web horizontal bars are passing through the joint, Fig. 4. Wall reinforcement in WB3 is identical to WB1 with two differences. First, a 6"x7" (152.4x177.8mm) concealed column, reinforced with 4-#4 (4-Ø12) longitudinal bars and #3 (Ø10) ties at 5" (127mm), is incorporated into the wall. Second, the two web vertical bars on each side are displaced slightly towards the boundary elements, Fig. 5. The concealed column longitudinal bars pass through the beam cage. As for WB2 and WB3, two of the web horizontal bars are passing through the joint.

The objective of this study is to observe and document the cracks and damage in the joint and its vicinity. Thus, the beams were designed to ensure that the majority of the damage and cracking would occur in the joint region and the wall near to the joint. The beams represent gravity beams in structural wall building systems. All test specimens have the same beam longitudinal and transverse reinforcement, 4-#5 (4-Ø16) bars at top and bottom and #3(Ø10) ties spaced at 5.5" (139.7mm) on center, respectively.

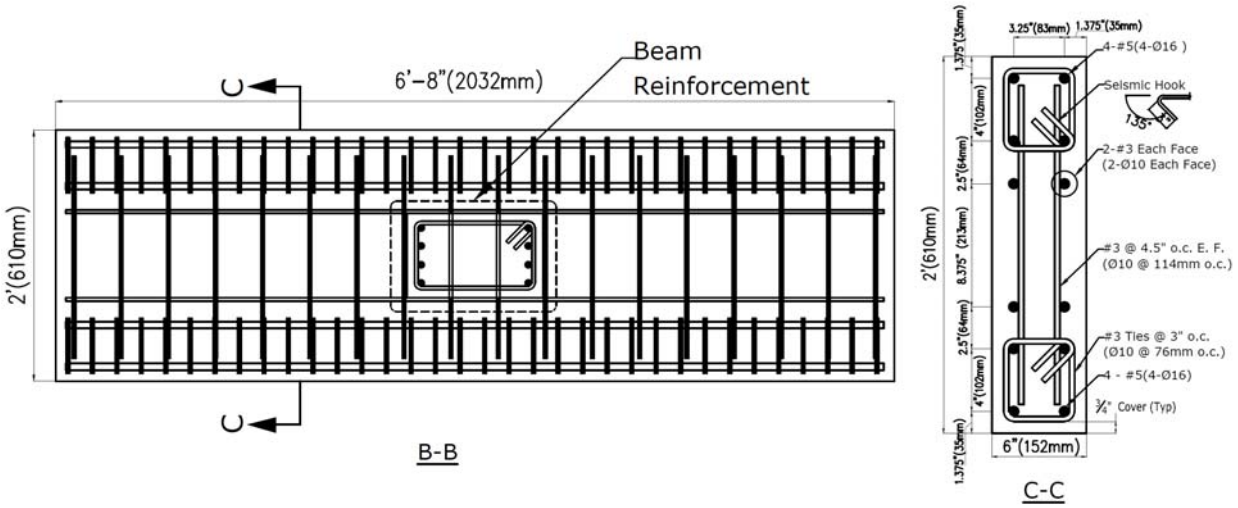

Fig. 3- Wall section reinforcement for WB1

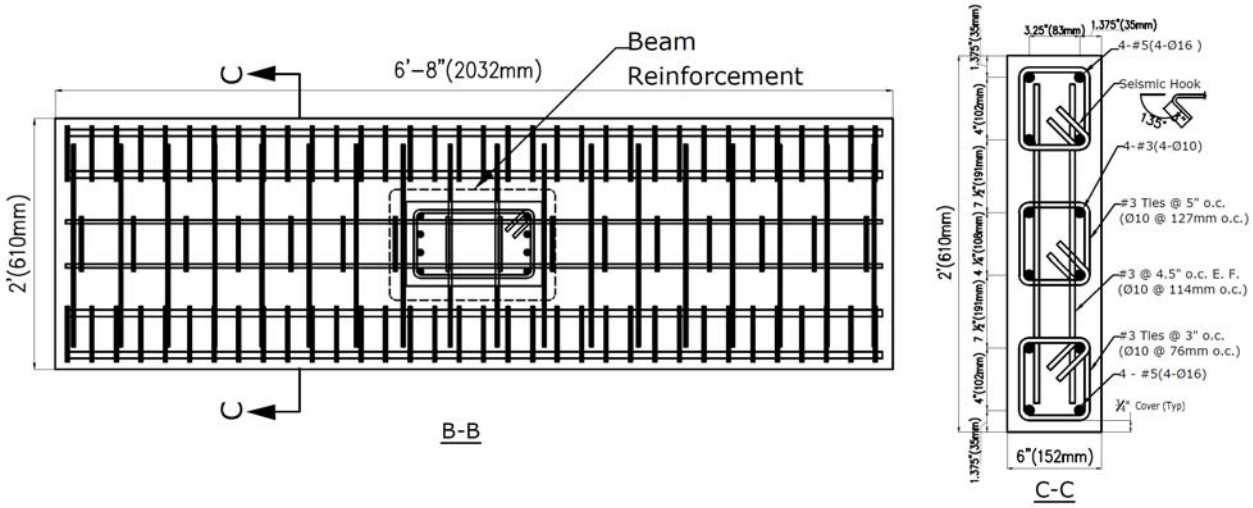

Fig. 4- Wall section reinforcement for WB2

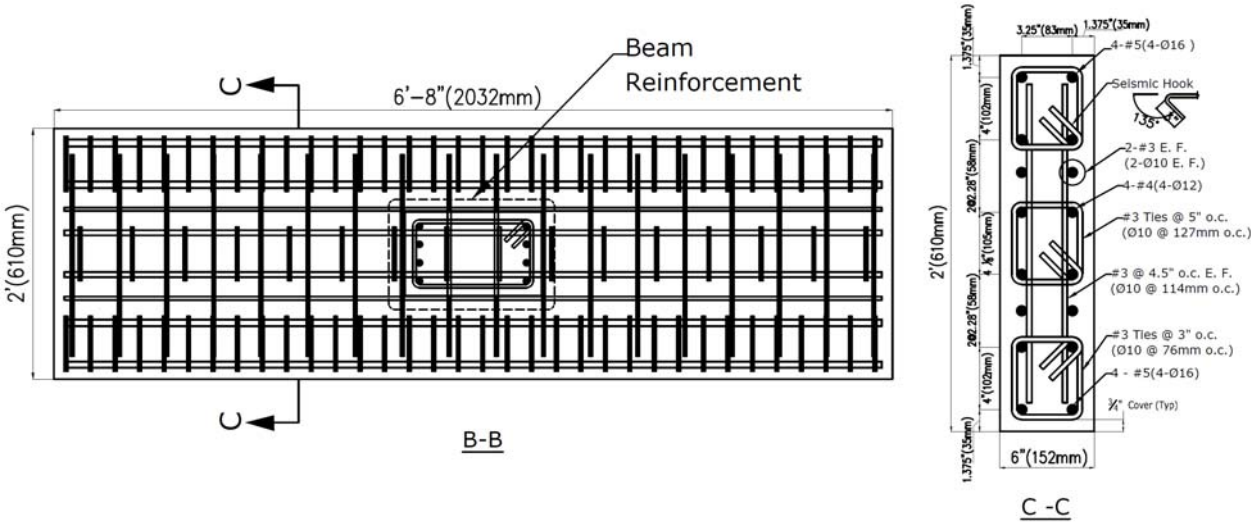

Fig. 5- Wall section reinforcement for WB3

The ratio of beam longitudinal bar diameter to wall thickness is 0.1 which is twice of what is required by ACI 318 code for beam-column connections in special moment resisting frames. The beam cross section and reinforcement details are shown in Fig. 2. Reinforcement details of the test specimens are shown in Fig. 2 through Fig. 5, and a summary is provided in Table 1.

2.2 Test Setup

The test arrangement used to apply cyclic loading consists of a two-dimensional steel frame as shown schematically in Fig. 6. The cyclic loading is applied by two 50-kip vertical hydraulic actuators acting simultaneously in opposite directions at each beam end. The actuators are connected to both the test rig and the transfer beams using pin connections to allow free rotation, Fig. 6. The lower end of the wall specimen is pinned to the test rig, while its top is restrained using roller-like support that allows rotation and vertical movement.

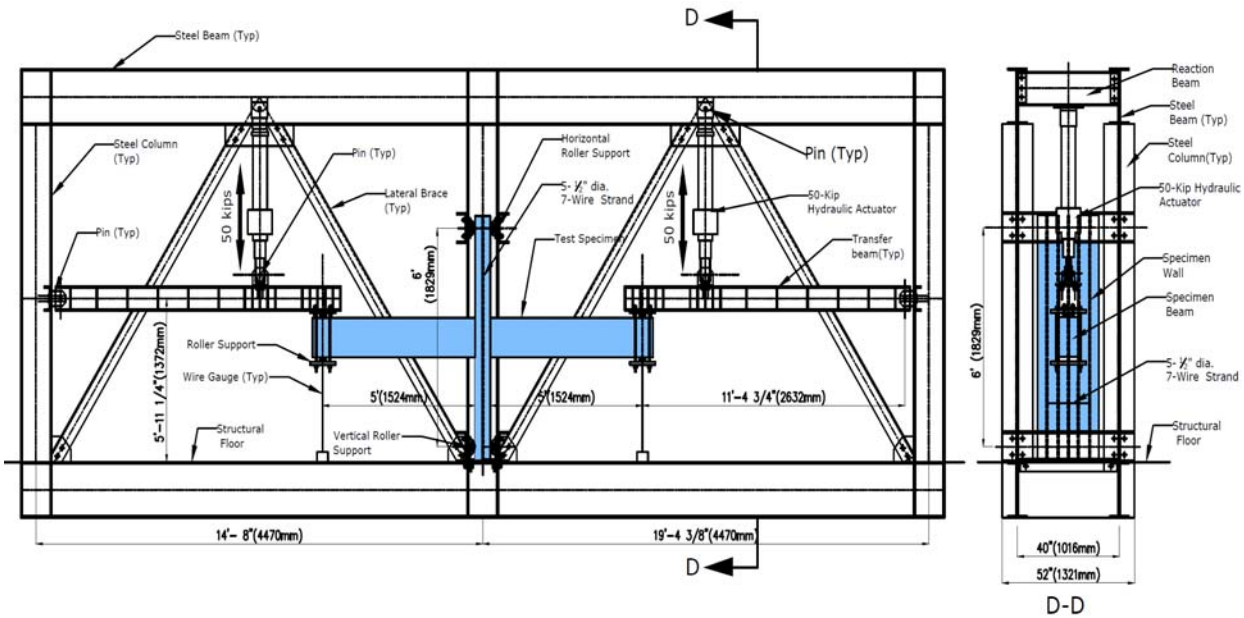
Note: 1in. = 24.5 mm; #3 bar = 10 mm dia. bar; #4 bar = 12 mm dia. bar; #5 bar = 16 mm dia. bar.

The cyclic loading is applied to the test specimen through the end of the specimen beam. The test protocol is load controlled up to 70% of yield load of wall and displacement controlled to the failure point of the specimen. Two complete loading cycles are applied at each displacement ductility level. The axial load is applied using 5-1/2” diameter, 270-kip 7-wire post tensioned strands passing through the wall section. The intension is to keep the axial load constant throughout the testing.



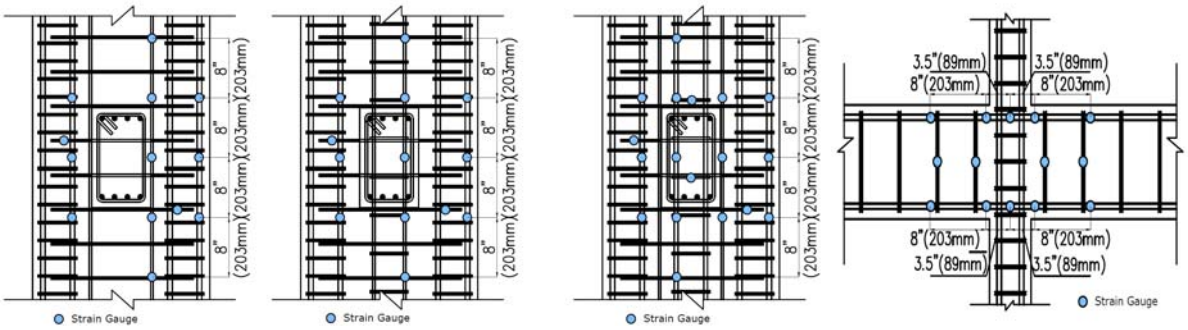


Fig. 6- Test Setup

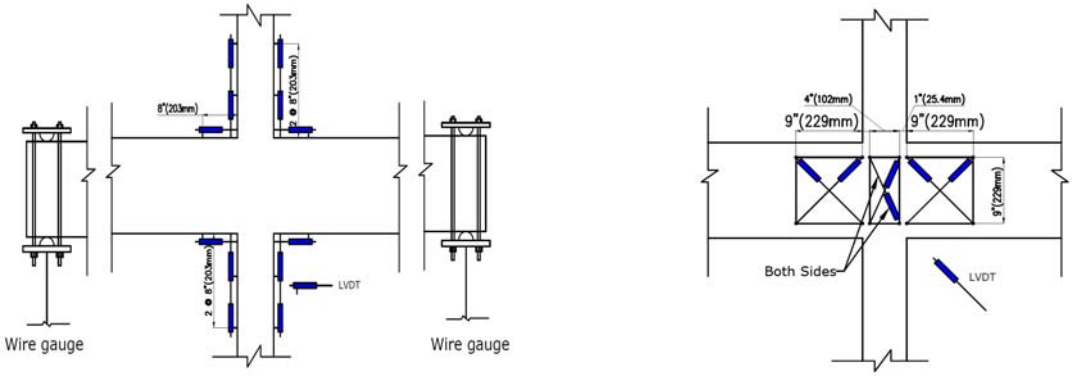

Instrumentation

In order to record the applied load, the specimen beam and wall deformation, and the strains in the reinforcing bars, the test specimens are instrumented with build-in load cells, LVDTs (linear variable displacement transducers), wire gauges, and strain gauges, as shown in Figures7 and 8. To collect data from these instruments instantaneously, they are connected to a computer-based data acquisition system. The strain in the reinforcing bars is monitored in each specimen using a minimum of 27 strain gauges, Fig. 7. The lateral load is applied to the transfer beam (Fig. 6) and is recorded using built-in load cells on the 50kip (222 KN) hydraulic actuators. Other load cells are mounted on the top end of the wall to measure the axial load. Two wire gauges are used to record the imposed displacements at the beam ends, Fig 8a. Two more wire gauges are used to measure slippage and the horizontal movement at the wall supports. A total of 20 LVDTs are mounted on the joint and its vicinity. Flexural deformation is determined based on the displacement measured by eight LVDTs, as illustrated in Fig 8a, while the shear deformation in the beam and the joint is measured by eight LVDTs, as shown in Fig. 8b. Four LVDTs are provided to measure crack width at the beam-wall interface, Fig 8a. All the test specimens have the same LVDT arrangement. Besides using the above electronic instrumentations, visual observations are recorded using photograph and videotaping.

3. CONCLUSIONS

Test specimens are currently under construction and are scheduled to be tested this spring. The seismic response of the beam-wall joints will be determined and evaluated. Analytical study will be conducted to confirm the validity of the experimental study. Design recommendations will be developed based on results of both the experimental and analytical studies.

SEISMIC VULNERABILITY ASSESSMENT METHOD OF LOW-RISE RC BUILDINGS WITH MASONRY INFILL WALLS

Hamood Alwashali [1] and Masaki Maeda [2]

1) Master student, Department of Architecture and Building Science, Tohoku University, Japan,
2) Professor, Department of Architecture and Building Science, Tohoku University, Japan,
hamood@sally.str.archi.tohoku.ac.jp, maeda@archi.tohoku.ac.jp

Abstract: A practical seismic evaluation method that is more effective especially in developing countries is proposed. The proposed method is a recalibration of Shiga figure (Shiga, et al) to be applicable to RC buildings with masonry infill using mathematical models analysis. The damage evaluated by the proposed method is applied to the fragility curves of HAZUS and probability of damage is studied. Average structural damage and economic loss of a whole city could be easily estimated in a short time based on the probability of damage of each zone in the proposed method. Finally, the proposed method is then compared to actual earthquake damage which showed quite good agreement.

1. INTRODUCTION

RC buildings with masonry infill are a common practice in many developing countries. Poor performance of RC buildings with masonry infill was noticed in many earthquakes, recently in China 2008 Wenchuan earthquake and Haiti earthquake 2010; see Figure 1.The performance of these buildings could be improved by special detailing of frames, strengthen walls by reinforcement and other retrofitting techniques. However, the problem is that existing buildings makes a huge considerable number therefore seismic evaluation method is necessary to screen vulnerable buildings.

Figure 1 Damage of Building with masonry infill in China 2008 Wenchuan earthquake

In developing countries, the main issue is usually economic cost. Professional engineers and the time needed to seismically evaluate a whole city will be of a high cost. In addition, if almost all buildings are considered unsafe then the possible action of the government and people is no action because building a new city seems much easier. Therefore a proposed method should filter buildings into categories according to their vulnerability level. In other words, buildings with higher possibility of collapse and severe danger are filtered and have higher priority to be retrofitted. From the above points it is concluded that a simple, low cost and fast seismic screening method is needed as a first screening method.

The original concept of the method proposed in this study is not new and was introduced first by Shiga (Shiga 1968) for the Japanese buildings. The Shiga map screens the buildings into zones with different vulnerability levels according to their column sectional area, wall sectional area and floor area. This method was based on actual data of damaged buildings from Tokachi-Oki earthquake in 1968. A similar method was presented by Hasan and Sozen (Hasan 1997) using the damage data from Erzincan earthquake in 1992 in Turkey. Certainly there isn't better than a detailed analysis of each building and judgment of professional engineers. However, issues such economic costs and the time needed that were mentioned before makes these methods practical for preliminary screening of vulnerable building. The problem is that this method is only applicable to its region because of different seismicity level, material properties and structural details. Actual earthquake damage data is needed to construct Shiga map. As for countries with infrequent earthquakes (return period of 50~100 years), damage data is usually unavailable. Waiting for an earthquake to construct such method is not an option, 2010 Haiti disaster is a recent example. This paper presents a recalibration of Shiga`s method to be suitable to RC buildings with infill walls in different seismic regions. To make this study more realistic, a case study of RC buildings with masonry infill walls in Jordan is considered.

2. PROPOSAL OF SEISMIC EVALUATION METHOD

2.1 Method Flowchart:

The main Flowchart of the proposed method is shown in Fig. 9 Jordan will be used as an example for the proposed method

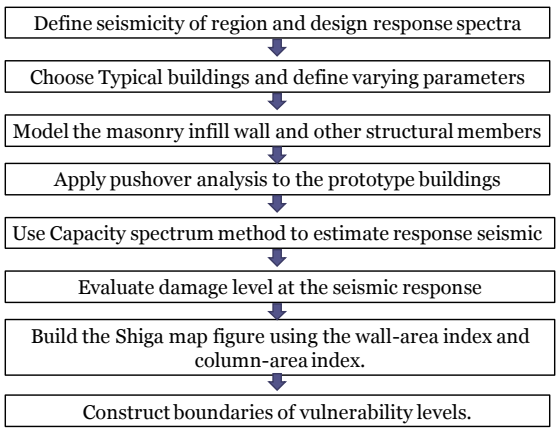

Figure 2 Flowchart of the proposed method

2.2 Define seismicity of Jordan

Jordan is a Middle East country located along the seismically active Dead Sea Transform Fault that extends 1000 km from the Red Sea to Turkey. The seismicity in Jordan is thought to be as moderate. Seismic hazard of Jordan with maximum PGA of about ~0.25g near the Dead Sea is shown in figure 3 (Earthquake hazard report 2007). Current estimates predict a major earthquake in the region roughly every 200 years. During the past ten years, an earthquake of magnitude Mw = 5.1 occurred in the Dead Sea basin on February 11th, 2004 and followed by an Mw = 4.7 earthquake on July 7th, 2004.

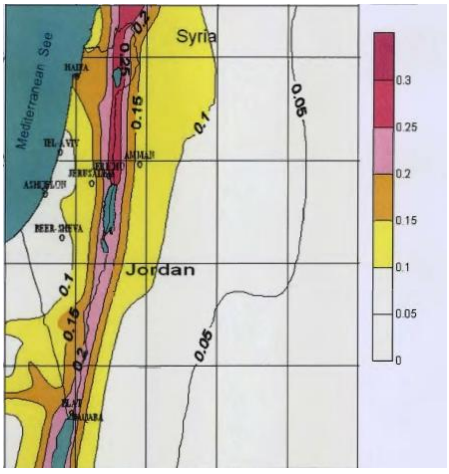

Figure 3. Hazard map with probability of occurrence of 10% in 50 years (Earthquake hazard report 2007)

Different regions have different seismicity levels in Jordan. UBC code (UBC 1997) is used to construct the design response spectrum for two soil types for PGA=0.2g, soil Type SB (rock) and soil Type Sc (very dense soil and soft rock), shown in Fig. 4. In this study, the response spectra of Sc Soil type were used.

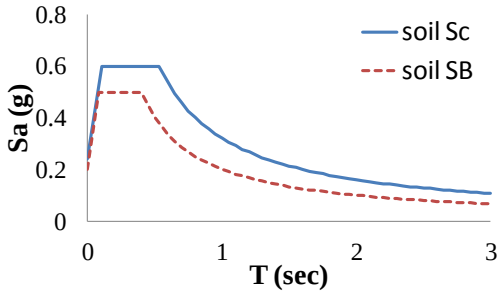

Figure 4 Design response spectra for two soil types Jordan

2.3 Typical buildings in Jordan

RC structures are widely used in Jordan. Typical building plan is shown in Fig. 5. The exterior infill walls are composed usually of 3 layers; stone facing, plain concrete and hollow concrete blocks as shown in Fig. 6. The exterior walls are of thickness ranging from 300~350 mm. These walls are bounded by slender RC columns. The interior columns are usually more reinforced than exterior columns. Exterior masonry walls are sometimes allowed to work as a bearing wall for buildings less than 12 m in height. This resulted in a large number of low rise buildings with masonry infill used usually as residential and commercial buildings in the main cities. This practice is not based on a structural analysis; it is based on past experiences and practices in surrounding countries. As for the partition walls inside the building, hollow concrete blocks of thickness ≈100mm is used. This partition walls are placed randomly and might not be bounded by any columns. The influences of the partition walls are ignored in this paper, only their weight were included. Slabs are ribbed slab (One-way joists) of thickness of 250mm~300mm. Typical beam and column sizes and reinforcement are shown in figure 7. RC walls are commonly used around stair cases and elevators in recently designed buildings (after 2000), see Fig. 4. These RC walls are usually placed in one direction which is mainly the transverse direction.

Figure 7. Typical column and beam

2.4 Prototype buildings characteristics

3 prototype buildings with different floor areas were used for analysis. Figure 8 shows the structural plan of prototype building B. Analysis was done for the X- direction (direction with no RC walls in the staircase) which is usually the weakest direction. Many cases were assumed for each building, assuming number of stories ranging from 1 till 4 stories and varying the places and number of masonry infill walls. Since exterior facings of buildings have usually many opening, exterior infill walls with opening of 1m^2 in each wall and thickness 300 mm were assumed, see Fig. 9. The interior partition walls were ignored in this paper, only their weight was included. Exterior columns (bounded by infill walls) and Interior columns are assumed to have dimensions of 200mm x 500mm and 300mm x 500mm respectively

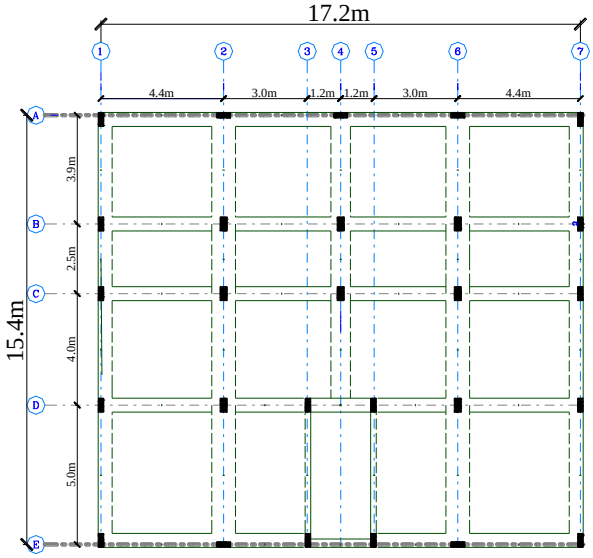

Figure 8 structural plan of prototype building B

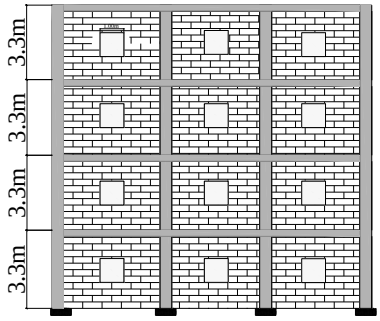

Figure 9 Typical elevation plan of exterior frame

2.5 Modeling of structure

In this study a simple two-dimensional pushover analysis using computer program SNAP is used. Infill walls are idealized as diagonal strut, beams and columns are idealized by two nonlinear rotational springs at their ends, a nonlinear shear spring in the middle and a linear axial spring, see Figure 10 and Figure 11. A tri-linear relation is used for rotational and shear springs, see Figure 12 and Figure 13. The contribution of slab to the beams flexural strength was ignored. The beam-column connection is assumed to be rigid. The distribution of lateral forces along the height in the pushover analysis is based on the Ai distribution prescribed in the AIJ provision (AIJ 1999). The cracking and yield moment of rotational spring and shear spring of columns and beams are estimated using AIJ standard (AIJ 1999). The infill wall is modeled as an equivalent diagonal compression strut with width, W_{ef}, calculated using Eq(1) and Eq(2) which are based on recommendations given in FEMA 356 (FEMA 2000). The equivalent struts have the same thickness and modulus of elasticity as the infill wall it represent.

$$W_{ef} = 0.175(\lambda_h H)^{-0.4}\sqrt{H^2 + L^2} \qquad (1)$$

$$\lambda_h = \left[\frac{E_w t_w \sin(2\theta)}{4E_c I_c H_{\inf}}\right]^{\frac{1}{4}} \qquad (2)$$

Where: E_w and E_c are the moduli of elasticity of the infill wall and the concrete .H_{inf}, H and L are the net height of the infill wall, the storey height, and the bay length of the frame. θ = arctan(H/L) (the inclination of the diagonal). t_w = is the thickness of the infill wall, I_c = moment of inertia of the column of the frame,

The axial strength of the equivalent strut of the infill panel is determined by dividing the expected infill shear strength, V_{ine} , by Cosθ (θ= arctan(H/L). The expected infill shear strength (V_{ine}) is determined by Eq(3) and Eq(4) using the methodology given in Section 7.5.2.2 in FEMA 356 (FEMA 2000) :

$$V_{ine} = V_{me}.An \qquad (3)$$

$$Vme = \frac{0.75\left(Vte + \frac{P}{An}\right)}{1.5} \qquad (4)$$

Where; V_{me} :bed joint shear strength, P : gravity load, An : area of net mortared of infill wall and V_{te} : Average bed-joint shear strength. Due to lack of research on the wall infill properties used Jordan, bed joint shear strength, V_{te}, is assumed 0.7 N/mm^2 and Elasticity of infill wall, E_W, of 9500N/mm^2. These values could be easily acquired in future research. To account for the influence of openings in the walls, initial stiffness and maximum force were reduced using the factor $\lambda_{opening}$ calculated using Eq(5) based on the work of Dawe and Seah (Dawe1988).

.

$$\lambda_{opening} = 1 - \frac{1.5 L_{opening}}{L\,\text{inf}}; \lambda_{opening} \geq 0 \qquad (5)$$

Figure 14 shows the backbone curve of infill wall. The d value shown in the Figure 14 is taken using Table 7-9 in FEMA356 (FEMA 2000) for assumed ratio of frame to infill strengths ≤ 0.7 (the frame is assumed to have small strength compared to the infill panel).

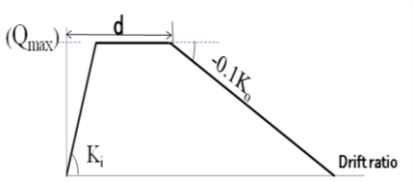

Figure 14 Strut spring back bone curve

2.6 Seismic response and damage evaluation:

The seismic response of the structure is calculated using methodology for calculating target displacement given in Section 3.3.3.3.2 in FEMA 356(FEMA 2000).

The damage evaluation is judged by approximating the amount and level of damage in the infill walls and columns in the first and second story of each building at the seismic response displacement given by the pushover analysis. The damage states employed are similar to those proposed in HAZUS99 (FEMA 1999) with some modification for the severe damage in which total and partial collapse is added. Where *Slight Structural Damage*: Diagonal (sometimes horizontal) hairline cracks on most infill walls; cracks at frame-infill interfaces. *Moderate Structural Damage*: Most infill wall surfaces exhibit larger diagonal or horizontal cracks; some walls exhibit crushing of brick around beam-column connections. Diagonal shear cracks may be observed in concrete beams or columns. *Extensive Structural Damage* (named as *severe damage* in this paper): Most infill walls exhibit large cracks; some bricks may dislodge and fall; some infill walls may bulge out-of-plane; few walls may fall partially or fully; few concrete columns or beams may fail in shear resulting in partial collapse and in imminent danger of collapse. Structure may exhibit permanent lateral deformation.

However, it is difficult to state when exactly the masonry infill wall could be called moderately damage or severely damaged in the backbone curve of figure 14. In figure 15 a suggested figure for damage evaluation is proposed. The elastic region till about 0.8 Q_{max} is considered with none damage, from 0.8Qmax till about half of C value is considered having slight damage. Severe damage starts from the point where the wall drops to 80% of its maximum shear strength.

The d value shown in figure 14 in many prototype buildings were calculated to be about 0.4% of inter-story drift using Table 7-9 in FEMA356. The moderate damage in many cases studied in this paper starts at drift of about 0.25%. This values quite well agrees with many experiments carried by (Merhabi et al 1996) were the first major crack occurred at drift between 0.17%~0.36% for strong infill and weak frame specimens.

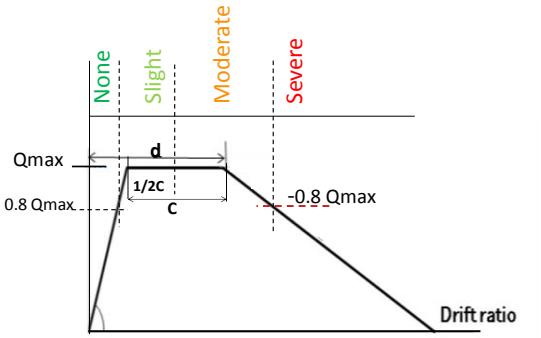

Figure 15 Proposed damage states of masonry infill

When more than half of the masonry infill walls strength degrades to 80% of its shear strength the buildings is considered severe. This might be quite conservative for buildings having strong frames which could carry the seismic demand even after the masonry walls are crushed. However, it is thought to be appropriate in the case study of Jordan where the masonry infill walls support part of the gravity load and the surrounding RC frame is lightly reinforced and weak, therefore the degradation and crushing of masonry infill walls could cause instability of structure and imminent danger of partial or total collapse.

To make the method clear, the proposed method is illustrated by example using one of the cases of the prototype buildings shown in figure 8:

This case is of a four storied structure having masonry infill walls in all its exterior axes. Axes A and E (see figure 8) have masonry walls with openings of 1m^2, columns and beams are modeled as stated previously. Axes B, C and D have no infill and modeled as moment frames. A displacement-controlled pushover analysis is applied to the longitudinal direction. The bilinear idealization of the capacity curve represented by base-shear and roof displacement is shown in figure 16. The total weight of the building was calculated to be 12900 kN with average weight per unit area of 12.5 kN/m^2.

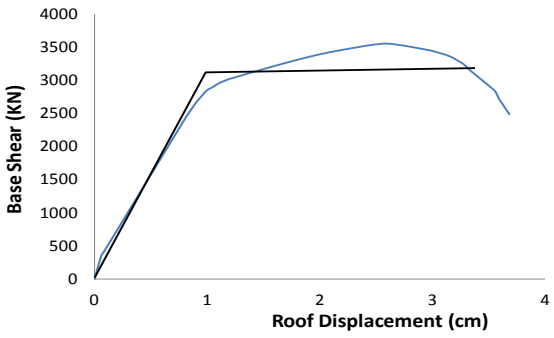

Figure 16 Bilinear idealization of the capacity curve

The performance point was calculated using the target displacement method for nonlinear analysis to be of 3.28cm of roof displacement. At this performance point more than 90% of the number of walls in the 1st floor has degraded to less than 80% of their maximum shear strength. Force-Displacement curve of strut spring of one of the walls in 1st floor is shown in figure 17. In additional, plastic hinges were formed on both ends of few columns of 1st floor. As for the 2nd floor all walls has reached the moderate region proposed in figure 15. Upper floors are still in their slight region. Since most of the infill walls of 1st story are evaluated as severe at performance point, this building is considered as severe.

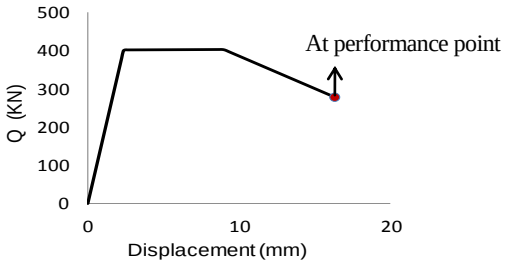

Figure 17 Force-Displacement curve of one of the masonry infill walls of 1st floor in the illustrated example

The Total area of floors, total cross sectional area of columns of 1st floor and total cross sectional area of masonry infill walls of this case (cross sectional area of openings in walls are deducted) of 1st floor are 1059.5m^2, 3.1m^2 and 6.63 m^2 respectively. The Column index, CI, which is percentage ratio of the cross sectional area of columns in 1st floor to the total floors area, is 0.29. The Wall index, WI_{inf} which is the percentage ratio of the cross sectional area of infill walls in 1st floor to the total floors area is 0.63.

3. Results:

Properties and results of the prototype buildings are shown in Table 1. The Column index, CI, is percentage ratio of the cross sectional area of columns of 1st story to the total floors area of the prototype buildings. The Wall index, WI_{inf} is the percentage ratio of the cross sectional area of infill walls (the length of the openings in infill walls are deducted from the total infill length) of the total of 1st floor to the total floors area of the prototype buildings.

The Column index, Wall index (WI) and damage expected of each building are shown in Figure 18. Fig. 18 is based on the concept of Shiga map. Hasan and Sozen (Hasan1997) used a similar figure for actual damage of buildings in Erzincan earthquake. The figure 18 is divided into vulnerability zones by the lower boundary line and upper boundary line. There are 3 Vulnerability Zones, for which zone A (danger zone) is the most vulnerable and zone C (safe zone) is the least. The boundary lines here are assumed based on the damage evaluated. However, the boundary lines assumed here could be adjusted based on the probability of expected damage and acceptable seismic hazard which are discussed in next section (section of probability of damage)

Thinking of results as capacity provided by the building versus seismic demand by earthquake, then capacity is thought to be provided by columns and infill walls strength, which is product of the shear stress and cross sectional area of columns and walls shown of the left side of Eq (6). The

Table 1 Properties and results of the prototype buildings

Building No.	Total Column area m^2	Total Infill Wall area m^2	Total Area m^2	Column index%	Infill Wall index %	Evaluated Damage level

demand needed is the product of the total weight of the building and response acceleration coefficient of earthquake (marked as C_a) and reduction factor (marked as D_s) to account for the ductility which the building posses.

Capacity ≥ Demand

$$\tau_c . A_C + \tau_w . A_W \geq W . C_a . D_s \qquad (6)$$

Where A_c: is the area of columns(mm^2), τ_c: is the shear strength of columns (N/mm^2), A_w: is the area of masonry infill (mm^2), τ_w: is the shear strength of masonry infill walls (N/mm^2) , W: is total weight of building, Ca: response acceleration coefficient of earthquake.

Total weight of the buildings (W) is the product of total area of floors (A_f) and average weight per unit area. The average weight per unit ranged for the studied cases between 12 kN/m^2~14 kN/m^2. Taking 13 kN/m2 as the average weight per unit area and assuming reduction factor Ds = 1 Therefore;

$$\tau_c . A_C + \tau_w . A_W \geq 0.013 N/mm^2 . A_f . C_a \qquad (6)$$

The response acceleration coefficient for Soil C spectra used in this case study for buildings with short periods (low-rise buildings) is 0.6g. Dividing both sides by A_f (area of floor), Therefore:

$$\tau_c . \frac{A_C}{A_f} + \tau_w . \frac{A_w}{A_f} \geq 0.0078 N/mm^2 \qquad (7)$$

Eq(7) is expressed in terms of column index (CI percentage ratio of column area to total floor area) and Wall index (WI_{inf}: percentage ratio of infill wall area to total floor area) and shown in Eq (8):

$$\tau_c . CI + \tau_w . WI_{inf} \geq 0.78 N/mm^2 \qquad (8)$$

The column shear strength τ_c and Wall shear strength τ_w of lower boundary shown in figure 18, are $1N/mm^2$ and $0.6N/mm^2$, respectively

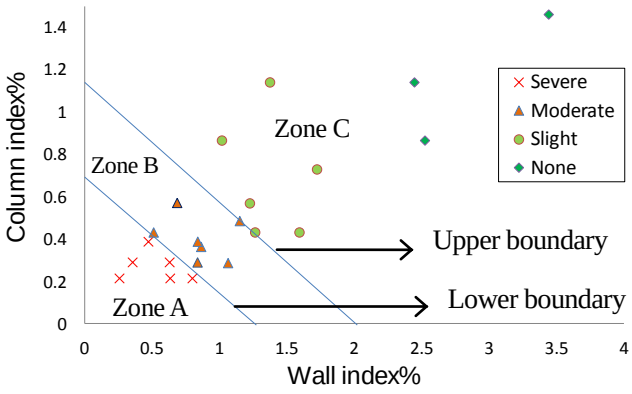

Figure 18 Proposed evaluation map

To make this method more practical; Eq (9) and Eq (10) are proposed. The inventory buildings having CI and WI_{inf} in index *less than 0.78N/mm²* are more vulnerable and therefore have higher priority to undergo a detailed analysis and seismic retrofit. Buildings having CI and WI_{inf} index *more than 0.78* N/mm^2 in Eq (10) have lower priority to be

checked. This boundary lines could be changed based on probability of damage and resources available for the seismic evaluation discussed later.

$$1.0\ CI+0.6\ WI_{inf} \geq 0.78\ N/mm^2 \quad (9)$$

$$0.65\ CI+0.37\ WI_{inf} \geq 0.78\ N/mm^2 \quad (10)$$

It should be noted here that Jordan has regions with different seismicity levels and soil condition. Therefore, different regions have different vulnerability zones and boundaries.
It is suggested that infilled frames with openings exceeding 50 percent of the panel area should be ignored.

4. Damage Probability:

Buildings evaluated to be in zone A (danger zone) does not imply that all buildings would be severely damage but it means that buildings in zone A are more probable to have severe damage. Vice versa is also true, a building in zone C (safe zone) does not imply that it would not be damaged but means that it less likely to be severely damaged.
Probability of damage could be checked using varies of methods; one of the most widely used is fragility curves. Fragility curves for the case of buildings in Jordan are still in its early stages of research. In this paper, HAZUS fragility curves are used to estimate damage probability.

4.1 Introduction of HAZUS fragility curves

HAZUS is a project conducted for the National Institute of Building Science (NIBS), under a cooperative agreement with the Federal Emergency Management Agency (FEMA). HAZUS is an estimation methodology for loss estimates from hazards and economical damage for structures and infra-structures in the United States. The probabilities of structural and non-structural damages to structures and life-lines as well as direct and indirect economical losses induced by natural disasters such as earthquake, flood and storm can be estimated.

In this paper, fragility curves for ground shaking damage for Low-rise RC buildings with masonry infill and pre-code design level is used. Pre-code damage functions was selected since it was recommended by HAZUS for older buildings that were not designed for seismic loads which is similar to the case of Jordan buildings built before seismic code was implemented in 2005. However, the fragility curves of HAZUS are derived for US buildings, thus the applicability of it to buildings in Jordan needs further research.

The fragility curves of HAZUS uses for 4 levels of damage states of structural damage; slight damage, moderate damage, extensive damage (severe damage) and complete damage. The description of slight damage and moderate damage of this paper are the same of that of HAZUS as stated before. The Complete damage state in HAZUS is defined as buildings which have collapsed or have partial collapse. The fragility curves are characterized in terms of spectral displacement as shown in figure 19.

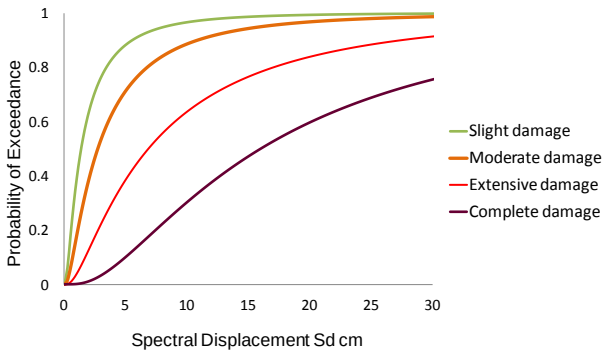

Figure 19 Fragility curves of Pre-code Low-rise RC buildings with unreinforced masonry infill

The performance point of each of the previous prototype buildings are transferred into spectral displacement using of Eq (11)

$$\Delta(Sd) = \frac{\Sigma(m_i \cdot \delta_i^2)}{\Sigma(m_i \cdot \delta_i)} \quad (11)$$

Where m_i is the weight of each floor and δ_i is displacement of each floor at the response point.
Figure 20 shows the damage state probability for the example building mentioned in the previous section which had performance spectral displacement of 2.9cm (3.24 cm roof displacement).

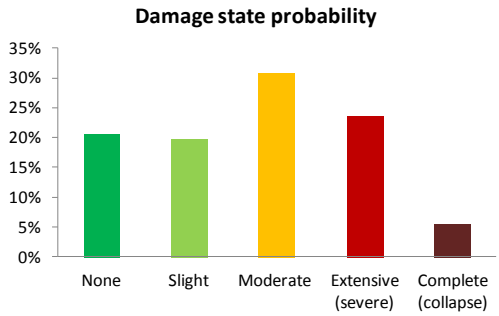

Figure 20 Damage probability of illustrated example

Using the fragility curves the damage state probability is studied for all selected buildings` cases in each zone. The four buildings just below the lower boundary that are in red circle marked as (a) in figure21 had an average probability of severe damage and collapse damage of *25.3% and 6.7%* respectively. This means that if you have about 100 buildings having similar Column index and wall index similar to those in circle(a) then 25 buildings will be heavily damaged and 7 buildings will collapse. Obviously, the weaker the building (smaller column and wall indices) than those in circle (a), then severe damage and collapse probability increases.

As for buildings in the orange circle marked as (b) in figure 21, the average probability of severe damage and collapse are *17.4% and 2.5%* respectively. This means that many buildings in this region can be heavily damaged, but only less than 2.5% will collapse.

As for buildings in the green circle marked as (c) in figure 21, the average probability of severe damage and collapse are *5.2% and 0.2 %* respectively. Buildings in this region are unlikely to collapse or partially collapse.

All the low-rise RC buildings with masonry infill walls in the city could be screened in a short time using only the column and wall indices. Those buildings then are checked are plotted proposed Shiga map for case of Jordan and classified into zones. Based on the percent of number of buildings in each zone then average structural damage and economic loss could be easily estimated. In additional, screening the city using this study helps to estimate roughly the resources needed for buildings` retrofit and risk mitigation.

The lower and upper boundaries proposed here could be modified easily based on the philosophy of the acceptable damage in the risk mitigation project and also based on the available resources for seismic evaluation and retrofit.
Understanding the probability of damage of each zone is an indispensable part of the proposed method

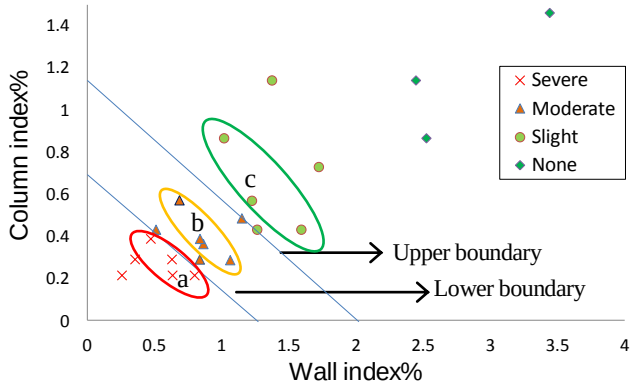

Figure 21 selected buildings for checking damage probability

5. Comparison with earthquake damage:

There is no recent major earthquake in Jordan. The nearest country with earthquake damage data is Turkey. RC buildings with masonry infill walls are commonly used in Turkey. Jordan and Turkey are Middle Eastern countries and they also shares the dead fault which runs through Jordan till the south-eastern part of Turkey (see figure 22). However, similar structure detailing and material quality in both countries is Not checked yet.

Figure 22 Dead Sea fault passing Jordan

5.1 Erzincan Earthquake Turkey; Data and Comparison

Erzincan 1992 earthquake is of magnitude 6.8 and PGA of ≈0.5g. The acceleration time history for NS and EW direction is shown in figure 23 and figure 24. The Architecture institute of Japan, AIJ, investigated a heavily damaged area in Erzincan earthquake (AIJ Report1993). It was reported that out of the 424 buildings investigated 28 (6.6%) collapsed and 68 (16.8%) were heavily damaged.
Erzincan`s response spectra (see figure 25) at short period is NS≈0.8g and EW ≈ 1.2g *which is much larger* than response spectra of 0.6g used in the proposed method especially in EW direction.

The damaged buildings data are collected by METU (Middle East Technical University) and AIJ and were mentioned by Hasan and Sozen (Hasan1997). Data contain also buildings with RC walls; therefore the data are filtered for buildings having only RC columns and Infill walls. The proposed boundaries are compared and plotted with data of damaged buildings by Erzincan earthquake 1992 in Turkey, see fig ure26.

The METU definition of damage state is different from the one used in this paper. Definitions of the damage state in the METU data as follows: Light: Reinforcement exposed but not buckled near joint faces. Fine flexural cracks in structural and nonstructural elements, Moderate: Reinforcement buckled near joint faces and/or inclined cracks in structural walls. Severe: Structural failure of individual elements.

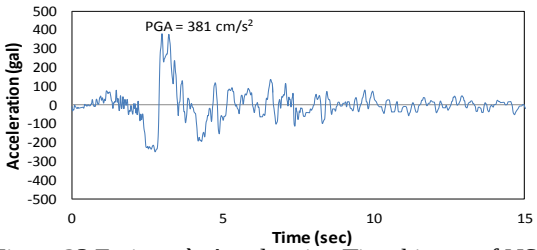

Figure 23 Erzincan`s Acceleration Time history of NS

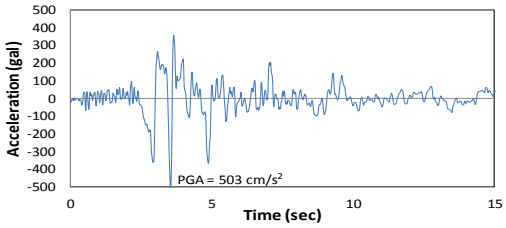

Figure 24 Erzincan`s Acceleration Time history of EW

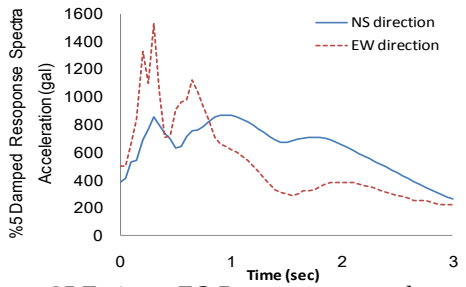

Figure 25 Erzincan EQ Response spectra damped 5%

The boundaries from the proposed buildings showed good agreement with damage of the Erzincan`s buildings. However, the Erincan`s response spectra (about 1g) is much larger than the response spectra in Jordan (about 0.6g). Then why good correlation was observed?

First the METU definition of damage state is different from the one used in this paper. Definition of the damage state of moderate state in METU indicates the reinforcement bars could be seen and they have already buckled. This moderate damage state of METU is thought to be as severe damage states used in this study and therefore the moderate damaged buildings in figure 26 could be considered severe by damage states of this study.

Another possible reason is that the duration time for major ground shaking of Erzincan EQ is less than 10 seconds (very short) & only one displacement cycle of large amplitude as shown in figure 23 and figure 24. Therefore cyclic degradation of masonry walls was not significant which helped to show good performance.

In addition, the strength of materials used in Erzincan building is unclear and could be much stronger the strength values assumed for buildings in Jordan.

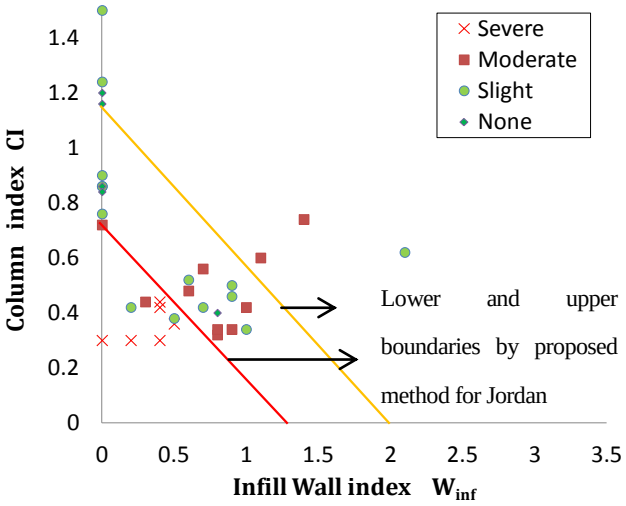

Figure 26 Comparison with data of damaged RC buildings with masonry infill of Erzincan earthquake 1992

6. CONCLUSIONS

Due to economical and time problems, a first screening method that is more practical and simple was introduced. The proposed method is fast and could be adjusted to be suitable to other regions with different seismicity and structural detailing. Buildings identified as vulnerable should undergo a more detailed procedures for further seismic evaluation.

An average structural damage and economic loss of a whole city could be easily estimated in a short time based on the probability of damage of each zone in the proposed method. In additional, screening the city using this study helps to estimate roughly the resources needed for buildings` retrofit and risk mitigation.

In future research, more prototypes with different Column and Wall indices should be checked to increase the accuracy of constructing the vulnerability zones.

Further improvements needs to be studied in further research such as adding regularity reduction index for buildings with irregular shapes. Material quality index should also be introduced to account for buildings construction quality and deterioration after construction. Even though captive columns are not commonly observed in Jordanian buildings, but captive columns should also be investigated in further research. In addition, Jordan`s material properties experiments are needed to account for the assumed values in this paper.

Abstract: In this paper, experimental study for axial collapse of reinforced concrete structure composed of shear and flexural member was conducted. From the experiments and equilibrium of force when column failed by axial load, axial capacity analysis model of failed shear column was proposed. Idealized backbone curve of failed shear column was also constructed from the model. This model showed good agreement with shear column of specimens. After that, pushover collapse analyses of frame model of specimens were conducted. The model mentioned above was installed to the frame model. From the results, collapse analysis method and model are almost valid in comparison with especially more brittle specimens.

1. INTRODUCTION

Some of old reinforced concrete structures might have shear critical members. Failure of shear critical columns may cause a total collapse of building because of rapid degradation of horizontal and axial capacity. In Japanese seismic code and design standards (AIJ.2004), deterioration in shear resistance in column has not been considered because of complexity and unclearness of such behavior. Therefore, safety limit state of buildings (maximum deformation point of buildings to prevent collapse) is generally taken at the first occurrence of shear failure of a structural member.

However, this safety limit state is conservative because buildings might not collapse directly after shear failure if the horizontal and vertical forces can be redistributed from failed members to surrounding members. In addition, previous research (Mukai et.al 2010) showed that redistribution behavior was observed in experiment of RC frame including shear and flexure columns.

Main goal of this paper is to estimate that kind of behavior of RC frame. In this paper, an analytical model of residual axial capacity of column was constructed. After that, static cyclic loading experiments of reinforced concrete frames composed of brittle shear and ductile flexural columns were conducted to confirm suitability of the model.

2. MODEL OF RESIDUAL CAPACITY OF BRITTLE SHEAR COLUMN

2.1 Review of Previous Model

For reasonable collapse assessment, analytical model of deterioration of shear and axial capacity is needed. In past, models to assess the backbone characteristics of such brittle members considering shear-axial interaction were proposed by Elwood and Moehle (2004) and Yoshimura (2008), and the authors (2012).

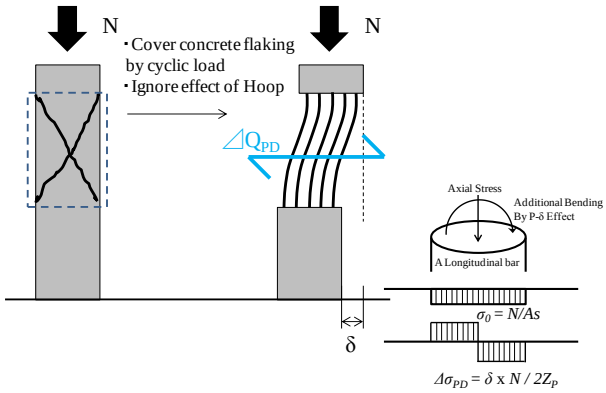

Figure1 Residual axial capacity model

Residual axial capacity model in authors' previous paper (2012) is shown in Figure1. And EQ.(1) is constructed from equilibrium of stress when longitudinal bars yield and column reaches axial collapse.

$$N_{R_L} = \frac{As \cdot \sigma_y}{\left(1 + \frac{As \cdot \delta}{2Z_p}\right)} \quad (1)$$

Where; N_{R_L}: residual axial capacity by longitudinal bars, Z_p: plastic section modulus of longitudinal bars, As: total area of longitudinal bars, σ_y: yield stress of longitudinal bars, δ: lateral drift of column.

As shown in Figure1, P-δ effect to longitudinal bars was considered in Eq.(1). Basic assumption of this model is

as follows;

1) Cover concrete was totally removed due to shear failure and cyclic loading
2) The influence of transverse reinforcements is small and therefore ignorable
3) Horizontal force of column is assumed to reach zero by capacity deterioration when vertical load N exceeds vertical capacity of column

In this paper, the effect of transverse reinforcement (mentioned assumption 2)) will be taken into consideration and is thoroughly studied.

2.2 Effects of transverse reinforcement

Transverse reinforcement contributes to residual capacity of column by confining crushed concrete. This effect is illustrated in Figure 2. After shear failure, wedge shaped area (see figure 2) is formed top and bottom of the damaged area. Transverse reinforcement resists the axial load N by confining the crushed concrete area. When vertical collapse occur, transverse reinforcements yield and equilibrium of force is constructed as shown in Eq.(2). Eq.(2) and Eq.(1) are added to form Eq.(3).

$$N_{R_T} \cdot \tan\gamma = \frac{2D_e \cdot A_{sw} \cdot \sigma_{wy}}{s \tan\phi} \tag{2}$$

$$\begin{aligned} N_R &= N_{R_L} + N_{R_T} \\ &= \frac{A_s \cdot \sigma_y}{\left(1 + \frac{A_s \cdot \delta}{2Z_p}\right)} + \frac{2D_e \cdot A_{sw} \cdot \sigma_{wy}}{s \tan\phi \tan\gamma} \end{aligned} \tag{3}$$

Where; N_R: total residual axial capacity, N_{R_T}: residual axial capacity by transverse reinforcement, D_e: effective width of the column, A_{sw}: total area of transverse bars, s: space of transverse bars, φ:angle of shear crack, γ:angle of wedge shaped area.

In previous research by Yoshimura (2008), backbone characteristics of residual shear and axial capacity were proposed (as shown in Figure3). In the backbone curve, collapse displacement is defined as R_u which is the point where shear capacity reaches zero and axial load N exceeds axial capacity N_R. Based on Eq.(3), the collapse displacement R_{u0} could be calculated by Eq.(4). Referring to Yoshimura model and Eq.(4), backbone curve of residual capacity could be calculated.

$$R_{U0} = \delta / h_0 = \frac{2Z_p}{A_s \cdot h_0} \left(\frac{A_s \cdot \sigma_y}{N - \frac{2D_e \cdot A_{sw} \cdot \sigma_{wy}}{s \tan\phi \tan\gamma}} - 1 \right) \tag{4}$$

Where; h_0: internal height of column.

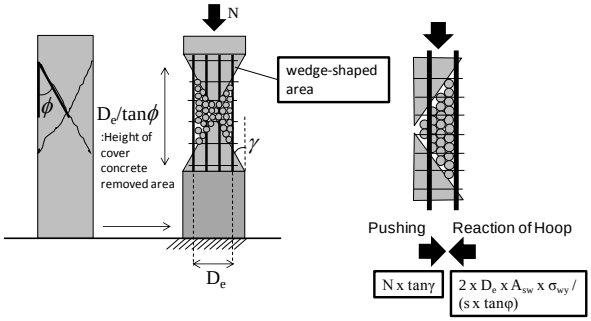

Figure2 Confinement effect of transverse bars

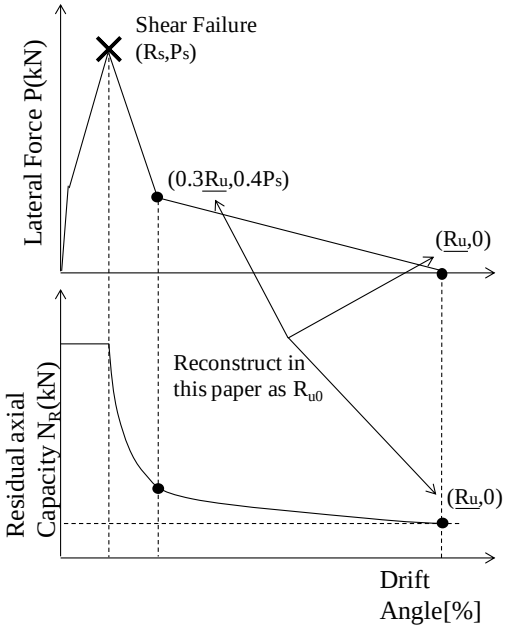

Figure3 Backbone curve of shear and axial capacity

3. EXPERIMENTAL STUDY OF RC FRAME INCLUDING SHEAR COLUMN

3.1 Test Specimen

Tests were conducted for five specimens; the example drawings are shown in Figure 4 and 5. These specimens are single story and two bays frame structures. Specimen F0101 (conducted with Fukuyama et al (2011)) was designed as a one-half scale and the others were designed as a 3/8 scale of typical building in Japan. Every member except for center column was designed so that flexure yielding precedes shear failure. Center columns were not provided with adequate transverse reinforcement and they were designed to demonstrate shear failure. Material properties of the specimens are shown in Table 1.

Main parameters of these specimens are p_w which is the area of transverse reinforcement normalized by the hoop spacing and column width and $N/A_s\sigma_y$ which is applied axial load divided by capacity of longitudinal reinforcement of center column. $N/A_s\sigma_y$ is index of axial capacity carried by longitudinal bars. Table2 shows the basic properties of center

columns. Center column of F0101 specimen has higher axial capacity as shown in Table2. Specimen F0109 has the poorest lateral reinforcement, therefore, expected to have brittle axial collapse. F0203 and F0103 are almost identical specimen except for transverse reinforcement. These specimen has designed to confirm effects of N_{R_T} (residual axial capacity by transverse reinforcement). F0102 has almost same longitudinal reinforcement ratio (p_g: section area of longitudinal bars normalized by cross section area of each column) with F0101 although axial load is two times larger than F0101.

In addition, side columns and half of beams of F0109 were reused at F0103, F0203 and F0102 because these members were less damaged.

3.2 Measurement and Loading Cycles

Horizontal cyclic loads are applied by two hydraulic jacks fixed at the ends of beams. Load cells to measure axial stress and shear stress are installed at middle of side columns of F0101 (see Figure4), bottom of center column and middle of beams of the other specimens (see Figure5).

F0101 was subjected to three cycles of 1/800rad, 1/400rad, 1/200rad, 1/100rad, 1/50rad and 1/33rad of story drift angle which are calculated as average horizontal displacement of the side columns divided by story height which is the height from top of stub to center of top joint of the each column. The others were subjected to two cycles of 1/800rad, 1/400rad, 1/200rad, 1/100rad and 1/67rad of story drift angle.

In addition, although cyclic loading were conducted until specimens showed axial collapse, additional axial load was applied to center column of specimens which didn't show axial collapse.

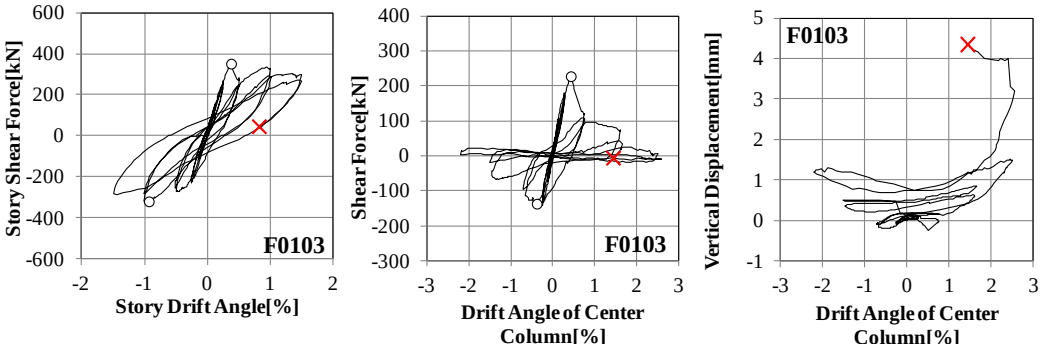

Figure6 Results of F0103

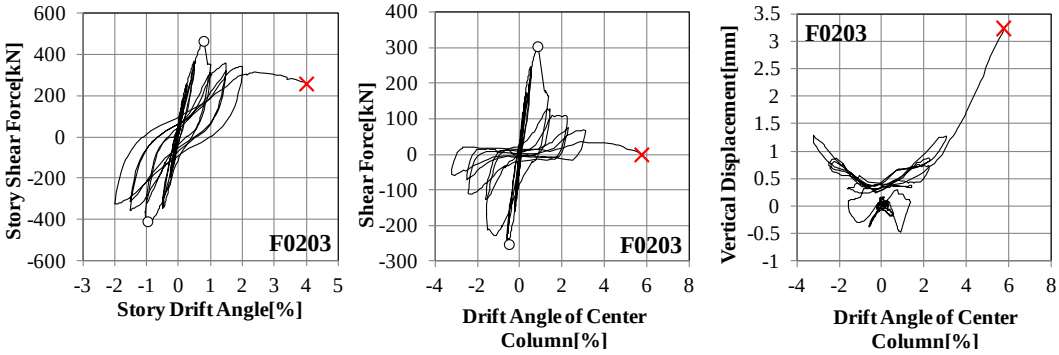

Figure7 Results of F0203

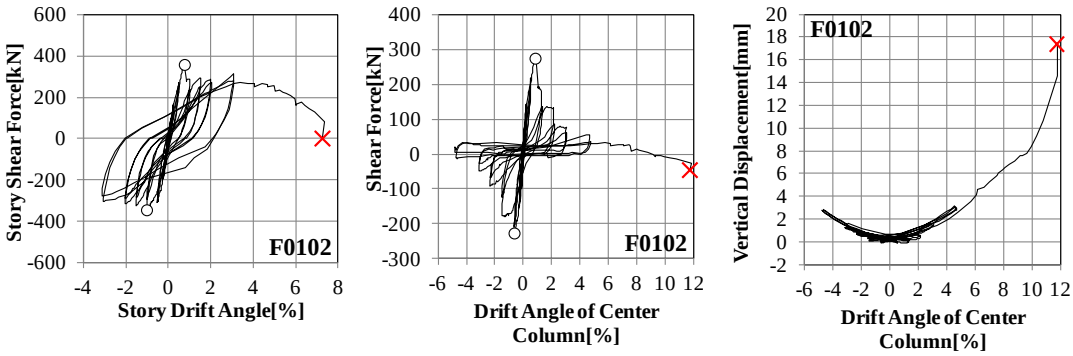

Figure8 Results of F0102

3.3 Test Results

In this paper, results of F0203, F0103 and F0102 will be mentioned in detail and refer to authors' previous paper (2011) for F0101 and F0109. Results of F0103, F0203 and F0102 are shown in Figure6, Figure7 and Figure8, respectively.

F0103 specimen showed about 350kN of maximum story shear force at 0.36% of story drift angle (see Figure6). After that, shear failure of center column occurred and shear capacity of the column and story rapidly decreased. After the cycle of 1/67rad, vertical displacement (downward direction as +) rapidly increased and vertical collapse (3hinges in the beams) was observed. In addition, at the point of vertical collapse, shear capacity of the center column reaches almost zero.

F0203 showed more ductile behavior than F0103(see Figure7). About 450kN of maximum story shear force was shown at 0.8% of story drift angle. Gradual decreasing of shear capacity was observed after shear failure of center column. In the process of decreasing, although vertical displacement was increased, vertical collapse was not observed until 4% of story drift angle. Ductility of F0203 was significantly improved by comparing F0103 which was given a half of transverse reinforcement.

In specimen F0102, at 0.75% of story drift angle, about 350kN of maximum story shear force and shear failure of center column were observed (see Figure8). Shear capacity of story decreased until 2% of story drift angle, after that, it raised until 4% of story drift angle. The reason is that shear force of side columns raised at that region regardless of decreasing of shear capacity of the center column. In region of over 4% of story drift angle, story shear capacity was decreased because side columns also showed shear failure (see Figure9). Vertical displacement of a side column significantly increased, therefore, relative vertical displacement of center column which means deformation of a beam wasn't increased. It is the reason why vertical displacement when F0102 collapsed such a large vertical

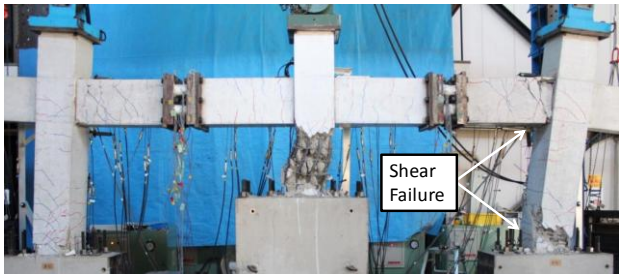

Figure9 F0102 at 6% of story drift angle

displacement (see Figure8). Then horizontal loading was stopped and additional axial load was applied to center column. Because of additional loading, vertical displacement of the column is rapidly increased and specimen showed vertical collapse.

3.4 Observation of Pictures

Figure10 shows pictures when shear failure occurs. Angles of shear crack are almost 30° on average, therefore, 30°was taken as φ.

After the loading, for center column of F0103, F0203 and F0102, broken concrete was raked from the core of columns to observe the wedge shaped area mentioned above as shown in Figure11. The angles of wedge shaped area is also shown in Figure11, they ranged from 24° to 57° and 40°on average, therefore, 40°is taken as γ.

In addition, referring Figure11, although snapped transverse reinforcements were observed, all the bars are may not be effective to resist to axial load. On average, half of transverse reinforcements were snapped and they're estimated to work as confinement, therefore, the effect of transverse reinforcements are considered as half(see Eq.(5),(6)).

$$N_R = \frac{A_s \cdot \sigma_y}{\left(1+\frac{A_s \cdot \delta}{2Z_p}\right)} + \frac{2D_e \cdot A_{sw} \cdot \sigma_{wy}}{s \tan 30° \tan 40°} \frac{1}{2} \qquad (5)$$

$$R_{U0} = \frac{2Z_p}{A_s \cdot h_0}\left(\frac{A_s \cdot \sigma_y}{N - \frac{D_e \cdot A_{sw} \cdot \sigma_{wy}}{s \tan 30° \tan 40°}} - 1\right) \qquad (6)$$

4. PUSHOVER ANALISYS

4.1 Analytical model and method

Pushover analyses are carried out to check suitability of the model mentioned above and estimate vertical collapse of structures. Structural model is shown in Figure12. First, members were distinguished as flexure members or shear members. Flexure members consist of an elastic shear spring, an elastic axial spring and inelastic flexure springs. Tri-linear model is applied to inelastic flexure springs based on AIJ standard (2010). Shear members have elastic flexure springs,

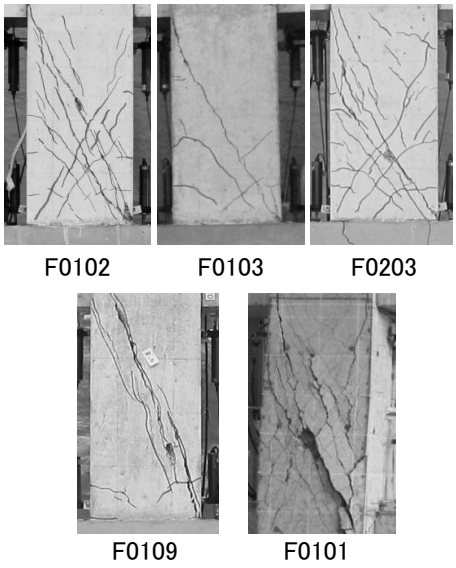

Figure10 Pictures at shear failure

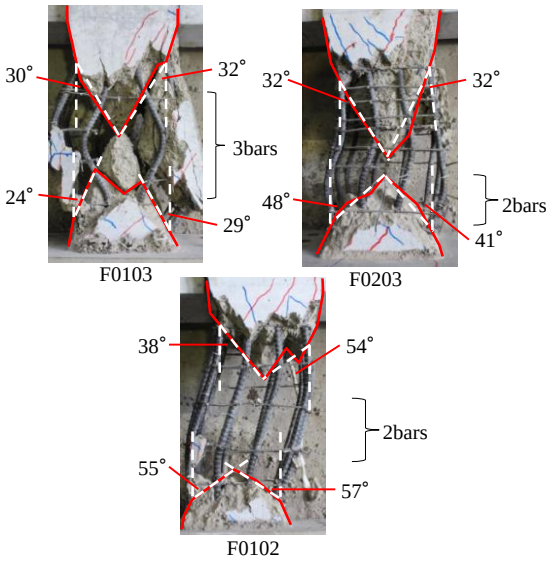

Figure11 Angles of wedge shaped area and snapped transverse reinforcement

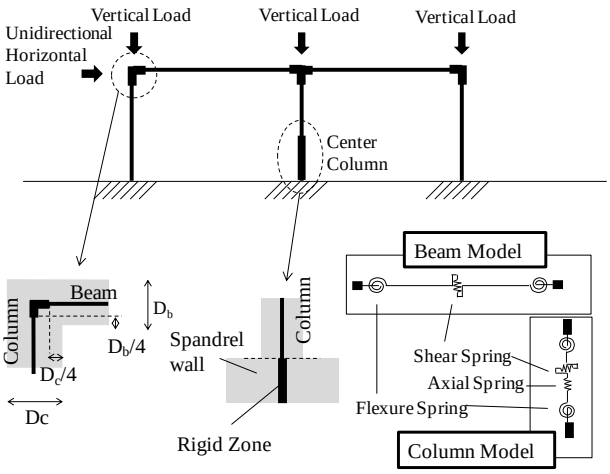

Figure12 Structural modeling

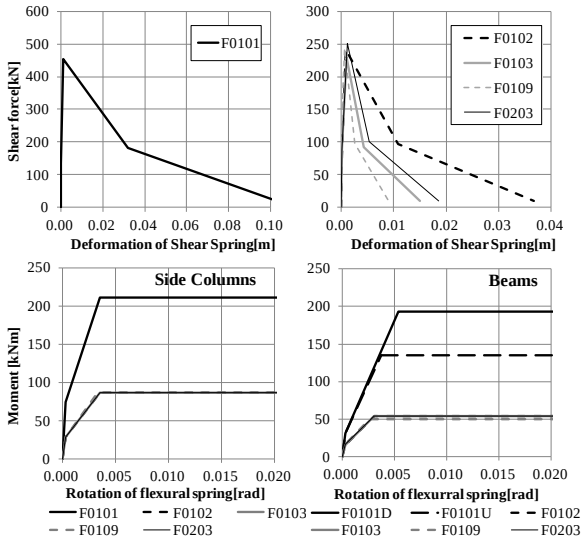

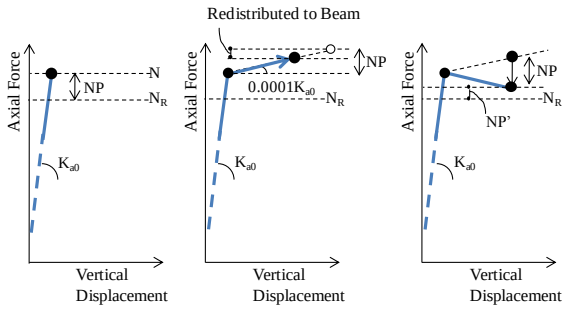

Figure 13 Backbone curve of inelastic springs

(a)Calculate NP (b) Calculate Force to Beams (c)Cancel NP

Figure14 Calculation of inelastic axial spring

an inelastic shear spring and an inelastic axial spring. quad-linear model similar to Figure 3 is applied to inelastic shear spring assuming 10kN as minimum shear capacity. Inelastic shear springs and flexure springs used in the analysis are shown in Figure13.

Calculation methodology of stress and displacement of inelastic axial spring is a bit complicated. As shown in Figure 14, residual axial capacity shown in Eqn.(5) and axial force carried by column is compared step by step. When former becomes lower than later, unbalanced load NP is calculated (Figure14(a)). To calculate vertical load carried by beams, then, stiffness of axial spring of the column was changed to 0.0001Ka (Ka: elastic axial stiffness) and NP was applied as vertical load to node at top of the column (Figure14(b)). After that, as shown in Figure14(c), NP was canceled from the column and NP' was calculate as residual unbalanced load (if NP' is not negligible, back to Figure14(a)).

Moreover, for F0101 and F0102 which were applied additional axial load in the middle of experiment, additional cases of pushover analysis are carried out because increasing vertical load in the middle of pushover is difficult. In these

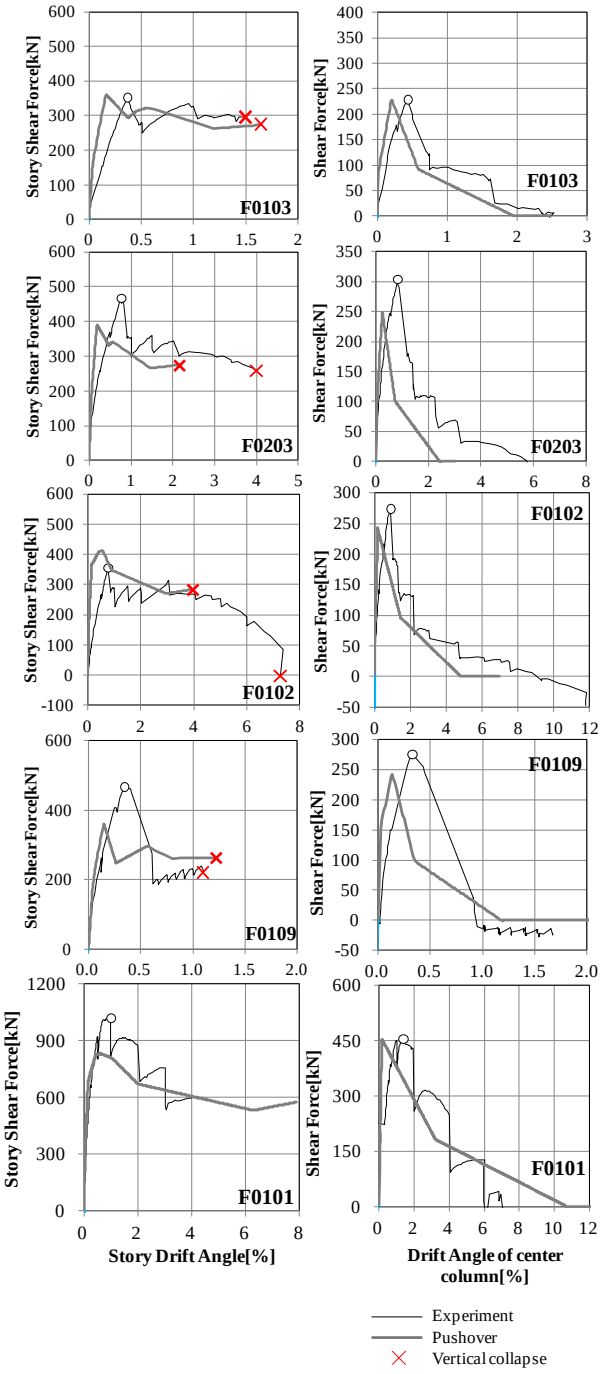

Figure 15 Comparison of experimental with analytical results

cases, maximum vertical load observed in the experiment was applied in the analysis (initial vertical load was applied in basic cases). If the model and analytical method are valid, experimental results expect to range between basic case and additional case.

4.2 Analytical Results

Figure15 shows analytical results and backbone curve of experimental results. As for Figure15, analytical results show good agreement with experiment especially their capacity degradation slope. Magnitude of correlation of

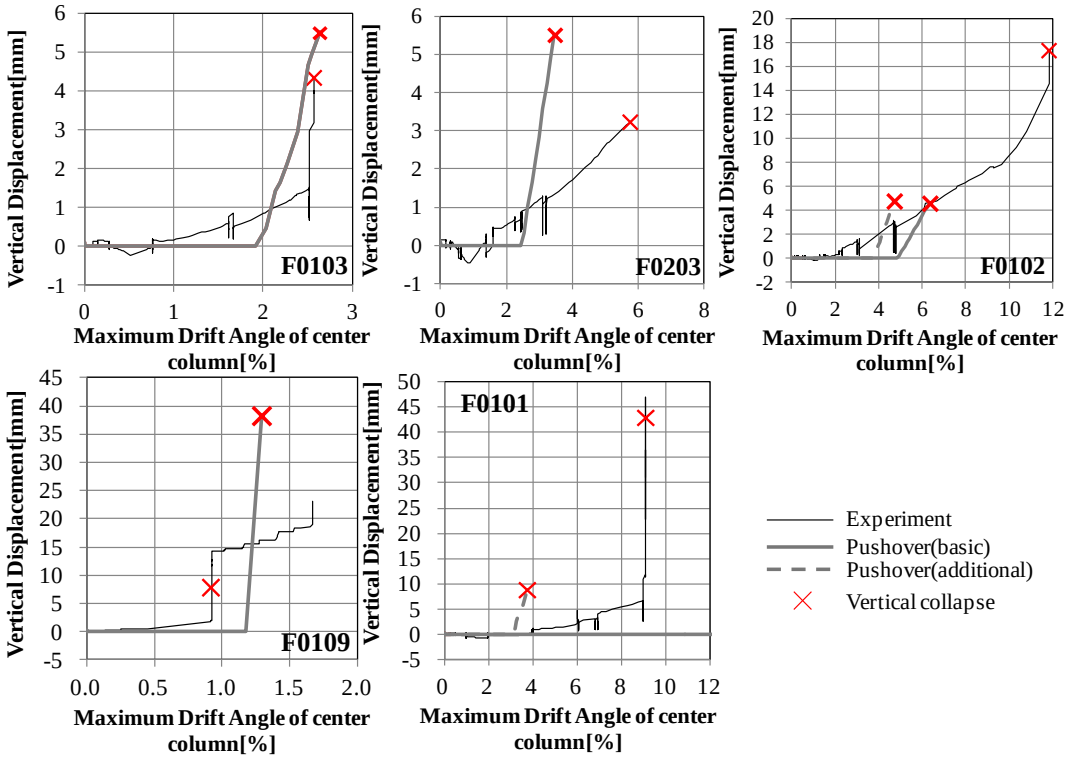

Figure16 Comparison of vertical displacement

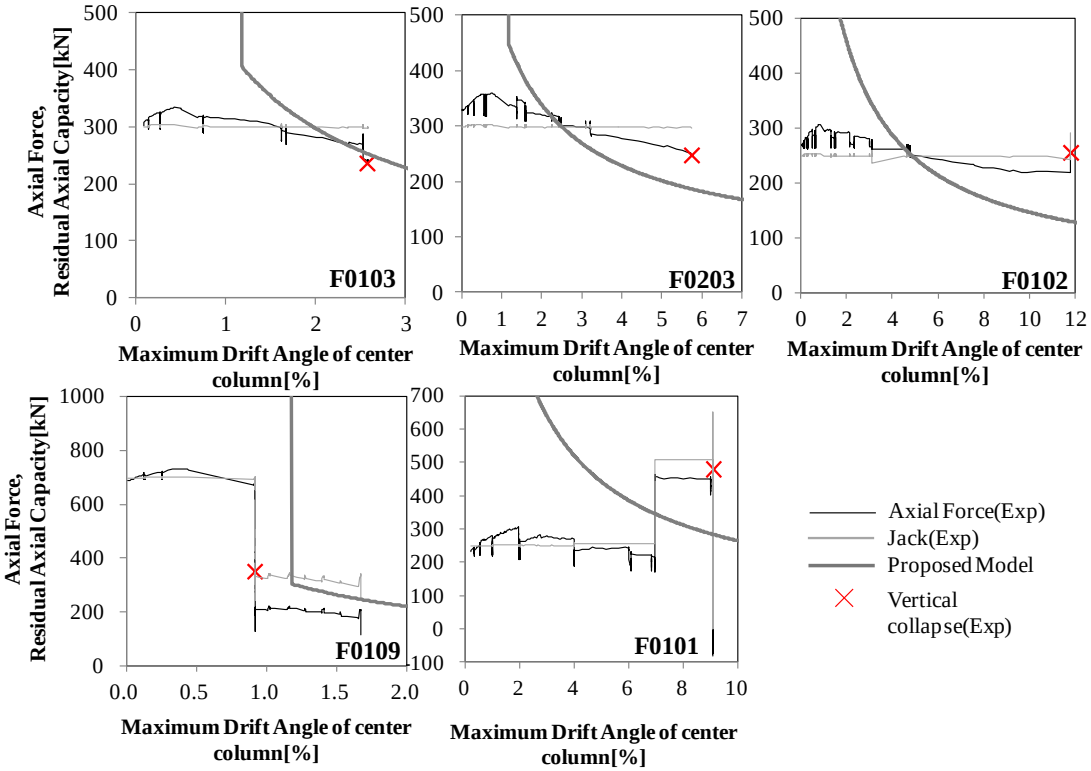

Figure17 Comparison of axial load (experimental with analytical model)

ductility of center column calculated by the model is also shows higher suitability. However, their maximum capacity were almost underestimated and elastic stiffness of analysis was more or less higher (but these are not main point of these studies).

Vertical displacement and maximum lateral drift of center column was shown in Figure16. In addition, for F0102 and F0101, the results of additional cases are also shown in Figure16. Analysis of more brittle specimens such as F0103 and F0109 shows higher suitability with the experiment especially point of vertical collapse and tendency of increment of vertical displacement. Although the other

specimens are not good to estimate point of vertical collapse, all these analyses could estimate as safe side of experiment. In addition, collapse displacement of F0102 was significantly larger than both basic case and additional case of pushover.

Figure17 shows that residual axial capacity of the model and vertical loading process of the experiment. Vertical load to center column applied by jack in the experiment was also shown in Figure17, difference between axial load and vertical load by jack is distributed to beams as shear force. Axial capacity degradation and vertical load redistribution behavior was observed.

As shown in Figure17, All the specimens except F0103 and F0109 collapsed at higher axial force than residual axial capacity by the model. On the contrary, for more brittle specimen such as F0103 and F0109, residual axial capacity of specimens at collapse shows good agreement with the model. These results suggest that residual axial capacity by the model is almost valid for brittle specimens although tend to underestimate ductility for other specimens.

5. CONCLUSIONS

Contributions of this paper are shown in as follows;

1) From the Equilibrium of force, model to estimate the residual capacity of the column was constructed
2) Experimental study of RC frame including shear and flexure column was carried out. Vertical collapse was observed in the experiment.
3) Capacity degradation slope estimated by proposed model showed good agreement with experiment.
4) Displacement that vertical collapse occurred could be estimated by pushover analysis especially for more brittle specimens.

Abstract: Cyclic loading test of subassemblies of continuously buckling restrained braced RC frames is conducted to evaluate the behavior of the connection details of BRBs and its influence on the surrounding RC components. Each subassembly consists of a RC beam-to-column joint with two columns (lower and upper stories), a beam framing into it and a set of BRBs that are diagonally connected to the beam-to-column joint. To achieve necessary boundary conditions, the specimen is rotated 90 degrees and is loaded with two displacement-controlled horizontal actuators at the column bottom and the beam end. It was observed that for all the specimens, BRBs yield and start to dissipate energy at an early stage with story drift ratios much smaller than those at beam yielding. The concrete corbels and the pre-stressing anchor bolts provide not only sufficient strength but also large stiffness to minimize the deformation loss in the BRB connections.

1. INTRODUCTION

In recent years, applications of BRBs in reinforced concrete (RC) frames have attracted much attention, in which, the connection of BRBs to RC frames is important. However, there are not commonly accepted details of installing BRBs on RC frames. The authors suggested a continuously buckling restrained braced frame system in which the BRBs are arranged in the form of a Warren truss (Maida et al, 2011). The corresponding BRB connection detail in the proposed system, which consists of anchor bolts and RC corbels, has been confirmed effective through component tests and subassemblage tests with BRBs simulated by force-controlled jacks (Qu et al, 2011). However, some other important issues, such as the performance of the BRBs in the proposed system, need to be investigated. To do this, subassemblies consisting of RC beam, column and BRBs of the proposed system were subjected to cyclic loading. The major parameter of this test investigation was the proportion of the yield strength of the BRBs in the upper and the lower stories. This experiment confirmed the influence of the unbalanced BRB force in the upper and the lower stories on the performance of the BRB connection.

2. EXPERIMENTAL PROGRAM

The specimens were 1/2 scale RC beam and column subassemblies with BRBs that resembles the trial design of a high-rise RC building (Kikuta et al, 2010). The details of the specimens are shown in Fig. 2.1 and 2.2. Specimen properties are shown in Table 2.1. For each specimen, BRBs in the upper and the lower stories were attached to the beam-to-column joint through a single gusset plate. The inclination angle of the BRBs was 40.4 deg. A group of eight anchor bolts fastened the gusset plate to the concrete joint and high strength non-shrink grout was filled between the gusset plate and the two RC corbels projecting from the column. Mortar filled steel tubes were used to restrain the buckling of the core of the BRBs (Fujimoto et al, 1988).

The major difference among the specimens was in the proportion of the yield strengths of the BRBs in the upper and the lower stories, and in the mechanism of resisting the horizontal force on the gusset plate. Four specimens were tested. These were '75-75N' of 750 kN BRBs for both the upper and the lower story; '50-75N' of a 500 kN BRB in the upper and a 750 kN BRB in the lower story, which resembled the case for a middle story of a high-rise building where the yield strength of the BRBs is changed; '0-75N' of only a 750 kN BRB in the lower story, which resembled the top story of a building. In the above three specimens, the

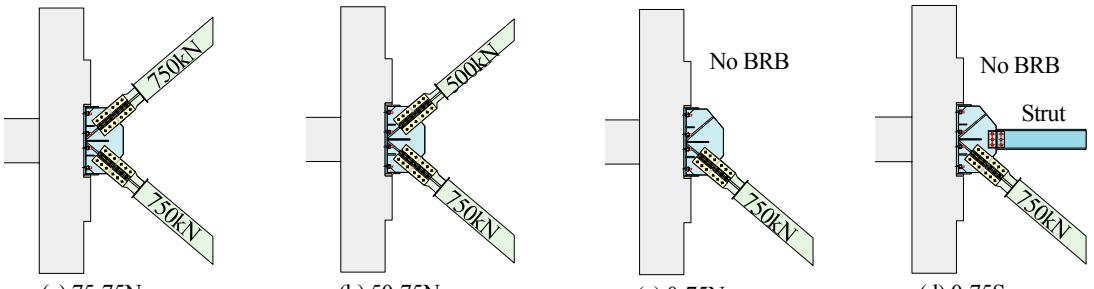

Figure 2.3. Configuration of BRBs and strut

anchor bolts for fastening the gusset plate was pre-tensioned to increase the stiffness of the connection. In the fourth specimen, namely '0-75S' in which only a 750 kN BRB was installed in the lower story, the anchor bolts were not pre-tensioned. Instead, a steel strut was installed to help resisting the horizontal force on the gusset plate (see Fig. 2.3).

High strength steel rods of 17 mm diameter were used for the anchor bolts. For each of the first three specimens, the group of eight steel rods was prestressed to provide 571.2 kN pre-tension, which equals the horizontal component of the yield strength of a single 750kN BRB, that is, $P_y\cos\alpha$, where P_y is the yield strength and α is the inclination angle of the BRB. In other words, each anchor bolt in the group was prestressed to 71.4 kN.

The test setup is shown in Fig. 2.4 and Photo 2.1. The

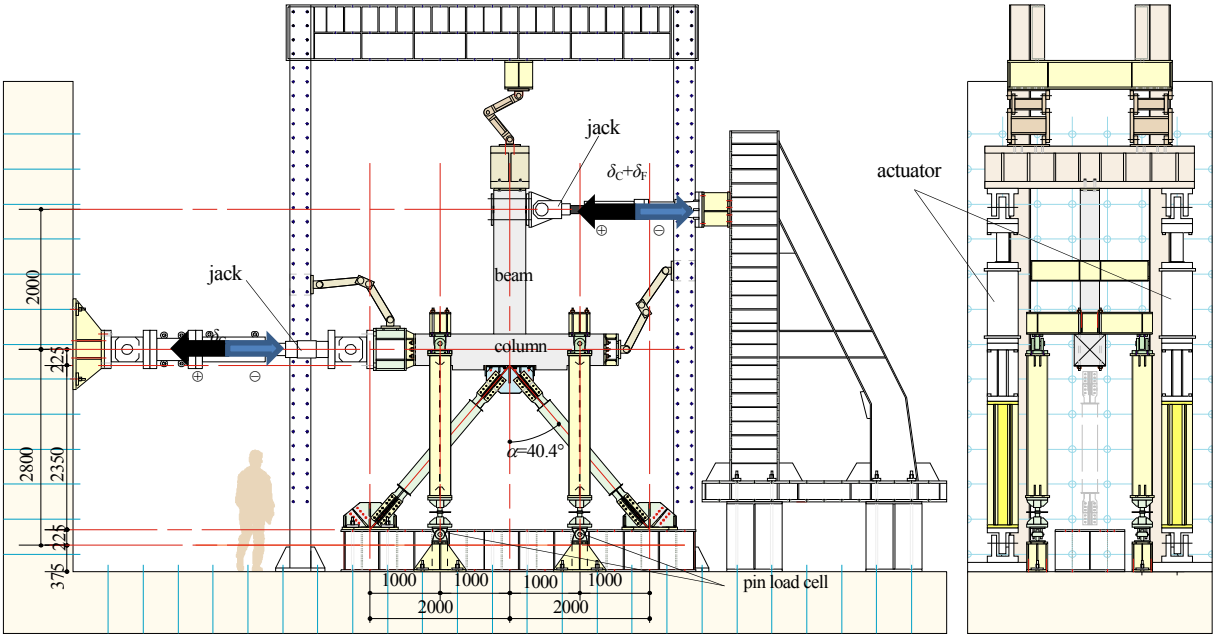

Figure 2.4. Experimental setup

Photo 2.1. Experimental setup

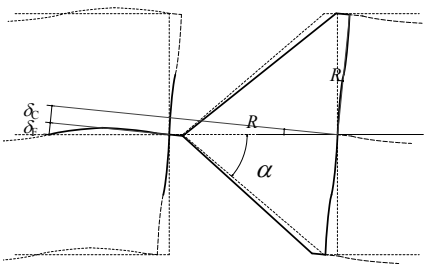

Figure 2.5. Deformation of building

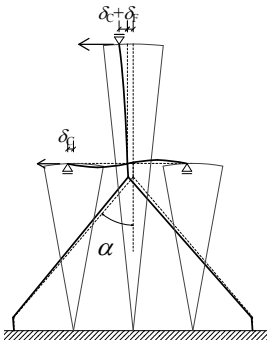

Figure 2.6. Deformation in experiment

specimen was rotated 90 degrees clockwise. The top and the bottom of the column were supported by pin rollers that allow for horizontal movement. The beam was restrained at its free end by two actuators in its axial direction. The bottom of the column and the beam free end were driven by two horizontal displacement-controlled jacks to impose deformation to the specimen.

The displacement of the two horizontal jacks kept a certain proportion during the loading. When the column was displaced by δ_C, resulting in a story drift ratio R, the beam end should be displaced by $\delta_C+\delta_F$ in order to create the deformation pattern as shown in Fig. 2.5. The two vertical actuators were also displacement-controlled to exhibit zero displacement during the test. Cyclic loading with increasing displacement amplitudes was conducted. For each specimen, two cycles were carried out for story drift ratio amplitudes of 1/1600, 1/800, 1/400, 1/200, 1/100. After that, only one cycle was carried out for amplitudes of 1/50 and 1/33.

3. EXPERIMENTAL RESULTS

3.1 Global response

The crack patterns at story drift ratio R = -1/100 of all specimens are shown in Fig. 3.1. For all specimens, flexural cracks occurred on the beam ends at an early stage. Afterwards, flexural-shear cracks accompanied the increase of the story drift ratio. The longitudinal rebar of beam yielded at R = 1/120 for the '75-75N' specimen, and shear cracks were observed at R = 1/100 on the beam-to-column joint.

The story drift ratio versus shear force relationship of the '75-75N' specimen is shown in Fig. 3.2(a). The story shear force can be separated into two parts, that is, the contribution of the RC part in the subassembly, θ_F, and that of the BRBs, which is directly related to the axial force of the BRBs, N_{BRB}. The hysteresis of the RC part and the BRB

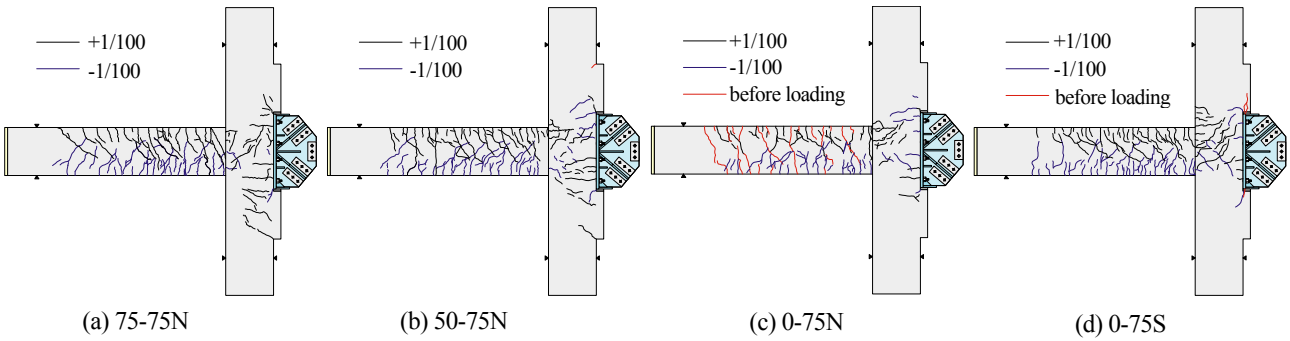

Figure 3.1. Cracks of RC part at R=+1/100 and R=-1/100

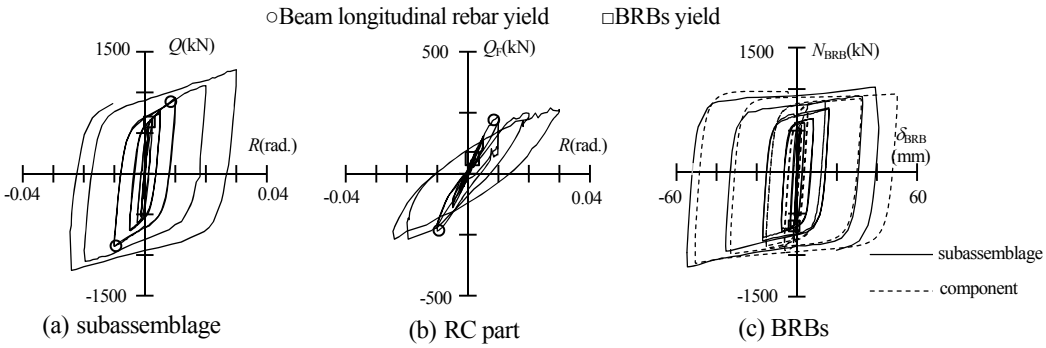

Figure 3.2. Behavior of '75-75N' specimen

in the lower story is shown in Fig. 3.2(b) and (c). Compressive force was acted on the beam in positive loading because of the difference in the yield strength of the upper and the lower BRBs for '50-75N', '0-75N' and '0-75S' specimens. As a result, the yield strength of the beam was a little bit increased for these specimens. The accumulative hysteretic energy dissipation of the RC part, W_F, and that of the upper BRB, W_{DU}, and the lower BRB, W_{DL}, for '75-75N' specimen are shown in Fig. 3.3. At R = -1/100, the energy dissipated by the lower BRB, W_{DU} = 98.6kNm, by the upper BRB, W_{DL} = 96.0kNm, and by the RC part, W_F = 9.2kNm. It is evident that the BRBs are very effective in dissipating energy in a RC frame by the fact that the energy dissipation in each BRB was approximately 10 times that in the RC part. Only the results for '75-75N' specimen is shown here as an example. Similar observations were made for all the other specimens.

The development of the crack width of the beam of '75-75N' specimen is shown in Fig. 3.4. The crack width was measured on the beam surface at the projecting position of the longitudinal rebars. The total and the maximum width is the sum and the maximum of the width of all the cracks on the beam surface going through the longitudinal rebars, respectively. For all the specimens, the total crack width was about 2 mm and the maximum one was about 0.2 mm at R = -1/100.

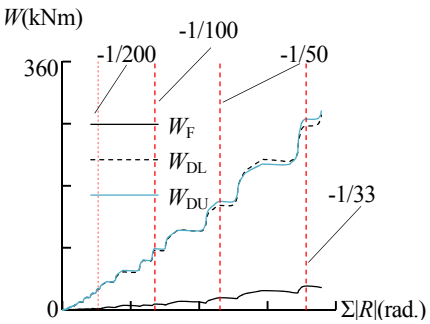

Figure 3.3. Hysteretic energy dissipation

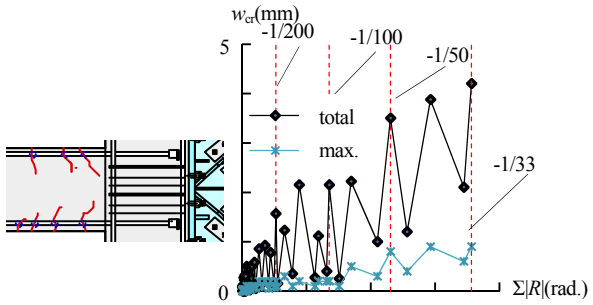

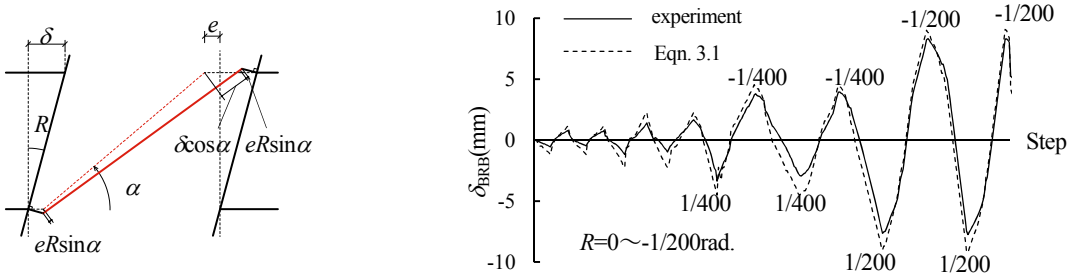

Figure 3.4. Crack width on beam

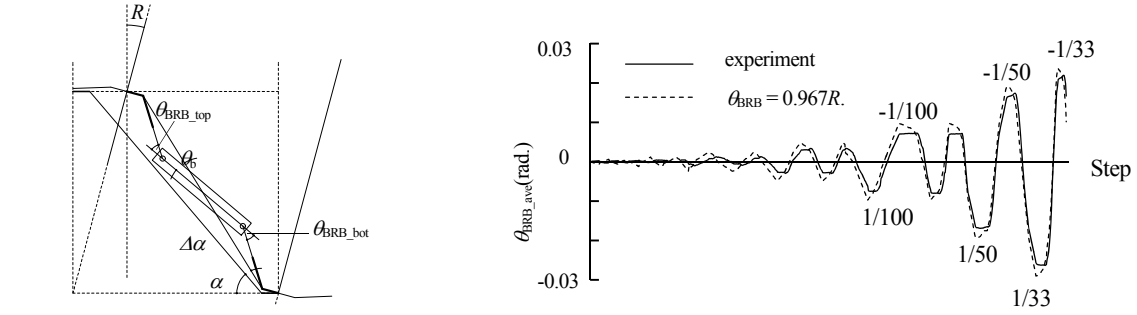

3.2 Behavior of BRBs

The axial deformation of BRBs measured in the experiment is compared with the ideal work point-to-work point deformation calculated from the story drift ratio (Eqn. 3.1) in Fig. 3.5. The latter can be regarded as a maximum deformation a BRB should be able to sustain if the connection is rigid. In the experiment, however, it was observed for '0-75N' and '0-75S' specimens that the measured axial deformation of the BRB was only 40 ~ 50% of the ideal displacement when the deformation of the subassembly was small, for example, the story drift ratio is less than 1/400. When the story drift ratio became larger, the ratio of the measured BRB deformation and the ideal brace

(a) work point-to-work point deformation calculated (b) Comparison between experiment and Eqn. 3.1

Figure 3.5. Axial deformation of BRBs '75-75N'

(a) plastic rotations at both ends calculated (b) Comparison between experiment and $\theta_{BRB} = 0.967R$.

Figure 3.6. Rotation of BRB end of '75-75N' specimen

displacement increased significantly. It is no less than 90 % for story drift ratio greater than 1/200 for all the specimens.

$$\delta_{BRB} = \delta \cos\alpha + 2eR \sin\alpha \qquad (3.1)$$

where e is eccentricity of the BRB work point with respect to the column and beam centerlines.

Different from component test of a single BRB subjected to uniaxial loading, the BRBs in the subassembly test sustained obvious plastic rotations at both ends (Fig. 3.6(a)). The measured end rotation is shown in Fig. 3.6(b). The rotation θ_{BRB_ave} is taken as the average of θ_{BRB_top} and θ_{BRB_bot} as shown in Fig. 3.6(a). It increased with the increase of the story drift ratio of the subassembly. This rotation can be estimated by the equation proposed by Kozai Club. (1998) from the story drift ratio R. For the present test, $\theta_{BRB} = 0.967R$. The estimated rotation is compared with the measured one in Fig. 3.6(b).

3.3 Behavior of BRB connection

The relationship of the horizontal displacement of the gusset plate, δ_H, versus the horizontal force on the gusset plate, P_{DH} (see Fig. 3.7), for '0-75N' and '0-75S' specimens are compared in Fig. 3.8. The tensile force on the gusset plate of the two specimens was almost the same. Notwithstanding, the maximum horizontal displacement of '0-75S' specimen was about 1.1 mm in both the pulling and the pushing direction, while that of '0-75N' specimen was only about 0.25 mm in the pulling and negligible in the pushing direction. The pre-tension of the anchor bolts seems more effective than installing a strut for resisting the tensile force on the gusset plate.

The relationship of the vertical displacement of the

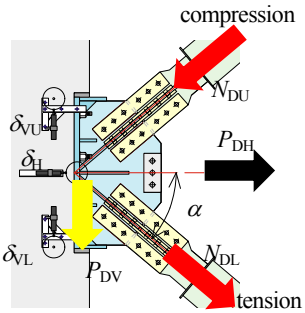

Figure 3.7. Location of displacement transducers

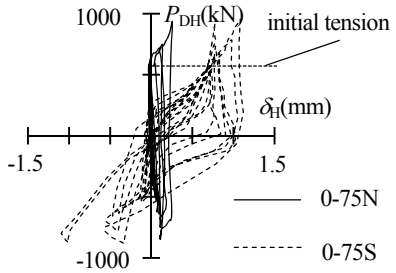

Figure 3.8. Horizontal displacement of gusset plate - tension of gusset plate relations

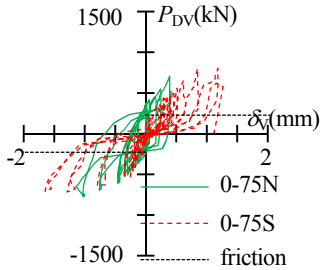

Figure 3.9. Vertical displacement of gusset plate - shear force of gusset plate relations

gusset plate, δ_V, versus the shear force on the gusset plate, P_{DV}, for '0-75N' and '0-75S' specimens are compared in Fig. 3.9. The vertical displacement δ_V is taken as the average of δ_{VU} and δ_{VL} as shown in Fig. 3.7. The possible friction force between the gusset plate and the underneath concrete in '0-75N' specimen is also shown as dashed lines in the figure, assuming a coefficient of friction of 0.4 (AIJ, 2011). For the '0-75N' specimen, the gusset plate has no vertical displacement until the shear force exceeds the friction force and the corbel begins to carry the extra shear force. As a result, the shear force carried by the corbel in the '0-75N' specimen was much smaller than that in the '0-75S' specimen, where there was much less friction force on the gusset plate-to-concrete interface. Accordingly, the shear deformation, δ_V, in the '0-75N' specimen is much smaller than that in the '0-75S' specimen during the positive loading, as can be seen in Fig. 3.9. In this sense, the pre-tensioning of the anchor bolts also has an effect on the shear resistance of the BRB connection.

4. CONCLUSIONS

In this study, cyclic test of the subassemblies of continuously buckling restrained braced RC frame was conducted. It is confirmed by the test results that both the RC frame and the BRBs in the system exhibit stable hysteretic behavior. In addition, the performance of the horizontal resistance of the BRB connection was investigated. It seems more effective to introduce initial tension into the anchor bolts to resist the horizontal force than to install a steel strut.

Abstract: In Japan, the stress transmission of R/C column and beam joints is calculated differently depending on their type of joint.In interior joints, main bars are continued through the joint panel both vertically and horizontally. Thus, the ultimate strength of interior joints is more reliable.However, in knee joints main bars are not continued. Additionally, since there is no load on knee joints from above, frictional force between concrete and main bars weakens and makes the joint panel relatively easy to break under stress transmission.In the previous studies Hotta and Nishizawa (2012), it's concluded that the sufficient inside radius of the main tensile bars that were continuously arranged through the panel from beam to column improves structural performance and prevents bearing failure of the joint panel when the joints were tested in closing direction.The objective of this following study is to show the influence of the inside radius of the main tensile bars which is separated in the joint panel as a practical design under stress transmission by conducting closing load.

1. INTRODUCTION

In Japan, the stress transmission of R/C column and beam joints is calculated differently depending on their type of joint. This calculation does not take into account the various arrangements of main tensile bars. However, the way main tensile bars are arranged is quite important because their bending radius affects the bearing failure of joint panel under stress transmission. In the previous studies Hotta and Nishizawa (2012), the objects of the studies were main tensile bars whose arrangement was continued. It was concluded that the bigger the bending radius of main tensile bars in joint panels under stress transmission, the bigger the shear strength of joint panels.

The objective of this following study is to show the influence of the inside radius of the main tensile bars which is separated in the joint panel as a practical design under stress transmission by conducting closing load.

2. OUTLINE OF TESTS

2.1 Specimens

As shown in Figure 1, there are four specimens that were made and tested. Each specimen's column and beam dimensions were the same. Column's dimension is 200x100mm. Beam's dimension is 200x80mm. All main tensile bars were separated in the joint panels.But their bending radiuses were different and thus, categorized into two types: LB26 type and LB80 type.

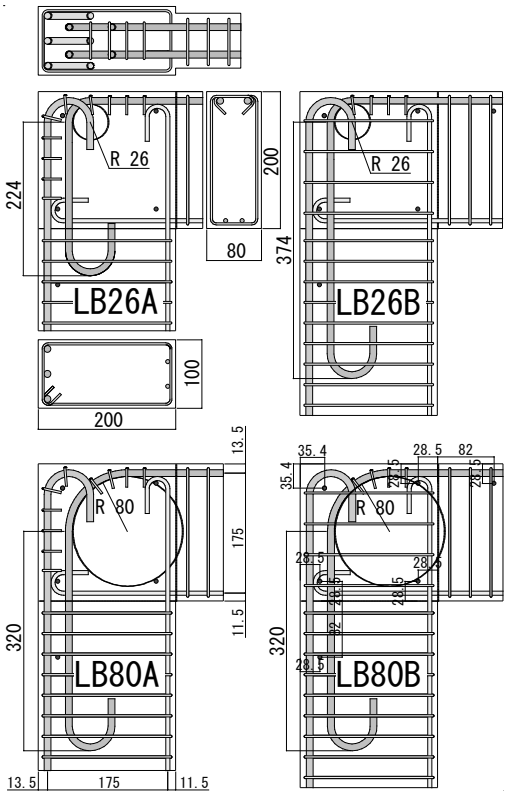

Figure 1. Dimension and detail of bar arrangement

As shown in Table 1,D10 deformed bars were used for main

tensile bars and D6 deformed bars were used for compressive bars. The columns and the beams were laterally strengthened by sufficient hoop reinforcements which were round bars with diameter of 3mm.

Table 1. Mechanical properties of reinforcing bars

Bar	Yield strength [N/mm^2]	Tensile strength [N/mm^2]	Young`s modulus $\times 10^5$[N/mm^2]
D10	459(457)	640(633)	1.92(1.83)
D6	387(381)	546(537)	1.93(1.86)
φ3	554(541)	617(627)	1.97(1.89)

In Table 2, mechanical properties of concrete are shown. First values are of LB26B, LB80A and LB80B specimens. Values in brackets indicate that of LB26A specimen.

30.7(34.9)	2.54(2.68)	2.48(3.05)

2.1.1*LB26 type*

As illustrated in Figure 1, in joint panel, beam's main tensile bars were bent at 26 mm radius and their tails were anchored in column.In LB26A specimen, the length of the anchor was 224 mm. In joint panel, there was no lateral reinforcement.In LB26B specimen, the length of the anchor was 374 mm. In the joint panel, there were four lateral reinforcement bars placed at 45 mm span.

2.1.2*LB80 type*

As illustrated in Figure 1, in joint panel, beam's main tensile bars were bent at 80 mm radius and their tails were anchored in column. The length of anchor was 320 mm.In LB80A specimen, there was no lateral reinforcement in the joint panel.In LB80B specimen, there were four lateral reinforcement bars placed at 45 mm span in the joint panel.

2.2 Loading method and measuring method of deflection

All dimensions of specimens and loading method are outlined in Figure 2. The specimens were set to the pin and pin-roller blocks of a loading apparatus at both end plates by PC bars. The external load *P* was horizontally applied from the roller block in closing direction. The lengths of column and beam are the same and symmetrical, therefore, the axial force *N* and the shear force *V* are the same. Measurement apparatuses were set to both sides of specimens at measurement terminal points which are shown in Figure 3. These measurement apparatuses were to measure elongation of the beams and the columns, their end rotations, and shear deformation of the joint panel. Strain of reinforcing bars was not measured in the test at all because putting strain gauges influences bond characteristics of the bars

Figure 4 shows the arrangement of pi gauges to measure elongation between the measurement terminals set at the tensile region of the joint panel and the members near the critical section.

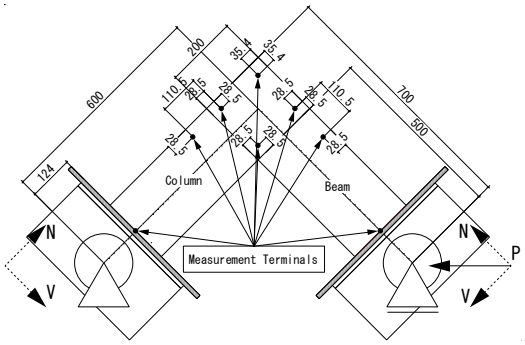

Figure 2. Method of loading

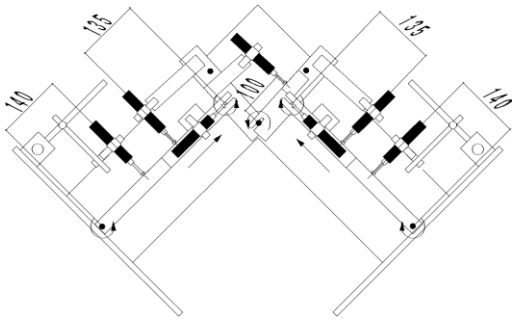

Figure 3. Apparatus for measuring deformation

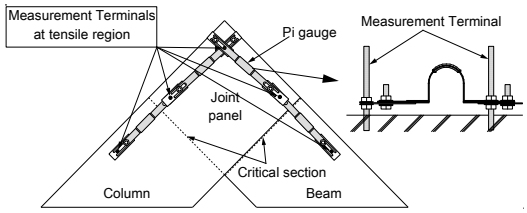

Figure 4. Pi gauges for measuring member's displacement

3. TEST RESULTS

3.1 Load deflection curves

Figures 5 and 6 show load versus deflection curves for all four specimens.Vertical axes stand for horizontal force applied to the roller end and horizontal axes stand for horizontal displacement of pin points and member's angle/joint shear strain.

There are four curves shown in each figure. The bold curve represents the relationship between horizontal displacement and horizontal load. The other three curves show each member's angle and shear strain of the joint panel.

As illustrated in Figures 5 and 6, there is horizontal line "Diagonal crack load" which was calculated by the Eq. (1).

$$V_{cr} = f_t b_j l_{dh} \quad (1)$$

Where f_t is tensile strength of concrete of which value is

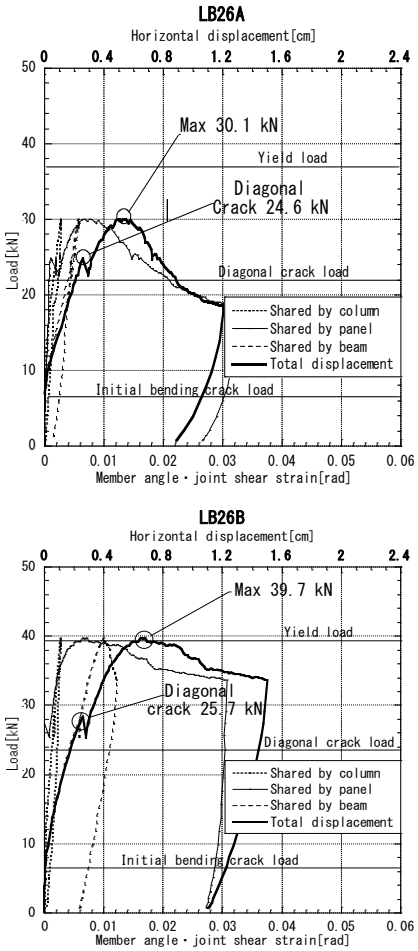

Figure 5. Load-deflection curves for LB26 type

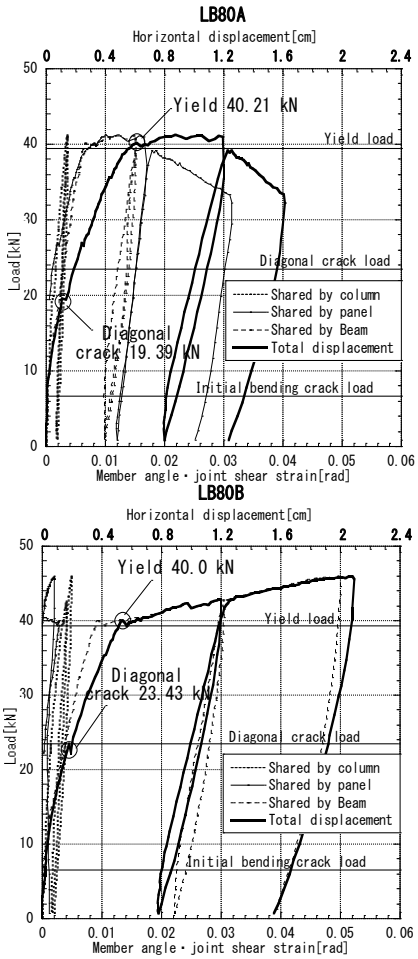

Figure 6. Load-deflection curves for LB80 type

indicated in Table 2 as splitting strength. b_j is effective breadth of joint panel and l_{dh} is distance between critical section of the beam and the end tensile reinforcing bars.

There is "Initial bending crack load" horizontal line which was calculated by Eq.(5) based on elastic section analysis of beams and occurs when the tensile strength of concrete reaches the splitting strength. As shown in Figure 2, when horizontal force*P* is applied, axial force*N* and shear force*V* are loaded to the beams and columns. Because the length of beams and columns is the same, *N* is equal to *V*.

$$V = N = \frac{P}{\sqrt{2}} \tag{2}$$

The moment*M*at critical section of beam is equal to shear force of beams *V* multiplied to the length of beams *l*.

$$M = Vl = Nl = \frac{Pl}{\sqrt{2}} \tag{3}$$

When axial force *N* is loaded to the beam, the tensile stress of concrete is calculated by following Eq. (4):

$$\sigma_t = \frac{M}{Z_e} - \frac{N}{A_e} \tag{4}$$

Substituting for Eq.(4) from Eq.(2) and Eq.(3) the initial bending crack load P_{cr} is solved for, when the tensile strength of concrete σ_t reaches the splitting strength f_t.

$$P_{cr} = \frac{\sqrt{2} \cdot f_t \cdot A_e \cdot Z_e}{A_e l - Z_e} \tag{5}$$

Where, A_e is equivalent sectional area of critical section of the beams and Z_e is equivalent section modulus of critical section of the beams.*l*is the length of the beam which is from critical section of the beam to pin roller end. The calculated value of the initial bending crack load is equal to 6.51kN. In the case of LB26A specimen, compared to other specimens, materials used had different strength. Therefore, LB26A specimen's initial bending crack load resulted in 6.9kN. LB26A's observed initial bending crack load was 8.77kN. LB26B's was 9.74kN. LB80A and LB80B were 10.77kN. Since initial bending crack loads were observed visually, observed values were slightly higher than calculated values.

Also, there is "Yield load" line which was calculated by plastic section analysis of beams and occurs when the tensile

stress of reinforcing bars reaches to the yield strength at the critical section of the members.The value of yield load was calculated as 39.9kN. In the case of LB26A, calculated yield load was 37kN.

Diagonal crack due to splitting failure of concrete occurred near the calculated crack load in all specimens and all specimens except LB26A reached calculated yield load.

Figures 7 and 8 show first diagonal crack and crack that occurred when horizontal force reached the maximum load respectively.

In the case of LB26A, many cracks around the corner where tensile bars of the beam and the column were lapped could be observed. Cracks might have been caused due to crushing of concrete. When it reached maximum load, a greater deformation was observed in the joint shear strain than member's angles (see Figure 5).

In the case of LB26B, because of the presence of lateral reinforcement in the joint panel, it had better performance results than LB26A.

Before the horizontal force reached the maximum load, beam's angle was increasing at a greater rate than joint shear strain. But once it reached the maximum load, joint shear strain started to increase rapidly and joint panel hardnessstarted to weaken gradually.Thus, it is difficult to determine whether the main tensile bars of the beam yielded or not by just looking at the figure, even though the maximum load exceeded calculated yield load. As shown in Figure 8, cracks that occurred during the maximum load are concentrated mostly where the main tensile bars of the beam bend at 90 degrees. It can be concluded that while there is lateral reinforcement, main tensile bars' smaller radius resulted in the bearing failure.

In the case of LB80A, there was no lateral reinforcement, but bending radius was bigger than LB26 type specimens. As illustrated in Figure 6, the corner lapping (where bending radius is approximately three times bigger) distributed the compressive pressure in the joint panel evenly. Thus, joint panel's strength improved and the beam yielded.

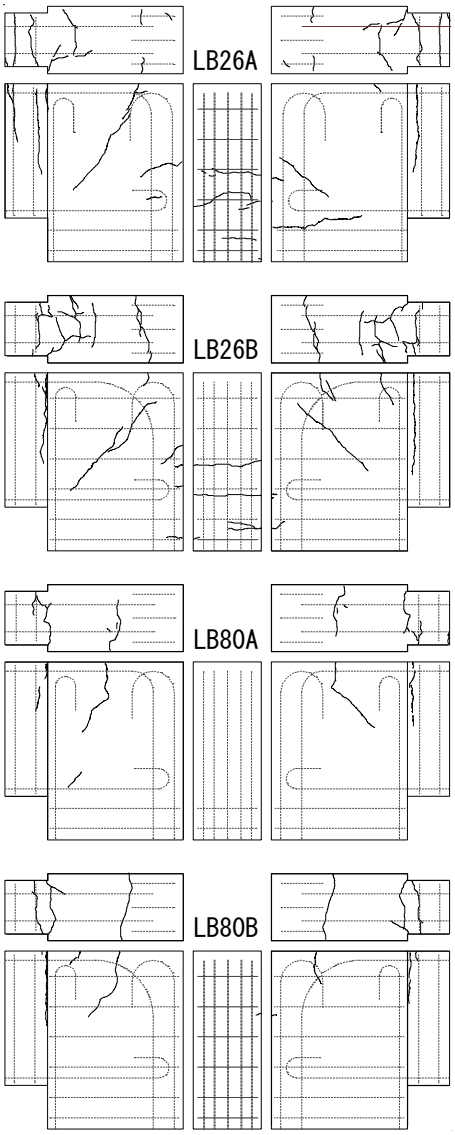

Figure 7. First splitting crack of joint panel for all specimens

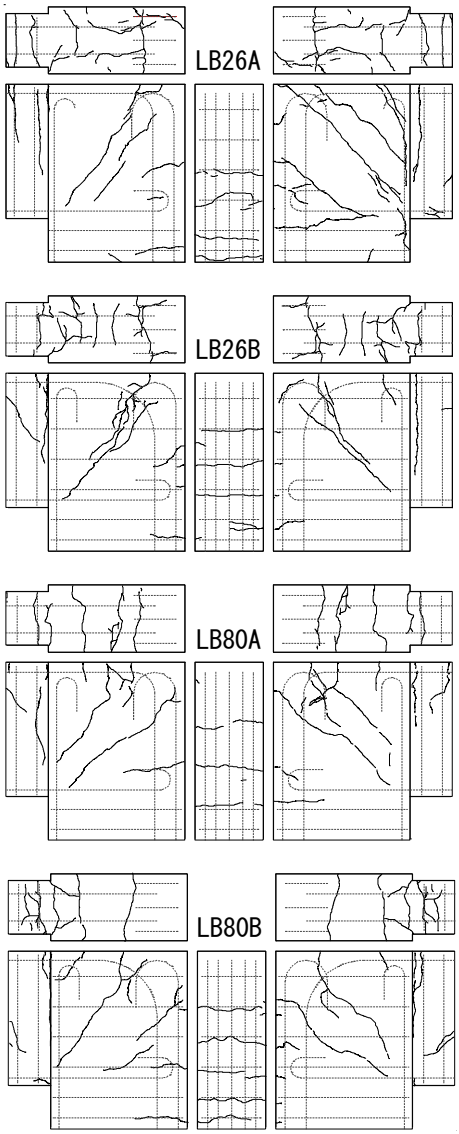

Figure 8. The crack that occurs during the maximum load for all specimens

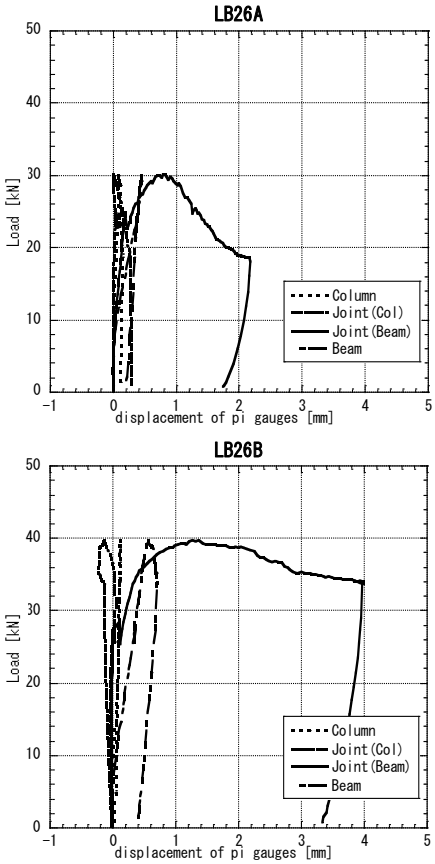

Figure 8. Pi gauge's displacement for LB26 type

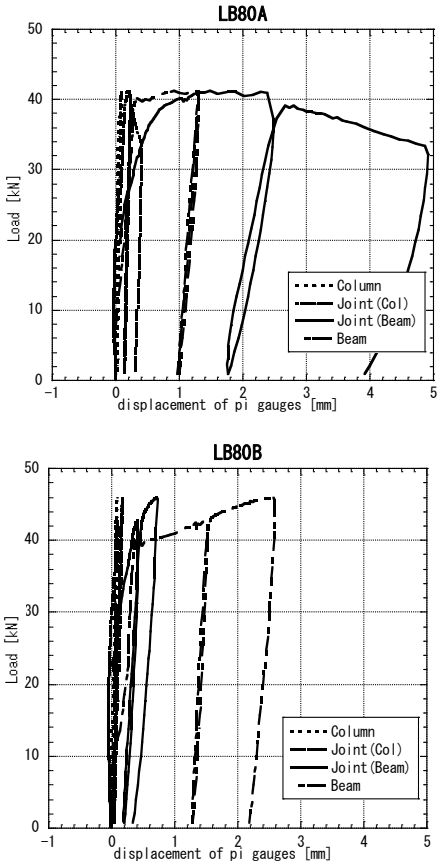

Figure 9. Pi gauge's displacement for LB80 type

In the case of LB80B, there were lateral reinforcements in the joint panel such as LB26B. The maximum load exceeded yieldload. As shown in Figure 6, there was no deformation in the joint panel, but angle of the beam changed parallel to horizontal displacement. Both the presence of the lateral reinforcement and the bigger bending radius have influenced to result in a better shear strength and to prevent any bearing failure.

3.2 Pi gauge curves

Figures 9 and 10 show pi gauge curves for all four specimens.Vertical axes stand for horizontal force applied to the roller and horizontal axes stand for pi gauge displacement. There are four curves in each figure.These figures show which member was displaced the most.

LB80B's beam displacement was the greatest compared to the other members.

In the case of LB26A, LB26B, LB80A, beam side displacement of joint panels were the greatest. This indicates that both LB80B's lateral reinforcement and bigger bending radius influenced, therefore the deformation in the joint panel was minimal.

4. CONCLUSION

Based on the test results, it is concluded that bending radius of main tensile bars of the beam in the joint panel affect shear strength of joint panel. More specifically, bending radius and shear strength of joint panel have a positive relationship.Also, adding lateral reinforcement in the joint panel increases shear strength performance of joint panel.

Abstract: The objective of this study is aimed to develop the shear walls in composite CES structures composed of steel and fiber reinforced concrete. In this study, cyclic loading tests were conducted on CES shear walls with eccentrically arranged wall panel, and the structural performance, such as strength, deformability and failure modes, were investigated. The experimental variables were the position of wall panel and shear span ratio. As the result, it was clarified that the position of wall panel on the maximum shear force of CES shear walls had little effect. The deformability of CES shear walls was reduced by effect of eccentrically arranged wall panel. It was confirmed that the ultimate strength can be evaluated by the equation given by AIJ standard for structural calculation of SRC structure.

1. INTRODUCTION

Steel reinforced concrete (SRC) structures are typical composite structural systems consisting of steel and reinforced concrete (RC), which have an excellent earthquake resistance and deformability. However, the design process and construction work are more complicated than those for steel structures and RC structures. In order to solve these problems, Concrete Encased Steel (CES) structural system consisting of fiber reinforced concrete (FRC) and encased steels only, have been proposed by the authors as a new composite structural system (Kuramoto et al. 2007, Matsui et al. 2009), and continuous and comprehensive studies have being conducted to make it practical. Cyclic loading tests were also carried out on CES shear walls with different anchorage methods for the CES frame and FRC wall panel (Suzuki et al. 2011), and the basic structural performances, such as strength and failure modes, of the CES shear walls were investigated. As a result, it was confirmed that the effect of anchorage condition of wall longitudinal reinforcement on shear strength and flexural strength of CES shear walls is small. In addition, the deformability of CES shear walls improves by omitting anchorage of wall longitudinal reinforcement.

In practical use, on the other hand, a shear wall facing outside of the building was arranged eccentrically to boundary columns. In RC shear walls with eccentrically arranged wall panel, the position of wall panel has little effect on maximum shear force as shown in the existing study by Mochizuki et al. (2005). However, in CES shear walls, confinement effect from the steel to the wall panel was decreased, because the centre position of the wall panel and the position of the steel in column were different. Therefore, it is considered that the deformability of eccentric wall specimen is lower than that of non-eccentric wall specimen.

In this study, cyclic loading tests were carried out on CES shear walls with eccentrically arranged wall panel. The basic structural performance, such as ultimate strength, deformability and failure modes, of the CES shear walls were investigated.

2. TEST PROGRAM

2.1 Description of Specimen

The specimens were designed to simulate the lower two stories of a multi-story shear wall in a medium rise building, and were one-third-scale of prototype walls. Four specimens were prepared for this test.

The configurations and bar arrangements of the specimens are shown in Figures 1 and 2. Details of the sections are shown in Table 1. The column had a 250mm square cross-section, and the beam section was 200 mm x 250 mm. The column span length was 1,800 mm, and the wall thickness was 100 mm. The experimental variables were the shear-span ratio and the position of wall panel. The shear-span ratio was 1.1 in Specimens CWAS and CWCS, and it was 1.65 in Specimens CWAF and CWCF. Specimens CWAS and CWCS were expected to be shear failure mode. Specimens CWAF and CWCF were expected to be flexural failure mode. The position of wall panel for Specimens CWAS and CWAF were at the centre of the boundary column. On the other hand, the position of wall panel for Specimens CWCS and CWCF were arranged on the outside of the boundary column section (Figure 2). The longitudinal wall reinforcing bars in all specimens were bent into the wall panel. The transverse wall reinforcing bars for Specimens CWAS and CWAF were fixed by welding them to the steel web in the boundary columns. On the other hand, the transverse wall reinforcing bars for Specimens CWCS and CWCF were fixed by 90-degree hook in the boundary columns. In addition, the H-section steels of the boundary columns were anchored to the upper and lower stabs in all specimens.

The mechanical properties of the FRC and steel used are shown in tables 2 and 3, respectively. Poly vinyl alcohol (PVA) fibers with a diameter of 0.66 mm and length of 30 mm were used for FRC. The volumetric ratio of the fibers was 1.0 %.

2.2 Loading Program

The loading apparatus used is shown in Figure 3. The specimens were loaded with horizontal cyclic shear forces using a hydraulic jack with a 2,000 kN capacity, while applying a constant axial force ratio of 0.2 (N/N_0=0.2, where N=axial load, N_0=axial load capacity including steel of boundary columns) using two vertical manual jacks, each of which had a 2,000 kN capacity. During the testing, additional moment was also applied to the top of the

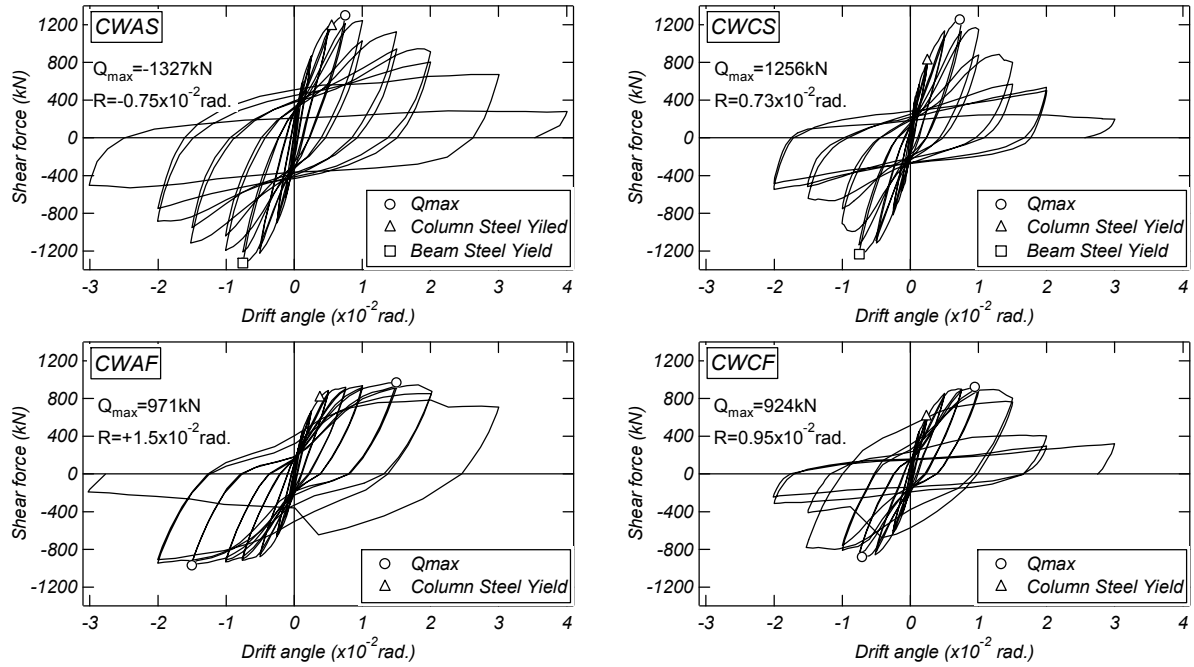

Figure 4 Shear Force Versus Drift Angle Relation Ships

specimen using the two vertical jacks to maintain the prescribed shear-span ratio of 1.1 or 1.65, using the following equations.

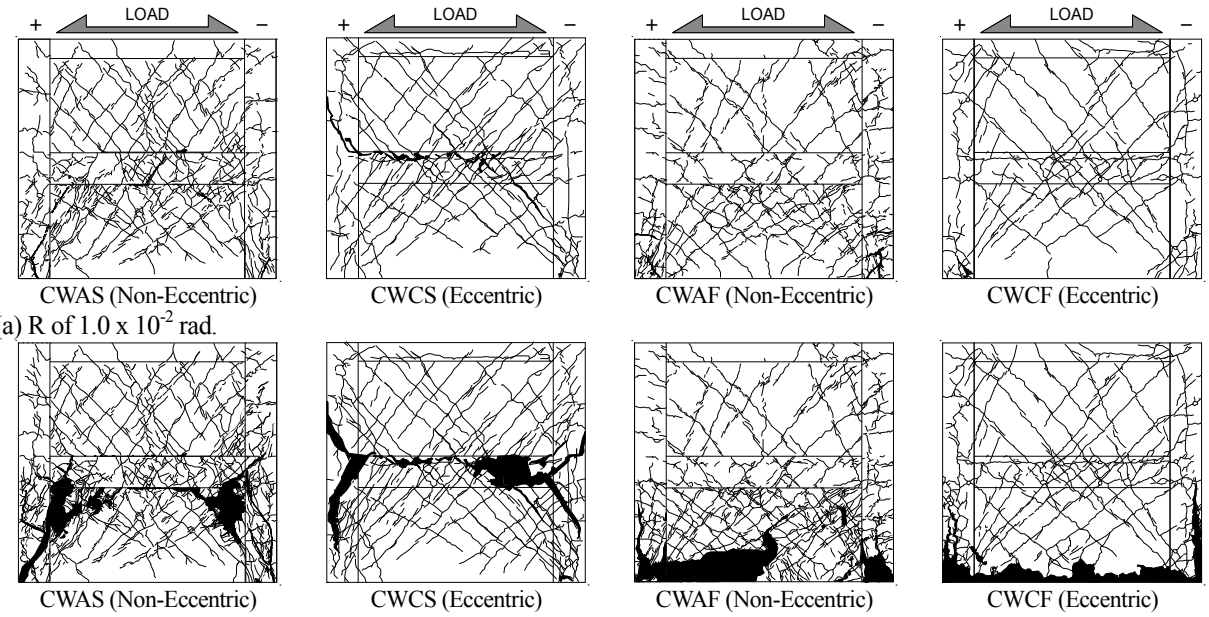
$$N_e = \frac{N_c}{2} - \frac{Q}{l}(h-a) \quad N_w = \frac{N_c}{2} + \frac{Q}{l}(h-a) \quad (1)$$

where, N_e: axial force of east side jack, N_w: axial force of west side jack, N_c: constant axial force, Q: shear force, l: distance between vertical jack, h: assumed height of applied shear force, and a: actual height of applied shear force.

The loading was conducted by controlling the relative drift angle R, given by the ratio of the height corresponding to the measuring point for the horizontal displacement at the top of the specimen, h_0 (2,050 mm), to the horizontal deformation δ, i.e., $R=\delta/h_0$. The horizontal load sequences consisted of one cycle for R of 0.0625 x 10^{-2} rad. and 0.125 x 10^{-2} rad. respectively, and after this from R of 0.25 x 10^{-2} rad. two cycles for each relative drift angle were applied.

3. EXPERIMENTAL RESULTS

3.1 Hysteresis Characteristics and Failure Modes



Shear force versus drift angle relationships of all specimens are shown in Figure 4. Cracking patterns of all specimens are shown in Figure 5 after the loading cycle of 0.75 x 10^{-2} rad. and after final loading cycle.

In all specimens, flexural cracks at the bottom of column occurred in the cycle of 0.0625 x 10^{-2} rad. Shear cracks at the first story wall panel occurred in the cycle of 0.125 x 10^{-2} rad.

In Specimen CWAS with non-eccentrically arranged wall panel, the maximum shear force reached -1,328 kN at R of -0.75 x 10^{-2} rad. In Specimen CWCS with eccentrically arranged wall panel, the maximum shear force reached 1,256 kN at R of 0.73 x 10^{-2} rad. It is found that the maximum shear force of Specimen CWAS was slightly larger than that of Specimen CWCS, because the concrete strength of Specimen CWAS was larger than that of Specimen CWCS. The deformability of Specimen CWAS and CWCS was different after reaching the maximum shear forces. While the shear force of Specimen CWAS decreased gradually, that of Specimen CWCS decreased drastically.

In Specimen CWAS with non-eccentrically arranged wall panel, slip between wall panel and beam was observed after the maximum shear force. Therefore, the damaged area was concentrated at the upper corner of the first story wall panel. On the other hand, in Specimen CWCS with eccentrically arranged wall panel, the damaged was concentrated on the boundary beam, especially in the cover concrete. This is because the eccentricity of the wall panel left a portion of the beam without protection of reinforcing bars.

In Specimen CWAF with non-eccentrically arranged wall panel, the maximum shear force reached 971 kN at R of 1.5 x 10^{-2} rad. In Specimen CWCF with eccentrically arranged wall panel, the maximum shear force reached 924 kN at R of 0.95 x 10^{-2} rad. It is found that the maximum shear force of Specimen CWAF was larger than that of Specimen CWCF, because the steel of the column for Specimen CWAF occurred strain hardening. However, hysteresis characteristics of both specimens were almost the same until the maximum shear force. The deformability of Specimens CWAF and CWCF were rather different after reaching the maximum shear force. Specimen CWAF showed significant strength deterioration at R of 3.0 x 10^{-2} rad. On the other hand, Specimen CWCF showed significant strength deterioration at R of 1.5 x 10^{-2} rad. These situations

(a) R of 1.0 x 10^{-2} rad.

(b) After Final Loading Cycle

Figure 5 Cracking Patterns (pictures show south side)

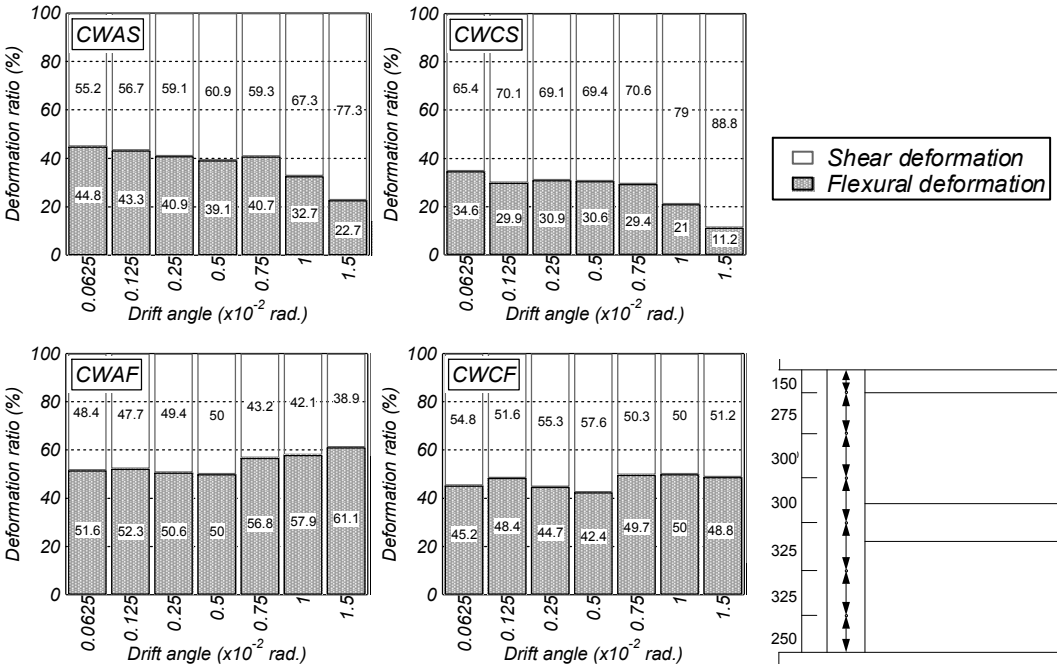


Figure 6 Deformation Components

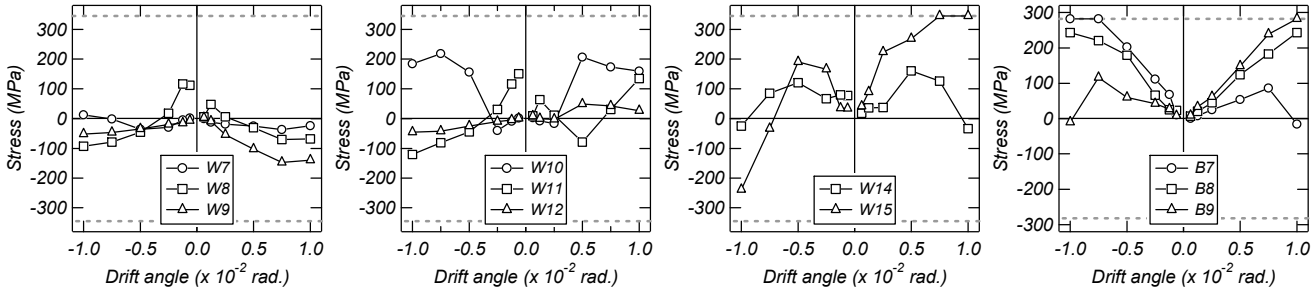
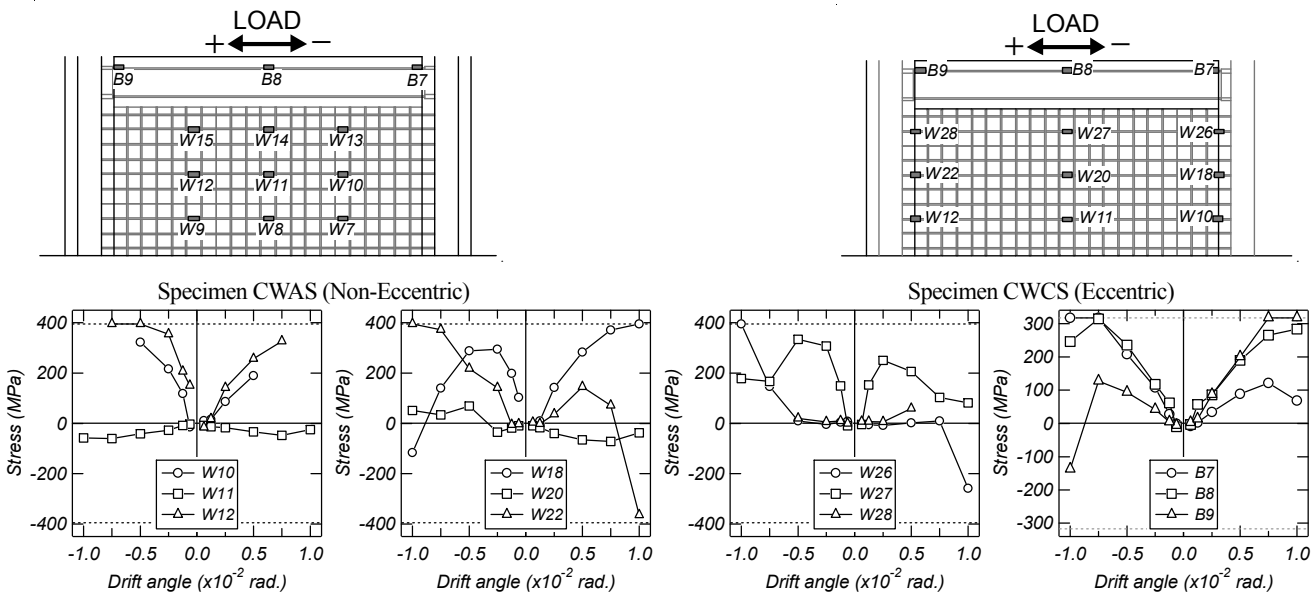
Figure 7 Measured Displacements



are corresponding to the failure process of both specimens. In Specimen CWAF with non-eccentrically arranged wall panel, the compressive failure of the wall panel occurred in the cycle of 1.5 x 10^{-2} rad. In Specimen CWCF with eccentrically arranged wall panel, the compressive failure of the wall panel occurred in the cycle of 3.0 x 10^{-2} rad. It was found that the deformability of Specimen CWCF was less than that of Specimen CWAF.

Thus, it is confirmed that the position of wall panel had little effect on the maximum shear force of the CES shear walls and that the eccentricity of wall panel reduce the deformability of CES shear walls.



3.2 Deformation Components

Figure 6 shows the contribution of shear deformation and flexural deformation to the total deformation of the all specimens until R of 1.5 x 10^{-2} rad. Flexural deformation was calculated using the axial displacement of boundary columns, as shown in Figure 7, while shear deformation was calculated by subtracting the flexural deformation from the total deformation.

The results for Specimens CWAS and CWCS which

(a) Specimen CWAS (Non-Eccentric)

(b) Specimen CWCS (Eccentric)

Figure 8 Yield Situations for Transverse Wall Reinforcing Bars and Steel of Beam

had the shear failure mode showed that the shear deformation increased at R of 1.0 x 10^{-2} rad. after maximum shear force. The results for Specimens CWAF and CWCF which had the flexural failure mode showed that the deformation ratios were almost the same. However, the shear deformation in Specimens CWCS and CWCF with eccentricity was larger than that for Specimens CWAS and CWAF without eccentricity of the wall panel. One of the reasons is that the deformability of eccentric wall specimen was less than that of non-eccentric wall specimen.

3.3 Transition of Stresses in Wall Transverse Reinforcing Bars and Beam Steel

Figure 8 shows the stresses of the transverse wall reinforcing bars and steel flange of the beam in Specimens CWAS and CWCS, which exhibited shear failure. The stresses were calculated using the measured strain and the bilinear hysteresis assumption for the steel. The strains were measured on the reinforcement of the wall panel, and the upper flange of the beam.

In Specimen CWAS, the transverse reinforcement at the position W15 of the wall panel yielded at R of 0.75 x 10^{-2} rad. In Specimen CWCS, the transverse reinforcement at the position W12 of the wall panel yielded until R of 0.75 x 10^{-2} rad. However the stresses on the wall reinforcement hardly yielded in both specimens.

As for steel in the beam, the stresses increased with increase of drift angle in both specimens. In addition, the upper flange in the beam was near to the yielding at R of 0.75 x 10^{-2} rad. in both specimens. It was confirmed that the steel in the beam effectively contributed to resist the shear force.

4. EVALUATION OF ULTIMATE STRENGTH

The calculation results of the ultimate strengths for all specimens are listed in Table 4. The flexural strength was calculated using Eq. (2), which is equation given in the"AIJ Standards for Structural Calculation of Steel Reinforced Concrete Structures" omitting the term of the reinforcing bars in the boundary column. Moreover, the wall longitudinal reinforcing bars were not considered in the calculation for the Specimens without wall reinforcement anchorage.

The shear strength was calculated using the Truss-Arch Equation (Eq. (3)). It is assumed that the flexural capacity of the boundary column contribute to the shear strength of the CES shear walls, as expressed, ${}_{CS}M_U$, Eq. (4). The shear strength was calculated by adding the lower steel flange of the beam to the transverse wall reinforcement, because it was observed that the steel flange of the beam yielded at the

Table 4 Calculated Strength and Maximum Shear Force

Specimens			*CWAS*	*CWCS*	*CWAF*	*CWCF*
Maximum shear force		Q_{exp} *(kN)*	1,328	1,256	971	924
Flexural strength		Q_{mu} *(kN)*	1,178	1,183	786	789
Shear strength	Truss-Arch Eq	Q_{su} *(kN)*	1,319	1,295	1,202	1,208
Ratio of maximum shear force to calculated strength	Flexural strength	Q_{exp}/Q_{mu}	-	-	1.24	1.17
	Truss-Arch Eq	Q_{exp}/Q_{su}	1.01	0.97	-	-

maximum strength of the wall, as shown in Eq. (6).

Flexural strength equation

$$Q_{mu} = \left(\frac{N_U}{2} + {}_{sCS}A \cdot {}_s\sigma_y\right) {}_W l / h_w \tag{2}$$

Shear strength by Truss-Arch equation

$$Q_{su} = {}_W t \left\{ {}_W l_t \cdot p_{se} \cdot {}_W\sigma_Y \cot\phi + \tan\theta(1-\beta) {}_W l_a \cdot \nu \cdot {}_c\sigma_B \frac{}{2} \right\} \tag{3}$$

$$ {}_W l_a = {}_W l + \frac{1}{\cos\theta} \sqrt{\frac{2 {}_{CS}M_U}{\nu \cdot \sigma_B \cdot {}_W t(1-\beta)}} \tag{4}$$

$$\beta = \frac{2 p_{se} \cdot {}_W\sigma_Y}{\nu \cdot {}_c\sigma_B} \tag{5}$$

$$p_{se} = {}_w p + \frac{a_f \cdot \sigma_{fy}}{{}_W t \cdot h_w \cdot {}_W\sigma_y} \tag{6}$$

$$\tan\theta = \sqrt{\left(\frac{h_w}{{}_W l + D}\right)^2 + 1} - \frac{h_w}{{}_W l + D} \tag{7}$$

where N_U: total axial force in the boundary columns (N); ${}_{sCS}A$: cross section of the steel in the boundary column (mm^2); ${}_s\sigma_y$: yield strength of the steel in the boundary column (MPa); ${}_W l$: distance between the centres of the boundary columns of the wall (mm); h_w: assumed height of applied lateral force (mm); ${}_W t$: thickness of wall; ${}_W l_t$: equivalent wall length of truss mechanism (=l); p_{se}: lateral reinforcement ratio; a_f: cross section of the steel flange in the boundary beam (mm^2); σ_{fy}: yield strength of the steel flange in the boundary beam (MPa); ϕ: angle of truss mechanism ($\cot\phi = 1$); θ: angle of arch mechanism; β: contribution ratio of the compressive concrete in the truss mechanism; ν: effective factor for the compressive strength of concrete; ${}_c\sigma_B$: concrete strength (MPa); ${}_W l_a$: equivalent wall length of arch mechanism; ${}_{CS}M_U$: ultimate flexural moment of the boundary column.

As for Specimens CWAS and CWCS with shear failure mode, the ratios of the maximum shear force to the calculated by Truss-Arch Equation were about 1.0. Therefore, good agreements were obtained between the maximum strength and the calculated strength.

As for Specimens CWAF and CWCF with flexural failure mode, the ratios of the maximum shear force to calculated flexural strength was about 1.2. Thus it is showed that the flexural strength of CES shear walls can be approximately estimated by Eq. (2).

5. CONCLUSIONS

In this study, cyclic loading tests of CES shear walls with eccentrically arranged wall panel were conducted. The failure mode, lateral load carrying capacity and deformation capacity of the CES shear walls were examined. The following conclusions can be drawn.

1) Regardless of failure mode, the position of wall panel had little effect on the maximum shear force of CES shear walls.
2) The shear deformation for eccentric wall specimens was larger than that for non-eccentric specimens, and then a reduction of the deformability of CES shear walls with eccentrically arranged wall panel was observed.
3) It was confirmed that the steel in the beam effectively contributed to resist the shear force.
4) In the CES shear walls with eccentrically arranged wall panel, it was confirmed that the ultimate flexural strength can be evaluated by the equation in the AIJ design standard for SRC structure, and that the ultimate shear strength can be evaluated using the Truss-Arch Equation.

Abstract: This paper studies the applicability of nonlinear solid-element finite element analysis (FEA) for reinforced concrete (RC) structures considering cracking failure. A highly advanced parallel FEM program, ADVENTURECluster, combined with a reformulated nonlinear concrete constitutive relationships and particle discretization scheme (PDS) for cracking simulation, is used to conduct nonlinear analysis for a RC column. Results are presented and applicability of the FEA is discussed.

1. INTRODUCTION

Reinforced concrete, as the main construction material, is most widely used for civil infrastructures, which encompass both aboveground buildings and underground tunnels. Design of these RC structures or their functional parts, usually requires nonlinear structural analysis to accurate estimate their mechanical behavior subjected to various kinds of static and dynamic loads. Such nonlinear analysis is especially important for the ultimate state design. However, with complex nonlinear response such as softening and cracking, the nonlinear behavior of RC structures is particularly difficult to be accurately evaluated, resulting in difficulties for their design.

Typically, experimental analysis using scale-down models is a standard approach to evaluate the nonlinear response of RC structures. However, for large and complex civil infrastructures, such experiments are generally costly, labor-intensive and time-consuming, and they are usually restricted to a few critical case studies, which may not be sufficient to represent the true response of real structures.

Recently, owing to the rapid development of computer technology and numerical schemes, large-scale computations based on finite element method (FEM) using an enormous number of solid elements can be easily and accurately carried out via high-performance computing. The ease and accuracy of such numerical simulations make it a prominent alternative for the traditional experimental analysis. Besides, for numerical computations, solid-element FEA offers advantages in constructing a numerical model, since it requires only material properties, and no structural member experiments are needed. Therefore, FEA using solid elements is much easier to tune material parameters than that using structural member.

In this paper, we seek to examine the applicability of nonlinear FEA with more than 1,000,000 solid elements to evaluate the nonlinear response of RC structures including cracking failure. A highly advanced parallel FEM program, ADVENTURECluster, is used to conduct such nonlinear FEA with solid elements. The program is enhanced with two essential features for numerical simulation of RC structures: nonlinear concrete constitutive relationships, and the ability to model brittle failure due to multiple-cracking. Since solid-element FEA with successful implementation of these two features entails an essential validation process, especially for its applicability to the complex seismic response of large civil infrastructure with composite materials. We focus our presentation in this paper on such a validation process.

2. NONLINEAR CONCRETE CONSTITUTIVE RELATIONSHIPS

Maekawa and his colleagues (Maekawa et al. 2003) have been developing original concrete elasto-plastic constitutive relationships which are attaining the highest reputation in the field of concrete engineering. Therefore, we employ Maekawa's concrete constitutive relations as the model of concrete. Though Maekawa's concrete relations

are well validated, its formulation is less transparent to be implemented in a general purpose FEM code. In this section, we reformulate the concrete relations so that it becomes easier to be implemented.

Maekawa's concrete constitutive relationships are rationally formulated in terms of elastic strain and its invariants. Denoting elastic/plastic strain and stress by $\boldsymbol{\epsilon}^{E/P}$ and $\boldsymbol{\sigma}$, respectively, a set of the original relations can be expressed as follows:

$$\boldsymbol{\sigma} = \mathbf{c} : \boldsymbol{\epsilon}^{E}, \tag{1}$$

$$\mathrm{d}\boldsymbol{\epsilon}^{P} = \boldsymbol{\ell} : \mathrm{d}\boldsymbol{\epsilon}^{E}. \tag{2}$$

Here, $\mathbf{c}$ is isotropic elasticity tensor, which is a forth-order tensor-valued function of elastic strain invariants. d- stands for the incremental of -, and $\boldsymbol{\ell}$ is another forth-order tensor.

From Eq. (1) and Eq. (2), $\mathrm{d}\boldsymbol{\sigma}$ can be expressed in terms of $\mathrm{d}\boldsymbol{\epsilon}$ as:

$$\mathrm{d}\boldsymbol{\sigma} = \mathbf{c}^{EP} : \mathrm{d}\boldsymbol{\epsilon},$$

here, $\mathbf{c}^{EP}$ is forth-order elasto-plastic tensor expressed as:

$$\mathbf{c}^{EP} = (\mathbf{c} + \nabla\mathbf{c} : \boldsymbol{\epsilon}^{E}) : (\mathbf{I} + \boldsymbol{\ell})^{-1}. \tag{3}$$

where, $\nabla\mathbf{c}$: $\boldsymbol{\epsilon}^{E}$ is a forth-order tensor with its component being $(\partial c_{ijpq}/\partial\varepsilon^{E}_{kl})\varepsilon^{E}_{pq}$. $(.)^{-1}$ denotes inverse of (.). $\mathbf{I}$ is forth-order symmetric unit tensor.

From Eq. (3), the calculation of elasto-plastic tensor $\mathbf{c}^{EP}$ includes complicated derivative of $\mathbf{c}$, namely $\nabla\mathbf{c}$, as well as inverse tensor $(\mathbf{I} + \boldsymbol{\ell})^{-1}$. When a problem with a large number of DOFs is solved, heavy computational loads are required. This formulation of concrete constitutive relationships is difficult to be implemented into a general FEM code.

In order to simplify the computation of elasto-plastic tensor $\mathbf{c}^{EP}$ and to reduce numerical loads, we reformulate Maekawa's concrete constitutive relationships to a more transparent form.

Regarding the damaging progress as a yield condition, we reformulate Maekawa's constitutive relations in a form similar to non-associated flow rule. Denoting dg and $\mathbf{d}$ as the incremental quantity and the direction respectively, the plastic strain increment $\mathrm{d}\boldsymbol{\epsilon}^{P}$ can be expressed as,

$$\mathrm{d}\boldsymbol{\epsilon}^{P} = dg\mathbf{d}.$$

In Maekawa's concrete constitutive relations, the second-order tensor $\mathbf{d}$ is given as,

$$\mathbf{d} = DP\boldsymbol{\delta} + \boldsymbol{\epsilon}^{E}/J_2^{E}$$

Here, D and P are functions of $\boldsymbol{\epsilon}^{E}$; $\boldsymbol{\delta}$ is Kronecker's delta; and J_2^{E} is the second invariant of deviatoric elastic strain.

The shear plastic relation between the second invariant of plastic strain and the second invariant of elastic strain in Maekawa's constitutive relations is introduced as the yield function (Yamashita et al. 2011), which can be written as:

$$f(J_2^{P}, J_2^{E}) = J_2^{P} - H(J_2^{E}) = 0,$$

Here, H is an empirical polynomial function of J_2^{E}. According to the consistency condition, that is $\mathrm{d}f = 0$, we simplify the plastic strain increment and elasto-plastic tensor $\mathbf{c}^{EP}$ as:

$$\mathrm{d}\boldsymbol{\epsilon}^{P} = \mathbf{L} : \mathrm{d}\boldsymbol{\epsilon} \tag{4}$$

$$\mathbf{c}^{EP} = (\mathbf{c} + \nabla\mathbf{c} : \boldsymbol{\epsilon}^{E}) : (\mathbf{I} - \mathbf{L}). \tag{5}$$

Here, $\mathbf{L} = \mathbf{d} \otimes (H'/2(1 + H'))(\mathbf{e}^{E}/J_2^{E})$, H' is the derivative of H with respect to J_2^{E}.

The reformulated plastic strain increment in Eq. (4) can now be explicitly calculated from strain increment $\mathrm{d}\boldsymbol{\epsilon}$ and this reformulation results in a more transparent form of elasto-plastic tensor $\mathbf{c}^{EP}$ described in Eq. (5), which no longer involves inverse tensor. Computational loads are reduced in the calculation process of elasto-plastic nonlinear FEA. Also, in order to further reduce the numerical load, we derived an explicit expression of the gradient of the elasticity tensor $\nabla\mathbf{c}$. Indeed, with the above reformulation, it becomes much more straightforward to implement the constitutive relationships into a general FEM program.

3. NUMERICAL ALGORITHM

As explained in Section 2, we obtained a more transparent form of concrete constitutive relationships which allow straightforward implementation into a general FEM framework. However, the elasto-plastic tensor of concrete is still non-symmetric and non-positive definite during the softening stage. The global stiffness matrix constructed from such an elasto-plastic tensor is thus non-symmetric and non-positive-definite, posing difficulties for nonlinear FEA of RC structures using a fast solver based on CG method.

In order to tackle this essential difficulty and to make the fast solver based on CG method applicable, we developed a numerical algorithm to solve a matrix equation with a non-symmetric and non-positive-definite coefficient matrix. In this algorithm, the non-symmetric and non-positive-definite matrix is replaced by a suitable symmetric and positive-definite matrix, and an additional term is added to the original equation so that the replacement is compensated.

The original governing equation of elasto-plastic FEM analysis for nodal displacement increment $\mathrm{d}\boldsymbol{u}$ is written as:

$$\boldsymbol{K}^{EP}\mathrm{d}\boldsymbol{u} = \mathrm{d}\boldsymbol{f}. \tag{6}$$

where, $\boldsymbol{K}^{EP}$ is global stiffness matrix constructed from elasto-plastic tensor $\boldsymbol{c}^{EP}$ as $\boldsymbol{K}^{EP} = \sum_e \boldsymbol{B}_e^{T}\boldsymbol{c}^{EP}\boldsymbol{B}_e$, it is neither symmetric nor positive-definite. $\mathrm{d}\boldsymbol{f}$ is external

nodal force increment.

Here, we use the following constitutive relation for deriving an alternative governing equation:

$$\mathrm{d}\boldsymbol{\sigma} = \mathbf{c} : \mathrm{d}\boldsymbol{\epsilon} + \mathrm{d}\boldsymbol{\sigma}^*, \tag{7}$$

in which $\mathrm{d}\boldsymbol{\sigma}^*$ is a second-order tensor given as:

$$\mathrm{d}\boldsymbol{\sigma}^* = (\mathbf{c}^{EP} - \mathbf{c}) : \mathrm{d}\boldsymbol{\epsilon} = -\mathbf{c} : \mathrm{d}\boldsymbol{\epsilon}^P + (\boldsymbol{\nabla}\,\mathbf{c} : \mathrm{d}\boldsymbol{\epsilon}^E) : \boldsymbol{\epsilon}^E. \tag{8}$$

Eq. (6) is accordingly replaced by:

$$\boldsymbol{K}\mathrm{d}\boldsymbol{u} = \mathrm{d}\boldsymbol{f} + \mathrm{d}\boldsymbol{f}^*. \tag{9}$$

Here, $\boldsymbol{K} = \sum_e \boldsymbol{B}_e^T\, \mathbf{c}\boldsymbol{B}_e$, $\mathrm{d}\boldsymbol{f}^*$ corresponds to the compensated term $\mathrm{d}\boldsymbol{\sigma}^*$.

In Eq. (9), $\mathrm{d}\boldsymbol{f}^*$ is computed directly from $\mathrm{d}\boldsymbol{\sigma}^*$ rather than being computed from the complex elasto-plastic tensor $\mathbf{c}^{EP}$. Furthermore, as shown in Eq. (8), $\mathrm{d}\boldsymbol{\sigma}^*$ can be obtained explicitly since $\mathrm{d}\boldsymbol{\epsilon}^P$ can be computed explicitly from $\mathrm{d}\boldsymbol{\epsilon}$ of the previous step (see Eq. (4)). Therefore, there is no need to compute $\mathbf{c}^{EP}$ and $\boldsymbol{K}^{EP}$. Better computational performance can be expected. Meanwhile, since $\mathbf{c}$ is symmetric and positive-definite, it is guaranteed that the global stiffness matrix $\boldsymbol{K}$ is symmetric and positive-definite, hence a fast solver based on CG method can be applied.

4. CRACKING SIMULATION METHOD

It is essential to consider cracking that takes place in concrete to evaluate failure patterns and ultimate capacity of RC structures. Currently, cracking functionality has been implemented in modern FEM packages. However, targeting at analyzing the initiation and propagation of a single or a few cracks, they are not suitable to analyze the complicated cracking process in concrete.

Cracking that occurs in concrete forms non-smooth facets accompanying many branching surfaces. Determining such multiple-crack configurations becomes the main difficulty for simulating cracking propagation in concrete. Since a crack is treated as a discontinuity in displacement field in numerical simulation, special treatment should be made to deal with the numerous and scattered displacement discontinuities.

In this study, we employ an alternative which is capable of determining multiple-crack configuration in concrete in a straightforward manner, based on strain/strength of concrete. This alternative, however, needs a new discretization scheme which is applicable to displacement filed with numerous discontinuities. Particle Discretization Scheme (PDS) (Hori et al. 2005) is a candidate of such a discretization scheme. In PDS, two sets of non-overlapping characteristic functions of Voronoi blocks and Delaunay blocks are employed to discretize displacement field and its derivatives.

Denoting $\phi^\alpha(\boldsymbol{x})$ and $\psi^\beta(\boldsymbol{x})$ as non-overlapping characteristic functions of Voronoi block Φ^α and Delaunay block Ψ^β respectively, the field variables is expressed as:

$$u(\boldsymbol{x}) = \sum_\alpha f^\alpha\, \phi^\alpha(\boldsymbol{x}),\ \ \boldsymbol{\nabla}u(\boldsymbol{x}) = \sum_\beta q^\beta\, \psi^\beta(\boldsymbol{x})$$

where $u(\boldsymbol{x})$ is the displacement function, $\boldsymbol{\nabla}u(\boldsymbol{x})$ is the derivative of $u(\boldsymbol{x})$. The non-overlapping characteristic function satisfy $\phi^\alpha(\boldsymbol{x}) = 1$ for $\boldsymbol{x} \in \Phi^\alpha$, $\phi^\alpha(\boldsymbol{x}) = 0$ for $\boldsymbol{x} \notin \Phi^\alpha$, $\psi^\beta(\boldsymbol{x}) = 1$ for $\boldsymbol{x} \in \Psi^\beta$, and $\psi^\beta(\boldsymbol{x}) = 0$ for $\boldsymbol{x} \notin \Psi^\beta$.

PDS can easily simulate multiple-crack configuration because cracks can be straightforwardly expressed along the boundaries of discontinuities between Voronoi blocks.

5. NUMERICAL APPLICATION

In order to exam the applicability of the enhanced code, a simple reinforced concrete cantilever column with qausi-static loading is simulated. The dimensions and layout of the reinforcements inside the column are shown in Figure 1. The RC cantilever column is a 500 x 500 x 1350 mm^3 structure member. There are 5 main reinforced bars with a diameter of 22 mm located in both two sides and equally spaced stirrups with a diameter of 10 mm in the vertical direction.

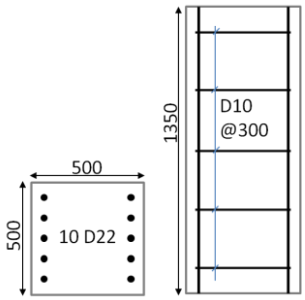

Figure 1 Layout of Reinforcements inside RC Column

5.1 Numerical Model

Figure 2 shows the numerical model and mesh model of the RC cantilever column. It is a detailed reasonably detailed model preserving all the reinforcements in the real body. The model is meshed with 3D tetrahedral solid elements which share nodes on the interface between concrete and steel bars. In total, there are 178,903 nodes, 1,068,331 elements and 536,709 DOFs.

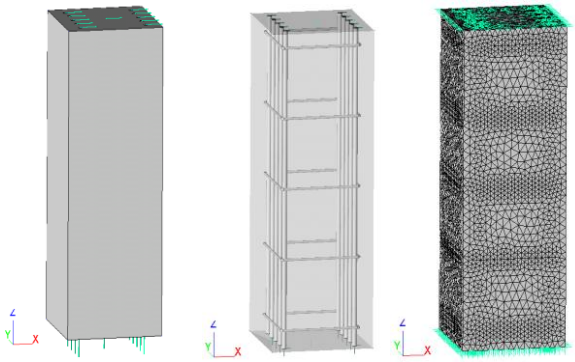

Figure 2 Numerical Model and Mesh Model of the RC Cantilever Column

Von Mises isotropic hardening constitutive model is adopted for reinforced bars, and the reformulated Maekawa's concrete constitutive relationships are employed to model concrete. The material properties are shown in Table 1. Load is increasingly applied in x direction on the top surface of the column, and the bottom surface is fixed in x, y and z directions.

Table 1 Material Properties

Material	Young's Modulus	Poisson's Ratio	Yield Stress	Compressive Strength
Concrete	20GPa	0.2	-	31.3MPa
Main bars	210GPa	0.3	442.3MPa	-
Stirrups	210GPa	0.3	385MPa	-

5.2 Results and Discussions

Using ADVENTURECluster combined with reformulated concrete constitutive relations and PDS, numerical simulation was carried out. Figure 3 compares the load-displacement curves of the numerical and experimental results. The localized pull out effect of reinforcing bar was observed, in the experiment, when load reaches around 140kN. Due to the current limitation of the code, simulation stopped when this level of load is reached. The comparison in Figure 3 shows that the numerical result agrees quite well with the experimental one (Nakajima et al. 1997).

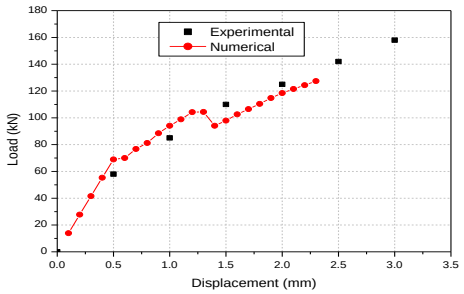

Figure 3 Load-displacement Curves

Figure 4 shows the cracking pattern and deformation with a factor of 20 of the RC column. In order to let the calculation run to a higher load level, a smaller Young's modulus is employed for concrete. Figure 5 shows the cracking pattern and deformation, using the smaller Young's modulus. As expected, the cracking pattern clearly indicates shear failure identical with the experimental result..

Figure 4 Cracking pattern of RC Column (127kN)

Figure 5 Failure Pattern of RC Column

As mentioned, cracking can only occur along the boundary of the Voronoi blocks in PDS. If the nodes of tetrahedral elements are shared on the interface between concrete and steel bars, cracking is not allowed along this interface, since full Voronoi blocks here contain both materials and the Voronoi boundaries do not coincide with the interface. In order to allow this interface cracking and improve the numerical results in the local areas, we employed different mesh for concrete and steel materials respectively. This simple treatment results in broken Voronoi blocks which contain single material and their boundaries are along the interface so that cracking can occur between concrete and re-bars. With the latter way of meshing, the total number of nodes, elements and DOFs are 246,198, 1,079,174 and 738,594, respectively.

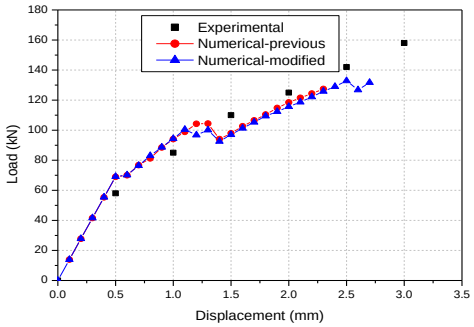

Figure 6 Comparison of Load-displacement Curves

Figure 6 shows the total load-displacement curves of the two mesh patterns. It indicates the total behavior of the RC column, using broken Voronoi blocks along the material interface, does not differ much from that of the original model. However, when we focus on the local area around the boundary of concrete and steel, we can see big difference. Figure 7 compares the stress distribution of concrete at the same load level for the two mesh cases. We can see that if cracking is not allowed to occur along the interface, the maximum tensile stress and compressive stress on the bottom surface of concrete reach 216.7MPa and 53.7MPa, respectively. This is obviously incorrect. While if we separate the meshes of the two materials so that cracking is allowed along their interface, the values are reduced to 4.6MPa and 19.9MPa respectively, showing a significant improvement of local stress prediction.

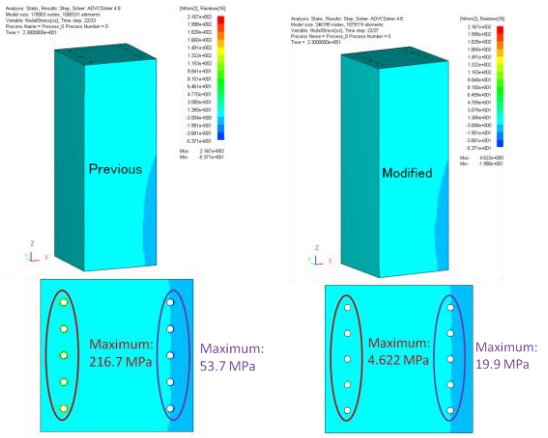

Figure 7 Comparison of Nodal Stress Distribution of Concrete

On the other hand, stress of the reinforcing bars increased, in the latter case, due to the released stress from cracked concrete. These results can be seen from Figure 8-9. It is also because cracking is allowed along the material boundary, stress of the reinforcing bars is not uniformly distributed, and stress concentration on the bars can be seen from Figure 9.

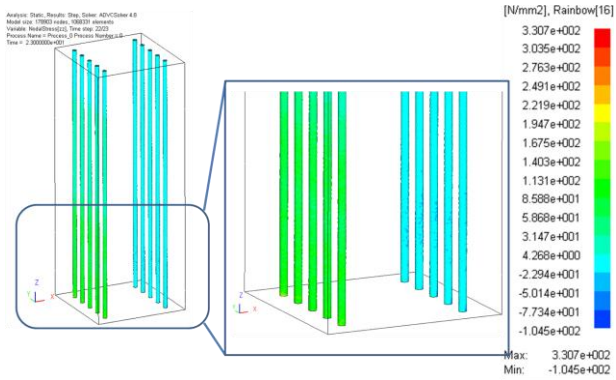

Figure8 Nodal Stress Distribution of Reinforcing Bars

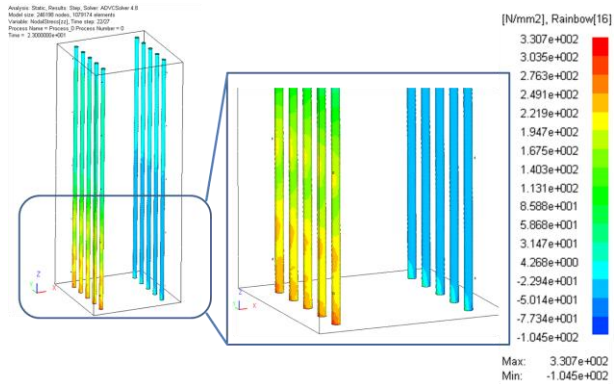

Figure9 Nodal Stress Distribution of Reinforcing Bars Using Modified Mesh

From the results discussed above, we can see that the reformulated nonlinear concrete constitutive relationships and PDS were successfully implemented into ADVENTURECluster. The nonlinear solid-element FEA is demonstrated capable of analyzing the nonlinear response and cracking behavior of RC structural member.

5. CONCLUDING REMARKS

We have implemented reformulated nonlinear concrete constitutive relationships and PDS into a highly advanced parallel FEM program, ADVENTURECluaster, for the nonlinear FEA of RC structures. As a numerical example to demonstrate its applicability, a RC cantilever column was simulated for its nonlinear response with multiple cracking failure under static load. The numerical results showed reasonable agreement with the experimental results, indicating a preliminary success of the enhanced program. However, further efforts are still needed to examine its applicability to more complex and larger RC structures.

Abstract: Compared to the Chinese seismic code GB50011-2001, the strong-column weak-beam (SCWB) ratios and other seismic fortification measures have been largely modified in the new version GB50011-2010. However, the rationality and effectiveness of these modifications in GB50011-2010 for collapse safety of reinforced concrete (RC) frame buildings haven't been quantitatively checked. This study applies probabilistic assessment to assess the seismic collapse risk of RC frame buildings of varying height that are designed according to GB50011-2001 and GB50011-2010, respectively, in high seismic region. The probabilistic assessment relies on collapse fragility analysis based on incremental dynamic analysis (IDA), accounting for uncertainties in ground-motion characteristics and structural modeling. The influence of building height and an increase in the SCWB ratios introduced in GB50011-2010 on seismic collapse safety are investigated. The results can provide reference for building design and seismic code revise.

1. INTRODUCTION

The new version of Chinese seismic code, GB50011-2010 still follows the three level performance objectives and two stages seismic design procedure. The three level performance objectives require that the building should sustain a minor earthquake without any damage, a moderate earthquake with repairable damage, and a strong earthquake without collapsing (GB 50011, 2001 and GB50011, 2010). The third performance objective is the last defense line to protect the safety of life and property. For both the current seismic code and the former one, this performance level is achieved through internal forces adjustment under a minor earthquake level in the first design stage and checking the building deformation under a strong earthquake level in the second design stage. But only the deformation of important buildings or irregular buildings will be checked in the second design stage. The ordinary buildings try to meet this performance level by seismic concept design and details of seismic design which are lack of quantitative evaluation.

Current seismic design methods in seismic codes follow the capacity-ductility rule. For RC frame buildings, the SCWB is one of the most important seismic fortification measures in ensuring the preferred failure mode under strong earthquakes. Increasing the SCWB ratio delays column hinging, thereby increasing the deformation capacity of the entire building and the number of structure components involved in the collapse mechanism. The SCWB ratios have been substantially increased in the new seismic code, but the influence of these revisions on the seismic collapse safety haven't been quantitatively investigated.

Therefore, two sets of RC frame buildings which locate in high seismic region (intensity 8) are designed according to GB50011-2010 and GB50011-2001, respectively in this paper. The seismic collapse risk of these two sets is quantitatively assessed through seismic collapse fragility analysis. The influence of both the building height and an increase in the SCWB ratios introduced in GB50011-2010 are considered.

2. MODEL DESIGN

Two sets of RC frame buildings are designed according to GB50011-2001 and GB50011-2010, respectively. The stories of these buildings are 1, 2, 4, 6, 8 and 10. The plan of the buildings is shown in Figure 1(a). This kind of buildings is common in the teaching buildings and office buildings. The elevation of the buildings is shown in Figure 1(b). The height of the first floor is 4.2m, and the upper floors are 3.6m. The floor characteristic dead load is 5.0 kN/m^2 and the characteristic live load is 2.0 kN/m^2. These buildings are

located in intensity 8 area, the earthquake group is the first, and the site class is the 2nd.

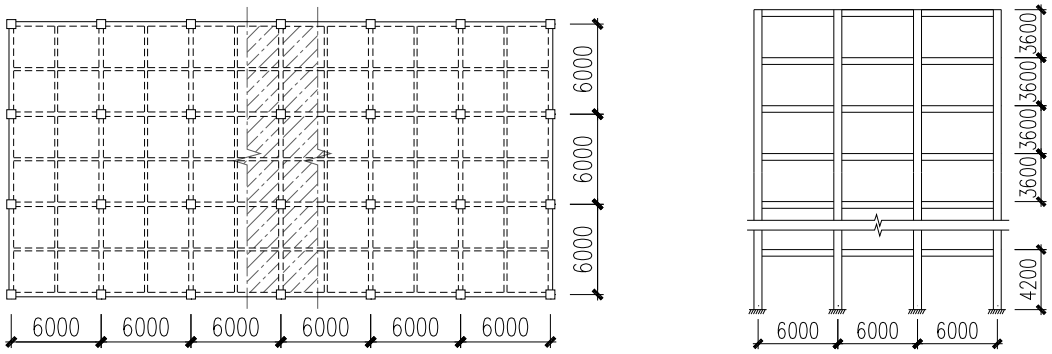

Table 1 Seismic Fortification Measures (μ_{max} = limit value for the design axial compression ratio of column, ρ_{min}= minimum longitudinal reinforcement ratio in column)

Seismic Code	Height(m)	SCWB	μ_{max}	ρ_{min}
GB50011-2010	≤24	1.5(1.5)	0.75	0.85
	24~30	1.7(1.7)	0.65	1.05
	>30	1.7(1.7)	0.65	1.05
GB50011-2001	≤24	1.2(1.25)	0.80	0.70
	24~30	1.2(1.25)	0.80	0.70
	>30	1.4(1.5)	0.70	0.90

The related seismic fortification measures for the two sets of buildings are listed in Table 1. The SCWB is ratio between the required sum of design column end moment and the sum of design beam end moment. The numbers in the brackets are the SCWB ratios of the lower end of column at the first story. When the height of the buildings designed according to GB50011-2010 or GB50011-2001 is higher than 24m or 30m, the required sum of design column end moment should also be 1.2 times of the sum of the actual beam end moment. The longitudinal slab rebar near the top of the beam is considered when calculate the actual beam end moment in GB 50011-2010.

Table 1 illustrates that for buildings whose height is less than 24 or higher than 30m, the SCWB ratios, the minimum reinforcement ratio of column and the limit value of design axial compression ratio in GB50011-2010 are about 1.2 times greater, 0.15% larger and 0.05 stricter than those in GB50011-2001, respectively. If the height of the building is between 24m and 30m, stricter seismic fortification measures should be used in GB50011-2010, Comparing with GB50011-2001.

The building design is carried out by using the code-conforming PKPM (version 2005 and 2010) procedure. The column section size of 1, 2, 4, 6-story buildings is primarily controlled by the limit value of elastic story drift ratio under a minor earthquake. While, the column section size of 8, 10-story buildings is mainly controlled by the limited value of design axial compression ratio. Try to make the maximum design axial compression ratio and elastic story drift of the buildings close to the limited value of the related codes, which means these buildings just meet the minimum requirements of the related codes. The influence of slab on beam stiffness is also considered during the design. The earthquake force is determined by CQC method. The characteristic value of cube compression strength obtained from standard test on 150mm side long cube specimen is 35MPa. The characteristic yield strength of longitudinal reinforcement is 400MPa. And the characteristic yield strength of the stirrup used in GB50011-2001 and GB50011-2010 is 235 MPa and 300MPa, respectively. The details of the buildings design are listed in Table 2.

3. SEISMIC COLLAPSE FRAGILITY ANALYSIS

3.1 Seismic Collapse Fragility Analysis Process

The collapse safety is evaluated by using seismic collapse fragility analysis method. Seismic collapse fragility is the probabilistic relationships between structure collapse probability and ground motion intensity. The process of the collapse fragility analysis basing on IDA analysis method (Vamvatsikos and Cornell, 2002) is listed below:

1) Establish the structure numerical analysis model which can accurately simulate the seismic response of structures.

2) Select a group of ground motion records which can represent the characteristic of ground motion of the building site. The number of the selected ground motion records should be enough to reflect the ground motion randomness. And a proper IM (Intensity Measure) should be used to normalize the ground motion.

3) For one of the ground motion record, gradually increase the IM and do the nonlinear time history analysis until the structure collapsed.

4) Repeat the step 3) for all the ground motion records.

5) Take the structure collapse capacity, the ground motion intensity when the structure collapsed, as random variable, and then estimate the parameters by assuming it follows lognormal distribution model. At last, the collapse

fragility curve can be obtained.

6) Properly adjust the collapse fragility results considering the structure model uncertainty.

Table 2 Design Characteristics of the Buildings (μ = maximum design axial compression ratio of column, θ = elastic story drift ratio, θ≤ 1/550, B = width, H = height, ρ_l = longitudinal reinforcement ratio, ρ_l'= compression reinforcement ratio, ρ_t = transverse reinforcement ratio)

Seismic Code	Design ID	Total Stories	Height (m)	μ	θ	Column					Beam

3.2 Nonlinear Analysis Model

Accurate numerical structural analysis model is the basis of the collapse fragility analysis. Because the structure becomes highly nonlinear during the collapse analysis, the numerical analysis model should not only seize the main strong nonlinear feature, but also have robust convergence ability. The lumped plasticity beam-column elements are used to simulate the nonlinear behavior of the columns and beams. The lumped plastic hinges are modeled by using a nonlinear hinge model with degrading strength and stiffness proposed by Ibarra et al, as shown in Figure 2 (Ibarra and Medina, 2005). Key parameters of this model include the plastic rotation capacity $\theta_{cap,pl}$, the post capping rotation θ_{pc} , the ratio of maximum to yield moment Mc/My and an energy-based degradation λ. The key parameters are predicted from a series of empirical relationships relating design characteristics to model parameters and calibrated to experimental data (Haselton and Deierlein, 2007). The axial compression ratio and transverse reinforcement ratio are the two important design parameters to determine these model parameters. As the decreasing of the axial compression ratio, the deformation capacity and the energy dissipation of the component increase, so the four key parameters will increase. The $\theta_{cap,pl}$, θ_{pc} and λ increase with the increase of transverse reinforcement ratio. To account crack action the effective component stiffness are determined on the basis of deformations at 40% of the yield strength. The influence of slab in the width of 600mm on each side of the beam is considered, when establish the beam model. The axial-flexure-shear interaction isn't accounted during the analysis.

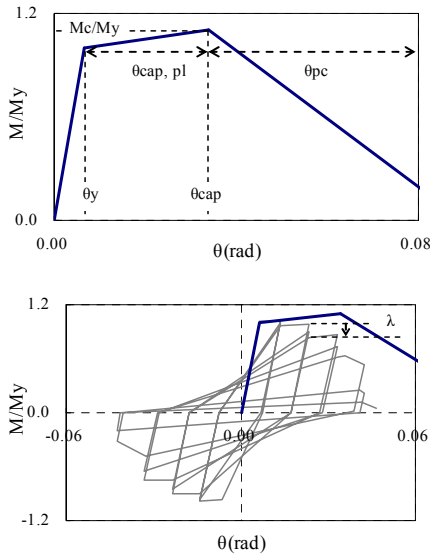

Figure 2 Monotonic and Cyclic Behavior of RC Beam-Column Hinge Model

The shade part of frame in Figure 1(a) is taken out to represent the entire building. So a two-dimensional three-bay nonlinear analysis frame model is created for each building by using the OpenSees structural analysis platform (OpenSees, 2012) with robust convergence algorithms developed by Haselton and Goulet (2007). The Rayleigh damping corresponding to 5% of critical damping in the first and third modes is applied.

3.3 Ground Motion Record

A lot of ground motion records will be used as input in IDA analysis to consider the randomness of the ground motions. A set of 22 pair of ground motions for Far-Field are suggested by ATC-63 (FEMA P695, 2009). Each pair of records has two components. To approximately account for three-dimensional ground motion effects (i.e., the maximum ground motion component), the lower collapse capacity from each pair of ground motions is recorded as the structure collapse capacity.

According to ATC-63, Shome and Cornell (1998) and Luco and Cornell (2007), the spectral acceleration response at the structure's estimated first-mode period $Sa(T_1)$ is a useful IM, with efficiency and sufficiency comparable or superior to other available scalar IMs such as PGA that can be calculated independently of the structure. So the IM selected for this paper is the 5% damped $Sa(T_1)$.

3.4 Collapse Criteria

There are several potential local and global collapse mechanisms of RC frame structures, notably (1) loss of gravity-load-carrying capacity of a column, (2) local collapse of beam-slab system, and (3) global side-sway collapse caused by dynamic instability in one or more stories (Haselton and Goulet, 2007). It is assumed that the detailing provisions of the design code will effectively prevent local collapse modes (1) and (2). The collapse point of collapse mode (3) is defined as the point of dynamic instability (not numerical non-convergence) when any further increase in the intensity of the record causes the drifts to increase without bound (Haselton and Goulet, 2007). The IDA curve becomes flat in this point.

3.5 Adjustment of Structure Collapse Fragility Analysis Results

The largest uncertainty of collapse fragility analysis results lies in characterizing the earthquake ground motion and simulating the structural response. If it is assumed that the structure collapse capacity follows the lognormal distribution model, the uncertainty introduced by ground motion can be considered by using the fitted logarithmic standard deviation ($\sigma_{ln,\,RTR}$) obtained from section 3.1 step 5). The uncertainty of simulating the structural response is mainly result from the modeling uncertainty. Lie et al. (2009) and Haselton and Deierlein (2007) have shown how to deal with this uncertainty in collapse fragility analysis. In this paper, the modeling uncertainty is calculated as $\sigma_{ln,\,modeling}$= 0.5 (Haselton and Deierlein, 2007). Then combined this two types of uncertainty, the resulting total uncertainty is $\sigma_{ln,\,total}^2=\sigma_{ln,\,RTR}^2+\sigma_{ln,\,modeling}^2$.

4. COLLAPSE FRAGILITY ANALYSIS RESULTS

4.1 Result of Collapse Risk

Collapse fragility analysis results for the two sets of buildings are summarized in Table 3. The collapse risks are described by the collapse margin ratio (CMR) and conditional collapse probability for the 2% in a 50-year level of ground motion intensity P[C|$Sa_{2/50}$].

Table 3 Summary of Collapse Risks of RC Buildings

Seismic Code	Design ID	Fist-mode period (T1) (s)	Sa,c(g)	$\sigma_{ln,RTR}$	CMR	P[C|$Sa_{2/50}$] (%)
GB50011-2001	101	0.43	2.15	0.41	2.55	7.84
	201	0.63	1.83	0.36	3.07	3.27
	401	1.07	1.00	0.36	2.70	5.21
	601	1.40	0.78	0.40	2.68	6.46
	801	1.75	0.59	0.35	2.48	6.24
	1001	2.00	0.66	0.30	3.19	1.72
GB50011-2010	110	0.43	2.80	0.40	3.32	3.14
	210	0.63	2.10	0.32	3.52	1.68
	410	1.07	1.22	0.38	3.29	2.92
	610	1.40	0.93	0.42	3.20	3.72
	810	1.67	0.86	0.35	3.46	2.11
	1010	1.95	0.72	0.28	3.33	1.78

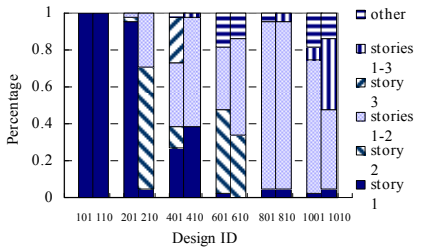
The collapse margin ratio is the ratio between the median collapse capacity Sa,c and the 2% in a 50-year ground motion level $Sa_{2/50}$, CMR= Sa,c/$Sa_{2/50}$. The CMRs for GB50011-2001-conforming buildings range from 2.48 to 3.19, with an average of 2.78. While, the CMRs for GB50011-2010-conforming buildings range from 3.20 to 3.52, the average value is 3.35.

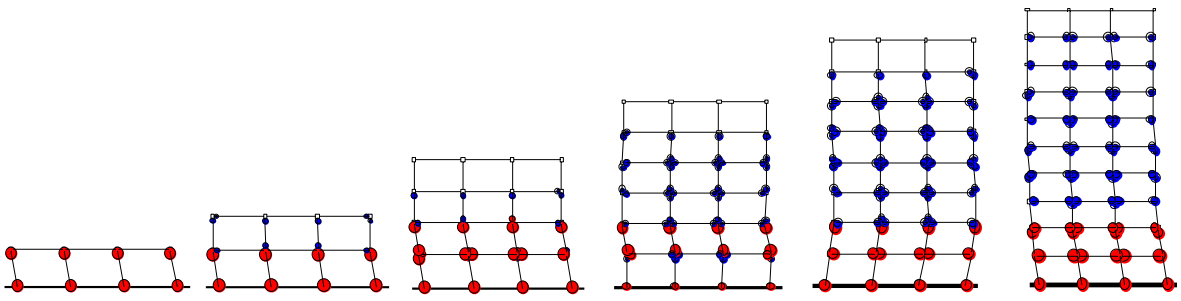
The GB50011-2001-conforming buildings, have an average P[C|$Sa_{2/50}$] of 5.12%, ranging from 1.72 to 7.84%. In contrast, GB50011-2010-conforming buildings, have an average P[C|$Sa_{2/50}$] of 2.56%, which are approximately 0.57 times smaller than that of GB50011-2001-conforming buildings, ranging from 1.68 to 3.72%. All buildings can sustain a strong earthquake without collapsed, according to the recommendation of ATC-63 that the building can achieve the no collapsing with strong earthquake object, if the collapse probability is less than 10%.

4.2 Collapse Mechanisms

Figure 3 illustrates the primary collapse mechanisms for all buildings and also provides the proportion of ground motions that caused the primary collapse mechanisms. Figure 4 shows the predominant collapse mechanisms for each building and corresponding percentage. The size of the circles shows the magnitude of the plastic deformation in each plastic-hinge. The blue plastic hinge means $\theta_{cap,pl} \leqslant$ plastic rotation $< \theta_{pc}$, and red plastic hinge means the plastic rotation $\geqslant \theta_{pc}$.

Figure 3 and Figure 4 indicate that the collapse mechanisms for GB50011-2001-conforming and GB50011-2010-conforming 1-story building are almost the same. 2-story building designed according to GB50011-2001 and GB50011-2010 are quite different. As the GB50011-2001-conforming 2-story building collapses in a single first-story mechanism, while the collapses for the GB50011-2010-conforming 2-story building occurs in a stories 1-2 mechanism and a single second-story mechanism. However, the collapses primarily occur in the bottom 2 stories for 4, 6, 8-story building. And there is little difference between these two sets. For 10-story building designed by GB50011-2001, the bottom 2 stories are mainly involved in the collapse mechanism. In contrast, for 10-story buildings designed by GB50011-2010 the bottom 3 stories are involved.





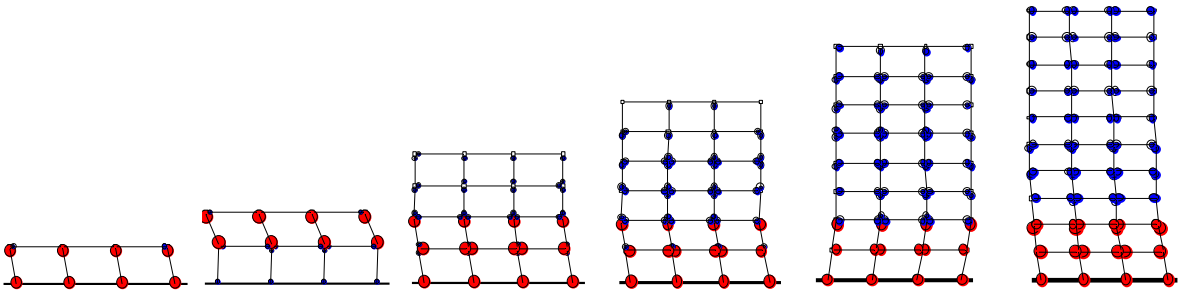


Figure 3 Summary of Collapse Mechanisms

(a)

(b)

Figure 4 Primary Collapse Mechanisms for Buildings of Various Heights: (a) Buildings designed according to GB50011-2001, and (b) Buildings designed according to GB50011-2010

4.3 Influence of Building Height on Collapse Safety

Figure 5 illustrates the relationship between building height and $P[C|Sa_{2/50}]$. It indicated that even designed by the same version of seismic code, the collapse risk of buildings with different height is different from each other. The results suggest that GB50011-2001-conforming 1, 6 and 8-story building have slightly higher collapse risk compared with buildings with other height. While, the collapse risk of GB50011-2010-conforming 1 and 6-story building are a little higher. The high collapse risk of 1-story buildings is result from the lack of plastic redistribution of internal forces. And the stricter seismic fortification measures (larger SCWB, lower maximum axial compression ratio and larger minimum longitudinal reinforcement ratio of column) result in increased collapse safety for taller buildings.

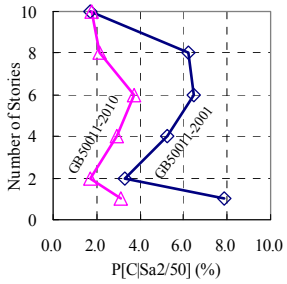

Figure 5 Collapse Risk as A Function of Building Height

4.4 Influence of Increase SCWB on Collapse Safety

The SCWB ratios used for 1, 2, 4 and 6-story buildings for GB50011-2001 and GB50011-2010 is 1.2(1.25) and 1.5(1.5), respectively. And the maximum axial compression ratio of the same height of buildings designed by GB50011-2001 and GB50011-2010 are almost the same. So the difference between the SCWB ratios of GB50011-2001 and GB50011-2010 is the only reason resulting in the different collapse risk of buildings. The ratio of $P[C|Sa_{2/50}]$ for GB50011-2010-conforming buildings ($P[C|Sa_{2/50}]_{10}$) to GB50011-2001-conforming buildings ($P[C|Sa_{2/50}]_{01}$) is shown in Figure 6. The average $P[C|Sa_{2/50}]$ of the four buildings designed according to GB50011-2010 is just 0.51 times of that for the four buildings designed according to GB50011-2001. For low-rise and mid-rise buildings increasing the SCWB ratios, introduced in GB50011-2010 can dramatically reduce the collapse risk.

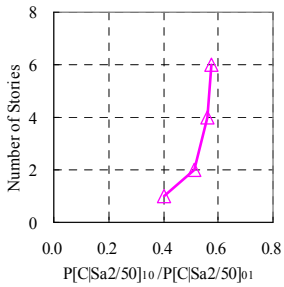

Figure 6 The Ratio Between $P[C|Sa_{2/50}]_{10}$ and $P[C|Sa_{2/50}]_{01}$

5. CONCLUSIONS

The probabilistic assessment based on nonlinear dynamic analysis is applied to quantitatively evaluate the seismic collapse safety of RC frame buildings of varying height that are designed according to GB50011-2001 and GB50011-2010. The results are summarized below:

1) The buildings designed either by GB50011-2001 or GB50011-2010 can sustain the 2% in a 50-year level of ground motion intensity without collapsed.

2) An increase in the SCWB ratio in GB50011-2010 does not significantly improve the building collapse mechanisms. Only the bottom two stories (or one story for 1-story building) are mainly involved in resisting the earthquake.

3) Even designed by the same version of seismic code the collapse risk of buildings with different height is different from each other.

4) For low-rise and mid-rise buildings increasing the SCWB ratios, introduced in GB50011-2010 dramatically reduce the collapse risk of buildings.

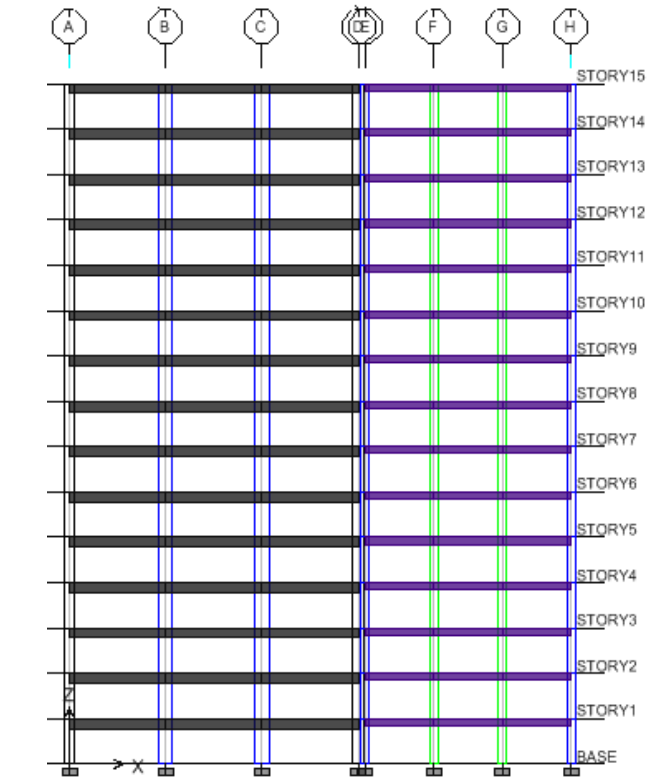
Abstract: This paper presents the seismic response analysis of multi-storey reinforced concrete (RC) frame buildings with 15-storey and 3-bay during collisions considering the horizontal, vertical and rotational movements of the supporting soil through incorporating spring-damper systems at the foundation level. Both buildings are designed according to the Egyptian Code of Practice (ECP). The finite element software ETABS has been used to perform the analysis using the well-known earthquake motion named the El-Centro to excite the buildings model. Nonlinear spring impact elements are applied to simulate the induced pounding force at the points of contact of the colliding frames. To investigate the effect of soil-structure interaction (SSI) on the seismic response in terms of stories displacements, drifts, accelerations, shearing and pounding forces, two types of analysis are performed: first, the developed model is analyzed assuming rigid base soil and second, the analysis is carried out with the consideration of SSI effect. The results of the three dimensional finite element analysis with and without SSI are compared to each other. Based on the obtained results, it has been found that the performance of the RC multi-storey buildings frames is substantially influenced by SSI incorporation during collisions.

1. INTRODUCTION

Interactions between adjacent structures that do not have appropriate separation gaps have been repeatedly observed during strong earthquakes. In most of the seismic pounding analyses, buildings are considered to be fixed bases. These analyses have been proved to be valid only for buildings founded on hard and very stiff soil. In the reality, the underlying soil affects the seismic response of the buildings, whereas the consideration of underlying soil adds extra degrees of freedom at the foundation level and also allows energy dissipation, in additional to decrease the global stiffness of structural system especially for massive and stiff structures constructed on relatively soft soil (Wakabayashi 1985, Wolf 1987 and Stewart et al. 1999a). Although many analytical, numerical and experimental studies have been conducted into the pounding phenomenon, the numbers of those which take into account the effects of the underlying soil flexibility on the dynamic response of the pounding structures are very limited.

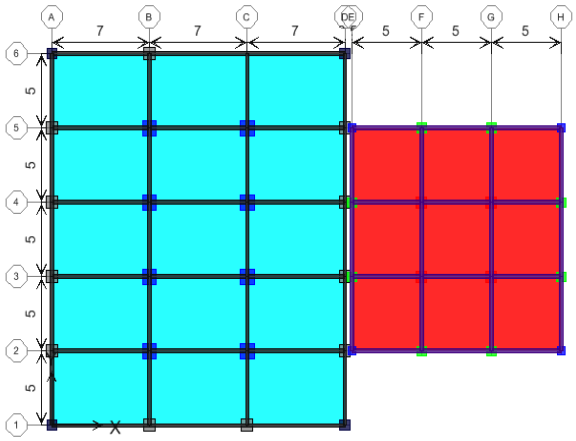
The SSI and its influence on the pounding of the adjacent buildings have been studied by Rahman et al. (2001), Chouw (2002) and Shakya and Wijeyewickrema (2009). Rahman et al. (2001) studied the pounding behavior of two 6-story and 12-story moment-resistant, reinforced concrete frame structures incorporating the effects of the soil flexibility considering impacts at different story levels. In their studies, the adjacent buildings and underlying soil were modeled using the FEM-BEM method with the RUAUMOKO software package; the seismic responses to the El-Centro earthquake were obtained via an inelastic dynamic analysis, and the Hertz contact force model was used to represent the pounding between the adjacent buildings. Rahman et al. (2001) found that the shift of period due to the underlying soil altered the time at which the first impact occurred, which had consequences on the subsequent poundings. Chouw (2002) performed an analysis on impacting two buildings linked by a pedestrian bridge taking into account the effect of soil flexibility by employing the boundary element in the Laplace and the time domain. The effects of SSI on mid-column seismic pounding in reinforced concrete buildings of unequal heights under near-field and far-field earthquakes were also studied by Shakya and Wijeyewickrema (2009). They used the SAP 2000 software to model the adjacent buildings and the underlying soil.

A review of the above cited few papers indicates that the analyses have performed using two dimensional finite element analysis for collisions between buildings of unequal heights.The purpose of the present study is to investigate the coupled effect of both supporting soil flexibility and pounding phenomenon on the response of multi-storey RC frame buildings with 15-storey and 3-bay during collisions considering the horizontal, vertical and rotational movements of the supporting soil through incorporating spring-damper systems at the foundation level using ETABS



software. The first fifteen seconds of the N-S component of the 1940 El Centro earthquake (peak ground acceleration PGA = 0.348g) is utilised as the external dynamic excitation. Impact forces and acceleration time-histories of colliding buildings with respect to different gaps size between the colliding structures, in additional to envelopes of maximum story shears and storeys drift have been considered as the parameters to investigate the effects of soil on seismic pounding.

2. BUILDING MODEL



This study investigates pounding of adjacent multi-storey reinforced concrete frame buildings with 15-storey and 3-bay during collisions as shown in figure 1. A three-dimensional finite element model has been defined incorporating the effects of soil flexibility and non-linear time-history analyses have been performed. A heave building is assumed to collide with adjacent light building, as shown in figure 1. The fundamental periods of the buildings with different conditions are shown in table 1. The model has coincident Rigidity/stiffness Center and Mass Center that is located at the geometric center of the floor [from symmetry as shown in floor plan 1(c)]. The two buildings having story height 3.2m for all floors [figure 1(b)]. Concrete with compressive strength f_c' = 3500 t/m^2, unit weight γ_c = 2.5t/m^3, modulus of elasticity E_c = 2.1x10^6 t/m^2, which is determined according to ECP-2003 and Poisson's ratio υ = 0.2 and reinforcing steel with yield strength f_y = 3.6x10^4 t/m^2 are used for analysis and design. The design process requires the determination of the loads that act on the RC buildings. In general, these loads are categorized as gravity loads, which include dead loads (DL) and live loads (LL); and lateral loads, which include earthquake loads.

The dead loads include the own weight of the structural elements, the weight of flooring cover (0.2 t/m^2 for heave building and 0.15 t/m^2 for light building). According to EGP-2008, the live load for heave building is 0.4 t/m^2, and for light building is 0.2 t/m^2. The heave building is provided with 0.22 m thick floor slabs which are considered as rigid floor diaphragms, and also 0.16 m thick slabs for light building. The dimensions of all frame members which used in the parametric study are shown in table 2. Both buildings are designed according to the ECP. The finite element software ETABS has been used to perform the analysis considering 5% damping ratio using the well-known earthquake motion named the El-Centro to excite the buildings model.

The buildings under study here are residential buildings with a mass of 500 tons and 120 tons per story for heave and light building, respectively; and a lateral stiffness in compliance with ECP-2003. The fundamental period of the buildings can be found from their mass and stiffness.

3. STRUCTURAL POUNDING MODEL

To simulating pounding force, Connection modeling was done using a GAP joint element, which has only got pressing behavior as shown in Fig. 2. The behavior of the element is such that it behaves nonlinearly with bilinear hardness, i. e. in the case the two adjacent buildings are touching each other, the hardness of gap element is active otherwise, the hardness is considered to be zero. The force-deformation relationship of the gap element is given by:

$$f_G = \begin{cases} K_G[(U_i - U_j) - gap] & \text{if } (U_i - U_j) > gap \\ 0 & \text{if } (U_i - U_j) < gap \end{cases} \quad (1)$$

Where f_G is the force, K_G is the spring constant, U_i and U_j are the displacements of the element's nodes i and j and gap is the initial gap opening. The axial stiffness of the gap element must be selected large enough to transfer compression forces across the gap with a minimum of deformation within the gap element compared to the stiffness of the nodes on the surface. Accordingly, the stiffness of gap element K_G is set to be 100 times higher than that of linear element so that it works nearly rigid when the gap is closed.

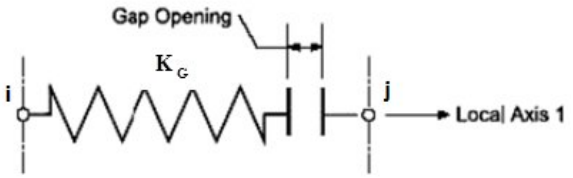

Figure 2 GAP Element and its Function

4. SOIL MODELLING

The discrete model has been formulated for the mat foundations embedded in the halfspace and located at the base of the structure to represent the soil and interaction mechanisms (Richart and Whitman, 1967). Springs and dashpots have been employed in the model in order to account for the transitional, rotational and vertical movements of the soil including damping. For a raft of length L and width B , The parameters of springs and dashpots for sway, rocking and vertical, which represent the SSI, are computed using the following expressions (Whitman and Richart. 1967):

$$k_h = 2(1-\nu)G\beta_x\sqrt{BL}, \quad c_h = 0.576k_h r_h\sqrt{\frac{\rho}{G}}$$

$$k_r = \frac{G}{1-\nu}\beta_\phi BL^2, \quad c_r = \frac{0.3}{1+\beta_\phi}k_r r_r\sqrt{\frac{\rho}{G}} \quad (2)$$

$$k_v = \frac{G}{1-\nu}\beta_z\sqrt{BL}$$

where ν is the Poisson's ratio of the soil, G is the shear modulus, β_x β_ϕ and β_z are the correct constants of swaying and rocking springs, respectively; ρ is the density of soil. The maximum shear modulus at low strain, G_{max}, is related to the shear wave velocity,V_s , according to the following expression (Richart and Whitman, 1967):

$$G_{max} = \rho(V_s)^2 \quad (3)$$

The shear modulus used in the analysis incorporating the SSI has been reduced in order to maintain closer behaviour of the soil. The modulus reduction curves (G/G_{max} - γ) are often used to solve dynamic problems when shear strains, γ, drive the soil beyond its elastic range. As the soil enters into the inelastic stage, the shear modulus of the soil is reduced substantially what is correspondingly related to the decrease in the shear wave velocity. In the case of the study conducted, the reduced shear modulus G has been assumed to be 50% of G_{max} calculated according to Eq. 3 (see Richart and Whitman, 1967).

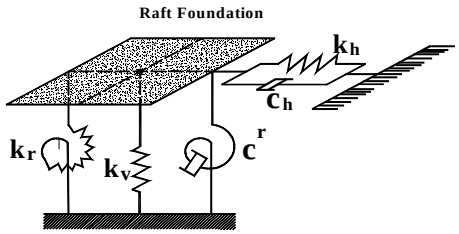

Figure 3 Equivalent Soil Springs to Model Horizontal, Vertical, and Rotational Soil Movements

5. NUMERICAL RESULTS

The effects of soil flexibility on the nonlinear seismic response of two 15-storey adjacent buildings with equal heights and insufficiently separated by several gap distances is considered and the response of the buildings to the El-Centro earthquake record is obtained during the occurrence of pounding. The mat size under the heavy building is of 21.7mx25.7m while under the light building is of 15.55mx15.55m. The supporting soil properties used to calculate the coefficient of frequency independent springs are shown in Table 3.

Table 3 Sandy Soil Type with Different Densities and Shear Wave Velocities at Depth of 15 m

Sandy Soil density γ (kg/m^3)	1.89×10^3
Poisson's ratio ν	0.3
Shear wave velocity V_s (m/sec)	150

The nonlinear dynamic analyses have been carried under the El-Centro earthquake record (Imperial Vally Irrigation Station, N-S component, PGA = 0.342g) for three different gaps of 20mm, 50mm, and 100mm. Two cases have been studied using the same parameters: (a) colliding buildings without incorporating the soil flexibility and (b) colliding buildings incorporating the horizontal, vertical and rotational movements of the supporting base soil.

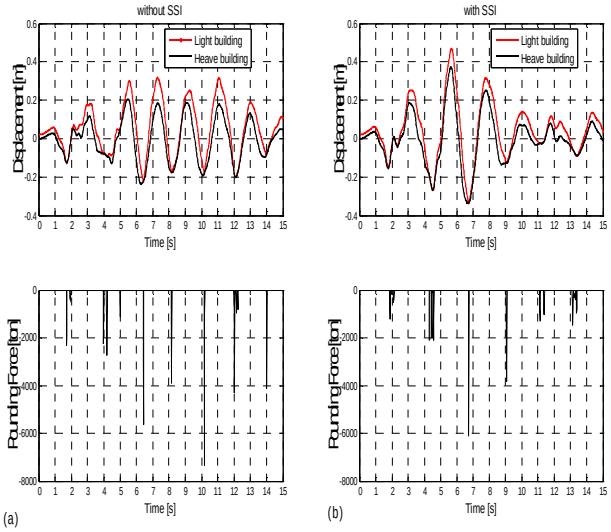

Figure 4 Displacement, and Pounding Force Time-Histories of the Top Floor (a) without SSI and (b) with SSI under the El-Centro Earthquake for Gap Size of 20 mm

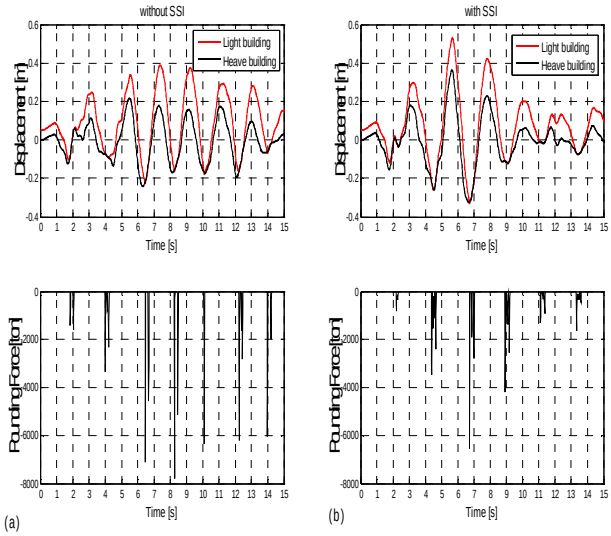

Figure 5 Displacement, and Pounding Force Time-Histories of the Top Floor (a) without SSI and (b) with SSI under the El-Centro Earthquake for Gap Size of 50 mm

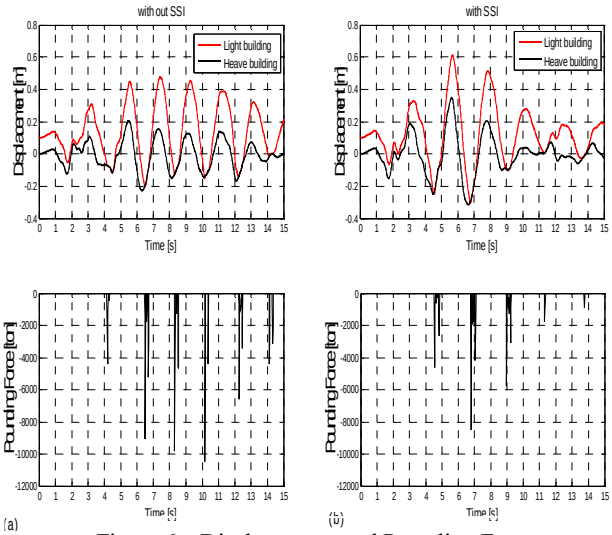

Figure 6 Displacement, and Pounding Force Time-Histories of the Top Floor (a) without SSI and (b) with SSI under the El-Centro Earthquake for Gap Size of 100 mm

Figures 4,5,6 show the sequence of collision forces at the top floors of the heavy and light buildings, (because the top floors experience the most critical condition) during the response to the Elcentro ground motion records. It can be seen that a reduction in the values of the induced pounding forces in the case of SSI inclusion compared with the case of assuming that the supporting soil exhibits as a rigid base for all the considered separation distances. Consequently, the SSI inclusion reduces the value of the peak pounding force. It has also been noticed that considering soil flexibility effect causes slight decreases in the number of impacts compared with the case of ignoring it as can be seen in Figures 4, 5, and 6. In addition, the inclusion of soil flexibility leads to change in pounding forces locations compared with the locations of the induced impact forces considering rigid base soil. The obtained nonlinear displacements for the storeys of adjacent buildings during collisions with and without considering soil flexibility effect for 20mm, 50mm and 100mm gaps are presented in Figures 4, 5, and 6 respectively. The results show that SSI effect during collisions increases the storeys displacements compared to the case for SSI exclusion.

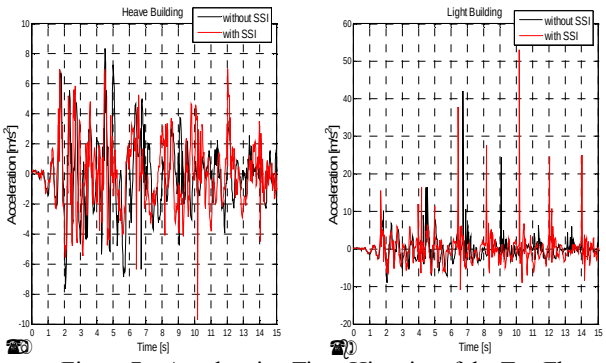

Figure 7 Acceleration Time-Histories of the Top Floor without and with SSI for: (a) Heave Building Storeys; (b) Light Building Storeys under the Elcentro Earthquake for Gap Size of 20 mm.

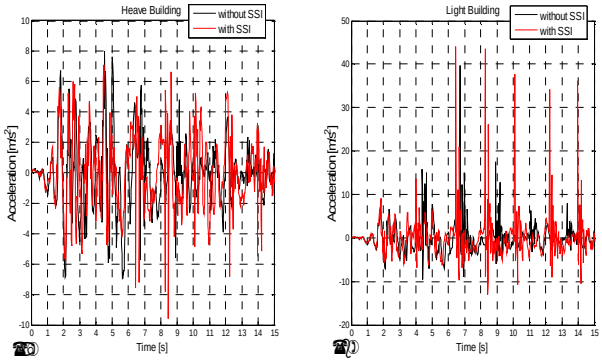

Figure 8 Acceleration Time-Histories of the Top Floor without and with SSI for: (a) Heave Building Storeys; (b) Light Building Storeys under the Elcentro Earthquake for Gap Size of 50 mm.

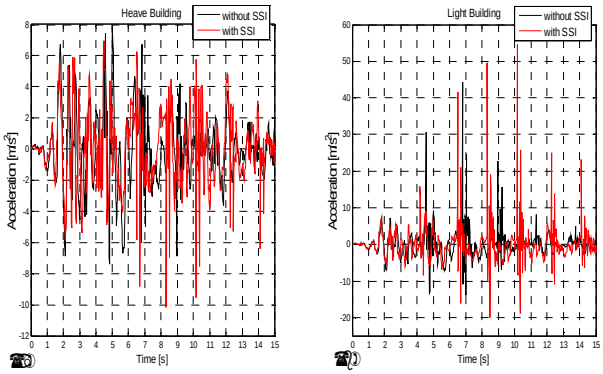

Figure 9 Acceleration Time-Histories of the Top Floor without and with SSI for: (a) Heave Building Storeys; (b) Light Building Storeys under the Elcentro Earthquake for Gap Size of 100 mm.

Figures 7, 8, and 9 give the acceleration time-histories of the colliding two buildings without and with SSI at the top floors of the heave and light buildings, for different gap sizes, under the El-Centro earthquake record. An increase in the peak acceleration can be observed as a result of soil flexibility incorporation, for all the considered separation distances. Those peak accelerations for both buildings occur at the time of impact (compare Figures 4, 5, and 6 and Figure 7, 8, and 9) for the case without and with SSI.

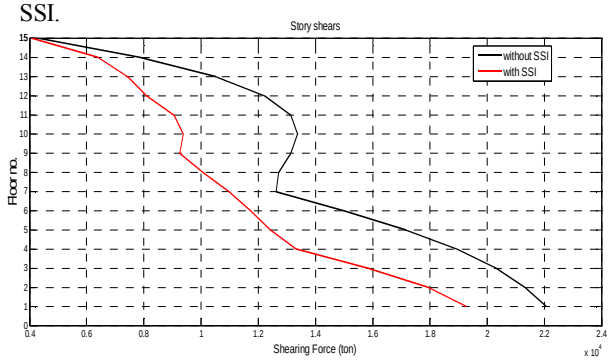

Figure 10 Envelopes of Maximum Story Shears of the Heave Building without and with SSI under Elcentro Earthquakes

The envelopes of maximum story shears of the heave building due to collisions with the light building under the El-Centro earthquake motion without and with SSI for 2cm gap are shown in Figure 10. It can be seen from the figure that interactions between adjacent structures incorporating the soil flexibility effects result in the decrease in the obtained maximum shearing forces for the storeys of the heavy building compared with those obtained ignoring the soil flexibility effect.

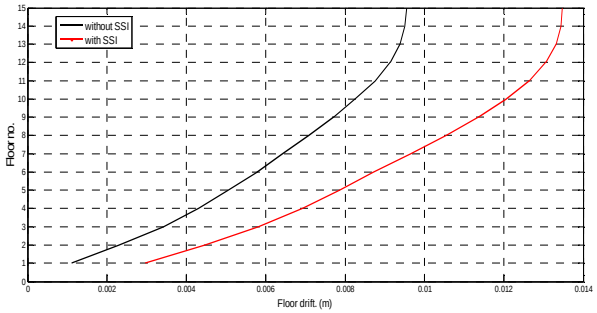

Figure 11 Story Drift of the Heave Building without and with SSI under Elcentro Earthquakes

The envelopes of maximum story shears of the heave building due to collisions with the light building under the El-Centro earthquake motion without and with SSI for 2cm gap are shown in Figure 11. It can be seen from the figure that interactions between adjacent structures incorporating the soil flexibility effects result in the decrease in the obtained maximum shearing forces for the storeys of the heavy building compared with those obtained ignoring the soil flexibility effect.

6. CONCLUSIONS

The current research work investigates the effect of soil flexibility on the nonlinear response time-history analysis of colliding two 15-storey adjacent buildings under the El-Centro ground motion record. Three different gap sizes are used in the study. The nonlinear seismic response of the highest stories of the colliding buildings considering and ignoring SSI effect in terms of displacement, acceleration and pounding force time-histories as well as the storeys peak shearing forces and peak drifts are presented and compared with the associated time-histories results excluding the SSI effects. The results of the study indicate that the SSI inclusion amplifies the obtained displacement and acceleration time-histories while pounding force time-history is reduced due to such inclusion of SSI. For the stories of both heavy and light buildings compared with the obtained values ignoring the SSI effect. In addition, the soil flexibility incorporation significantly reduces the stories peak shearing force during collisions. However, it has been found that the SSI effect increases the drift of all the stories of the buildings during collisions compared to the induced drifts during collisions of rigid base buildings. The study indicates the necessity of considering base soil flexibility during the nonlinear analysis of colliding buildings.

Abstract: The purpose of this paper is to evaluate the elastic local buckling strength of rectangular hollow section member subjected to axial force and biaxial bending. The effects of parameters such as axial force ratio and loading angle on the plate buckling coefficient are also clarified. It is shown that the buckling strength takes minimum when one axial bending acts on the column and the strength takes maximum when diagonal axial bending acts on the column. By considering the stress in the member, it is possible to enlarge the Japanese width-thickness ratio limit of the plate elements. This study is also intended to understand the elasto-plastic behavior of rectangular hollow section column under biaxial bending precisely.

1. INTRODUCTION

In Japan, rectangular hollow section column is commonly used in steel structures. In addition to axial force, biaxial bending acts on the column by seismic force and wind force. Although a lot of studies about the column have been conducted, there are few studies about the column under biaxial bending. Those studies about biaxial bending (for instance, Kojima et al. 2009 Ishida et al. 2011) have revealed the post local buckling behavior and the plastic deformation capacity of the column under biaxial bending.

However, in most of the previous studies, the local buckling characteristic and the property of the column material such as residual stress are intermingled. Thereby, it is difficult to specify how well each the local buckling characteristic and the property of the material affects the elasto-plastic behavior of the column. Since the buckling strength relating to the shape of the column has not been examined in detail, the effects of parameters such as loading angle and axial force ratio on the buckling strength are not clarified sufficiently. Because of this, in the current Japanese design criteria (AIJ 2005), the boundary conditions and the stress distributions of the plate elements constituting the column are simplified and the width-thickness ratio limit may be evaluated on an excessive safe side.

The purpose of this paper is to evaluate the elastic local buckling strength of rectangular hollow section column under biaxial bending by theoretical analysis with energy method (Timoshenko 1961) and numerical analysis with FEM. The effect of each parameter on the elastic buckling coefficient is also clarified. Moreover, the width-thickness ratio limit of the plate elements is calculated by basing on the buckling coefficient obtained by analysis. The calculated limitation is compared to the current limiting value in Japanese design criteria.

According to previous study by Wang and Ikarashi (2010), it is possible to predict plastic deformation capacity if elastic buckling strength is clarified in the case of H-shaped beam. This study is also intended to reveal the elasto-plastic behavior of the column under biaxial bending precisely.

2. OUTLINE OF ELASTIC LOCAL BUCKLING ANALYSIS OF RECTANGULAR HOLLOW SECTION COLUMN UNDER BIAXIAL BENDING

2.1 Analytical model

Figure 1 shows the analytical model of this study. In this paper, as shown in Figure 1, the elastic local buckling strength of rectangular hollow section column subjected to constant axial force P and biaxial bending with loading angle θ is evaluated by theoretical analysis and numerical analysis. In theoretical analysis, the buckling strength is derived from energy equation based on classical theory (Timoshenko 1961). In this paper, the buckling strength is clarified by energy method when loading angle θ is 0 or 45 [deg.]. The buckling strength is also clarified by FEM when θ is 0, 5, 10, 15, 20, 25, 30, 35, 40 or 45 [deg.].

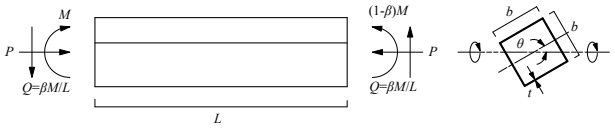

Figure 1 Analytical model

Elastic local buckling stress σ_{cr} in Eq. (1) is defined as a summation of bending stress σ_b and compressive stress σ_c. The elastic local buckling stress σ_{cr} means the elastic local buckling strength in this study. The buckling stress σ_{cr} is the maximum value of normal stress of the column when elastic local buckling occurs. As shown in the following equation, σ_{cr} can be expressed with plate buckling coefficient. The buckling strength is evaluated with buckling coefficient in this paper. Buckling coefficient is not affected by width-thickness ratio but affected by aspect ratio, boundary conditions and stress distributions. Variable $k_\sigma(\theta,p)$ expresses the buckling strength with the value of loading angle θ and the value of axial force ratio p.

$$\begin{aligned}\sigma_{cr} &= \sigma_b + \sigma_c \\ &= \left\{ {}_b k_\sigma(\theta,p) + {}_c k_\sigma(\theta,p) \right\} \frac{\pi^2 E}{12\left(1-\nu^2\right)} \frac{1}{\left(b/t\right)^2} \\ &= {}_n k_\sigma(\theta,p) \frac{\pi^2 E}{12\left(1-\nu^2\right)} \frac{1}{\left(b/t\right)^2}\end{aligned} \quad (1)$$

In this study, the analytical parameters are end moment ratio β, aspect ratio λ, loading angle θ and axial force ratio p. As shown in Eq. (2), aspect ratio λ is the dimensionless number of length divided by width. Variable p is the ratio of compressive stress to the buckling stress with a plate whose 4 edges are simply supported under pure compressive force. Axial force ratio p can be expressed by Eq. (3).

$$\lambda = \frac{L}{b} \quad (2)$$

$$p = \frac{{}_c k_\sigma(\theta,p)}{4} = \frac{k_n \, {}_b k_\sigma(\theta,p)}{4} \quad (3)$$

2.2 Outline of elastic local buckling analysis with energy method

In theoretical analysis, the elastic local buckling strength with loading angle θ 0 or 45 [deg.] is evaluated by energy method. An essential factor of local buckling of rectangular hollow section column is a buckling of the plate elements so that the elastic local buckling strength of the plate elements is clarified by energy method. In this section, the part of derivation process of the buckling strength under diagonal axial bending is shown.

Figure 2 is the normal stress and shear stress distribution of the compressive plate element constituting rectangular hollow section column under diagonal axial bending. The out-of-plane displacement function of the plate element w, normal stress distribution function $f(x,y)$ and shear stress distribution function $g(y)$ are expressed as Eq. (4), (5) and (6) respectively. Variable m, n, M and N in Eq. (4) are natural numbers and k_n in Eq. (5) is the ratio of compressive stress to bending stress. When diagonal axial bending acts on the column, local buckling of both two compressive plate elements is likely to occur around the compressive edge. Thereby, the boundary condition on the compressive edge can be assumed as simple support. On the other hand, the rotation on the edge where bending stress does not occur should be restricted by the plate element of tensile side. Hence, the boundary condition on the side of neutral axis is regarded as fixed support. Thus, the boundary conditions on the three edges are assumed as fixed support and the boundary condition on the one edge is assumed as simple support when the column is subjected to diagonal axial bending. Note that these boundary conditions hold only when compressive stress is sufficiently small compared to bending stress. If compressive stress is dominant, the boundary condition of the long edge regarded as fixed support can be assumed as simple support.

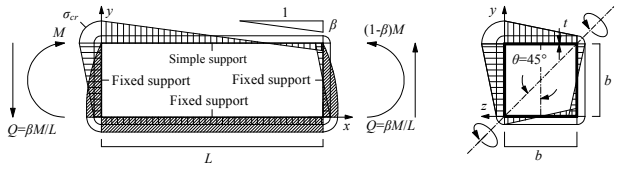

Figure 2 Normal stress and shear stress distribution of plate element under diagonal axial bending

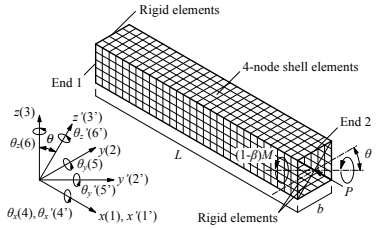
$$\begin{aligned}w = \sum_m^M \sum_n^N a_{mn} &\left\{ \cos\frac{(m-1)\pi x}{L} - \cos\frac{(m+1)\pi x}{L} \right\} \\ &\cdot \left\{ \sin\frac{n\pi y}{b} - \frac{n}{n+1}\sin\frac{(n+1)\pi y}{b} \right\}\end{aligned} \quad (4)$$

$$f(x,y) = \frac{y}{b}\frac{L-\beta x}{L} + k_n \quad (5)$$

$$g(y) = -\frac{3}{2b^2}y^2 + \frac{3}{2} \quad (6)$$

Buckling conditional expression is Eq. (7). ΔU is the strain energy and ΔT is the work done by the external forces.



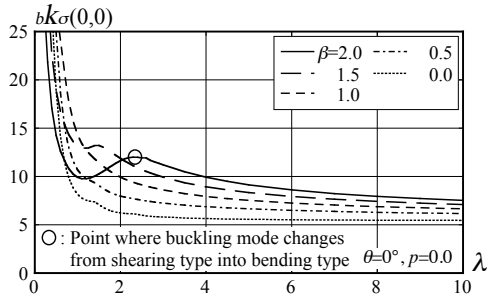
$$\frac{\partial \Delta U}{\partial a_{mn}} = \frac{\partial \Delta T}{\partial a_{mn}} \quad (7)$$

Eq. (7) is a system of homogeneous linear equations in assistant variable a_{mn}. Solving Eq. (7) as eigenvalue problem gives plate buckling coefficient.

2.2 Outline of numerical analysis with FEM

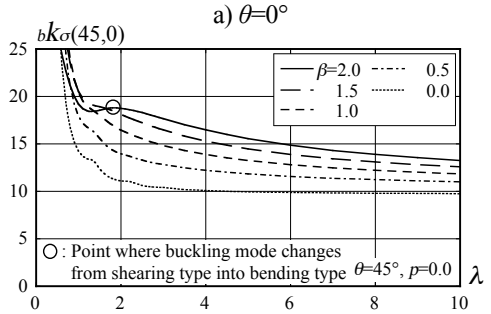
In numerical analysis, the elastic buckling stress σ_{cr} is evaluated when one end bending (β=1.0) or antisymmetric bending (β=2.0) acts on the column. Figure 3 shows the model of numerical analysis in this study. This model is mainly composed of 4-node shell elements. Rigid elements are set at the both ends of the column. The each number of axes in Figure 3 expresses degree of freedom corresponding

to the displacement and the rotation. The boundary conditions at the ends of the column are listed in the table of Figure 3. General-purpose FEM program Abaqus/Standard Version 6.8-4 is used to conduct numerical analysis in this study.



β	Boundary	Constraind degrees of freedom
1.0	End 1	1, 2, 3, 4, 5, 6
	End 2	2', 6'
2.0	End 1	1, 2, 3, 4, 5, 6
	End 2	2', 4', 5', 6'

Figure 3 Numerical analysis model

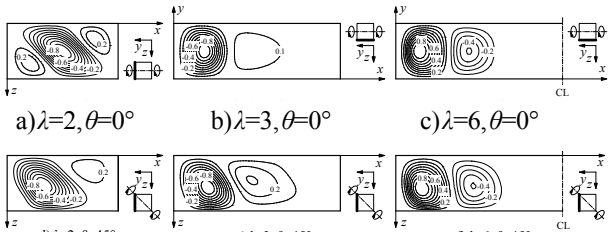


3. EVALUATION OF ELASTIC LOCAL BUCKLING STRENGTH OF RECTANGULAR HOLLOW SECTION COLUMN UNDER BIAXIAL BENDING

3.1 Evaluation of elastic local buckling strength without axial force

Figure 4 is the relationship between elastic buckling coefficient obtained by theoretical analysis and aspect ratio when rectangular hollow section column is not subjected to axial force but only subjected to biaxial bending. Figure 4 a) shows the elastic local buckling strength with the column under one axial bending and b) shows the buckling strength with the column under diagonal axial bending. The buckling coefficient corresponding to bending stress, ${}_bk_\sigma(\theta,0)$, is shown in Figure 4.

a) θ=0°



b) θ=45°

Figure 4 Effects of end moment ratio on elastic local buckling strength

According to Figure 4 a) and b), each ${}_bk_\sigma(0,0)$ and ${}_bk_\sigma(45,0)$ converges at a specific value as aspect ratio λ increases. It can be also seen that ${}_bk_\sigma(0,0)$ and ${}_bk_\sigma(45,0)$ become larger with the increase of end moment ratio β. If the column has large aspect ratio, the effect of β on the buckling strength is small. This is because the effect of shear stress on the buckling strength is small and the effect of bending stress is dominant at the large range of λ. In contrast, buckling coefficient becomes small with the decrease of λ in the small range of λ when the column is under antisymmetric bending (β=2.0). This is because the effect of shear stress on the buckling strength increases when λ decreases, compared to the effect of bending stress.

Figure 5 shows the buckling form of the plate element constituting rectangular hollow section column when the column is under antisymmetric bending (β=2.0). The buckling forms illustrated in the following figures are those of λ=2, 3 or 6 and θ=0 or 45 [deg.] when the column is subjected to the bending described on the right of each figure. The buckling form of the plate element expressed by bold line is shown in Figure 5. The elastic local buckling mode of a) is shearing type and the modes of b), c), e) and f) are bending type. The reason why buckling form of d) is close to the bending type, compared to a), is that the plate element of d) is affected by both bending and shear. As shown in Figure 5, the elastic local buckling mode of the column under antisymmetric bending changes from shearing type into bending type with the increase of λ. In Figure 4, ○ expresses the point where the local buckling mode changes when the column is under antisymmetric bending. Shearing type appears only when λ is less than 3. Therefore, the mode becomes bending type regardless of β if column has aspect ratio designed generally.

a) λ=2, θ=0° b) λ=3, θ=0° c) λ=6, θ=0°

d) λ=2, θ=45° e) λ=3, θ=45° f) λ=6, θ=45°

Figure 5 Buckling forms of plate element

Figure 6 shows the relationship between the buckling coefficient obtained by both theoretical and numerical analysis with aspect ratio. Bold lines express the results of theoretical analysis and thin lines express the results of numerical analysis. Figure 6 a) shows the buckling coefficient with the column under loading at one end (β=1.0). Figure 6 b) shows the buckling coefficient with the column subjected to antisymmetric bending (β=2.0). As shown in Figure 6 a) and b), it can be seen that the larger the angle θ is, the larger the elastic local buckling strength is. In other words, the bending stress becomes the largest when diagonal axial bending acts on the column and becomes the smallest when one axial bending acts. When the column is under

diagonal axial bending, the results of analysis with energy method are larger than the results of numerical analysis. This result indicates that the realistic boundary condition of the edge around neutral axis is not strictly fixed support.

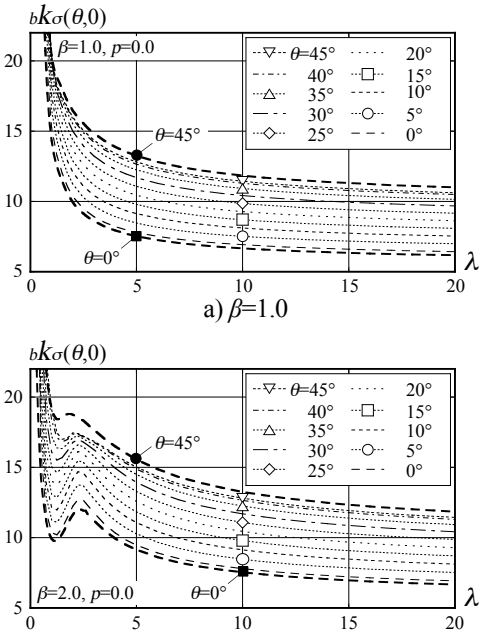


Figure 6 Effects of loading angle on elastic local buckling strength

3.2 Effects of axial force on elastic local buckling strength

Figure 7 shows the relationship between $_ck_\sigma(\theta,p)$ and $_bk_\sigma(\theta,p)$ when rectangular hollow section column is subjected to both constant axial force and biaxial bending. Variable $_ck_\sigma(\theta,p)$ is bucking coefficient corresponding to compressive stress in the column. According to Figure 7 a) and b), $_ck_\sigma(\theta,p)$ converges at a specific value with the decrease of $_bk_\sigma(\theta,p)$ regardless of loading angle θ. When variable k_n is large as possible, $_bk_\sigma(\theta,p)$ is 0.0, the convergence value is larger than 4.0. This result means that the edges of the plate elements of the column are not simply supported. It can be also seen that the larger the angle θ is, the larger the coefficient $_bk_\sigma(\theta,p)$ is while axial force ratio p is constant. Buckling coefficient $_bk_\sigma(\theta,p)$ takes maximum value when θ is 45 [deg.] and takes minimum value when θ is 0 [deg.] regardless of p.

Figure 8 shows the relationship between normalized $_ck_\sigma(0,p)$ and $_bk_\sigma(0,p)$. Plate buckling coefficient $_ck_\sigma(0,p)$ of the vertical axis is divided by the $_ck_\sigma(0,p_{max})$. Variable p_{max} is the maximum value of axial force ratio. On the other hand, $_bk_\sigma(0,p)$ of the horizontal axis is divided by the $_bk_s(0,0)$. According to Figure 8, the correlation curve of compressive stress and bending stress approaches straight line when the effect of shear stress on the column decreases.

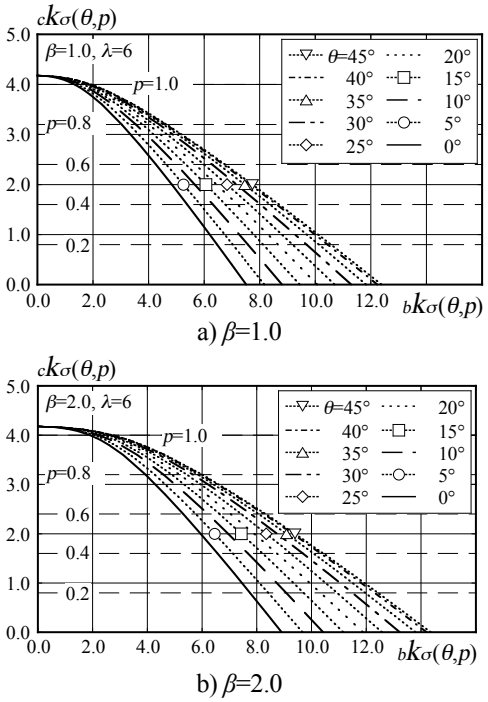

Figure 7 Effects of loading angle on interaction between compressive stress and bending stress

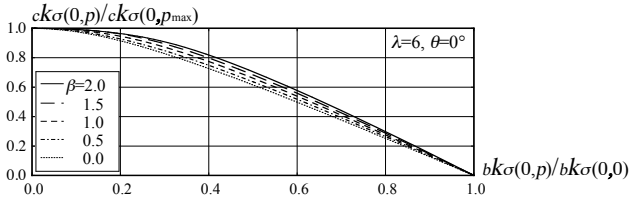

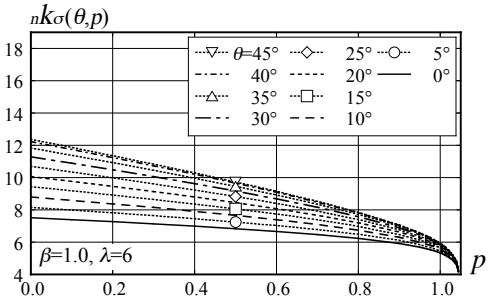

Figure 8 Effects of end moment ratio on interaction between compressive stress and bending stress

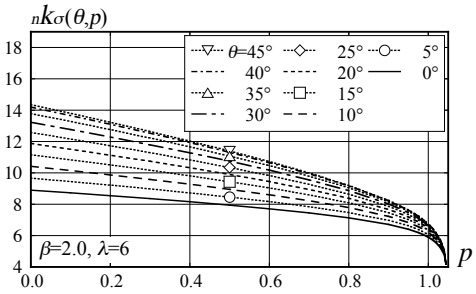

Figure 9 shows the relationship between $_nk_\sigma(\theta,p)$ and axial force ratio p. Elastic buckling coefficient $_nk_\sigma(\theta,p)$ is corresponding to the maximum value of normal stress in the member. The elastic local buckling strength of the column under both axial force and biaxial bending is indicated in Figure 9. According to Figure 9 a) and b), $_nk_\sigma(\theta,p)$ decreases when p becomes larger regardless of end moment ratio β. It can be also seen that $_nk_\sigma(\theta,p)$ becomes larger as loading angle θ increases. The buckling strength takes maximum value when the column is under diagonal axial bending and the strength takes minimum value when the column is under one axial bending regardless of p.

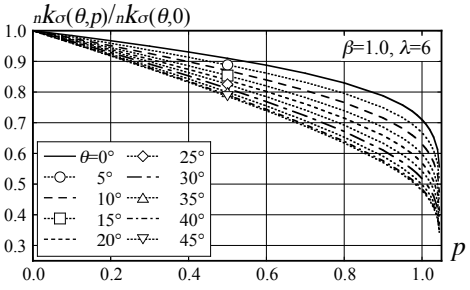
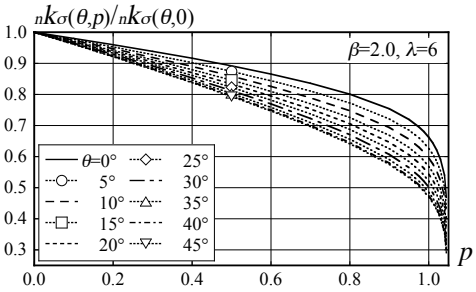
Figure 10 shows the decrease rate of the elastic local buckling strength by axial force ratio p. The vertical axis in Figure 10 is normalized buckling coefficient divided by the buckling coefficient without axial force. According to Figure 10, the decrease rate of the buckling strength by p becomes minimum when θ is 0 [deg.] and this rate becomes maximum when θ is 45 [deg.]. In particular, the buckling coefficient with the column subjected to pure compressive force is about 0.3 times as large as the buckling coefficient with the column only subjected to diagonal axial bending.

This result indicates that the buckling strength with the column under bending is larger than the strength with the column under axial force.

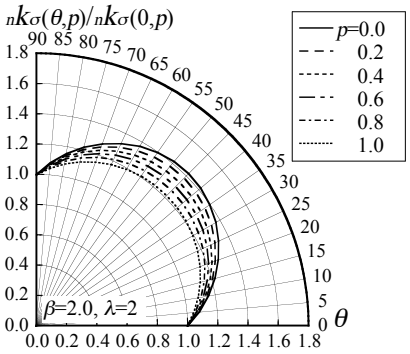


a) β=1.0

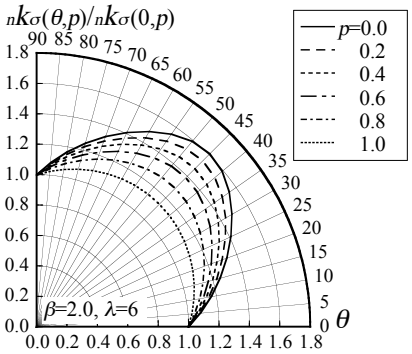


b) β=2.0

Figure 9 Relationship between elastic local buckling strength and axial force ratio



a) b=1.0



b) b=2.0

Figure 10 Decrease rate of elastic local buckling strength by axial force

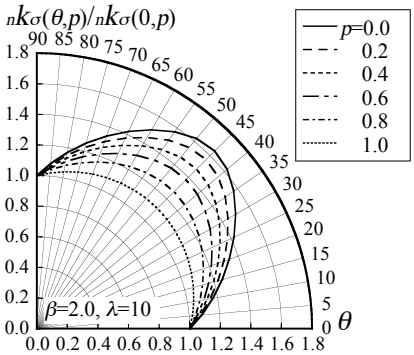


Figure 11 is the relationship between $_nk_\sigma(\theta,p)$ and loading angle θ on the polar coordinate. The radial lines in Fig.ure 11 are the normalized buckling coefficient divided by the buckling coefficient with θ=0 [deg.]. According to Figure 11, it can be confirmed that the buckling strength takes maximum when θ is 45[deg.] regardless of axial force ratio p. In particular, as shown in Figure 11 b), the buckling strength under diagonal axial bending is about 1.4 times than the buckling strength under one axial bending when p is 0.6. It can be also seen that the curve has a tendency to spread outside with the increase of aspect ratio λ. This means that the effect of θ on the buckling strength becomes larger when λ increases. In addition, the curve approaches circle with the increase of p. This means that the effect of θ on the buckling strength becomes smaller when p increases.

a)λ=2

b)λ=6

c)λ=10

Figure 11 Relationship between elastic local buckling strength and loading angle

According to Figure 12 b), although width-thickness ratio limitation decreases with the increase of axial force ratio p, the current Japanese limiting value is smaller than the calculated limitation even when p is 1.0. This indicates that the capacity of rectangular hollow section column is underestimated in the Japanese current criteria. The buckling coefficient with the column subjected to both axial force and bending is larger than the buckling coefficient with the column subjected only to axial force. In the current Japanese criteria, 4.0 is used for the value of ${}_nk_\sigma(\theta,p)$ in Eq. (8). Buckling coefficient becomes 4.0 when a plate simply supported around is under pure compressive stress. However, the realistic boundary conditions of the plate elements constituting the column are not strictly simple support. It is possible to enlarge the limiting value of width-thickness ratio if the stress distributions in the member are considered.

4. CONCLUSIONS

In this study, the elastic local buckling strength of rectangular hollow section column under biaxial bending is evaluated. In addition, the effect of each parameter on buckling coefficient is clarified:
The main conclusions are:

1. The elastic local buckling mode of rectangular hollow section column under antisymmetric bending changes from shearing type into bending type with the increase of aspect ratio. In particular, the mode becomes bending type regardless of end moment ratio if the column has aspect ratio designed generally;
2. The elastic local buckling strength becomes larger with the increase of loading angle regardless of axial force ratio. The buckling strength becomes minimum when one axial bending acts on the column and becomes maximum when diagonal axial bending acts on the column;
3. It is possible to enlarge the Japanese width-thickness ratio limit of rectangular hollow section column by considering the stress distributions in the member.

Notation

b	Width
t	Thickness
L	Length
M	Bending moment
Q	Shear force
P	Axial force
σ_{cr}	Elastic buckling stress
σ_b	Bending stress
σ_c	Compressive stress
${}_nk_\sigma(\theta,p)$	Plate buckling coefficient corresponding to normal stress with value of loading angle θ and value of axial force ratio p
${}_bk_\sigma(\theta,p)$	Plate buckling coefficient corresponding to bending stress with value of loading angle θ and value of axial force ratio p
${}_ck_\sigma(\theta,p)$	Plate buckling coefficient corresponding to compressive stress with value of loading angle θ and value of axial force ratio p
β	End moment ratio
λ	Aspect ratio
θ	Loading angle
p	Axial force ratio
k_n	Compressive stress ratio to bending stress
E	Young's module
ν	Poisson's ratio
σ_y	Yield stress
F	Design strength

Abstract: Shaking table test is great effective methods in seismic engineering field. However, shaking table tests generally conduct with small-scale frames to clear its behavior under dynamic loading because full-scale shaking table test is difficult to conduct by limit of experimental device. In small-scale test, there is the severe problem that the effect of gravity does not match the full-scale buildings by the scaling-effect, therefore, small-scale test is not corresponded to full-scale test. Our study proposes a new method of shaking table test with small-scale model that is able to overcome the scaling effect at the general experimental site. The method subsumes the concept of 'inverted shaking table'. This paper shows validly the new test method through the examination of dynamic test with single frame model.

1. INTRODUCTION

It is important to grasp the detail of collapse behavior of buildings under earthquakes in evaluation of structural safety. Shaking table test on real-scale structure is known as most effective method to achieve collapse behaviors of buildings. However, full-scale tests are able to conduct only few facilities; such as E-Defense, and cost great money and labor to execute. Full-scale tests are not easy to execute, while, small-scale tests with reduced-model are comparative easy. Small-scale test is not perfectly corresponded to full-scale test because it has some severe problems; (1) Reduced-model has quite small gravity and has less P-△ effect than real buildings (scaling effect), (2) Connection details and characteristics of section in reduced columns and beams are different from real building's, (3) The natural period of reduced model is small, therefore, it is necessary to special facilities with high-speed dynamic actuators, and the natural period of input wave needs to change. It has been not to develop a test method to overcome all these problems because it is very hard.

Our study proposes a new method of shaking table test with reduced-model that is able to overcome the problems of scaling effect and the national period between specimen and input wave. The method is based on the concept of 'inverted shaking table'. The concept is developed that shaking table test with reduced-model is able to conduct more easily and effectively in a general experimental site.

This paper shows the concept, experiment system based on the concept, and a series of dynamic test with the system.

2. TEST PROCEDURE

2.1 Inverted Shaking Table System and Specimen

Weight of reduced building model is small. It means vertical load of reduced model does not act to collapse the model as shown in Figure1. While, if vertical load as same as full-scale building is added to reduced model, the model is unstable and hard to set up in experiment system (Figure 2). Due to overcome this issue, a new experiment system (Inverted shaking table system) as shown in Figure 3 is developed.

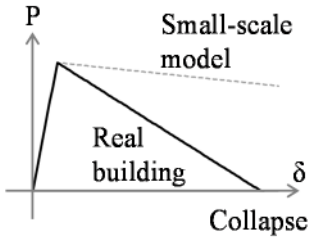

Figure 1 Difference of Behavior by P-△ effect

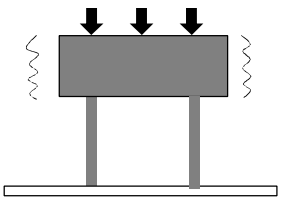

Figure 2 Unstable Model

In inverted shaking table system, specimen is set upside down at fix plate. Inertial mass of specimen connect to counter weights through a wire lope and some pulleys. This means that load from counter weights use as vertical load inputted specimen. Here, the wire lope is set not to touch other member or parts through a hole on the fix plate. Fix plate is connected dynamic actuators. This system is able to set vertical load freely by changing counter weights though initial horizontal force and the natural period keep the values. Enough height between specimen and pulley makes keeping the load from counter weights almost vertical when specimen has large deformation. Moreover, specimen is able to set with a stable position because specimen suspended to jigs.

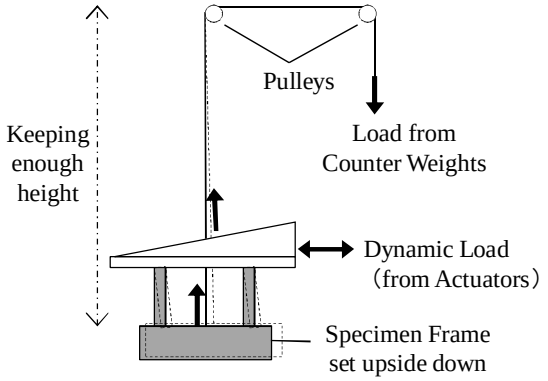

Figure 3 Inverted Shaking Table System

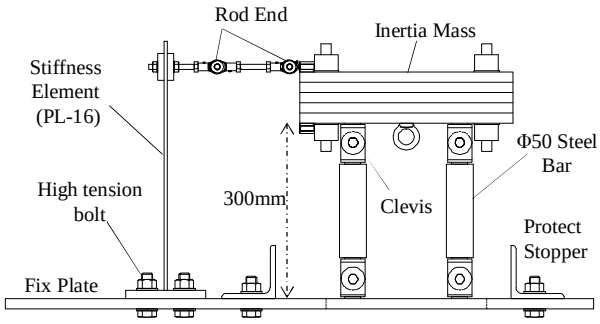
Specimen and jigs in this small-scale test shows in Figure 4. Specimen is a three-dimensional 1x1 span frame with inertia mass and four columns. All of the specimen parts in this test have weights under almost 20kgf for easy carrying. Specimen has 300mm height and inertia mass have changing from 100 to 140kg by the number of mass plate. Each column is a steel bar and the connection between column and other part is a pair of clevises due to pin joint. Stiffness of specimen is added by stiffness element which is separate to inertia mass and columns. Specimen is able to change inertia mass or stiffness, so that it is possible to shaking table test without adjusting time of input earthquake records. The connection between frame and stiffness element is made of combining some rod ends and screw bars.



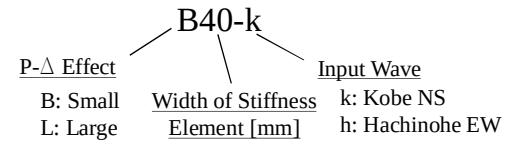


Figure 4 Detail of Specimen

Table 1 shows specimen list. Parameters of this test are the national period, vertical load for P-△ effect, and input earthquake record. The national period of each specimen is during 0.4sec to 1.2 sec due to simulate dynamic behavior of general steel building. Figure 5 shows detail of stiffness elements. The national period is set by changing width or length of stiffness elements; basic type is B40, long-period types are B40s and B60, and short-period type is B30.

W in Table 1 means vertical load given by subtracting M1 from M2. Here, M1 in Table 1 means inertia load, and M2 in Table 1 means value of counter weights. W is set two value; 392N and 588N. Input waves are JMA Kobe NS record in 1995 Kobe earthquake (Kobe NS in following) and Hachinohe EW record in1968 Tokachi-oki earthquake (Hachinohe EW in following).

Table 1 Specimen List

Stiffness Element	Specimen	Input Wave	M1 [kg]	M2 [kg]	W [N]	T_1 [sec]	Base Shear
B40	B40-k	Kobe NS	100	140	392	0.80	0.26

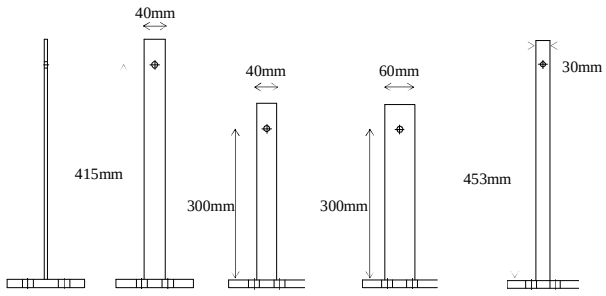

Figure 5 Stiffness Elements

2.2 Test Set-up and Measurement

Test set-up shows Figure 6 and Figure 7. Horizontal dynamic load is input by two 2,000kN actuators. Specimen is set at jig upside down, moreover, jigs and loading block are combined by PC steel bar.

Measurement in this test are follows; (1) Four accelerators ware set on the jigs and specimen for absolute acceleration, (2) Four potentiometer-type displacement transducers ware set near the jigs and specimen for absolute

horizontal displacement, (3) Two laser-type displacement transducers ware set for absolute vertical displacement, (4) Two strain gauges were glued on the stiffness element for grasping force added to stiffness element. Here, measurement is located at bilateral symmetry to loading dimension due to check torsion of specimen and backup.

Excitation list shows Table 2. In each specimen, free vibration was firstly added in order to check measurement system and measure the national period and damping factor. After the check earthquake record was input. Elastic excitation is the acceleration level that specimen was keeping within elastic area by pre-analysis. From the third excitation, earthquake record was added original, 1.25 times to original, 1.5 times to original by acceleration level. Maximum level in Kobe NS was 1.25 times as original record because spec of actuator is limited. Each excitation was finished in case that specimen collapsed

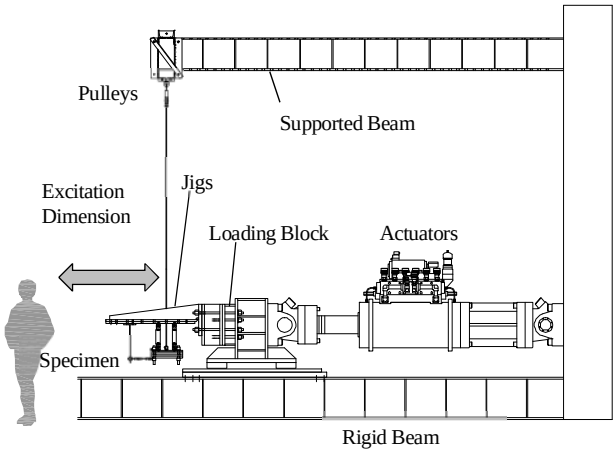

Figure 6 Test Set-up

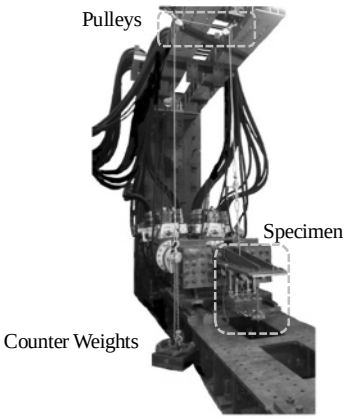

Figure 7 Specimen and Counter Weights

Table 2 Excitation List

	Kobe NS		Hachinohe EW	
	Input Level	Max. Acc.	Input Level	Max. Acc.
Free Vibration	-	-	-	-
Elastic Excitation	Kobe NS×0.1	82 gal	Hachinohe EW×0.6	107 gal

×1.25	Kobe NS×1.25	1003 gal	Hachinohe EW×1.25	224 gal
×1.5	-	-	Hachinohe EW×1.5	269 gal

3. TEST RESULTS

Figure 8 shows Fourier spectrum in order to check wheatear earthquake record was able to input in each excitation as expected. 'Expected' in Figure 8 means input wave, and 'Response' means measurement value by accelerators on jigs. The left graph shows Kobe NS x1.25, the right graph shows Hachinohe EW x1.5, vertical line in both graph shows the national period of each specimen. Response value is not corresponded to expected value at the area that the national period is around 0.1 sec or over 3.0 sec in Kobe NS, while at the area that the national period is over 5.0 sec in Hachinohe EW. However, Response value is well corresponded to expected value at the area that the national period is during 0.2 sec to 2.0 sec in both input wave.

Table 3 shows test result list. *T* and *h* in the table are each the national first period and damping factor measured at elastic excitation. *Ke* in the table is unloading stiffness at elastic excitation. *h* varied in each specimen especially B30 series, although *T* and *Ke* are almost corresponded to calculated value.

Figure 9 shows Q_h versus δ relationships. δ in the figure is relative displacement calculated by horizontal measured displacement value of jigs and specimen. Q_h is horizontal shear force as shown in Figure 10. Bending moment at the point of stiffness element (M_G) is calculated by strain gauge. According to force balance around gauge, M_G is given by Eq. (1) below:

$$M_G = Q_h \times V \pm Q_v \times h \quad (1)$$

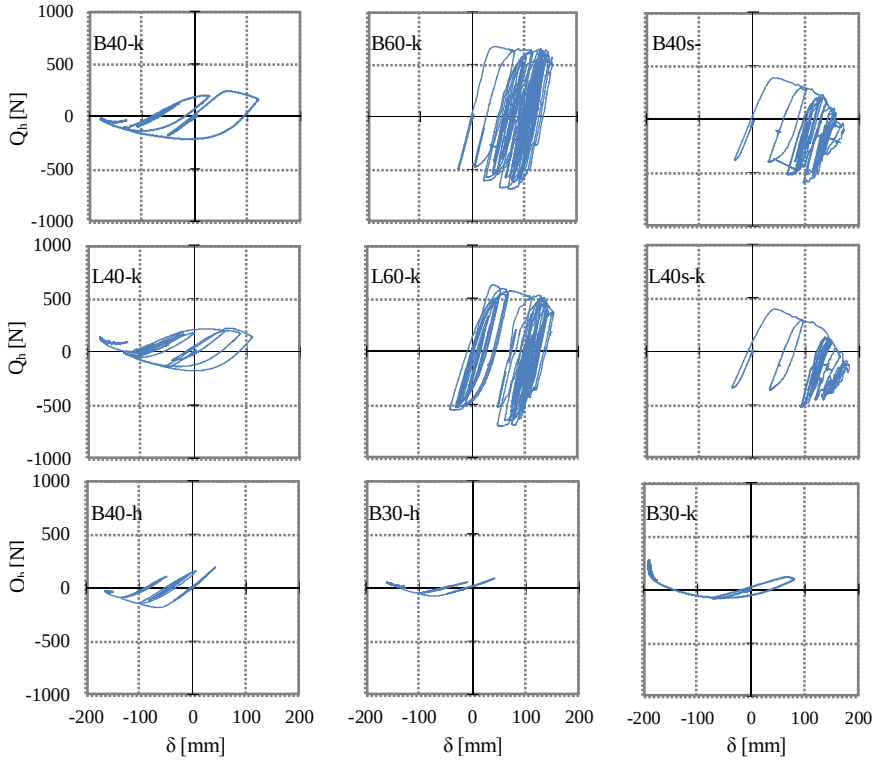

Figure 9 Q_h versus δ Relationship

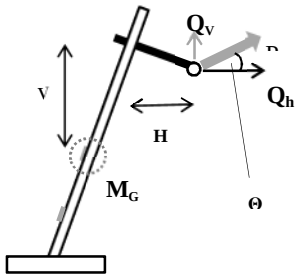

Figure 10 Force Balance around Stiffness Element

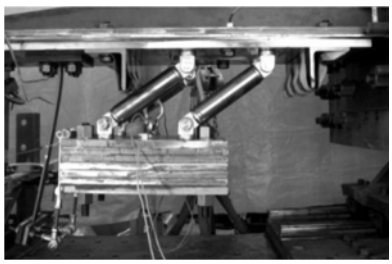

Figure 11 Collapse of B30-k

Q_h is given by Eq. (2) is changing Eq. (1);

$$Q_h = \frac{M_G}{V \pm \tan\theta \times h} \tag{2}$$

Here, the sign of *Qv* (positive or negative) in Eq. (1) changes according to displacement dimension of specimen because bending dimension caused by *Qv* is not always same to bending dimension caused by *Qh* when specimen have large deformation.

Collapse in this test is decided at the time of unloading stiffness changes negative, not to collapse perfectly by running columns into a protect stopper. The reason is that deformation of specimen is limited according that the wire lope which linked up counter weights to inertia mass touched fix plate when specimen has a large deformation. The solution of this trouble is only making longer the length of hole through the fix plate and jigs than present. This is one of our future works.

Showing Figure 9 again, specimen B40-k, L40-k, and B30-k collapsed at the excitation of Kobe NS x1.0, specimen B40-h collapsed at the excitation of Hachinohe EW x1.25. Figure 11 shows a picture after B30-k which had maximum displacement in all specimens collapsed. In this picture, collapse shows inertia mass close upper fix plate. On the other hand, specimens of B60 and B40s series did not collapse even inputting the excitation of Kobe NS x1.25 (2nd). These specimens has finished because displacement did not increase.

Figure 12 shows deformation of specimen. In case that specimen frame deformed the side of stiffness element as shown in Figure 12 (a), specimen was able to have large displacement by acting rod end and screw bar in the connection between frame and stiffness element. However,

in case that specimen frame deformed the opposite side of stiffness element as shown in Figure 12 (b), deformation of specimen was limited because the connection between frame and stiffness element stretched. Also, short stiffness elements of specimens have small horizontal deflection. This is the reason that specimens of B60 and B40s series stopped deformation without collapse.

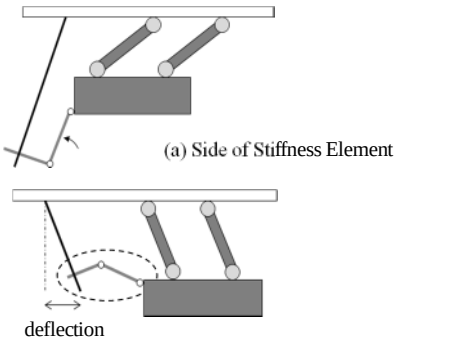

Figure 12 Deformation of Specimen

4. APPLICATIONS OF TEST RESULTS

4.1 Comparison to Response Analysis

Due to verify the test results obtained by new method of small-scale shaking table test, a series of response analysis inputting earthquake record is executed. Analysis model is single degree of freedom system and its hysteresis model is bi-linear type. Elastic stiffness of bi-linear uses the value of *Ke* as shown Table 3. Plastic stiffness (the second stiffness) k_2 and yield shear force *Qy* are calculated by way as shown in Figure 13 in each specimen. In analysis, k_2 and *Qy* of bi-linear uses average value to each k_2 and *Qy*.

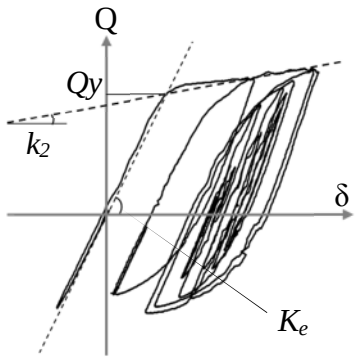

Figure 13 Modeling way of Bi-linear

Figure 14 shows some examples comparison between response analysis results and test results. Break line is shear force brought by P-△ effect. Response analysis results are almost corresponded to test results. This means new method of small-scale shaking table test is able to reproduce behavior of building under earthquake. Table 4 shows acceleration level when specimen collapsed both in analysis and shaking table test. Here, the decision of collapse in analysis is shown in Figure 15. Both specimens in shaking table test and in response analysis collapsed at almost similar excitation.

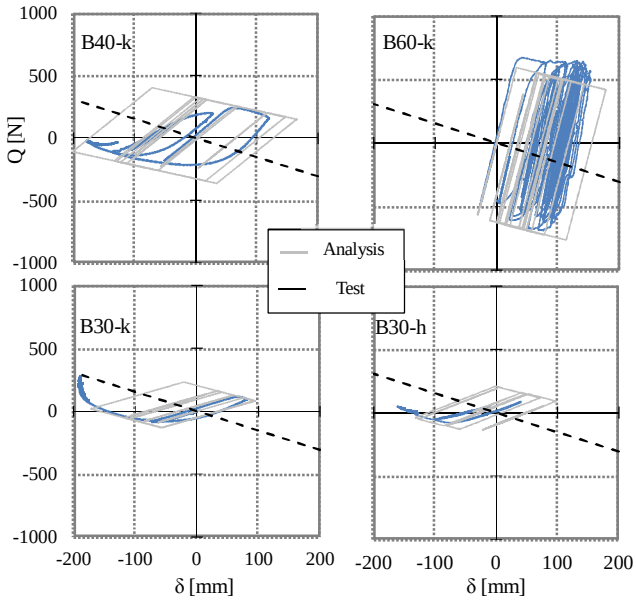

Figure 14 Comparison between Analysis and Test

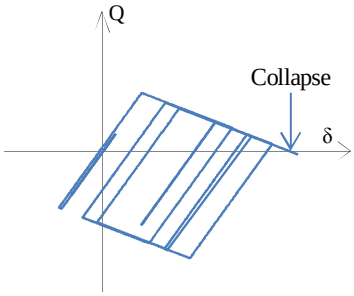

Figure 15 Definition of Collapse in Analysis

Table 4 Level when Specimen collapsed

Specimen	Response Analysis	Shaking Table Test
B40-k	Kobe NS x1.25	Kobe NS x1.0
L40-k	Kobe NS x1.0	Kobe NS x1.0
B60-k	Kobe NS x1.5	-
L60-k	Kobe NS x1.25	-
B40s-k	Kobe NS x1.0	-
L40s-k	Kobe NS x1.0	-
B30-k	Kobe NS x1.0	Kobe NS x1.0
B40-h	Not collapse even x1.5	Hachinohe EW x1.5
B30-h	Hachinohe EW x1.5	Hachinohe EW x1.25

4.2 Influence to Results caused by Vertical Load

Inversed shaking table system has a merit that vertical load is able to change with keeping the spec of specimen. In case of changing vertical load, displacement of specimen also changes by P-△ effect. Figure 16 shows comparison of displacement between B60-k and L60-k. The horizontal axis means cumulative time from excitation of Kobe NS x1.0 to the excitation of Kobe NS x1.25 (2nd). The vertical axis is horizontal relative displacement (δ). L60-k has small δ at

the excitation of Kobe NS x1.0 because damping factor of this specimen is large as already shown in Table 3. Increasing input level, δ of L60-k increases quickly and finally it exceeds δ of B60-k. This means that difference of vertical load influences directly to value horizontal displacement when specimen has large deformation.

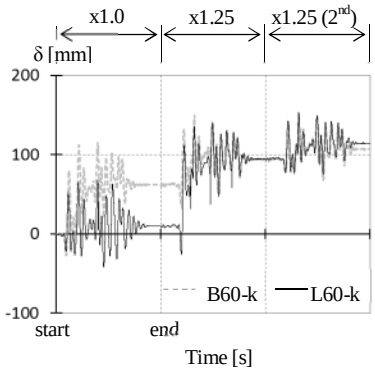

Figure 16 Comparison between B60-k and L60-k

5. SAMMARY

A new test method of shaking table system with reduced-model due to reproduce collapse behavior of buildings is proposed in this paper. Using the new method, a series of dynamic test is conducted. The important findings are follows;

1. Results of the shaking table test matches response analysis of single degree freedom model.
2. Collapse behavior by P-△ effect is able to reproduce in shaking table test with small-scale model inputting earthquake record along the real axis of time.
3. Shaking table test is able to conducted with portable parts and general experimental apparatus

On the other hand, some problems to execute test was happened. These problems are follows;

1. Deformation of some specimen was limited because wire lope and jigs are touched each other during the excitation. At last, the specimen was finished without collapsing perfectly.
2. Some specimen did not collapse because their stiffness element was not able to follow the large deformation of specimen.

The new test method will reproduce more accurate behavior of models up to collapse by improving some operative problems such as above.

NUMERICAL ANALYSIS ON PLASTIC DEFORMATION CAPACITY OF STEEL BEAM UNDER VERIOUS LOADING HISTORIES

Satoshi Yamada[1], Yu Jiao[2], and Shoich Kishiki[3]

1) Associate Professor, Structural Engineering Research Center, Tokyo Institute of Technology, Japan
2) Assistant Professor, Dept. of Architecture, Tokyo University of Science, Japan Chile
3) Lecturer, Dept. of Architecture, Osaka Institute of Technology, Japan

Abstract: Ductile fracture occurs when the steel beam reaches its ultimate plastic deformation capacity. In order to evaluate the plastic deformation capacity of beam determined by ductile fracture, it is necessary to clarify the plastic strain capacity of the beam-end flange. In this paper, the in-plane beam analysis was conducted to achieve the strain history at the fracture zone. A hysteresis model of the structural steel effective in evaluating material damage was introduced into this analysis. Moreover, loss of beam section due to the weld access holes and the local out-of-plane bending of the tube wall on the RHS column were taken into account to the analytical model. The analytical method was proved by comparing the analytical results to the experimental results from a database. The plastic strain capacity of beam-end flange till ductile fracture was evaluated by studying the analytical flange strain histories.

1. INTRODUCTION

In the 1994 Northridge earthquake and the 1995 Kobe earthquake that occurred one year later, a great deal of steel beam damage due to brittle fracture was observed. After that, many efforts have been made to prevent the brittle fracture mostly due to the lack of ductility and poor weld. However, even though the brittle fracture can be avoided during earthquakes; there is still a possibility of the flange ductile fracture, which is often observed at the beam-end. Especially in the WF composite beam connected to RHS column that is commonly used in Japan, ductile fracture occurs due to the decrease of the joint efficiency and the strain concentration on the flange.

Ductile fracture occurs when the beam reaches its ultimate plastic deformation capacity. The plastic deformation capacity of steel beams has been discussed for decades. Almost all the research work related to the evaluation of the beam's ultimate plastic deformation capacity bases on the results of steel beam tests. (Suita et.al, 1998, Jiao et.al, 2011, etc.) For different sizes of steel beam made of different types of steel, subjected to distinct earthquake effects, in order to obtain accurate evaluation results, the above mentioned beam tests must consider as many parameters as possible. The parameters of the tests should include at least the material's yield strength/ratio, the beam's moment gradient, as well as loading history. Consequently, a huge number of beams need to be tested, which is hardly reasonable. Therefore, it is necessary to find a method that can evaluate the plastic deformation capacity of the steel beams with different parameters.

In this paper, a new in-plane beam analysis method was proposed to achieve the strain history at the fracture zone. A hysteresis model of the structural steel effective in evaluating material damage was introduced into this analysis. Moreover, loss of beam section due to the weld access holes and the local out-of-plane bending of the tube wall on the RHS column were taken into account to the analytical model. The analysis is proved to be valid by comparing the analytical results to the experimental results from an experimental database. The stress-strain histories at the beam-end flanges till fracture were obtained through the analysis. By studying the strain capacity of both the skeleton curves and Bauschinger parts that were derived from the stress-strain histories, the plastic strain capacity of beam-end flange till ductile fracture was evaluated using the same evaluation method of the plastic strain capacity of the structural steel under axial strain histories

2. ANALITICAL METHOD

2.1 Assumptions

The in-plane analysis of the ideal cantilever wide-flange beams subjected to cyclic loading histories was conducted under the following assumptions:
1) The assumption of the plane section.
2) The deformation due to shear force is considered to be always elastic.
3) There is no out-of-plane deformation of the beam.
4) The beam reaches its maximum load without local buckling.

2.2 Basic algorithm

The algorithm of this analysis is based on the monotonic in-plane analy (Yamada, M. et. al. 1966). The basic idea is to obtain the moment-curvature relation (M-φ) of a certain beam section through the internal force balance under the assumption of the plane section. Additionally, the load-deformation relation (M-θ) of the beam can be derived by integrating the moment-curvature relation along the beam span. This analytic method is known to be sufficiently accurate before the beam reaches its maximum strength.

2.3 Material hysteresis model

A material hysteresis model that is effective in material damage evaluation is very important for the cyclic beam analysis in this study. A multi-linear hysteresis model of structural steel considering Bauschinger effects based on the monotonic true stress-strain relation (Yamada, S. et. al. 2002) was employed in this analysis. The hysteresis loops are made up of the skeleton curves and the Bauschinger parts. The skeleton curves are picked up from the coupon tests results (converted into the true stress-strain relation). Each fragment of the Bauschinger part is simplified as a bi-linear curve, with the requirement that the bi-linear curve dissipates approximately same amount of plastic energy as the Bauschinger part does.

2.4 Modeling of the decrease of joint efficiency

The joint efficiency of the beam web at the beam-to-column connection γ_w is defined in Equation (1) .

$$\gamma_w = \frac{{}_jM_{wu}}{M_{wu}} \tag{1}$$

where ${}_jM_{wu}$ is the maximum moment of the beam web at the connection considering the loss of the beam section and local bending of the column tube wall, $M_{wu} = \sigma_{wu} \cdot Z_{wp}$ is the ideal maximum moment of the beam web at the connection, σ_{wu} is the tensile strength of the beam web, and Z_{wp} is the plastic section modulus of the full section beam web. The calculation method of γ_w (Equations (1)) is suggested in the Japanese "Recommendation for design of connections in steel structures" (AIJ 2006).

$${}_jM_{wu} = m \cdot Z_{wpe} \cdot \sigma_{wy} \tag{2}$$

where σ_{wy} is the yield stress of the beam web, $Z_{wpe} = \frac{1}{4}(H - 2t_f - 2S_r)^2 \cdot t_w$ is the plastic section modulus of the beam web considering the loss of cross section, and m is the normalized bending strength of the beam web at the beam-to-column connection $m = \frac{{}_jM_{wu}}{M_{wp}}$, where M_{wp} is the full plastic moment of the beam web considering the loss of section due to the weld access holes. Here, m is controlled by the size of the column, beam, and the weld access holes as well as the yield strengths of the column and beam. In design, it is possible to approximate m as follows: for the RHS columns, $m = \min\left\{1,\ 4\frac{t_c}{d_j}\sqrt{\frac{b_j \cdot \sigma_{cy}}{t_w \cdot \sigma_{wy}}}\right\}$, where σ_{cy} is the yield stress of the column, H is the beam height, t_f is the thickness of the beam flange, S_r is the loss of cross section in the beam height dimension (usually the length of the weld access hole along the beam height), t_w is the thickness of the beam web, t_c is the thickness of the RHS column, d_j is the inner distance of two diaphragms, $b_j = B_c - 2t_c$ is the width of the yield area on the RHS column obtained from the yield line theory, and B_c is the width of the RHS column. In this paper, only the most commonly used steel beams with weld access holes are discussed.

In the recent monotonic beam analysis (Suzuki et.al 1999), a part of the beam web (the isosceles right triangle ABC in Figure 4) close to the column face was set to be ineffective in transferring the bending stress from the column. So that the ultimate moment (when the stress at each point of the web section equals to the ultimate strength of beam web σ_{wu}) of rest of the web cross section would be the same as ${}_jM_{wu}$ mentioned previously. h_r is the length of the ineffective area in the web along the beam height, which can be expressed in Equation (3).

$$h_r = \sqrt{1 - \frac{m \cdot \sigma_{wy}}{\sigma_{wu}}} \cdot (H - 2 \cdot t_f - 2 \cdot S_r) \tag{3}$$

Nevertheless, this method didn't consider the loss of section due to weld access holes. With the effect of the weld access holes, the ineffective area of the web should be the pentagone ADCEB. Furthermore, two rectangles at the location of the weld access holes, with the length of each side equals to S_r and the length of the weld access hole along the beam span respectively, should also be set to be ineffective in carrying the bending stress. Figure 1 shows three ineffective parts of the beam close to the column face in the analysis. Note here, shear force is carried by the net beam section without weld access holes.

Moreover, comparing with the beam flange, the strength of the diaphragms and the full-penetrated weld area is considered to be much higher. In the cyclic in-plane beam analysis, these parts were assumed to be always elastic.

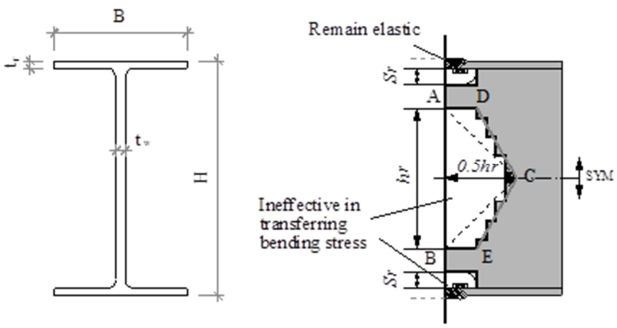

Figure 1. The ineffective area of the beam web

3. VERIFICATION OF THE IN-PLANE BEAM ANALYSIS

3.1 Experiment of steel beams subjected to various cyclic loading histories

In order to verify the analytical method introduced in Section 2, total 13 T-type beam-column subassemblies were tested under four different loading histories. (Jiao et.al (2011), Kobayashi (2005), Okada et.al (2003) and Yamada, S. et.al (2011)) Test set-up is shown in Figure 2. In the tset, load-deformation relationships and local strain histories of the flange surface close to the toe of the weld access hole were collected. The beam was shop welded onto the column via through-diaphragms with the improved type of weld access holes and solid end tab in accordance with Japanese Standard Specification JASS 6. In order to prevent local buckling, stiffeners were welded to the beams near the column faces and the loading points.

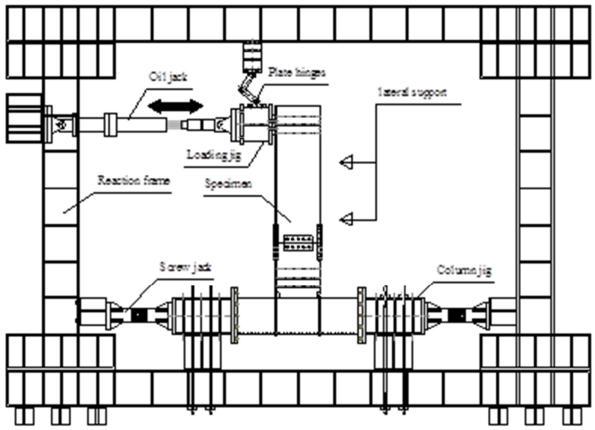

Figure 2 Tset set-up

3.2 Comparison of the experimental and analytical results

The in-plane analysis of all the steel beams specimens in the database was conducted. Figure 3 shows the example of the comparison of analytical and the experimental results of the load-deformation relations of some specimens. Two specimens from each series of the cyclic loading beam test were listed as examples. Good correspondences between the experimental and analytical results can be found from these graphs. The measurements of the plastic strain gauges on each flange are compared with the nominal analytical strain history results at the same position, shown in Figure 4. The experimental strain value of certain flange is the average value of the gauges attached on the flange.

The analytical strain histories of the beam flange match the experimental strain histories well before fracture occurred. When it comes closer to the fracture points, although relatively larger disagreement can be seen from the graph, it is still within the range of tolerable range. The disagreement observed might because of the soar of the local strain due to the sudden strain concentration at the fracture area on the flange. In addition, there is also a possibility of the existence of the measurement error from the plastic strain gauges after many loading cycles in large strain regions. Summing up the above verification, the cyclic in-plane beam analysis is effective in simulating the overall beam behavior (load-deformation relation) and local material behavior (strain history) during the loading procedure till fracture.

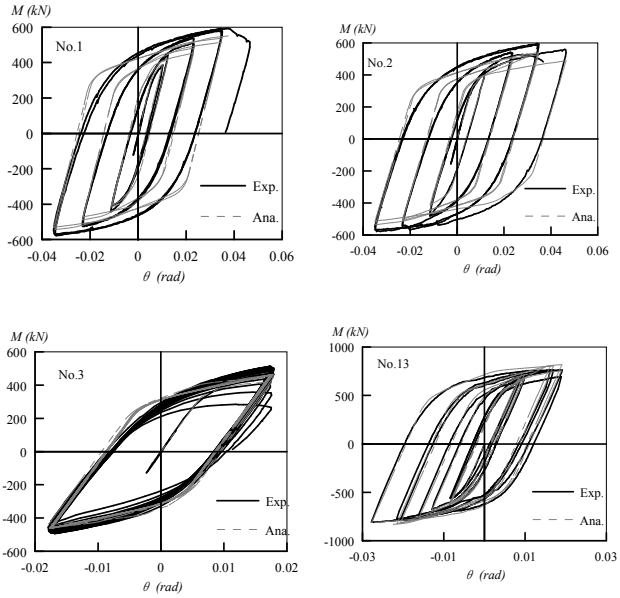

Figure 3 Comparison of the analytical and experimental results ; load-deformation relations

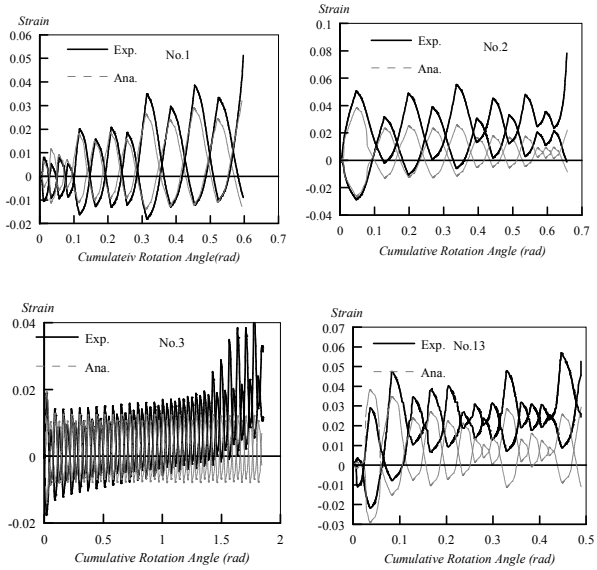

Figure 4 Comparison of the analytical and experimental results ; Strain histories

4. EVALUATION OF THE PLASTIC DEFORMATION CAPACITY OF STEEL BEAMS SUFFERING DUCTILE FRACTURE

The average surface stress-strain histories of the section at the toe of the weld access hole can be obtained from the analyses. The cumulative strain capacity of the beam flange is evaluated based on the average flange surface strain histories of the section at toe of the weld access hole through the same evaluation method of the strain capacity of structural steel mentioned (Jiao et.al, 2010) The fracture condition of steel beam-end flange subjected to random cyclic loadings is proposed in this section.

Refer to the evaluation method of the plastic strain capacity of steel material introduced in the reference (Jiao et.al, 2010), the cumulative plastic strain ratio ($\eta_S^+, \eta_S^-, \eta_B^+, \eta_B^-$) at the toe of the weld access hole on the fractured flange of each specimen was output from the analyses. Where $\eta_S^+, \eta_S^-, \eta_B^+, \eta_B^-$ are the cumulative plastic strain ratio defined as the cumulative plastic strain of both tension and compression side in the skeleton curve and Bauschinger part ($_t\varepsilon_S^+, _t\varepsilon_S^-, _t\varepsilon_B^+, _t\varepsilon_B^-$) divided by yield strain $_t\varepsilon_y$ (Equations (4)-(7)). The total plastic deformation capacity was the summation of that obtained from each part of the hysteresis loops, which can be written as $\eta_T = \eta_S^+ + \eta_S^- + \eta_B^+ + \eta_B^-$.

$$\eta_S^+ = {}_t\varepsilon_S^+ / {}_t\varepsilon_y \quad (4)$$

$$\eta_S^- = {}_t\varepsilon_S^- / {}_t\varepsilon_y \quad (5)$$

$$\eta_B^+ = {}_t\varepsilon_B^+ / {}_t\varepsilon_y \quad (6)$$

$$\eta_B^- = {}_t\varepsilon_B^- / {}_t\varepsilon_y \quad (7)$$

Here, all the values were normalized by dividing the cumulative plastic strain ratio of material test η_0, in order to eliminate the effect of different materials and steel lots.

The growing processes of η_S^+ / η_0 and η_T / η_0 of all the specimens in the database are plotted in Figure 3. The points in Figure 5 show the fracture points of the beam specimens from the database. The cumulative plastic strain ratio η_S^+ / η_0 and η_T / η_0 of the beam-end flange also shows a linear relation at the fracture point. Equation (8) expresses the linear relation. Ductile fracture of the beam flange occurs when the cumulative plastic strain ratio at the critical area satisfies this equation. Note here, since η_S^+ / η_0 is always less than η_T / η_0, the scope of Equation (8) ends when it hits the monotonic growing processes line, where $\eta_S^+ / \eta_0 = \eta_T / \eta_0$.

$$\eta_T / \eta_0 = 7 \cdot (1 - \eta_S^+ / \eta_0) - 0.5 \quad (8)$$
$$(0.22 < \eta_S^+ / \eta_0 \le 0.8125)$$

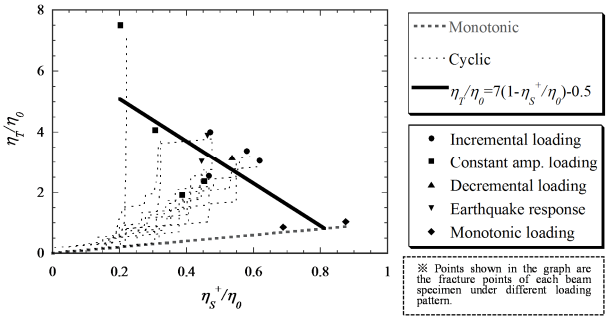

Figure 5 Growing processes of η_S^+ / η_0 and η_T / η_0

5. CONCLUSIONS

The plastic deformation capacity of the structural components till ductile fracture plays a significant role in seismic design because it is one of the indexes of structural performance. In this paper, the fracture condition of the steel beam flange was discussed by studying the average flange surface stress-strain history of the beam section at the toe of the weld access hole. The in-plane analyses of the steel beams subjected to cyclic loading histories were conducted to obtain the above mentioned average stress-strain history. A hysteresis model of the structural steel considering Bauschinger effect, which is effective in evaluating material damage, was introduced into this analysis. Moreover, the analytical model takes into account the decrease of the joint efficiency, which directly affects the strain capacity of the beam flange. By comparing the analytical load-deformation relation as well as the local strain histories to the experimental results from a database, the analytical simulation was proved to be authentic.

The plastic strain capacity of beam flange till ductile fracture was evaluated using the evaluation method. This method focuses on the relation between the cumulative plastic strain ratio of both the skeleton curves and the Bauschinger parts derived from the average beam-end flange stress-strain histories obtained in the in-plane analysis. At the fracture zone of the beam flange, there is a linear relation between the ultimate normalized cumulative plastic strain ratio of the skeleton curve on the tension side (η_S^+ / η_0) and the total normalized cumulative plastic strain ratio (η_T / η_0). Ductile fracture of the beam flange occurs when the cumulative plastic strain ratio at the critical area satisfies Equation (8).

Abstract: Buckling restrained braces (BRBs) are widely used in the world as seismic resistant and seismic energy dissipation devices. As an energy dissipation brace, one key limiting state of BRBs is governed by cumulative deformation capacity until core-plate fracture. Such capacity will always be less than that of the steel material employed. The view expressed in this paper is that the mechanism decreasing cumulative deformation capacity in the BRB is attributable to local buckling of the core plate, which leads to non-uniform strain distribution of the core plate in a longitudinal direction. This decrease in the cumulative deformation capacity of the BRB can be explained by applying the fatigue performance formula for the relevant steel material to the strain encountered at the local zone of the core plate. A ratio that compares degree of strain concentration at this localized zone with the total normalized deformation is proposed as determining the strain at the core plate local zone relative to total normalized deformation. In addition, the effect of the exponential value of the fatigue performance formula on methods for predicting cumulative deformation capacity of the BRB is investigated.

1. INTRODUCTION

Buckling restrained braces (BRBs) are widely used as seismic resistant and energy dissipation devices. As an energy dissipation brace, one key limiting state of BRBs is determined by cumulative deformation capacity until the core plate fractures. The BRB's capacity for stable dissipation of energy when its restraint conditions are satisfied allows for absorption of seismic energy. This absorption eventually leads to fracture of the BRB. Since BRBs are generally designed to avoid fracture during seismic events, determining cumulative capacity for energy dissipation proves crucial in evaluating performance and in assessing any needed replacement.

Several researchers have confirmed that the core plate of the BRB undergoes a high-mode buckling deformation that leads to non-uniform strain distribution. In particular, Takeuchi and Hajjar, et al., (2010) studied such high-mode buckling of the core plate in BRBs.

Cumulative deformation capacity of the BRB itself is most generally evaluated directly, using the Manson–Coffin fatigue formula to resolve fatigue performance in BRBs. However, cumulative deformation capacity should be evaluated initially by applying the fatigue performance formula to the strain concentration zone in the steel material of the core plate itself.

In this paper, the mechanism that decreases cumulative deformation capacity of the BRB— other than steel material specifications— is sought in examination of local buckling of the core plate. This buckling leads to non-uniform strain distribution of the core plate in a longitudinal direction. This, in turn, causes a plastic strain concentration in the localized zone. Decrease in the cumulative deformation capacity of the BRB is accounted for by applying the fatigue performance formula for steel material to the strain at the local zone. A ratio comparing strain concentration degree at the local zone with the total normalized deformation is proposed to differentiate strain at the local zone from the total normalized deformation. Finally, the cumulative deformation capacity of the BRB is evaluated using the local zone strain already calculated from the total normalized deformation.

In addition, the effect of the exponential value of the fatigue performance formula on the methods for predicting cumulative deformation capacity of the BRB was investigated.

2. FATIGUE FORMULA FOR BRB

From various past experiments on BRBs, Takeuchi and Ida, et al., (2008) proposed the following low-cycle fatigue formula for the BRB as Eq. (1):

$$\Delta\varepsilon_n = 0.5 \cdot N_f^{-0.14} + 54.0 \cdot N_f^{-0.71} \quad (1)$$

Here, $\Delta\varepsilon_n$ is the normalized deformation amplitude, and N_f is the fracture cycle number. In addition, the results of Takeuchi and Shirabe, et al., (2006) have been employed in

Eq. (1) to obtain Eq. (2.2) for a fracture cycle number of less than 20.

$$N_f = \left(1 - \frac{3\Delta\varepsilon_n}{70}\right) \cdot \left(\frac{\Delta\varepsilon_n^{-1.41}}{3.63\times10^{-3}}\right) + 0.75 \qquad (2)$$

This modification expresses a partial concentration of plastic strain in the core plate at ultra-low fatigue failure zones, where stress exceeds maximum value and the tangent modulus becomes negative. The fatigue formula for a BRB derived jointly from Eqs. (1/ 2) is consistent with results based on the experimental data from Nakamura and Takeuchi, et al., (2000), as shown in Figure 1. In this figure, the fatigue performance of the BRB will be less than the fatigue performance of the steel material determined on the basis of the normalized deformation amplitudes given by Eq. (3)

$$\begin{cases} \Delta\varepsilon_n = 0.74N_f^{-0.11} + 35.0N_f^{-0.47} & (\mathrm{SS400}) \\ \Delta\varepsilon_n = 0.47N_f^{-0.087} + 33.0N_f^{-0.48} & (\mathrm{LY100}) \\ \Delta\varepsilon_n = 0.88N_f^{-0.14} + 72.0N_f^{-0.55} & (\mathrm{LY225}) \end{cases} \qquad (3)$$

3. STRAIN CONCENTRATION AT CORE PLATES

Takeuchi and Suzuki, et al., (2006) have proposed an index of strain-concentration-ratio for ordinary circular tube braces, whereby the local strain at the point of plastic strain concentration is divided by the normalized deformation. The strain concentration ratio is defined by individual specification of each brace. This index enables one to estimate local plastic strain without significant calculation, such as arise from use of the finite element method. Brace fracture is then simply defined by the point at which local strain value becomes equivalent to the fatigue formula for the steel material. Therefore, this method efficiently assesses brace fracture using a macro-model of the braces in question. In this paper, the authors have attempted to evaluate BRB fracture using a similar method.

In our study, the BRB is constituted by a plane steel core plate restrained by a mortar filled steel tube, as shown in Table 1 and in Figures 2 and 3. The mechanical property of SN400 is assumed to be same as that of SS400. Hypothetically, the core plate exhibits a high-mode local buckling deformation continuously within the clearance between the core plate and the restrainer s under cyclic loading. In such case, the local buckling deformation y is calculated from the half amplitude of the local buckling wave l_p as Eq. (4).

$$\begin{cases} y = s\sin\left(\pi x / l_p\right) \\ s = s_0 + 0.5\nu_p\varepsilon_{ntm}t_c \end{cases} \qquad (4)$$

Here, ε_{ntm} is the maximum value of normalized tensile deformation, and s_0 is the initial value of the clearance between core plate and restrainer. Although local buckling occurs both in- and out-of-plane, only the latter is considered

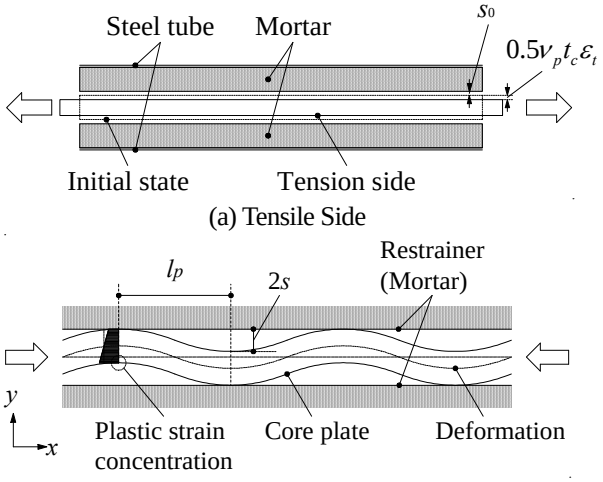

Figure 3 Core Plate Deformation

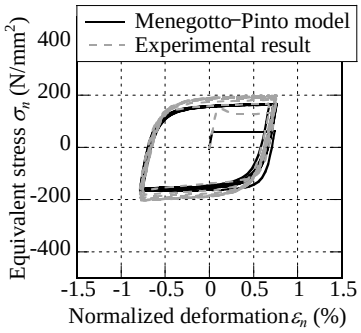
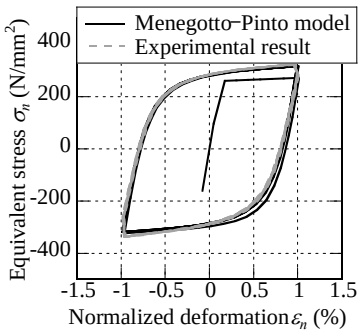
initially. The half amplitude of the local buckling wave l_p is calculated as Eq. (5),

$$l_p = \pi t_c \sqrt{E_t / 3\sigma_{cy}} / 2 \tag{5}$$



where t_c represents thickness of the core plate, σ_{cy} yield stress of the core plate, and E_t the tangent modulus of the steel material. The stress–strain hysteresis curve can be modeled by the modified Menegotto–Pinto model, as proposed by Yamazaki and Kasai, et al., (2006). The hysteresis curve calculated using the Menegotto–Pinto model is consistent with the experimental results obtained by Nakamura and Takeuchi, et al., (2000) as demonstrated in Figure 4. Here, ε_n is the normalized deformation, while σ_n is the equivalent stress calculated by dividing axial force by initial sectional area. The amplitude of the normalized deformation $\Delta\varepsilon_n$ is defined as Eq. (6), as shown in Figure 5.

$$\Delta\varepsilon_n = \varepsilon_{ntm} - \varepsilon_n \tag{6}$$



The tangent modulus E_t is directly calculated using the proposed Menegotto–Pinto model. Here, for ease, the tangent modulus is approximated by the normalized deformation function as Eq. (7), illustrated in Figure 6.

$$E_t = \begin{cases} \begin{cases} -3.68\times10^5\,\Delta\varepsilon_n + E(\mathrm{SS400}) \\ -1.12\times10^5\,\Delta\varepsilon_n + E(\mathrm{LY100}) \quad \left(0 \le \Delta\varepsilon_n \le 2\varepsilon_y\right) \\ -4.84\times10^5\,\Delta\varepsilon_n + E(\mathrm{LY225}) \end{cases} \\ \begin{cases} 6.45\times10^3\,\Delta\varepsilon_n^{-2.04} + E(\mathrm{SS400}) \\ 1.27\times10^3\,\Delta\varepsilon_n^{-1.84} + E(\mathrm{LY100}) \quad \left(2\varepsilon_y \le \Delta\varepsilon_n\right) \\ 1.93\times10^3\,\Delta\varepsilon_n^{-2.65} + E(\mathrm{LY225}) \end{cases} \end{cases} \tag{7}$$

The local buckling deformation gives the bending strain ε_b as in Eq. (8).

(c) LY225

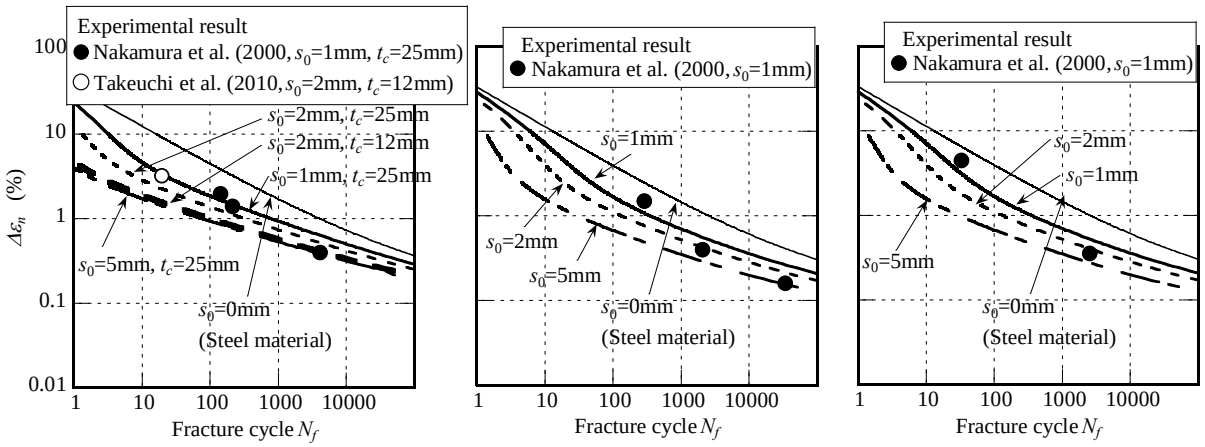
Figure 6 Tangent Modulus of Core Plate

$$\varepsilon_b = t_c/2\left(\pi/l_p\right)^2 s = 6s\sigma_{cy}/E_t t_c \tag{8}$$

The geometrical deformation ε_g is additional to the normalized deformation ε_n as in Eq. (9).

$$\varepsilon_g = 1/4\left(\pi s/l_p\right)^2 = 3s^2\sigma_{cy}/E_t t_c^2 \tag{9}$$

The local strain amplitude $\Delta\varepsilon_h$ at the point at which the most concentrated plastic strain occurs in the core plate is calculated using Eq. (10), and strain concentration ratio is α_c as defined by Eq. (11).



$$\Delta\varepsilon_h = \Delta\varepsilon_n + \varepsilon_b - \varepsilon_g \tag{10}$$

$$\alpha_c = \frac{\Delta\varepsilon_h}{\Delta\varepsilon_n} = \frac{\Delta\varepsilon_n + \varepsilon_b - \varepsilon_g}{\Delta\varepsilon_n} \tag{11}$$

Local in-plane strain may also be calculated using Eqs. (6) ~ (10) by substituting the thickness of the core plate t_c for the width of the core plate B_c. The local in-plane strain is generally one eighth (1/8) the local strain out-of-plane. Moreover, maximum strain positions do not necessarily coincide in- and out-of-plane. Therefore, the effect of in-plane local buckling generally does not significantly affect cumulative deformation capacity of a BRB, so that out-of-plane strain is considered as predominant overall.

4. EVALUATION OF CUMULTAIVE DEFORMATION CAPACITY

A BRB fracture can be established as the point at which local strain— calculated from normalized deformation ε_n and multiplied by strain concentration ratio α_c— is consistent with the fatigue formula given in Eq. (3). Using this evaluation method, the BRB fatigue formula may be assessed as shown in Figure 7. The plots in this figure show experimental results derived from Nakamura and Takeuchi, et al., (2000) and Takeuchi and Ohyama, et al., (2010). This fatigue formula is by and large consistent with experimental results. Here, strain amplitude derived from experimental results using random amplitudes is assessed by the rain-flow method as the average plastic strain amplitude, and cumulative plastic strain is the sum of all plastic strains. The initial clearance between the core plate and the restrainer s_0 is set at 1 mm in Nakamura and Takeuchi, et al., (2000) and at 2 mm in Takeuchi and Ohyama, et al., (2010). Figure 7 demonstrates that performance given by the BRB fatigue formula decreases as the clearance s between core plate and restrainer increases. Therefore, the strain-concentration-ratio

(a) SS400 (b) LY100 (c) LY225

Figure 7 BRB Fatigue Formulas Based on Eqs.

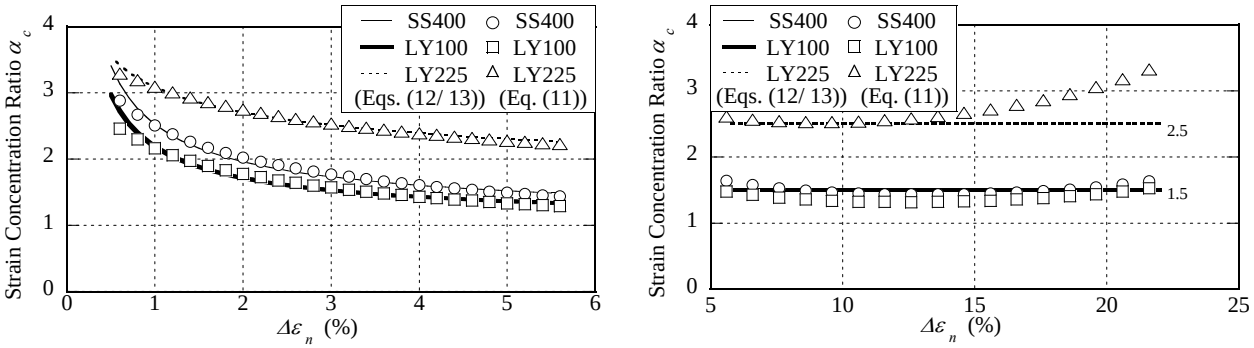


Figure 8 Strain Coefficient Ratio

α_c of a BRB may be described as a function of clearance s. For example, the strain-concentration-ratio α_c is approximated as in Eqs. (12/ 13) by the least squares method, as shown in Figure 8, where ε_y is the yield strain and $\Delta\varepsilon_{low}$ the strain amplitude, when the fracture cycle number is 20.

$$\alpha_c = \frac{\Delta\varepsilon_h}{\Delta\varepsilon_n} = \begin{cases} 1 & \left(\Delta\varepsilon_n \le 2\varepsilon_y\right) \\ 1+25\dfrac{s}{t_c} f\left(\Delta\varepsilon_n\right) & \left(2\varepsilon_y \le \Delta\varepsilon_n \le \Delta\varepsilon_{low}\right) \\ 1+25\dfrac{s}{t_c}\beta & \left(\Delta\varepsilon_{low} \le \Delta\varepsilon_n\right) \end{cases} \quad (12)$$

$$\begin{cases} f\left(\Delta\varepsilon_n\right) = \begin{cases} 1.90\Delta\varepsilon_n^{-0.62} & (\text{SS400}) \\ 1.51\Delta\varepsilon_n^{-0.64} & (\text{LY100}) \\ 2.82\Delta\varepsilon_n^{-0.35} & (\text{LY225}) \end{cases} \\ \beta = \begin{cases} 0.5 & (\text{SS400}) \\ 0.5 & (\text{LY100}) \\ 1.5 & (\text{LY225}) \end{cases} \end{cases} \quad (13)$$

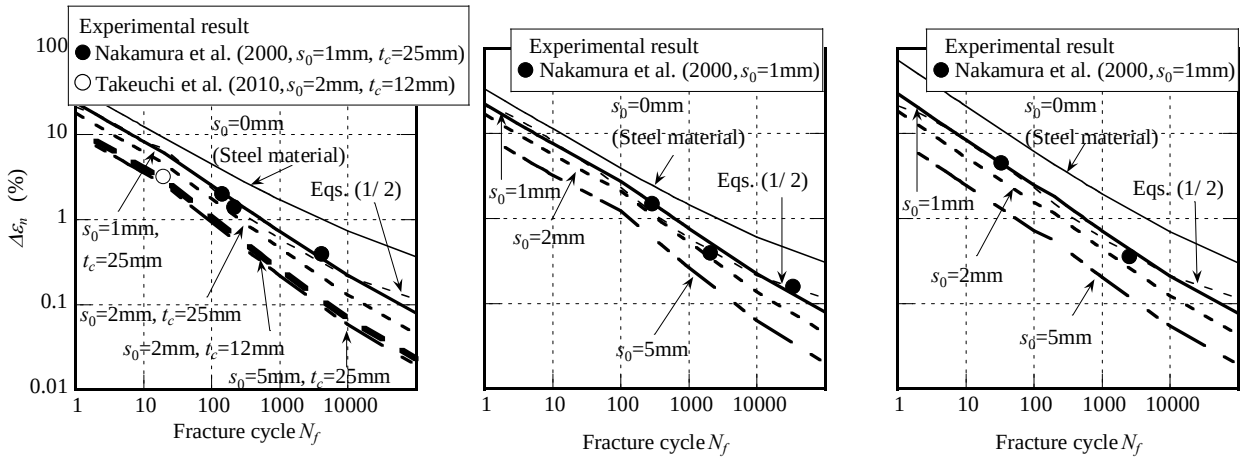
In Figure 9, Eqs. (12/ 13) are compared with behaviour of restrainers, which is generally consistent with our test results.

5. DAMAGE INDEX ASSESSMENT

The fatigue evaluation of BRBs was originally based on constant stress amplitudes. Conversely, the amplitude of the response of each member subjected to seismic input is random. In such a case, stress amplitude distribution is generally determined by the rain-flow method.

As an approach to applying the fatigue formula under random amplitude, as in Eq. (3), Miner (1945) defined a fatigue condition based on Eq. (14). Here, as soon as the cumulative damage factor of individual amplitude reaches 1.0, the element is considered as exhibiting fatigue failure.

$$D = \sum_{i=1}^{m} D_i = \sum_{i=1}^{m} \frac{n_i}{N_{fi}} \quad (14)$$



Here, D is the damage factor, n_i the number of cycles for the strain amplitude, and N_{fi} the number of failure cycles for a given strain amplitude. Additionally, Takeuchi and Ida, et al., (2008) proposed a method whereby average plastic strain amplitude is applied to fatigue failure conditions, as performed in evaluation in the previous section. In this section, the difference between Miner's rule and average plastic strain amplitude is discussed. The number of fracture cycles is defined for average plastic strain amplitude by Eq. (15).

$$\overline{N_f} = \left(\frac{\overline{\Delta\varepsilon_p}}{C_2}\right)^{-\frac{1}{m_2}} \quad (15)$$

Here, $\overline{\Delta\varepsilon_p}$ is the average plastic strain amplitude, and C_2 and m_2 are exponential values of the fatigue formula within the range of the plastic region. Cumulative plastic strain is calculated as in Eq. (16).

$$\sum \overline{\Delta\varepsilon_p} = 2\cdot\overline{N_f}\cdot\overline{\Delta\varepsilon_p} = \frac{2\cdot\overline{\Delta\varepsilon_p}^{\frac{m_2-1}{m_2}}}{C_2^{-m_2}} \quad (16)$$

Conversely, cumulative plastic strain calculation by applying Miner's rule is shown as Eq. (17)

(a) SS400 (b) LY100 (c) LY225

Figure 9 BRB Fatigue Formulas Based on Eqs.

$$\begin{cases} \sum \overline{\Delta\varepsilon_p} = 2\sum_{i=1}^{m} n_i \Delta\varepsilon_p \\ \sum_{i=1}^{m} \dfrac{n_i}{N_{fi}} = 1 \end{cases} \tag{17}$$

When the exponential value m_2 = 1.0, Eq. (16) will be identical to Eq. (17), with both evaluations perfectly consistent. Thus, the difference between evaluations must rely on the exponential value m_2.

To investigate the influence of the exponential value m_2, seismic response analysis results obtained by Takeuchi and Miyazaki (2006) were used. The analysis model was a 15-story, rigid BRB frame. For seismic-wave input, BCJ-L2, El Centro NS, Hachinohe EW, Taft EW, and JMA Kobe NS were applied. Maximum velocities for these seismic wave inputs were normalized at 75 cm/s. The ratio of the stiffness of the frame to that of the BRB was 1.0. BRB core plate material was LY225.

Figure 10 displays damage factors calculated using Miner's rule with average plastic strain amplitude; Figure 11 shows their ratios, indicating that damage factors increase as the exponential value m_2 decreases from 1.0. From Eq. (1) we see the exponential value m_2 is 0.71, and the damage factor calculated using Miner's rule is approximately 1.2 times that calculated using average plastic strain amplitude. Takeuchi and Ida (2008) reported that the damage factor calculated using average plastic strain amplitude affords a degree of accuracy better than that calculated by Miner's rule— and easier to evaluate, as it does not require individual amplitudes. To obtain the results of this study, the present authors have taken average plastic strain amplitude as an index for evaluating cumulative deformation capacities of BRBs under the strain of random amplitudes in preference to applying Miner's method.

6. CONCLUSIONS

In this paper, the cumulative deformation capacity of BRBs is assessed using steel materials fatigue formula and mechanical models. In addition, evaluation of damage factors regarding such material under random amplitudes through seismic response analysis is discussed. Conclusions are here summarized in the following statements:

1) Strain-concentration-ratios of BRBs may be attributable to a mechanism that reveals high-mode local buckling as it occurs in the clearance between core plate and restrainer.
2) The fatigue formula for a BRB evaluated from strain-concentration-ratio shows the clearance affecting the cumulative deformation capacity of a BRB, which in turn explains the test results.
3) The damage factors for steel materials calculated by Miner's rule slightly increases from those calculated using average plastic strain amplitude, as the exponential value of the fatigue formula decreases from 1.0.

Abstract: This paper discusses the development of empirical formulations for modeling the post-buckling behavior and fracture of three main steel brace shapes (HSS, round HSS and W-shapes). These formulations are based on extensive calibrations of a state-of-the-art fiber-based steel brace model. The calibration process is based on an optimization scheme that utilized several hundreds of monotonic and cyclic tests on steel braces that have been conducted worldwide during the last 40 years and have been assembled into a steel brace database. The utilization and importance of the predictive formulations is demonstrated through a case study of a 2-story special concentrically braced frame (SCBF). Its seismic performance is assessed through collapse due to P-Delta effects accelerated by structural component deterioration due to cyclic loading. Emphasis is placed on the reserved capacity of the SCBF once its steel braces fracture and structural damage is concentrated in local stories. This is particularly important in the case of major aftershocks once the primary lateral resisting system of SCBFs is severally damaged.

1. INTRODUCTION

Performance-Based Earthquake Engineering (PBEE) necessitates the use of advanced simulation models to compute engineering demand parameters of frame buildings subjected to earthquakes. The input parameters of such models need to be calibrated with large sets of experimental data for reliable computed dynamic response predictions. In the case of steel braced frames, the need for a comprehensive set of data that will allow to realistically model the post-buckling behaviour and fracture due to low cycle fatigue of various shapes of steel braces is evident.

Tremblay (2002) and Lee and Bruneau (2005) compiled a partial dataset of 76 and 66 specimens, respectively. However, these datasets were employed (1) to assess the expected post-buckling compressive resistance of steel braces at different compression ductility levels; (2) to quantify the extent of hysteretic energy dissipation achieved by braces in compression and (3) to develop regression equations that estimate the out-of-plane rotation of rectangular Hollow Structural Section (HSS) braces to fracture. None of these datasets was employed for the development of modelling parameters that control post-buckling behaviour and fracture initiation due to low cycle fatigue. More recently, Hsiao et al. (2012b) compiled a dataset of 44 rectangular HSS sections. They developed a strain-based analytical model that is able to simulate the buckling capacity and post-buckling response of Special Concentrically Braced Frames (SCBFs). However, to the best of our knowledge, there is no information for round HSS and W-shape steel braces.

This paper discusses the development of predictive equations for comprehensive modelling of post-buckling behaviour and fracture due to low cycle fatigue of HSS, round HSS and W-shape steel braces that are commonly used in modern steel construction of CBFs designed in highly seismic regions. These equations are developed based on several hundreds of monotonic and cyclic tests on steel braces that were conducted as part of 24 different experimental programs in Japan, U.S., Canada and Europe that are briefly summarized herein. The utilization of these relationships is demonstrated through a case study of a 2-story SCBF designed in urban California. The reserved capacity of the SCBF is quantified once the steel braces fracture through incremental dynamic analysis from the onset of damage to collapse.

2. FIBER-BASED INELASTIC BRACE MODEL

The inelastic brace model developed by Uriz (2005) is employed herein in order to develop modeling guidelines for simulating the post-buckling behaviour and fracture of steel braces. This model is employed in the OpenSees simulation platform (McKenna 1997). In brief, the brace component model, which is shown in Figure 1, is divided into eight segments in order to represent well the local strains and stresses of a steel brace. The brace cross section is discretized into fibres (see Figure 1). Depending on the cross

section, a different discretization process is employed. A uniaxial stress-strain formulation is assigned to each one of the fibre elements. This formulation is described with the Menegotto-Pinto model (see Figure 1). Global buckling is captured with an initial camber, which is assigned at the mid-length of the steel brace (see Figure 1). Based on a sensitivity study with a number of different steel brace shapes, an initial camber of 0.1% of the brace length was found to adequately capture the flexural buckling local of a brace regardless its shape. This agrees with earlier studies by Uriz (2005). The out-of-plane flexibility and bending strength of the gusset plates is simulated with the zero-length spring, whose hysteretic behaviour is controlled with the proposed model by Hsiao et al. (2012a). Note that the modeling approach discussed herein is only applicable for steel braces that fail at their mid-length due to inelastic buckling and fracture due to low cycle fatigue at the same location. Steel braces that fail at their end locations due to premature net section fracture are not covered as part of this investigation.

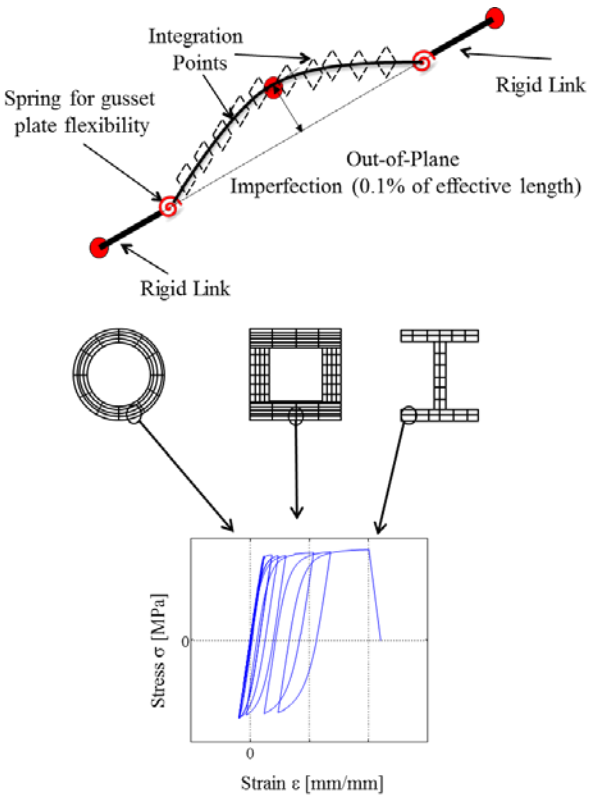

Figure 1 Description of the steel brace component model

Fracture due to low cycle fatigue is simulated with the Fatigue material model (Uriz 2005), which is available in the OpenSees simulation platform. This model is based on a linear strain accumulation rule based on a Coffin-Manson relationship (Manson, 1965) in the logarithmic domain:

$$\varepsilon_i = \varepsilon_0 (N_f)^m \quad (1)$$

In this equation, ε_0 is a material parameter that indicates the strain amplitude ε_i at which one complete cycle of an undamaged material will cause fracture. The coefficient m is a material parameter that relates the sensitivity of the total strain amplitude of the material to the number of cycles to fracture N_f. Fracture is initiated according to a modified rain-flow-counting rule based on Miner's rule that was developed by Uriz (2005). The modeling approach is summarized in Karamanci and Lignos (2012) and in Lignos et al. (2012).

3. STEEL BRACE DATABASE FOR INELASTIC MODEL CALIBRATION

The calibration process of the inelastic model discussed in Section 2 is facilitated with the utilization of a steel brace database that includes 317 steel braces of different geometries, materials and testing procedures. A total of 158 HSS, 65 W-shape, 55 round HSS, 37 angle and channel sections and 2 T sections are included in the database. These braces have been fabricated from 14 different material grades that are used in the U.S., Canada, Japan and Europe. Figure 2 shows the normalized buckling load versus slenderness based on the measured yield stress of each steel brace (noted λ_m) for the four classes of steel braces per CSA-S16-09 (2009) compactness criteria. The slenderness parameter λ_m as defined in the equation:

$$\lambda_m = \frac{kL}{r}\sqrt{\frac{F_{y,m}}{\pi^2 E}} \quad (2)$$

In this equation, k is the effective length factor, L is the centerline length of the brace, r is the radius of gyration of the steel brace cross section in the plane of buckling, E is the modulus of elasticity and $F_{y,m}$ is the measured or expected yield stress of the steel material. From this figure, the majority of the steel braces are distributed well within the design buckling loads by CSA-S16-09 (2009). Extensive details regarding the steel brace database are summarized in Karamanci and Lignos (2012).

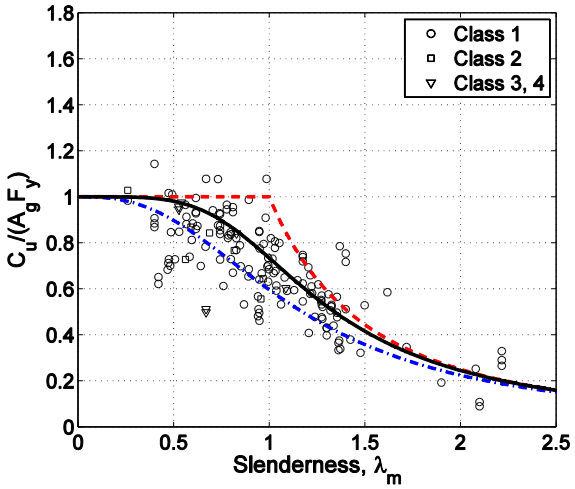

Figure 2 Normalized buckling load versus slenderness based on measured yield category by ductility classes

3.1 Optimization-Based Calibration Process

The input parameters of the hysteretic response of the inelastic model discussed in Section 2 is calibrated with the experimental data that was assembled as part of the steel brace database discussed in this section.

Several considerations were employed for the qualification of steel braces to be used as part of the calibration process of the inelastic steel brace model. Emphasis is placed on steel braces that experience fracture due to low cycle fatigue at their mid-span, where a plastic hinge occurs. Steel braces that experience net section failures are not part of this investigation. Another consideration is related with the brace slenderness ratio, *kL/r*. In particular, steel braces that fail the slenderness limit for axially loaded members, $kL/r < 200$ (see AISC-360-10 2010, CISC 2010) are not considered as part of the calibration process. An optimization scheme was developed to calibrate the input parameters of the inelastic steel brace model discussed in Section 2. To facilitate this process, an interactive interface was developed in MATLAB programming language. This interface was linked with the OpenSees simulation platform (McKenna 1997). In order to calibrate the two parameters ε_o and m of Eq. (1) that control the fatigue life of a steel brace, the Mesh Adaptive Search Algorithm was employed since the objective function (see Eq. 3) is non-differentiable:

$$H(\varepsilon_o, m) = \sqrt{\sum_{i=1}^{N}\left[F_{\exp.}(\delta_i) - F_{simul.}(\delta_i)\right]^2} \tag{3}$$

From the above equation, the objective function H is the square root of the sum of the squares of the differences between the simulated $F_{simul.}$ and experimentally measured $F_{exp.}$ axial force of the brace for each axial displacement δ_i (total of N points) of the testing loading protocol. Specific details regarding the optimization algorithm and its constraints are summarized in Karamanci and Lignos (2012). Figure 3 shows a successful calibration using this optimization scheme. Note that the parameter m can be treated as constant and equal to -0.3. This assumption agrees with earlier findings by Ballio and Castigliori (1995).

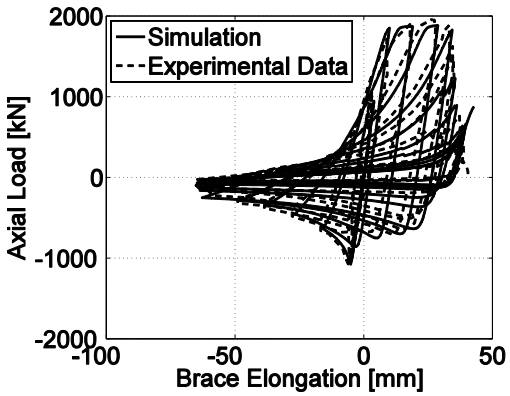

Figure 3 Sample calibrated rectangular HSS steel braces (data from Haddad et al. 2004)

4. MULTIVARIATE REGRESSION FORMULAS TO MODEL FRACTURE OF STEEL BRACES

This section summarizes predictive equations for cyclic buckling and fracture of the three main steel braces (HSS, round HSS and W-shapes). The parameter ε_0 that controls fracture is estimated based on multivariate regression analysis (Chatterjee et al. 2000). The global and local slenderness ratios and the material yield stress F_y are found to have an effect on the fracture life of a steel brace.

4.1 Rectangular HSS Braces

A power-law fitting model was found to best describe the dataset of rectangular HSS braces. For this dataset the predictive equation for ε_o based on a 95% confidence bound is:

$$\varepsilon_0 = 0.291\left(\frac{kL}{r}\right)^{-0.484}\left(\frac{w}{t}\right)^{-0.613}\left(\frac{E}{F_y}\right)^{0.3} \tag{4}$$

In Eq. (4), the expected yield stress of the steel brace F_y is normalized with respect to the Young's modulus E. The predictor w/t is the slenderness ratio of the HSS cross section as defined per AISC-360-10 (2010). Equation (4) is obtained for the following range of predictive parameters:

- $27 \leq kL/r \leq 85$
- $4.20 \leq w/t \leq 30.40$
- $223 \leq F_y \leq 532$ MPa

The coefficient of determination R^2 and the standard error of the mean of the regression of the statistical sample of the HSS braces is 0.493 and 0.249, respectively. These values indicate a relatively good match between the predicted and calibrated ε_o values for rectangular HSS braces. This is also confirmed from Figure 4 that shows the predicted versus calibrated ε_o values for the HSS dataset.

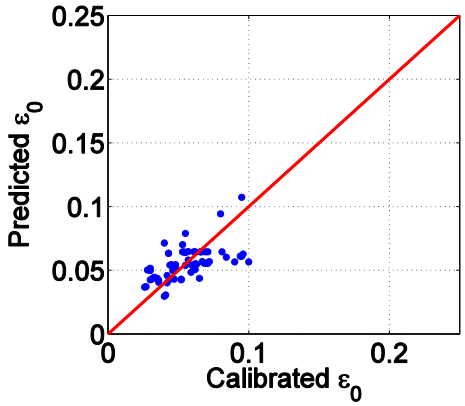

Figure 4 Predicted versus calibrated εo values for HSS braces using Equation (4)

4.2 Round HSS Braces

This section summarizes the proposed recommendations for

modelling the post-buckling behaviour and fracture due to low-cycle fatigue of round HSS braces. Similarly with HSS braces, the *kL/r*, *D/t*, where *D* is the outer diameter of the round cross section of the brace, *t* is its through thickness and F_y parameters are the ones that mostly affect the fracture life of round HSS braces. The predictive equation for the parameter ε_o of round HSS braces based on a 95% confidence bound is:

$$\varepsilon_0 = 0.748\left(\frac{kL}{r}\right)^{-0.399}\left(\frac{D}{t}\right)^{-0.628}\left(\frac{E}{F_y}\right)^{0.2} \quad (5)$$

Equation (5) is obtained for the following range of predictive parameters:

- $29 \leq kL/r \leq 128$
- $12.75 \leq D/t \leq 39.91$
- $326 \leq F_y \leq 521\ MPa$

Figure 5 shows the predicted versus calibrated ε_o values for the subset of round HSS steel braces. This figure indicates that Eq. (5) reliably predicts the parameter that controls fracture due to low cycle fatigue for round HSS braces. The coefficient of determination R^2 of Eq. (5) is $R^2 = 0.636$ and the standard error is 0.146. Note that the exponential coefficients of the predictive parameters in Eq. (5) suggest that the local slenderness term, *D/t*, is the most dominant parameter affecting ε_o of round HSS braces. This agrees with earlier findings by Fell et al. (2009).

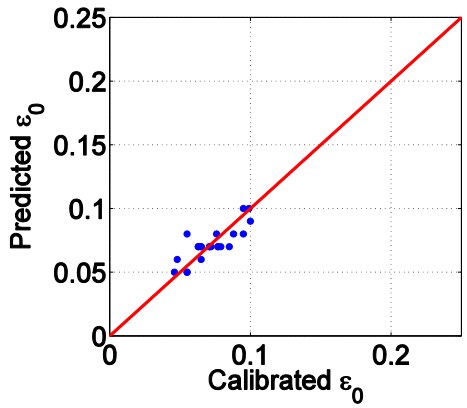

Figure 5 Predicted versus calibrated εo values for round HSS braces using Equation (5)

4.3 W-Shape Braces

In the case of W-shape braces, the parameters *kL/r*, $b_f/2t_f$, h/t_w, and F_y are found to influence the fracture life of W-shape braces the most. For the dataset of W-shape braaces the predictive equation for ε_o based on a 95% confidence bound is:

$$\varepsilon_0 = 0.0391\left(\frac{kL}{r}\right)^{-0.234}\left(\frac{b_f}{2t_f}\right)^{-0.169}\left(\frac{h}{t_w}\right)^{-0.065}\left(\frac{E}{F_y}\right)^{0.351} \quad (6)$$

Equation (6) is obtained for the following range of predictors:

- $39 \leq kL/r \leq 153$
- $4.19 \leq b_f/2t_f \leq 10.20$
- $7.99 \leq h/t_w \leq 49.40$
- $284 \leq F_y \leq 414$ MPa

The local slenderness ratios $b_f/2t_f$ and h/t_w are defined based on the AISC-360-10 (2010) seismic provisions. Figure 6 shows the predicted versus the calibrated εo values for the W-shape braces. This plot indicates that Eq. (6) can be reliably used for predicting the cyclic buckling and fracture of W-shape steel braces. Note that the same equation considers the influence of the web local slenderness on the fracture life of a W-shape brace. However, the flange local slenderness has a stronger influence on ε_0 compared to h/t_w since it is expected that the local instabilities will first be triggered at the flange of the W-shape. The coefficient of determination and the standard error of Eq. (6) for the dataset of the W-shape braces is 0.592 and 0.161, respectively.

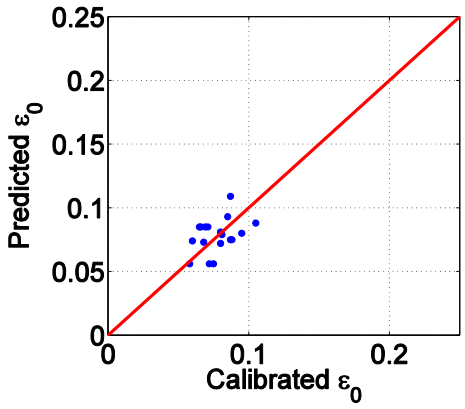

Figure 6 Predicted versus calibrated εo values for W-shape braces using Equation (6)

5. CASE STUDY

The predictive equations discussed in Section 4 for various types of steel braces are utilized in order to conduct a post-fracture evaluation of a 2-story steel braced frame and in particular to quantify its collapse capacity when it is subjected to a set of ground motion records. The one-bay, two-story Special Concentric Braced Frame (SCBF) is designed and built in accordance with the AISC Seismic Design Provisions (AISC 1997) and the Load and Resistance Factor Design (LFRD) (AISC 1993) as discussed in Uriz (2005). Figure 7 shows the basic dimensions of the prototype CBF. Its total height is 5.8 meters (19ft) and its bay width is 6.1 meters (20ft). The first story of the SCBF is 3.0 meters (10ft) tall and the upper story is 2.8 meters (9ft) tall suggesting that the frame is a nearly full-scale representation of the prototype design (Uriz 2005). A chevron configuration bracing system employing square

HSS braces of ASTM A500 GR.B steel is used as the lateral load resisting system. The beams and columns of the frame are W-shape members of ASTM 992 and ASTM 572 Grade 50 steel, respectively. Connection details are designed based on AISC (1993, 1997) provisions. The gusset plate connections are determined using the uniform force method (AISC 1993) and designed to allow for a fold line formation equal to twice the thickness of the gusset plate. The steel braces are reinforced with steel plates in the gusset plate connection region in order to prevent premature fractures at the reduced net section. Uriz (2005) tested quasi-statically the 2-story SCBF through complete failure using the AISC symmetric loading protocol. The next section summarizes the basic modeling approach that was employed for all the structural components of the 2-story SCBF in order to assess its collapse capacity.

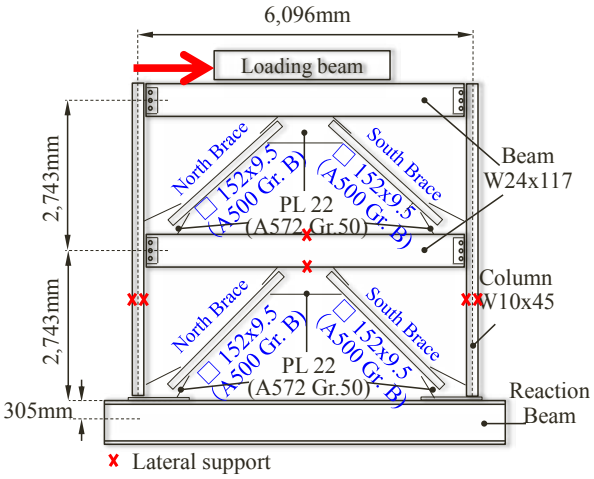

Figure 7 Geometry and member sizes of the 2-story SCBF

5.1 Analytical Model of the Special Concentrically Braced Frame

A 2-dimensional (2-D) analytical model is built in OpenSees (McKenna 1997) in order to simulate the seismic performance of the 2-story SCBF, which is shown in Figure 7. Strength and stiffness deterioration of various structural components of the SCBF is considered as part of its 2-D numerical model. In particular, the steel columns and beams are modeled with elastic elements with concentrated plasticity springs at their ends. These springs utilize the bilinear modified Ibarra-Medina-Krawinkler (IMK) deterioration model (Ibarra et al. 2005, Lignos and Krawinkler 2011). The deterioration parameters that determine the behaviour of these springs are determined based on multivariate regression equations developed by Lignos and Krawinkler (2011). These equations have been adopted by ATC-72 (ATC/PEER 2010) modelling guidelines for tall buildings.

The gusset plate beam-to-column shear connections of the test frame are modeled with the pinching version of the modified IMK model, which was implemented in OpenSees for this purpose (Lignos and Krawinkler, 2012). The properties of these springs are calibrated based on experimental data from cyclic static tests of typical composite shear tab connections from Liu and Astaneh (2000). More recent experimental data on the cyclic behaviour of gusset plate beam-to-column shear connections have become available by Stoakes and Fahnestock (2011). This experimental data can also serve for the same purpose. Figure 8 displays an example of the hysteretic moment-rotation behaviour of the modified IMK model with pinching hysteretic response that can represent each of the aforementioned cases.

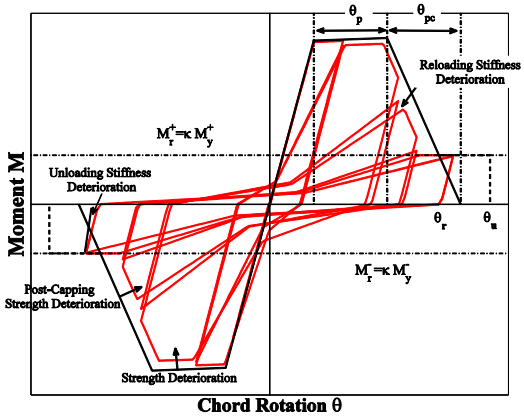

Figure 8 Typical hysteretic behavior of the modified IMK model with pinching hysteretic response

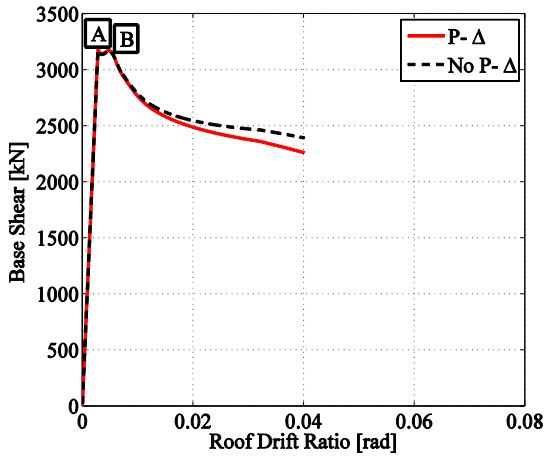
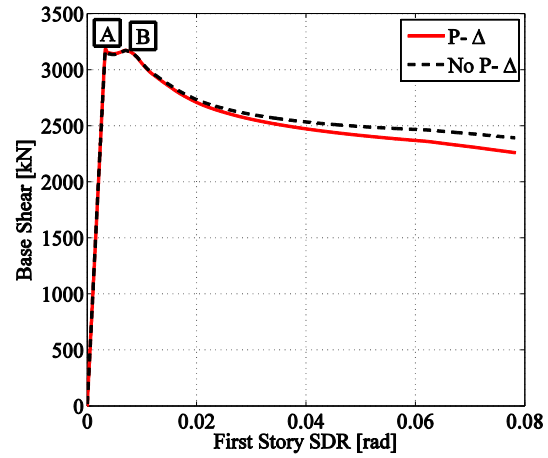
The modified IMK model is able to capture the deterioration in strength, post-capping strength, unloading stiffness and reloading stiffness based on a parameter Λ that defines the reference energy dissipation capacity of a gusset plate beam-to-column connection. More information about the modified IMK model can be found in Karamanci and Lignos (2012).

The out-of-plane flexibility and flexural strength of the gusset plates are modeled with concentrated plasticity springs that are placed between the physical ends of the braces and the rigid offsets that represent the rest of the gusset plates. These springs utilize the Menegotto-Pinto material model. The flexural stiffness and strength of these springs is determined with the proposed relationships by Hsiao et al. (2012a).



The steel braces are modeled with the approach discussed in Section 4.1. The parameter ε_0 that is used to model fracture due to low-cycle fatigue is determined based on the multivariate regression Eq. (4). The determined fracture parameters ε_0 and m used for all the steel braces are 0.064 and -0.3, respectively, given their kL/r and w/t ratios and their measured yield stress.

5.2 Pushover Analysis



A pushover analysis is conducted with the 2-story SCBF, assuming a first mode lateral load pattern as determined by the equivalent lateral force procedure (IBC, 2003). P-Δ effects are considered in the analysis with a presence of a fictitious leaning column. Due to similitude, 1000kN per

story was assumed to represent the gravity and seismic loading that this frame carries.

Figure 9a shows the pushover curve in terms of base shear versus roof drift ratio (defined as the roof displacement normalized by the total height of the test frame). Figure 9b shows the base shear versus first story drift ratio. From these figures it is concluded that a first story collapse mechanism forms since the plastic deformation is concentrated at the first story of the SCBF. In these figures, point A represents the point that global buckling of the south lower story brace occurs. Point B represents the formation of plastic hinges at the top and bottom of the first story columns. The upper story beam, columns and braces remained elastic during the pushover analysis. In Figures 9a and 9b we have also superimposed the same results without the consideration of P-Δ effects. A comparison of the two curves (noted as P-Δ and No P-Δ) shows that the strength deterioration of the structural components of the test frame is significant compared to the geometric effects that are associated with the vertical load applied to the 2-story SCBF.

(a)

(b)

Figure 9 Pushover analysis of the 2-story SCBF based on a first mode lateral load pattern; (a) Base shear versus roof drift ratio; (b) base shear versus first story SDR

5.3 Collapse Assessment

In this section, a collapse assessment of the 2-story SCBF is conducted through Incremental Dynamic Analysis (IDA: Vamvatsikos and Cornell, 2002). A set of 40 ground motions, compiled by Medina and Krawinkler (2003) is used for this purpose. These ground motions represent ordinary records with a Magnitude $6.5 < M < 6.9$ and a distance $13 < R < 40$km from the rapture zone. The 5% damped spectral acceleration at the first mode period of the test frame $S_a(T_1,5\%)$ is used as an Intensity Measure (*IM*) to scale incrementally the 40 ground motions. In order to conduct the nonlinear response analysis a $\zeta=2\%$ Rayleigh damping approximation at the first and second mode of the 2-story SCBF is used to simulate viscous damping. The first and second modes of the 2-story CBF frame are 0.30sec, and 0.1sec, respectively. The Rayleigh damping matrix is formed based on the tangent (current) stiffness of the structural components of the 2-story SCBF in order to avoid issues related with artificial damping forces as discussed in Karamanci and Lignos (2012).

A time-variant integrator has been developed and implemented in the OpenSees simulation platform that guarantees numerical convergence of the equations of motion particularly at large deformations. The numerical stability of this integrator and its reliability to compute the response history of frame structures through collapse has been validated with recent small and full-scale collapse experiments (Lignos et al. 2011, 2012b, Suita et al. 2008). Dynamic collapse due to sidesway instability is traced once a story or a number of stories displaces sufficiently and the second order shear due to P-Delta effects accelerated by component deterioration fully offsets the first order story shear force of the 2-story SCBF. This implies that dynamic collapse due to sidesway instability should be traced base on a combination of criteria that associate large story deformations and story shear forces. This is consistent with recent shake table collapse experiments (Lignos et al. 2011, 2012b, Suita et al. 2008). Figure 10 shows an example of such definition. The results have been computed based on the scaled intensity of the fault normal record from the Canoga Park station during the Northridge 1994 earthquake. The scaled intensity of this ground motion represents a Maximum Considered Earthquake (MCE) in urban California for 0.3seconds with 2% probability of exceedence in 50 years. Figure 10a shows the first and second story drift ratio histories of the SCBF during the ground motion. This figure suggests that a first story collapse mechanism forms in the 2-story SCBF since the lateral deformations at the same story become excessive. Figure 10b shows the base shear versus first story drift ratio SDR_1 of the same frame. From this figure, once the steel braces fracture, the framing action solely contributes to the lateral resistance of the 2-story SCBF. When the first story deformations become excessive the 2-story SCBF collapses. The collapse point is the one associated with zero base shear force (see Figure 10b).

Figure 10c shows the hysteretic response of the two steel braces of the first story of the SCBF. From this figure,

both braces fracture and once they lose their tensile load carrying capacity their axial resistance remains at zero for the rest of the dynamic response of the 2-story SCBF. Note that the upper story steel braces remained elastic throughout the entire nonlinear response of the 2-story SCBF.

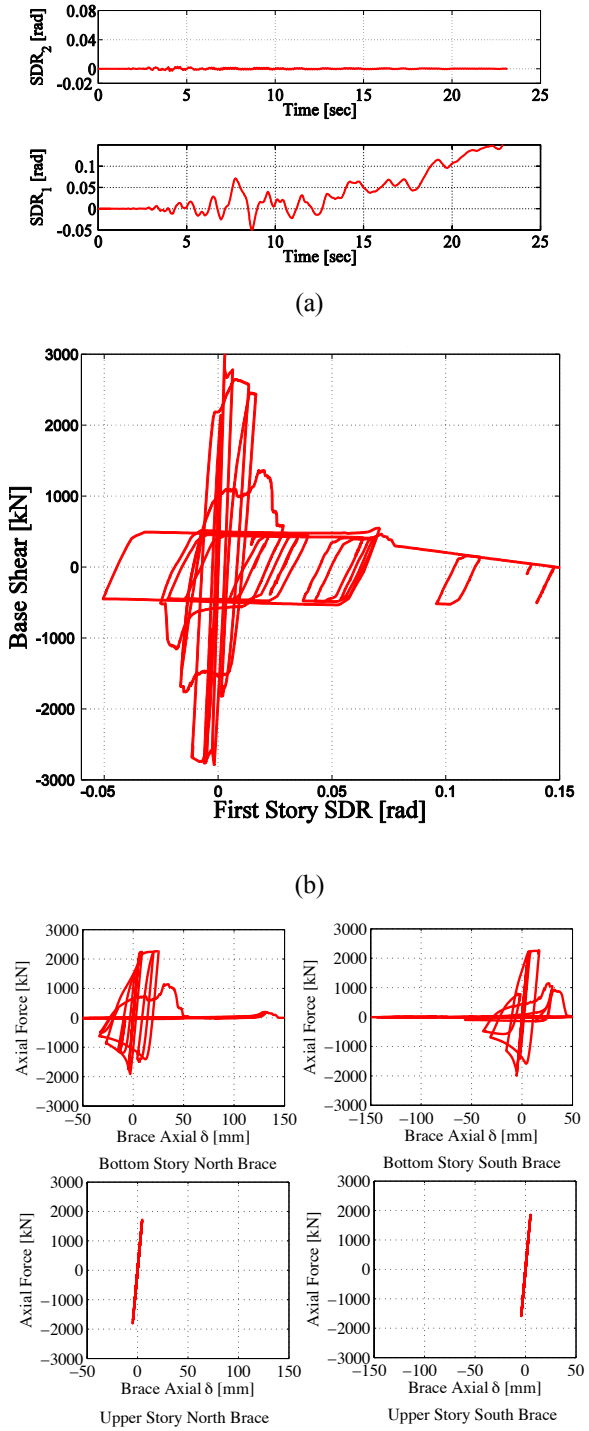


Figure 10 Nonlinear dynamic analysis of the 2-story SCBF for a scaled intensity of the Canoga Park record from the Northridge 1994 earthquake; (a) story drift ratio histories; (b) base shear versus first story drift ratio; (c) steel brace hysteretic response

Figure 11a shows the incremental dynamic analysis results for the 2-story SCBF in terms of IM versus maximum story drift ratios (SDRs). Once each one of these curves becomes flat, dynamic instability of the 2-story SCBF occurs. The collapse assessment of the 2-story SCBF in a probabilistic basis is seen through the collapse fragility curves as suggested by Ibarra et al. (2002). Figure 11b shows the collapse fragility curve of the 2-story SCBF. From this curve, the median collapse capacity of this frame is 1.17g and the logarithmic standard deviation of the 40 collapse intensities is 0.43.

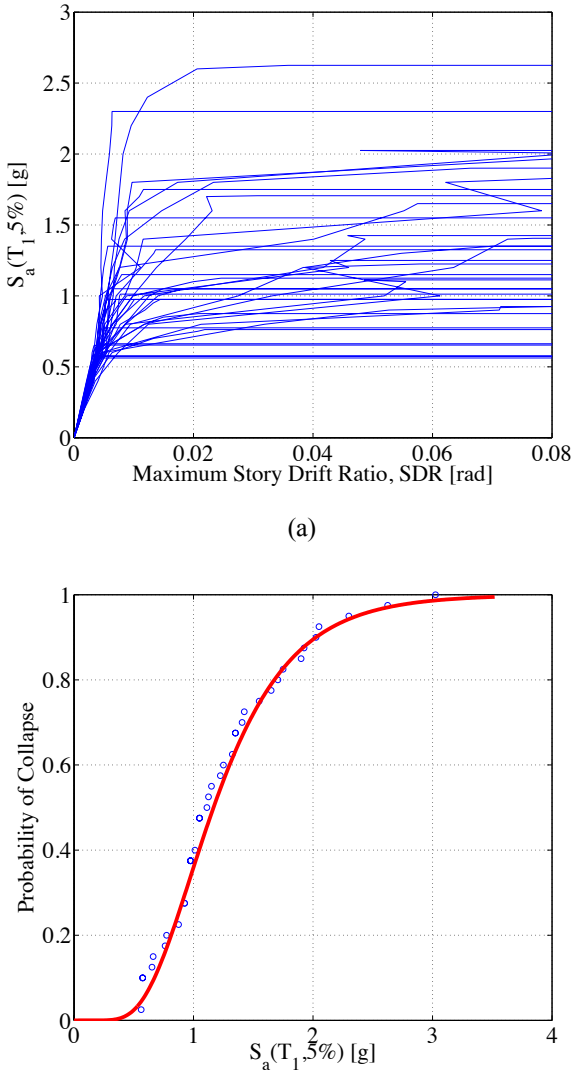

Figure 11 IDA curves and collapse fragility curve of the 2-story SCBF

6. CONCLUSIONS

This paper discusses the development of predictive equations for modeling the inelastic cyclic buckling and fracture of rectangular Hollow Square Steel (HSS) braces,

round HSS and W-shape braces. These cross sections are typically used in the modern steel construction of Concentrically Braced Frames (CBFs). These relationships are based on extensive calibrations of the hysteretic response of a state-of-the-art steel brace model with available experimental data from steel braces that have been assembled into a recently developed steel brace database. The effectiveness of the proposed relationships is demonstrated through a case study of a 2-story special concentrically braced frame (SCBF) designed in urban California. A 2-Dimensional (2-D) representation of the 2-story SCBF is built in the OpenSees simulation platform. Component deterioration of various components including steel braces, gusset plate beam-to-column connections, beams and columns is explicitly considered as part of 2-D the numerical model. The following findings from the present study are summarized as follows:

- The effect of global slenderness ratio *kL/r* on the fracture life of HSS and round HSS steel braces diminishes once these braces buckle globally and local buckling forms at their mid-span.
- The effect of local slenderness ratio of the individual cross sections is found to be the most critical parameter to control the fracture life of a steel brace regardless of its structural shape.
- W-shape braces are more resilient against fracture than round HSS. Rectangular HSS steel braces have the lowest fracture life compared to the other two steel brace shapes that were examined.
- Once steel braces fracture, the primary lateral resistance of a steel brace is attributed to its framing action only. However, once strength deterioration of steel columns of CBFs occurs, dynamic collapse due to sidesway occurs.
- Dynamic collapse of CBFs should be traced based on a combination of criteria that associate large story drift deformations and story shears at these deformations.

In the author's opinion, reliable collapse assessment of steel braced frames is a difficult task due to various failure mechanisms that may occur in such frames. However, the present study is a step towards the quantification of the reserved capacity of modern concentrically braced frames once their steel braces fracture during severe ground shaking.

Abstract: Steel shear wall with slits (SSWS) is an efficient structural component equipped both loading-resistant capacity and energy dissipating ability. Recently the study of the design details and the design procedure for using the component as an effective energy consumption device in the steel frames subject to seismic load is reported. In the previous laboratory tests on full scale SSWS and other large scale steel shear wall, the slippage of bolt connection and accompanied noise were noticed. Based on observation and analysis, rational method is proposed to evaluate the shear force and its distribution on bolt connection linking SSWS and frame beams, and proper arrangement of bolt is suggested. Furthermore, the influence of axial stress on the thin SSWS is carefully studied. By the criteria to keep the horizontal ultimate strength of SSWS, the limitation for axial stress ratio is determined. Two assemblages of SSWS together with its surrounding frames were tested under cyclically horizontal load and constant vertical load to check the validity of the proposal. The test results show that the presence of finite vertical load does not affect the performance of SSWS, and the synergistic effect for frame and SSWS is quite noticeable. Finally, the design rules are put forward to guarantee that the yielding of SSWS precedes the yielding of frame members. A quantitative method in calculating energy dissipation capacity is proposed. And a practical design approach considering yielding sequence and energy dissipation are also addressed and discussed.

1. INTRODUCTION

Steel shear wall with slits (SSWS), which is designated to resist seismic load, is observed significantly functional in seismic design and retrofit of structures for its stable response as well as noteworthy features in engineering practice (Hitaka and Matsui 2003).

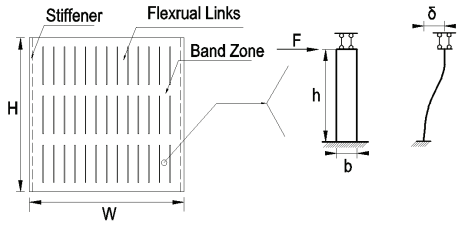

Figure 1 Configuration of SSWS

Observations in the previous laboratory tests on full scale SSWS and other large scale steel shear wall (Chen Y.Y. et al 2009) indicate that the slippage of bolt connection might impose adverse impact on performance of the component, leading to undesirable failure mode ultimately. As for its behavior in structural system, critical issues concerning the influence of axial stress induced by gravity load and the performance of the global system combining with frame are needed to be investigated. Moreover, past designs were generally carried out based on elastic theory, which might not incorporate the function as energy dissipative device into procedure. Moreover, the actual response and performance in inelastic range is still unclear if not considered directly.

In this research, two assemblages of SSWS together with its surrounding frames were experimentally investigated under a combination of cyclically horizontal load and constant vertical load. To eliminate the undesirable bolts slippage in connection area, a proper arrangement of bolt was proposed and applied into tested specimens. The detailed results of tests and corresponding numerical analysis incorporating the evaluation of vertical load and bolts force distribution are reported herein to validate the proposal. Observations regarding the synergistic effect of system is also addressed and discussed.

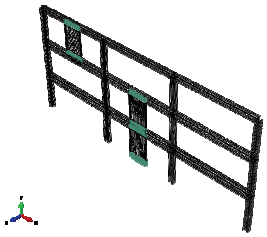
Further, to achieve a more rational design of system incorporating inelastic behavior, the yielding sequence of different components and energy concept are employed. Calculation method in dealing with plastic energy dissipation of SSWS is addressed. A practical design procedure considering energy dissipation and yielding sequence are also presented and discussed.

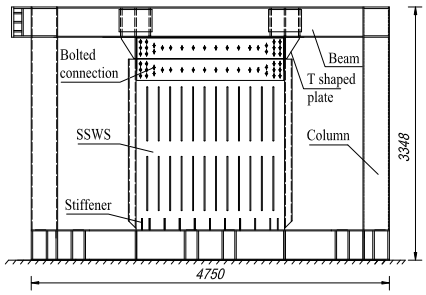
2. EXPERIMENTAL PROGRAM

2.1 Test specimens

Practically, SSWS is generally installed in frames with bolted connection. In this study, the full scale tests based on

two specimens incorporating SSWS and surrounding frame components were conducted to simulate the behavior of different subassemblies in system, and different boundary constraints were considered during test procedure. Specifically, the specimen FSSWS1 was intended to simulate the subassemblies when the SSWS were located in the same bay from the bottom floor to the above floor while the specimen FSSWS2 corresponded to cases where SSWS were not arranged continually in vertical direction considering the flexibility of beam (Figure 2). The frame was composed of H shaped beam and cold-formed square tubular column with nominal yield stress of 345MPa while SSWS was constructed with steel plate with nominal yield stress of 235MPa. The dimension and detail of specimens were determined based on practical structure, given in Figure 3 and Table 1.





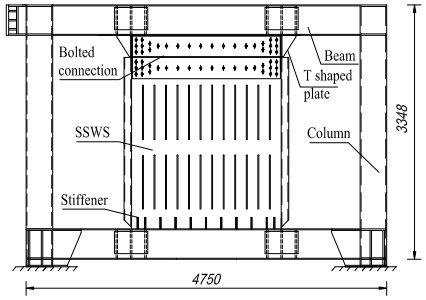


Figure 2 Steel frame-SSWS system

Table 1 Dimension and boundary condition of specimens

Specimen	Beam	Column	Boundary condition
FSSWS1	H400×200×8×13	350×12	Fixed
FSSWS2	H400×200×8×13	350×12	Partially fixed

(a) Specimen FSSWS1

(b) Specimen FSSWS2

Figure 3 Configuration and detail of specimens

The SSWS in two specimens were designed with the same parameters (plate thickness 12mm), and detailed information is illustrated in Figure 4.

In dealing with the undesirable early slippage of bolts observed in past research, an improved detail of bolt arrangement was proposed and applied to specimens, as illustrated in Figure 5. It is believed reasonable to introduce this modified arrangement to eliminate the potential slippage due to non-uniform force distribution in connection area, and the detailed analysis concerning the bolt force is presented in following parts.

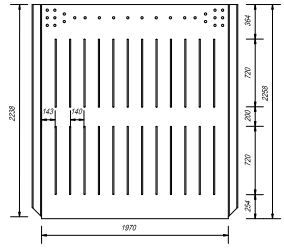

Figure 4 Dimension of SSWS

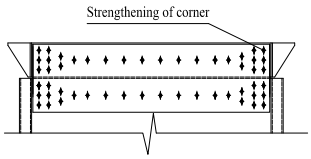

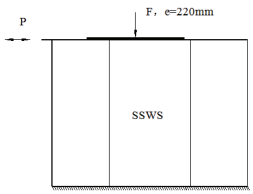

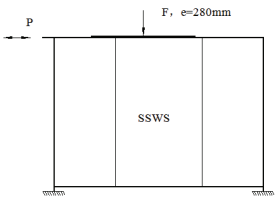

Figure 5 detail of proposed arrangement of bolts

2.2 Test setup and loading procedure

A constant vertical load was applied on SSWS during test since the SSWS can bear a proportion of gravity load in building structure. In this study, the vertical load was determined as 350kN and 650kN for specimen FSSWS1 and FSSWS2, respectively (a value of 300kN was close to the accumulated live load on the bottom floor of a 30-story building according to current Chinese codes). During the test procedure, the constant vertical load was firstly applied to specimens, and lateral cyclic load was subsequently incorporated. The loading diagram and test setup are illustrated in Figure 6 and Figure 7.

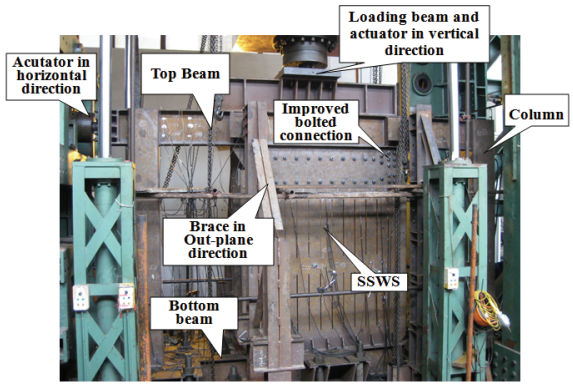

Figure 7 Test setup

3. TEST RESULTS AND ANALYSIS

3.1 Overview

With the load increasing, the specimens began to develop plasticity with a favorable sequence. The SSWS firstly yielded and dissipated energy. In the subsequent stage, the beam and column also developed inelasticity and dissipated energy. During the loading process, the distortional buckling of flexural links and out-plane deformation of panel occurred when plastic deformation was sufficiently large, as shown in Figure 8. The fractures initiated at end of slits were also noticed at large drift, as observed in related studies (Hitaka and Matsui 2003;Gotes and Liu 2010).

It should be noted that even though the out-plane deformation occurred, the global response was still relatively stable in spite of stiffness degradation in SSWS, as the frame was also significantly functional in inelastic range. This was reflected by cyclic curves presented next. Essentially, the synergistic effect was dependent on the property of the structure behaving as a dual system in which SSWS and frame both can provide considerable energy dissipation capacity. And the application of a dual system can lead to a more flexible adjustment of stiffness allocation as well energy dissipation distribution, which is addressed in a practical design approach in this study.

Further, during the load cycles, no observations regarding the slippage of bolted connection was captured, for no obvious deformation of bolts and holes observed, as indicated in Figure 9.This implies the effectiveness of proposed arrangement of bolt connection stated above.

(a) FSSWS1 (b) FSSWS2

Figure 8 Out-plane deformation of specimens

Figure 9 No obvious deformation of hole and bolts(after test)

3.2 Analysis of bolt force in connection

Slippage of bolts in connection was observed in past full scale tests in SSWS, which inevitably employed the undesirable failure mode of the system. Essentially, this was mainly induced by the non-uniform distribution of internal force induced by both overturning moment and shear force when the SSWS was subjected to a large lateral loads, as conceptually illustrated in Figure 10. It reveals that a conventional consideration of a uniform bolts arrangement might increase the risk of connection failure, especially in both ends of connection plate, which had been demonstrated in past full scale tests (Chen Y.Y. et al 2009). In this study, a non-uniform distribution of strain intensity in connection area was also observed, demonstrating the necessity of proposed modified bolts arrangement.

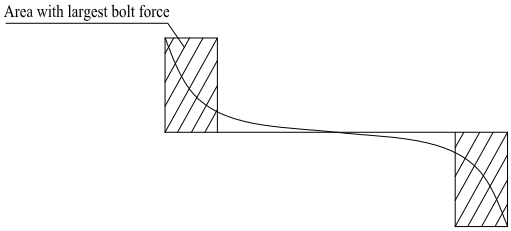

Figure 10 Conceptual illustration of bolt force distribution

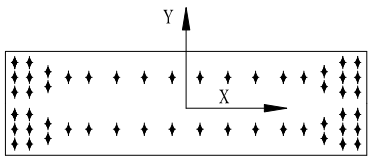
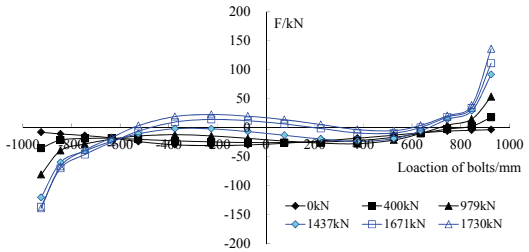
On the other hand, numerical analysis was also conducted to investigate the bolt force distribution in this research. The vertical internal forces distribution(Y direction in Figure 11) corresponding to different lateral load levels in connector which was intended to simulate bolts are plotted in Figure 12, where *F* denotes the bolt force in vertical direction .





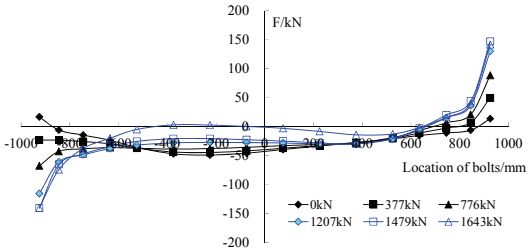


Figure 11 Bolts arrangement in cover plate in connection

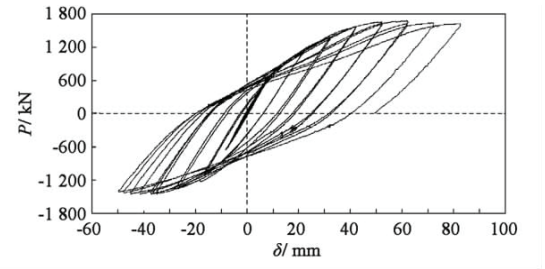
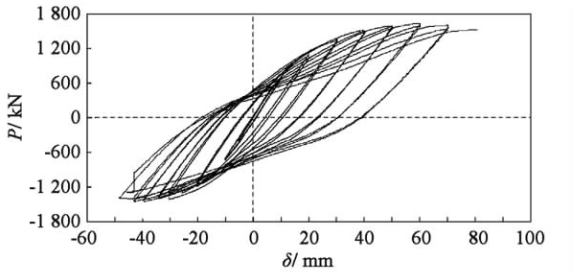
(a) FSSWS1



(b) FSSWS2

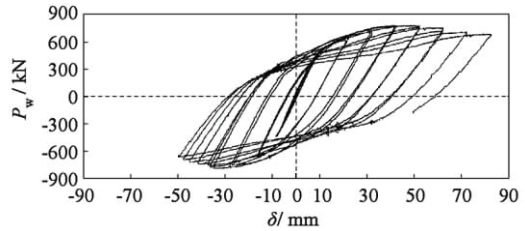
Figure 12 Vertical internal force in bolts



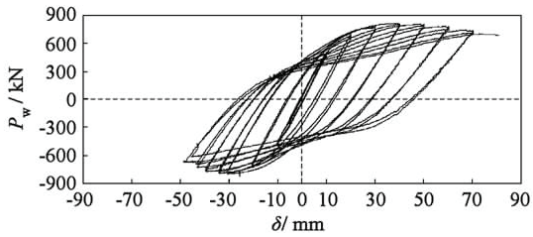
As can been seen, when the lateral load was relatively small, the corresponding bolts force in vertical direction was not significant. Nevertheless, the bolts force at both ends grew sharply as the lateral load increased, which essentially reveals the adverse effect induced by overturning moment, demonstrating the rationality of proposed bolts arrangement.

3.3 Hysteretic behavior

The global load-deformation curves of FSSWS1 and FSSWS2 are shown in Figure 13, where δ denotes the relative lateral displacement between top beam and bottom beam of specimens, and P denotes the total lateral force applied on specimens. Compared with related research (Hitaka and Matsui 2003; Chen Y.Y. et al 2009;Gotes and Liu 2010) concentrating on the behavior of panel only, the test results exhibit a more stable response of system for no obvious pinching and strength degradation observed. The results radically reveal that the assemblages of SSWS and surrounding frame components are significantly functional in resisting the seismic load. On the other hand, the corresponding load-displacement curves of SSWS in each specimen can also be captured with equilibrium relationship, which are plotted in Figure 14, where P_w denotes the lateral load taken by SSWS.

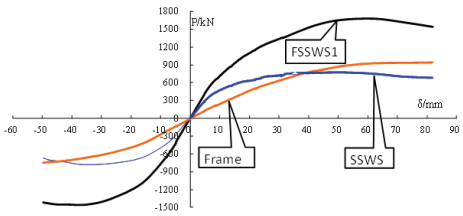


(a) FSSWS1

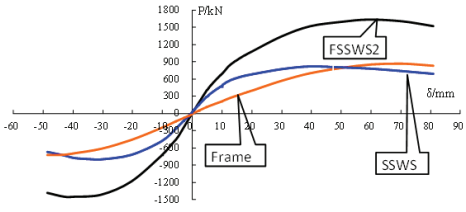


(b) FSSWS2

Figure 13 Load-displacement curves of specimens



(a) SSWS in FSSWS1

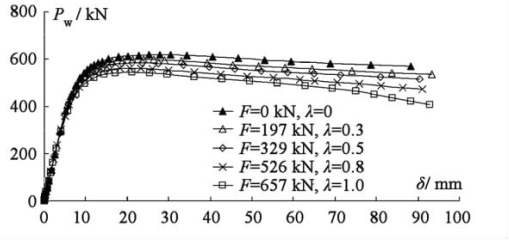


(b) SSWS in FSSWS2

Figure 14 Load-displacement curves of SSWS in specimens

Further, the skeleton curves of specimens are illustrated in Figure 15. It essentially reveals the synergistic effect of the structure working as a dual system. In the elastic range, both SSWS and frame provided lateral stiffness to resist lateral loads and SSWS played a predominant role in this stage for relatively larger stiffness. As the SSWS experienced the degradation of stiffness in inelastic range, the contribution of frame became more significant. This synergistic effect was reflected by the stable response in test. In the perspective of energy dissipation, the system exhibited a favorable behavior that different parts might contribute to energy absorption with a favorable sequence. This desirable sequence divided the global performance of system into certain states, making the design more reasonable for considering the concept of damage control and resilience. Moreover, although different boundary conditions were considered in specimens, there were not obvious differences in performance observed or reflected in results curves, indicating the flexibility of allocation of SSWS in system practically.

(a) FSSWS1



(b) FSSWS2

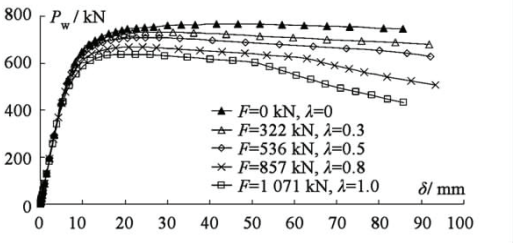


Figure 15 Skeleton curves of specimens

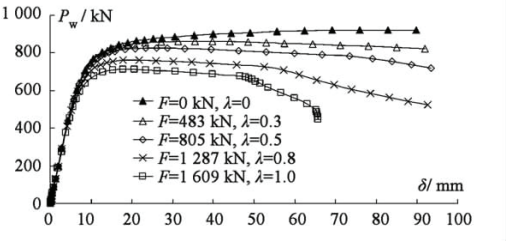
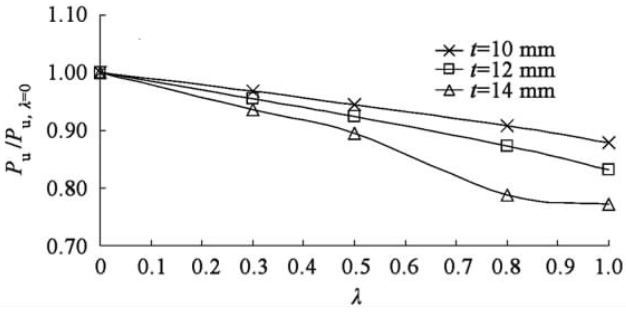
3.4 The influence of axial force in SSWS



Although a constant axial load was applied in specimens, there was no significantly adverse effect observed. To evaluate the influence induced by axial stress, numerical analysis was also conducted. Specifically, based on the model of SSWS in specimens, the axial stress was introduced as a parameter, defined with a ratio of axial load to corresponding buckling load ($\lambda=F/F_{cr}$).Pushover analysis were carried out with variation of plate thickness and λ. The results are illustrated in Figure 16, indicating that the axial load in SSWS might induce reduction in strength. Nevertheless, this reduction is believed not significant as only approximation of 10% in strength was observed at a stage with λ of 0.5. It is pointed out the aforementioned analysis did not incorporate the noticeable synergistic effect of system as the frame will also bear a proportion of vertical load practically, and it is thought conservative to define λ as 0.5 as a threshold of axial load in engineering practice.



(a) t=10mm

(b) t=12mm

(c) t=14mm

Figure 16 Influence of axial load in SSWS

4. DESIGN METHOD

4.1 The yielding sequence

Practically, when a frame-SSWS system is subjected to lateral loads, it is expected that the SSWS yield earlier than the frame components as energy dissipative devices, which can also reflects the concept of damage control design (J.J. Connor. et al 1999).With a preselected yielding sequence ensured, the system will exhibit a more reasonable performance, as the damage can be constrained in SSWS, making the whole system essentially operational by replacing the panels after earthquakes. Accordingly, a critical issue lies within the practical approach to achieve the expected sequence. Conceptually, the behavior of system might be reflected by the idealized illustration given in Figure 17.

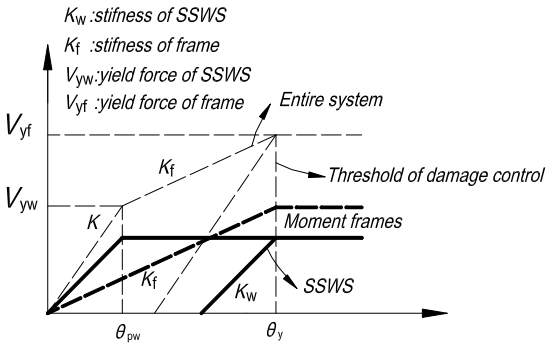

Figure 17 Idealized behavior of frame-SSWS system

Accordingly, the yielding sequence can be determined given by Eq.(1),

$$\frac{V_{yw}}{K_w} < \alpha \frac{V_{yf}}{K_f} \qquad (1)$$

in which α is defined as an index to control the yielding sequence. The yielding sequence can be explicitly designed by adjusting the strength and stiffness of SSWS and frame, as SSWS with relatively larger stiffness and lower strength tends to yield earlier.

4.2 Application of energy concept in SSWS

SSWS can be viewed as an excellent energy dissipative device when subjected to lateral loads. Accordingly, the plastic energy dissipation can be determined with plastic theory (Ke K. and Chen Y.Y. 2012), the plastic energy absorbed by panel can be determined by Eq.(2).

$$E_{pw} = \left(\frac{n\Delta}{h} - \frac{nmf_y h}{3Eb}\right)\frac{f_y b^2 t}{2} \qquad (2)$$

In Eq.(2), E_{pw} = plastic energy dissipation of SSWS; n=number of links in a row; m =number of rows in wall; Δ= total lateral displacement of the wall; f_y=yield stress; E =Young's modulus and t= thickness of plate. Eq.(2) can be used to measure the plastic energy dissipation under certain drift of SSWS. It also reveals that the energy dissipation capacity can be adjusted with geometric parameters of slits in SSWS as well as the material property quantitatively, which is believed a significant index in design procedure. An

optimized design can be achieved combining the adjustment of strength and stiffness (Hitaka and Matsui 2003).

4.3 Design procedure considering energy dissipation

As the energy dissipation capacity can be determined, a practical approach is constructed in designing the system and is illustrated in the flow chart given by Figure 18.

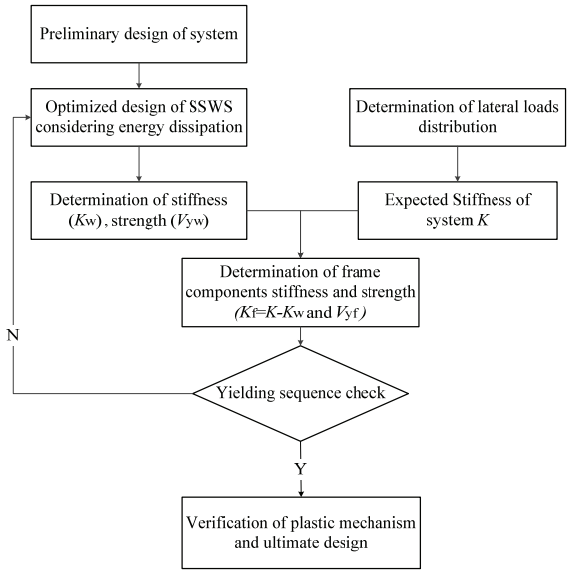

Figure 18 Design procedure considering energy dissipation

More specifically, the design procedure is based on optimization of energy dissipation capacity of SSWS given in Eq. (2). This motive is thought to be rational viewing the SSWS as the predominant energy dissipative devices in earthquakes. A sequence design is also involved as a criterion in procedure with aforementioned derivation. In essence, the target of proposed design is to concentrate damage reflected by plastic energy into replaceable SSWS by adjusting the stiffness and strength of different components in the system. Considering that the frame-SSWS will behave as an integrated system that all components will bear the service loads as well as seismic loads, the application of energy concept and an explicit concern of yielding sequence can effectively take the inelastic behavior into consideration, which is thought to be more reasonable compared with conventional value-based (force or displacement) design methodology.

5. CONCLUSIONS

Full scale laboratory test on two assemblages of SSWS with surrounding frame components were performed. Critical issues concerning the slippage of bolts in connection area, the influence of SSWS allocation and the effect of axial stress in SSWS were carefully studied experimentally and numerically.

Test results indicate that the proposed arrangement of bolts can effectively eliminate the undesirable slippage under large drift observed in past research, which was also validated by numerical analysis.

In order to investigate the performance of SSWS in frame system, specimens were tested with different boundary constraints. Since no significant differences in behavior were observed, it is believed that the discontinuous arrangement of SSWS in structure may not impose an adverse effect on system, providing much flexibility in engineering practice.

During test procedure, a constant vertical load was applied to specimens to simulate the vertical load in structural system, while no obvious adverse effect induced by axial stress was observed. Parametric study was carried out subsequently to evaluate the influence of vertical load. Although the existence of axial stress will lead to reduction in strength as indicated by analysis, it is believed the effect is not significant when the axial load is not large. Accordingly, a value of 0.5 is recommended as limitation of axial load ratio ($\lambda=F/F_{cr}$). When the axial stress is in this range, its effect might be minor and can be neglected in practice.

Over all, two specimens behaved with desirable performance during load cycles, which is believed contributed by the synergistic effect as SSWS and frame worked as a dual system. Based on test results, the design method is also studied with application of energy concept and damage control design philosophy. A practical design procedure incorporating yielding sequence control and energy dissipation optimization are addressed and discussed.

Abstract: Two types of I-shape buckling-restrained steel plate shear walls are introduced, which are characterized by large aspect ratio and small aspect ratio. Thus, 5 series of large-aspect-ratio specimens with 1/3 scale and 3 small ones but with full scale are tested both monotonically and cyclically, in order to make a thorough investigation into their seismic performance such as energy-absorbing capacity and deformability, and so on. The test results indicate that the I-shape buckling-restrained steel plate shear wall with large aspect ratio is capable of dissipating earthquake energy stably and efficiently, judging from its almost spindle-shape hysteretic curves, as well as excellent deformability. Meanwhile, the small-aspect-ratio one also proves to be an ideal structural member, which exhibits even fatter hysteretic curves when the buckling restrainer is upgraded from the reinforced concrete panels to the stiffened steel cases. Apparently, the buckling restrainer is the key parameter deciding the seismic performance. Finally, the theoretical model for both walls is put forward, from which the yielding strength and initial stiffness can be predicted precisely to a large extent. And he theoretical model agrees with the test results to a satisfactory degree.
Keywords: Buckling-restrained, aspect ratio, seismic performance

1. INTRODUCTION

For the past four decades, steel plate shear walls (SPSWs) have been widely used as lateral resisting members in tall buildings. However, the premature buckling under lateral forces proves to be detrimental to the capability of energy dissipating and serviceability to a large degree, when subjected to medium-strong earthquakes. Thus, buckling restrainers are applied to improve its seismic performance by preventing the buckling, after considering that simply thickening the steel plate is not economical at all.

Apparently, the larger flexural stiffness of buckling restrainers, the higher efficiency of restraining, and the better performance. Currently, commonly used form of restrainers is reinforced concrete panel (RC panel), which shows larger flexural stiffness, compared to the steel stiffeners.

In 1995, a steel plate shear wall, composed of a steel plate stiffened with RC panels at both sides, was first introduced[1]. The steel plate is connected to the reinforced concrete with bolts that play an important role in preventing the buckling of the steel plate, which resists lateral forces between the stories by yielding in shear. However, cracks and buckling are also developed in the RC panels at the same time. And due to the failure of the RC panels, the hysteretic curve exhibits obvious pinching problem, as shown in Figure 1. Following experimental investigations, conducted by Astaneh-Asl A. (2004)[2], Y.L. Guo(2005)[3], K.C. Tsai (2006)[4] and G.Q. Li(2007)[5] have also indicated that, although the RC panel is capable of providing buckling restraining to a certain amount of degree, it's still prone to fracture significantly, due to the brittleness of concrete. And the hysteretic curve is also not fat enough to absorb earthquake energy as much as possible.

Besides, in most cases, the aspect ratio of buckling-restrained steel plate shear walls (BRSWs) that have been studied both experimentally and theoretically is small, that is to say, the width of the steel plate is no smaller than the height and the shearing deformation far outweighs the flexural one. However, in some cases the construction space left for the wall is so limited that only a large-aspect-ratio one is suited. And sometimes the required steel plate is so thin that it is even unavailable.

Therefore, BRSW with large aspect ratio is investigated, for the first time, both experimentally and theoretically. Meanwhile, knowing that RC panels of common rectangular-shape BRSW tend to fracture at the corners, due to the severe stress concentration, the steel plate is then I shaped to function in a more ductile way by shifting the high-stress zone from the corners to the inside, as shown in Figure 2.

Finally, more efficient buckling restrainers, modified reinforced concrete panels and stiffened steel cases, are put

forward and experimentally studied in this article.

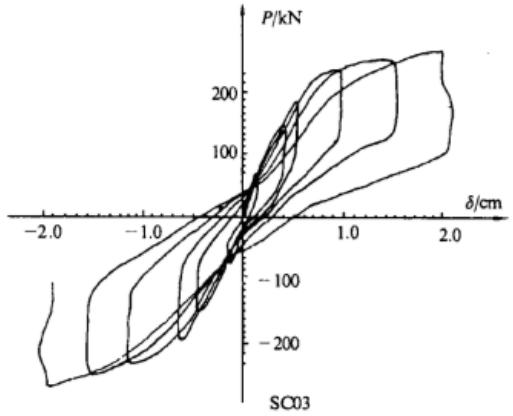

Figure 1. Hysteretic curve of lateral displacement and force

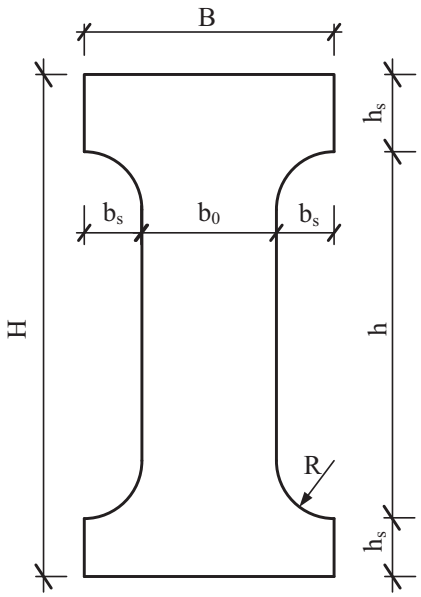

Figure 2. I-shape steel plate

2. TESTS ON LARGE-ASPECT-RATIO WALLS

2.1 Experimental specimens

Four series of BRSWs with different aspect ratios, from 2:1 to 4:1, have been designed, along with one control group, SPSWs with aspect ratio of 3:1. And all above-mentioned specimens are in a scale of 1/3, due to the limitation of the laboratory.

All the steel plates are 3.5mm in thickness and 900mm in height, made from structural steel Q235 that is widely used in China, the nominal yielding strength of which is 235MPa and 308MPa from the coupon tests. The detailed dimensions of the steel plate are summarized in Table 1, in which IC signifies BRSW and I signifies SPSW, as well as that -1 denotes monotonically loading and -2 means cyclically loading.

Besides, the buckling restrainers also adopt RC panels, 35mm thick with two-layer reinforcement, the volumetric ratio of which is 0.25%. And the both-side RC panels connect to inside steel plate through plain bolts. These bolt holes are designed slotted eyes, with a horizontal distance of 60mm, which allows the steel plate and the RC panels to inter-slip to a drift ratio of 1/30, back and forth.

Table 1. The detailed dimensions of the steel plate

series	specimen	H/B	H/b_0	h/b_0	R(mm)

2.2 Setups

In order to fully focus on the hysteretic performance of the BRSW and also to reuse the loading frame, the hinge frame is thus applied, as shown in Figure 3, in which the lower beam is anchored to the ground and the BRSW is high-strength bolted to the upper and lower beams through so-called fin plates. The actuators, loading capacity of which is 20 tons, are located at each side of the frame. And the out-of-plane supports at both sides ensure that the frame keeps functioning in plane.

The story drift ratio of the frame is measured as the key parameter, and the out-of-plane displacement of upper beam and specimen is also monitored as auxiliaries.

Figure 3. The hinge frame

2.3 Loading protocol

In the monotonic loading, the target drift ratio is 5%. And in the cyclic loading, the protocol is based on displacement control and elaborated in Figure 4.

Meanwhile, at the time that there is an obvious inflection point in the lateral force-displacement curve，the state of initial yielding is assumed to be reached. And when the strength deteriorates to a degree of 15%, it is assumed

that the BRSW is not able to carry loads any more.

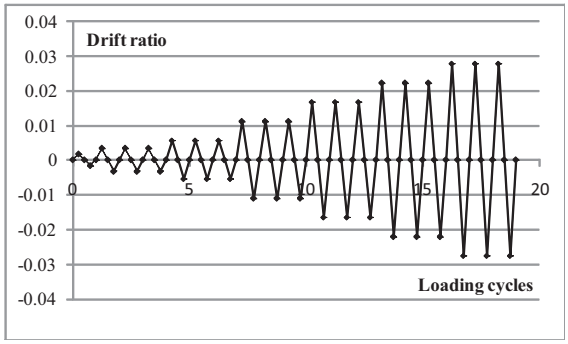

Figure 4. Cyclic loading protocol

3. RESULTS OF LARGE-ASPECT-RATIO WALLS

3.1 Overview

I-180 (SPSWs)

There is no surprise to see that both SPSWs have buckled at the very beginning of the loading since the critical shear buckling strength is significantly smaller than the yielding strength. And the location of buckling is all around the reduced sections, as shown in Figure 5 and Figure 6. The ultimate out-of-plane displacement is up to almost 35mm.

Both monotonic and cyclic curves, along with each FEM curve, are shown in Figure 7 and Figure 8, from which typical pinching problem, due to the buckling, can be observed.

Figure 5. Buckling of the monotonically loaded specimen

Figure 6. Buckling of the cyclically loaded specimen

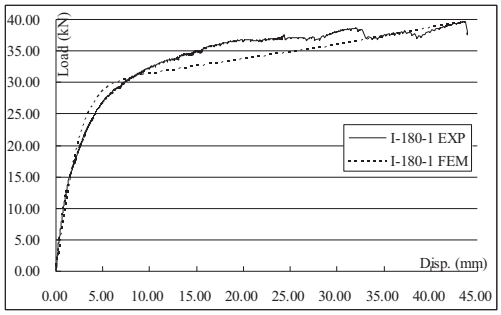

Figure 7. The monotonic curves of I-180-1

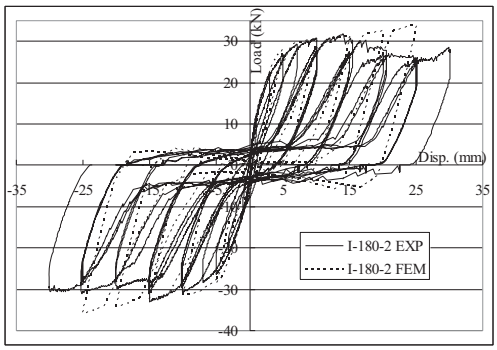

Figure 8. The cyclic curves of I-180-2

IC-280A and IC-280B

Thanks to the RC panels, the maximum out-of-plane displacement of these BRSWs is only 4mm. And no significant cracks develop, except for a few micro cracks that are mainly result from the tightening of bolts before loading, as shown in Figure 9 and Figure 10.

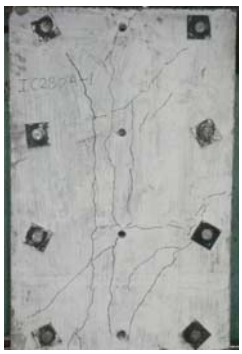

Figure 9. The cracks of the RC panel before loading

Figure 10. The cracks of the RC panel after loading

And although no observable buckling is seen from outer appearance during the loading, the hysteretic curves do have shown the pinching, as exhibited in Figure 11, as well as the monotonic curves shown in Figure 12, which is very much believed that there is an un-ignorable gap between the steel plate and the RC panels.

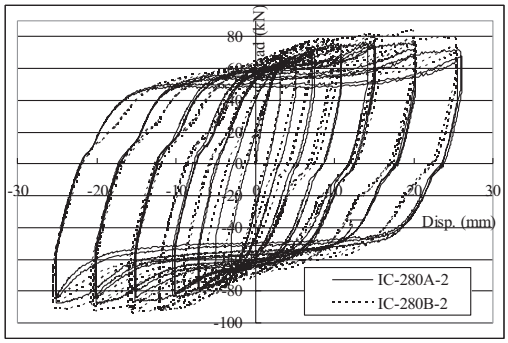

Figure 11. The hysteretic curves of IC-280

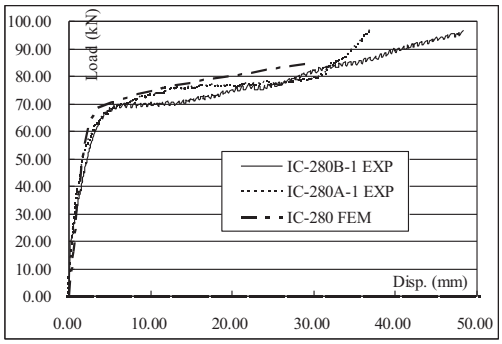

Figure 12. The monotonic curves of IC-280

IC-180

Similar to the IC-280, there is no significant crack observed after loading, except some cracks because of the tightening before the test. And several diagonal cracks between bolts have developed with the loading, as shown in Figure 13. However, the hysteretic curve, shown in Figure 14, still pinches apparently. The monotonic curve along with the FEM curve is also presented in Figure 15.

Figure 13. The diagonal cracks between the bolts

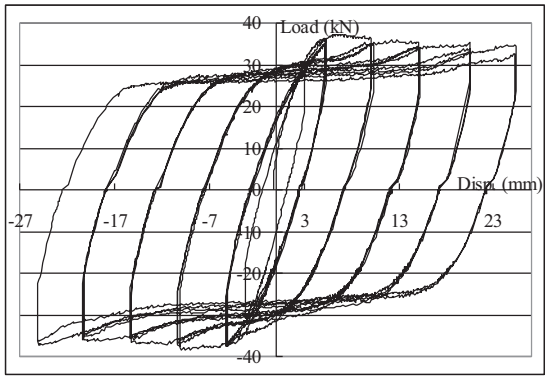

Figure 14. The hysteretic curve of IC-180-2

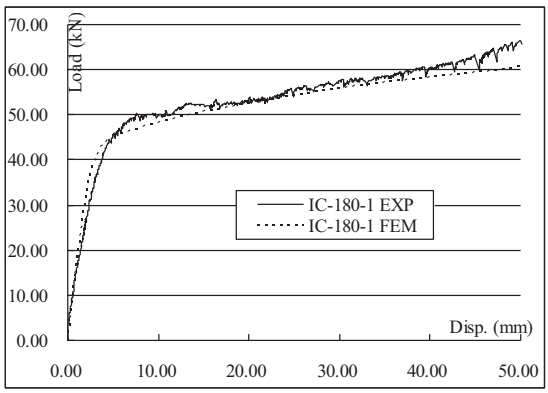

Figure 15. The monotonic curve of IC-180-1

IC-140

The failure of the RC panels in IC-140 is even minor, compared to the above specimens, as shown in Figure 16. The hysteretic curve is thus fatter than previous specimens, as shown in Figure 17, which is most likely due to the fact that narrower width of the steel plate enhances the critical shear buckling strength and lower the demands on the buckling restrainer.

The monotonically loaded curve of IC-140-1 is plotted in Figure 18 below.

Figure 16. RC panel of IC-140 after loading

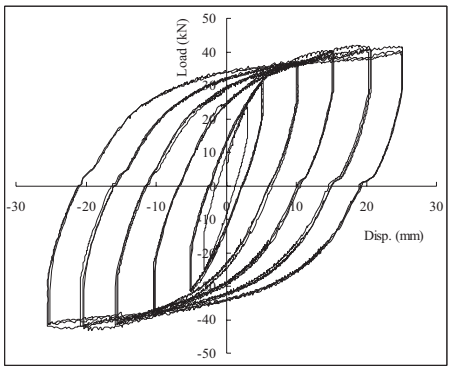

Figure 17. The hysteretic curve of IC-140-2

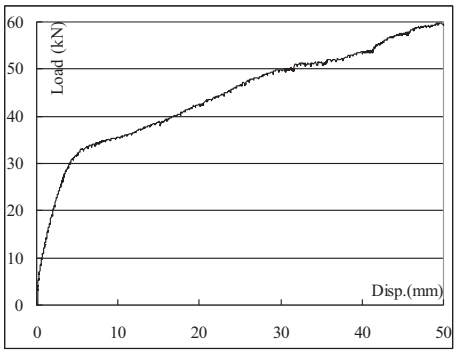

Figure 18. The monotonic curve of IC-140-1

3.2 The energy-dissipating coefficient

The energy-dissipating capability can be defined by the amount of energy, which is just equivalent to the area of the hysteretic loop. And to make it easier, the dimensionless parameter, energy-dissipating coefficient defined by the Figure 19 and Eq. (1), is introduced.

Therefore, the calculated energy-dissipating coefficient of above-mentioned specimens is listed in Table 2. Ordinarily, the hysteretic loop with a spindle shape has a coefficient of 3, more or less.

From Table 2, it can be seen that the BRSWs with large aspect ratio do have absorbed a great deal of energy, since the coefficient is almost 3.

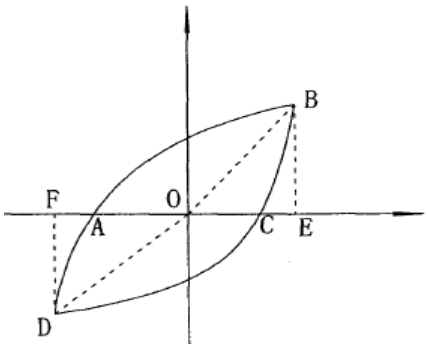

Figure 19. The definition of energy-dissipating coefficient

$$E = \frac{S_{ABCD}}{S_{OBE} + S_{ODE}} \quad (1)$$

Table 2. The energy-dissipating coefficient

Drift ratio	1/300	1/150	1/100	1/60	1/50	1/40
I-180-2	0.5	0.6	0.7	0.8	0.9	0.8
IC-280A-2	1.4	1.9	2.5	2.5	2.5	2.5
IC-280B-2	1.1	1.6	2.3	2.3	2.4	2.4
IC-180-2	1.2	1.6	2.4	2.7	2.8	2.8
IC-140-2	1.3	1.5	2.1	2.2	2.5	2.6

3.3 The cumulated plastic deformation

Similarly, the deformability can be evaluated by the ratio of cumulated plastic deformation to the yielding displacement, which is denoted as CPD in short. Therefore, CPD of those specimens are listed in Table 3, from which it is concluded that the maximum CPD have already exceeded 200 to a large extent and certainly meet the demands.

Table 3. The CPD

Drift ratio	1/300	1/150	1/100	1/60	1/50	1/40
I-180-2	4	16	52	111	195	303

IC-280B-2	9	31	89	181	308	470
I-180-2	4	19	61	130	227	361
IC-140-2	3	12	43	96	172	285

4. TESTS ON SMALL-ASPECT-RATIO WALLS

4.1 Experimental specimens

3 full-scale BRSWs (IC-1600, ISC-1600-1 and ISC-1600-2) with small aspect ratio of around 0.6 have been tested cyclically, in which the steel plates are 30mm, 25mm and 25mm thick respectively, and made of three parts that are welded together, as shown in Figure 21. The upper and lower parts are made from Q345 and the middle BLY225, aims to take advantage of the ductility of low-yield point steel. And the nominal yielding strength of BLY225 steel is 225MPa and 213MPa from the coupon tests.

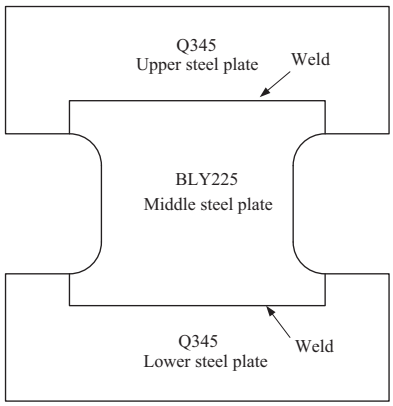

Figure 21. The three-part steel plate

Besides, RC panels are improved with extra built-in channel steels and used in IC-1600, as sketched in Figure 22. Stiffened steel case is used as buckling restrainer in ISC-1600-1, while a certain amount of concrete is casted in the stiffened steel case of ISC-1600-2, as shown in Figure 23 - Figure 25.

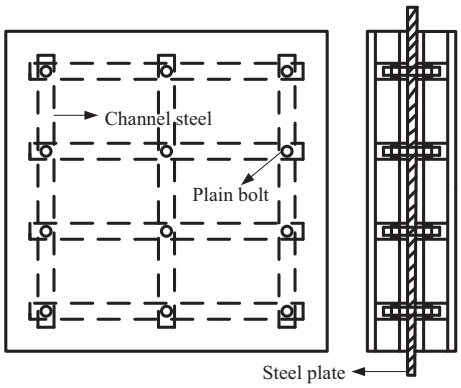

Figure 22. RC panel with built-in channel steels

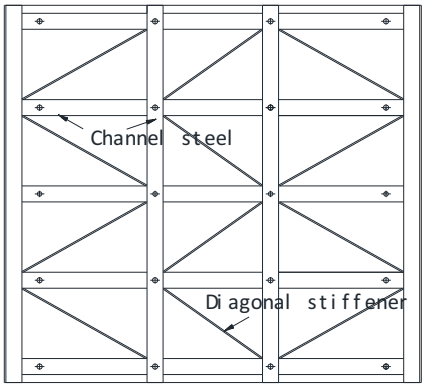

Figure 23. The plan of the stiffened steel case (ISC-1600-1)

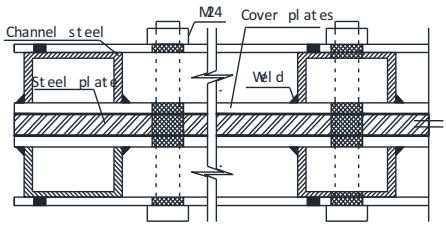

Figure 24. The section plan of the stiffened steel case

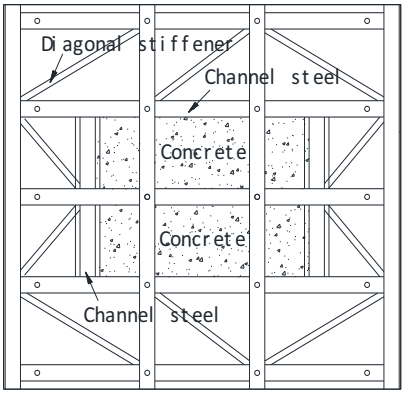

Figure 25. The plan of the stiffened steel case (ISC-1600-2)

4.2 Setups

Similar to previous setups, still a hinge frame but with full scale，as shown in Figure 26. The similar measurements are also presented in Figure 26.

Figure 26. The hinge frame

4.3 Loading protocol

Certainly, following tests also adopt displacement control principle and exactly same criterion to previous. The detailed protocol is plotted in Figure 27.

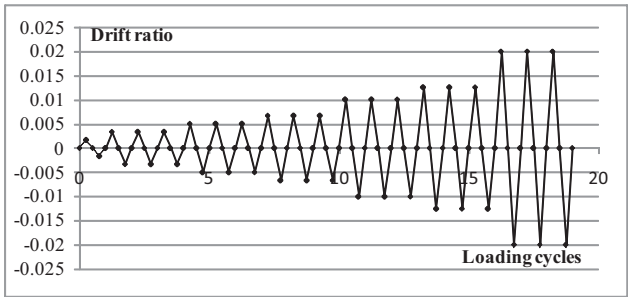

Figure 27. The loading protocol

5. RESULTS OF SMALL-ASPECT-RATIO WALLS

5.1 Overview

IC-1600-1

No significant cracks occur until the drift ratio exceeds 1/100, which is blamed to inadequate reinforcement. Before that, the buckling restraining, provided by the RC panels, is adequate, judging from the fact that there is no obvious pinching in hysteretic curve, as indicated in Figure 28.

After first cycle of 1/80 drift ratio, the out-of-plane displacement of the specimen is up to 10mm, and after the second cycle of 1/80, the RC panels have already fractured severely because of the buckling, as shown in Figure 29 and Figure 30.

ISC-1600-1

Still, nothing can be observed from outside, due to the

large flexural stiffness of stiffened steel case. However, through the gap between the steel cases, buckling of the inner steel plate is noticed, when the drift ratio reaches 1/100, as shown in Figure 31. Therefore, a micro pinching occurs in the hysteretic curve, as plotted in Figure 32.

Finally, the maximum drift ratio achieves 1/50, when further loading degrades the strength to a degree of more than 15%. And after removing the both-side steel cases, the buckling shape of the steel plate is clearly presented, as shown in Figure 33. So does the local failure of steel case shown in Figure 34.

ISC-1600-2

There is nothing significant noticed during the test, when specimen ISC-1600-2 is finally loaded to target drift ratio of 1/50. Much milder local failure occurs, thanks to the strengthened steel case by concrete, as shown in Figure 35. Therefore, a spindle-shape hysteretic curve is obtained, as shown in Figure 36.

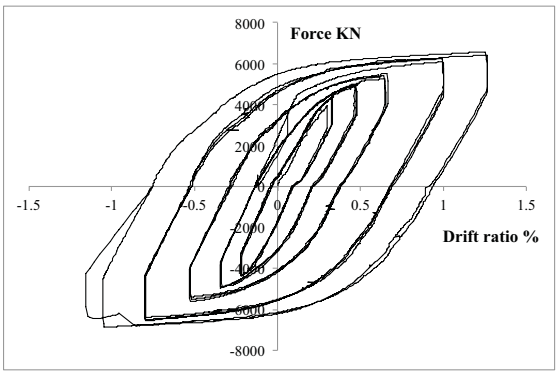

Figure 28. The hysteretic curve of IC-1600-1

Figure 33. The buckling of inner steel plate after test

Figure 34. The local failure of stiffened steel case

Figure 35. The local failure of the steel case

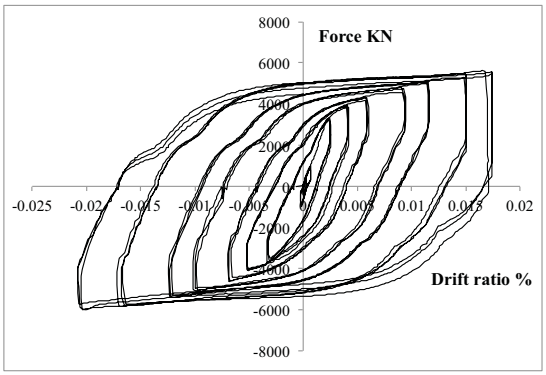

Figure 36. The hysteretic curve of ISC-1600-2

5.5 The energy-dissipating coefficient

The calculated energy-dissipating coefficient is listed in Table 4, from which it is concluded that RC panels with built-in channel steels and stiffened steel cases can provide even stronger buckling restraining, compared to the ordinary RC panels, since the maximum coefficient has already exceeds 3 in specimen ISC-1600-2. And the steel case strengthened by concrete provides the strongest restraining.

Table 4. The energy-dissipating coefficient

Drift ratio	1/300	1/200	1/150	1/100	1/80	1/50
IC-1600-2	1.0	1.6	2.0	2.3	2.8	\
ISC-1600-1	1.6	1.9	2.1	2.4	2.4	2.7
ISC-1600-2	1.4	2.1	2.8	2.9	3.2	2.9

5.6 The cumulated plastic deformation

And without suspense, the deformability of these specimens also meet the demands, since the maximum cumulated plastic deformation exceeds 200 times of yielding displacement, as indicated in Table 5.

Table 5. The CPD

Drift ratio	1/300	1/200	1/150	1/100	1/80	1/50
IC-1600-2	5	16	34	64	90	\
ISC-1600-1	15	41	80	138	219	352
ISC-1600-2	12	36	67	120	189	304

6. THEORETICAL MODEL

6.1 Yielding strength

Similar to the rectangular steel plate, the yielding line of I-shape steel plate is around reduced section. Therefore, a parametric study on the location of yielding line has been conducted, as shown in Figure 37. And the analysis indicates that this location is directly influenced by H, h_s and b_s, which have been defined in Figure 38. The distance between the yielding line and the centerline of steel plate is thus obtained by Eq.(2).

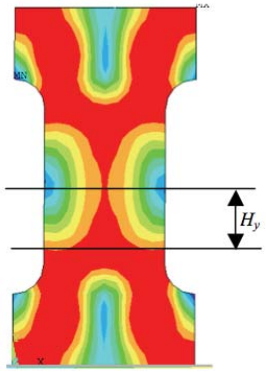

Figure 37. The yielding line of I-shape steel plate

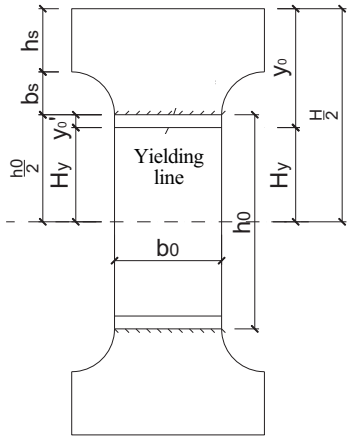

Figure 38. The dimension of I-shape steel plate

$$H_y = 0.88(\frac{H}{2} - h_s - b_s) \quad (2)$$

After confirming the position of yielding line, the yielding strength Q_y of I-shape BRSW with different aspect ratios can be predicted by Eq.(3) - Eq.(5), in which M_p is the yielding moment and Q_p is the yielding shear force.

$$Q_y = \frac{M_p Q_p}{\sqrt{Q_p^2 H_y^2 + M_p^2}} \quad (3)$$

$$M_p = \frac{t b_0 f_y}{4} \quad (4)$$

$$Q_p = \frac{t b_0 f_y}{\sqrt{3}} \quad (5)$$

6.2 Initial stiffness

Numerically, I-shape wall is equivalent to rectangular wall. Therefore, initial stiffness of I-shape BRSW can be obtained by introducing an equivalent width of steel plate, which is expressed in Eq.(6). After series of numerical study and parametric analysis, the magnification factor β_b can be gotten by Eq.(7), approximately. Besides, given h_s and b_s that don't outreach the range below, as expressed in Eq.(8), Eq.(6) is able to predict the yielding strength precisely to a satisfactory degree.

$$K = \frac{Et}{2.6\frac{H}{\beta_b b_0} + (\frac{H}{\beta_b b_0})^3} \quad (6)$$

$$\beta_b = 1.05(\frac{4(h_s + b_s)b_s - \pi b_s^2}{Hb_0} + 1) \quad for\ \frac{H}{B} \geq 1$$
$$\beta_b = 0.96(\frac{4(h_s + b_s)b_s - \pi b_s^2}{Hb_0} + 1) \quad for\ \frac{H}{B} < 1 \quad (7)$$

$$0.10B \leq b_s \leq 0.30B, \quad 0.10H \leq h_s \leq 0.22H \quad (8)$$

6.3 Verification by tests

Based on given equations, the yielding strength and initial stiffness of all above-mentioned specimens are obtained, as summarized in Table 6 below, compared with the test results. And from the comparison, it is concluded that the theoretical model can predict the yielding strength (Q_y) and initial stiffness (K) to a satisfactory degree.

Table 6. Comparison of Q_y and K between theoretical and test results

	Q_y(KN)			K (KN/mm)		
	Theory	test	Error %	Theory	test	Error %
IC-280A	68.3	70.3	-2.9	35.4	36.4	-2.8

IC-180	30.6	46.6	-34.4	15.9	16.4	-3.2
IC-140	19.1	34.1	-44.0	10.2	12.8	-20.4
IC-1600-1	4812	4705	2.3	1213	603	101.2
ISC-1600-1	4010	4004	0.2	1010	1001	0.9
ISC-1600-2	3980	4100	-2.9	983	837	17.4

7. CONCLUSIONS

5 series of BRSWs with large aspect ratio and 3 BRSWs with small aspect ratio have been experimentally studied, in which the large aspect ratio ones are buckling restrained by ordinary reinforcement concrete panels. One of the small aspect ratio BRSWs is buckling restrained by reinforcement concrete panels with built-in channel steels, while the others use stiffened steel cases. The test results indicate that BRSWs with either large or small aspect ratio exhibit excellent capability of energy dissipating, as supreme as deformability, judging from the obtained energy dissipating coefficient and the cumulated plastic deformation.

Besides, corresponding theoretical models, which are used for calculating the yielding strength and initial stiffness are put forward and also verified by previous test results. Above all, the equations are capable of predicting the yielding strength and initial stiffness to a satisfactory degree.

Abstract: Composite concrete steel-plate shear walls with binding bars are composed of a slender rectangular steel plate box infilled with concrete and connected by binding bars using bolt connection. In this paper, cyclic testing and numerical analysis were performed on three composite walls whose aspect ratios are 1.5 to investigate their seismic behavior. These specimens are designed with different spacing of binding bars. The failure modes and deformation performance were observed. Valuable results were evaluated including the hysteretic curves, bearing capacity and skeleton curves. Numerical analysis was performed to analyze the effects of different axial compression ratios and spacing of binding bars. The results indicate that bolt connection is feasible between two steel plates. The seismic performance of bolted double steel plates-concrete filled composite shear walls is well and the seismic performance was enhanced effectively by increasing the number of binding bars especially when axial compression ratio is high.

1. INTRODUCTION

Composite concrete steel-plate shear walls with binding bars (SCS walls), defined herein as concrete-filled slender steel box walls with binding bars connecting the two long-side plates (Figure 1.), are characterized by high strength and significant deformation ductility for compressive and shear loading due to the composite action of steel plates and concrete. The SCS wall can serve as both a structural unit and a prefabricated construction system. If the SCS wall can be applied to the super tall or tall buildings, the cross section of the structural element could be largely decreased, which would save much space and beautify the architecture. The existence of the steel plates replaces the building template, which facilitates the energy conservation and environmental protection.

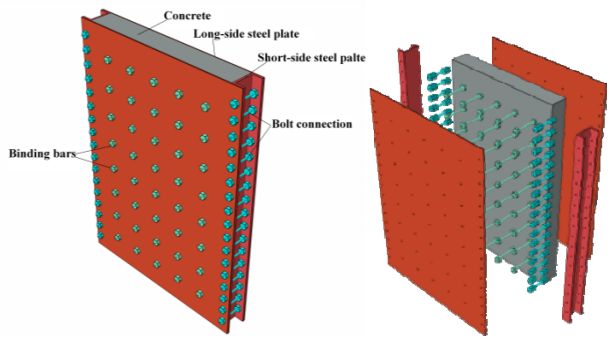

Figure 1 Composite concrete-steel plate shear walls with binding bars

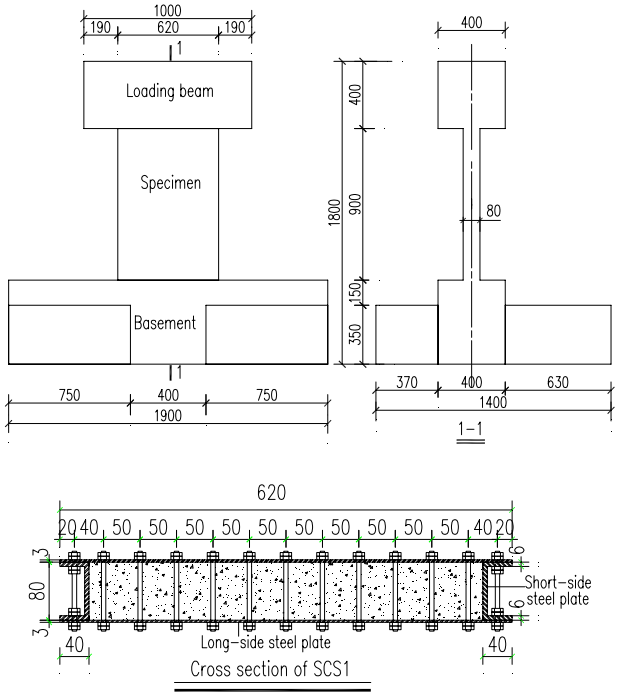
Many researchers have carried out experimental and analytical study and found that this kind of composite wall is characterized by high strength and ductility.

Wright *et al*. (1995) conducted some pilot studies on the composite concrete and steel plate walling system and found that the steel sheeting provides similar characteristics to conventional framework for concrete casting. Three 1/4 scale specimens of SCS walls were built to take cyclic shear loading test by Emori K. (2002). The shear test exhibited high strength and significant ductility of SCS walls. Wielded connection was used between the insert plates and the long-side steel plate, which would result in the deficiency of the steel plates and be difficult to be applied to the engineering. Anwar *et al*. (2004) presented the studies of the in-plane shear behavior of such walls and it was found that the walls could provide high shear resistance if adequate boundary connections between sheeting and concrete were ensured. Tae-Sung *et al*. (2009) took in-plane cyclic loading test of double skin composite walls. Nie *et al*. (2011) conducted the cyclic loading tests on low shear-span ratio composite walls. Mydin *et al*. (2011) have finished some tests to study the structural behaviour of composite concrete and steel plate shear walls under axial compression. The test results have shown that the seismic performance of such composite shear walls was much better than the conventional shear walls.

In this study, cyclic lateral loading tests were conducted on three specimens of SCS walls to investigate its seismic performance. The wielded connection was normally used to connect two steel plates, but bolt connection was used between the long-side steel plate and short-side steel plate in the test which was different from existing research. The

feasibility of the bolt connection between the steel plates was tested, and the influence of the spacing of binding bars on the buckling behavior of steel plates was investigated.



2. EXPERIMENTAL PROGRAM

2.1 SPECIMEN DESIGN AND FABRICATION

Three specimens of SCS walls were designed (Table 1) and quasi-static cyclic loading test was conducted in Tongji University (Figure 2 and Figure 3). The cross section of the specimens is 86mm×620mm and the detail is show in Figure 2. The aspect ratio of these three specimens is 1.5. The concrete strength grade is C30 and Q235 steel is used for steel plates. The yield stress of the binding bars is 400MP. Diameter of the binding bars is 6mm, thickness of short-side steel plates is 6mm, thickness of long-side steel plates is 3mm and thickness of core concrete is 80mm. Bolt connection was used between the long-side steel plate and short-side steel plate, which also could prevent buckling of the wing of shot-side steel plate.

Table 1 Parameters of specimens

NO.	Cross section (mm)	Spacing of binding bars (mm)	Axial compression ratio
SCS1	620×86	50	0.3
SCS2	620×86	100	0.3
SCS3	620×86	150	0.3

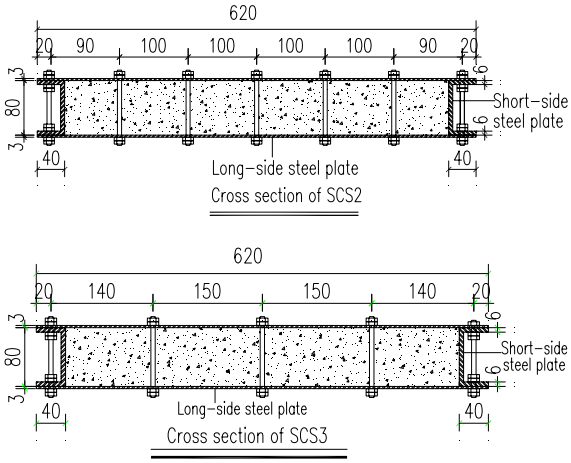


Figure 2 Cross section and detailing of composite concrete and steel plate shear walls with binding bars

Two ends of the specimen are embedded into the reinforced concrete loading beam and basement.

The axial compression ratio is a very important parameter which can affect the ductility of the SCS walls and it is calculated by Equation 1.

$$n = \frac{N}{f_c A_c + f_y A_s} \tag{1}$$

where n=axial compression ratio, N=the axial force, f_c=the uni-axial compressive strength of concrete, f_y=the yield stress of the steel plate, A_c=the cross section area of the core concrete, and A_s=the cross section area of the steel.

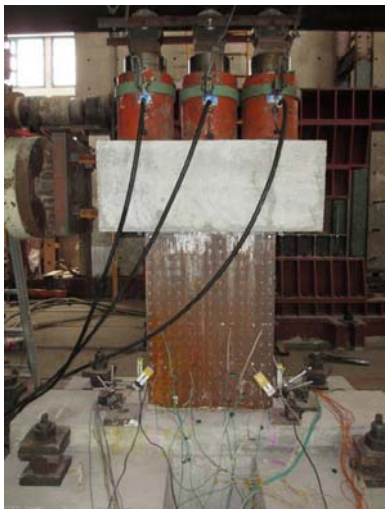

Figure 3 Test setup and specimen SCS1

2.2 EXPERIMENTAL PHENOMENA

In the tests, the axial loads remained unchanged and the gradually increasing positive and negative lateral loads were repeatedly applied so as to subject specimens to both bending and shear forces simulating the behavior of SCS walls under earthquakes. The load actuator was hinged together with the loading beam, therefore, the forces on the roots of specimens are the largest.

The failure positions were focused on their roots. The

loading process could be divided into three stages: pre-yielding stage (from beginning to yielding point on the load-displacement envelope curve), plastic stage (from yielding point to the peak point) and failure stage.

2.2.1 SPECIMEN SCS1

The binding bar spacing of specimen SCS1 is 50mm. The hysteretic force-displacement curve of SCS1 is plotted in Figure 4. The performance of SCS1 in three stages are described as follows.

(1) Pre-yielding stage

The specimen yielded when the lateral force reached 318.5KN (-307.6KN) at the drift ratio of 1/131 (-1/134). During this process, some voice could be heard because of the crack of the concrete and the friction between the concrete and steel plate. There was no evident phenomenon on the steel plates or binding bars and the state of the specimen was well.

(2) Plastic stage

When the lateral force reached the peak value 383.1KN (-364.9KN) at the drift ratio of 1/64 (-1/56) , elastic buckling deformation took place in the bolt connection area of the long-side steel plate in the root on the edge, where a small gap was opening and closing continuously with the increasing repeatedly lateral load. The buckling did not develop to the central part of the root.

(3) Failure stage

When the lateral load is reduced to 85 percent of the peak value at the drift ratio of 1/36 (-1/34), the specimen was considered to come to failure. The convex buckling area of the long-side steel plates developed gradually from the edge to the central part of the specimen and the deformation of long-side steel plates on both sides were almost symmetrical. The lateral load was reduced slowly before the fracture of the bolt connection. With the increasing of lateral displacement, five bolt connections were broken, the lateral force was largely reduced, the long-side and short-side steel plates was toned and the core concrete was crushed as shown in Figure 5.

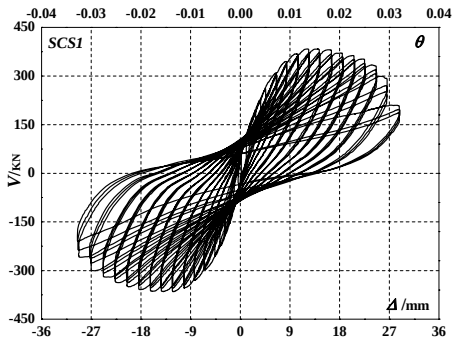

Figure.4 The hysteretic force-displacement curves of SCS1

Figure 5 Fracture of long-side and short side steel plates of specimen SCS1

2.2.2 SPECIMEN SCS2

The binding bar spacing of specimen SCS2 is 100 mm. The hysteretic force-displacement curve of SCS2 is plotted in Figure 6. The performance of SCS2 in three stages are described as follows.

(1) Pre-yielding stage

The specimen yielded when the lateral force reached 306.8KN (-271.9KN) at the drift ratio of 1/162 (-1/170). During this process, some voice could be heard because of the crack of the concrete and the friction between the concrete and steel plate. There was no evident phenomenon on the steel plates or binding bars and the state of the specimen was well.

(2) Plastic stage

When the lateral force reached the peak value 372.0KN (-325.7KN) at the drift ratio of 1/80 (-1/68) , elastic buckling deformation took place in the bolt connection area of the long-side steel plate in the root on the edge, where a small gap was opening and closing continuously with the increasing repeatedly lateral load. The buckling did not develop to the central part of the root but the buckling area is larger than that of SCS1.

(3) Failure stage

When the lateral load is reduced to 85 percent of the peak value at the drift ratio of 1/56 (-1/54), the specimen came to failure. The convex buckling area of the long-side steel plates developed symmetrically and gradually from the edge to the central part of the specimen. With the increasing of lateral displacement, fifteen bolt connections was broken continuously, the lateral force was largely reduced, the local buckling of long-side and short-side steel plates took place , the core concrete was crushed on the whole cross section and one vertical and several diagonal cracks appeared on the core concrete as shown in Figure 7.

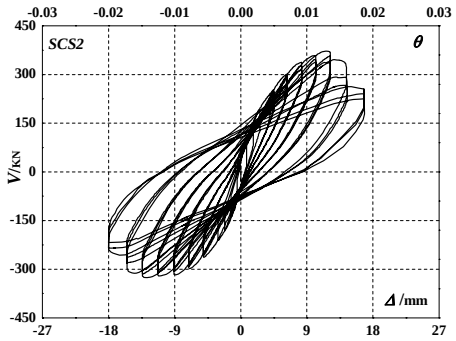

Figure.6 The hysteretic force-displacement curves of SCS2

Figure.7 Buckling of long-side and short side steel plates and crush of concrete of specimen SCS2

2.2.3 SPECIMEN SCS3

The binding bar spacing of specimen SCS3 is 150 mm. The hysteretic force-displacement curve of SCS3 is plotted in Figure 8. The performance of SCS3 in three stages are described as follows.

(1) Pre-yielding stage

The specimen yielded when the lateral force reached 253.2KN (-271.9KN) at the drift ratio of 1/206 (-1/192). During this process, some voice could be heard because of the crack of the concrete and the friction between the concrete and steel plate. There was no evident phenomenon on the steel plates or binding bars and the state of the specimen was well.

(2) Plastic stage

When the lateral force reached the peak value 305.5KN (-293.5KN) at the drift ratio of 1/105 (-1/90) , elastic buckling deformation took place in the bolt connection area of the long-side steel plate in the root on the edge, where a small gap was opening and closing continuously with the increasing repeatedly lateral load. The buckling also took place in the central part of the root.

(3) Failure stage

When the lateral load is reduced to 85 percent of the peak value at the drift ratio of 1/69 (-1/66), the specimen came to failure. The convex buckling area of the long-side steel plates developed asymmetrically and gradually on the edge and the central part of the specimen. With the increasing of lateral displacement, nineteen bolt connections were broken continuously, the lateral force was largely reduced, the local buckling of long-side plates took place, the core concrete was crushed on the whole cross section and two cross inclined cracks appeared on the core concrete as shown in Figure 9. But no large deformation or local buckling of the short-side steel plate took place when the specimen came to failure. The binding bar spacing of SCS3 is too large to prevent convex buckling of long-side steel plate effectively and the buckling of long-side steel plate took place before yielding of the steel, which made its ultimate capacity largely decreased.

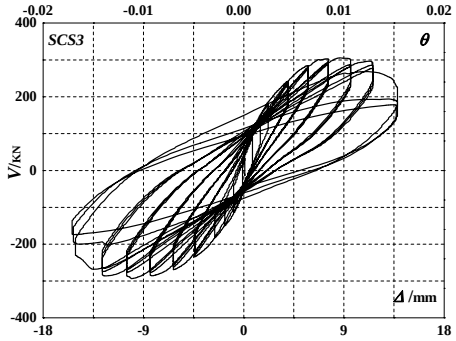

Figure 8 The hysteretic force-displacement curves of SCS3

Figure 9 Buckling of long-side steel plates and crush of concrete of specimen SCS3

2.2 EXPERIMENTAL RESULTS ANALYSIS

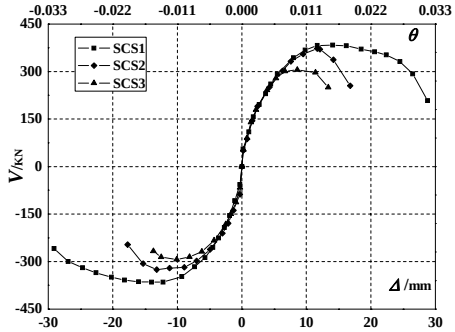

Figure 10 Comparison of load-displacement envelope curves of three specimens

Figure 10 shows the comparison of load-displacement envelope curves of three specimens under different drift ratios. When the drift ratio was less than 1/200 in the yielding stage, there was no evident difference on the

envelope curves of specimens. But the binding bar spacing has an obvious influence on the ultimate capacity and ductility of SCS walls. Specimens with different binding bar spacing exhibited different ultimate capacity: the smaller the binding bars spacing, the greater the ultimate capacity (V_u) and the drift ratio (θ_u) at ultimate strength as shown in Figure 10.

Table 1 shows the typical values of the specimens. The ultimate capacity of SCS1 is 2.85% greater than that of SCS2 in compression direction and 11.74% greater than that of SCS2 in tension direction. The ultimate capacity of SCS2 is 21.76% greater than that of SCS3 in compression direction and 3.63% greater than that of SCS3 in tension direction. The ductility of the specimens was evaluated by the displacement ductility coefficient μ, which is evaluated as $\mu = \theta_d/\theta_y$. With the decrease of binding bar spacing, the ductility of the specimen was obviously improved especially when the binding bar spacing was reduced from 100mm to 50mm. The displacement ductility coefficient of SCS1 is 27.2% greater than that of SCS2 in compression direction and 22.7% greater than that of SCS2 in tension direction.

3. NUMERICAL ANALYSIS

3.1 FINITE ELEMENT MODEL

A finite element model of SCS wall was built in software ABAQUS to simulate its seismic behavior (Figure.11).

Shell element S4 was used to simulate the behavior of the long-side steel plate including its buckling behavior. Truss model was applied to the binding bars and continuum element was applied to concrete and short-side steel plate.

The elastic modulus of loading beam and the basement is set the same as steel. The ends of concrete and steel plates are embedded into the beam and basement to simulate the boundary condition. The binding bars are embedded into the concrete and tied to the long-side steel plates. A surface-to-surface contact was defined between the steel and concrete. The penalty method that permits some relative motion of the surfaces when they should be sticking was selected to simulate the tangential and normal behavior between the concrete and steel. The friction coefficient was taken as 0.6 (Rabbat and Russell,1985).

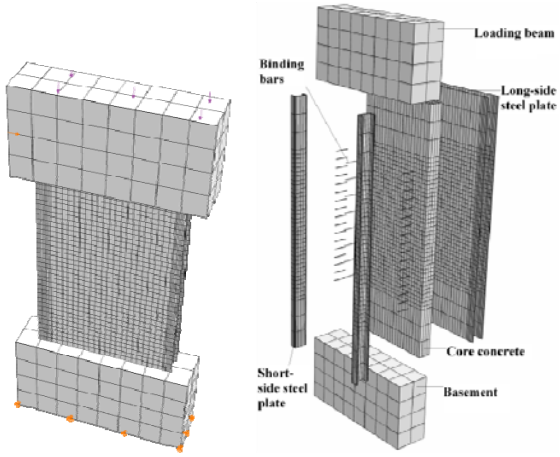

Figure.11 Finite element model

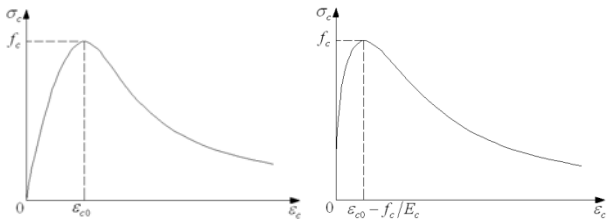


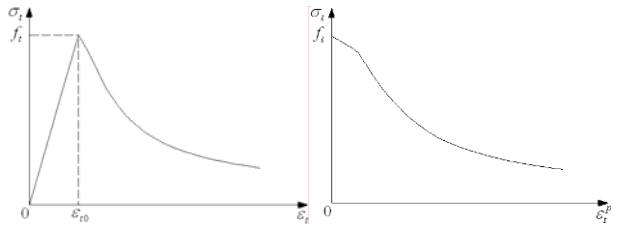
The model of the steel and concrete used in the FEM analysis are as follows:

(1) The damaged plasticity model (Table 2) (Chen, X., &Zhou, D.Y., 2009.) was used for concrete. The failure surface of it was shown in Figure.14. The dilation angle of the concrete was 30^0. The uniaxial compressive stress-strain curve of concrete (Eq. 2) proposed by Guo, Z.H. (1991) was used in analysis as shown in Figure.12. The ascending part of the tensile stress-strain curve of the concrete was linear and the descending part of it was proposed by Guo Z.H. (1991) (Eq.3) as shown in Figure.13.

$$\left.\begin{aligned} y &= \alpha_a x + (3-2\alpha_a)x^2 + (\alpha_a - 2)x^3, (0 \le x \le 1) \\ y &= x/[\alpha_d (x-1)^2 + x],\ (x > 1) \end{aligned}\right\} \quad (2)$$

where $x = \varepsilon_c/\varepsilon_{c0}$, $y = \sigma_c/f_c$, $\varepsilon_{c0} = (700 + 172\sqrt{f_c}) \times 10^{-6}$, $\alpha_a = 2.4 - 0.0125 f_c$, $\alpha_d = 0.157 f_c^{0.785} - 0.905$.

f_c is the uni-axial compressive strength of the concrete, ε_{c0} is the peak compressive strain of the concrete, α_a、α_d are the parameters of the stress-strain curve.



(a) Stress-strain curve (b) Stress-plastic strain curve

Figure.12 Uniaxial compressive stress-strain curves of concrete

$$\left.\begin{aligned} y &= x, \qquad (0 \le x \le 1) \\ y &= x/[\alpha_t (x-1)^{1.7} + x],\ (x > 1) \end{aligned}\right\} \quad (3)$$

Where, $x = \varepsilon_t/\varepsilon_{t0}$, $y = \sigma_t/f_t$, $\varepsilon_{t0} = 65 \times 10^{-6} f_t^{0.54}$, $\alpha_t = 0.312 f_t^2$, f_t is the tensile strength of the concrete, ε_{t0} is the peak tensile strain, α_t is a parameters of the tensile stress-strain curve.

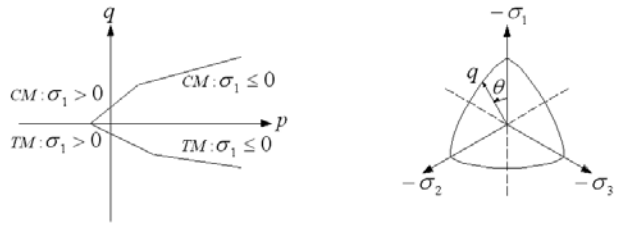
(a)Stress-whole strain curve (b) Stress-plastic strain curve

Figure.13 Uniaxial tensile stress-strain curves of concrete

Table 2 Damaged Plasticity Model

Yielding function		Plastic potential function
$\sigma_1 \le 0$	$f = q - 3\alpha p + \gamma\sigma_1 - (1-\alpha)\sigma_c = 0$	$g = q - p\tan\psi$
$\sigma_1 > 0$	$f = q - 3\alpha p + \beta\sigma_1 - (1-\alpha)\sigma_c = 0$	

Where, $q = \sqrt{\left((\sigma_1-\sigma_2)^2+(\sigma_2-\sigma_3)^2+(\sigma_3-\sigma_1)^2\right)/2}$, $p = -(\sigma_1+\sigma_2+\sigma_3)/3$, $\cos\theta = (-2\sigma_1+\sigma_2+\sigma_3)/2q$. α 、 β 、 γ are material parameters. ψ is the dilation angle.



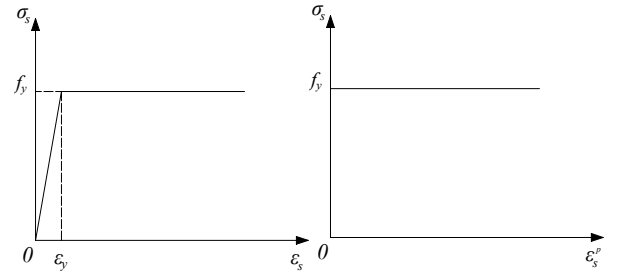


Fig.14 The failure surface of damaged plasticity model

(2) The constitution rule for steel was based on the plasticity theory with the Von Mises (1928) yielding condition. The stress-strain relationship for the steel box and insert plate were simply assumed as bi-linear models as shown in Figure.15.

The strain hardening effect was not considered in this model. The elastic modulus of steel before yielding is 200,000N/mm^2 and the elastic modulus of steel after yielding is 0N/mm^2 as shown in Figure.15. The dilatancy effect of concrete cause the bulging of the steel plate which could cause the buckling of the steel plate.

3.2 RESULTS ANANALYSIS

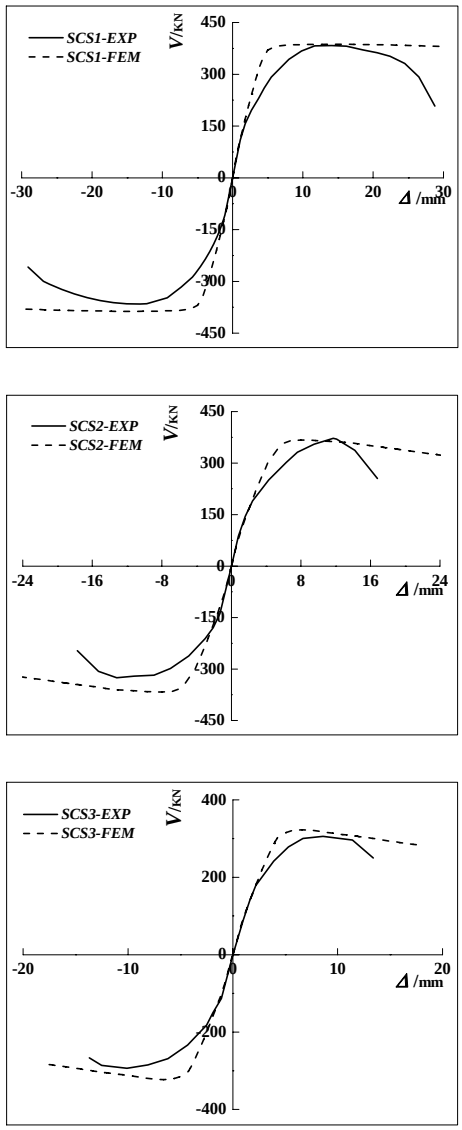

Figure.16 Comparison of load-displacement envelope curves between the FEM and experimental results

The calculated load-displacement curve of SCS1, SCS2 and SCS3 are shown in Figure. 16. The negative curve is drawn anti-symmetrically by the positive curve. The computed load-displacement envelope curves are in close agreement with those obtained by the tests of three specimens up to the yielding strength. During the plastic process, from yielding point to the peak point on the curve, the computed lateral stiffness is much larger than that obtained by the tests of three specimens. The FEM could not take into account of the damages during the cyclic loading tests. Therefore, the stiffness degradation of test results is much faster than that of computed results. During the failure stage, the strength degradation of the test results is more evident than that of computed results. When the bolt connections were coming into fracture in the tests, the strength began to degrade rapidly but it could not be simulated exactly in the numerical analysis. The computed ultimate capacities ($V_{u,FEM}$) of SCS1 and SCS2 are in close agreement with the experimental ones which are obtained by

the average value of peak loads ($V_{u,EXP}$) on the positive and negative curves as shown in Table 3. The computed ultimate capacities ($V_{u,FEM}$) of SCS3 is in good agreement with the experimental one ($V_{u,EXP}$) which is obtained by the average value of peak loads ($V_{u,EXP}$) on the positive and negative curves as shown in Table 3. This finite element model is acceptable to simulate the behavior of SCS walls and some parameter analysis was made as follows on the basis of this finite element model.

Table 3. Comparison of ultimate capacities between the test results and computed results

NO.	Test results $V_{u,EXP}$ *(KN)*	Computed results $V_{u,FEM}$ *(KN)*	$V_{u,FEM}/V_{u,EXP}$
SCS1	374.00	382.54	1.03
SCS2	348.85	367.20	1.05
SCS3	299.51	339.90	1.13

Figure.17 shows the influence of binding bar spacing on the ultimate capacity and a comparison was made between the experimental and analytical results. The computed ultimate capacities are little greater than the experimental ones and the computed ultimate capacity is decreasing with the decrease of binding bar spacing which is consistent with the experimental results. The decreasing of binding bar spacing can both weaken the confining effect of core concrete and reduce the buckling stress of the steel plate.

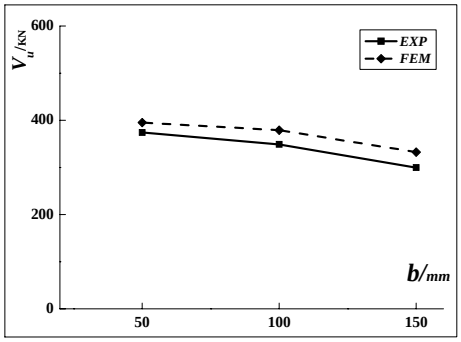

Figure.17 Comparison of influence of spacing of binding bar on the ultimate capacity

In order to study the influence of axial compression ratio to the ultimate capacity of SCS walls, six models (*SCS1-n*) were analyzed according to SCS1, six models (*SCS2-n*) were analyzed according to SCS2 and six models (*SCS3-n*) were analyzed according to SCS3. The axial compression ratio was changed from 0.1 to 0.6 accordingly. Figure.18 represents the ultimate capacity-axial compression ratio curves with different binding bar spacing.

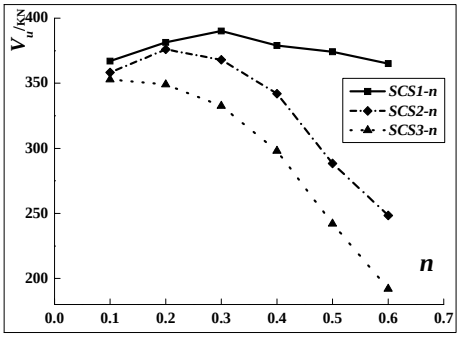

Figure.18 The ultimate capacity-axial compression ratio curves

It can be seen from curve *SCS1-n* in Figure 18 that the ultimate capacity increased when the axial compression ratio changed from 0.1 to 0.3 and decreased when the axial compression ratio changed from 0.3 to 0.6. The maximum value of ultimate capacity of SCS1-n models is obtained when the axial compression ratio is 0.3. The maximum value of ultimate capacity of SCS2-n models is obtained when the axial compression ratio is 0.2. For the models SCS3-n the ultimate capacity decreased with the change of axial compression ratio from 0.1 to 0.6. It can be concluded that with the increasing of binding bar spacing, the adverse effect of axial compression ratio on the ultimate capacity is greatly increased.

4. CONCLUSIONS

Three specimens of SCS walls were tested experimentally under cyclic loading condition and three models of each SCS walls with different axial compression ratios were selected and analyzed using the finite element method allowing nonlinear behavior for the material. Based on the test observations and analysis of the data, the following conclusions were obtained.

(1) The seismic performance of composite concrete and steel plate shear walls with binding bars is very well. Its ultimate bearing capacity and ductility are both great.
(2) The bolt connection between the long-side steel plate and the short-side steel plate is feasible. If the bolt connection is strengthened to avoid its fracture, the ductility would be highly improved.
(3) The decrease of spacing of binding bars has an evident effect on the ductility and the shear capacity. When the binding bar spacing is 50mm, the effect of axial compression ratio on the ultimate capacity is not evident and the ultimate capacity comes to maximum value at the axial compression ratio of 0.3.
(4) The stiffness degradation speed of the SCS wall with small binding bar spacing is slower, indicating that the behavior of this structure is correspondingly more stable and therefore more favorable for seismic resistance.

Abstract: The "steel tube-double steel plate-concrete composite wall" consists of concrete filled steel tubular (CFST) boundary elements and a double "skin" composite web where two steel plates are connected by tie bolts with space between them filled with concrete. In this paper, the behavior of the composite walls was examined through experiments in which five slender rectangular wall specimens were subjected to axial forces and lateral cyclic loading. The specimens failed in local buckling of the steel tubes and plates, fracture of the steel tubes, and concrete crushing at the wall base. The extent of the CFST boundary element was found to significantly affect the wall's deformation capacity. The area ratio of steel plates had a minimal effect on the deformation capacity of the slender walls. The addition of circular steel tubes embedded in the CFST boundary elements obviously increased the strength of the walls. When the CFST boundary element's extent was 0.2 times the wall's sectional depth and the axial force ratio was no more than 0.25, the walls had an ultimate drift ratio of around 0.03. Design formulas used to calculate the flexure strength of the walls were proposed, and the prediction had good agreement with the test results.

1. INTRODUCTION

The use of composite structural members that combine the advantages of two constructional materials, steel and concrete, has gained popularity. A variety of steel-concrete composite walls have been developed. These composite walls can be classified into three categories. The first category consists of steel panels combined with concrete walls, for instance, the single skin composite wall (Zhao and Abolhassan 2004) and the double skin composite wall (Emori 2002, Hossain and Wright 2004, Eom et al. 2009). The second category comprises of steel frame boundary and infilled RC walls (for example, Tong et al, 2005, Liao et al. 2009). The third category are the so-called steel reinforced concrete (SRC) walls which include additional steel (or steel tubes) embedded at the wall boundary elements (for example Wallace et al. 2000, Qian et al. 2012). Extensive studies, including both experimental testing and numerical simulation, have indicated that these composite walls are characterized by a combination of good strength, stiffness and deformation capacity properties, exhibiting an excellent seismic performance.

This paper proposes an innovative composite wall, named "the steel tube-double steel plate-concrete composite wall", which is particularly well suited for use in high-rise buildings in regions of high seismicity. Fig.1 shows a sketch of typical cross-section of the rectangular composite wall. Rectangular steel tubes act compositely with infilled concrete to form the concrete-filled steel tubes (CFSTs), serving as the wall boundary elements. Additional circular steel tubes could be embedded at the CFST boundary elements for further enhancement of the earthquake-resistant capacity of the wall. Double steel plates, as the skins of wall web, are connected by tie bolts, with the space between them filled with concrete. The CFST boundary elements primarily resist the bending moment exerted on the wall, while the double steel plates, together with the filled concrete, primarily resist the shear force exerted on the wall. The steel tubes and plates are used as the formwork for the concrete filler, enabling rapid construction of the walls. The filled concrete prevents early buckling of the steel tubes and plates, whereas the confinement provided by the steel tubes increases the strength and ductility of the filled concrete. Therefore, such a cross-sectional arrangement of the composite wall is expected to enhance the wall's seismic performance.

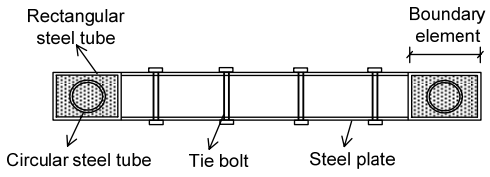

Figure 1. Sketch of cross-section of steel tube-double steel plate-concrete composite wall

The objective of this paper is to examine the seismic behavior of the proposed composite walls through a series of quasi-static tests of rectangular wall specimens. The first section introduces the experimental program in detail. The second section presents the test results, including the failure mode, lateral load-carrying, deformation and energy dissipation capacities of the walls. The third section proposes simplified formulas used to evaluate the wall's flexural

strength, and calibrates them through comparisons with the test results.

2. EXPERIMENTAL PROGRAM

2.1 Test Specimens

2.1.1 Specimen Design

A total of five test specimens, labeled SW1 to SW5, were tested. The specimens were designed to represent the lower stories of structural walls in high-rise buildings, and were fabricated at approximately 1/6 scale to accommodate the capacity of the loading facility. All specimens had the same overall geometry, as shown in Fig. 2. The wall was 2600 mm tall, and had a rectangular cross-section with a depth of 1100 mm and a thickness of 140 mm. The aspect ratio (i.e., height-to-width ratio) of the wall was about 2.5, ensuring a flexure-dominated deformation mode. A RC foundation beam with a cross-section of 750 mm by 600 mm was cast together with the wall, through which the specimen was securely clamped to the reaction floor. A RC top beam with a cross-section of 300 mm by 300 mm was cast as well, through which the vertical and horizontal loads were applied to the wall.

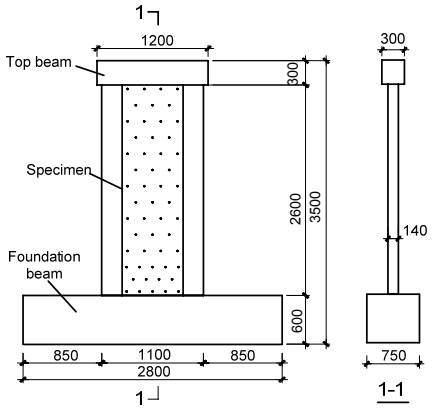

Figure 2. Elevation view of wall specimens (Unit: mm)

Fig. 3 shows the sectional dimensions and details of the wall specimens. The specimens were designed to satisfy the "strong shear and weak bending" mechanism, and the test results showed that all specimens failed in a flexural mode. Three variables were considered for design of the specimens: (1) the extent of the CFST boundary element, (2) presence or absence of embedded circular steel tubes at the CFST boundary elements, and (3) the area ratios of the steel tubes and of the steel plates. The extent of the CFST boundary element of Specimen SW1 was equal to the cross-sectional thickness of the wall. For Specimens SW2 through SW5, the extent of the CFST boundary element was designated to be 0.2 times the wall's cross-sectional depth, according to the provision for RC walls stipulated by the Chinese Code for Seismic Design of Buildings (GB 50011-2010). Circular steel tubes were embedded at the CFST boundary elements for Specimens SW1 through SW4, whereas no additional circular tubes were placed in Specimen SW5. The area ratios of the steel tubes and of the steel plates varied for different specimens by changing the thickness of steel tubes and plates. Details on this variable are described later in Subsection 2.2.2.

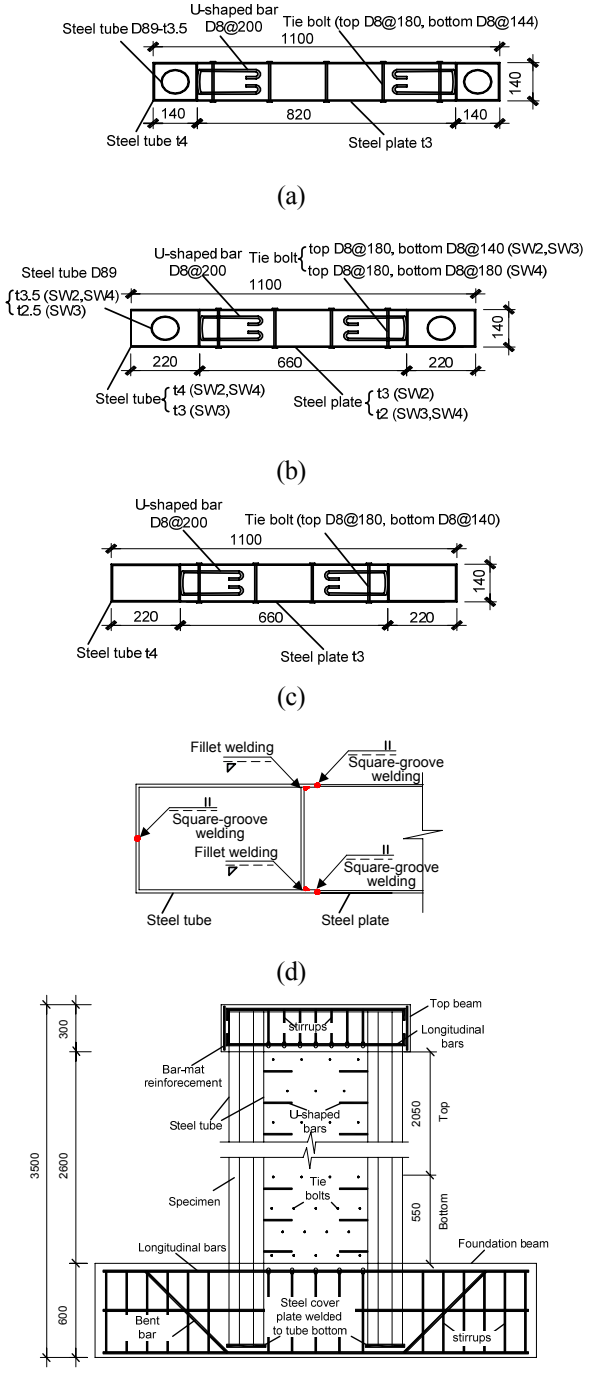

Figure 3. Section dimensions and details (Unit: mm): (a) SW1, (b) SW2 through SW4, (c) SW5, (d) Welding details of steel tubes and steel plates, and (e) Elevation drawing of steel tubes and reinforcement for SW2

The rectangular steel tubes were fabricated by connecting cold-formed thin plates with full penetration square-groove welds and with fillet welds, as shown in Fig. 3(d). The rectangular steel tubes and steel plates were

connected by full penetration square-groove welding. D8 (Diameter = 8mm) U-shaped bars, which were welded to the rectangular steel tubes and extended into the web concrete, were used to ensure the shear transfer between the CFST boundary elements and wall web concrete. The U-shaped bars extended 180 mm to the web concrete, and had a vertical spacing of 200 mm. Double steel plates were fastened to each other by D8 (Diameter = 8 mm) high strength bolts. The vertical and horizontal spacings of tie bolts were 200 and 180 mm, respectively, and the ratio of the bolt spacing to steel plate thickness varied from 60 to 90 for different specimens. Note that the region from the base of the wall up to a height equal to 0.5 times the cross-sectional depth of the wall was supposed to form a plastic hinge and to experience significant inelastic deformation. Therefore, the spacing of tie bolts in this region was reduced to 140 to 150 mm and the ratio of the bolt spacing to steel plate thickness was around 45 to 70.

Fig. 3(e) shows an elevation drawing of the steel tube and reinforcement for Specimen SW2. The steel tubes and plates were extended into the RC foundation and top beams to achieve full anchorage. The anchorage depth of the rectangular steel tubes within the foundation beam was no less than 2.5 times the tube's sectional depth. In addition, a steel cover plate was welded at the tube bottom and three rows of rebars were welded along the tube perimeter as ribs, which also contributed to secure anchorage. Reinforcing details of the foundation and top beams were designed to ensure that the beams were damage free during testing.

2.1.2 Material Properties

The concrete used in the specimens had a strength grade of C40 (nominal cubic compressive strength $f_{cu,d}$ = 40 MPa, and design value of axial compressive strength $f_{c,d}$ = 19.1 MPa). Specimens SW1 and SW4 were cast with a batch of concrete, and Specimens SW2, SW3 and SW5 with another batch of concrete. Actual cubic compressive strength $f_{cu,t}$ of the concrete was tested on cubes of 150 mm size and the results are shown in Table 1(a). Note that the actual value (referred to as "test value" hereinafter) of axial compressive strength of concrete $f_{c,t}$ was taken as 0.76 $f_{cu,t}$ according to Chinese Code for Design of Concrete Structures (GB50010-2010).

Steel tubes and plates were fabricated from Grade Q235 steel (nominal yield strength f_y = 235 MPa, and design value of yield strength $f_{y,d}$ = 215 MPa). The U-shaped bars were plain steel bars, and their strength grade was HPB235 (f_y = 235 MPa). D8 tie bolts had a strength grade of 8.8 (nominal ultimate strength f_u = 800 MPa, and the ratio f_y/f_u = 0.8). The material properties of steel were measured by coupon tests, and the test values of yield and ultimate strengths $f_{y,t}$ and $f_{u,t}$ are shown in Table 1(b).

Table 1(a) Material properties for concrete

Specimen No.	cubic compressive strength, $f_{cu,t}$ (MPa)	Axial compressive strength, $f_{c,t}$ (MPa)
SW1, SW4	44.0	33.4
SW2, SW3 & SW5	40.8	31.0

Table 1(b) Material properties for steel

Nominal thickness (mm)	Measured thickness (mm)	Yield strength, $f_{y,t}$ (MPa)	Ultimate strength, $f_{u,t}$ (MPa)
2.0	1.83	332.4	440.7
2.5	2.38	345.7	393.2
3.0	2.94	322.1	433.5
3.5	3.12	383.7	461.3
4.0	3.73	298.6	443.6
8.0 (bolt diameter)	7.63 (bolt diameter)	788.3	914.0

2.2 Test variables

Besides the extent of the CFST boundary element, and presence or absence of circular steel tubes at the CFST boundary elements, the major test variables were the axial force ratio applied to the wall, and the area ratios of the steel tubes and of the steel plates.

2.2.1 Axial Force Ratio

The axial force is one of the critical concerns for the design of a ductile structural wall. An increase of the axial force ratio increases the depth of the compression zone of the wall section and consequently decreases the ductility of the wall. For the steel tube-double steel plate-concrete composite wall, the axial force ratio is defined as follows:

$$n_d = \frac{N_d}{f_{c,d}\left(A - \sum\left(A_a + A_p\right)\right) + \sum\left(f_{a,d}A_a + f_{p,d}A_p\right)} \quad (1a)$$

$$n_t = \frac{N_t}{f_{c,t}\left(A - \sum\left(A_a + A_p\right)\right) + \sum\left(f_{a,t}A_a + f_{p,t}A_p\right)} \quad (1b)$$

in which, n denotes the axial force ratio; N denotes the axial load applied on the specimen; f_c denotes the axial compressive strength of the wall concrete; f_a and f_p denote the yield strengths of steel tubes and steel plates, respectively; A denotes the gross cross-sectional area of the wall; A_a and A_p denote the gross cross-sectional areas of steel tubes and steel plates, respectively; and subscripts d and t represent the values of design and test, respectively. According to GB50011-2010, the load factor (i.e., the ratio of the design value of the axial load to the actual value) was 1.2. The material strength reduction factor (i.e., the ratio of the design value of material strength to the corresponding test value) was also considered. Allowing for both the load factor and material strength reduction factor, the design value of the axial force ratio was approximately 1.9 times the corresponding test value. It is notable that, under the same axial compressive load, the axial force ratio of the composite wall is 35%~40% lower than the corresponding RC wall with the same sectional geometry, due to the increase in the axial load-carrying capacity provided by the steel tubes and plates. It is beneficial to reduce the wall thickness if it is governed by the limit of axial force ratio in design.

Table 2 shows the axial compressive loads applied to the specimens and the corresponding axial force ratios. Specimens SW1 and SW2 had the similar axial force ratios,

with a design value of 0.45 to 0.49 and a test value of around 0.25. Specimens SW3 through SW5 had the similar axial force ratios with the design value of 0.36 to 0.39 and the test value of 0.20.

Table 2 Axial force ratio of specimens

Specimen No.	N (kN)	n_d	n_t
SW1	2061	0.49	0.25
SW2	1908	0.45	0.24
SW3	1431	0.38	0.20
SW4	1546	0.39	0.20
SW5	1431	0.36	0.20

2.2.2 Area Ratios of Steel Tubes and of Steel Plates

Steel tubes and steel plates for the composite walls are analogous to the reinforcing bars for the RC walls. Accordingly, the area ratios of the steel tubes and of the steel plates are critical factors for design of the composite walls. The area ratio of the steel tubes is defined as the ratio of the cross-sectional area of the steel tubes to that of the CFST boundary element. The area ratio of the steel plates is defined as the ratio of the cross-sectional area of the steel plates to that of the wall web. Table 3 lists the area ratios of the steel tubes and of the steel plates for the specimens. The area ratio of the rectangular steel tubes for Specimens SW2, SW4, and SW5 was 0.085, larger than the ratio of 0.068 for Specimen SW3. The area ratio of the steel plates for Specimens SW1, SW2 and SW5 was 0.042, larger than the ratio of 0.026 for Specimens SW3 and SW4.

The confinement index of CFSTs is used to quantify the extent of confining of the infilled concrete by the steel tubes. The confinement index combines the area and strength ratios of the steel tubes and the infilled concrete, given by:

$$\theta = \frac{f_a A_a}{f_c A_c} \tag{2}$$

in which, θ denotes the confinement index; f_a and f_c denote the yield strength of the steel tubes and the axial compressive strength of the infilled concrete, respectively; A_a and A_c denote the cross-sectional areas of the steel tube and infilled concrete, respectively. The CFST confinement indices for the test specimens are listed in Table 3 as well.

Table 3 Parameters of steel tubes and plates

Specimen No.	Rectangular steel tube			Circular steel tube			Steel plate
	B/t	ρ	θ	D/t	ρ	θ	ρ
SW1	37.5	0.104	1.0	28.5	0.043	1.8	0.042
SW2	59.0	0.085	0.9	28.5	0.027	1.9	0.042
SW3	74.8	0.068	0.8	37.4	0.021	1.3	0.026
SW4	59.0	0.085	0.8	28.5	0.027	1.8	0.026
SW5	59.0	0.085	0.9		——		0.042

Note: 1) θ represents the confinement index of CFSTs.
2) ρ represents the area ratios of the steel tubes and of the steel plates.
3) B/t represents the depth-to-thickness ratio of rectangular steel tubes, where B denotes the sectional depth of the rectangular tube; and D/t denotes the diameter-to-thickness ratio of circular steel tubes.

2.3 Test setup, loading program and instrumentation

Fig. 4 shows the test setup, where the specimen was placed in a load frame. The foundation beam was clamped to the reaction floor. The top beam was clamped to two hydraulic actuators, one in the horizontal direction and another in the vertical direction. A rigid steel beam was placed between the specimen's top beam and vertical actuators to distribute the vertical load uniformly on the wall section. The vertical actuator could move freely in the horizontal plane to accommodate the lateral displacement of the specimen. A pair of steel beams, which were clamped to the load frame and connected to the wall through rollers, were used to provide the out-of-plane restraint to the wall specimen. A vertical load was applied to the specimen initially and was maintained constantly for the duration of the test. Afterwards, cyclic lateral loads were applied quasi-statically by the actuator mounted horizontally to the reaction wall. The horizontal loading point (i.e., the mid-point of the top beam) was 2750 mm above the base of the wall. The shear span ratio for the wall specimens was 2.5.

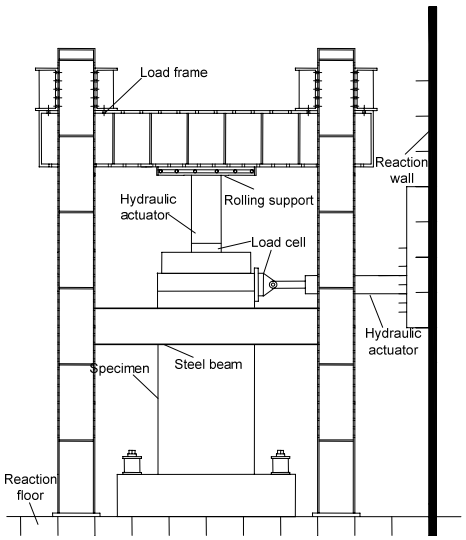

Figure 4. Test setup

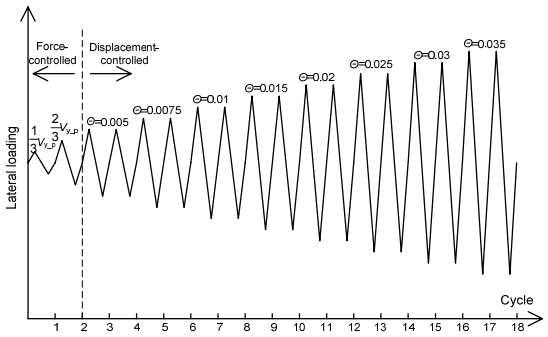

Figure 5. Loading history

Fig. 5 shows the history of lateral cyclic loading for the tests. Before the specimen yielded, the lateral loading was

force-controlled and one cycle was performed at each force level. Two levels were considered in this phase, which were 1/3 and 2/3 the predicted yield load of the specimen $V_{y,p}$. The loading was changed to displacement controlled after the specimen yielded. The lateral displacement of the wall top was monitored by the linear variable differential transformer (LVDT) 1#, as shown in Fig. 6. The displacement was expressed in terms of the drift ratio θ, which was defined as the ratio of the lateral displacement over the height of LVDT 1# relative to the base of the wall (i.e. 2550 mm). The lateral drift ratios increased in the sequence of 0.005, 0.0075, 0.01, 0.015, 0.02, 0.025, 0.03, and 0.035, and two cycles were repeated at each drift level. In each loading cycle, a push was exerted first, followed by a pull, where the push was defined as the positive loading and the pull as the negative loading. The test was terminated when the specimen completely failed due to steel fracture and concrete crushing developing at the base of the wall. Except for Specimen SW1 that failed at 0.03 drift, all other specimens failed at 0.035 drift.

Instrumentation was used to measure the loads, displacements and strains of the specimens. Load cells measured the vertical and lateral loads applied to the specimen. The LVDTs measured the global and local deformations of the specimen. Fig. 6 shows the locations of the LVDTs mounted on the specimen. Four LVDTs (i.e., LVDTs 1# through 4#) measured the lateral displacements at 650 mm intervals along the height of the wall. Two pairs of crossed LVDTs (i.e., LVDTs 5# through 8#) measured the shear deformation of the wall. Three LVDTs (i.e., LVDTs 9# through 11#) were mounted on the foundation beam to monitor any horizontal slip of the foundation beam along the reaction floor and any rocking of foundation beam during the loading. Seven LVDTs (i.e., LVDTs 12# through 18#) were mounted at the base of the wall to measure the local deformation from which the average vertical strains could be estimated. In addition, strain gauges were installed to measure the vertical, horizontal and shear strains of the steel tubes and plates. The gauges were located 20 mm and 500 mm above the base of the wall, as indicated by Sections A and B shown in Fig. 6. The strains of the two tie bolts at the base of the wall were also measured. The measurements were recorded automatically by a computer data acquisition system.

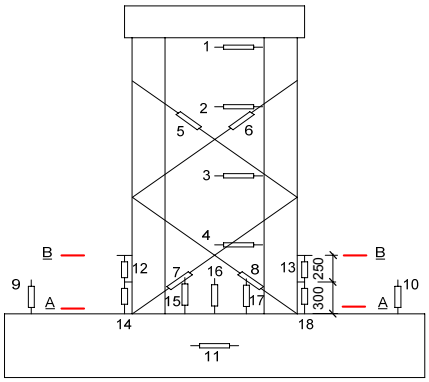

Figure 6. Specimen instrumentation

3. EXPERIMENTAL PROGRAM

3.1 Damage and Failure Mode

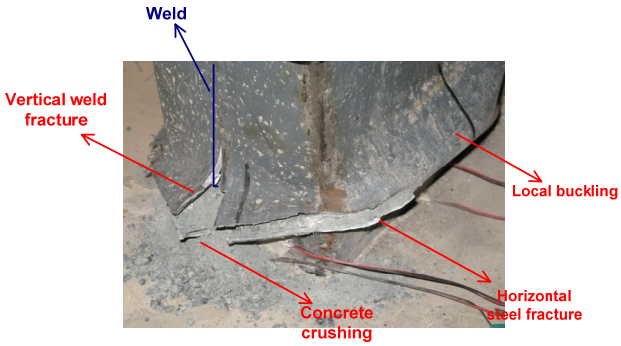
The wall specimens experienced similar damage patterns, which included local buckling of steel tubes and steel plates, fracture of steel tubes, and compressive crushing of concrete at the base of the wall. The damage process could be characterized by three stages: the elastic stage, damage developing stage, and failure stage. The damage observed at each stage is summarized as follows.

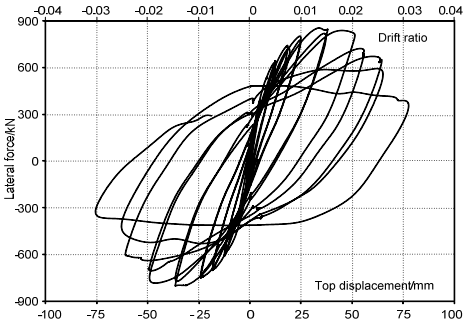
Elastic stage: This stage began from the onset of testing up to the instant when the lateral drift ratio reached 0.005. The specimens remained nearly elastic in this stage. None of local buckling of steel was observed. The strain measurements indicated that the steel tubes and plates did not yield, except that the steel at two farthest edges of the base of the wall yielded slightly.

Damage developing stage: This stage started from the 0.005 drift to the peak load of the specimens. The rectangular steel tubes sustained slight local buckling at the base of the wall when the drift ratio increased from 0.005 to 0.0075. The local buckling of steel tubes became noticeable upon further loading. The steel plates experienced local buckling at 0.015 drift. The specimens reached their peak loads when the drift ratio increased to approximately 0.02.

Failure stage: This stage began at the peak load and continued to the complete failure of the specimens. At further cycles after the peak load, the existing buckling of steel tubes and steel plates was significantly extended and aggravated, and new buckling occurred. The buckling was located in the region from the base of the wall up to a height equal to 0.5 times the sectional depth of the wall. For Specimen SW1 and SW4, vertical fracture developed along the weld of the compressive rectangular steel tubes at 0.025 drift. For Specimen SW2, SW3 and SW5, the vertical weld fracture occurred at 0.03 drift. The vertical weld fracture in steel tubes was caused by several cycles of large plastic transverse strains induced by the lateral expansion of infilled concrete in compression. Note that the weld quality of the thin steels was not high, which could accelerate the fracture. At further cycles, the steel tube in tension experienced tensile fracture of steel and the fracture was gradually extended in horizontal. Concrete crushing was observed at the base of the wall. Ultimately, the local buckling of the steel tubes interfered with the buckling of the steel plates. The wall specimens lost their vertical load-carrying capacity and suffered a complete failure. Fig. 7 shows photographs of Specimen SW4 post testing. A photograph of the details of a CFST boundary element after the test is shown in Fig. 8, where the buckling of steel tube, vertical weld fracture, horizontal steel fracture, and concrete crushing are annotated.

Figure 7. Photograph of Specimen SW4 after test





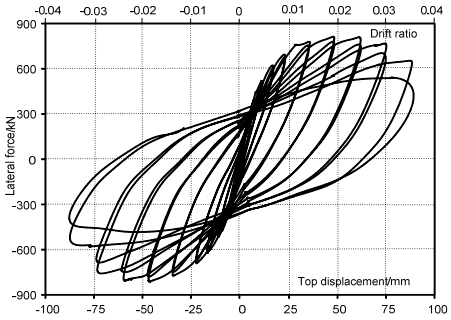


Figure 8. Photograph of CFST boundary element of Specimen SW4 at end of test

3.2 Force-Displacement Relationship

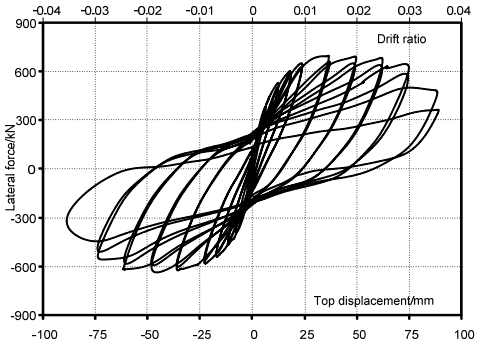

Fig.9 shows the measured lateral force versus top displacement relationships for the specimens. The hysteresis loops of all specimens were plump and not significantly pinched, showing the characteristics of the flexural failure mode. When the loading and unloading within a drift ratio less than 0.005, the hysteretic curves cycled almost linearly with minimal residual displacement. When the drift ratio exceeded 0.005, the loading stiffness clearly decreased and the strength steadily increased. Residual displacement was observed in unloading. After the peak load, the hysteresis curves showed slightly pinching effects, and the residual deformation became more noticeable. The strength of the composite walls dropped slowly, showing an excellent deformation capacity, except for Specimen SW1 that exhibited rapid strength degradation.

(c)

(d)

(e)

Figure 9. Hysteresis loops of lateral force versus top displacement relationships of specimens: (a) SW1, (b) SW2, (c) SW3, (d) SW4, and (e) SW5

The top displacement shown in Fig. 9 included the deformations induced both by flexure and by shear. The shear deformations were determined using measurements from the LVDTs placed diagonally from 0 to 1100 mm (i.e., DLVTs 7# and 8#) and from 1100 to 2200 mm (i.e., DLVTs 5# and 6#), as shown in Fig. 6. It is noted that the inelastic shear deformations were limited to the bottom 1100 mm of the wall and that the measurements between 1100 and 2200 mm were essentially elastic. Therefore, the shear deformations between 2200 and 2550 mm were assumed to be proportional to those measured between 1100 and 2200 mm. Fig. 10 shows the estimated shear deformations compared with the total deformations for Specimen SW2. As expected, the shear deformations were relatively small compared with flexure deformations, and they accounted for no more than 20% of the total deformations.

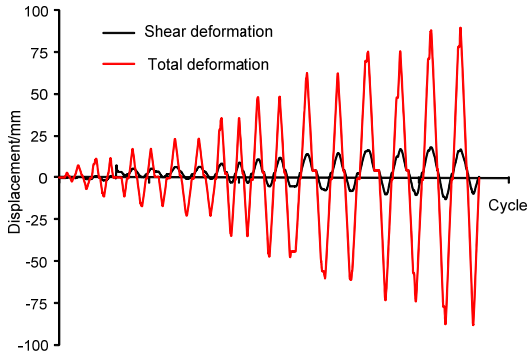

Figure 10. Shear deformations versus total deformation for Specimen SW2

Fig.11 shows the envelope curves of the lateral force versus displacement relationships. All specimens had nearly identical initial stiffness. The difference of the lateral load-carrying capacity and deformation capacity for the specimens will be described later.

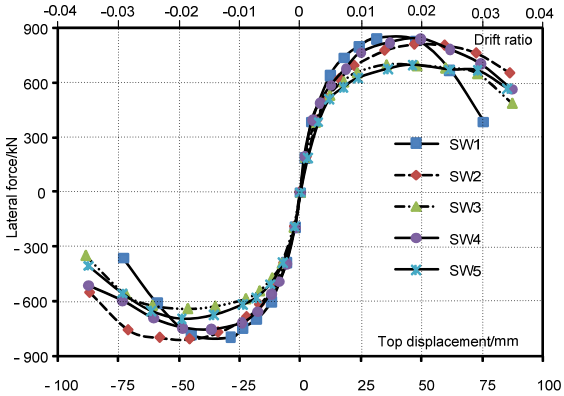

Figure 11. Envelope curves of lateral force versus top displacement of specimens

3.3 Lateral Load-Carrying Capacity

Table 4 shows the measured yield load $V_{y,m}$ and peak load $V_{p,m}$ of the specimens. Note that the values shown in Table 4 were calculated using the average values of the loads measured in the push and pull directions. The yield load point was determined by using the method proposed by Park et al. (1982). The yield loads were approximately 0.75 times the peak loads. Specimens SW1 and SW2 had similar peak loads, indicating that the extent of the CFST boundary element had minimal influence on the lateral load-carrying capacity of the composite walls. The peak load of Specimen SW4 was 20.0% higher than Specimen SW3, indicating that an increase in the area ratio of steel tubes increased the lateral load-carrying capacity of the composite walls. The comparison between Specimens SW4 and SW5 indicates that the presence of circular CFSTs at the boundary elements increased the yield load, and enhanced the peak load by 16.2%.

Table 4 Lateral load-carrying capacity of specimens

Specimen No.	Test results		Evaluated Peak load $V_{p,e}$ (kN)	$V_{p,m}/V_{p,e}$
	Yield load $V_{y,m}$ (kN)	Peak load $V_{p,m}$ (kN)		
SW1	669	814	839	0.97
SW2	614	809	810	1.00
SW3	509	669	630	1.06
SW4	597	799	778	1.03
SW5	532	698	633	1.10

3.4 Deformation Capacity

Table 5 shows the yield displacement Δ_y, ultimate displacement Δ_u, ultimate drift ratio θ_u, and displacement ductility ratio μ_Δ of the specimens. The yield displacement Δ_y was the displacement at the yield load $V_{y,m}$. The ultimate displacement Δ_u was defined as the post-peak displacement at the instance when the lateral load decreased to 85% of the peak load. The ultimate drift ratio was calculated as $\theta_u = \Delta_u / H$, where H was the height of the LVDT 1# relative to the wall base. The displacement ductility ratio was defined as $\mu_\Delta = \Delta_u / \Delta_y$. Note that the values shown in Table 5 were

calculated using the average values of the displacements measured in the push and pull directions.

Table 5 Deformation capacity of specimens

Specimen No.	Yield disp. Δ_y (mm)	Ultimate disp. Δ_u (mm)	Ultimate drift ratio θ_u	Disp. ductility ratio μ_Δ
SW1	13.72	56.12	0.022	4.09
SW2	16.26	79.16	0.031	4.87
SW3	12.45	75.58	0.030	6.07
SW4	13.81	69.84	0.027	5.06
SW5	13.88	75.53	0.030	5.44

Table 5 indicates the following four observations. (1) The ultimate drift ratio of Specimen SW1 was 0.022, much smaller than the ultimate drift ratio of 0.031 for Specimen SW2. It thus indicates that the extent of the CFST boundary element had significant effects on the deformation capacity of the composite walls. (2) The nearly identical ultimate drift ratios for Specimen SW3 through SW5 indicates that the area ratio of steel plates and addition of embedded circular steel tubes had a minimal effect on the wall's deformation capacity. (3) The ultimate displacements for Specimens SW2 through SW5 were similar, whereas the yield displacement of Specimen SW2 was larger than those of Specimens SW3 through SW5. Therefore, an increasing axial force ratio increased the yield displacement and decreased the ductility ratio of the composite walls. (4) When the CFST boundary element's extent was 0.2 times the wall's sectional depth and the test axial force ratio was 0.20 to 0.25, the wall specimens had a yield drift ratio of over 0.005 and an ultimate drift ratio of approximately 0.03.

3.5 Energy Dissipation Capacity

Fig.12 shows the cumulative energy dissipation curves for the specimens. The energy dissipated in each loading cycle is equal to the area enclosed by the corresponding hysteresis loop. The cumulative energy dissipated by Specimen SW1 was 28.6% lower than that of Specimen SW2, because the former had a smaller deformation capacity than the latter. Although the deformation capacity was similar, Specimens SW2 and SW4 showed a larger accumulative energy dissipation capacity than Specimens SW3 and SW5, because the former possessed greater strength than the latter.

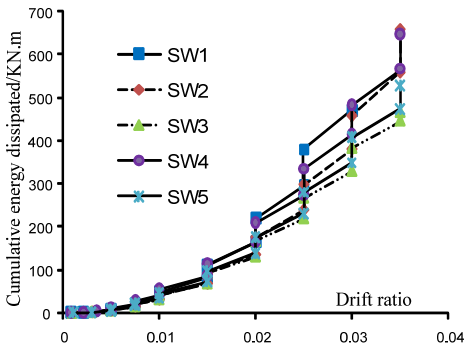

Figure 12. Energy dissipation curves for specimens

4. STRENGTH CAPACITY EVALUATION

Since the specimens displayed a flexure-dominated behavior, the lateral load-carrying capacity could be estimated from the flexure strength at the wall base section. The following assumptions were made in assessing flexural strength. (1) Initially plane sections remained plane after bending. (2) The compressive strength of unconfined concrete f_c was used for the wall concrete, except for the concrete filled in the circular steel tubes for which the strength increased significantly due to the confinement effect. Note that the confinement effect of rectangular steel tubes can not increase the strength of filled concrete, but improve its ductility (Sakino et al. 2004). Tensile strength of concrete was ignored. (3) The internal compressive force of concrete was calculated by using the equivalent rectangular stress block of average stress αf_c and the extent of βx from the extreme compression fiber, where x denotes the neutral axis depth and α and β are two parameters of the equivalent stress block. (5) Steel tubes in two edges yielded in tensile and in compression, respectively. The ultimate strength of steel was used, given the significantly hysteretic strain hardening that developed in the steel tubes. (6) Full plastic stress developed at the steel plates. Considering the relatively small plastic strain developed in steel plates, the yield strength of steel was used and the strain hardening effect was ignored. Fig. 13 illustrates the mechanism for simplified evaluation of the flexure strength of the wall section.

According to the force and moment equilibrium with respect to the wall's centroid, the follow equations were established:

$$N = N_c + N_{CFST} + \left(A_{p,c} - A_{p,t}\right) f_p - A_a^c f_a^c \qquad (3\text{-a})$$

$$M_p = N_c d_c + A_a^r f_a^r \left(h_w - l_c\right) + 0.5\left(N_{CFST} + A_a^c f_a^c\right)\left(h_w - l_c\right) + 0.5A_{p,c} f_p \left(h_w - x - l_c\right) + 0.5A_{p,t} f_p \left(x - l_c\right) \qquad (3\text{-b})$$

where N denotes the axial load applied on the wall; M_p denotes the flexural strength at the wall bottom section under the axial compressive load N; N_c denotes the compression reaction forces provided by the concrete excluding the concrete filled in the circular steel tubes; N_{CFST} denotes the reaction force provided by the circular CFST; $A_{p,c}$ and $A_{p,t}$ denote the gross cross-sectional areas of steel plates in compression and in tension, respectively; A_a^r and A_a^c denote the cross-sectional areas of the rectangular steel tube and the circular tube, respectively, at one boundary element; f_a^r, f_a^c and f_p denote the strengths of rectangular steel tube, circular steel tube and steel plate, respectively; f_c denotes the axial compressive strength of concrete; h_w denotes the depth of the wall section; l_c denotes the extent of the CFST boundary element; d_c denotes the distance between the centroid of the internal compressive force of concrete N_c and the centroid of the wall section; and x denotes the neutral axis depth.

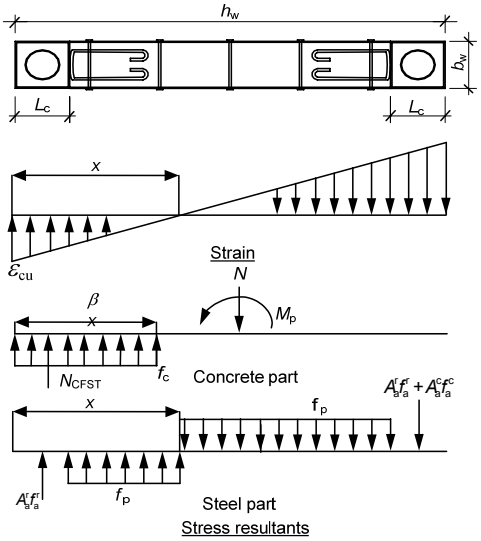

Figure 13. Flexure strength evaluation of wall section

The internal compressive force of concrete was calculated using the equivalent rectangular stress block, given by

$$N_c = \alpha f_c \left(\beta x b_w - A_{CFST} \right) \tag{4}$$

in which, A_{CFST} represents the gross cross-sectional area of the circular CFST; b_w denotes the thickness of the wall section. The value for α factor is taken to be 1.0 for the concrete of which the cubic compressive strength is not higher than C50, and the value of β factor is taken to be 0.85 for the walls (GB 50010-2010).

The compressive force of the circular CFST, N_{CFST}, was calculated by Eq. (5) which took into account the increase of concrete strength due to the confinement provided by the circular steel tube (Specification CECS 28: 1990).

$$N_{CFST} = f_{cor} A_{cor} \left(1 + 1.8\theta \right) \tag{5}$$

in which, f_{cor} and A_{cor} denote the axial compressive strength and cross-sectional area of the concrete filled in the circular steel tube, respectively; and θ denotes the confinement index of the circular CFST.

The flexure strength at the wall bottom section, M_p, was assessed by substituting Eqs. (4) and (5) into Eq. (3) and solving these equations. The lateral load-carrying capacity of the wall was then calculated. Table 4 shows the values of $V_{p,e}$ for the specimens and the comparison with the measured peak lateral load $V_{p,m}$ in the tests. The evaluated results for the composite walls are in good agreement with the test results, with errors no greater than 10%.

5. CONCLUSIONS

This paper proposed an innovative composite wall, named the steel tube-double steel plate-concrete composite wall. A series of quasi-static tests were carried out to examine the seismic behavior of slender composite walls. Major findings and conclusions obtained from this study are summarized as follows:

(1) The slender composite wall specimens failed in a flexural mode, characterized by the buckling of steel tubes and steel plates, fracture of steel tubes, and compressive crushing of concrete at the base of the wall.

(2) The extent of the CFST boundary element significantly affected the seismic behavior of the rectangular composite walls. An increase in the extent of the CFST boundary element increased the wall's deformation and energy dissipation capacities.

(3) The area ratio of steel plates showed a minimal effect on the deformation capacity of the slender composite walls that failed in a flexural mode.

(4) The addition of circular steel tubes embedded in the CFST boundary elements led to an increase in the lateral load-carrying capacity of the composite walls, but it did not increase the wall's deformation capacity.

(5) When the CFST boundary element's extent was 0.2 times the wall's sectional depth and the test axial force ratio applied to the wall was no more than 0.25, the wall specimens showed excellent deformation capacity, with a yield drift ratio of over 0.005 and an ultimate drift ratio of around 0.03.

(6) Simplified formulas were developed to evaluate the lateral load-carrying capacity of the composite walls. The evaluated results for the composite walls showed errors less than 10% when compared with the corresponding test results.

Abstract: There are many studies for seismic response behavior of lattice domes. Static seismic loads in consideration with vertical responses subjected to horizontal seismic waves are proposed in recent years. However, there are few studies dealing with actual response behavior of lattice domes by vibration tests. The seismic response behavior subjected to multi-directional input is not particularly investigated. Therefore, this paper is intended as an investigation of elastic seismic response behavior of single layer lattice domes subjected to horizontal bi-directional inputs by vibrational tests using small-scale models. In examination, the effects of phase difference between input waves and ratios of natural period of substructure to that of roof structure on response behavior are made clear. In addition, the evaluation methods for response accelerations those are adjusted to responses under horizontal bi-directional inputs are proposed.

1. INTRODUCTION

The lattice domes are used for the roofs of a gymnasium, an exhibition hall and so on. These structures are also used for evacuation facility and disaster prevention base in a time of disaster such as an earthquake or a typhoon. Therefore, it is hoped that these structures have sufficient earthquake performance for resisting large earthquake motions. For that purpose, there are many studies for seismic response behavior of lattice domes ((Kato and Mukaiyama 1996, Ogawa et al. 2003). Static seismic loads in consideration with vertical responses subjected to horizontal seismic waves are proposed in recent years (Takeuchi et al. 2004, Takeuchi et al. 2007). However, there are few studies dealing with actual response behavior of lattice domes by vibration tests (Maeda et al. 1999). The seismic response behavior subjected to multi-directional input is not particularly investigated. Therefore, this paper is intended as an investigation of elastic seismic response behavior of single layer lattice domes subjected to horizontal bi-directional inputs by vibrational tests using small scale models. In examination, the effects of phase difference between input waves and ratios of natural period of substructure to that of roof structure on response behavior are made clear. In addition, the evaluation methods for response accelerations those are adjusted to responses under horizontal bi-directional inputs are proposed.

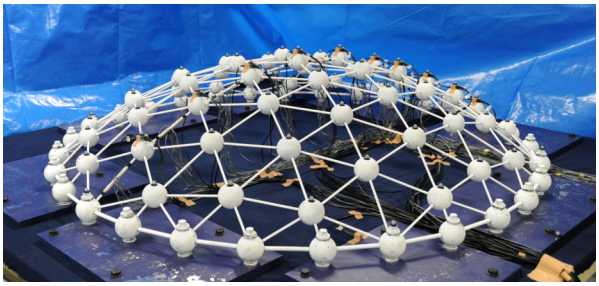

Photo 1 Experimental Model

2. OUTLINES OF VIBRATION TESTS ON SINGLE LAYER LATTICE DOME

The experimental model is the single layer lattice dome as shown in Photo 1 and Fig.1. The model consists of the ball joint system. The nodes of ball joint are steel balls with ϕ 63.5mm. The members of dome are acrylic resin (PMMA) round bar with ϕ 6.0mm. The steel balls and round bars are

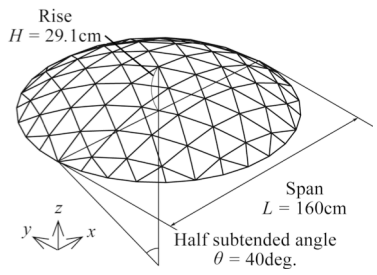

Figure 1 Shape of Single Layer Lattice Dome

Table 1 Results of Tension Test for Members and Bending Tests for Joints

Material (Diameter ϕ(mm))	Young's modulus E [N/mm^2]	Yield stress σ [N/mm^2]	Stiffness of rotational spring K_B [Nm/rad]	Dimensionless spring constant κ
PMMA(6.0)	4200	53.9	58.4	46.5

joined with the epoxy resin adhesives. For the boundary condition, the nodes of boundary of dome are pin supported by using the spherical washers. Table 1 shows the results of tension tests for members and bending tests for joints. The bending tests for joints are carried out as a simple beam test under concentrated loading.

Table 2 shows the parameters for experiments. The input directions of input waves are the uni-direction in NS direction, the uni-direction in EW direction and the bi-direction in NS and EW directions. The ratios R_T of the natural period of equivalent single mass system T_{eq} to the predominant natural period of dome structure T_R are adjusted to 0, 1 and 1.2. The names of models are defined as R_T =(the natural period ratio R_T), for example R_T=1 model. The parameter for bi-directional input is the phase differences between inputs in NS direction and EW direction. The phase differences are dealt with as the time differences, these time differences are represented by putting the time base of input wave in EW direction forward $-T_R/4 \sim +T_R/4$ ($T_R/8$ intervals). The input waves are are sine waves and JMA Kobe NS & EW (1995) which is an observed earthquake motion. At R_T=1, 1.2 models, the response accelerations of equivalent single mass system with period $T_{eq} = T_R$, $1.2T_R$ subjected to earthquake motions are used for input earthquake motion for vibration tests. The maximum accelerations of input earthquake motions A_{gmax} are standardized to be 300 cm/s^2 for R_T=0, 100 cm/s^2 for R_T=1, 1.2. The period of sine waves are set based on the natural period of dome structure T_R. The shaking table with bi-axis shaking systems of permanent magnet type (San-Esu Co., Ltd.) is used for the vibration tests.

Table 2 Parameters for Experiments

Input direction	Uni-directional input (NS direction) Uni-directional input (EW direction) Bi-directional input (NS & EW directions)
Natural period ratio R_T	0, 1, 1.2
Time differences between inputs for NS direction and EW direction	$-T_R/4$, $-T_R/8$ 0, $+T_R/8$, $+T_R/4$

At the design of experimental model, the law of similarity shown by following equations (1)~(4) (Matsuoka et al. 2006) are used.

$$T_m = \frac{1}{\lambda}\sqrt{\frac{\mu}{\rho}}T_p \quad (1)$$

$$\sigma_m = \frac{1}{\rho\alpha\lambda}\sigma_p \quad (2)$$

$$\varepsilon_m = \frac{\mu}{\rho\alpha\lambda}\varepsilon_p \quad (3)$$

$$\delta_m = \frac{\mu}{\rho\alpha\lambda^2}\delta_p \quad (4)$$

Table 3 shows the scale ratio of scale model to full-scale structure.

The supposed full-scale model is the single layer lattice dome with span of 70 m and natural period of 0.34 sec. The time axes of earthquake motions are shortened in one-ninth (1/9) by following the law of similarity. The positions for measurements are shown in Fig.2. The responses of dome structure are measured with the accelerometers, the motion capture systems (MC) and the strain gauges. The response accelerations in x, y and z directions are measured with the accelerometers and obtained by differentiating the measured displacements by MC twice with respect to time t. The out-of-plane and in-plane strains of ends of members are measured with the strain gauges. The absolute displacements of shaking table are measured with the laser displacement sensors.

Table 3 Parameters for Experiments

	Scale ratio	
Dimension	$1/\lambda=L_m/L_p$	1/44
Weight per unit volume	$1/\rho=\rho_m/\rho_p$	1/2.0
Young's modulus	$1/\mu=E_m/E_p$	1/49
Acceleration	$1/\alpha=\alpha_m/\alpha_p$	1/1.0
Stress	σ_m/σ_p	1/88
Strain	$\varepsilon_m/\varepsilon_p$	1/1.8
Deformation	δ_m/δ_p	1/79
Period	T_m/T_p	1/8.9

*Subscripts m and p represent the scale model and the full-scale model respectively.

3. VIBRATIONAL CHARACTERISTICS OF SINGLE LAYER LATTICE DOME

The eigenmodes of dome structure are measured by inputting sweep waves and sine waves. The natural periods are obtained from the predominant periods at Fourier spectra of the responses under sweeping sine waves. The mode order is determined by the length of period of mode. The shapes of eigenmode are obtained by inputting the sine wave with natural period of each mode.

Fig.3 shows the time history of strain of end of member and the damping factors at each amplitude ratio in free vibration. The damping factors are calculated from the amplitude ratios of strains in free vibration. The amplitude dependence occurs in the relationships between the damping factor and the amplitude of strain.

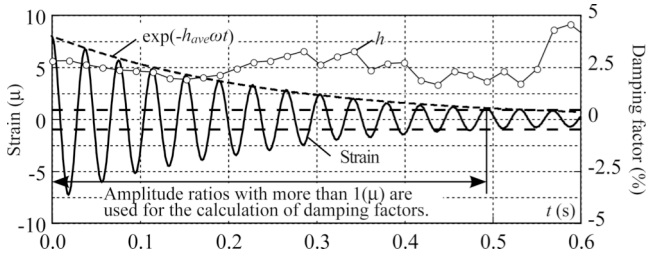

Figure 3 Time History of Strain of End of Member and Damping Factors at Each Amplitude Ratio in Free Vibration

Fig.4 shows the natural vibrational characteristics of dome structure. In the figures, the shapes of eigenmode, the natural periods, the damping factors, the phase differences between the nodes are indicated. The shapes of eigenmodes with maximum amplitude at all nodes are shown in figures because the phase differences are observed. The angles of phase differences are shown based on the phase of input wave. The lengths of straight line in figures represent the amplitudes. The amplitude ratios for calculating the damping factors are the average of amplitude ratios of strains with more than 1 μ. The damping factors in y direction are larger than those in x direction. The shapes of modes are close to the shapes with antisymmetrical 1 wave in any modes. However, the local deformations are observed at the shapes of higher order modes. The angles of phase differences between the nodes placed in symmetry about node O are about 180 deg. (opposite phase) in x direction. On the other hand, those are 140 ~ 270 deg. in y direction. In addition, the angles of phase differences between the nodes adjoining each other are small in x direction. The phases of these nodes are almost in coordinate phase. On the other hand, in y direction, the phase differences of these nodes are observed.

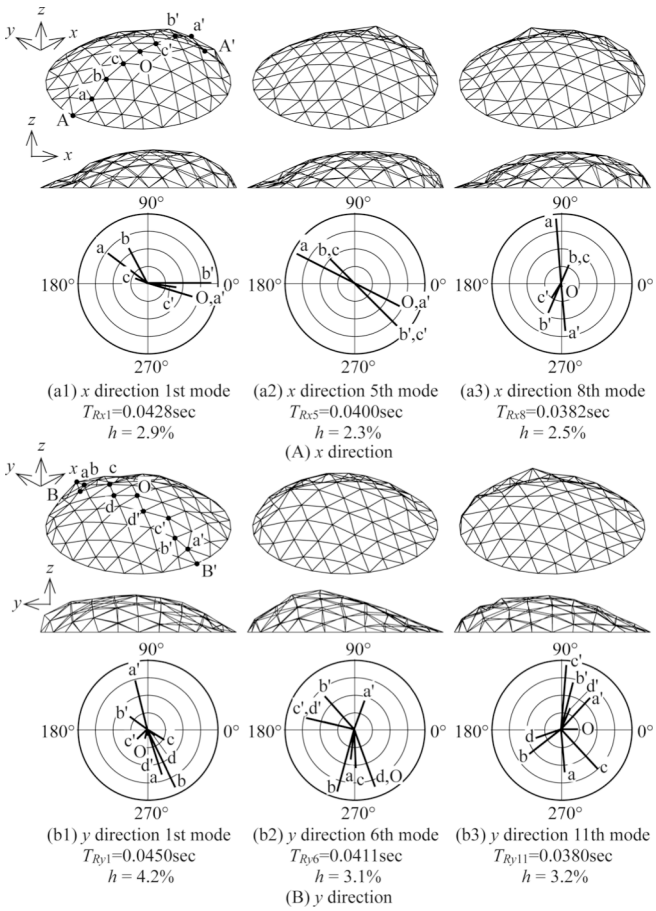

Figure 4 Natural Vibrational Characteristics of Dome Structure

Fig. 5 shows the vertical response magnification factors at node with maximum response of dome structure subjected to sine wave with natural period of each mode. There are a lot of predominant modes in narrow periodic band around 0.038 sec regardless of input direction. The average of periods of predominant modes in x and y directions are adopted as the period of dome structure T_R. In this experiments, the period T_R is 0.0381 sec which is the average of 8th mode in x direction and 11th mode in y direction.

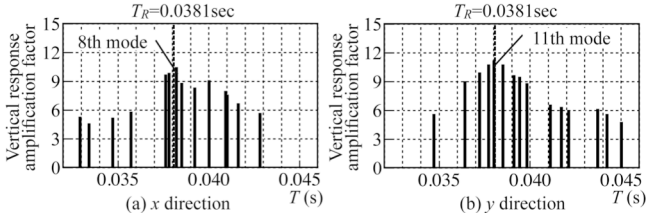

Figure 5 Vertical Response Magnification Factors at Node with Maximum Response Subjected to Sine Wave with Natural Period of Each Mode

4. SEISMIC RESPONSE BEHAVIOR OF SINGLE LAYER LATTICE DOME

4.1 Comparisons between Response Behavior under Uni-directional Input and that under Bi-directional Input

In this section, the response behavior under uni-directional input is compared with that under bi-directional input. The maximum vertical response acceleration magnification factors on line DOD' under sine waves with phase differences $T_p = +T_R/8, +T_R/4$ are shown in Fig.6. The distributions of maximum vertical response acceleration magnification factors on entire dome roof under sine wave with phase difference $T_p = +T_R/8$ are shown in Fig.7. The distributions of response magnification factors under bi-directional input obtained as the sum of time

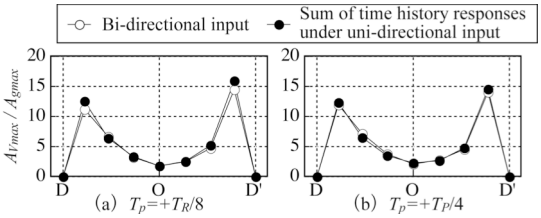

Figure 6 Maximum Vertical Response Acceleration Magnification Factors (line DOD', Sine Waves with Phase Differences $T_p = +T_R/8, +T_R/4$)

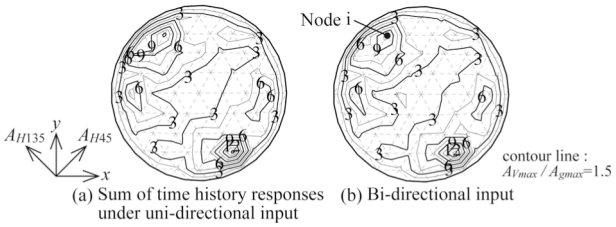

Figure 7 Distributions of Maximum Vertical Response Acceleration Magnification Factors (Sine Wave with Phase Difference $T_p = +T_R/8$)

history responses under uni-directional input are indicated in these figures. The response magnification factors are the response accelerations divided by the maximum input acceleration A_{gmax}. The distributions obtained as the sum of responses under uni-directional input are in agreement with the distributions under bi-directional input. However, the response magnification factors obtained as the sum of responses under uni-directional input disagree slightly with the distributions under bi-directional input at nodes with large responses. Fig.8 shows the time history horizontal response accelerations at node i those are decomposed in the directions A_{H135} and A_{H45} (shown in Fig.7). The horizontal responses under bi-directional input are smaller than the sum of responses under uni-directional input regardless of the direction of response. That is to say that the responses under bi-directional input are smaller than the sum of responses under uni-directional input regardless of the magnitude and direction of input acceleration vector of bi-directional input.

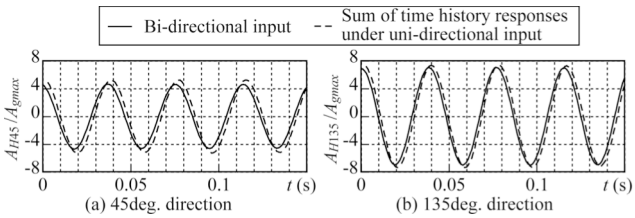

Figure 8 Time History Horizontal Response Accelerations at Node i (Decomposition in the directions A_{H135} and A_{H45}, Sine Wave with Phase Difference $T_p = +T_R/8$))

4.2 Effects of Natural Period Ratio on Response Behavior

In this section, the effects of the natural period ratio R_T on seismic response behavior of single layer lattice dome are examined. Fig.9 shows the maximum vertical response acceleration magnification factors on lines AOA'~ COC' under bi-directional input of JMA Kobe. The angle of phase difference shown in figures is about 90 deg. that the locus of input acceleration is a circular locus. The response magnification factors of R_T=1 are largest, those of R_T=0 are smallest. The shapes of distribution are the shape with large response at the periphery of dome at R_T=1, on the other hand, the shape with long wavelength at R_T=1.2. The distribution shape of R_T=1.2 is similar to the shape of 1st mode in x direction. Fig.10 shows the Fourier spectra for vertical response accelerations at nodes with maximum responses

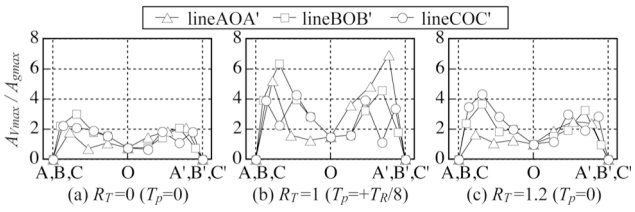

Figure 9 Maximum Vertical Response Acceleration Magnification Factors for Each R_T (lines AOA'~ COC', Bi-directional Input of JMA Kobe)

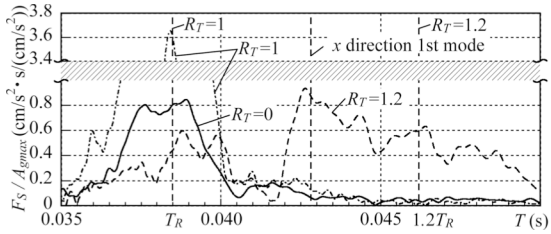

Figure 10 Fourier Spectra for Vertical Response Accelerations at Nodes with Maximum Responses for Each R_T (Bi-directional Input of JMA Kobe)

for each natural period ratio. The Fourier spectra are divided by the maximum input acceleration. The spectrum levels of R_T=1.2 are larger at 1.2T_R (the period of input wave) and the period of 1st mode in x direction. The spectrum of R_T=1 has peak value only at T_R, that of R_T=0 is large in the range of vicinity of T_R.

4.3 Effects of Phase Difference between Input Seismic Waves of Bi-directional Input on Response Behavior

The distributions of maximum vertical response acceleration magnification factors on entire dome roof under seismic waves with phase differences T_p = -T_R/8, 0, +T_R/8 are shown in Fig.11. The responses of R_T=1 model are indicated in figures. The loci of input accelerations for each T_p are shown in the upper right of each figure. The large responses occur at a lot of nodes at $T_p = +T_R/8$ that the locus of input acceleration is a circular locus. On the other hand at $T_p = -T_R/8$ that the locus of input acceleration is a linear locus, the large responses occur only at a few nodes. From the above, it follows that the distribution and the nodes with larger response vary according to the phase difference T_p.

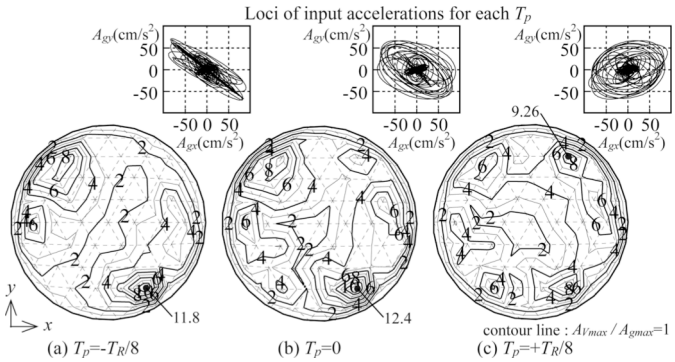

Figure 11 Distributions of Maximum Vertical Response Acceleration Magnification Factors for Each T_p (R_T=1, Bi-directional Input of JMA Kobe)

5. PROPOSITION OF RESPONSE ACCELERATION EVALUATION METHOD ADAPTED TO HORIZONTAL BI-DIRECTIONAL EARTHQUAKE MOTION

In this chapter, the response acceleration evaluation method adapted to the horizontal bi-directional earthquake motion is proposed.

First, the response accelerations under bi-directional input are estimated by adding the time history responses under uni-directional input in NS and EW directions. The input seismic wave is JMA Kobe. The comparisons between the maximum responses of estimated results and those of experimental values under bi-directional input are shown in Fig.12. Although a few differences are observed, the maximum responses of estimated results agree with the responses under bi-directional input, as mentioned in section 4.1.

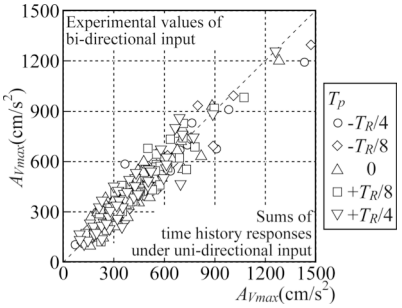

Figure 12 Comparisons between Maximum Responses of Sum of Time History Responses under Uni-directional Input and Those of Experimental Values under Bi-directional Input (R_I=1, JMA Kobe)

Next, the response accelerations under bi-directional input are calculated by square root of sum of squares (SRSS) of the maximum response accelerations under uni-directional input in NS and EW directions. Fig.13 shows the comparisons between the calculated maximum responses and the maximum responses of experimental values under bi-directional input. The calculated results are in approximate agreement with the maximum responses under bi-directional input. However, the nodes whose calculated results are disagreement with the results under bi-directional input are found.

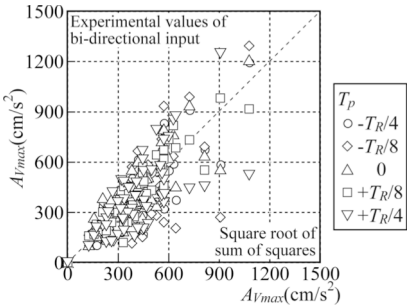

Figure 13 Comparisons between Square Root of Sum of Squares (SRSS) of Maximum Response Accelerations under Uni-directional Input in NS and EW directions and Maximum Responses of Experimental Values under Bi-directional Input (R_I=1, JMA Kobe)

Finally, the reconstructions of the instantaneous distributions when the maximum response accelerations occur are attempted by using the two vibration modes. The response accelerations of top of column for substructure are able to treat as the sine wave with specific period. Therefore it is supposed that the input waves to dome roof are represented as the periodic functions (equations (5) and (6)).

$$A_{NS}(t)=A_{NS}\sin(2\pi ft) \tag{5}$$

$$A_{EW}(t)=A_{EW}\sin(2\pi ft+\theta) \tag{6}$$

where A_{NS} and A_{EW} are the maximum accelerations of input waves, θ is the angles of phase differences between inputs in NS direction and EW direction.

it is supposed that the maximum response accelerations occur by the input accelerations at the time t' when the Euclidean norm of input acceleration comes to the maximum value, then the response acceleration for each node of dome roof under bi-directional input is evaluated by equation (7).

$$A_{2i}=\frac{A_{NS}(t')\cdot amp_{xi}\cdot Sa_{earthNS}+A_{EW}(t')\cdot amp_{yi}\cdot Sa_{earthEW}}{Sa_{sine}} \tag{7}$$

where amp_{xi} and amp_{yi} are the amplification factor for each node of the mode which appears in accordance with the period with input wave, Sa_{earth} and Sa_{sine} are the values of acceleration response spectra of input seismic wave and sine wave respectively.

Fig.14 shows the shapes of modes used for the evaluation and the distributions of response acceleration calculated by evaluation method and by vibration test under bi-directional input. Fig.15 shows the comparisons between the response accelerations obtained by evaluation method

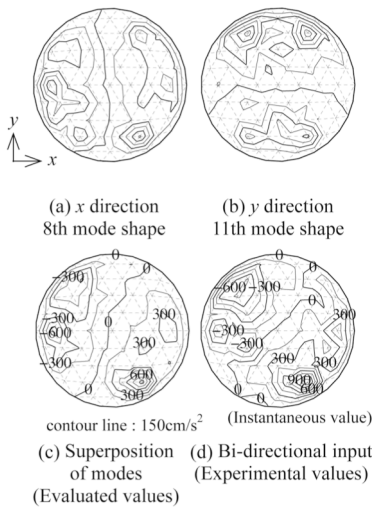

Figure 14 Shapes of Modes Used for Evaluation and Distributions of Response Acceleration Calculated by Evaluation Method and by Vibration Test under Bi-directional Input (R_I=1, T_p=0, JMA Kobe)

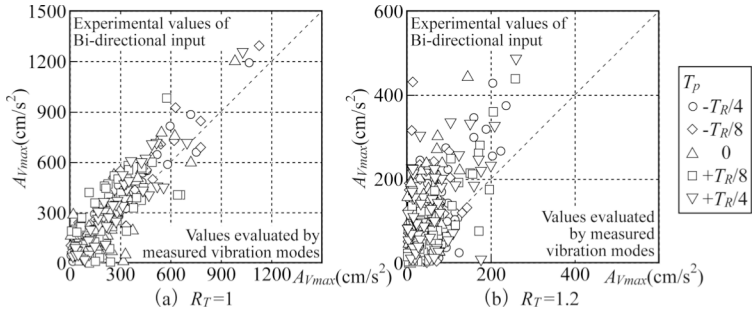

Figure 15 Comparisons between Response Accelerations Obtained by Evaluation Method Which Uses Two Vibration Modes and Those by Vibration Tests under Bi-directional Input (JMA Kobe)

and those by vibration tests under bi-directional input. At R_T=1 model the evaluated results are in approximate agreement with the response accelerations by vibration tests under bi-directional input. However, at R_T=1.2 model the response accelerations by vibration tests are larger than the evaluated results. It is for this reason that the plural modes excite at R_T=1.2 model as shown in Fig.10.

6. CONCLUSIONS

It is concluded as follows, from the above results.

1) At the single layer lattice dome with a lot of vibrational modes in narrow periodic band when the natural period of substructure (equivalent single mass system) is equal to that of predominant mode of roof structure (natural period ratio R_T=1), the response magnification factor becomes large.
2) The phase difference between input waves of horizontal bi-directional input affects the distributions of maximum response accelerations and the node at which the maximum response occurs.
3) The distribution of maximum response accelerations under bi-directional input estimated by adding the time history responses under uni-directional input agrees with the distribution of maximum response accelerations under bi-directional input.
4) When the natural period ratio R_T is 1, the distribution of response accelerations under bi-directional input evaluated by using the two vibration modes is in approximate agreement with the distribution of response accelerations under bi-directional input at the time when the maximum response acceleration occurs.

DAMAGE DETECTION FOR STEEL STRUCTURES USING THE HILBERT-HUANG TRANSFORM APPROACH

Wen-Ko Hsu[1)], Dung-Jiang Chiou[1)]

1) Research Center for Hazard Mitigation and Prevention, National Central University, Jhung-li, Taoyuan County, Taiwan, R.O.C.

Abstract: The objective of this study is to examine the relationship between structural damage and sensitivity indices using the Hilbert-Huang transform (HHT) method. Two damage detection indices are proposed: the ratio of bandwidth (RB), and the ratio of effective stiffness (RES). The nonlinear four bays multiple degree of freedom models with various predominant frequencies are constructed using the SAP2000 program. Adjusted PGA earthquake data (Japan 311, Chi-Chi 921) are used as the excitations. Next, the damage detection indices obtained using the HHT and the fast Fourier transform (FFT) methods are evaluated based on the acceleration responses of the structures to earthquakes. Simulation results indicate that, the column of the 1st floor is the first yielding position and the RB value is changed when the RES<90% in all cases. Moreover, the RB value of the 1st floor changes more sensitive than those from the top floor. In addition, when the structural response is nonlinear (i.e., RES<100%), the RB and the RES curves indicate the incremental change in the HHT spectra. However, the same phenomenon can be found from FFT spectra only when the stiffness reduction is large enough. Therefore, the RB estimated from the smoothed HHT spectra is an effective and sensitive index for detecting structural damage.

1. INTRODUCTION

Structural health monitoring (SHM) has received considerable attention recently in structural engineering. While SHM attempts to detect structural damage in buildings, various approaches have been developed for detecting damage based on various methods (Sun et al. 2002, Lei et al. 2003, Rucka et al. 2006, Ren et al. 2008, Nair et al. 2009 and Akanshu et al. 2010).

It has been proposed in several previous studies that the empirical mode decomposition (EMD) and Hilbert–Huang transform (HHT) methods can be used for nonstationary and nonlinear time series analysis (Huang et al., 1998, 1999). This method has also been extensively adopted for the detection of structural damage. Based on EMD and HHT, Yang et al. (2003a) proposed a linear least-square fit procedure to identify the natural frequency and damping ratio from the instantaneous amplitude and phase angle for each modal response. Frequently, all eigenvalues and eigenvectors of linear structures are found to be complex (Yang et al. 2003b). The HHT based method has been extended further to identify general linear structures with complex modes using the free vibration response data polluted by noise. Although structural damage information is generally extracted from the measured data, recorded acceleration data in the damage location normally have a discontinuity relationship when the damage event occurs. Huang et al. (1998, 1999) showed the feasibility of using EMD and HHT to decompose a signal in the time-frequency domain more precisely than wavelet analysis can. Consequently, two methods were proposed based on EMD and HHT for detecting structural damage (Yang et al. 2004). The first method extracts damage spikes due to a sudden change of structural stiffness from the measured data. The damage time instant and damage locations can then be detected. The second method can detect the damage time instant and determine the natural frequencies and damping ratios of the structure before and after damage. These two proposed methods are then applied to a benchmark problem. According to those results, the proposed methods can detect damage and evaluate related structures efficiently.

However, the mode mixing problem often occurs with the HHT method when intermittency is involved in the data. A new ensemble empirical mode decomposition (EEMD) method (Wu and Huang 2004) was proposed to overcome the intermittence phenomenon. The latest new HHT ensemble skills method has been utilized to analyze the Tai-power Building's strong-motion station records from 1994-2006 (Su et al. 2008). According to those results, the acceleration relations between the basement and the 27th story (top) are not proportional, even when the building maintains elasticity. The relationship between structural damage and the sensitivity indices is obtained using the HHT method (Chiang et al. 2011). Three sensitivity indices are proposed: the ratio of rotation (RR), the ratio of shifting value (SV) and the ratio of bandwidth (RB). Simulation results indicate that the RB obtained from the HHT spectra displays a trend of incremental change with an increasing RR, making it an effective and sensitive index for detecting structural damage. Next, a damage index, the ratio of bandwidth (RB) is used to demonstrate the effectiveness from real steel models for detecting structural damage

(Chiou et al. 2011). Results indicate that, when the response of the structure is in the elastic region, the RB value only slightly changes in both the HHT and the fast Fourier transform (FFT) spectra. Additionally, RB values estimated from the HHT spectra vs. the PGA values change incrementally when the structure response is nonlinear i.e., member yielding occurs, but not in the RB curve from the FFT spectra.

Tang (et al. 2011) proposed a different damage detection index, the ratio of equivalent damping ratio (RED). It is evaluated using the FFT and HHT methods for analysis of the shaking table test data obtained from the benchmark models. The results show that the RED estimated from the smoothed HHT spectra is an effective and sensitive index for detecting structural damage. Furthermore, the changes in RED present more sensitivity at the top floor than other floors. The proposed RED strategy will be used to establish an on-line health monitoring scheme for detecting structural damage in steel structures right after the occurrence of ground motion. Atul (et al. 2011) propose an improved HHT combined with wavelet packet decomposition for diagnosis of damage in structures. Numerical simulation studies have been conducted by solving a bridge girder as a numerical example to validate the proposed time series analysis based damage diagnostic method. Results present the combined wavelet packet and EMD based sifting process can successfully decompose a signal into components with simple frequency content.

Referring to the results of Chiang (et al. 2011) and Tang (et al. 2011), the single bay MDOF models are constructed to obtain the acceleration spectra based on the HHT and FFT methods during earthquakes. In fact, a multiple bays model can be found easily in a real structure. Whether the damage detection index, RB (or RED) proposed by Chiang (et al. 2011) keeping provide the sensitivity of damage detection in a complex structure or not, the objective of this study is to discuss the relationship between RB and the change of ratio of effective stiffness, RES for four bays steel structure subjected to earthquakes. First, the three, five and ten story four bays steel models are established using the SAP2000 program. Two types time history earthquake data (Japan 311, Chi-Chi 921) are adopted as the excitations. Next, the rotational stiffness of columns of these structures is then simulated using Wen's model (Wen 1976). The nonlinear time history analysis is used to generate the acceleration data from models. Then the damage indices, RB and RES can be obtained from HHT and FFT spectra separately based on the acceleration responses of the structures to earthquakes. Additionally, Tang (et al. 2011) shows the trend of RB in top floor is more sensitive than other floors while the nonlinearity is happened to a structure. In this study, the change of RB in the first yielding floor will be discussed with the top floor deeply to demonstrate the RB of roof provides more sensitivity than other floors.

2. Hilbert -Huang Transformation (HHT)

The HHT, developed by Huang et al. (Huang *et al*. 1998, 1999), consists of a two step-empirical mode decomposition (EMD) and the Hilbert spectral analysis (HSA). The principles and procedures for the HHT method are briefly summarized in this section. Detailed information can be found in the quoted references (Huang *et al*. 1998, 1999).

The EMD method involves the extraction of the IMFs from a given time series.Once all IMFs are sifted from a given signal $x(t)$, it can be expressed as follows:

$$x(t)=\sum_{i=1}^{n} c_i(t)+r_n(t) \tag{1}$$

where n is the total number of the IMFs, and $r_n(t)$ denotes the final residue which represents the DC component containing the overall trend of $x(t)$. The $c_i(t)$ are almost orthogonal to each other and have nearly zero means.

For an arbitrary time series $X(t)$, the Hilbert transformation, $Y(t)$, is defined as follows:

$$Y(t)=\frac{1}{\pi} P\int_{-\infty}^{\infty}\frac{X(t')}{t-t'}dt' \tag{2}$$

where P indicates the Cauchy principal value.
With this definition, $X(t)$ and $Y(t)$ can be combined to form the analytical signal $Z(t)$

$$Z(t)=X(t)+iY(t)=a(t)e^{i\theta(t)} \tag{3}$$

where

$$a(t)=\left[X^2(t)+Y^2(t)\right]^{1/2}$$

$$\theta(t)=\arctan\left(\frac{Y(t)}{X(t)}\right).$$

From the polar coordinate expression in Eq. (3), the instantaneous frequency can be defined as

$$\omega(t)=\frac{d\theta(t)}{dt}. \tag{4}$$

Applying the Hilbert transform to the IMFs components of $X(t)$ in Eq. (3), the data $X(t)$ can be written as follows:

$$X(t)=\Re\sum_{j=1}^{n} a_j(t)e^{i\int\omega_j(t)dt} \tag{5}$$

where R is the real part of the value.

Similar to the Fourier amplitude spectrum, the Hilbert amplitude spectrum $H(\omega,t)$ is the time-frequency distribution of the amplitude. The marginal spectrum $h(\omega)$ is a measure of the total amplitude (or energy) contribution from each frequency value. It represents the accumulated amplitude over the entire data span in a probabilistic sense. The marginal spectrum is obtained by the integration of the Hilbert spectrum over the time duration T:

$$h(\omega)=\int_0^T H(\omega,t)dt. \tag{6}$$

3. Sensitivity of damage detection

3.1 Damage detection index

Structural damage is usually represented by the natural frequency and the damping ratio of the structure changes

when any structural member is damaged due to strong ground motion. The most obvious of these indexes is the change in the equivalent damping ratio of the structure before and after damage by earthquakes. Furthermore, a damage detection index, the ratio of an equivalent damping ratio RED, has been derived by Tang et al. (Tang et al. 2011). The procedures of the derivation are briefly summarized as follows:

As is well known, the half-power bandwidth (Chopra 2001) is related to the equivalent damping ratio of an SDOF structure. Then the definition of the ratio of bandwidth RB can be expressed as follows:

$$RB = \frac{f'2 - f'1}{f2 - f1} \tag{7}$$

where the bandwidth ($f2 - f1$) or ($f'2 - f'1$) denotes the half-power bandwidth, as estimated from the acceleration frequency response curve Ra, as shown in Figure 1.

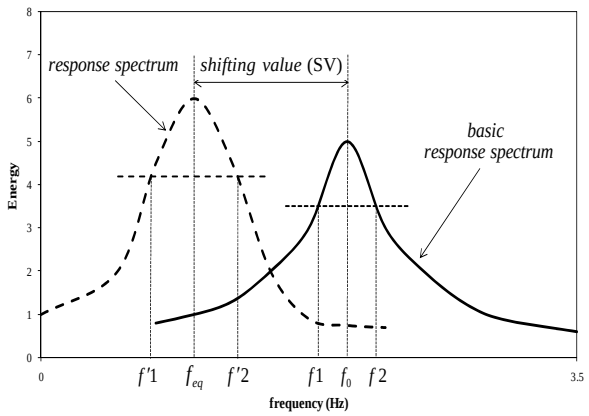

Figure 1 Definition of the ratio of bandwidth (RB) and definition of the ratio of equivalent damping ratio (RED) (Tang et al. 2011)

Besides, the change of stiffness to a member can be observed when the structure is in nonlinear region. Figure 2 shows the hysteresis of a column during a strong ground motion. The change of stiffness can be expressed to a new damage detection index, the ratio of effective stiffness, RES. The derivation of RES is shown as follow:

$$K_{eff} = \min\left(\frac{M_{\max}}{R_{\max}}, \frac{M_{\min}}{R_{\min}}\right) \tag{11}$$

$$RES(\%) = \frac{K_{eff}}{K_0} \tag{12}$$

In which, the K_{eff} can be calculated from a hysteresis taking the minimum positive stiffness or negative stiffness to the structure during an excitation. Then the RES can be evaluated from K_{eff} to K_0. Hence, if RES=100%, the structure remains in the elastic region. However, if RES<100%, the nonlinear behavior of the structure exists and is revealed in the acceleration responses.

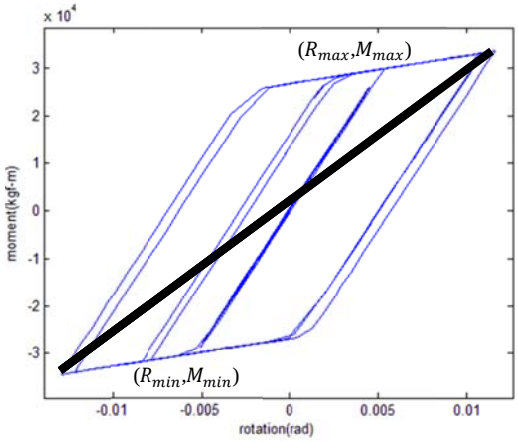

Figure 2 Definition of the ratio of effective stiffness (RES)

3.2 Sensitivity of detecting damage to MDOF models

Figure 3 presents four bays three and ten story steel models generated by the SAP2000 program. The length of one bay is 3 m and the height of one story is 4 m.

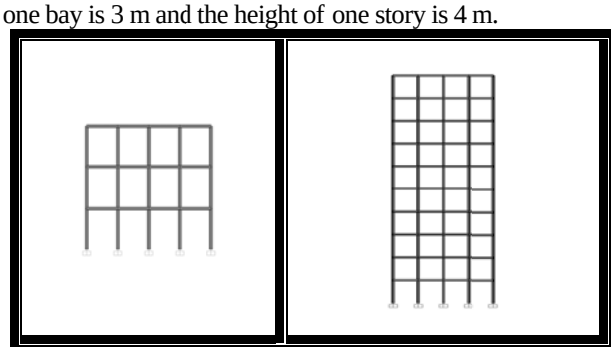

Figure 3 Four bays MDOF steel structures with two types

Table1 lists the member section and the modal frequency of these models. The rotational stiffness of columns of these structures is then simulated using Wen's model (Wen 1976). Furthermore, the Japan 311 (MYG010, IWT026, TCG009) and Chi-Chi (TCU138, CHY008, ILA061) earthquakes are adopted as the excitations. The time history records are shown in Figure 4.

Table 1 Modal frequency and frame section of the structures

		Three-story	Ten-story
Section	Beam	W12X22	W12X22
	Column	W18X35	W18X35
Modal frequency (Hz)	f_1	3.4	1.0
	f_2	11.2	3.4
	f_3	20.2	5.8

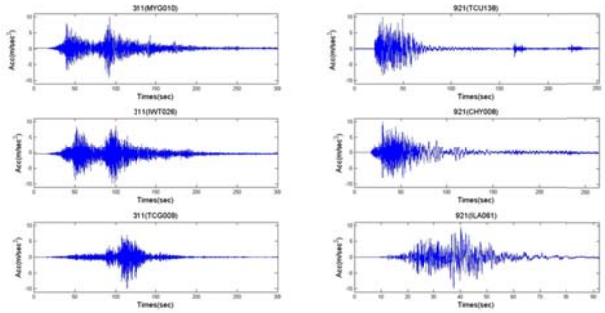

Figure 4 Time history records of Japan 311 and Chi-Chi 921 earthquakes

Next, the acceleration responses of the floor for each case are evaluated after inputting the adjusted Japan 311 and Chi-Chi 921 earthquake excitations (PGA = 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.8 and1.0g). In which, for example, if the first yielding point is occurred at PGA=0.2g, the increment of PGA value changes to 0.02g (0.2g, 0.22g, 0.24g,…, 0.3g). Then the change of RES and RB can be observed more clearly before and after yielding of the structure. There are 18 response cases (three models and six earthquakes) used to evaluate the damage indices. The sensitivity indices RB and RES are computed from the acceleration response data using the HHT and FFT methods. Given the difficulty in estimating the bandwidth based on the original structural response spectrum, the moving average method with span 3 (Chou 1975) is used to smooth the spectrum to evaluate the indices.

A portion of the above results are summarized in Figures 5 and 6.The acceleration response spectra (PGA=0.1g, 0.6g, 0.8g and 1.0g) for three-story models from first and top floor using the FFT and HHT methods respectively are shown in Figure 5 and 6. Both the change of bandwidth in the predominant frequency cannot be observed clearly at 1F and 3F from FFT spectra in the 311 (TCG009) cases as shown in Figure 5. Opposite to the FFT spectra, the change of bandwidth can be seen obviously when the responses of three-story structure before and after first column yielding occurred from HHT spectra as shown in Figure 6.

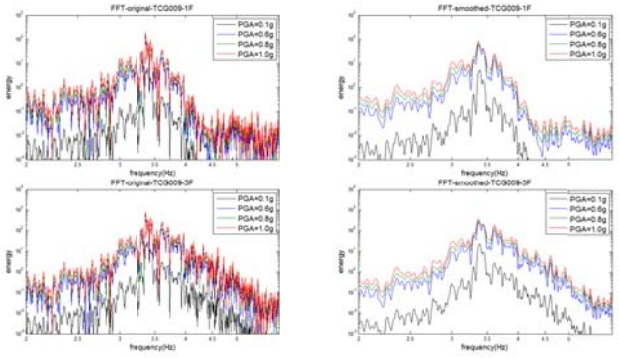

Figure 5 Acceleration response spectra obtained using FFT for three -story cases (TCG009)

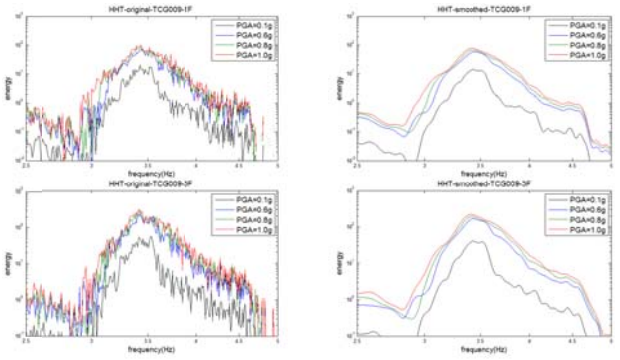

Figure 6 Acceleration response spectra obtained using HHT for three -story cases (TCG009)

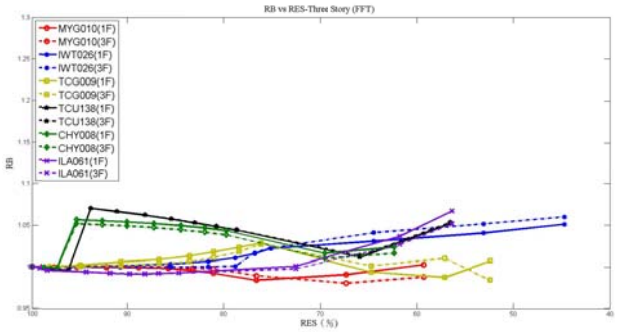
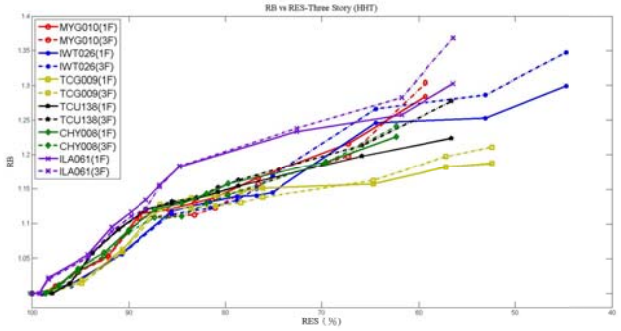
Figure 7-10 display the results of RB with RES for three type structures in all cases from FFT and HHT spectra. In which, the change of RB with RES are summarized in Figure 7 and 9 based on FFT spectra. For example, the maximum value of RB is 1.0703 when the RES=93.78% in the TCU138 (3F) case as shown in Figure7. Then the RB decreases with a decreasing RES, when the RES=56.54%, the RB reduces to 1.0535. Next, for ILA061 (1F) case, the RB almost retain around 1.0 when the RES=100%~72%. The change of RB can be observed when the RES<61.74% as shown in Figure7. That is to say, in the FFT spectra, RB occasionally increases with decreasing RES, and occasionally decreases with RES. The same phenomena also can be seen in ten-story cases. Besides in the MYG010 and TCU138 cases, the RB almost has no change with RES as shown in Figure 9. Therefore, no steady trend of change is found for the RB vs. RES when analyzed with the FFT method.





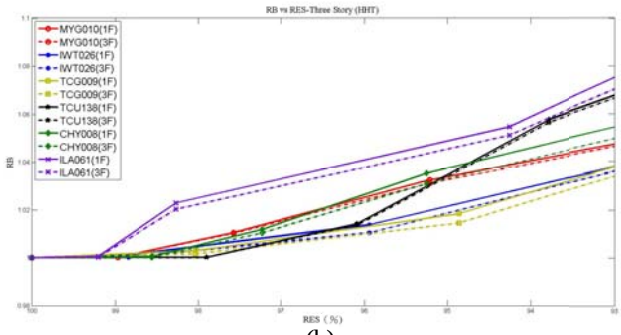


Figure 7 Results of RB vs. RES using FFT for all cases (three-story)

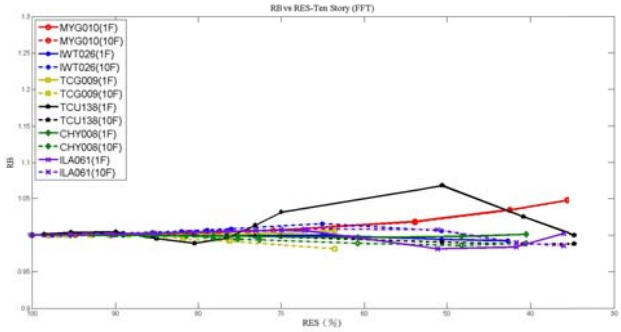
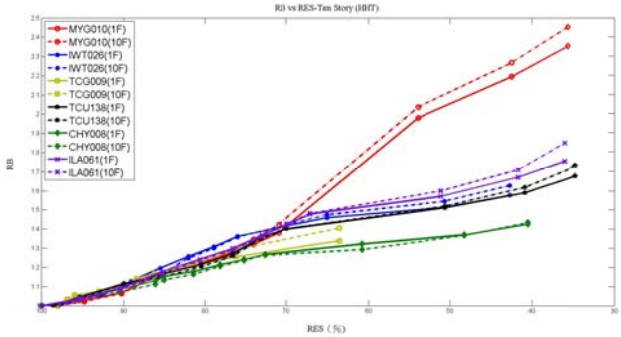
(b)

Figure 8 Results of (a) overall (b) zoom-in RB vs. RES using HHT for all cases (three-story)





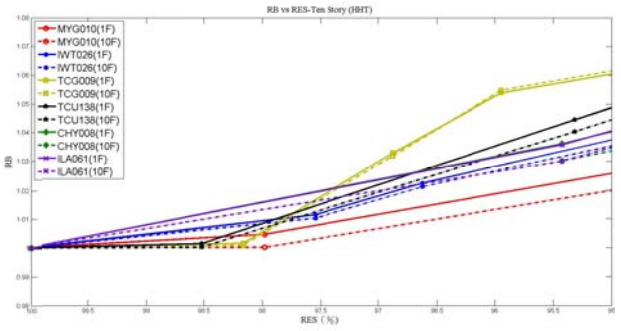


Figure 9 Results of RB vs. RES using FFT for all cases (ten-story)

(a)

(b)

Figure 10 Results of (a) overall (b) zoom-in RB vs. RES using HHT for all cases (ten-story)

Figure 8 and 10 indicate the analyzed results from HHT spectra. The positive trend of RB vs. RES can be found clearly for three-story model in all cases as shown in Figure 8(a). For example, the change of RB can be observed (RB=1.0229 at 1F; RB=1.0203 at 3F) when the first column yielding occurred (RES=98.27%) in ILA061 case. Moreover the change of RB at 1F shows more sensitive than that at 3F in the initial yielding stage of three-story model as shown in Figure 8(b). Next the RB increases with a decreasing RES both at 1F and 3F. When the RES<84.68%, the RB of 3F begins to larger than the RB at 1F. And the maximum of RB is 1.3683 at 3F when the RES reduces to 56.37% as shown in Figure 8(a). It means that the change of RB at 1F shows higher sensitivity while the yielding of column just occurred. As the degree of damage goes on, the change of RB at 3F presents the highest sensitivity in detecting structural damage.

The similar analyzed results also can be obtained from ten-story cases as shown in Figure 10. When the 1F column begins to yield (RES<100%), the change of RB at 1F is larger than those at 10F as shown in Figure 10(b). With the damage increasing, the incremental of RB at 10F is greater than RB at 1F as shown in Figure 10(a). For instance, when the RES=94.81%, the RB= 1.0271 at 1F but the RB=1.0211 at 10F in MYG010 case. Then the RES decreases with increasing structural damage, when the RES reduces to 35.59%, the RB increases to 2.3542 at 1F and the RB reaches to 2.4732 at 10F. Therefore, the change of RB at first yielding floor presents more sensitive than top floor. But when the damage grows up, the RB at top floor still shows the highest sensitivity for damage detection of a structure.

3. CONCLUSIONS

This study proposes the RB and RES as the damage detection indices to detect the structural damage of the steel structure to strong ground motions. Two type four bays MDOF steel models are constructed to subject the adjusted PGA Japan 311 and Chi-Chi 921 earthquakes. The acceleration response spectra evaluated from the first yielding floor and roof are using HHT and FFT methods respectively.

The simulation results indicate that the change of RB can be seen clearly when the RES<90% in all cases from HHT spectra. Moreover, the RB at first yielding floor changes more sensitive than those at roof when the response of a

structure is in initial yielding stage (RES<100%) from HHT spectra. With the nonlinear hysteresis grows up, the RB increases with a decreasing RES can be observed clearly especially the incremental change in RB at roof shows the highest sensitivity to detect the structural damage. Opposite to the results of HHT, the sensitive damage detection phenomena cannot be obtained from FFT spectra. The change of RB can be observed while the reduction of RES is large enough. However, there is no steady relationship between RB and RES from FFT spectra. Therefore, the damage detection index RB evaluated from HHT spectra presents more sensitive than FFT spectra. Moreover, the first yielding floor can be detected precisely and the structural damage can be observed in the top floor using damage detection index, RB from the HHT spectra.

Abstract: Probability of severe ground motions generate potential seismic safety problem on various existent high-rise steel and concrete filled steel tubular (CFT) buildings, due to the effects of local-failure of steel and CFT members on the seismic damages have not been clearly included in current performance-based seismic design. The global seismic-resistant capacity of high-rise buildings may be significantly affected by the local-failure of structural members. In this study, deterioration behavior after local buckling of steel and CFT members is incorporated in the incremental dynamic analysis (IDA) of existent high-rise S and corresponding CFT buildings (based on equivalent horizontal stiffness) with various levels of member deterioration. Performance-based earthquake damages of these high-rise building models are analytically investigated and compared in terms of the ductility response and cumulative hysteretic energy of the beam and column members in the planar weak-beam frame models of high-rise steel and CFT buildings. Analytical results show that the effect of member deterioration significantly amplified the member damages of high-rise buildings to various extent based on deterioration parameters. High-rise CFT buildings incorporating member deterioration demonstrates higher collapse margin than that of the corresponding high-rise steel building.

1. INTRODUCTION

Great east Japan earthquake (AIJ 2011) has manifested enormous power to destroy infrastructures and human life. Furthermore, very high probability of extreme ocean-ridge earthquakes also exists in the future (e.g. 30 years). Furthermore, since the seismic risk of long-period ground motions associated with long duration on the structures with long 'first mode' natural period (e.g., high-rise building) has been focused by researchers during the Tokachi earthquake (2003), the seismic damages and energy-dissipating capacity of such building structures become more important for the assessment of the seismic safety of varied existent high-rise buildings. Energy dissipation has been treated as an indicator for the seismic performance of building structures, since Housner (1956) suggested an energy-based design approach. Thereafter, Akiyama et al. (1985) proposed the relation between energy dissipating capacity of structure and its corresponding demand by using an indicator of cumulative plastic deformation.

In this study, we especially concentrate on the member damages of the existent high-rise steel and CFT buildings based on the indexes of the ductility ratios and the cumulative plastic deformation of beam and column members. Moreover, due to the strength and stiffness deteriorations of steel and CFT members under cyclic loading has significantly influences on the failure mechanism of such members, the effect of member deterioration on the member damages of above buildings structures is also comparatively evaluated. The deterioration margin and collapse margin of various deteriorating model are also quantified and compared with non-deteriorating model.

2. MEMBER DETERIORATION

2.1 Steel members

Accurate stress-strain models for rectangular steel tube and H-shaped steel members associated with strength deterioration caused by local-buckling, Bauschinger effect, and unloading stiffness deterioration, as shown in Figure 1, are developed on the basis of Menegotto-Pinto model (1973), in order to be capable of capturing the effect of member deterioration on the seismic damages and collapse-resistant capacity of high-rise steel and CFT buildings. Formulae to define the parameters (as shown in Figure 1) in deteriorating model for various steel members and the corresponding preliminary studies on the calibration of deteriorating stress-strain models of steel and concrete have been conducted by Bai et al. (2012).

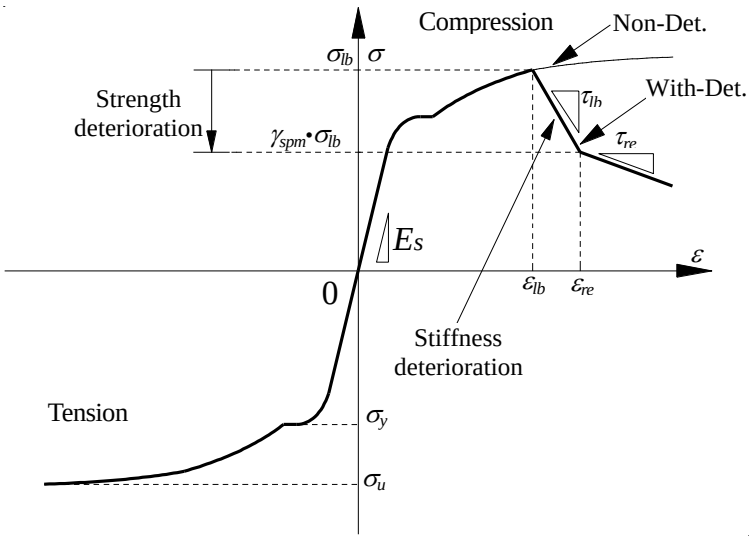

Figure 1 Deteriorating stress-strain model for steel members

2.2 Confined Concrete

Confining effect on the strength and deformability of the in-filled concrete in square CFT section is considered by utilizing Sakino-Sun model (1995), as shown in Figure 2. Flat curve after peak-point is analogous to non-deterioration situation, and on the other hand, the post-peak deterioration is considered by capturing the inflexion point of the Sakino-Sun model to maintain equilibrium in deterioration and residual branches.

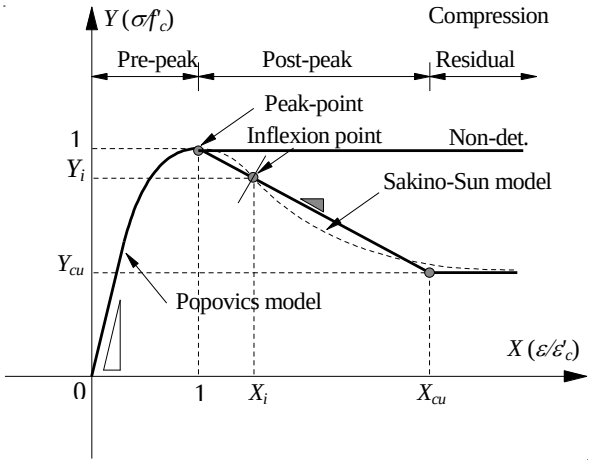

Figure 2 Deteriorating model of confined concrete

In order to respectively predict the deterioration gradient and residual strength of the confined concrete, we specifically simplified the deterioration branch (post-peak branch and residual branch) into bi-linear relation, as shown in Figure 2, where, according to the reference (Bai et al. 2012) the ultimate point (X_{cu}, Y_{cu}) between post-peak branch and residual branch is defined by

$$\begin{cases} X_{cu} = \dfrac{\varepsilon_{cu}'}{\varepsilon_{cc}'} = 1.96\left(\dfrac{V}{W}\right)^{0.88} + 4.77 \\ Y_{cu} = \dfrac{\sigma_{cu}'}{f_{cc}'} = \lim\limits_{X\to\infty} \dfrac{VX + (W-1)X^2}{1 + (V-2)X + WX^2} = 1 - \dfrac{1}{W} \end{cases} \quad (1)$$

Moreover, both deteriorating stress-strain models for steel members (H-shaped steel, square HST and CFT) and the confined concrete in square CFT members have been calibrated by Bai et al. (2012), based on extensive database of such structural members.

3. VARIOUS HIGH-RISE BUILDINGS

3.1 Square HST and CFT columns

Based on the various statistical databases (AIJ 2007) on the existent high-rise steel and CFT buildings, increasing cases of high-rise CFT building necessitate the assessment on their seismic safety under severe seismic excitations. Furthermore, in order to compare and quantify the collapse margin of high-rise CFT buildings to analogical high-rise steel buildings, only the square HST column in high-rise steel building models are replaced by the square CFT column based on equivalent horizontal stiffness K [$(12EI)/l^3$]. As shown in Figure 3, the equivalent square CFT column which is analogous to square HST column, can make the tubular section be more compact by keeping the same width-thickness ratio (B/t) than associated HST column, or safe the steel material by reducing the thickness of steel tube.

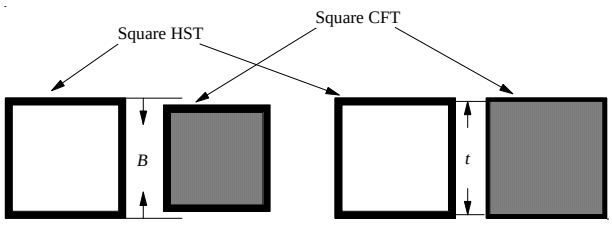

Figure 3 Equivalent square CFT and HST column

As mentioned above, both of the above advantages show different deterioration features for CFT column due to the local-buckling of steel tube and confining effect to in-filled concrete are overtly affected by B/t of tube, as discussed in Section 2. Therefore, we respectively employ the compact CFT column and uncompact CFT column in

high-rise CFT building models, in order to be analogous to FA_c-FA_b model and FB_c-FB_b high-rise steel building models (ASCCS Bai et al. 2012). Figure 4 shows the different criterion (FA, FB) of width-thickness ratios of square HST columns (MLIT 2007) and CFT columns (AIJ 2008).

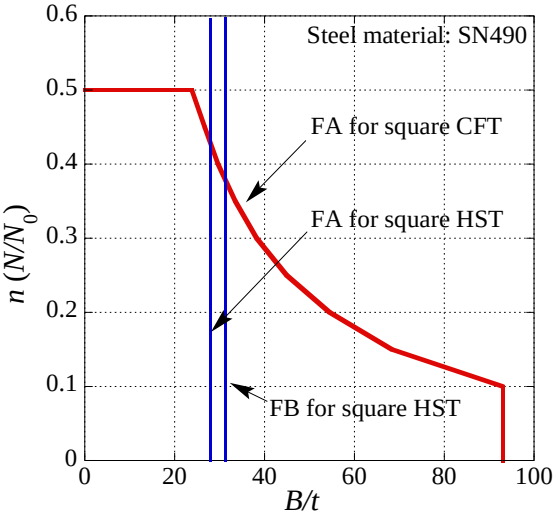

Figure 4 Dependence of *B/t* and *n* (N/N_0) on the ranks of square HST and CFT columns

3.2 High-rise steel and CFT buildings

According to the assessment on the structural system, member, and material in existent high-rise buildings (AIJ 2007), for the existent high-rise steel and CFT buildings, moment-resistant frame structures with H-shaped steel girder and square HST or CFT columns were preferred during 1980~1990 in Japan. Thus, various existent high-rise steel and CFT buildings [i.e., 20, 30 and 40 story levels (denoted as 20S, 30S and 40S), compactness ranks of columns and beams (denoted as FA_c-FA_b, FB_c-FB_b for high-rise steel buildings, and FA_c-FA_b, FA'_c-FB_b for high-rise CFT buildings)] with planar moment-frame models are seismic designed by current building standard. The component section, elevation and plan views of the planar models are shown in Figure 5.

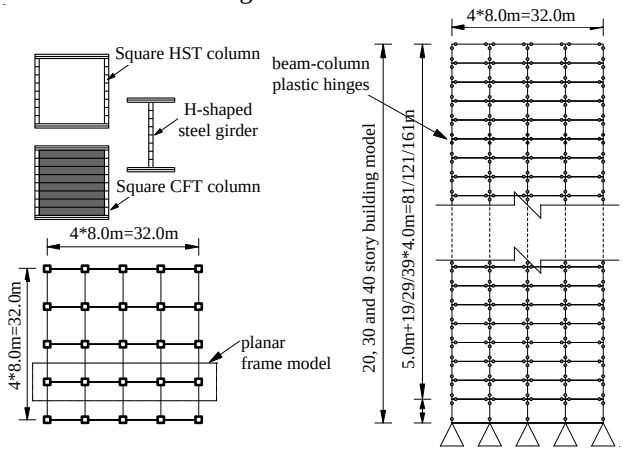

Figure 5 Component section, Plane and elevation views of high-rise building models

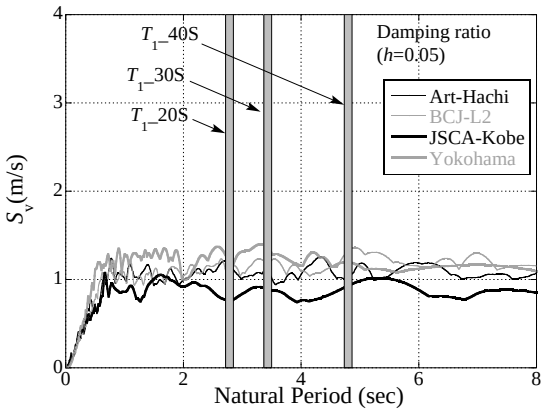
4. EARTHQUAKE WAVES

With respect to the seismic excitations on structures, peak ground velocity (i.e., PGV) likely to have higher correlation as an intensity measure with the performance parameters (e.g., maximum and residual drift, ductility and hysteresis energy) of high-rise building structures with long natural period. Thus, in order to simulate large earthquake excitations on high-rise building and also try to relatively eliminate the record-to-record uncertainty, analogous typical artificial-waves (i.e., Art-Hachi, BCJ-L2, JSCA-Kobe and Yokohama) for seismic design are picked, as shown in Table 6. The maximum and cumulative member damages of various high-rise buildings under high-level intensity earthquakes are assessed on the basis of incremental dynamic analyses [IDA (Vamvatsikos and Cornell 2002)] controlled by the incremental factors ϕ from elastic to collapse, based on the PGV of each artificial waves.

Table 1 Details of artificial earthquake waves

Ground motion	PGA (gal)	PGV (kine)	Duration (sec)
Art-Hachi	466.7	64.0	163.8
BCJ-L2	355.7	80.4	120.0
JSCA-Kobe	469.5	58.7	60.0
Yokohama	350.2	62.0	80.0

Moreover, according to the pseudo velocity response spectrum of such artificial earthquake waves as illustrated in the Figure 6, nearly flat velocity excitations of such waves is observed on long 'first-mode' natural periods high-rise building models.



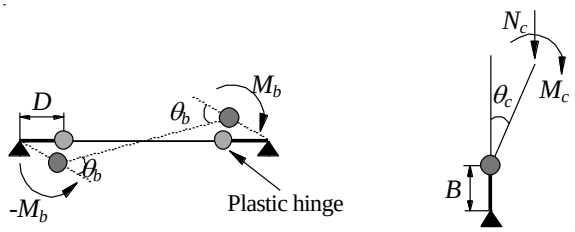


Figure 6 Pseudo velocity response spectrum of artificial earthquake waves

4. PLASTIC DAMAGES

4.1 Plastic hinge mechanism

The plastic-hinge rotation at the inside beam and column members in high-rise steel buildings are also initiated. Plastic-hinge rotation is an index for evaluating the plastic-deformation capacity of local regions (Wakabayashi, 1986). Local buckling and damage of steel members can be examined by normalized rotation of steel member, i.e., ductility ratio. As introduced in Section 2, the strength and stiffness deterioration of various steel and CFT members caused by local buckling under cyclic loading is expected to

show significant impact on the nonlinear dynamic responses of such steel members (Bai et al. 2012). Thus, more widely the plastic-hinges and more severe the ductility ratios are correspondingly induced at the endings of beam member and column-base of the weak-beam high-rise buildings. Figure 7 shows the definition of the ductility ratio of girder and column-base in high-rise steel and CFT buildings.

(a) Girder (b) Column-base

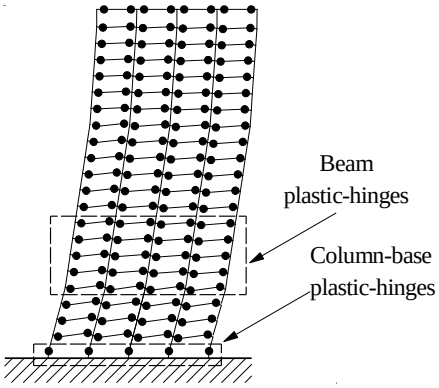
Figure 7 Plastic hinge rotations for beam and column

Thus, the effect of the member deterioration on the local-responses (i.e. component responses) of the critical regions (i.e., plastic hinges) in existent high-rise buildings are focused, in order to reveal how much the member damages of such buildings structures has been initiated. For the high-rise building structures under time-history earthquake excitations (time-history analysis), maximum ductility ratios (μ_b, μ_c) of H-shaped steel girder and square HST/CFT column-bases at bottom story are feasible to be treated as the damage index calculated by

$$\begin{cases} \text{Max.}\mu_b = \dfrac{\max(\theta_b)}{\theta_y} \\ \text{Max.}\mu_c = \dfrac{\max(\theta_c)}{\theta_y} \end{cases} \tag{2}$$

where, $\max(\theta_b)$ and $\max(\theta_c)$ are the maximum responses of plastic-hinge rotation at beam and column base, θ_y is the rotation at yield point of beam/column members that is calculated by $\theta_y=(M_y/K)$, K (=6EI/l) is the flexural stiffness of beam/column members, M_y (=$Z\times F_y$) is bending moment capacity at yield point, Z (=I/(D/2)) is section modulus, F_y is yield strength of steel material.

For the high-rise steel and CFT buildings designed by weak-beam moment-resistant frame, beam and column-base plastic-hinge mechanism of high-rise steel building is assumed (in Figure 8). In particular, plastic-hinge at the column base of the bottom-story of high-rise building could modify the side-sway of high-rise buildings and the phenomenon of deformation concentration can be observed at lower-story (Uetani 1996). Therefore, we respectively compare the ductility ratios of beam and column-base between deteriorating and non-deteriorating models.



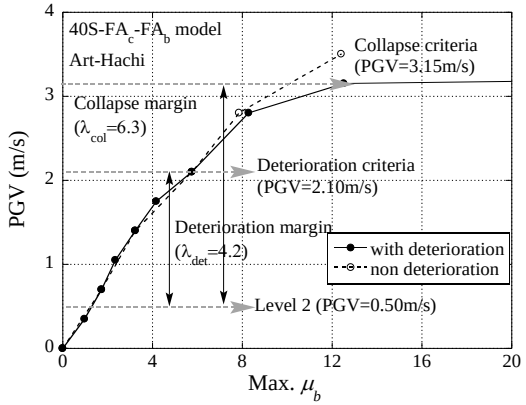


Figure 8 Plastic-hinge mechanism of high-rise steel building

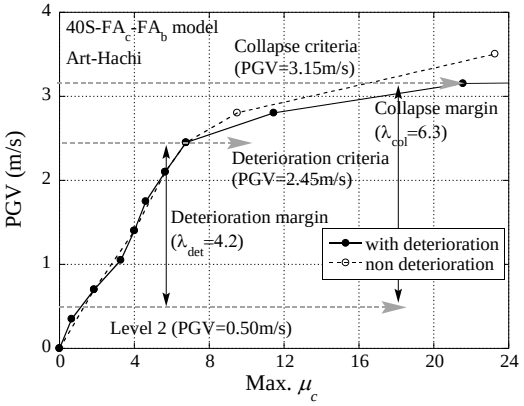
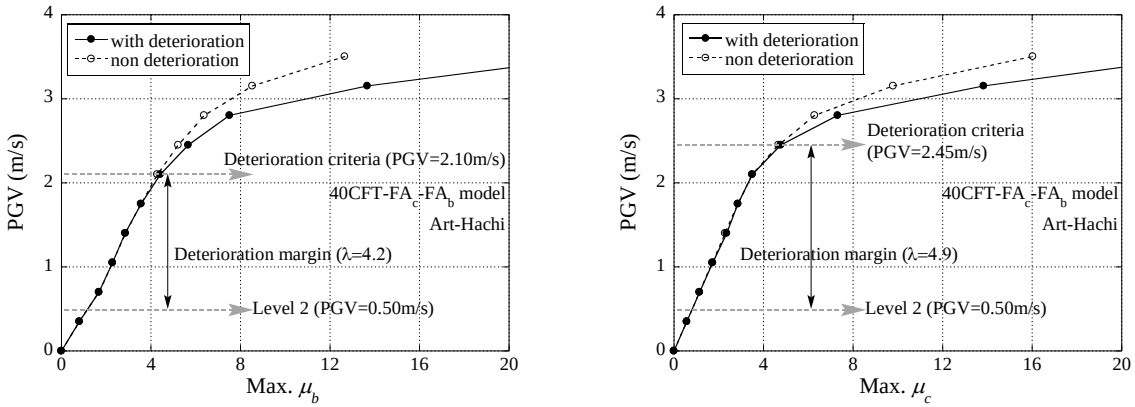


4.2 Incremental ductility ratios

In order to capture the criterion of the effect of member deterioration on ductility ratios of high-rise buildings, the maximum ductility ratios of the deteriorating and non-deteriorating building models (i.e., high-rise steel and CFT building) under incremental dynamic loadings (e.g., Art-Hachi) are compared, as shown in Figures 9~10. Meanwhile, indexes for indicating the deterioration margin and collapse margin of the corresponding high-rise buildings comparing to the intensity measure of level 2 (PGV=0.50m/s) are separately proposed as follows

$$\begin{cases} \lambda_{col} = \dfrac{PGV_{col}}{PGV_{level\,2}} \\ \lambda_{det} = \dfrac{PGV_{det}}{PGV_{level\,2}} \end{cases} \tag{3}$$



(a) Maximum ductility ratio of beam members

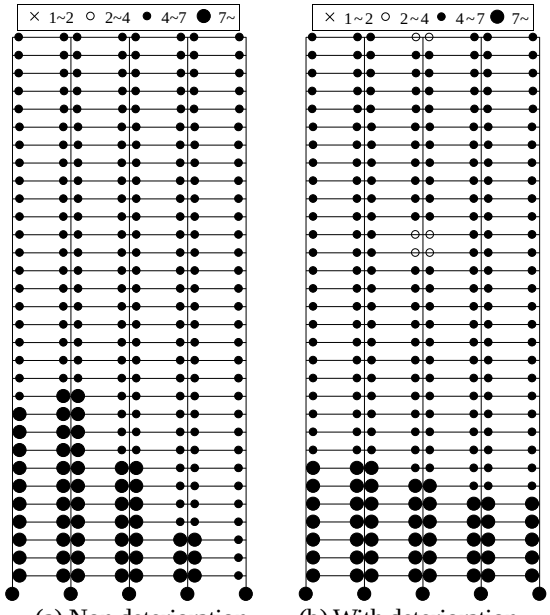
(b) Maximum ductility ratio of column members

Figure 9 Dependence of member deterioration on ductility ratios of high-rise steel building

(a) Maximum ductility ratio of beam members (b) Maximum ductility ratio of column members

Figure 9 Dependence of member deterioration on ductility ratios of high-rise CFT building

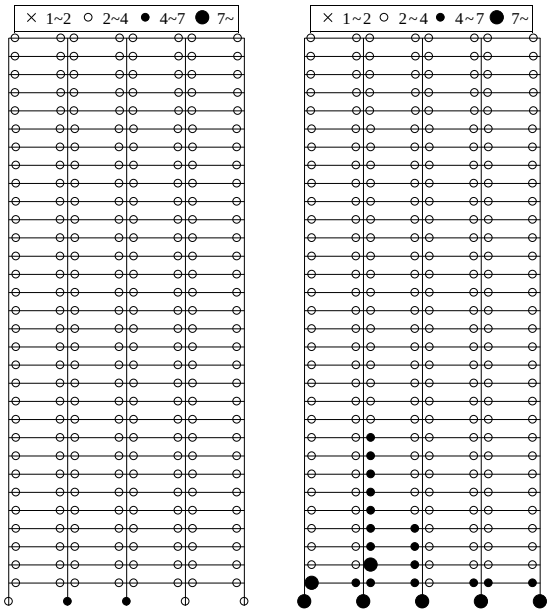
As observed in Figures 9~10, effect of member deteriorations gradually shows extensive influence on the maximum ductility ratios of each corresponding members (i.e., girder and column) of various high-rise buildings (steel and CFT structure). Some relationships can be observed as follows.



(a) With respect to the relationship between the maximum ductility ratios of the deteriorating and the corresponding non-deteriorating steel models, in Figure 9, Even though the effect of deterioration on the ductility ratios of beam and square HST column base is simultaneously initiated at the incremental factor of ϕ=3.0, which indicates the same deterioration margin (λ_{det}=4.2), seismic-resistant capacity of such building to significantly deteriorates since then and collapse is induced eventually. Collapse margin λ_{col}=6.3 is correspondingly derived for this Low-det. High-rise steel building.

(b) Likewise, for the effect of member deterioration on maximum ductility factors of high-rise CFT buildings, as shown in Figure 10, effect of member deterioration on ductility ratios of beam and column-base is initially captured at the incremental factor of ϕ=3.0 and ϕ=3.5, the reason why column-base deterioration emerges later than that of beam deterioration is that weak-beam mechanism makes beam firstly yield. However, the sway collapse of such Low-det. High-rise CFT building has not been observed, no matter for deteriorating model and non-deteriorating model. This indicates that λ_{col} is larger than 7.0.

(c) Based on the viewpoint of seismic-redundancy of structures, deterioration margin and collapse margin on the basis of intensity measures (PGV) of earthquake are assessed. Within the range of incremental factor ($\phi \leq 5.0$), collapse of high-rise steel buildings is induced, while is not feasible to high-rise CFT buildings. Furthermore, for the deterioration margins of steel and CFT models, various ductility redundancies of column-based are also captured, due to the various deteriorations of square HST and CFT columns, e.g., λ_{det} of the square CFT column-base of associated high-rise CFT building models is 4.9 [shown in Figure 10 (b)], but λ_{det} of the square HST column-base of associated high-rise steel building models is 4.2 [shown in Figure 9 (b)].



4.2 Collapse mechanism

Conventionally, the plastic collapse criterion of steel member and frame are considered by the occurrence of plastic-hinge, based on the elastic-perfectly plastic assumption. While, in this study, as mentioned in Section 2, we think the local-buckling of steel members is the criteria of member's failure (collapse), and the collapse of frame is subsequently considered to be occurred by extensive local-failure of members at critical regions (e.g., endings of beam and column-based). Thus, member damages based on the ductility ratios of beam and column-based in the weak-beam frame are expected to indicate the collapse mechanism of corresponding high-rise buildings. We specifically show the collapse mechanism of existent high-rise steel buildings with Low-det. and High-det. levels (i.e., 40S-FA$_c$-FA$_b$ and 40S-FB$_c$-FB$_b$ model). Figures 11~12 respectively show the ductility ratios of low-det. and high-det. high-rise steel buildings, at the time that collapse is induced in deteriorating model under Art-Hachi wave.

(a) Non deterioration (b) With deterioration

Figure 11 Collapse of low-det. high-rise steel building

(a) Non deterioration (b) With deterioration

Figure 12 Collapse of high-det. high-rise steel building

As shown in Figure 11, it is obvious that the low-det. model (40S-FA_c-FA_b) shows ductile behavior to resist collapse being occurred (Art-Hachi, ϕ=5.0), even though extensively severe member damages are both observed in deteriorating and non-deteriorating models. Furthermore, as shown in Figure 13, relatively large μ_b (≤15) can still not generate collapse, but sudden increasing ductility ratios at lower-story of high-rise building make it collapse.

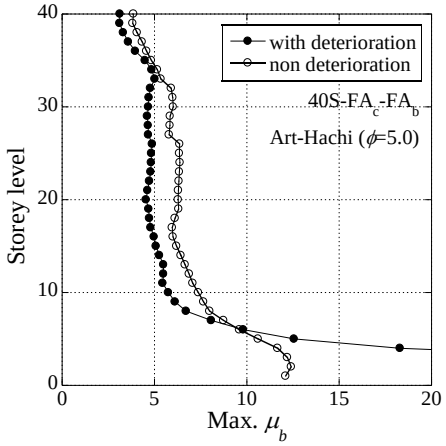


Figure 13 Collapse of high-det. high-rise steel building

Contrarily, the corresponding high-det. high-rise building model (40S-FB_c-FB_b) demonstrates non-ductile behavior to resist collapse occurring (Art-Hachi, ϕ=2.0), as shown in Figure 12. In particular, extremely large ductility factor μ_c of the square HST column-base caused by the column deterioration is the key reason to make the building structure collapse at bottom story.

5. CUMULATIV PLASTIC DAMAGES

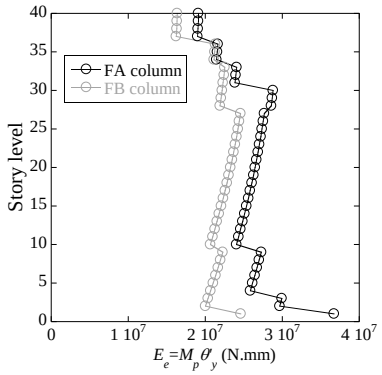
Kato and Akiyama (1975) have proposed a hypothesis in which the term cumulative plastic deformation is introduced. The cumulative plastic deformation (η) implies the dissipated energy that is obtained from the hysteretic loops of the members (E_h) divided by energy product of the full-plastic moment (M_p) and corresponding yield rotation (θ'_y) of the members in high-rise buildings Thus, for the cumulative plastic deformations of each model under incremental dynamic loading, the maximum η of beam and column can be calculated by

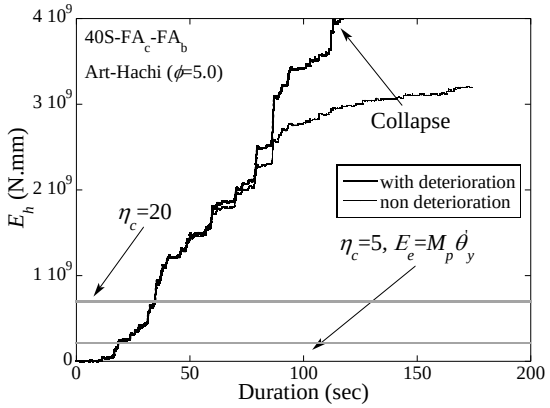
$$\eta_{b,c} = \frac{\max.E_h(\tau)}{E_e} = \frac{\max.E_h(\tau)}{{}_{b,c}M_p \times {}_{b,c}\theta'_y} \qquad (4)$$

where E_h is hysteretic energy dissipation of beam and column components, M_p is the full-plastic moment of beam and column components, θ'_y is the rotation corresponding to M_p with elastic modulus.

5.1 Steel and CFT deteriorations

In addition to ductility ratio (μ), cumulative plastic deformation (η) is also capable of representing the member damages of various high-rise building based on hysteretic energy dissipation. Although the ultimate energy-dissipating capacity (E_e) of various ranks (FA, FB) of steel and CFT components is slightly different, as shown in Fig. 14, if the effect of member deterioration after peak-point show considerable influence on collapse-resistant capacity of such high-rise buildings is still not clearly. Thus, in order to quantify the effect of member deterioration (local-buckling) on the energy-dissipating capacity of high-rise steel and CFT building models (low-det. and high-det.) under severe earthquake excitation, the time history responses of the maximum η of each building model are calculated and demonstrated in Figures. 15~16.





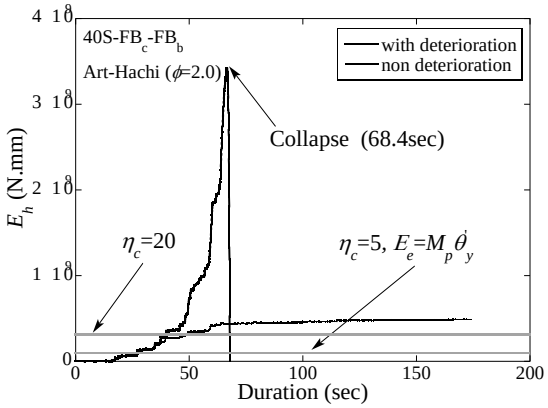


Figure 14 Energy-dissipating capacities of various square HST columns with FA and FB of *B/t* ranks

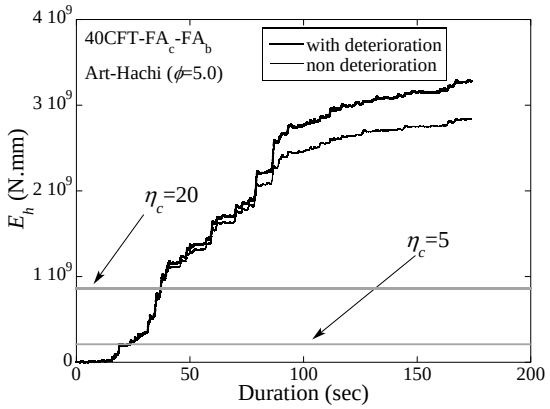
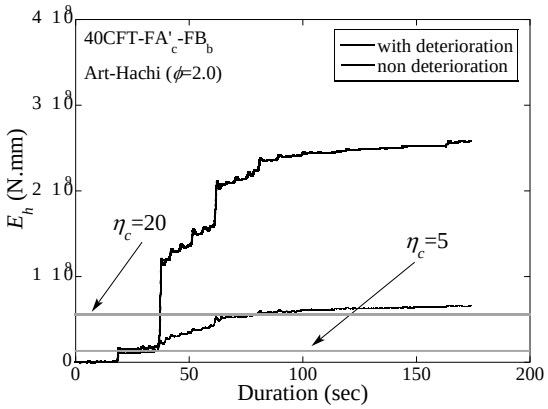
Due to different collapse mechanisms of various high-rise building models is induced, as mentioned in Section 4.2, we correspondingly compare the maximum η between deteriorating and non-deteriorating models, and between square HST and CFT columns as well.

(a) According to the comparison between the low-det. steel and CFT models, as shown in Figures 15~16 (a), although difference between the maximum η cumulation of non-deteriorating steel and CFT models are hardly observed, degrading of energy-dissipating capacity of the steel model



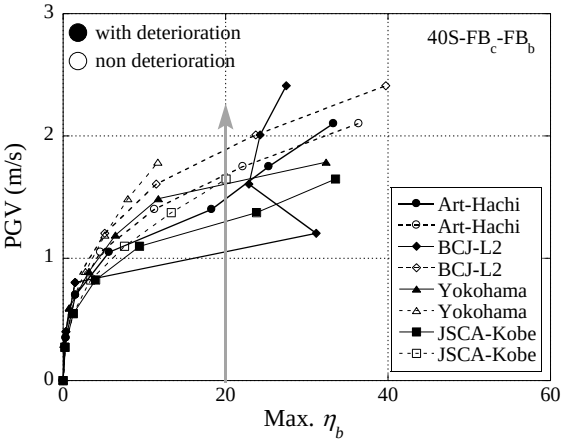
(a) Low-det. 40S-FA_c-FA_b model



(b) High-det. 40S-FB_c-FB_b model

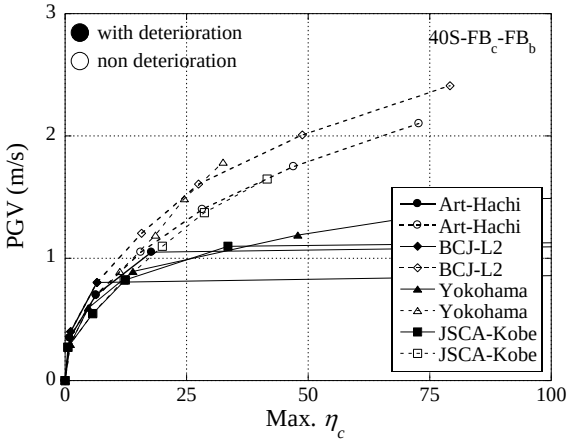
Figure 15 Maximum Hysteretic energy at the largest energy-dissipated element of high-rise steel building model

(a) Low-det. 40S-FA_c-FA_b model



(b) High-det. 40S-FB_c-FB_b model

Figure 15 Maximum Hysteretic energy at the largest energy-dissipated element of high-rise CFT building model



due to the member deterioration is gradually larger than that of CFT building model. In addition, it is noted that extremely large h has been cumulated in both deteriorating and non-deteriorating models under severe earthquake (e.g., Art-Hachi, ϕ=5.0).

(b) On the other hand, for the high-det. steel and CFT building models, as shown in Figures 15~16 (b), ignoring the member deterioration would overestimate the energy-dissipating capacity of steel model compared with CFT model, and non-ductile collapse of steel model is captured at the duration of 68.4sec of Art-Hachi wave (ϕ=2.0).

In addition, to be analogous to the incremental dynamic responses of ductility ratios as shown in Section 4, the maximum η of beam (max. η_b) and column (max. η_c) members of high-det. high-rise steel building model (40S-FB_c-FB_b) are also compared between deteriorating and non-deteriorating consideration, as shown in Figure 17.

(a) Max. η_b of beam component

(b) Max. η_c of column component

Figure 17 Incremental responses of maximum cumulative plastic deflection of beams and columns:

As shown in Figure 17, firstly, various earthquake waves induced similar incremental responses of the maximum h of beam and column, but the aleatory uncertainty caused by earthquakes is still not avoided due to the various energy inputting of each wave. Besides, the amplified effect of member deterioration on the max. η_b of beam component is significantly different from that of column (max. η_c) from the initial range of deterioration is observed. In particular, energy-dissipating capacity of beam members deteriorates stably, and in the case of BCJ-L2 waves [as shown in Figure 17 (a)], the strengthening of energy-dissipating capacity of beam is even observed, which is owing to the extreme softening (collapse) of column, as shown in Figure 18 (b). In contrast, maximum h of column is suddenly increased from initial deterioration to final collapse. This process is mainly because that the developing of column deterioration produces more cycles and larger hysteresis loops under incremental earthquake excitations.

3. CONCLUSIONS

On the basis of above works addressed on ductility and energy dissipation of the members of high-rise steel and CFT buildings, the effects of member deterioration on the member damage and collapse mechanisms were quantified and discussed above.

The effect of member deterioration is initiated at the lower-story portion of high-rise steel and CFT building, and extended upward. The plastic-hinge rotations produced at beam and column-base is significantly amplified by member deterioration, and the occurring of various collapse mechanisms (ductile and non-ductile) of high-rise steel buildings with deterioration can be captured. Furthermore, deterioration margin and collapse margin based on ductility and energy are completely different, but the unified processes of the deterioration and collapse producing of beam and column members are analogical between ductility and energy. Even though the high-rise CFT buildings has the identical horizontal stiffness with that of high-rise steel building, collapse margin of high-rise CFT building is obviously larger than corresponding steel building.

Abstract: A full-scale four-story steel building specimen was experimented on the E-Defense shake-table in 2007, inputting various scales of ground motion until collapse. To extend the discussion on the building specimen performance in the experiment, this study addresses the deterioration of column shear strength resulting in the base shear strength degradation and finally the collapse of the whole building. Degradation of column strength is defined as the state when the displacement of the building still increases but column shear capacity cannot increase any further and drops down, induced by plastification and local buckling of column wall at both ends. From this point of view, the sequence of deterioration is detected and clarified for each column. Then, the study specifies timing ranges of deterioration of story shear strength before the building settles down on the supporting table due to collapse. The study also finds out the difference of degradation behavior among each column during the excitation loading due to the corresponding position of columns on the building plan.

1. INTRODUCTION

In September 2007, a full-scale four-story steel building was experimented to collapse on the E-Defense which is the world's largest three-dimensional shake-table located in Miki City, Hyogo Prefecture, Japan. The ground acceleration histories recorded at the JR Takatori station during the 1995 Hyogo-ken Nanbu earthquake were used as the input for the shake-table experiments under various scales. Experimental result shows that collapse occurred under the 100% Takatori motion, due to local buckling leading to deterioration of columns in the base story.

Elastic and elastoplastic behavior of the building specimen in the experiment was studied and presented in several papers by Suita et al (2009), Yamada et al (2009) and Shimada et al (2010). Collapse mechanism is also discussed; however, detailed behavior of each column in accordance with global behavior of the building was not indicated in details. To give further comprehension about the building specimen performance in the test, this study addresses the deterioration of column shear strength resulting in the base shear capacity degradation and finally the collapse of the whole building. Interaction of column axial force and biaxial bending moment capacity is observed in the response of the building, especially under strong shaking. The study also investigates behavior of column base and its influence on column bending deformation, which takes also an important part in global behavior of the building specimen.

2. GENERAL INFORMATION

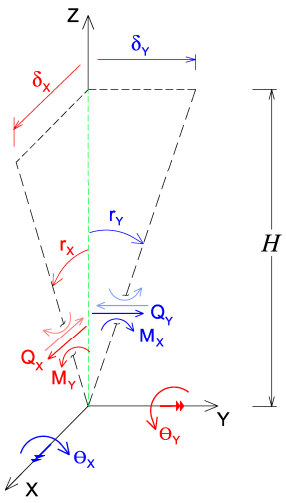
2.1 Building specimen

The building specimen is a full-scale four-story steel moment frame with concrete slabs and autoclaved aerated concrete panels for exterior walls. The plan dimension is 6×10 m, and the total height from the upper surface of stiff foundation to the roof is about 14 m (Fig. 1). Wide-flange sections are used for beams and hollow square sections are used for columns. Steel material type is SN400B and BCR295 for beams and columns, respectively. Section shapes are given in Table 1.

The building specimen is subjected to the input Takatori ground acceleration histories under various scales. Up to 20% Takatori ground motion, the building behaves almost elastically. Then, along with gradually increased scale factors, yielding is observed more obviously in the building behavior, especially in Y-axis. This paper mainly discusses about the two strongest shaking cases, including 60% and 100% Takatori motion when column deterioration occurs.

2.2 Sign convention

All kinds of forces and deformation mentioned in this paper follow sign convention as fully displayed in Fig. 2. Rotational vector is supposed to follow the right-hand screw rule; however, there is only one exception that the sign of rotational vector about X-axis (related to θ_X, M_X) is defined oppositely so as to be consistent with the sign of translational vector causing rotation about this axis. It is also noted that story drift angle is symbolized by r_X and r_Y for X & Y-dir, respectively.



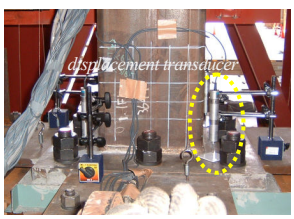


Figure 2 Sign Convention

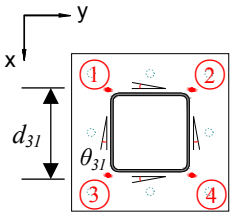

Figure 3 Measurement of Base-Plate Deformation

2.3 Measurement information

Details of general measurement devices (for recording member forces, building displacement, etc.) and processing method for experimental output data are fully described in the publication by Suita et al (2009). This paper gives further information about the measurement of column base-plate deformation. The column is fixed to the stiff foundation by eight anchor bolts M36 (ABR490) through a 50 mm thick base-plate (600×600 mm) welded to column bottom end.

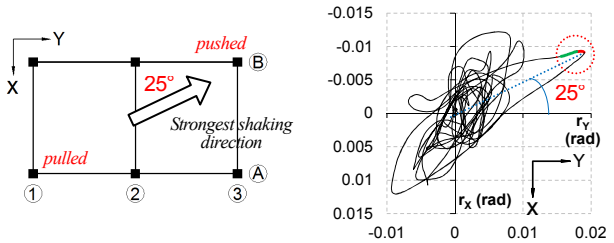
Base-plate displacement of each column is recorded at four places close to column corners, as can be seen in Fig. 3. Upward displacement is defined positive sign. Base-plate rotation angle on each side of column wall is computed using Eq. (1) in which, u_i, u_j - uplift displacement of two conjunctive points i & j, d_{ij} - distance between points i & j. Average rotation angle of two parallel sides is assumed base-plate deformation angle with respect to that side.

$$\theta_{ij} = \frac{u_i - u_j}{d_{ij}} \quad (1)$$

3. 60% TAKATORI LOAD CASE

3.1 Column behavior

Subjected to 60% Takatori ground motion which is 1.5 times larger than the Japanese Level-2 design earthquake (i.e. peak ground velocity at 0.75 m/s), the building performed inelastic behavior. Significant yielding occurs at around 6 s



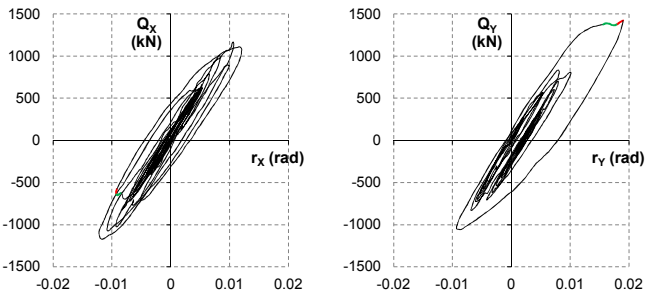


Figure 4 Base Story Drift Orbit (60% Takatori)

(a) X-dir. (b) Y-dir.

Figure 5 Base Shear vs. Base Story Drift (60% Takatori)

elapsed from the excitation start. At that moment, the base story drift reaches to r_Y = 0.019 rad and r_X = 0.009 rad (as highlighted in Fig. 4). Basically, the building moves in 45° diagonal direction and is subjected to balance biaxial bending. However, due to severe yielding in Y-dir rather than X-dir. (displayed by base shear hysteresis curves in Fig. 5), the farthest translational orientation angle of the building at 6.05 s is about 25° with respect to Y-axis.

It is noteworthy that during the time when yielding happens (5.93~6.05 s), hysteresis curve of base shear Q_Y has a little strange performance with a sudden pinching after yielding, exactly occurring from 6.00 s to 6.05 s. Such behavior is also found in column shear hysteresis curves, as can be seen in Fig. 6 for typical columns A1 & B3 at two opposite corners. This phenomenon can be explained due to the interaction of column axial force. Fig. 7-a superposes typical column shear history (Q_Y - primary axis) with story drift history (r_Y - secondary axis). Up to 5.99 s, absolute column axial force (N - primary axis) shown in Fig. 7-b is still increasing in accordance with story drift; however suddenly turns down from 6.00 s and later on, resulting in higher moment capacity of column section. It is the reason why column shear increases after yielding as shown in Fig. 6. On the other hand, it should be noted that upper stories do pull back the base story which is still moving further away during this time, stopping the development of column seismic axial force. Time-history of overturning moment induced by upper stories (M_{OVT-X} - secondary axis) shown in Fig. 7-b proves this situation. In summary, those all interactions are thought to be a reasonable interpretation for pinching behavior in the base shear hysteresis curve.

3.2 Influence of column base rigidity on column bending behavior

Detailed uplift displacement [unit: *mm*] and rotation angle of base-plates at 6.05 s for all columns are given in Fig. 8. It should be noted the building is pulled in corner A1 and pushed in corner B3 at this moment (as can be seen in Fig. 4). Therefore, a gradual increase of base-plate uplift and inclination is identified starting from the corner B3 through to A1, clearly shown in Fig. 8. Base-plate rotation angle $\theta_{X\text{-}BASE}$ of A1 & B3 is selected to plot for comparison in Fig. 9-a, indicating that the separation of column base-plate occurs more significantly in A1 than B3.

Consequently, the rigidity of column base A1 becomes smaller than that of column B3 at the opposite corner. It can hence be deemed that the actual bending deformation of column end B3 must be larger than A1 at 6.05 s. This fact is proved in Fig. 9-b which apparently displays the resultant moment $M_{X\text{-}BOT}$ developed at the bottom-end of column B3 much larger than that of column A1 during the yielding time. In the meantime, column top-end moments $M_{X\text{-}TOP}$ of A1 & B3 are almost equal (Fig. 9-c), stating that the different shear behavior between each column does not come from column top but from the different base-plate fixity behavior during the excitation loading. In other words, different loosening of each base-plate during seismic excitation causes different biaxial bending response of each corresponding column.

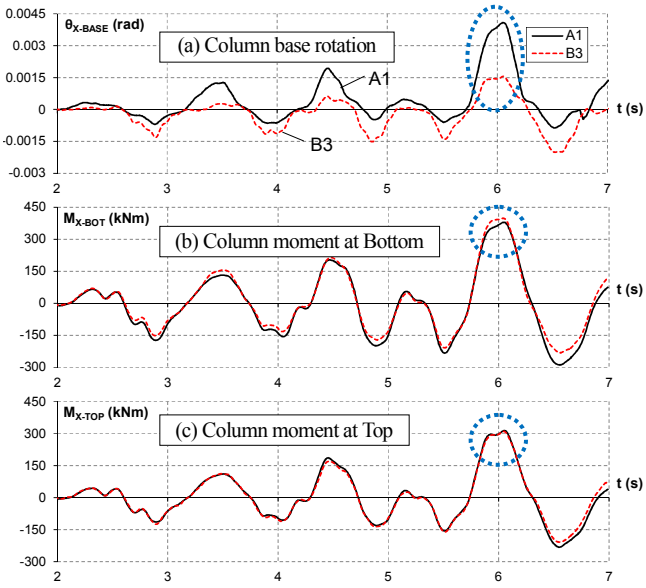

Figure 9 Column Behavior Comparison (60% Takatori)

4. 100% TAKATORI LOAD CASE

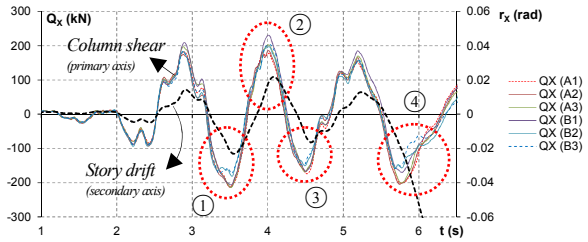
4.1 Shear strength deterioration

Before advancing into details, this section summarizes timing ranges of column shear deterioration in the 100% Takatori case. Degradation of column shear is defined as the state when the displacement of the building still increases but column shear capacity cannot increase any further and falls down. From this point of view, the building behaves elastically during the first three seconds elapsed from the start of 100% Takatori excitation. Nonlinear behavior was only observed after 3.00 s. Histories of column shear forces superposed with those of base story drift angle (given in Fig. 10-a for X-dir. & 10-b for Y-dir., where column shear curves represented by colored lines are respect to primary axis, and story drift represented by heavy dashed line is respect to secondary axis) indicate four specific timing ranges of column deterioration before collapse, namely as follows:

① 3.26~3.55 s; ② 3.76~4.05 s;
③ 4.48~4.66 s; ④ 5.68~6.22 s.

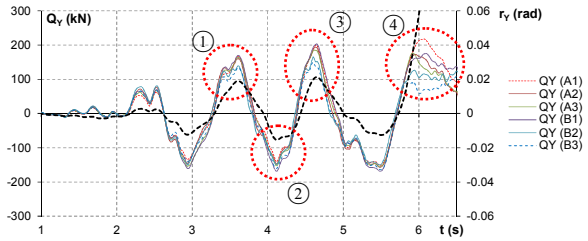
4.2 Stages of column shear strength deterioration

The first degradation of column strength (denoted by range ① in Fig. 10) occurs at 3.32 s to column B2 in X-dir. even the story drift angle is not very large (r_X = -0.006 rad) at that time. Column B3 deteriorates right after that at 3.37 s. Other columns still maintain capacity in X-dir. during this duration. However, all columns perform deterioration in Y-dir., starting from columns B2 & B3 at 3.42 s, then to columns B1, A1, A2 and A3 at 3.44 s. Story drift angle in Y-dir. at this level is approximately 0.01 rad. Especially, column B2 gets degradation again at 3.54 s and 3.85 s.



The second deterioration of column strength (denoted by range ② in Fig. 10) can be deemed to start at 3.85 s where columns B1, B2 & B3 deteriorate in both X-dir. and Y-dir. On the other hand, columns A1, A2 & A3 begin degradation in X-dir. at 3.92 s.

The third degradation of column strength (denoted by range ③ in Fig. 10) takes place at 4.50 s where columns B2 & B3 perform significant deterioration of about 20% capacity in both X-dir. and Y-dir. No further deterioration is observed for other columns during this range.



The forth and also the most severe deterioration of column strength (denoted by range ④ in Fig. 10) that leads to the overall collapse mechanism of the building starts from 5.68 s. Damage to columns occurs earlier in X-dir. than in Y-dir. From 5.68 s and later on, story drift angle r_X = -0.012 rad and keeps increasing whilst column shear forces Q_X start decaying. Out of columns B2 & B3 degraded already from previous stages, column A2 deteriorates at 5.73 s, then column A1 & A3 at 5.75 s, and finally degradation of column B1 takes place at 5.78 s.

After that, when story drift r_Y overpasses 0.01 rad, column shear forces in Y-dir. start deterioration. At 5.79 s, column B3 decays earliest and most significant where almost 50% shear capacity is lost. Column B2 degrades mostly at the same time with column B3 but still remains larger capacity of about 65% peak column strength. Then, column B1 deteriorates at 5.85 s, column A3 at 5.91 s, and column A2 at 5.95 s. Story drift angle r_Y corresponding to those moments is 0.018, 0.031 and 0.042 rad, respectively. Deterioration of those columns is about 10-15% shear capacity. Finally, the strongest column A1, which is under tension, keeps up strength the best and only starts decaying until 6.08 s when the story drift r_Y is equal to 0.082 rad.

After all, the building reaches to peak displacement in X-dir. at 6.22 s and then turns back, but still keeps up moving forward in Y-dir. until the building touches the supporting table and surrounding fence. Discussion on this final duration is to be presented in the upcoming section. Deterioration sequence of column shear behavior in both X and Y-dir. is summarized in Table 2.

(a) X-dir.

(b) Y-dir.

Figure 10 Time-History of Column Shear vs. Story Drift

Table 2 Deterioration Sequence of Column Shear Behavior

Range	t (s)	Q_x	Q_y
①	3.32	B2 starts deterioration	
	3.37	B3 starts deterioration	
	3.42		B2, B3 start deterioration
	3.44		B1, A1, A2, A3 start deterioration
	3.54		B2 deteriorates again
②	3.85	B2, B3 deteriorate	
	3.92	A1, A2 deteriorate	
③	4.50	B2, B3 deteriorate	B2, B3 deteriorate
	4.60		B2, B3 deteriorate again
④	5.68	B2, B3 deteriorate	
	5.73	A2 deteriorates	
	5.75	A1, A3 deteriorate	
	5.78	B1 deteriorates	
	5.79		B3 deteriorates
	5.81		B2 deteriorates
	5.85		B1 deteriorates
	5.91		A3 deteriorates
	5.95		A2 deteriorates
	6.08		A1 deteriorates

4.3 Deterioration sequence of column capacity

As presented in the previous section, the building experiences the most vulnerable time starting from 5.79 s elapsed from the start of 100% Takatori excitation. Fig. 11 plotting the base story drift orbit shows the significant yielding and Segment A-B-C (elapsed from 5.74 s to 6.22 s) is selected to discuss. During this segment timing, some important instants should be noted, such as (A) 5.74 s starting at story drift $r_Y = 0$ while $r_X = -0.02$ rad; (B) 5.93 s when the column seismic axial force reaches to peak value and then turns back due to resistant movement of upper stories; and (C) 6.22 s when the building reaches to peak r_X and then unloading in X-axis happens. Total collapse finally takes place a little moment after that.

Subject to 100% Takatori ground motion, the building specimen has the same yielding translational direction (about 30° diagonal with respect to Y-axis) as in case of 60% Takatori. The study again explores behavior of two typical columns A1 & B3 like the aforementioned 60% load case. In this diagonal direction, timing from 5.74 s to 6.22 s, column A1 is subject to largest seismic tension whilst column B3 has the most significant seismic compression. It is one of reasons why deterioration of column moment B3 is more severe than A1 (as displayed in Fig. 12). $M_{Y\text{-}BOT}$ of column A1 starts decaying from point A (5.74 s) but at that time $M_{Y\text{-}BOT}$ of column B3 has deteriorated already. Advancing to point B (5.93 s), column B3 has $M_{Y\text{-}BOT} = -87$ kNm while column A1 has $M_{Y\text{-}BOT} = -216$ kNm. Column B3 suffers the most resistance loss of about 50% capacity and becomes damaged first. As a result, loss of bending moment capacity leads to deterioration of column shear.

Comparative behavior of column shear (typically Q_Y) is selected for plotting in Fig. 13-a. It can be realized that due to the position of each column over the building plan, deterioration sequence of column shear is varied. Starting from point A (5.74 s), the building moves forward in Y-dir. Compression keeps up developed in column B3. On the contrary, tension is increasing in column A1. However, up to point B (5.93 s), column axial forces all of sudden turn back although base story displacement is still growing up (as shown by column axial force history in Fig. 13-b, with respect to primary axis). It is because of the resistant displacement of upper stories helping pull back the base story. Overturning moment induced by those upper stories (shown in Fig. 13-b, with respect to secondary axis) clarifies this situation.

Correlation between bending moment behavior at column bottom-end and top-end is investigated by exploring the changing trend of inflection point position (see Figs. 13-c & d for column A1 & B3, respectively). Effective length of the 1st story column (defined as the height from the column base to the center line of girder) is 3500 mm. Before the vulnerable time, inflection point is still stable at around the middle of column effective height. But when the column bottom-end deteriorates capacity and yields, the column top-end still remains capacity and works better. Therefore, the inflection point is shifted down significantly. Column bottom-end is deemed to get damaged earlier than top-end.

(c) Column moment vs. Inflection point position (A1)

(d) Column moment vs. Inflection point position (B3)

Figure 13 Time-History Curves (100% Takatori)

To summarize the situation, Fig. 14 plots the extracted base story drift orbit measured in the collapse test with segment A-B-C-D (5.74 ~6.50 s). Drift orbit of the upper 2nd story is also plotted in this figure, showing that unloading happens to upper stories after point B (5.93 s) while the frame in the base story is still yielding and moving forward because of losing resistance. Unloading in X-axis might have started from this point of time. But the base story keeps up displacement along this way until point C (6.22 s).

In addition, to easily follow column behavior during the vulnerable time, Fig. 15 shows the integrated graphs for column forces (N, Q & M), tracing the same column top-end translational orbit with segment A-B-C-D given in Fig. 14. Column axial force diagram is shown uppermost. Plotted in the middle are column shear vectors Q_X & Q_Y. Resultant bending moment vectors M_Y & M_X at column bottom-end are plotted lowermost. Values of force vectors corresponding to each important point are indicated in the figure. The spline connecting vectors in series gives a relative diagram depicting behavior trend of column forces in accordance with the building displacement history.

Biaxial moment vector M_{XY} defined as the addition of partial moment vectors M_X and M_Y is adopted to evaluate moment capacity of columns. M-N (moment – axial force) interaction rule is visible in Fig. 15. During the pre-collapse time, moment capacity of column A1 becomes much larger than that of column B3 because the absolute axial force developed in A1 is smaller than in B3. On the other hand, local buckling occurring significantly in column B3 additionally reduces column strength, which means the column subjected to both compression and biaxial bending tends to be damaged by local buckling earlier than being subjected to pure biaxial bending only.

5. CONCLUSIONS

This study gives further investigation on the building specimen performance in the collapse test, addressing the column strength deterioration. Some concluding remarks can be stated as followings:

(1) The interaction of column axial force on bending moment capacity was observed in the test. The changing of column axial force during the seismic loading results in the changing of biaxial bending moment capacity of the cross section. As a result, column shear capacity might deteriorate.

(2) Interaction of column axial force is also found in mechanism of local buckling. The column subjected to both compression and biaxial bending tends to be damaged by local buckling earlier than being subjected to pure biaxial bending only.

(3) Discrepancy of degradation behavior among each column during the seismic loading due to the different position of columns on the building plan is also clarified in the study. On the other hand, loosening behavior of each base-plate during seismic excitation also comes from column position distribution, which slightly takes part in reducing rigidity of column base, resulting in different bending response of each relevant column.

Abstract: Columns are subjected to bi-axial bending moment, since buildings behave 3-dimensionally under seismic excitations. However, only few researches on post local buckling and deterioration behavior of RHS columns under bi-directional horizontal forces have been reported. In this study, at first, the simple horizontal loading protocol was proposed based on the investigation of random horizontal displacement orbits obtained by elasto-plastic response analyses of multi-story steel frames subjected to bi-directional horizontal ground motions. After that, using the simple loading protocol, a series of tests on RHS columns subjected to bi-directional horizontal cyclic loading and constant axial force were conducted. The experimental results were compared with the analytical results using multiple shear spring (MSS) model.

1. INTRODUCTION

In Japan, Rectangular Hollow Section (RHS) steel tubes are generally used as columns for steel buildings. Columns are subjected to bi-axial bending moment that because buildings behave 3-dimensionally under seismic excitations. In order to evaluate the seismic resistance of steel building structures, it is important to clarify the bi-axial bending behavior of RHS-columns including deterioration range governed by local buckling. However, only few researches on post local buckling and deterioration behavior of RHS columns under bi-directional horizontal forces have been reported.

In this study, to investigate the hysteresis of RHS columns including post local buckling and deterioration range under bi-axial bending moments, a series of tests on RHS columns subjected to bi-directional horizontal cyclic loading and constant axial force were conducted. In addition, the experimental results were compared with the analytical results using multiple shear spring (MSS) model.

2. CYCLIC LOADING TEST ON RHS COLUMNS UNDER BI-DIRECTIONAL HORIZONTAL FORCES

2.1 Test Specimen

The test specimen consist of RHS column; □-200×9 (BCR295, Width-to-thickness ratio: 22.2, length: 1734mm) and steel plates welded to both ends of RHS-column to connect to the loading frame, as shown in Figure 1. Tensile coupon test of the flat part of RHS column was conducted using JIS-1A testing sample and the result is shown in Figure 2.

2.2 Horizontal Loading Protocol

The simple horizontal loading protocol was proposed based on the investigation of random horizontal displacement orbits obtained by elasto-plastic response analyses of multi-story steel frames subjected to bi-directional horizontal ground motions. The configuration of the horizontal loading protocol is shown in Figure 3 (1). The horizontal loading protocol was configured as follows,

1. The basic shape of the horizontal loading protocol consists of three ellipses. The angle of shifting major axis of each ellipse was set to -30 deg., 0 deg., +30 deg. from the main axis direction of the horizontal loading protocol and frequency of loading was 1 to 2 to 1.
2. The ellipticity of each ellipse was set to 0.3.
3. A displacement-controlled cyclic loading was applied with increasing the length of major axis of an ellipse. Displacement amplitude was increased by $2\theta_{pc0}$. Where, θ_{pc0} is the elastic column rotation corresponding to the full plastic moment with axial force of the column under uni-axial bending M_{pc0}.
4. The rotational direction was constant.

The outline of the loading order is shown in Figure3 (2). The four loading steps make one set. Displacement amplitude was increased after finishing the one set. The four loading steps that make one set are as follows (At the first set, step 0 is added to one set),

Step 0: At the first set, loading from the original point O along the main axis direction of the horizontal loading protocol toward the point A. (Point A is the intersection of the ellipse of 0 degree).

Step 1: Loading clockwise along the ellipse of 0 degree from the point A. After go around along the ellipse of 0 degree, continuously loading to the point B (Point B is the intersection that can transition smoothly to the ellipse of +30 degree).

Step 2: Loading clockwise along the ellipse of +30 degree from the point B. After go around along the ellipse of +30 degree, continuously loading to the point C (Point C is the intersection that can transition smoothly to the ellipse of 0 degree).

Step 3: Loading clockwise along the ellipse of 0 degree from the point C. After go around along the ellipse of 0 degree, continuously loading to the point D (Point D is the intersection that can transition smoothly to the ellipse of -30 degree).

Step 4: Loading clockwise along the ellipse of -30 degree from the point D. After go around along the ellipse of -30 degree, continuously loading to the point E (Point E is the intersection that can transition smoothly to the ellipse of 0 degree of the next set).

After finishing the first set, cyclic loading was applied by repeat the step 1-4.

2.3 Parameters

The test parameters were main axis direction of the horizontal loading protocol and axial force ratio. The main axis direction of the horizontal loading protocol was set to 0 or 45 degree from principal axis of the column cross-section. Constant axial force was applied to the specimen and axial force ratio was set to 0.2 or 0.4 for each of the main axis direction. The list of test parameters is shown in Table 1.

2.4 Test Setup

The test specimen was placed in the loading frame, as

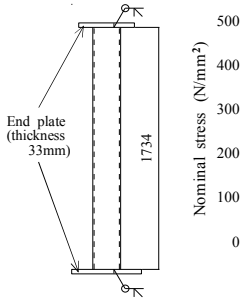

Figure 1 Test Specimen

shown in Figure 4 (1), (2). Both ends of the column were fixed on the reaction jig and the horizontal loading jig. The specimen was subjected to a horizontal force by the two horizontal jacks through the horizontal loading jig. Constant axial force was applied by three vertical jacks through the reaction jig. To load under the condition of anti-symmetric bending moment, the reaction jig was kept horizontally. Instrumentation was placed to monitor loads and deformation of the specimen. Displacement transducers monitored the deformation of the specimen and test jig. Strain gauges were attached to the column in order to confirm if the inflection point located at mid height of the column. The rotation angle of the column, axial force and bending moment, assuming an anti-symmetric distribution bending moment along the column height, were calculated by Equation (1) -(7) (Figure 5).

$$Q_x = F_{ew_x} + F_{ns_x} \quad (1)$$

2.5 Test Results

The maximum strength of all specimens was governed by local buckling. Loading was continued either until the specimen completely lost their axial force supporting capacity or until before local buckling wave comes in contact with the jig. All specimens were observed that the inflection point located close to mid height of the column by strain gauges. Figure 6 (1)-(4) show the x axis and y axis moment-rotation relationships, the load orbits, and the displacement orbits for all specimens that were normalized M_{pc0} and θ_{pc0}. In these figures, ● plot shows the maximum resultant moment of x axis and y axis $\sqrt{M_x^2 + M_y^2}$. Solid line shows the behavior till the maximum resultant moment. Broken line shows the behavior after reaching the maximum resultant moment.

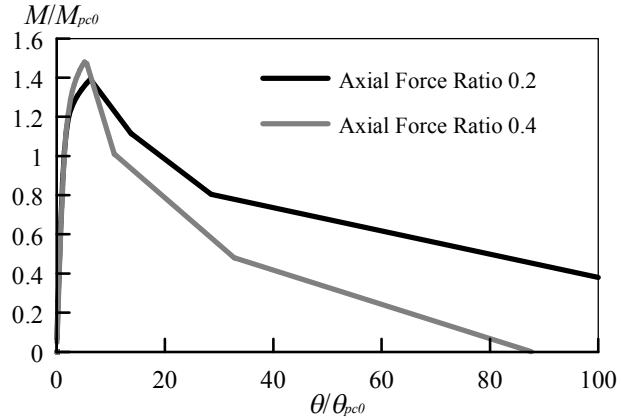

Figure 9 Calculated Load-Deformation Relationships under Monotonic Loading

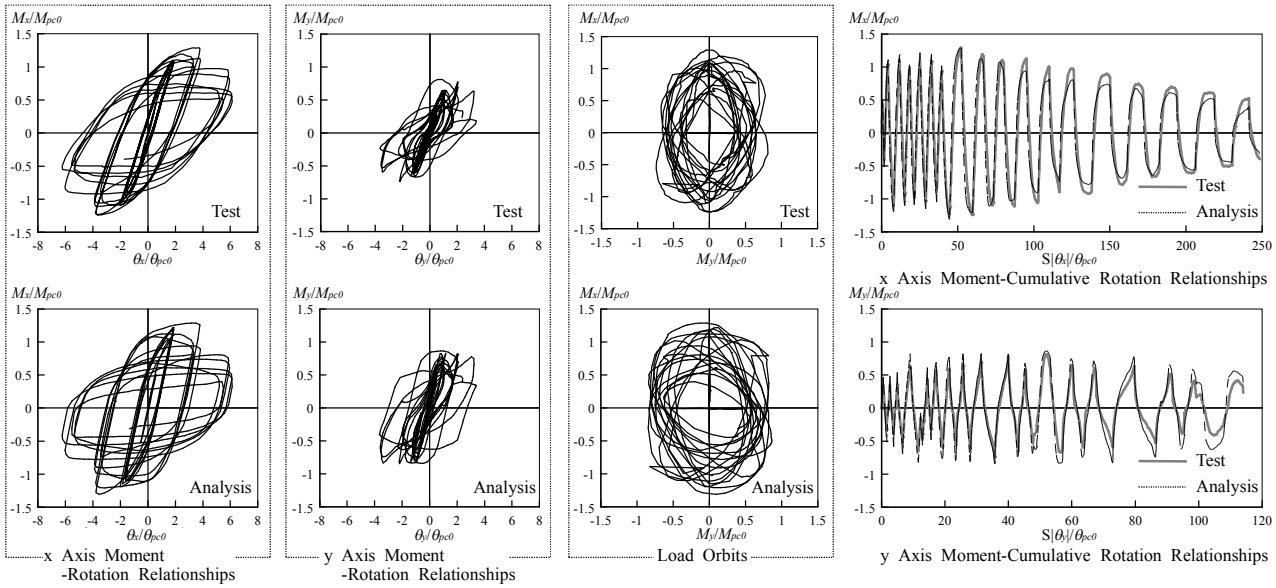
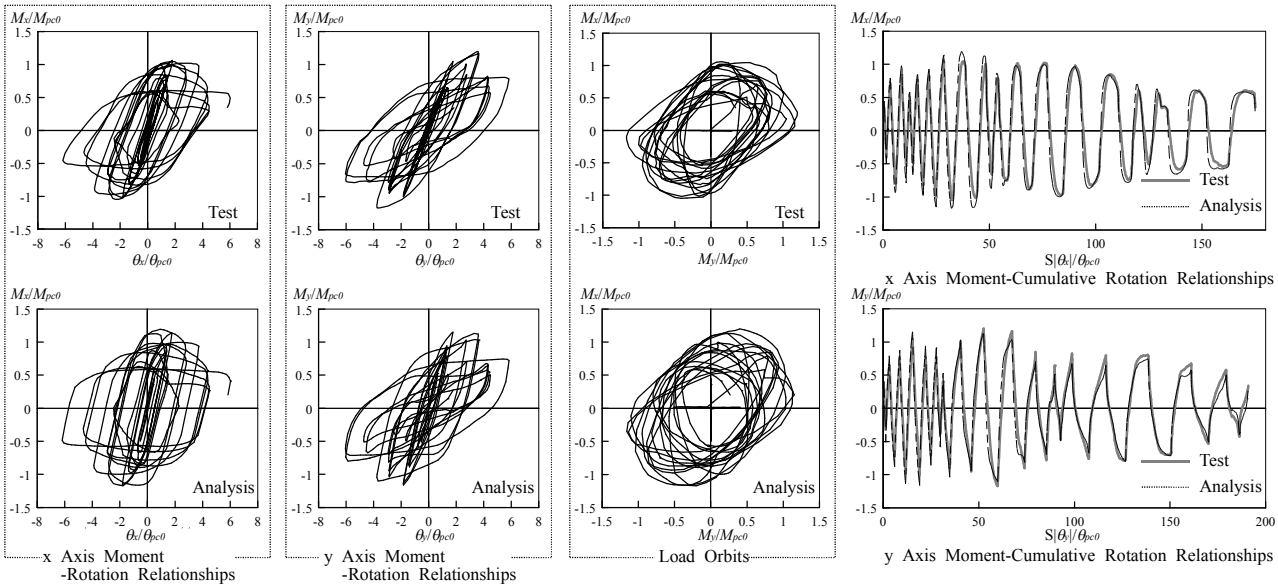


As observed from the displacement orbits, in the second set that set the length of major axis of an ellipse to $4\theta_{pc0}$, all specimens reached the maximum resultant moment on the step 1. In comparison of the maximum resultant moment of specimens which were set the main axis direction to 0 or 45 degree, in case of axial force ratio 0.2, specimen CB00_0.2_22 was $1.29M_{pc0}$, specimen CB45_0.2_22 was $1.24M_{pc0}$, in case of axial force ratio 0.4, specimen CB00_0.4_22 was $1.39M_{pc0}$, specimen CB45_0.4_22 was $1.41M_{pc0}$, hence, the maximum resultant moment of 0 degree and 45 degree were almost same.

3. ANALYSIS OF RHS COLUMNS SUBJECTED TO BI-DIRECTIONAL HORIZONTAL FORCES USING MSS MODEL



3.1 Analytical Model

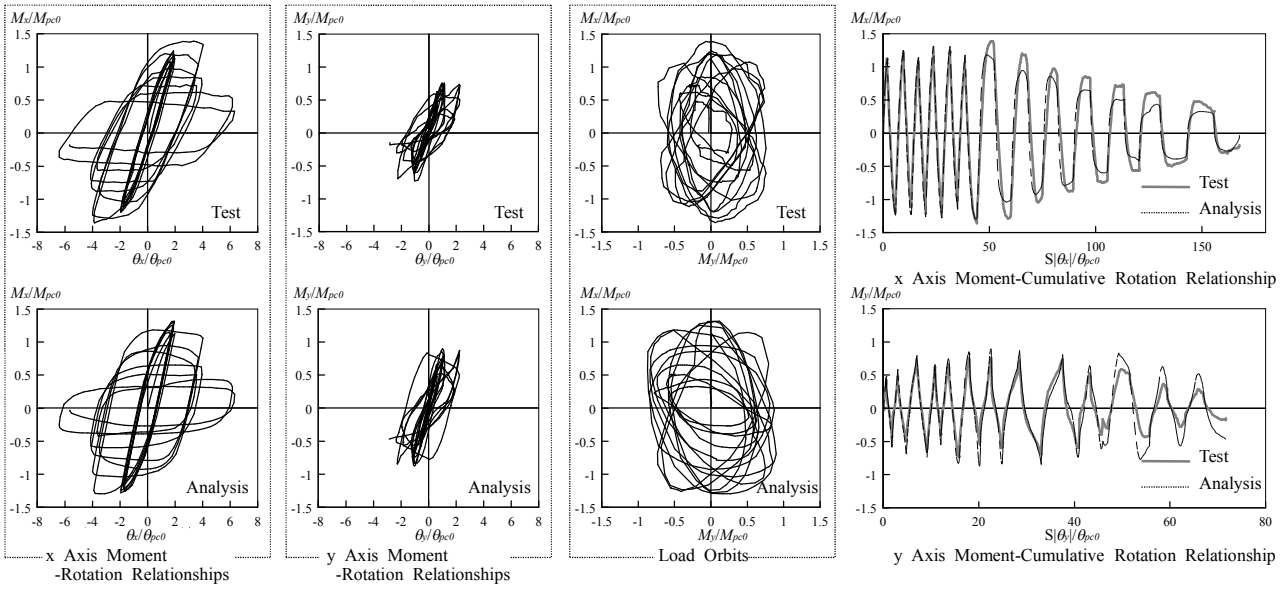
In this study, MSS (Multiple Shear Spring) model shown in Figure 7 was used. In the MSS model, the bi-directional horizontal behavior is expressed by the equal shear springs which placed at an equal angle. The reason to use this model is that RHS columns have small directionality of the structural characteristics.

Before the maximum strength, the hysteresis model used in this analysis consists with the skeleton curve which corresponds to the load-deformation relationship under monotonic loading, Bauschinger part, and elastic unloading

(1)CB00_0.2_22

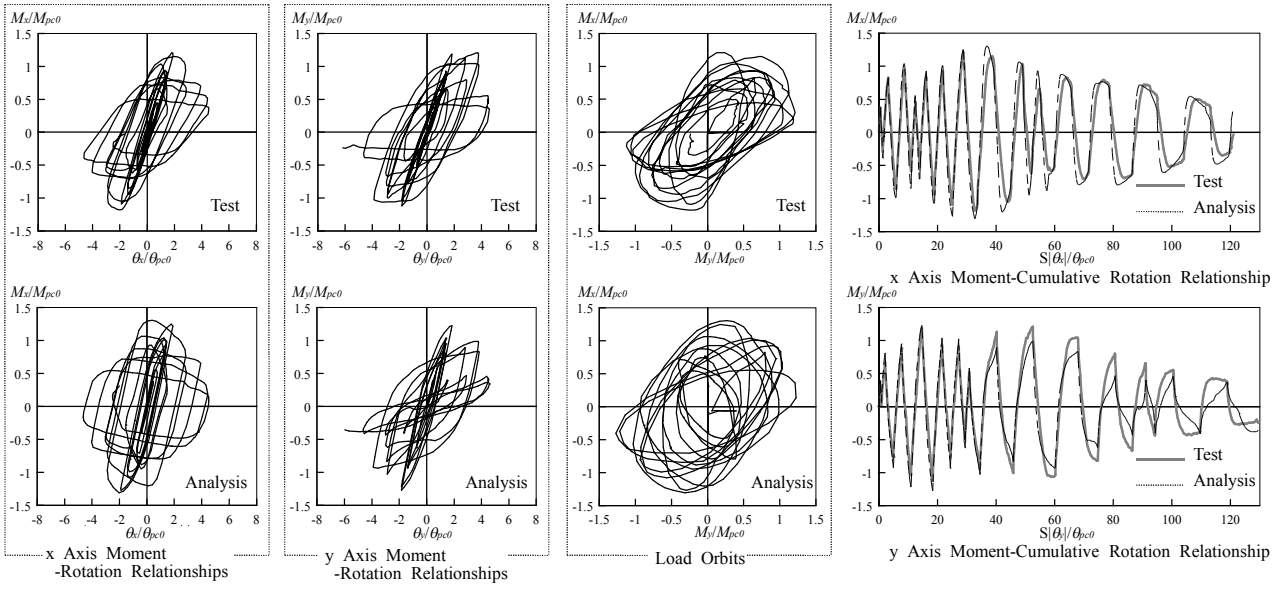
(2)CB45_0.2_22

Figure 10 Comparison between Experimental and Analytical Results



part, as shown in Figure 8 (1). After the maximum strength, the hysteresis model consists with the degrading part which corresponds to the extended skeleton curve, the upgrading part, and unloading part, as shown in Figure 8 (2). Among them, the extended skeleton curve approximately corresponds to the load-deformation relationship including deterioration range under monotonic loading. Using the calculated load-deformation relationship of RHS column under monotonic loading including deterioration behavior governed by local buckling, as shown in figure 9, the extended skeleton curve was modeled. In the analysis, the extended skeleton curve was divided into the element springs in the MSS model. By consideration of accuracy, the number of shear springs was set to 16.

As the Bauschinger part, Akiyama and Takahashi's model was applied. As the upgrading part, the bilinear model proposed by Yamada et al. was applied.



3.2 Comparison Between Experimental and Analytical Results

Figure 10 (1)-(4) show the x axis and y axis moment-rotation relationships, the load orbits, and the x axis and y axis the moment-cumulative rotation relationships for all experimental and analytical results that were normalized M_{pc0} and θ_{pc0}.

Regarding the x axis and y axis moment-rotation relationships of all specimens, although the errors of unloading stiffness were observed in deterioration range that because degrading of unloading stiffness is ignored in this hysteresis model, overall, the analytical results including deterioration range agreed the experimental results. Moreover, the analytical model also is able to trace the load orbits. On the basis of these investigations, it can be concluded that the analytical model using the MSS model

(3)CB00_0.4_22

(4)CB45_0.4_22

Figure 10 Comparison between Experimental and Analytical Results (Cont.)

closely approximated the hysteresis of RHS columns including the deterioration range under bi-directional horizontal forces and constant axial force.

4. CONCLUSIONS

To investigate the hysteresis of RHS columns including post local buckling and deterioration range under bi-axial bending moments, a series of tests on RHS columns subjected to bi-directional horizontal cyclic loading and constant axial force were conducted using the simple horizontal loading protocol. The test parameters were main axis direction of the horizontal loading protocol and axial force ratio. The maximum strength of each specimen was governed by local buckling. In comparison of the maximum resultant moment $\sqrt{Mx^2 + My^2}$ of specimens which were set the main axis direction to 0 or 45 degree, the maximum resultant moment of 0 degree and 45 degree were almost same.

In addition, the experimental results were compared with the analytical results using MSS model. The analytical model using the MSS model closely approximated the hysteresis of RHS columns including the deterioration range under bi-directional horizontal forces and constant axial force.

Abstract: In multistory steel structures, for it is convenient to attach the external wall, the edge of the beam is aligned with the face of the column. This is called an eccentric beam-to-column connection. In case of such connection type, the panel zone is also subjected to torsion. Therefore, the outside panel will take a larger amount of shear force than the inside panel, hence it will yield before the inside panel. Further on, because of the eccentricity, the strain in the beam flange may be asymmetric, which leads to early fracture of the beam. However, since the beam web is connected to the column skin plate near the outside panel, the resistance of the web might increase. Experimental tests were conducted to investigate the behavior of the eccentric beam-to-column connections under cyclic loading.

1. INTRODUCTION

Usually, in the exterior frames of a multistory steel structure, the edge of the beam is aligned with the column face, because it is convenient to attach the nonstructural walls.

Such a connection is called eccentric beam-to-column connection because the longitudinal axis of the beam is shifted to the exterior with respect to the center of the column. Therefore because of this eccentricity, the strain distribution in the beam flange is asymmetric, which might lead to early fracture in this region.

In addition, since the beam web is connected to the column skin plate in the region of the outside panel, the joint efficiency of the web might increase. Another phenomenon that has to be accounted for in eccentric beam-to-column connections is the torsion that occurs in the panel zone, (Tanaka et al. 1999). This may be due to the fact that the outside panel is acted upon by larger shear forces than the inside one, hence it will probably yield earlier than the inside panel. In order to closely investigate the behavior of eccentric beam to column connections, a set of tests was conducted.

2. TEST PROGRAM

2.1 Specimens and Parameters

In the present experiments, 6 specimens were tested as listed in Table1.Each specimen consists of two members: a rectangular hollow section column (RHS column) and an H-shaped beam. In order to achieve a smooth stress flow from the flange of the beam to the column, two steel plates are welded to the RHS column as shown in figure 2. The parameters of the present test are the thickness of the panel and the eccentricity ratio of the beam (Table 1). The latter is defined as: e/D_c.

2.2 Test Setup

In figure 3, the test setup is shown. The beam is set on the vertical direction and the column on the horizontal one. Loading is applied at the free end of the beam.

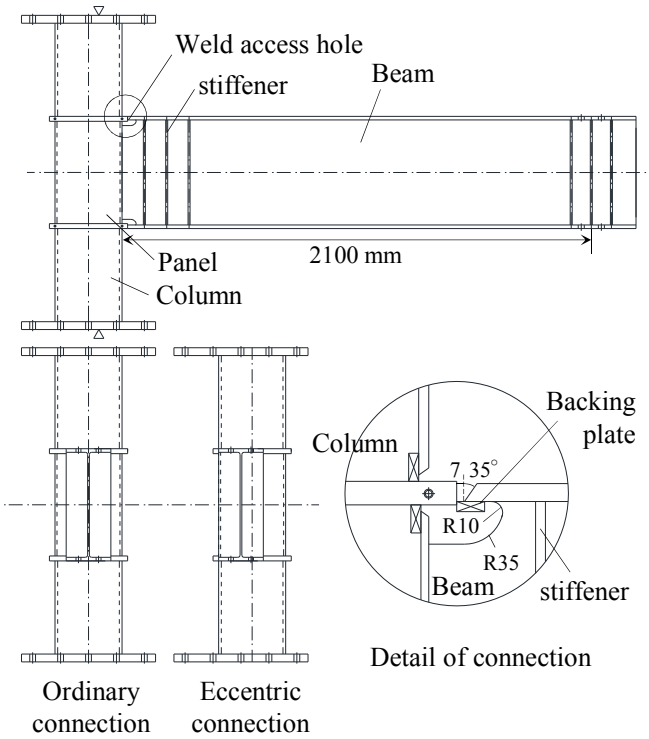

Figure 2 Test Specimen

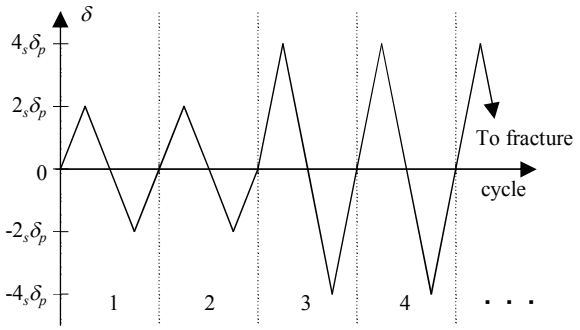

Figure 4 Loading History

2.3. Loading History

Displacement controlled cyclic loading is applied at the free end of the beam in the horizontal direction. The loading history of this test consists of incremental displacement amplitude with intervals of $2_s\delta_p$ as shown in figure4, (Japan Iron and Steel Federation 2002). $_s\delta_p$ represents the elastic deformation of beam to column connection when in the element that yields first the full plastic strength is reached ($_s\delta_p$=20 mm). Moreover, because of the restrictions of the loading system, the displacement amplitude after 3 cycles is set to $4_s\delta_p$ until the fracture of the beam.

2.4. Measurement System

In this experimental study, $_bM$, $_b\theta$, $_pM$, and $_p\gamma$ are defined as follows: $_bM$ = bending moment of beam; $_b\theta$ = rotation of beam; $_pM$ = moment of panel; and $_p\gamma$ = shear deformation of panel.

Figure 5 shows how the displacements and shear force are measured. $_bM$, $_b\theta$, $_pM$, and $_p\gamma$ are calculated using these measurement data (Eq.(1) to (7)) .

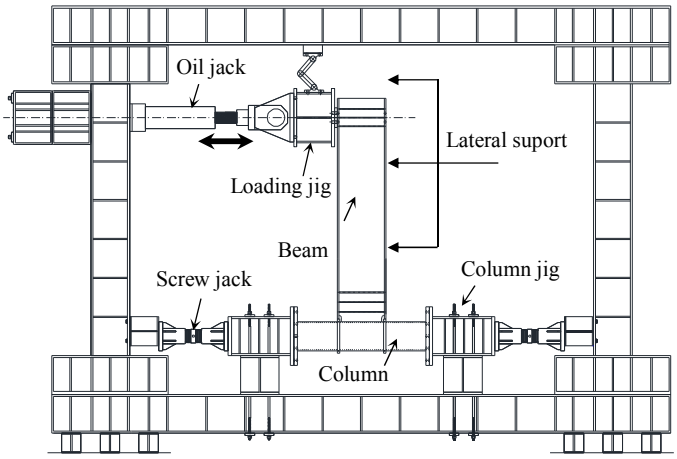

Figure 3 Test Setup

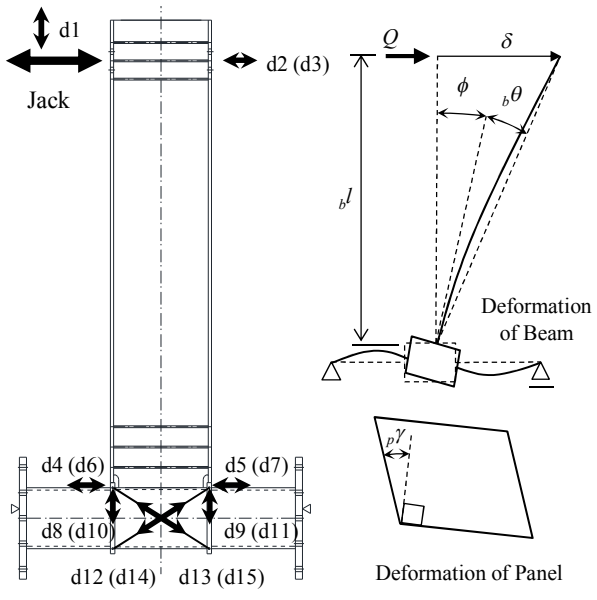

Figure 5 Measurement System

$$ {}_bM = Q \cdot l_b \tag{1}$$

where Q = horizontal load of oil jack ; and l_b = length of beam.

$$ {}_b\theta = \frac{\delta}{l_b} - \phi \tag{2}$$

$$ \delta = -\frac{\mathrm{d2}+\mathrm{d3}}{2} - \frac{\mathrm{d4}-\mathrm{d5}+\mathrm{d6}-\mathrm{d7}}{4} \tag{3}$$

$$ \phi = \left(\frac{1}{2}+\frac{e}{D_c}\right)\frac{(\mathrm{d9}-\mathrm{d8})}{h_b} + \left(\frac{1}{2}-\frac{e}{D_c}\right)\frac{(\mathrm{d11}-\mathrm{d10})}{h_b} \tag{4}$$

where δ = displacement at load application point ; ϕ = rotation angle in the connection ; and h_b = distance between centers of the beam flanges.

$$ {}_pM = {}_bM - Q \cdot \frac{L_b}{L_c} \cdot h_b \tag{5}$$

where L_b = distance between load application point and the center of the panel ; and L_c = length of the column.

$$ {}_p\gamma_{ex} = \frac{\sqrt{h_b^{\,2}+h_c^{\,2}}}{2 \cdot h_b \cdot h_c} \cdot (\mathrm{d13}-\mathrm{d12}) \tag{6}$$

$$ {}_p\gamma_{in} = \frac{\sqrt{h_b^{\,2}+h_c^{\,2}}}{2 \cdot h_b \cdot h_c} \cdot (\mathrm{d15}-\mathrm{d14}) \tag{7}$$

where h_c = distance between centers of the column flanges.

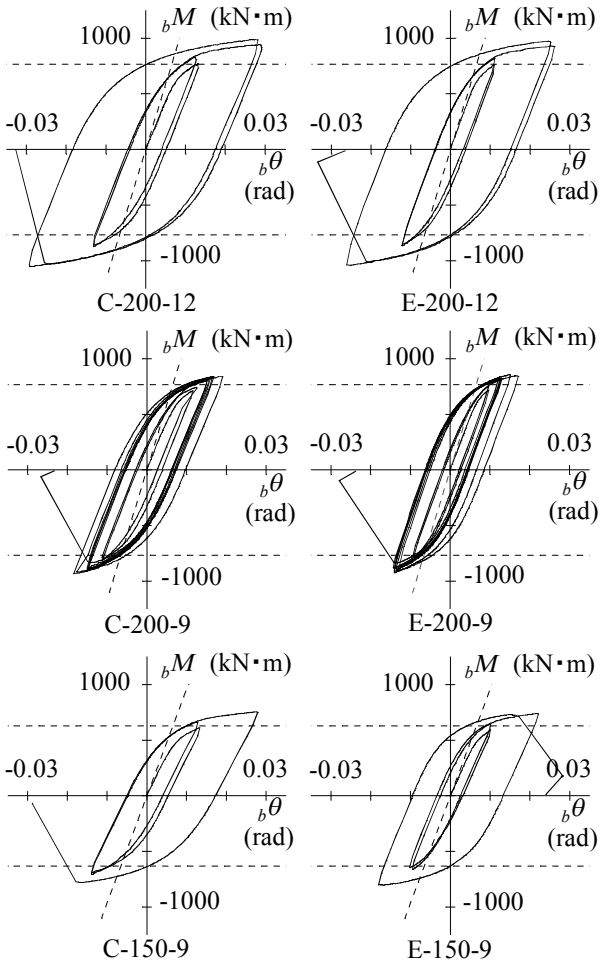

Figure 6 Behavior of beam

3. TEST RESULTS

3.1 Moment-Rotation Relationships of the Beam

In figure 6 one can observe the hysteretic behavior of the beam. Full plastic moments and the calculated value of elastic stiffness are also shown in this figure. All six specimens have fractured in the beam flange.

The influence of the eccentricity of the eccentricity on the plastic energy dissipation was investigated. In figure 7, the hysteretic behavior of the beam under cyclic loading can be decomposed into skeleton curve, Bauschinger part and an elastic unloading part. The energy dissipation of a steel beam serves as the sum of the energy dissipation in skeleton curve and Bauschinger part, and is defined as in Eq.(8).

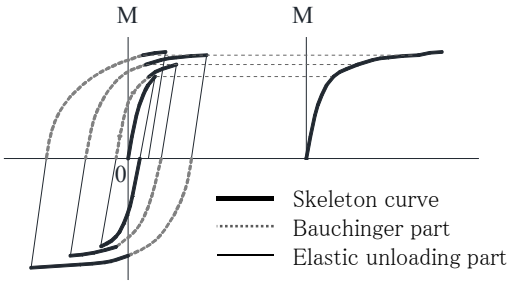

Figure 7 Skeleton Curve

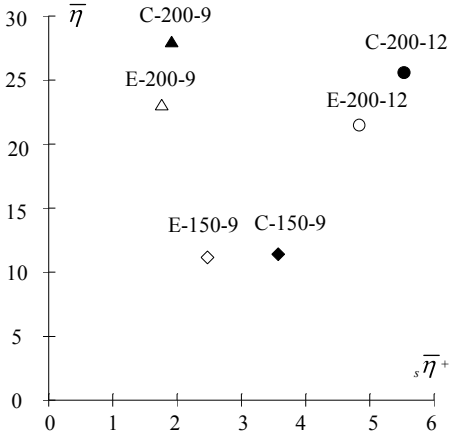

Figure8 Plastic deformation capacity of beam

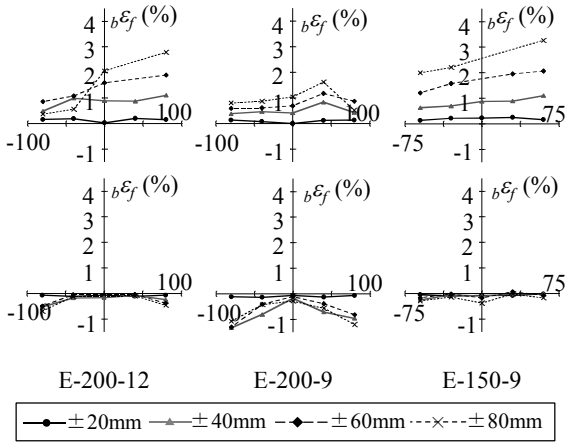

Figure 9 Strain distribution of the beam flange

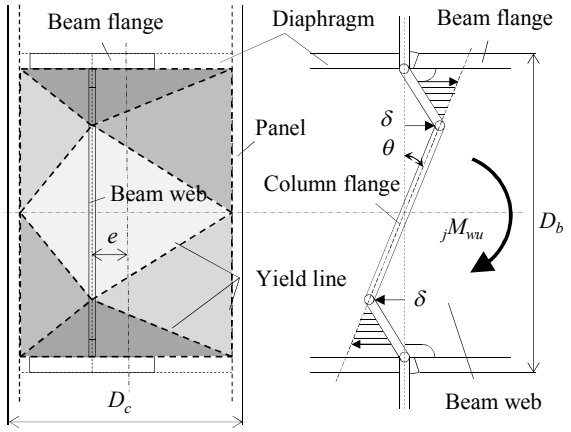
$$W_P = W_S + W_B \quad (8)$$

W_P, W_S, and W_B are defined as follows: W_P = dissipated energy of beam; W_S = dissipated energy of skeleton curve; and W_B = dissipated energy of Bauschinger part.

In this study, these dissipated energies are normalized by the unit plastic energy dissipation obtaining the equivalent cumulative plastic deformation ratio: $\overline{\eta}$



$$\overline{\eta} = {}_S\overline{\eta} + {}_B\overline{\eta} \quad (9)$$

$$\overline{\eta} = \frac{W_p}{M_p \cdot \theta_p} \quad (10)$$

$${}_S\overline{\eta} = \frac{W_S}{M_p \cdot \theta_p} \quad (11)$$

$${}_B\overline{\eta} = \frac{W_B}{M_p \cdot \theta_p} \quad (12)$$

In figure 8, the plastic deformation capacity of the beam is shown. On the vertical axis is the equivalent cumulative plastic deformation ratio of beam. On the horizontal axis is the one of the skeleton curve. The plastic energy dissipation of the hysteresis curve of eccentric connection is smaller than one of ordinary connection. In addition, for the connections in which the panel is designed to yield first, deformation of the beam is rather small because the one of the panel increases. Hence the number of cycles until the beam fractures also increases, which leads to larger energy dissipation capacity than for the connections in which the beam yields first.

(a) Yield line on column face (b)Yield field of beam web

Figure 10 Collapse Mechanisms of Beam Web

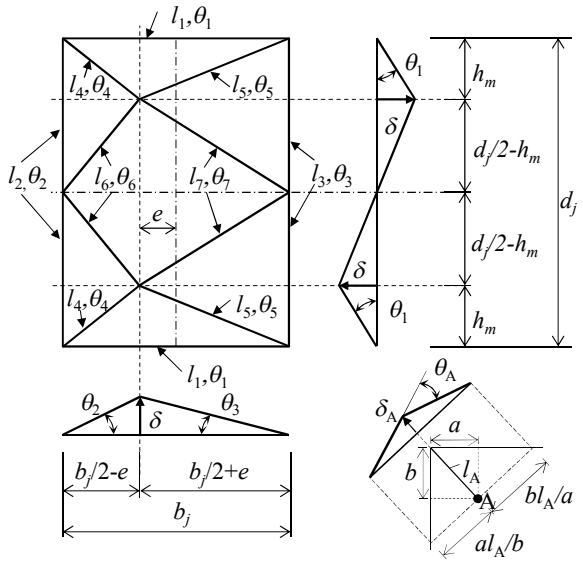


Figure 11 Plastic Rotation of Yield Line

3.1 The joint efficiency of the Beam Web

The joint efficiency of the web increases due to the fact that the beam web is connected to the column skin plate near the outside panel. In order to assess the influence of the joint efficiency of the eccentric beam web, both experimental and theoretical approaches are used, (Matsumoto et al. 1999).

In figure 10, the theoretical one is calculated from the collapse mechanisms for such web connections, (Suita K. and Tanaka T 2000).

Internal work - deformation of column skin plate

In figure 11, internal work of deformation of column skin plate is

$$E_c = 2M_0 \sum_{n=1}^{7} l_n\theta_n = \frac{-4h_m^2 b_j d_j - h_m b_j^3 + 2h_m b_j d_j^2 + 4h_m b_j e^2 + b_j^3 d_j - 4b_j d_j e^2}{h_m(b_j - 2e)(b_j + 2e)(d_j - 2h_m)} {}_c t_f^2 \, {}_c F_{fy} \delta \quad (13)$$

where δ= displacement at the point where the deformation of column skin plate is maximum ; l_n = length of the yield line(n=1~7) ; θ_n = rotation of the yield line (n=1~7); ${}_cF_{fy}$ = yield strength of column ; ${}_ct_f$= thickness of column ; and M_0 = full plastic moment of each length (M_0=${}_ct_f^2 {}_cF_{fy}$/4).

Internal work -deformation of beam web

In figure 10(b), the yield field is assumed in the beam web. Plastic deformation of the beam web at the upper and lower ends is

$$\delta_w = \frac{d_j(h_m - S_r)2}{(d_j - 2h_m)h_m}\delta \quad (14)$$

Internal work of deformation of beam web is

$$E_b = 2\frac{\delta_w(h_m - S_r)}{2} {}_b t_w \, {}_b F_{wy} = \frac{d_j(h_m - S_r)^2}{(d_j - 2h_m)h_m} {}_b t_w \, {}_b F_{wy}\delta \quad (15)$$

where ${}_bF_{wy}$ = yielding strength of beam web ; and ${}_bt_w$ = thickness of beam web. The formula of the principle of virtual work may be thought of as

$${}_jM_{wu}\theta = E_c + E_b \quad (16)$$

Further on, knowing that the angle θ can be expressed as shown in Eq.(17), and by replacing Eq.(13), (14) into Eq.(16), it result that ${}_jM_{wu}$ can be computed using Eq.(18).

$$\theta = \frac{2\delta}{d_j - 2h_m} \quad (17)$$

$$ {}_jM_{wu} = \frac{-4h_m{}^2 b_j d_j - h_m b_j{}^3 + 2h_m b_j d_j{}^2 + 4h_m b_j e^2 + b_j{}^3 d_j - 4b_j d_j e^2}{2h_m (b_j - 2e)(b_j + 2e)} {}_ct_f{}^2 {}_cF_{fy} + \frac{d_j (h_m - S_r)^2}{2h_m} {}_bt_w \cdot {}_bF_{wy} \quad (18) $$

The minimum value of h_w is found by applying Eq.(19). By doing so, the yielding strength ${}_cF_{fy}$ will become the ultimate strength ${}_cF_{fy}$ and h_w will result as shown in Eq.(20).

$$ \frac{\partial {}_jM_{wu}}{\partial h_m} = 0 \quad (19) $$

$$ h_m = \sqrt{\frac{{}_bt_w {}_bF_{wy} S_r{}^2 + b_j {}_ct_f{}^2 {}_cF_{cfy}}{{}_bt_w {}_bF_{wy} - 4{}_ct_f{}^2 {}_cF_{fy} b_j / (b_j{}^2 - 4e^2)}} \quad (20) $$

Next, by replacing Eq.(20) into Eq.(18), ${}_jM_{wu}$ is found to be Eq.(21).

$$ {}_jM_{wu} = \gamma_w \cdot {}_bM_{wp} \quad (21) $$

The joint efficiency of the beam web is defined as: γ_w

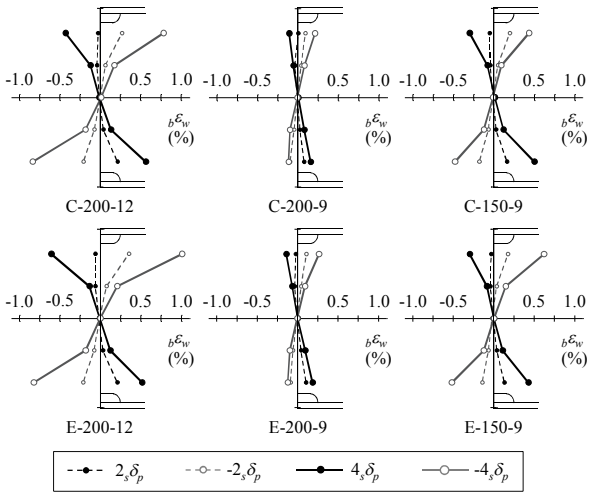

Figure 12 Strain Distribution of Beam Web

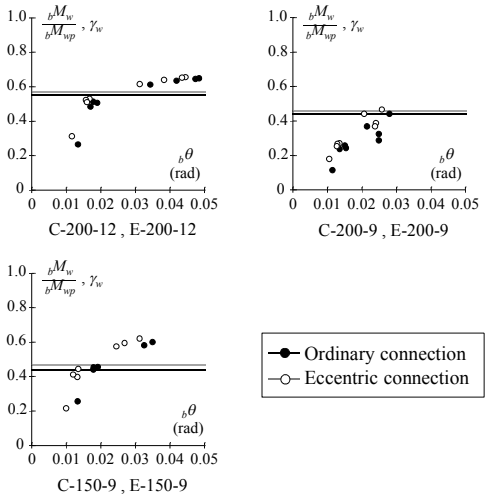

Figure 13 Joint Efficiency of the Beam Web

The experimental value of the joint efficiency of the web is calculated from the strain distribution (Figure 12) and coupon test result.

In figure 13 the joint efficiency for the ultimate state of the beam web is shown. On the vertical axis is the joint efficiency of beam web. On the horizontal axis is the deformation of beam.

In both experimental and theoretical results, the joint efficiency of the beam web in eccentric connection is slightly larger than that of ordinary connection. Hence one can say that the influence of the eccentricity on the joint efficiency is small.

4. MOMENT-ROTATION RELATIONSHIPS OF THE PANEL ZONE

Figure 14 shows the force-deformation relationships for the panel. Full plastic strengths and the calculated value of elastic stiffness as also shown in this figure. ${}_pM$, ${}_p\gamma$, ${}_p\gamma_i$, and ${}_p\gamma_o$ are defined follows: ${}_pM$ = panel moment; ${}_p\gamma$ = shear deformation of panel; ${}_p\gamma_i$ = shear deformation of inside panel; and ${}_p\gamma_o$ = shear deformation of outside panel.

Figure 15 shows the skeleton curves for the panel of eccentric connections. On the vertical axis is the moment of each inside and outside panels based on the moment assignment ratio in the elastic region. The horizontal axis represents the deformation of the panel. After yielding (white point), the deformation of the outside panel increases. In addition, for ordinary connections, the deformation of the panel before its yielding is also considerable. However, when the sum of the moments of the inside and outside panels reaches the yielding strength, the outside panel in the eccentric connections has larger deformations than the one in ordinary connection. On the other hand, the deformation of

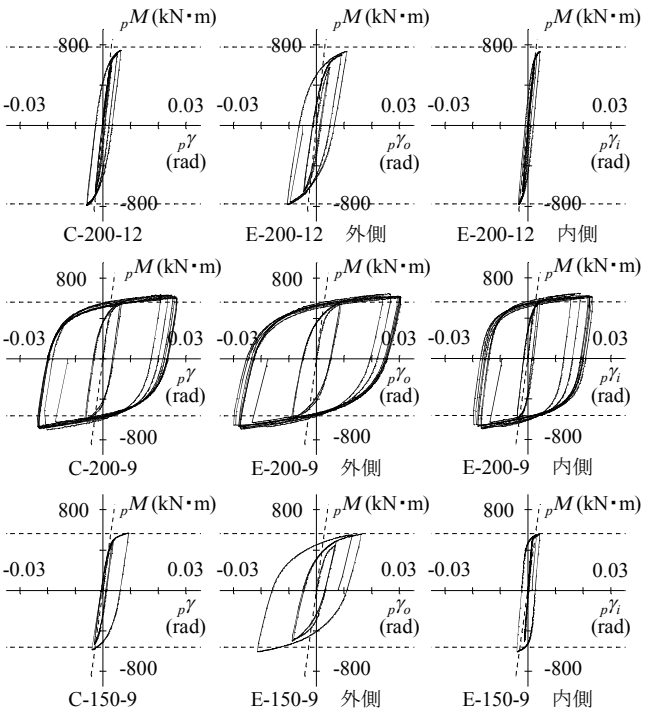

Figure 14 Behavior of Panel Zone

inside panel stops at the beginning of the plastic incursion zone.

5. ENERGY DISSIPATION OF THE BEAM TO COLUMN CONNECTION

Figure 16 shows the energy dissipation of the beam to column connection. One can notice that even though the energy dissipation of beam in eccentric connection is smaller than that in ordinary connection, the difference is not so large. For the connections in which the panel is designed to yield first, deformation of the beam is rather small because the one of the panel increases. Hence the number of cycles until the beam fractures also increases, which leads to larger energy dissipation capacity than for the connections in which the beam yields first. This can be noticed in Figure 16 where the energy dissipation of the panel for both panel yielding type and beam yielding type is shown. The panel yielding type has energy dissipation 3.2 times and 3.3 times larger than the beam yielding type. Moreover, for the specimen with large eccentricity, the energy dissipation increased by 1.2 times due to the eccentricity.

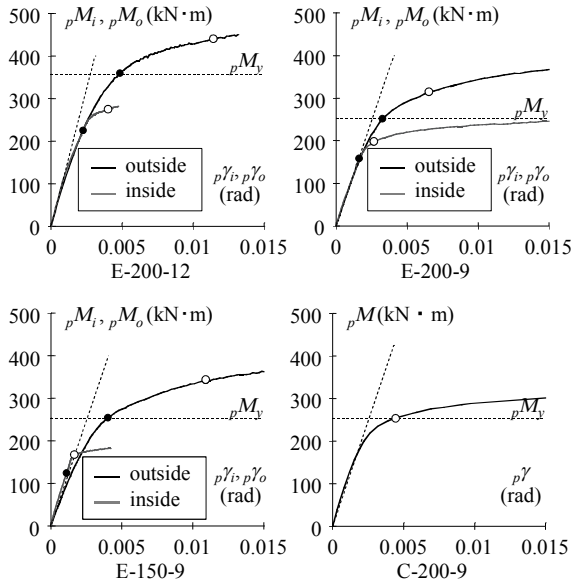

Figure 15 Skeleton curves for the panel of eccentric connection

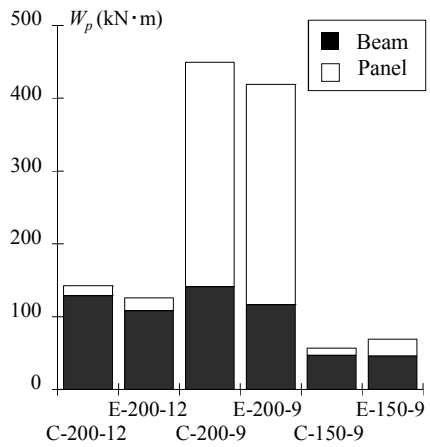

Figure 16 Energy dissipation of the beam to column connections

6. CONCLUSIONS

The main purpose of the present study was to investigate the influence of the beam eccentricity on the plastic deformation capacity of the eccentric beam to column connections under cyclic loading. This has been achieved by conducting a set of tests and then comparing the experimental data with the theoretical results in terms of joint efficiency, strains etc.

Based on these results, it can be concluded that for eccentric connections, the joint efficiency of the beam web for the ultimate states is slightly larger than that corresponding to centric connections. This leads to an increase in the stiffness of the beam. In addition, due to the fact that the strain distribution in the beam flanges is asymmetric, the plastic deformation capacity of an eccentric connection slightly decreases.

Another important conclusion is that the behavior of the outer panel at yielding can be predicted by applying the moment assignment ratio in elastic range.

In the end, it can be concluded that the presence of the eccentricity can be accounted for by using appropriate computation methods and does not represent a major problem in structural safety.

EVALUATION OF THE COMPOSITE BEAM STRESS SUBJECTED TO BENDING AND AXIAL FORCE

Yoriyuki MATSUDA[1], Kazuhiko KASAI[2]

1) Graduate student, Graduate school of Tokyo Institute of Technology, Japan
2) Professor, Structural Engineering Research Center, Tokyo Institute of Technology, Japan
matsuda.y.ag@m.titech.ac.jp, kasai@serc.titech.ac.jp

Abstract: The composite beam cross section does not remain plane due to the slip that occurs at the interface of the slab and the steel beam. For this reason, it is difficult to evaluate how the load is distributed to slab and steel beam. In addition, the column portion in contact with the concrete can deform due to low rigidity and cause the slip in the vicinity, but the influence of this behavior on the composite beam has not been discussed. Moreover, it is necessary to consider large axial force produced by damper reaction force for a composite beam in the frame of the passively controlled structure which uses a damper to a structure to reduce a seismic response.

1.1 RESEARCH BACKGROUND

The beam of a steel structure is designed as a composite beam that is concrete slab and steel beam are united by a stud connector. Its cross section does not remain plane due to the slip that occurs at the interface of the slab and the steel beam. For this reason, it is difficult to evaluate how the load is distributed to slab and steel beam (Internal force). Furthermore, osculating plane of column and concrete slab is judged with fixed end, but there is possibility of bending deformation out of plane of column flange and estrangement of column and concrete slab, and it is not argued whether it is proper (Figure 1) .

In addition, in frame of the passively controlled structure which uses a damper to a structure to reduce a seismic response, to evaluate internal force is still more difficult by existence of gusset plate and by bending moment by story drift and axial force by damper act on frame (Figure 2).

1.2 RESEARCH METHODS

This research suggests formula and easy analysis method to get internal force about composite beam that bending moment and axial force act.

This research suggests formula and easy analysis method that can reproduce the effect of the slip and the change of boundary condition in fixed end that are the element to affect composite beam behavior.

2. THE INFLUENCE THAT A SLIP GIVES TO BEHAVIOR OF THE COMPOSITE BEAMS

Resistance for the slip (slip rigidity) is one of the important elements to influence behavior of composite beam, and this size affects strain distribution in case external force acts on the composite beam. As an example, strain

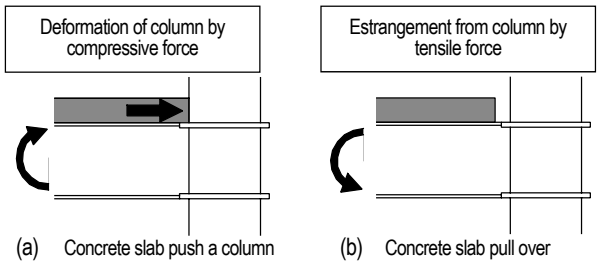

Figure 1 Boundary condition of concrete slab on column contact point

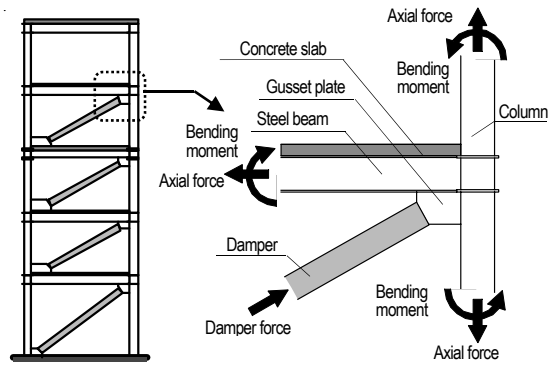

Figure 2 Stress which acts on passively controlled buildings

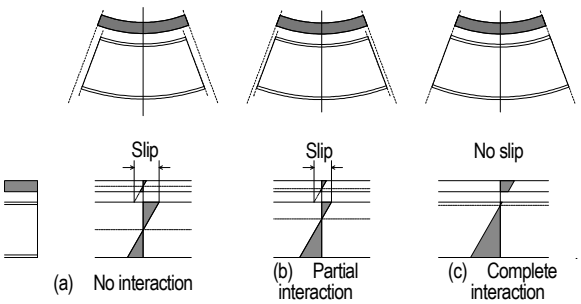

Figure 3 Composite beam deformation and strain distribution

distribution in the case of composite beam subjected to shear force and axial force shown in Figure 3.

When slip rigidity is zero, there is no interaction between the concrete slab and the steel beam. For this case, there are two neutral axes. They are at the center of gravity of the concrete slab and the steel beam. The slip occurs by a difference of strain which arises in bottom of concrete slab and top of steel beam (Figure 3a). When the slip rigidity increases, two neutral axes approaches, and slip decreases (Figure 3b). When the slip rigidity is large enough, the slip does not occur and remain plane (Figure 3c).

3. COMPOSITE BEAMS SUMMARY

This research examines the cantilever composite beam shown in Figure 4 and Figure 5. Shear force and axial force act on the center of gravity of the steel beam of the free end. Positive bending moment acts on composite beam by positive shear force and tensile force acts on composite beam by positive axial force.

Where, y_c is distance of each the center of gravity of steel beam and concrete slab, E_s is Young's modulus, A_s is cross-sectional area of steel beam, I_s is moment inertia of steel beam. Cross section and geometrical moment inertia of concrete express it in A_c/n and I_c/n with n (ratio of Young's modulus of steel beam and concrete). k_0 is rigidity of column, k is slip rigidity. In addition, Cross section and geometrical moment inertia of concrete do not consider a part of ditch.

4. ANALYSIS OUTLINE

The analysis model of composite beam is shown in figure 6. It's had advanced member, which column flange plate bending deformation on concrete slab end. Analysis were carried out on cantilever composite beam subjected to a axial force and shear force. The analysis assumption follows:

1) The models consisted of beam element, truss element and rigid element. A beam, shear connector and column flange plate is beam element part. A concrete slab is truss part. Which beam and shear connector linked by rigid element. Moreover, beam curvature and concrete slab curvature share the same rotation on each section.
2) All elements were in elastic region.
3) Beam node, slab node pitch and shear connect arrangement pitch was 16.5mm.
4) Axial and shear force were acting free end of steel section centroid.
5) Each element set up was centroid of each member.

5. FORMULA IN CASE OF SHEAR FORCE ACTS ON THE COMPOSITE BEAMS

Inter force equilibrium and deformation under pure bending force from shear force are shown in Figure 7. In this case, internal force is 3 ingredients of the axial force which acts on concrete slab and steel beam, the bending moment which

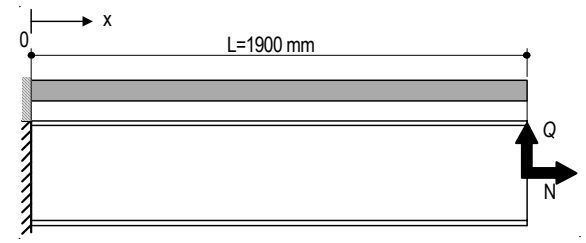

Figure 4 Cantilever composite beam

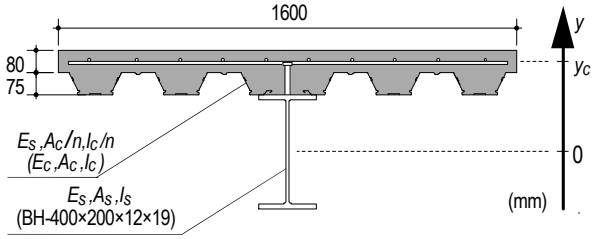

Figure 5 Detail and geometrical rules of composite beam

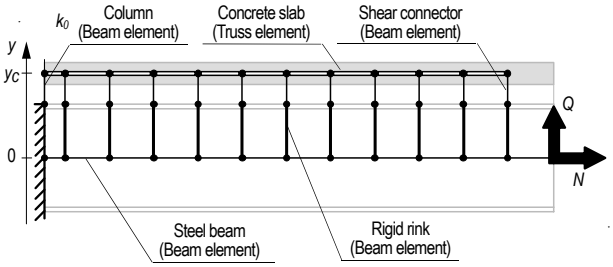

Figure 6 Analysis model of composite beam

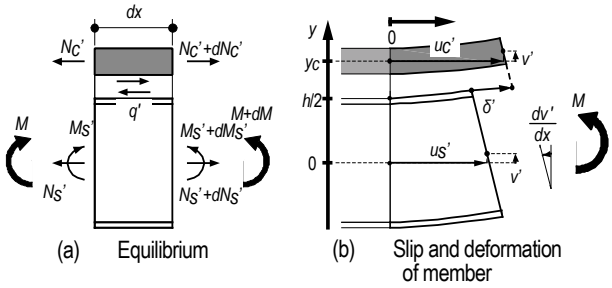

Figure 7 Inter force equilibrium and deformation under pure bending force from shear force

acts on steel beam and expresses it in N_c', N_s', M_s'. Inter force equilibrium is obtained from Equ. (1a-c). Slip is obtained from Equ. (1d).

$$0 = N_s' + N_c' \ , \ M = M_s' - N_c' y_c$$

$$-\frac{dN_s'}{dx} = \frac{dN_c'}{dx} = q' = k\delta' \ , \ \delta' = u_c' - u_s' + \frac{dv'}{dx} y_c \quad \text{(1a-d)}$$

The differential equation about axial force which acts on concrete slab can be obtained from Equ. (2a).

$$\frac{d^2 N_c'}{dx^2} - C N_c' = \frac{k y_c}{\sum EI} QL - \frac{k y_c}{\sum EI} Qx$$

$$C = k \frac{\overline{EI}}{\overline{EA} \sum EI} \ , \ \sum EI = E_s I_s + E_s \frac{I_c}{n}$$

$$\frac{1}{\overline{EA}} = \frac{1}{E_s A_s} + \frac{1}{E_s A_c / n} \ , \ \overline{EI} = \sum EI + \overline{EA} y_c^{\,2} \quad \text{(2a-e)}$$

A general solution and the boundary condition of Equ (2a) is as follows.

$$N_c'(x) = A'\cosh\left(\sqrt{C}x\right) + B'\sinh\left(\sqrt{C}x\right) + \frac{\overline{EA}}{EI} y_c Q\left(x - L\right) \tag{3}$$

$$N_c'(0) = N_{c0}', N_c'(L) = 0, \frac{dN_c''(0)}{dx} = \frac{k}{k_0} N_{c0}' \quad \text{(4a-e)}$$

Than the above, N_c' can be obtained from Equ. (5).

$$N_c'(x) = \left[\frac{\left\{\sinh\left(\sqrt{C}L\right)\cosh\left(\sqrt{C}x\right) - \cosh\left(\sqrt{C}L\right)\sinh\left(\sqrt{C}x\right)\right\}}{\sqrt{C}\cosh\left(\sqrt{C}L\right) + k/k_0 \sinh\left(\sqrt{C}L\right)} \right.$$

$$\left. \cdot\left(1 + L\cdot k/k_0\right) - L + x \right] \frac{\overline{EA}}{EI} y_c Q \tag{5}$$

6. FORMULA IN CASE OF AXIAL FORCE ACTS ON THE COMPOSITE BEAMS

6.1 FOR AXIAL FORCE ACTING ON THE CENTROID OF THE BEAM

Since axial force of external force is acting on the centroid of the steel beam, it is divided into axial force and bending moment which axial force causes (Figure 8). Where, e is distance of each the centroid of steel beam and composite beam.

Inter force equilibrium and deformation under pure axial force are shown in Figure 9. In this case, internal force is 2 ingredients of the axial force which acts on concrete slab and steel beam and expresses it in N_c", N_s". Balance of force is obtained from Equ. (6ab). Slip is obtained from Equ. (6c).

$$N = N_s'' + N_c'' \quad , \quad \frac{dN_s''}{dx} = -\frac{dN_c''}{dx} = q'' = k\delta''$$

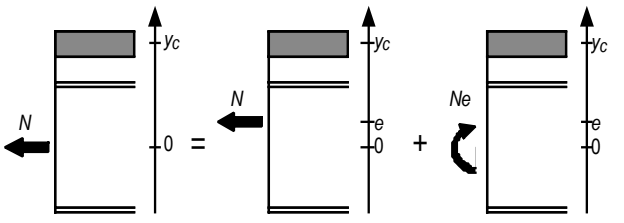
$$\delta'' = u_s'' - u_c'' \tag{6a-c}$$

The differential equation about axial force which acts on concrete slab can be obtained from Equ. (7a).

$$\frac{d^2 N_c''}{dx^2} - D N_c'' = -\frac{k}{E_s A_s} N \quad , \quad D = \frac{k}{\overline{EA}} \tag{7ab}$$

A general solution and the boundary condition of Equ (7a) is as follows.

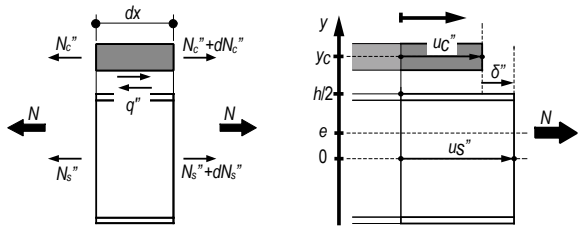
$$N_c''(x) = A''\cosh\left(\sqrt{D}x\right) + B''\sinh\left(\sqrt{D}x\right) + \frac{A_c/n}{A_s + A_c/n} N \tag{8}$$



$$N_c''(0) = N_{c0}'', N_c''(L) = 0, \frac{dN_c''(0)}{dx} = \frac{k}{k_0} N_{c0}'' \quad \text{(9a-c)}$$

Than the above, N_c"can be obtained from Equ (8) and (9a-c).

$$N_c''(x) = \frac{A_c/n}{A_s + A_c/n} N \left[1 - \frac{\cosh\left(\sqrt{D}x\right)}{\cosh\left(\sqrt{D}L\right)} \right.$$



$$- \frac{k\left\{\sinh\left(\sqrt{D}L\right) - \tanh\left(\sqrt{D}L\right)\right\}\cosh\left(\sqrt{D}x\right)}{\sqrt{D}\left\{k_0\cosh\left(\sqrt{D}L\right) + \sqrt{\overline{EA}k}\sinh\left(\sqrt{D}L\right)\right\}}$$

$$\left. + \left\{\cosh\left(\sqrt{D}L\right) - 1\right\}\sinh\left(\sqrt{D}x\right) \right] \tag{10}$$

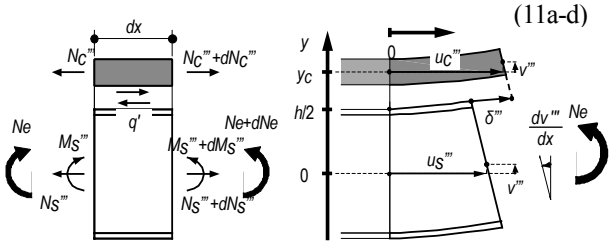
Figure 8 Disassembly of axial force

(a) Equilibrium (b) Slip and deformation

Figure 9 Inter force equilibrium and deformation under pure axial force



6.2 FOR THE BENDING BY THE AXIAL FORCE

Inter force equilibrium and deformation under pure bending moment from axial force are shown in Figure 10. In this case, internal force is 3 ingredients of the axial force which acts on concrete slab and steel beam, the bending moment which acts on steel beam and expresses it in N_c"', N_s"', M_s"'. Balance of force is obtained from Equ. (11a-c). Slip is obtained from Equ. (11d).

$$0 = N_s''' + N_c''' \ , \ Ne = M_s''' - N_c''' y_c$$

$$-\frac{dN_s'''}{dx} = \frac{dN_c'''}{dx} = q''' = k\delta''' \ , \ \delta''' = u_c''' - u_s''' + \frac{dv'''}{dx} y_c$$

(11a-d)

(a) Equilibrium (b) Slip and deformation

Figure 10 Inter force equilibrium and deformation under pure bending force from axial force

e can be obtained from N_c", N_s" and balance of the moment in the centroid of composite beam (Figure11).

$$e = \frac{N_c''}{N} y_c \tag{12}$$

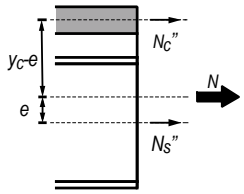


Figure 11 Distance of each section and composite beam

The differential equation about axial force which acts on concrete slab can be obtained from Equ. (13).

$$\frac{d^2 N_c'''}{dx^2} - C N_c''' = \frac{k y_c^{\,2}}{\sum EI}\left\{ A''\cosh\left(\sqrt{D}x\right) + B''\sinh\left(\sqrt{D}x\right) + \frac{A_c/n}{A_c/n + A_s} N \right\} \tag{13}$$

A general solution and the boundary condition of Equ (13) is as follows.

$$N_c'''(x) = A'''\cosh\left(\sqrt{C}x\right) + B'''\sinh\left(\sqrt{C}x\right) + \frac{k y_c^{\,2}}{\sum EI}\frac{1}{D-C}\left\{ A''\cosh\left(\sqrt{D}x\right) + B''\sinh\left(\sqrt{D}x\right)\right\} + \frac{\overline{EA}}{\overline{EI}} y_c^{\,2}\frac{A_c/n}{A_c/n + A_s} N \tag{14}$$

$$N_c'''(0) = N_{c0}''', N_c'''(L) = 0, \frac{dN_c'''(0)}{dx} = \frac{k}{k_0} N_{c0}''' \tag{15a-c}$$

Than the above, N_c''' can be obtained from Equ. (14) and (15a-c). Where, this formula leaves it out, because an expression is long.

7. THE TOTAL OF EACH INGREDIENT

Internal force in case of shear force and axial force act on centroid of steel beam is a total of internal force by three components. Where, N_c is the axial force which acts on concrete slab, N_s is the axial force which acts on steel beam, M_s is the bending moment which acts on steel beam. N_c, N_s, M_s and equilibrium are as follows.

$$N_c = N_c' + N_c'' + N_c''' \quad , \quad N_s = N_s' + N_s'' + N_s'''$$
$$M_s = M_s' + M_s'''$$
$$N = N_c + N_s \quad , \quad M = M_s - N_c\left(y_c - y_s\right) \tag{16a-e}$$

8. RESULTS & DISCUSSION

Comparison of analysis and formula in case of $k_0=\infty$ or $k_0=0$ are shown in Figure 12 and Figure 13. The external force assumes that shear force is 60kN and axial force is 360kN. This external force is the experiment that assumed that steel damper attached frame to shown in Reference 3, and axial force is bigger than shear force because steel damper is elasticity.

A difference of Analysis and formula is less than 1% at the maximum and shows good correspondence. In addition, axial force of external force is relatively big, but S has a big influence on internal force. In other words positive and negative of initial force is decided by shear force.

In the case of k=0, it may be said that tensile force is near to a condition acting on concrete slab. Likewise, In the case

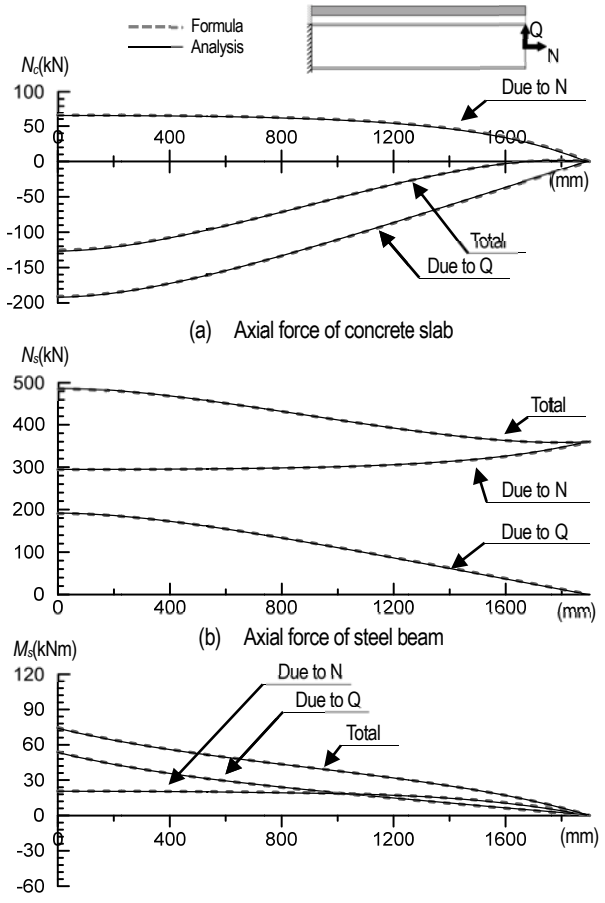

Figure 12 Force distribution subjected to shear force Q and axial force N ($k_0=\infty$)

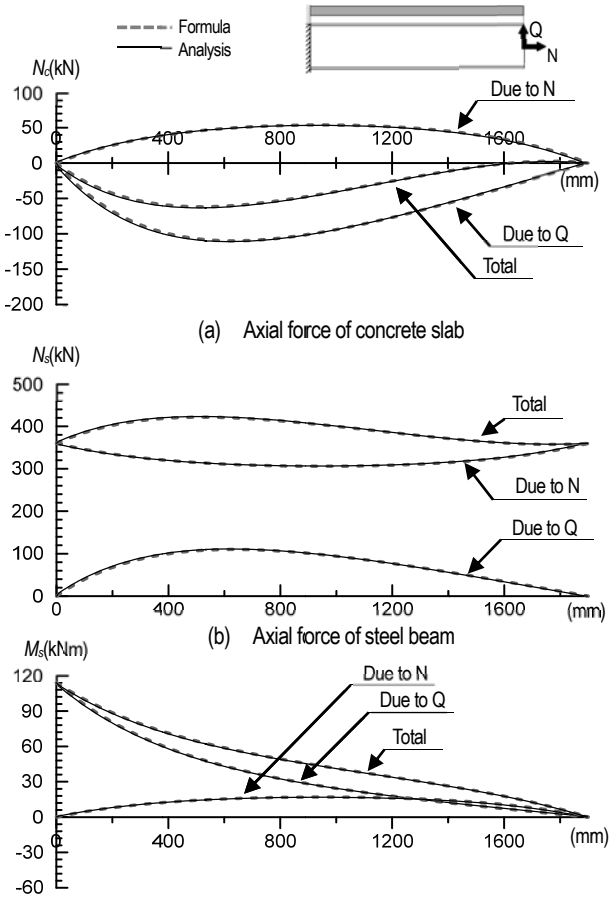

Figure 13 Force distribution subjected to shear force Q and axial force N ($k_0=0$)

of k=∞, it may be said that compressive force is near to a condition acting on concrete slab. In the case of k_0=0 has smaller 34% N_c and bigger 32% M_s than k_0=∞. In other words concrete slab becomes safe, but steel beam becomes dangerous. This shows that it is reduction of a composition effect.

When positive shear acts on composite beam, concrete slab bears compressive force, and concrete slab bears tensile force when positive axial force acts on composite beam. In other words, N_c decreases to a case of a positive and negative of shear force and axial force are same, and increases to a case of both are different.

9. WITH GUSSET PLATE

The cantilever composite beam with gusset plate shown in Figure 14 and Figure 15 is examined. The gray line of Figure 14 is the specification of the gusset plate of the specimen shown in the Reference 3. In this research, cutout portion of the gusset plate and the existence of the stiffener do not consider. A_{sg} is cross-sectional area of gusset plate, A_{s2} is cross-sectional area of the steel beam part which gusset attaches, I_{sg} is moment inertia of gusset plate, I_{s2} is moment inertia of the steel beam part which gusset attaches. y_s is centroid position of the steel beam part which gusset attaches.

Analysis model in consideration of gusset plate shown in Figure 16. In addition to the above-mentioned assumption, change of the center of gravity position of steel beam by gusset plate is connected by rigid rink.

About the formula, internal force in the case of gusset plate attaches steel beam demands the section that gusset plate attaches and the section that it does not attaches individually and gets it by agreeing on a border of both. In addition, the formula in consideration of deformation of column is not produced.

Comparison of analysis and formula in case of k_0=∞ is shown in Figure 17, analysis in case of k_0=0 is shown in Figure 18.

The ratio that concrete slab contributes to cross-section area and geometrical moment of inertia of composite beam decreases in the cross-section that gusset attaches steel beam. For this reason the absolute value of N_c becomes smaller than the cross-section that gusset does not attach steel beam. In addition, the absolute value of N_s which matches with it by horizontal force becomes small, too. On the other hand, M_s usually becomes big when moment inertia of steel beam becomes big. However, in the section that the gusset plate attaches, M_s becomes small because distance of each center of gravity of steel beam and slab becomes big by gusset plate.

Next, a difference of an effect by presence of gusset plate is considered. In composite beam which attached gusset plate, about the whole beam, N_c and N_s decrease and M_s is increasing. It is thought that an effect produced this in internal force of the whole beam because internal force in the sectional border where gusset plate attaches varies with gusset plate as having mentioned above.

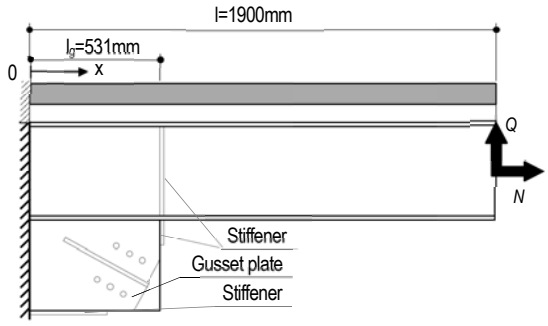

Figure 14 Cantilever composite beam with gusset plate

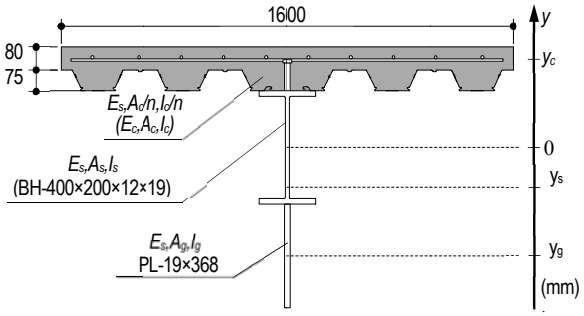

Figure 15 Detail and geometrical rules of composite beam with gusset plate

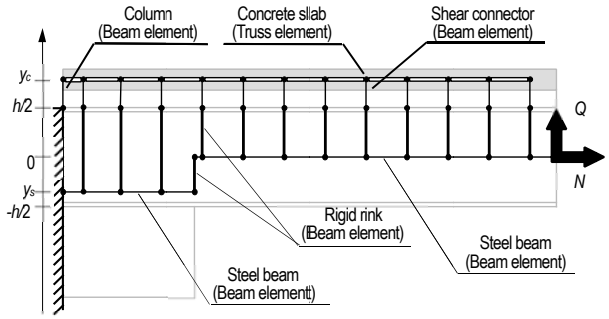

Figure 16 Analysis model of composite beam with gusset plate

From Figure 17 and Figure 18, in the case of k_0=0 has smaller 20% N_c than k_0=∞. Since contribution for composite beam of concrete slab decreased by gusset plate, the decline by k_0 is smaller than a case without gusset plate.

10. CONCLUSION

Analysis model and formula were proposed about internal force of composite beam that shear force and axial force act on, and consideration was performed from the result of analysis model and formula about the influence which deformation of column and gusset plate have. The following conclusions were obtained.

1) There are few differences of internal force provided from analysis model and formula.
2) By transformation of column, absolute value of N_c and N_s become small, and M_s becomes big. In addition, flexural rigidity becomes small, and deformation of column is equal to a decline of a composition effect.
3) In the case of gusset plate attaches the steel beam, N_c and N_s become small and M_s becomes large, and the influence that deformation of column gives to a

composition effect becomes small.

Abstract: Column base is one of the most important element of steel structures. It is important to investigate the effect of column bases on the ultimate earthquake resistance of steel frames. In this paper, a series of inelastic response analysis of multi-story steel frames with exposed type column bases, especially weak anchor bolt type column bases, were carried out. From the analytical results, following conclusions were obtained. The intensity of the damage concentration at the structural element of the 1st story in the frames with exposed column bases were much less than that of the frames with pin type column bases and the frames with fixed column bases. Ultimate earthquake resistance of the frames with exposed type column bases were similar to that of the frames with pin type column bases. If columns of the frames were ductile, ultimate earthquake resistance of the frames with exposed type column bases were similar to or a little better than that of the frames with fixed column base. If columns of the frames were not ductile, ultimate earthquake resistance of the frames with exposed type column bases were much better than that of the frames with fixed column bases.

1. INTRODUCTION

In steel moment-resisting frames, the column base plays a very significant function to transmit active loading from the soil to the structure and return inertia forces from the structure back to the ground. The failure of column bases will result in the collapse of structure, regardless if the beam-to-column connections behave in a ductile manner. Extensive researches have been conducted on the behavior of the column bases. However, few studies have been conducted to investigate the seismic response of the frame by considering the column base behavior. Exposed column base is commonly used in multi-story steel moment frames in Japan. And the column base is recommended to be designed as the anchor-yield type, which showed the slip behavior of the hysteresis curves.

In this paper, a typical 4-story steel frame was chosen as a prototype frame to investigate the effect of the hysteresis behavior of column base on the whole frame behavior. The strength deterioration of columns caused by local buckling and slip behavior of exposed column bases caused by elongation of anchor bolts are considered in this study.

2. PROTOTYPE FRAME

To help understand the effects of column bases on seismic safety and response, numerical simulations were carried out on a four-story, four-bay moment-resisting steel frame, which was introduced as a design example in Reference (JSSC, 2009). The prototype frame is designed according to the current Japanese specifications and practices (post 1995 Kobe earthquake). The prototype frame is five spans and four stories with a uniform story height of 3.5 m, as shown in Fig. 1. SN400B and BCR 295 steel are used for beams and columns, respectively. The seismically effective weight of the analyzed frame is 609 kN, 605kN, 598 kN, and 762 kN for the first floors and the roof. The wide flange beams with 500 mm in depth, 200 mm in width, 10 mm of flange thickness, and 16 mm of web thickness were used. And columns were square hollow sections of 350 mm in width and 19 mm in thickness. The information of beams and columns are listed in Table 1. The full plastic moment ratio between beam and column ($M_{p,c}/M_{b,c}$) is 1.82. To get the larger response of column, the ratio ($M_{p,c}/M_{b,c}$) was reduced by 75% intentionally. Therefore, in the analyzed frame the full plastic moment of column ($M_{p,c}$) is 766 kNm in the analysis. The fundamental period of the frame is 0.59 s.

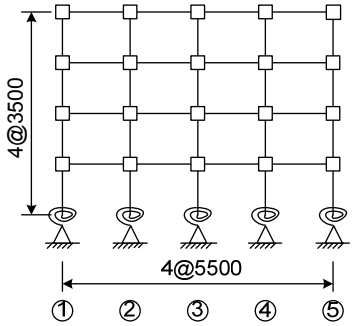

Fig. 1 Prototype frame (unit: mm)

Table 1 Component properties of prototype frame

	Section	Material	M_p (kNm)
Beam	H-500x200x10x16	SN 400B	560
Column	□-350x350x19	BCR 295	1021

3. ANALYSIS MODEL

Beams and columns in the analytical models employed in this study are represented by elastic elements with point plastic hinges at the ends. The point hinges are represented by rotational springs, whose properties are intended to represent all inelastic moment-rotation characteristics of flexural components (concentrated plasticity model). The hysteresis models of members used in this study are based on the experimental results. The hysteresis model could reproduce the strength deterioration caused by local buckling in the column and the slip behavior of the exposed column base. The hysteresis models of each component are introduced in details as follows.

Rayleigh damping ratio was assumed to be 2% for the first and second mode. P-Delta effects were considered in the numerical simulation.

3.1 Column

Past investigations have clarified that the load-displacement curve of steel members subjected to cyclic loading can be decomposed into the skeleton part, the Bauschinger part and the elastically unloaded part as shown in Fig. 2 (Kato et.al. 1968). The skeleton part is formed for each direction of loading connecting sequentially the inelastic part in each cycle of the M-θ curve (i.e., connecting the solid bold lines in Fig. 2(a)). The rest of the curve is composed of the elastically unloaded part and the softened part due to Bauschinger effect. The unloaded part keeps the initial elastic stiffness. The skeleton part is equivalent to the load-deflection relationship under monotonic loading (Kato et.al. 1968). And the hysteresis model of the Bauschinger part proposed by Akiyama (1990) is used to transfer the load-deflection curve under monotonic loading to the required hysteresis curves under various loading history.

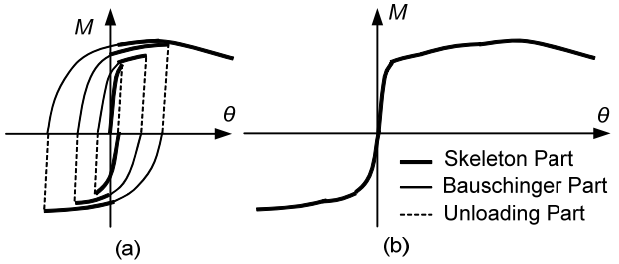

Fig. 2 Example of decomposition of a cyclic curve: (a) decomposition of a cyclic curve; (b) skeleton part

The load-deflection relationship of steel members under monotonic loading is able to be analyzed including the deterioration behavior governed by local buckling (Yamada et.al. 1995). As shown in Fig. 3, tetra-linear model (Yamada et.al. 1995) is used as the skeleton curve for the hysteresis model of the column. Therefore, the different strength deterioration caused by the different width thickness ratio could be considered in this model.

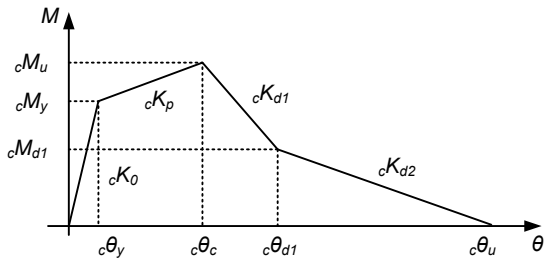

Fig. 3 Modeled Skeleton curve of column

Examples of the calculated load-deflection relationship of members are shown in Fig. 4. It is notable that the strength deterioration could be reasonably traced by the tetra-liner model proposed by Yamada (1995).

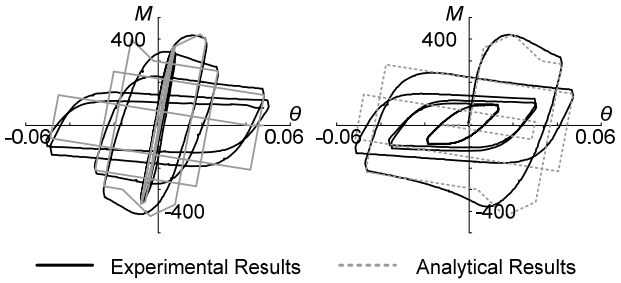

Fig. 4 Comparison of the experimental and analytical results of column hysteresis curve

3.2 Column Base

Exposed column bases have been popularly used for low-to medium-rise structures because of better constructability and low cost. In Japan, the yielding is allowed for the column bases (anchor bolts) under large earthquakes, if "ductile anchor bolts" are to be used (AIJ 2006, BCJ 2001). A "ductile" anchor bolt is defined by the yield ratio of the steel. The yield ratio of a ductile anchor bolt is no more than 0.75 (0.65 for some special anchor bolts). These values are determined so that the yield strength of the anchor bolt's shank exceeds the ultimate strength of its thread section. The column base connections with such anchor bolts posses the plastic rotation capacity of more than 0.03 rad. Yielding of base plates is not favored. The exposed column base exhibits slip behavior of hysteresis curves due to the elongation of anchor bolts under cyclic loading as observed in Fig. 5(a) (Cui et. al. 2009).

A numerical model as shown in Fig. 5(b) is used to reproduce the hysteresis behavior of the exposed column base. In this model, ${}_{cb}M_n$, ${}_{cb}M_y$, and ${}_{cb}K$ are the resisting moment to the axial force, yield moment of column base, and stiffness of column base, respectively. The detached moment ${}_{cb}M_n$ is affected by the axial force. The yield moment ${}_{cb}M_y$ and initial stiffness ${}_{cb}K$ of column base are controlled by the material and geometrical properties of anchor bolts and base plate (AIJ, 2006). Strain hardening

with 2% was considered to represent the strain hardening of the anchor bolts.

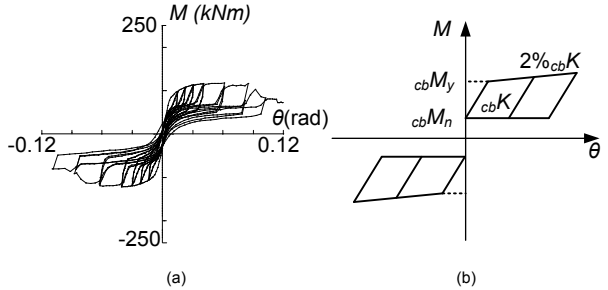

Fig. 5 (a) Hysteresis curve of column base; (b) Hysteresis model of column base

3.3 Beam and Panel Zone

Bilinear model was used for the skeleton curve of the hysteresis curve of beam and panel zone. The strain hardening of the beam and panel zone was 4% and 2%, respesctively. Composite slab action and the contributions of the gravity system to lateral strength and stiffness are not considered.

4. OVERVIEW OF ANALYTICAL STUDY

4.1 Parameters

The parameters of the analysis are the stiffness ratio between column base and column ($_{cb}K/_cK_0$), post-buckling behavior of column, and failure region (bottom end of column or column base). The analytical models are listed in Table 2.

Table 2 List of analytical models

Specimen name	$_{cb}K/_cK_0$	Width thickness ratio	Failure region
C-F	∞	25/43	C
C/B-2.0	2.0	25/43	C/B
C/B-1.0	1.0	25/43	C/B
C/B-0.5	0.5	25/43	C/B
C-P	0	25/43	C

*C— failure concentrated at the bottom end of the column
B – failure concentrated at the column base

In addition to the frame with pinned and fixed column base, three frames with partially restrained column bases were modeled. The stiffness ratio between column base and column varied from infinity (fixed, F), 2.0, 1.0, 0.5, 0.0 (pinned, P).

Two type width thickness ratios were used. The skeleton curve of the column with the two width thickness ratios is shown in Fig. 6. According to BCJ (2008), the column with width thickness ratio of 25 is cataloged as FA rank which is a ductile member, while the column with width thickness ratio of 43 is cataloged into FC rank as a non-ductile member. As illustrated in Fig. 6, the strength of the column with the width thickness ratio of 43 deteriorated sharply compared with another column.

The frames with partially restrained column bases were adopted to investigate the effect of failure region on the seismic behavior of frames.

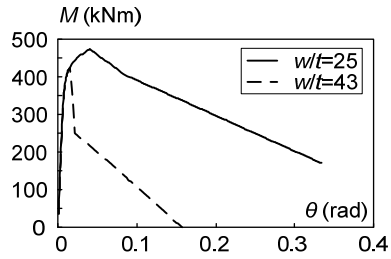

Fig. 6 Moment-rotation curves of column with different width thickness ratio

4.2 Ground Motion

Four ground motions were used. There are Hachinohe (t=36s), Kobe (t=0.84s), Elecentro (t=1.98s), and Takatori (t=0.61s) wave. Figure 7 shows the acceleration spectrum of the four ground motion waves with the damping ratio of 2%.The prototype frame was designed to resist level-2 input ground motion (PGV=500 mm/s). To get the extreme deformation of the frame, the input ground motion was scaled till the frame lose its resistance. For the frame failed at the bottom of column, the frame is assumed to lose its resistance when the 1st story column resistance is reduced to 80% maximum resistance. For the frame failed at the column base, the frame is assmued to lose its resistance when the column base rotation is larger than 0.03 rad.

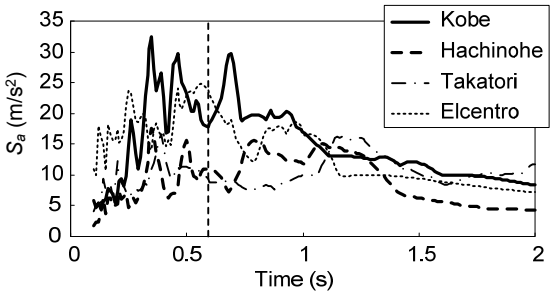

Fig. 7 Response Spectra

5. ANALYSIS RESULTS

5.1 Response Shear Force and Story Drift at Design Level

As shown in Fig.8, the large story drift angle occurred at the 1st story. When the column base is pin connected, the drift angle of the 1st story is larger than 3%, which indicated the collapse of the frame. When the S_a of input ground motion is relatively small (Hachinohe and Takatori, see Fig. 8), the peak story drift and shear force of each story are nearly the same regardless of the stiffness ratio of the column base and column ($_{cb}K/_cK_0$) and the failure region. When the S_a of input ground motion is relatively large (Kobe and ElCentro, see Fig. 8), the frame with the smaller column base stiffness ($_{cb}K/_cK_0$=0.5) show the larger peak story drift of each story. The effect of the post-buckling behavior of the column on the story drift is not significant.

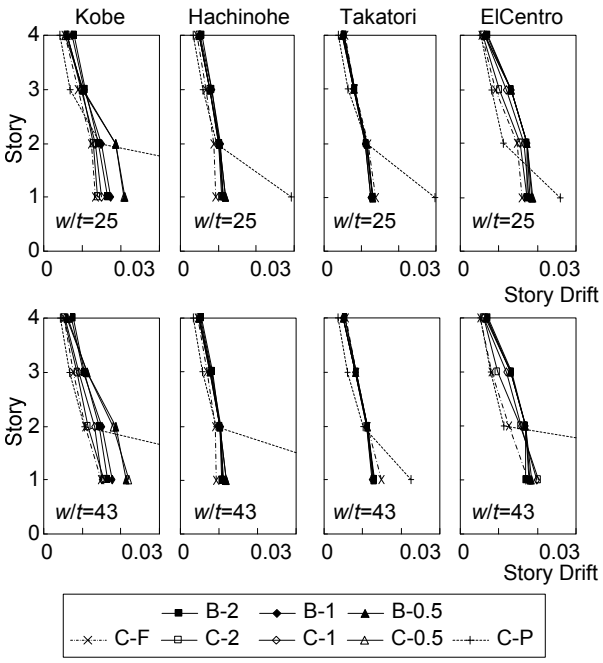

Fig. 8 Absolute peak drift angle

5.2 Response Hysteresis Curves of Story and Components

The response of the frame under level 3 (PGV=750 mm/s) Kobe ground motion is dicussed in this section. Figure 9 shows the response of the story shear force-story dirft relationship of the 1st story. There is no strength deterioration observed in the story shear force-drift angle relationship when the column has good post-buckling behavior with fixed column base connection. However, the same frame with fixed column base connection has severe strength deterioration and stiffness reduction if the column does not have the ability to resist the local buckling (larger width thickness ratio). Once the column base connection changed from fixed connection to pin connection, the damage on the 1st story became significantly. As shown in Fig. 9, the 1st story showed large permanent displacement and lose the resistance completely when the column width thickness ratio is 25 and 43, respectively.

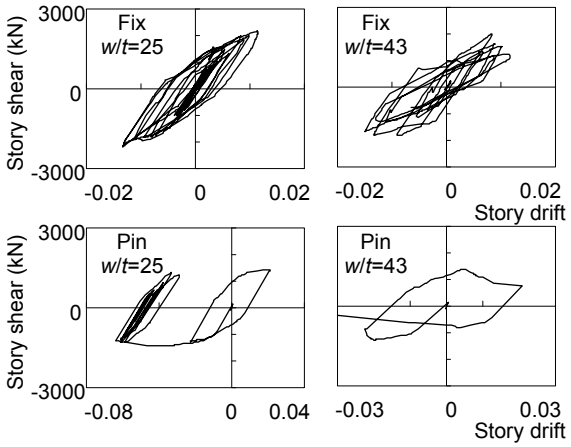

Fig. 9 1st story shear force-story drift relationship

Figure 10 shows the response hysteresis curves of the beam, bottom end of column, column base, and 1st story of the frame with exposed column base. It is noted that the damage concentrated in the 1st story when the frame with pin connection column base is released by using exposed column base, as shown in Fig. 10 (a). With the exposed

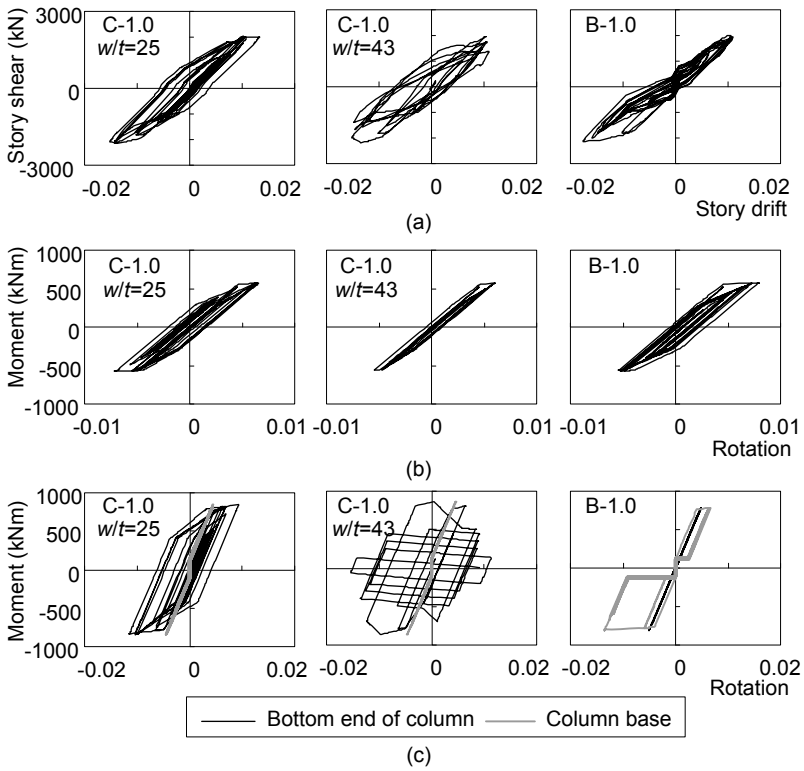

Fig. 10 Response hysteresis curves: (a) 1st story; (b) 1st story beam; (c) bottom end of 1st story column and column base

column base, the response of the frame is governed by the post-buckling behavior of the column, if the failure occurred at the bottom end of the 1st story column instead of the column base. As shown in Fig. 10 (c), the column with smaller width thickness ratio (w/t=25) showed fat hysteresis curve. On the contrary, the strength deteriorated signifcantly when the column width thickness ratio was increased to 43.

When the failure occured at the column base, the response of frame is regardless of the width thickness ratio of the column. As shown in Fig. 10 (a), the hysteresis curve of the 1st story is more pinch than the other two. It is because of the slip behavior of the column base (Fig. 10 (c)). Moreover, because the column did not lose its resistance capacity, the beam on the 1st floor could contribute more to transfer the force from 1st story column to the 2nd story column, as shown in Fig. 10 (b).

5.3 Relationship between the input ground motion and the 1st story column/column base ration

Figure 11 showed the relation between the level of input ground motion and the deformation of 1st story column/column base. The vertical axis represents the level of input ground motion. In Fig. 11 (a) and (b), the horizontal axis is the cumulative plastic rotation of the column end for the frame failed at the bottome end of column. The dot line indicated the plastic rotation of the column when the strength reduced to 80% of the maximum strength for the column with width thickness ratio of 25 and 43, respectively. And the horizontal axis is the column base rotation in Fig. 11(c). The dot line indicated the ultimate rotaion of the column base required by AIJ (2006).

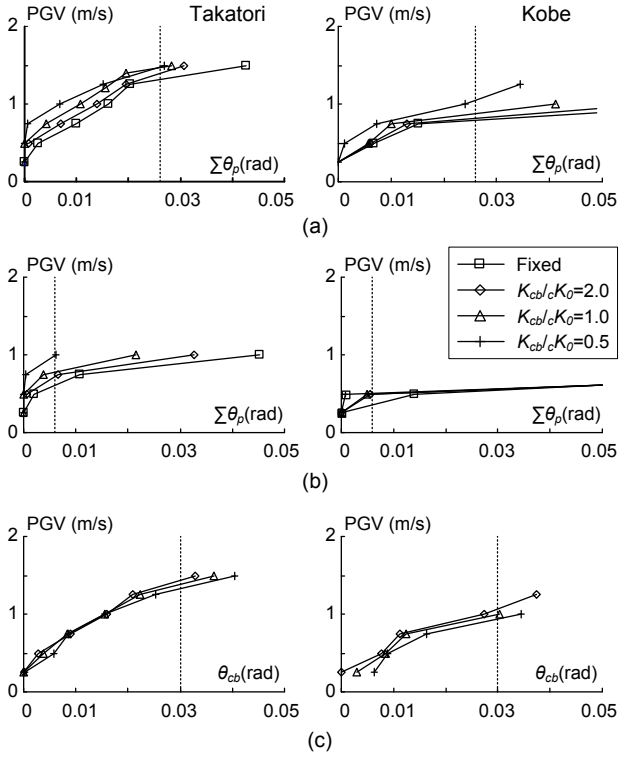

Fig. 11 Relation between input ground motion level and the cumulative plastic rotation of 1st story column or column base: (a) frame failed at the bottom of column, w/t=25; (b) frame failed at the bottom of column, w/t=43; (c) frame failed at the column base

As illustrated in Fig. 11 (a) and (b), the contribution of the column base rotation could increase the sesmic behavior of the frame if the frame was designed to fail at the bottom end of the column. Compard with the the frame failed at the bottom end of the column, the frame failed at the column base could resist larger level of input ground motion, as shown in Fig. 11(c).

5.4 Distribution of Accumulated Plastic Energy Absorption

As indicated in Fig. 8, the damage was concentrated in the 1st story. The dissipated energy in the 1st story is adopted in this section to discuss the effect of the column base behavior. The energy dissipation of the frame at the ultimate state is discussed in this section. Figure 12 shows the proportion of the energy dissipated by each component to the energy dissipated by the whole frame.

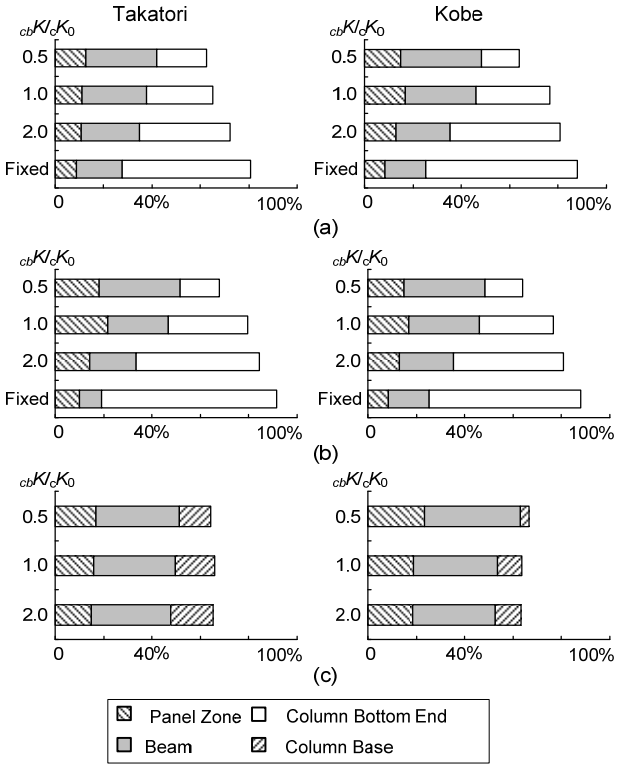

Fig. 12 Energy dissipation proportion of the 1st story: (a) frame failed at the bottom of column, w/t=25; (b) frame failed at the bottom of column, w/t=43; (c) frame failed at the column base

It is notable that the damage at the bottom of the 1st story column controls the frame behavior when the column base is completely fixed ($_{cb}K/_cK_0=\infty$). When the frame failed at the bottom end of the column, the energy dissipation proportion of each component is shown in Fig. 12 (a) and (b). The energy dissipated by the column was increased as $_{cb}K/_cK_0$ increased. Meanwhile, the energy dissipated by other components, such as panel zone and beam, was reduced as

$_{cb}K/_cK_0$ increased. If the column is non-ductile members (w/t=43), the dissipated energy of the frame is mainly contributed by the 1st story column. It might cause the sway failure of the frame, which is unfavorable.

When the frame failed at the column base instead of the bottom end of column, the frame response are the same with different width thickness ratio of the column. It is because that the damage was concentrated at the anchor bolts of the column base connection and the damage on the column was thereby reduced. As shown in Fig. 12, the energy was mainly dissipated by the panel zone and beam, which could be intentionally designed to dissipate more energy in practice. Same as observed when the frame failed at the bottom end of the column, the energy dissipated by the column base was increased as $_{cb}K/_cK_0$ increased. However, compared with the energy dissipated by the other components, the energy dissipated by the column base is relatively small.

6. CONCLUSIONS

Seismic analysis of frame was conducted. The effects of column post-buckling and slip behavior of column base were considered.

1. The intensity of the damage concentration at the structural element of the 1st story in the frames with exposed type column bases were much less than that of the frames with pin type column bases.

2. The seismic performance of the frame with fixed column base connection is affected by the post-buckling behavior of the column.

3. Using exposed column base, the damage could be distributed evenly in the frame. And the collapse caused by the non-ductile column could be avoided.

4. Absorbed energy by the exposed column base is fairly small.

Abstract: Special concentrically braced frames (SCBFs) are commonly used for seismic design of buildings. Their large elastic stiffness and strength efficiently sustains the seismic demands during smaller, more frequent earthquakes. During large, infrequent earthquakes, SCBFs exhibit highly nonlinear behavior due to brace buckling and yielding and the inelastic behavior induced by secondary deformation of the framing system. These response modes reduce the system demands relative to an elastic system without supplemental damping using a response modification coefficient, commonly termed the *R* factor. More recently, procedures put forth in FEMAP695 have been made to quantify the R factor through a formalized procedure that accounts for collapse potential. The primary objective of the research in this paper was to evaluate the approach for SCBFs. An improved model for SCBFs that permits simulation of brace fracture was used to conduct response history analyses. A series of 3-, 9- and 20-story SCBFs were designed and evaluated. Initially, the FEMAP695 method was conducted to estimate collapse and the corresponding R factor. An alternate procedure for scaling the multiple acceleration records to the seismic design hazard was also evaluated. The results show significant variation between the two methods. Of the three variations building studied, the large vulnerability was identified for the 3-story building. To achieve a consistent margin of safety against collapse, a significantly lower *R* factor is required for the low-rise SCBFs (3-story), while the mid-rise and high-rise SCBFs (9- and 20-story) may continue to use the current value of 6.

1. INTRODUCTION

Special concentrically braced frames (SCBFs) are commonly used as the primary lateral-load resisting system in buildings. These frames have beams, columns and braces concentrically joined at work points. In the design office, the system is initially designed as a vertical truss system, and the initial lateral stiffness and resistance of the frame is provided through the axial response of all members (beams, columns and braces). Conventional design uses reduced seismic loads. In larger, less frequent earthquakes, inelastic action in the brace is expected. This inelastic behavior is primarily governed by the severe buckling, post-buckling and tensile yield deformations of the brace; secondary yield mechanisms may occur in the gusset plate connection, beams and columns.

To assure that the system can achieve these large inelastic deformations without premature failure, current AISC SCBF design requires capacity design of the beams, columns and connections to meet the tensile and compressive capacity of the brace (AISC 2005a). Local and global slenderness limits are applied to the brace to assure that the brace can sustain multiple large drift cycles.

Currently there are few design restrictions on or understanding of the gusset plate, which leads to considerable variation in the gusset plate connections designed for SCBF systems. Prior research has shown that different gusset plate designs influence the seismic performance of the braced frame and that poorly designed gusset plates can severely decrease the drift capacity of an SCBF (Lehman and Roeder 2008). These findings have led to a new, balanced design procedure that provides a method for consistent gusset plate design and increasing the ductility of the braced frame system beyond that achievable with the current AISC SCBF seismic design criteria (Roeder et al. 2011a, Lumpkin et al. 2012) including a new elliptical clearance model (Lehman and Roeder 2008).

The method was developed and supported by a coordinated experimental and analytical research program on SCBF systems. In all, more than 30 single-story, single-bay frames were tested and analyzed (Johnson 2005, Herman 2006, Kotulka 2007, Powell 2010). A multi-story experimental program, including 3 two- and three-story frames (Roeder et al. 2011b, Lumpkin et al. 2012), was also conducted to investigate application of the design recommendations developed from the single-story research, to validate a design method for midspan gusset plate connections, and to evaluate the distribution of inelastic deformation between different stories.

Design of SCBFs depends on several seismic performance factors (SPFs). In particular, the response modification coefficient (*R* factor), which is used to reduce

the elastic seismic design loads to those used for member design, significantly influences the design and, therefore, would be expected to influence the performance of SCBFs. *R* factors were originally derived in an ATC-3-06 report (1978), with the historic values determined from engineering judgment and qualitative comparisons with the known response capabilities of a relatively few, well-understood seismic-force-resisting systems. In general, these *R* values were also related to the R_w values used in the Uniform Building Code for allowable strength seismic design. In the most recent provisions, the National Earthquake Hazards Reduction Program (NEHRP) Recommended Provisions for Seismic Regulations for New Buildings and Other Structures (FEMA 450) provided the *R* factors for more than 75 different seismic-force-resisting systems including SCBFs. However, the *R* values were somewhat arbitrarily assigned without appropriate verification of their seismic response characteristics. It has become clear that a more rational assessment of the *R* value is needed for all seismic resisting systems, including SCBFs.

In modern design, large, nonlinear inelastic deformations are expected during large seismic loads and the system must be detailed to sustain these demands. However, the seismic design forces must be large enough to result in sufficient strength and stiffness to meet the elastic demands in lesser events. The seismic design forces are determined by reducing the expected elastic seismic forces by the *R* value.

An analytical study was undertaken to evaluate the seismic performance and R values for SCBF systems. SCBF systems were designed based using newly proposed seismic design procedures (Lumpkin et al. 2012), and then nonlinear dynamic analysis were performed using practical, validated models as described below. The improved models of SCBFs combined with ATC-58 fragility curves allow accurate prediction of all performance limit states, such as no repair, possible brace replacement, brace fracture, and potential collapse, in the performance evaluations.

The impact of the R value was studied by evaluating the full seismic performance, including collapse. A series of SCBF buildings were designed using a range of R values. The building designs were assessed with two methods. The first method used the FEMA P695 incremental dynamic analysis (IDA) procedure (2008) to estimate collapse potential and to propose R values that consistently achieved the collapse prevention performance limit state. The second method included a suite of 20 acceleration records for the 10% and 2% in 50 year seismic hazards that were scaled to the seismic hazard level for the building site, and the predicted system performance was used to propose appropriate *R* factors of SCBF structural systems.

2. DESIGN OF THE MODEL BUILDINGS

A series of 3-, 9- and 20-story idealized SCBF buildings were designed using the equivalent lateral force procedure. The buildings were based on the model buildings in the SAC Steel project, adopting the basic floor plan, story height, and gravity loads (FEMA 355C). Appropriate modifications were made to translate the buildings to SCBFs. Figure 1 shows the typical elevations and floor plans of the different buildings considered here.

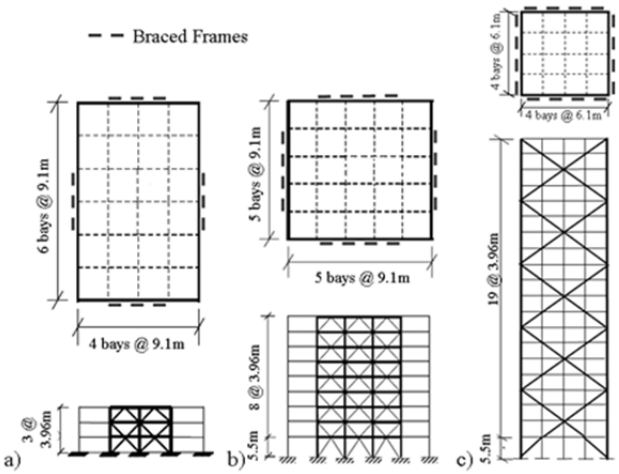

Figure 1. Elevations and Floor Plans of (a) 3-, (b) 9- and (c) 20-story Buildings.

A primary study parameter was the impact of variation in the *R* value. Several different *R* values were evaluated, and include: (1) *R* of 3, 4, 5, and 6 for the 3-story buildings, (2) *R* of 3, 6, 7 and 8 for the 9-story buildings, and (3) *R* of 3, 4, 6, and 8 for the 20-story buildings. Current codes employed an *R* value of 6 for SCBF systems.

The buildings were designed using the NEHRP recommended provisions (FEMA 450). All of the buildings were designed for a location in Seattle, WA, using a Seismic Design Category D with soil Site Class C. The 3-story buildings had 4-by-6 bays with identical story height, while the 9- and 20-story buildings have 5-by-5 and 4-by-4 bays, respectively and with a taller bottom story to reflect typical midrise construction, as shown in Fig. 1. The 20-story frame exceeds the height limit of 48.8m (160 feet) for steel SCBF as per NEHRP (FEMA 450), and the design requires peer review which was not considered by this study. Therefore, the designed 20-story buildings might be different in practice. However, it should be noted that this research used larger seismic design forces than the minimum required by the specification, and it is unlikely that the seismic performance of the buildings will be better than that predicted here.

The braced bays were situated along the perimeter of the buildings in a symmetric plan configuration using a multi-level X-bracing configuration, as illustrated in the figure. Table 1 summarizes the total gravity loads for individual floors and the roof (lighter loads were applied to the roof) for each building configuration. The buildings were designed to meet the NEHRP design spectrum using the United States Geological Survey's (USGS) mapped spectral acceleration values at 2% in 50 years hazard level for the location of Seattle (updated in 2008). All buildings are designed with equivalent lateral force procedures. The 20-story buildings would ordinarily be designed using the response spectrum procedure. The equivalent lateral force method was used to permit direct comparison of all building

heights. However, response spectra analyses were performed, and they showed that the equivalent static analysis resulted in larger member design forces and different distribution of forces over the frame than the response spectrum method. The following values were used: S_S (mapped spectral acceleration parameter at short periods) of 1.4g and S1 (mapped spectral acceleration parameter at a period of one second) of 0.53g. The site class effect was included and the damped spectra were adjusted to 2% of critical damping by the applying β_S and β_1 factors of 0.8. The resulting design spectral acceleration parameters were S_{DS} of 1.17g and S_{D1} of 0.57g. The buildings were considered to be general office buildings, and an occupancy importance factor, I, of 1.0 was used. The redundancy factor of 1.0 was used for all model buildings; while higher value of the redundancy factor would lead to heavier braces and stiffer structures, and would potentially increase the seismic design forces for load combinations including gravity load.

Table 1. Design Parameters and Periods

Model Buildings	R	Gravity Loads (kN)		C_S	T (sec.)	T_1 (sec.)
		Floor	Roof			
3-Story	3	9379	9011	0.390	0.31	0.34
	4			0.293		0.36
	5			0.234		0.37
	6			0.195		0.38
9-Story	3	9721	9317	0.258	0.73	0.69
	6			0.129		0.84
	7			0.111		0.88
	8			0.097		0.94
20-Story	3	2952	2610	0.144	1.31	1.49
	4			0.108		1.66
	6			0.072		1.85
	8			0.054		2.01

In the design of the 3-, 9- and 20-story buildings, the braces were all rectangular Hollow Structural Sections (HSS) and satisfied the AISC seismic compactness criteria (AISC 2005b). The gusset plate connections were rectangular and designed using two different methods to compare current and the proposed balanced design procedure (Roeder et al. 2011a). All of the beam-to-column connections of the frames were designed as welded-flange welded-web connections. Framing members were designed to develop the expected capacity of the braces. Table 1 shows the seismic response coefficient, C_S, design periods, T, and the fundamental periods obtained from modal analysis, T_1, for all the model buildings.

3. SYSTEM MODELING INCLUDING EFFECT OF GRAVITY FRAMES

To assess the seismic performance of SCBFs and the R value in a rational manner, comprehensive nonlinear dynamic analysis models are required. These models must include every yield mechanism and failure mode that impacts the seismic response of the frame and must be capable of simulating the response beyond initial fracture. These modeling requirements have been met for CBFs and proposed in prior studies. Detailed information on the modeling techniques used is provided in the following references (Hsiao et al. 2012a, 2012b).

All of the braced frame systems of the buildings in the study were modeled using the proposed simulation model of SCBFs, which consisted of the proposed spring models of gusset plate connection, rigid links and line-elements (Hsiao et al. 2012a), and the brace-fracture model (Hsiao et al. 2012b) to enable accurate simulation of the SCBF systems to well beyond brace fracture.

The gravity loads and second order effect (P-delta) effects were included in the simulation by employing a leaning column connected to the frame by rigid links, as illustrated in Fig. 2. When this secondary resistance was included, nonlinear springs simulating the combined rotational strength and stiffness of gravity beam-column connections were placed between the rigid link and the leaning column. Half of the building gravity loads at each floor level were supported by the leaning column, since each building model used two seismic frames in each direction to resist the lateral loads, as shown in Fig. 1.

The properties of the nonlinear spring were based upon Liu's model (2004) of shear-plate connections with composite slabs, and the springs were simulated using the Pinching4 material model in OpenSees. Each spring element had the number of the gravity bays within a half building, modeled using the total moment strength of all of the contributing single shear-plate connections (for example a multiplier of 12 was used for the 3-story model buildings to simulate the contribution of half of the total number of gravity connections). The rigid beams used in the gravity frame model were supported by rollers, which were slaved to the nodes at the middle of the frame in the lateral direction at each level.

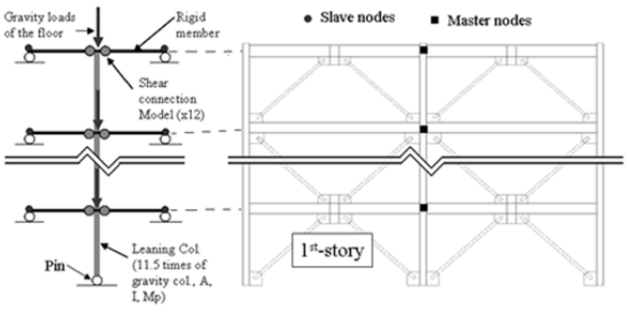

Figure 2. Illustration of the Simulation of P-delta Effect and the Lateral-load Resisting Contribution of Gravity Frames

The base of the leaning column was pinned. Wide-flange sections W10x49 and W12x65 were selected for the gravity columns of the 3- and 9-story buildings throughout the height, respectively. The gravity columns of the 20-story buildings varied: the smallest wide flange section was a W8x31 and the largest wide-flange section was a W14x90. To represent the initial axial and bending stiffness and strength of the gravity columns, a particular

cross section of the leaning column was adopted with a cross-sectional area, moment of inertia and plastic moment capacity equal to the total of the gravity columns in half the building (for example 11.5 columns total for the 3-story model buildings). The resulting models led to that the slenderness of the leaning column for the 3-story buildings was much lower than that for the 9- and 20-story buildings, while that of 20-story buildings was slightly larger than 9-story buildings. However, based on the analytical predictions, this variation did not have a great impact on the results.

To simulate the earthquake characteristics of the ground motions in Seattle, the SAC ground motion record sets assembled for Seattle (each set consists of 20 acceleration records) (FEMA 355C, Somerville 1997) were used in this investigation. All of the ground motions were applied using a time step of 0.005 sec. To represent the different seismic hazards, the records were appropriately scaled using the fundamental period of the structure and the periods resulting from the probable damage states. The details and the consequences of the scaling procedure are described below, in the section on multi-performance level evaluation.

4. COLLAPSE ASSESSMENT USING FEMA P695 METHODOLOGY

The FEMA P695 Incremental Dynamic Analysis (IDA) method was used to estimate collapse potential, as related to the R factors and the four idealized buildings. The following provides an overview of the methodology and its application to this research project. Further information is found in the reference report (ATC-63).

In the IDA and P695 methodology, considered buildings are grouped into "archetypes" that are expected to have similar performance characteristics. Archetype structures should be designed with a selected range of structural geometry and design parameters including structural configurations, seismic design categories, fundamental periods, etc. These archetypes were assembled into "performance groups" reflecting major changes in structural behaviors within the archetype design space. Given the archetype performance group development, nonlinear models are developed and nonlinear analysis and performance evaluation of the system are completed.

The FEMA P695 analysis method for evaluation of collapse potential was used in the research. Figure 3 illustrates the relations between the important design parameters used in the methodology. The figure shows three important design states. The elastic response is based on the assumption that 100% of the effective seismic weight of the structure, W, participates in fundamental mode of the system with a period of T1. The second is that the ratio of the mean spectra acceleration corresponding to the Maximum Considered Earthquake (MCE), SMT, to the seismic response coefficient, C_S (V/W, the ratio of the design base shear and the weight of the structure) is defined as 1.5 times of the R value. The third and final design concept is that the median spectral acceleration at collapse initiation is $\hat{S}_{CT}$, which is predicted using the IDA method.

The primary objective of the method is to evaluate the collapse potential of an archetype for a given R value. This evaluation compares the computed Adjusted Collapse Margin Ratio with the Acceptable Collapse Margin Ratio, which is based on the Collapse Margin Ratio. The following paragraphs briefly quantify each.

The Collapse Margin Ratio (CMR) is defined as the ratio of the median 5%-damped spectral acceleration of the collapse level ground motions, ŜCT, to the SMT at the fundamental period of the structure, T_1, of the MCE seismic hazard for the site. This ratio is shown in Fig. 3. The IDA procedure is used to determine $\hat{S}_{CT}$.

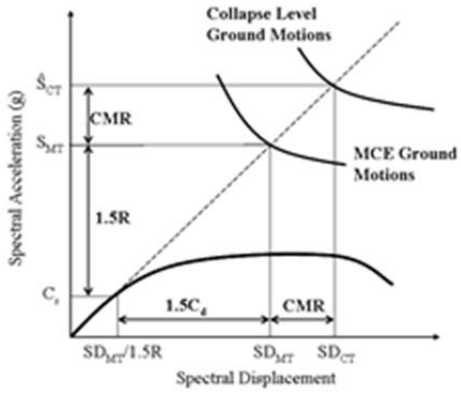

Figure 3. Illustration of the R Factor as Defined by the FEMA P695 Methodology (FEMA P695)

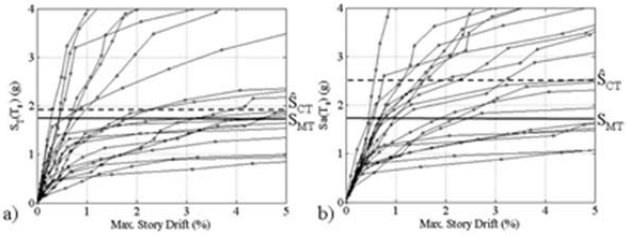

Figure 4. IDA Results for the 3-story Building (R=6) using (a) M1 and (b) M2 Scaling Methods with Collapse Story Drift Capacity of 5% Radians.

The method accounts for the frequency content (spectral shape) of the ground motions, and a consistent set of ground motion variation parameters is defined for different sites, hazard levels and structural periods (Baker and Comell 2006), where $\hat{S}_{CT}$ is determined using the forty-four selected acceleration records which satisfy the ground motion selection criteria. To account for statistical variation in the records, the CMR is multiplied by a simplified Spectral Shape Factor (SSF) to obtain the Adjusted Collapse Margin Ratio (ACMR). The SSF values are specified in the report, and depend on the structural period and the building ductility capacity.

Finally, the archetype is evaluated by comparing the

calculated ACMR to an acceptable ACMR which was specified according to the uncertainty factors of structural system, including the quality of design requirements, test data, numerical modeling, and a prescribed set of ground motions. By the FEMA P695 procedure, the acceptable AMCR should reflect conditional probability of collapse of 20% for individual archetype (AMCR20%). The ACMR of an individual archetype needed to be greater than the corresponding acceptable AMCR to pass the trial. If the determined ACMR was less than the Acceptable ACMR, the R value of the performance group does not meet the performance requirements of collapse prevention.

The 3- and 20-story buildings were evaluated using the FEMA P695 IDA procedure with design spectral acceleration, S_{DS}, of 1.17g, which is slightly greater than the value of 1.0g suggested by the methodology. For the research, the SAC ground motion set for 2% in 50-year seismic hazard in Seattle was used in place of the 44 ground motion records provided by the methodology. Originally, the SAC ground motion records had been scaled to fit the USGS mapped spectral acceleration values at multiple period points (FEMA 355C). For this research, all of the SAC acceleration records were scaled back to original ground motion records prior to the IDA process by simply dividing the SAC records by their scaling factors, which were from 0.94 to 10.04 with a median of 2.34, used for scaling the SAC ground motions given in the SAC report. The original records were subsequently increased until collapse was predicted for each record following the IDA process.

Two methods for scaling the intensity of ground motions were investigated. The first method, designated Method M1, collectively increased the entire set of ground motion records upon the median spectral acceleration of the record set at the fundamental period, so-called Record Set Intensity (RSI), $S_T(T)$, rather than using different intensities for each record. Using this method, the records were scaled as a group in proportional amounts, and the value of $\hat{S}_{CT}$ was defined as the RSI of the group when 50% of the records predicted failure.

The second method, designated Method M2, scaled each record individually, using different intensities for each record at the design period of T, Sa(T). Using this method, $\hat{S}_{CT}$ was defined as median at the period T1 of the response spectra that resulted in predicted collapse by the IDA procedure (FEMA 355F). Figures 4a and b shows the resulting IDA curves using the methods M1 and M2, respectively. It is apparent that scaling the ground motions in different ways significantly changed the distribution of the resulting IDA curves, which results in different CMRs for the same set of ground motions.

In an actual building, collapse will depend on the resistance of the gravity frame as well as the residual resistance of the braced frames. Braced frames dramatically lose most of their resistance and sustain increasing story drift after prediction of the brace fracture. In many IDA evaluations, the collapse prediction is based on flattening of the IDA responses curves, such as those shown in Fig. 4. The results show that some brace fracture curves flatten at relatively low spectral accelerations while others do not flatten at all. This is partly caused by the irregular characteristics of acceleration response spectra and the large increases or decreases that may occur with modest changes in period.

In this research, to account for these and other uncertainties, a potential collapse limit state corresponding to 5% drift was selected for two reasons. First, the nonlinear analyses were deemed to have sufficient accuracy to approximately 5% story drift. Second, experimentation indicates that most beam-column connections and columns do not retain sufficient resistance beyond this drift level. Tests, including SCBF gusset plate connections, indicate that they retain their basic moment resisting connection integrity well beyond brace fracture, but this integrity cannot be assured for drift levels larger than 5% (Lehman and Roeder 2008). This limiting story drift capacity was used to determine $\hat{S}_{CT}$. In Figs. 4a and b, $\hat{S}_{CT}$ was determined when the analyses for 10 out of 20 ground motions (50%) had a story drift greater than 5%.

The results shown in Fig. 4 were compared with the acceptable ACMR20% values in FEMA P695 to evaluate the collapse resistance of each system, as shown in Table 2. The P695 method requires an estimate of the system ductility and the structural fundamental period to determine the acceptable ACMR20%. Based on the prior experimental results (Lumpkin et al. 2012, Johnson 2005, Herman 2006, Kotulka 2007, Powell 2010), SCBF usually buckled around story drift of 0.3% and fractured brace around story drift of 2.5%, which led to the story-drift ductility of 8.3. The corresponding SSF values, required to scale to CMR to determine the ACMR, were 1.4 and 1.65 for 3- and 20-story buildings, respectively. (These values are for structures having the ductility greater than 8). An acceptable ACMR20% of 1.73 was determined, in which the 3-story and 20-story buildings were regarded as an archetype and the quality ratings for design requirements, test data, and numerical modeling were all quantified as "B-Good". The resulting total uncertainty factor was 0.65.

Table 2 summarizes the parameters and the results of the evaluations for the 3- and 20-story buildings with design R values of 6 and 3. As expected, decreasing the R-factor increases the CMR for all systems studied.

However, the results are not consistent between the two methods. Using method M1 (as defined in FEMA P695), both of the system designed using an R-factor of 3 "passes" the evaluation criteria, while the values of ACMR for the 20-story buildings were smaller than those for 3-story buildings. This result suggests that SCBF systems meeting current design will fail. In contrast, using scaling method M2, only the 20-story building designed with R=6 fails to meet the acceptable ACMR20%. The M1 scaling method suggested that R factor of 3 is appropriate for both of 3-story and 20-story buildings. The M2 scaling method suggest that R factor of 6 is appropriate for 3-story SCBFs, while an R value of 3 is needed for 20-story SCBFs. These contrasting results suggest significant ambiguity with the proposed method.

Finally, the analysis for both scaling methods M1 and M2 predicted greater potential for collapse with the 20-story SCBF than for the 3-story SCBF. These results are contrary to findings from prior earthquakes and other studies, in which low rise SCBFs have been deemed more vulnerable (Chen and Mahin 2010).

Table 2. Summary of Evaluations of the 3- and 20-story Buildings Using FEMA P695 IDA Procedure

Scaling Methods	M1 [$S_T(T)$]				M2 [Sa(T)]			
Model Buildings	3-Story		20-Story		3-Story		20-Story	
R Factors	6	3	6	3	6	3	6	3
S_{MT} (g)	1.76	1.76	0.65	0.65	1.76	1.76	0.65	0.65
$\hat{S}_{CT}$ (g)	1.88	2.8	0.55	0.82	2.5	3.35	0.65	0.93
CMR	1.07	1.60	0.85	1.26	1.42	1.91	1.00	1.43
SSF	1.4	1.4	1.65	1.65	1.4	1.4	1.65	1.65
ACMR	1.50	2.23	1.39	2.08	1.99	2.67	1.65	2.36
Accep. ACMR20%	1.73	1.73	1.73	1.73	1.73	1.73	1.73	1.73
Pass/Fail	Fail	Pass	Fail	Pass	Pass	Pass	Fail	Pass

5. MULTI-PERFORMANCE LEVEL EVALUATION PROCEDURE

The results of the P695 analyses revealed ambiguities in the method. To study these further and potentially eliminate them, an alternate evaluation approach for SCBFs was investigated. This procedure directly scaled each ground motions to the seismic hazard for the site (M2) with enhancements described below. In addition to investigating the collapse limit state, the resulting multiple damage limit states of the SCBFs were examined and considered. Therefore, the range of system performance limit states was evaluated (e.g., brace buckling, fracture) for each acceleration record and was then considered in the evaluation of the R factors, as opposed to only the collapse potential. Again, potential collapse of the structure was assumed if any floor level of the structural system developed a 5% story drift.

The 20 SAC Seattle ground motions were scaled to the 2/50 hazard level (MCE level). In addition, the seismic performance at the 10/50 hazard level was evaluated, using SAC 10% in 50 year records for Seattle (FEMA 355C). The target spectra for each hazard level followed the NEHRP recommended provisions (FEMA 450) using the corresponding USGS mapped spectral acceleration values representative of different hazard levels, 10/50 and 2/50. Without the reduction of 2/3, the 2/50 target spectrum is 1.5 times of the design spectrum, while the 10/50 target spectrum is slightly smaller than the design spectrum, as shown in Fig. 5a.

In addition to the 3- and 20-story SCBFs idealized buildings, an idealized 9-story SCBFs was investigated. A larger number of R values were evaluated for each system.

The evaluation of the P695 procedure revealed ambiguities associated with scaling ground motions and results that contradict the normal expected performance of the SCBF system (Chen and Mahin 2010, AIJ 1995). The research team considered various scaling approaches that have been used to evaluate the seismic performance of structures. Prior studies have scaled records using a single period, multiple periods, or a period range (FEMA 355C). Multi-period scaling was deemed important for SCBFs because SCBFs are initially stiff and significant shifts in structural period are expected beyond brace buckling and again beyond brace fracture. Therefore, an approach of scaling the ground motions to match the design response spectra prior to and beyond the brace fracture was used.

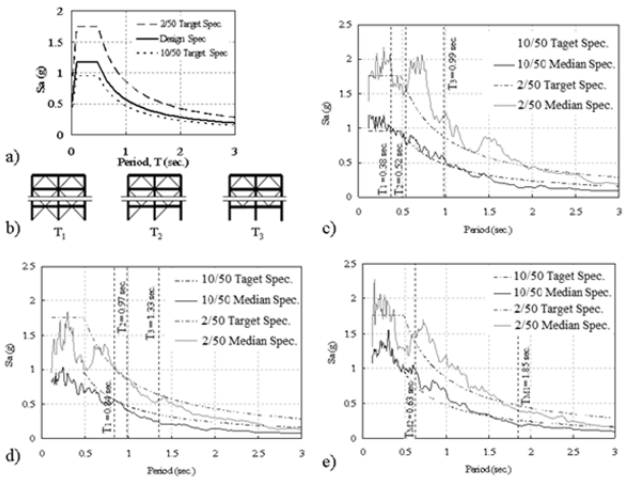

Figure 5. (a) Adopted Target and the Design Spectra at Seattle; (b) Illustrations of the Corresponding Frames for the Three Periods, T_1, T_2 and T_3; (c) the Scaled Median Acceleration Spectra and The Corresponding Target Spectra for the 3-, (d) 9- and (e) 20-story SCBF Buildings.

This conclusion was substantiated by a preliminary study. All of the idealized buildings were analyzed using earthquake records scaled to the first mode only. These analyses demonstrated that significant brace damage (buckling, yielding, and eventually fracture) was sustained by the 3 and 9-story building models, but much more limited brace damage in the 20-story building models. Conversely, the 20-story building models exhibited significant higher mode effects, and these higher modes must be including in the scaling procedure.

As a result two different scaling approaches were used. For the structures primarily governed by the fundamental mode prior to damage, i.e. the 3- and 9-story buildings, the following approach was used. For the 10/50 target spectrum, minimal nonlinearity was observed from the preliminary analysis and those ground motions were scaled to meet the 10/50 target spectrum using only the first (fundamental) period (T_1) of the structure. (Each ground motion was scaled independently and for the structure, that is the number of stories plus *R* factor, of interest.)

The analyses indicated structural damage occurred at the 2/50-hazard level, typically in the form of brace fracture at the critical story. Therefore multi-period scaling was used,

including the fundamental period (T_1) and two additional periods for the more severe damage states of the structure. The second period of interest (T_2) corresponded to loss of braces in one-direction. The third period of interest (T_3) corresponded to loss of all braces at the critical story were used. These two states are illustrated in Fig. 5b. The dynamic analyses indicated that the critical story was the bottom story for the 3- and 9-story building models.

Using this method, the following expressions of scaling factor, f10/50 and f2/50, were developed to scale each ground motions for each hazard level.

$$f_{10/50} = \frac{Sa_{1,t}}{Sa_{1,g}} \tag{1}$$

$$f_{2/50} = \frac{Sa_{1,t}}{Sa_{1,g}} w_1 + \frac{Sa_{2,t}}{Sa_{2,g}} w_2 + \frac{Sa_{3,t}}{Sa_{3,g}} w_3 \tag{2}$$

The expression is a weighted function of the spectra accelerations at the periods of interest. In the expression, $Sa_{i,t}$ is the target elastic spectral (acceleration) values corresponding to each T_i period as described previously (i =1 to 3), $Sa_{i,g}$ is the spectral (acceleration) value of the ground motion at the period T_i, and wi is the weight for the T_i period points. The weights were 0.55, 0.35 and 0.1 for T_1, T_2 and T_3, respectively. Using this scaling approach, the median scaled acceleration spectra at 10/50 and 2/50 hazard levels shown in Figs. 5c and d were developed comparing with the corresponding target spectra for the 3- and 9-story SCBF buildings, respectively. The values of three periods, T_1 to T_3, are indicated in the figures. The plots show that the median scaled (acceleration) spectra matches the target spectra on average between T_1 and T_3 period points, which is the region of primary variation in the period.

The preliminary analysis of the 20-story building models indicated significant contributions of the second mode in top and bottom stories with the first mode governing the response of the remainder of the building. To include the second mode effects, a modified scaling approach was adopted to scale the ground motions for use in the 20-story building analysis, basing the scaling function on the first two modal periods for both of the hazard levels. Note that because significant damage was not observed in high-rise building, the larger periods resulting from brace damage were not included as they had been in the 3- and 9-story scaling methods. The resulting expression, given in Eq. 3, was used to scale the ground motions for both of the 10/50 and 2/50 events.

$$f_{m,10/50} \; and \; f_{m,2/50} = \frac{Sa_{m2,t}}{Sa_{m2,g}} w_{m2} + \frac{Sa_{m1,t}}{Sa_{m1,g}} w_{m1} \tag{3}$$

In the expression, $Sa_{mi,t}$ is the target design elastic spectral acceleration value for the ith modal period (i=1 and 2), $Sa_{mi,g}$ is the spectral acceleration value of the ground motions at the ith modal period. For the second expression, weights of w_{m2} =0.6 and w_{m1} =0.4 were used. Figure 5e shows the median scaled acceleration spectra for 10/50 and 2/50 hazard levels and the corresponding target spectra for the 20-story SCBF building. The values of the first two mode periods, T_{M1} and T_{M2}, used for scaling were indicated in the figure.

A single set of the scaled ground motion records were used for the analyses, which were scaled based upon the computed periods of the 3-, 9- and 20-story buildings. In all cases, the computed periods for the buildings designed using an *R* value of 6 were used for the other *R*-value building design with the assumption that variation of the periods due to different *R* factors had a minor effect of the scaled ground motions.

The scaled 2% and 10% in 50 year (2/50 and 10/50) ground motions were used for the performance evaluation of SCBFs, which varied with building height. Figures 6a, b and c show the average Maximum Story Drifts (MSD) computed for the 3-, 9- and 20-story SCBFs for the 10/50 and 2/50 hazard levels, respectively. As noted in the figures, a range of *R* values were studied, and included *R*=3 and 6 for the 3-story building models, and *R*=3, 6, and 8 for the 9-and 20-story building models.

The deformation concentrated in the bottom story for the 3- and 9-story frames, which always occurred after brace fracture at that story. The results show that the 3-story SCBFs designed with *R*=6 had much more severe deformation and damage than the 9- and 20-story SCBF building models designed using the same response modification factor. In the 10/50 events, the average MSDs vary between 0.3% and 0.5%, and brace fracture was not predicted. During the 2/50 earthquakes, brace fracture initiated between drifts of 1.5% to 2%. As mentioned previously, brace fracture resulted in severe concentration of deformation. The average MSDs varied from 1% to 3% for the 3-story buildings for *R* values of 3 to 6, while the MSDs varied from 1% to 2% radian for 9-story buildings with *R* values of 3 to 8. These results show that brace fractures occurred in the 3-story building models, with a lesser number for 9-story building models.

The response of the 20-story building models differed significantly from the 3-story and 9-story building models in two ways. First the upper stories sustained some of the largest deformations. Response to the 2/50 ground motions indicates concentration of story drift and inelastic deformation occurred in both the bottom and upper stories due to the brace fracture. Further, the distribution of deformation along the height of the building depends on the R values used in the frame design. Finally, the resulting peak MSDs, which varied between 1.0 to 1.3%, indicated minimal brace fracture in these structures. These results suggest an increase in structural performance with building height, which is contrary to the results from the P695 methodology discussed earlier.

The average maximum story drift distributions shown in Fig. 6 provide interesting and valuable information, but they do not specifically quantify performance. The analytical models used to simulate SCBFs, discussed in the prior section, are capable of predicting both the global seismic behavior as well as the local performance including brace buckling capacity, out-of-plane brace displacement and the onset of brace fracture. This model allows more

comprehensive evaluation of the system performance at all performance levels.

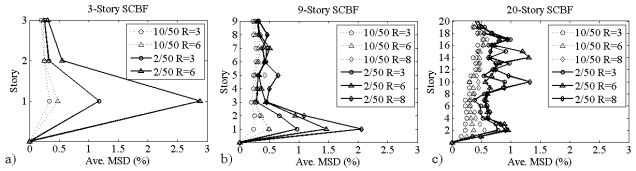

Figure 6. Seismic Responses of (a) the 3-story, (b) 9-story and (c) 20-story Buildings with Various R Factors at 10/50 and 2/50 Hazard Levels.

Several performance limit states were considered here including: 1) brace buckling, 2) possible replacement of the brace, 3) brace fracture, and 4) potential collapse of the building. The brace buckling (and yielding) and fracture behaviors were computed directly. Requirements for possible replacement of the brace was defined as: (1) the maximum out-of-plane displacement of the braces exceeded three times the brace depth or (2) prediction of brace fracture. These damage states are based upon definitions developed in a prior study on fragility curves of CBFs [24]. The same story drift limit of 5% was adopted as the potential collapse criteria, because experiments show that braced frames have considerable inelastic deformation capacity after brace fracture due to the gusset plate connections. Therefore basing collapse solely on brace fracture is unduly conservative. Experiments also show that these connections are unlikely to be reliable at drifts greater than 5%. The authors have greater confidence in the predicted damage states with this alternate evaluation procedure than with the IDA procedure, because the damage states are based upon experimental observation rather than an unverified analytical procedure.

All analytical responses were assembled to determine the occurrence probability of the four performance limit states. Figures 7a, b and c show the probabilities of those damage limit states for the 3-, 9- and 20-story buildings for each of the studied R factors at the 2/50 hazard level (MCE level), respectively.

As expected significant reductions in *R* factors effectively reduced the probabilities of all damage limit states beyond the brace buckling for all story-height buildings. Clearly brace buckling will occur in the 2%-in-50 year event, even for very low *R* values. Yet the results show that it is not the *R* factor alone to impact system performance. Clearly the number of stories impacts performance, with the 20-story building sustaining significantly less damage than the 3-story building for a given *R* factor. The reduced damage of the 20-story building might partially results from the use of equivalent lateral force procedure in design. These results suggest that a smaller *R* factor may be needed for consistent performance of all SCBF buildings. This clearly contradicts the prediction from the P695 IDA evaluation.

Figure 8 shows similar damage level comparisons for the 10/50 hazard level. Figure 5a shows that the 10/50 hazard level is very close to the design spectrum (2/3 of the MCE). Results show that the probability of brace buckling was high, but little additional damage was predicted regardless of the *R* value.

6. COMPARISON OF THE RESULTS USING THE PROPOSED AND FEMA P695 PROCEDURES

Comparison of the FEMA P695 methodology with the alternate method described here raises several major concerns about accuracy and reliability of the FEMA P695 procedure for evaluation of braced frames. In particular:

1) The probability of the potential collapse estimated by the P695 methodology was significantly higher for the 20-story building models than for the 3-story building models. In stark contrast, the alternate analysis procedure clearly showed that the 3 story frames had much larger story drift demands with increased structural damage and brace fracture (for the hazard level corresponding to the 2% in 50 year event). The later finding is consistent with findings from earthquake reconnaissance (AIJ 1995).

2) The FEMA P695 procedure would suggest that a relatively smaller *R* value is required for the 20-story (high-rise) buildings comparing with 3-story building. This

is clearly different than the large body of existing knowledge of earthquake engineering (Chen and Mahin 2010, AIJ 1995) in direct opposition to the alternate analysis performed here.

3) The FEMA P695 procedure is sensitive to the scaling methods used in IDA evaluation as shown by the different results achieved from scaling methods M1 and M2 in Table 2. This sensitivity increases the ambiguity of the method.

The results show that of the two evaluation methods, the proposed evaluation procedure is more reliable, for two reasons. First, the FEMA P695 focuses on an imperfect collapse assessment, which is difficult to validate. The alternate method evaluates validated multiple limit states to captures a wide range of performance states that are 1) documented by experimental observations, 2) important to the building owner and occupants, and 3) ignored by the P695 method.

Second, the alternate method provides a rational mechanism for scaling the earthquake ground motions to meet both the seismic hazard level and expected structural performance. Higher mode effects are considered in the evaluation of the high-rise buildings; effects of structural damage on the dynamic response are incorporated as appropriate.

Both methods used a modeling approach, which employed the most accurate modeling of braced frame behavior used to date, since the models were validated to simulate the full range of behaviors and damage states, including brace fracture, observed in experiments. This final point emphasizes the primary limitation with the P695 procedure. Focusing solely on the stability or toppling aspects of collapse does not provide a reliable method to provide consistent performance among building archetypes. Collapse prediction is a highly uncertain response mechanism, difficult to fully simulate in a nonlinear dynamic response analysis, and its validate is not possible with the current experimentation. The P695 procedure extends this uncertain prediction with statistical predictions that imply great accuracy and reliability of the prediction. Engineers and building owners are more concerned by the probability of brace fracture, reparability of the structure, and other structural performance states that impact building performance. The alternate procedure provides a mechanism to estimate structural performance for SCBF systems and provide a consistent level of performance using the *R* value method.

7. CONCLUSIONS

To investigate of the impact of and appropriate values for *R* factors of SCBF systems, 3-, 9- and 20-story SCBF buildings, which were designed based on the equivalent lateral force procedure with various *R* factors, were evaluated by nonlinear dynamic analysis. All of the buildings were idealized multi-story structures designed for the seismic hazards of Seattle, Washington. The buildings in the study were designed to account for the lower damping of steel structures (2%-damping) by amplifying the design base shear by 1.25 (=1/0.8) which is not required in NEHRP (2003), but 2% damping is closer to that typically measured in steel buildings. As a result, the resulting design *R* values with the consideration of this amplification, as adopted in the study, would be 0.8 times those obtained with the normal 5% damped spectrum. Two methods were used to evaluate the appropriate *R* factor values as well as their impact on the seismic performance and design parameters for SCBFs. Initially the P695 methodology was used. Finally, an alternative performance-based method was developed and used to evaluate the SCBF models.

The ground motions selected for analysis were from two bins, including the 2% in 50 year and 10% in 50 year Seattle SAC ground motions. Both methods used state-of-the-art line-element modeling which were experimentally validated. The modeling approach was also used to accurately predict the yielding and buckling behavior of the brace, the post-buckling behavior of the systems, the onset of brace fracture, and the post-fracture behavior of the system.

The research was carried out by first evaluating a pair of 3- and 20-story SCBFs designed with *R* factors of 3 and 6 using the methodology of FEMA P695 (ATC-63). These results were compared with the alternative evaluation process, which used an appropriate scaling method of ground motions to meet the higher mode and performance of a range of SCBF archetypes, including a series of SCBF buildings (3-, 9- and 20-story).

The results were compared with the P695 evaluate results to determine appropriate design parameters, R-factor, for SCBFs. The conclusions of the modeling requirements, ground motion scaling procedures, effectiveness of the P695 procedure and the proposed procedure follow.

The contribution of gravity frames to the lateral resistance had considerable impact on and reduces the seismic responses for the low-rise buildings (3-story buildings) and needs to be considered in the performance evaluation. For mid-rise and high-rise buildings (9- and 20-story buildings in the study), the effect of the gravity frame is relatively small.

The evaluation of SCBFs using the FEMA P695 methodology with the IDA procedure to assess collapse potential led to uncertainty of estimating the R factors. This uncertainty results from the variations of the resulting IDA curves by different scaling approaches of ground motions as well as the difficulty in predicting collapse.

In the alternate performance evaluation procedure, the proposed scaling method effectively reflects the characteristics of the structural systems to best represent the ground motion intensity at certain hazard levels. For first-mode-governed structures, such as the low- and mid-rise buildings, the proposed scaling method provided a reasonable fit of the ground motion response spectra to the design response spectra for the variation of structural periods due to brace fracture. For the taller buildings, which are mainly governed by the second mode, the scaling method assures the ground motion response spectra reasonably

matching the design response spectra at the first two mode structural periods.

Seismic performance evaluation and particularly collapse entails many variability and uncertainties. The alternative evaluation procedure is much better able to address these uncertainties and provide a better picture of SCBF performance than the FEMA P695 method.

By using the accurate analytical models including fracture prediction and proper scaling approach of ground motion records, the seismic performance of the SCBFs can be assessed at multiple damage levels for multiple hazard levels. This fulfills the objectives of performance based earthquake engineering and provides a mechanism for a more consistent design among building archetypes. Solely focusing on collapse does not fulfill this objective or provide this consistency.

The analytical results show that the appropriate R factors actually varied with the number of stories. The results suggest that if consistent safety against collapse is to be achieved, low-rise SCBFs (3-story) require smaller R value for low-rise buildings. An R factor of 3 is suggested. The results showed acceptable results for the mid-rise and high-rise SCBF buildings (9- and 20-story) designed with an R-value of 6.

Abstract: The gusset plates in a steel braced frame can be subjected to the forces not only from the brace but also from the effects of the frame actions. In this study, several finite element models are constructed to analyze the gusset to beam and column interface forces. It is found that the frame actions affect the gusset interface force distributions significantly. A simplified strut model to represent the gusset plate is adopted to evaluate the frame action forces. In addition, the Generalized Uniform Force Method (GUFM) is adopted as it provides more freedom for designers to configure the gusset plate shapes than using the traditional Uniform Force Method (UFM). In this paper, a performance based design method is proposed. The gusset interface force demands take into account the combined effect of the brace maximum axial force capacity and the peak beam shear possibly developed in the frame. The specimen design and key results of a series of full-scale 3-story buckling-restrained braced frame (BRBF) hybrid tests are discussed. The gusset interface cracks observed at the inter-story drift greater than 0.03 radians can be well predicted by using the proposed design method. The BRBF tests and analyses confirm that the proposed design method is quite reasonable. The paper concludes with the recommendations for the seismic design of gusset plate.

1. INTRODUCTION

The buckling-restrained brace (BRB) can be viewed as a high-efficiency energy dissipation device as it can dissipate the earthquake energy through its development of the full yield strength in both tension and compression in the BRB steel core (Watanabe et al. 1988). The gusset plates which connect the two BRB ends to the frame must be properly designed so that they can sustain the maximum axial force capacities induced from the BRBs. The UFM (Thornton 1984) has been widely adopted for the gusset designs for steel braced frames as it provides a straightforward design procedure to obtain an economical and admissible force distribution (AISC 2010). In addition, when the BRBF is deformed, the beam-to-column joint would either open or close. Thus, the corner gusset plate in the BRBF is required to sustain not only the BRB axial force but also additional forces resulted from the frame action. Several studies have reported that the gusset to beam or column interface fractures (Uriz et al. 2004) and the gusset plate ruptures (Kaneko et. al 2008) in large-scale steel braced frame tests. It is found that the frame action forces could create large force demands on the gusset plate. However, these force demands were often ignored in the design procedures commonly adopted by the practitioners. A research on the rib-reinforced steel moment connection has investigated the frame action forces on the reinforcing ribs by using an equivalent strut to represent the ribs (Lee 2002). Several researches on the force demands on the gusset plate resulted from braces and frame action effects have also been studied on the corner gusset connections (Kaneko et al. 2008, Chou et al. 2012). The frame action effects on the gusset interfaces can be calculated by using the aforementioned equivalent strut model. The gusset interface force results from BRB axial forces can be derived by either the UFM or the GUFM (Muir 2008). In this study, the GUFM is adopted for the gusset plate design which could allow the designers to configure the gusset shape more freely. A simple seismic performance design procedure for BRBF gusset plates is developed by incorporating the GUFM and the frame action forces computed from the equivalent strut model. The normal and shear stress distributions on the gusset interfaces induced from the BRB and frame actions are discussed in detail by using the finite element analysis. In this paper, the performance design considers the BRB's maximum axial force capacity and the maximum beam shear due to the frame action. Results of a series of a full-scale 3-story BRBF hybrid and cyclic loading tests are evaluated using finite element analyses. The gusset interface welding fractures, occurred prior to the BRB failure when the inter-story drifts exceeded 0.03 radians, are analyzed in detail. The test and finite element analysis results confirm that the proposed design method can satisfactorily predict the force demands on the gusset interfaces.

2. COMMON DESIGN METHODS FOR BRBF GUSSET PLATE

2.1 Generalized uniform force method

The UFM (Thornton 1984) has been widely adopted for the design of gusset plates in the concentrically braced frames (CBFs) and buckling restrained braced frames (BRBFs). It has been included in the AISC Manual of Steel Construction (AISC 2010) as it provides a straight-forward procedure to compute the forces on the gusset interfaces. For the BRBF gusset plate design, the BRB's maximum axial force capacity P_{max} is used as the force demand for the gusset plate. It can be computed as follows (AISC 2010):

$$P_{max} = \beta \times R_y \times \omega_y \times \sigma_y \times A_c \quad (1)$$

where A_c and σ_y are the cross section area and yield stress of the BRB steel core material. ω_y and R_y are the material strain hardening and overstrength factors. β is the compression strength adjustment factor. As illustrated in Figure 1a, the force components on the gusset to beam and column interfaces resulted from P_{max} can be calculated as follows:

$$V_{gc} = P_{max} \times \beta_g / r \quad (2)$$

$$H_{gc} = P_{max} \times e_c / r \quad (3)$$

$$V_{gb} = P_{max} \times e_b / r \quad (4)$$

$$H_{gb} = P_{max} \times \alpha_g / r \quad (5)$$

$$r = \sqrt{\left(e_b + \beta_g\right)^2 + \left(e_c + \alpha_g\right)^2} \quad (6)$$

$$\tan\varphi = \left(e_b + \beta_g\right) / \left(e_c + \alpha_g\right) \quad (7)$$

where φ is the inclination angle of the brace. According to the UFM, the gusset interface forces must be computed by using the gusset length and height ($2\alpha_g$ and $2\beta_g$). During the design, either the gusset length or the height must be determined first, and then the second undetermined dimension can be computed from the geometric relation of Eq. (7). Therefore, the gusset plate shapes can often be irregular or undesirable when the brace inclination angle or beam-to-column depth ratio is too large or too small. An alternative design method, the GUFM has been proposed (Muir 2008) for alleviating this issue. The GUFM allows the designers to have more freedom in choosing the dimensions of the gusset plate. As shown in Figure 1b, the GUFM assumes that the force directions on the gusset interfaces and the brace force pass through the same "Gusset control point" to achieve the moment equilibrium. The gusset to beam interface force passes through the intersection of the beam center line and column surface (Beam control point). Using the force equilibrium requirements for the gusset plate, beam, and column free bodies, the gusset interface forces can be computed as follows: (Muir 2008)

$$H_{uc} = \frac{P_{max} e_c \sin\varphi}{e_b + \beta_U} \quad (8)$$

$$V_{ub} = P_{max}\left[\frac{e_b\left[\left(e_b + \beta_U\right)\cos\varphi - e_c \sin\varphi\right]}{\alpha_U\left(e_b + \beta_U\right)}\right] \quad (9)$$

$$H_{ub} = P_{max}\cos\varphi - H_{uc} \quad (10)$$

$$V_{uc} = P_{max}\sin\varphi - V_{ub} \quad (11)$$

The detailed procedure of applying the GUFM will be given later. If the gusset length and height satisfy Eq. (7), the gusset interface forces would be identical computed from using either the UFM or the GUFM. The result of using the UFM is only one of the possible applications of the GUFM. Two gusset design examples using the UFM and GUFM are demonstrated. As shown in Figure 2a, the example frame is a one-story one-bay BRBF with top and bottom beams (594×302×14×23mm), two columns of 500mm deep, and a BRB with a maximum axial force capacity of 8800kN. The story height is 4m and the bay width is 7m. The gusset plate thickness is 38mm of SN490B steel (nominal yield stress is 325MPa). A BRB using the end-slotted connection (Lin et al. 2012) is adopted. The required welding length of the BRB joint section on the gusset plate is 420mm. A 75mm clearance (Figure 2a) is arranged between the BRB and the beam top surface. Figures 2b and 2c show the design results using the UFM and GUFM respectively. The horizontal gusset lengths (L_h) can be the same but the vertical gusset length (L_v) is shorter when the UFM is used because of the ration constraint of the gusset length and height given by Eq. (7). As a result, when the UFM is used, the gusset free edges may not be able to maintain vertical or horizontal due to the geometric configuration requirements. However, when the GUFM is adopted, the gusset plate free edges could be configured as horizontal, vertical, or any other slopes as desired. Figure 2c shows the results of using the GUFM to design the gusset plate with a vertical and a horizontal edge. This example clearly demonstrate that when the GUFM is used, the designer could more practically configure the gusset shape to meet the constructional space demands and still obtain desirable force distributions on the gusset interfaces than applying the UFM.

2.2 Frame action effects

As shown in Figure 3, the gusset plate in the braced frame are subjected to additional tension or compression forces P_{FA} due to the opening and the closure of the corner adjacent to the beam-to-column joint when the frame deforms. As shown in Figure 3a, the beam-to-column joint is opened when the BRB is compressed. In this case, the gusset plate is subjected to the compression due to the BRB compression force $P_{max,c}$, and subjected to a tension force $P_{FA,t}$ due to the opening of the beam-to-column. Likewise (Figure 3b), when the beam-to-column joint is closed, the BRB is in tension. The gusset plate is subjected to the tension force from the BRB tension $P_{max,t}$. In this case, the gusset is subjected to a compression $P_{FA,c}$ due to the closure of the beam-to-column joint. An equivalent strut model was developed to represent the reinforcing ribs in the welded moment connections (Lee 2002). As shown in Figure 4, the

two ends of the equivalent strut are located at the points of 0.6 times of the gusset length and height ($0.6L_h$ and $0.6L_v$) from the column and beam surfaces, respectively. The width of the strut can be assumed the same as the gusset plate thickness (t_g), and the depth is assumed equal to half of the strut length ($L_g/2$) (Kaneko et al. 2008). According to the study (Lee 2002), the closure or opening of the beam-to-column joint is accompanied by the presence of a beam shear. The gusset interface forces due to the frame actions can be computed from the equivalent strut axial force. When the strong column weak condition exits, the maximum force in the equivalent strut can be computed from the maximum beam shear V_{beam} as shown in Figure 4. The maximum beam shear can be conservatively estimated from assuming the beam plastic hinges have formed adjacent to the gusset tip and column face (Figures 3a and 3b). In addition, by using the force equilibrium of the strut and the compatibility condition that the strut elongation is identical to the beam flexural deformation, the horizontal (S) and vertical (N) force components (Figure 4) of the strut axial force can be computed as follows (Lee 2002):

$$S = \frac{d_b L_h V_{beam}\left(0.3L - 0.18L_h\right)}{4I_b/t_g + d_b L_h\left(0.3d_b + 0.18L_v\right)} \tag{12}$$

$$N = \frac{d_b L_v V_{beam}\left(0.3L - 0.18L_h\right)}{4I_b/t_g + d_b L_h\left(0.3d_b + 0.18L_v\right)} \tag{13}$$

$$V_{beam} = \frac{2R_{y,b}M_{p,beam}}{L - L_h} \le V_{p,beam} \tag{14}$$

where $M_{p,beam}$ is the beam flexural capacity and L is the beam clear span. The overstrength factor of the beam material ($R_{y,b}$) is considered. However, the beam shear V_{beam} need not to exceed the beam nominal shear strength ($V_{p,beam}$) (AISC 2010).

2.3 Combination of BRB axial forces and frame action effects

The corner gusset plate is subjected to the forces from both the BRB axial force and frame actions when the frame deforms. This combined force effect has been studied by researchers (Kaneko et al. 2008, Chou et al. 2012). In this study, the gusset plate design considers the ultimate state that the beam reaches maximum shear V_{beam} (Eq. (14)) and the BRB develops the maximum compression force $P_{\max}$ (Eq. (1)). The ideal capacity design of the gusset is to keep the gusset intact before BRB fails.

For the design of gusset plates, the first step is to select the gusset initial length (L_h) and height (L_v) considering the beam, column depths, and the sizes of BRB end joint to meet the welding or bolting requirement. Then the gusset interface force demands resulted from BRB axial force and the frame action can be computed by using the GUFM (Eqs. (8) to (11)) and the equivalent strut model (Eqs. (12) to (14)), respectively. Figures 5a shows the gusset interface forces when the BRB is in compression and beam-to-column joint opens. Figure 5b shows the BRB in tension with the closure of the beam-to-column joint. It can be found on both the beam and column interfaces, the shear force components result from the BRB and frame effects are always in the same direction. On the contrary, the normal forces on the interfaces due the two different effects are always in the opposite directions. Thus, the total force demands on the gusset interfaces can be computed by combining the BRB and frame actions together as follows:

$$H_c = S - H_{uc} \tag{15}$$

$$V_c = N + V_{uc} \tag{16}$$

$$H_b = S + H_{ub} \tag{17}$$

$$V_b = N - V_{ub} \tag{18}$$

where V_b and H_c are the normal force demands on the gusset to beam and column interfaces respectively. The H_b and V_c are the shear force demands on the gusset to beam and column interfaces respectively. Other design limit stated for the gusset should be considered including the yielding and buckling strength of the Whitmore area (Whitmore 1952, Thornton 1984) on the gusset plate must sustain the maximum BRB maximum axial force $P_{\max}$. The thickness of the gusset plate t_g and the BRB end-to-gusset plate welding length must designed to prevent the block shear failure (AISC 2010). In addition, the gusset plate is required to check other limit states including the von Mises yield criteria, tensile, and shear ruptures at the gusset interfaces. All these will be illustrated in the following sections. When the check of any of these aforementioned limit states is not satisfactory, the gusset plate shape or thickness is required to be reconfigured until all the limit states are qualified. In order to investigate the effectiveness of the proposed gusset plate design procedures and to gain insight into the stress distributions in the gusset interfaces, the results of the tests and finite element analyses of a full-scale 3-story BRBF are investigated.

3. ANALYTICAL INVESTIGATION USING FINITE ELEMENT METHODS

3.1 The 3-story full-scale BRBF hybrid tests

A full-scale 3-story BRBF specimen measuring 6.0m wide and 9.27m tall was tested using hybrid and cyclic loading procedures (Lin et al. 2012). Six BRBs with the same strength were installed in the frame specimen (Figures 6a and 6b). This test was to examine the newly developed BRB types and the performance of the gusset connections. The LA03 ground accelerations (Figure 7) with a peak ground acceleration of 530 gal were applied to the specimen twice. The maximum inter-story drifts are 0.0283, 0.0293, and 0.0095 radians for the first to the third stories respectively. The BRB axial forces reached the maximum axial force of 603kN in the first and second story. In the first hybrid test, all the gusset plates worked well without failure except the south BRB in the first story bulged out locally (Lin et al. 2012). Before the second test, only the gusset plates and two BRBs in the 1st story were replaced. The

second hybrid test adopted the same ground accelerations but the direction was reversed. A 20mm long weld crack was observed at the second story north top gusset to column interface after the peak inter-story 0.0327 radians was reached. This crack did not propagate until the end of the test. At the end of the second hybrid test, none of the BRBs was found failed except the gusset welding crack noted above. Test results showed that the cracks did not influence the BRBF strength notably. After the second hybrid test, the cyclic increasing roof displacements were applied without straightening the BRBF or repairing the weld crack in the specimen. During the cyclic loading test, the first story south bottom gusset-to-base plate interface weld fractured up to a length of 140mm (Figure 8a) while the inter-story drift reached 0.0320 radians. At the end of the test, the aforementioned weld crack in the second story north gusset extent to 85mm long at the end of the cyclic loading test (Figure 8b). The 2nd story gusset interface welding fracture has been investigated using finite element analyses. The analysis results and the design review for the gusset plate will be presented in the following sections.

3.2 Finite element analyses of the 3-story BRBF specimen

In order to investigate the gusset force distributions on the beam and column interfaces, three finite element models were constructed and analyzed by using ABAQUS (2010) program. The dimensions of the analytical models are identical to those in the 3-story BRBF specimen described above. The first model (FEM_C, C stands for combined) is for analyzing the 2nd story gusset plate under the combined effects of BRB and frame actions. The FEM_B and the FEM_F, models are for analyzing the gusset plate under the BRB axial force and frame action, respectively. Only part of the 2nd and 3rd stories is considered, the FEM_C is constructed as shown in Figures 6a, 9, and 10a. The simplified analytical model contains half of the middle beam segment which ranges from the middle Point C to the beam-to-column connection. The column ranges from the lower beam-to-column connection (Point A) to the mid-height of the 3rd story (Point B). The BRBs of the 2nd and the 3rd story and the lower beam are represented by using truss elements in order to consider axial forces only. A rigid link is introduced from Points E to B in the mid-height of the 3rd story to maintain the brace angles. The middle beam, column, and the gusset plates including the BRB end joint segments are represented by using 3D solid elements. The bilinear material model with a yield stress of 390MPa obtained from the coupon tests (Lin et al. 2012, Lumpkin et al. 2012) is adopted. The post yield stiffness is assumed 1% of Young's modulus. The reference axes and boundary conditions for the Points A to E are described in Figure 9. The forces and the deformations of the structural model are constrained in the yz plane. As illustrated in Figure 9, the y-axis displacements at Points D and E are imposed considering the maximum experimental displacements at these reference points when the inter-story drifts reached 0.035 and 0.0089 radians for the 2nd and 3rd stories, respectively. The contents of the FEM_B and FEM_F are similar to the FEM_C except the truss elements and the boundary conditions were modified. For the FEM_B (Figure 10b), the lower beam and the link were removed. In this case, the boundary conditions as shown in Figure 9 set Points A, B and C as hinges without any translation. Impose displacements on Points D and E will induce axial forces in the truss elements representing the BRBs. Likewise, for the FEM_F (Figure 10c), the truss elements for BRBs were removed and the same displacements stated above were applied at the beam ends (Points D and E) to get the gusset interface forces resulted from the frame action. In this manner, the gusset plate is subjected to the opening effects of the beam-to-column joint.

Tables 1 to 3 show the gusset interface forces compare the results of using Eqs. (8) to (18) and finite element analyses. Comparing the GUFM with the finite element analytical results caused by BRB force, Table 1 shows that the shear force component on each interface is underestimated and the normal force is overestimated. Table 2 compares the gusset interface forces caused by the frame action effects only. Compared with the finite element analytical results, the force components computed from the equivalent strut are only slightly underestimated. It is evident in Tables 1 to 2 that the interface forces resulted from the BRBs' axial force are relatively small compared with the frame action effects. It appears that more than half of the contribution of the gusset interface forces came from the frame action forces. Table 3 compares the gusset interface forces under the combined effects. All the combined interface force components calculated by using the proposed method (Eqs. (15) to (18)) are lower than the finite element analysis results. This seems reasonable as high stresses concentrated at the gusset tips cannot be included in the GUFM procedures or equivalent strut model.

Figure 11 shows the analytical normal, shear, and von Mises stress distributions along the gusset interfaces computed from finite element analyses. It can be found that when only the BRB force acts on the gusset plate, the normal stresses (Figure 11a) distribute uniformly along both the beam and column interfaces. However, the shear stresses (Figure 11b) distribute in a triangular pattern with the maximum value developed at the beam-to-column corner, and the minimum value almost equal to zero at the gusset two tips. In addition, when only the frame action occurs, both the normal and shear stresses distribute triangularly (Figure 11b) along the two interfaces with the maximum value at the gusset tips and the minimum value at the beam-to-column corner. Figure 11c shows the von Mises stress distributions considering the BRB and frame actions separately or combined. Although the frame action effect results in a high von Mises stress at the two gusset tips, the von Mises stress is also very high at the beam-to-column corner due to the high shear stress from the BRB action. The interface von Mises stresses under the combined effects are higher than the effect only from the BRB or the frame action. From Figures 11a and 11b, it appears that the normal and shear stresses under the BRB and frame actions can be

assumed to distribute linearly (triangularly or uniformly) as shown in Figures 12a and 12b. Table 4 and Figure 12c show the combined shear and normal stresses after distributing the shear and normal forces triangularly or uniformly on the gusset interfaces. In Table 4, the peak von Mises stresses at the two interfaces computed from the FEM_C analysis and the proposed procedures using the linearized stress distributions are also compared. It appears that the results of using these linearization procedures can predict these peak von Mises stresses satisfactorily. Therefore, the aforementioned linearization techniques are adopted to compute the peak stress demands for the design of the gusset plate. The detailed design procedures are presented in the following sections.

4. LIMIT STATES AND DESIGN PROCEDURES FOR GUSSET CONNECTIONS

4.1 Limit states of gusset plate seismic design

As shown in Figure 12, the normal and shear stresses can be assumed uniformly and triangularly distribute along the gusset interfaces. Therefore, based on the finite element analytical results, it appears that the stresses can be computed by using linear functions of positions at the gusset interfaces. The normal (σ_{GUFM}) and shear (τ_{GUFM}) stresses induced by the BRB axial force only are represented for the beam and column interfaces Figure 12a as:

$$\sigma_{GUFM,b}(x)=\frac{V_{ub}}{L_h t_g} \text{ and } \tau_{GUFM,b}(x)=\frac{2H_{ub}}{L_h t_g}\left(1-\frac{x}{L_h}\right) \quad (19)$$

$$\sigma_{GUFM,c}(y)=\frac{H_{uc}}{L_v t_g} \text{ and } \tau_{GUFM,c}(y)=\frac{2V_{uc}}{L_v t_g}\left(1-\frac{y}{L_v}\right) \quad (20)$$

where the subscript b and c represent the beam and column interfaces respectively. The x and y represent the distances from the beam-to-column corner to the points on the beam and column interfaces as shown in Figure 12. In addition, the triangularly distributed normal (σ_{FA}) and shear (τ_{FA}) stresses resulted from the frame action (Figure 12b) on the beam and column interfaces are represented using similar subscribes b and c as:

$$\sigma_{FA,b}(x)=\frac{2N}{L_h^2 t_g}x \text{ and } \tau_{FA,b}(x)=\frac{2S}{L_h^2 t_g}x \quad (21)$$

$$\sigma_{FA,c}(y)=\frac{2S}{L_v^2 t_g}y \text{ and } \tau_{FA,c}(y)=\frac{2N}{L_v^2 t_g}y \quad (22)$$

Thus, the interface normal (σ) and shear (τ) stresses under the combined effects (Figure 12c) can be expressed as:

$$\sigma_b(x)=\sigma_{FA,b}(x)-\sigma_{GUFM,b}(x), \quad 0\le x\le L_h \quad (23)$$

$$\tau_b(x)=\tau_{GUFM,b}(x)+\tau_{FA,b}(x), \quad 0\le x\le L_h \quad (24)$$

$$\sigma_c(y)=\sigma_{FA,c}(y)-\sigma_{GUFM,c}(y), \quad 0\le y\le L_v \quad (25)$$

$$\tau_c(y)=\tau_{GUFM,c}(y)+\tau_{FA,c}(y), \quad 0\le y\le L_v \quad (26)$$

The maximum stresses on the gusset interfaces for a properly designed gusset plate should satisfy the following requirements:

(1) Von Mises yield criteria

The maximum von Mises stresses are computed to combine the normal and shear stress demands on the two gusset interfaces. If the $\sigma_{y,g}$ is the yield stress of the gusset plate material, the limit on the demand-to-capacity-ratios (DCRs) of the von Mises stresses can be calculated as:

$$DCR_{m,b}=\max\left[\sqrt{\sigma_b(x)^2+3\left[\tau_b(x)\right]^2}\Big/\phi\sigma_{y,g}\right]\le 1.0 \quad (27)$$

$$DCR_{m,c}=\max\left[\sqrt{\sigma_c(y)^2+3\left[\tau_c(y)\right]^2}\Big/\phi\sigma_{y,g}\right]\le 1.0 \quad (28)$$

Without considering the possible material overstrength of the gusset plate, a strength reduction factor ϕ=1.0 in Eq. (27) and 28 has been considered in order to avoid a too conservative design.

(2) Tensile and shear rupture

The gusset must sustain the maximum normal and shear forces to avoid tensile and shear rupture failures of the plate (AISC 2010). According to Figure 12, the peak normal stresses are located at the two gusset tips where the tensile rupture failure is most likely to occur. Thus, using a strength reduction factor ϕ= 0.75, the DCR limit to prevent the tensile rupture on each gusset interface is:

$$DCR_{t,b}=\max\left[\sigma_b(x)/\phi\sigma_{u,g}\right]\le 1.0 \quad (29)$$

$$DCR_{t,c}=\max\left[\sigma_c(y)/\phi\sigma_{u,g}\right]\le 1.0 \quad (30)$$

The DCR limit to prevent the shear rupture on each gusset interface is:

$$DCR_{s,b}=\max\left[\tau_b(x)/\phi\tau_{u,g}\right]\le 1.0 \quad (31)$$

$$DCR_{s,c}=\max\left[\tau_c(x)/\phi\tau_{u,g}\right]\le 1.0 \quad (32)$$

where $\sigma_{u,g}$ and $\tau_{u,g}$ (equals to $0.6\sigma_{u,g}$) are the tensile and shear strengths of the gusset plate material.

4.2 Evaluations of the 3-story BRBF hybrid and cyclic loading test results

During the 3-story BRBF tests mentioned previously, the 2nd story gusset to column interface welding fracture was found during the second hybrid test. Another welding fracture was found on the 1st story gusset to base plate interface at the end of the cyclic loading test. Compare Table 1 with Table 2, it can be found that the results of using both the finite element analysis and the aforementioned design procedures show that more than half gusset interface forces is contributed from the frame action effects. This is because

the BRB force demands were relative small (P_{max}=603kN), and the beam size is significant to result in a rather high force demands on the gusset interfaces from the frame action (S=608kN and N=422kN). Figures 13 and 14 show the calculated stress distributions on the 2nd and 1st story gusset interfaces by using the aforementioned design procedures (Eqs. (19) to (26)). Compare Figure 13 with the finite element analytical results shown in Figure 11, both figures show that the peak normal and von Mises stresses concentrate at the gusset tips. Even though the stress distributions obtained from the finite element and simplified analyses are not exactly the same, however, the trends of the stress variation along the gusset interfaces are similar. Table 4 compares the maximum normal, shear, and von Mises stresses on the 2nd story gusset interfaces by using finite element analyses and the proposed design procedures. The peak stresses occur at the gusset tips on both beam and column interface. The peak von Mises stresses computed from the proposed design procedures and the finite element analysis are similar. However, the maximum normal and shear stresses computed from using the proposed design procedures are smaller than the finite element analysis results. This should be reasonable as bi-linear material model has been used in the finite element models, and the frame action in the finite element model results in a high strain and stress concentrations at the gusset tips. It should be noted that. Table 5 shows all the aforementioned limit state checks using Eqs. (27) to (32) for the two gusset plates failed during these tests. For the 1st story gusset, the highest DCR (1.51) is the von Mises stress on the gusset to base plate interface ($DCR_{m,b}$) where the crack was found at the end of the test. And the tension rupture $DCR_{t,b}$ of 1.13 also suggests that the gusset plate bottom edge may rupture. It appears that inadequate gusset thickness is responsible for the gusset fracture near the column base. For the 2nd story gusset, the highest DCR is the von Mises stress on the gusset to column interface ($DCR_{m,c}$=1.22) where the crack was found during the second hybrid test. The high DCR on the beam interface ($DCR_{m,b}$ of 1.03) also suggests that the gusset to beam interface may fail under the large inter-story drifts. Compare the higher $DCR_{m,b}$ of 1.51 in the 1st story than the $DCR_{m,c}$ of 1.22 in the 2nd story (1.22), it may help to explain that the 1st story gusset to base plate interface welding crack occurred rather suddenly and the crack length was more than 55% of the total welding length. However, the 2nd story gusset to column interface welding crack occurred at the gusset tip first in the second hybrid test, and then grew gradually during the cyclic loading test. At the end of the cyclic loading test, the crack length was 34% of the entire welding length of the 2nd story gusset to column interface. Although the maximum DCR in the 1st story gusset is as large as 1.51, the 1st story gusset to base plate weld crack did not occur only until the cyclic loading test. Furthermore, the maximum DCR in the 2nd story gusset is 1.22, however, the gusset interface weld crack was not found until the second hybrid test. Both of the two gussets sustained at least a complete hybrid test with maximum inter-story drift exceeding 0.03 radians. Therefore, these tests confirmed that the proposed design procedure would lead to a conservative and acceptable design.

5. CONCLUSION

Based on these tests and analyses, conclusions can be drawn as follows:

1. In this paper, the gusset interface forces resulted from BRB and frame actions are combined to compute the force demands for gusset plate seismic design.
2. The GUFM is adopted in the gusset plate design procedure as it provides more freedoms for designers to configure the gusset plate shape. The gusset interface forces computed from using GUFM well agree with the finite element analysis results.
3. The gusset interface forces demands result from the frame action effects can be computed from an equivalent strut model. The peak axial force in the strut can be estimated from a beam shear force corresponding to the beam plastic hinge forms at the gusset tip. The BRBF tests and the finite element analyses show that the equivalent strut models can satisfactorily estimate the peak frame action forces on the gusset plate.
4. Based on the finite element analysis results, when the BRB force acts on the gusset plate alone, the normal stress distributions can be assumed uniform along the gusset interfaces. The shear stress distributions can be assume triangular with the peak stresses at the beam to column corner and zero stress at the gusset tips.
5. When the frame action occurs on the gusset plate alone, both normal and shear stress distributions can be assumed triangular with the peak stresses developed at the gusset tips and zero stress at the beam-to-column corner.
6. When the BRB and the frame actions are combined, the calculated stress distributions and the finite element analysis results are similar. The peak von Mises stresses at the gusset interfaces can be well predicted using the proposed procedures.
7. The design limit states of the gusset plate interfaces include von Mises yield stress criteria, tensile, and shear rupture. Based on the BRBF design review and test results, even though the DCRs of the 2nd and 1st story gussets are greater than 1.0, these two gusset plates sustained at least a complete hybrid test with a peak inter-story drift more than 0.03 radian. This suggests that the proposed design procedure could lead to a conservative and acceptable gusset plate design.

Abstract: This paper presents experimental study on effect of out-of-plane stiffness of gusset plate on seismic performance of single angle brace with slenderness ratio of more than 100. Cyclic loading tests were performed with nine test specimens that have various gusset plate connection details. Test results shows AIJ design provision overestimated connection strength when braces connected to gusset plate with low out-of-plane stiffness; achievement of minimum requirements of strength ratio of connection strength to brace strength according to AIJ design provisions by considering effect of out-of-plane stiffness of gusset plate on connection strength results in improvement of deformation capacity of brace

1. INTRODUCTION

In recent earthquake, many conventional steel brace suffering the failure of their connections has been reported (Krawinkler, 1994, AIJ Kinki-branch 1996, AIJ, 2012). One of the conventional braces, single angle braces with large slenderness ratio of more than 100 are commonly used in low-rise conventional braced frame buildings such as factories and gymnasiums in Japan. These types of braces generally are connected to beam and column of frame thorough gusset plate with low out-of-plane stiffness, since they does not expect to resist the compression force. And also brace are connected to gusset plate thorough bolted connection. In the case of single angle braces, out-of-plane bending moment resulting from eccentricity of brace acts on their connection. Therefore, when the out-of-plane stiffness of gusset plate connection is small, severe out-of-plane deformation occurs at connection not only in compression but also in tension as shown in Figure 1. It is concerned that these out-of-deformation deformations induced by lack of out-of-stiffness lead to the decrease in tensile strength of connection since local strain concentration occurs around first bolt due to the secondary bending moment. As a result, brace connection would be failed at net section of brace prior to exert expected sufficient deformation capacity of brace. In this study cyclic loading tests were conducted to discuss the effects of out-of-plane stiffness of gusset plate connection on seismic performance of single angle brace.

2. TEST PROGRAM

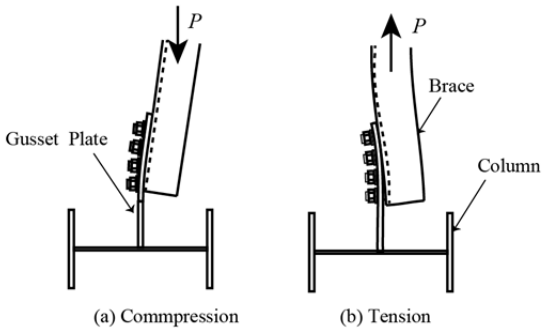

Fig.1 Out-of-plane Deformation of Gusset Plate

2.1 Test Specimen

Configuration of test specimen is shown in Figure 2.the test specimen is taken from the conventional low-rise braced frame building. the test Specimens consist of L steel brace with equal leg. whose slenderness ratio was 140, and gusset plate connection. The dimension of braces was 75mm(width and depth)×6mm (thickness) fabricated of SS400. Braces were connected to one side of gusset-plates with high strength bolts. List of specimens are shown in Table 1 Experimental parameters were connection details which includes the number of bolts(connection length), thickness of plate, with or without side stiffeners and geometric offset of last bolt l_o as illustrated in Figure 3 to alter the out-of-plane stiffness of gusset plate connection.

2.2 Calculated Strength

All of test specimens were designed in accordance with Japanese "Recommendations for Design of

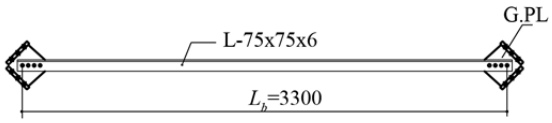

Fig. 2 Configuration of Test Specimen (L-4-6)

Fig. 5 Loading Protocol

Connections in Steel Structure" (AIJ, 2012). The calculated strengths of test specimens are summarized in Table 2. The strengths of connection and brace were calculated using the average measured cross-section dimensions and the measured material properties obtained from the coupon tests summarized in Table 3. The maximum connection strengths of all of specimens were determined by net section fracture regardless of thickness of plate and other connection details. In the case of specimens with five bolts, the ratio of maximum connection strength (N_u) to yield strength of brace (${}_bN_y$) ξ was 1.07. this values satisfied that of minimum requirement ξ_{req} (=1.05) to assure sufficient plastic deformation capacity of brace. On the other hand, ${}_jN_u$ / ${}_bN_y$ of the specimens with four bolts, ξ was 1.01. which was dissatisfied minimum requirement ξ_{req}. it is indicated that the specimens with four bolts would fail by forming net section failure at connection prior to exert plastic deformation capacity of brace.

2.3 Setup and Loading Protocol

Figure 4 shows setup of test specimen. Gusset plate connections were connected to rigid jig to neglect beam and column deformations on out-of-plane behavior of brace. Axial load was applied to specimen by oil jack. Tests were conducted by displacement control using average strain of L_b which was length between last bolt hole of one side connection and that of other side connection described in Figure 4. Figure 5 shows loading protocol. The amplitudes of applied average strain were 0.1, 0.5, 1 and 2%. After cyclic loading, monotonic loading in tension was conducted until specimen was failed, when specimen did not fail during cyclic loading. Longitudinal displacements and out-of-plane displacements as well as applied load were measured by using LVDTs and load cell embedded in oil jack respectively. Strain gauges were attached at brace net section and gusset plate.

3. TEST RESULTS AND DISCUSSIONS

3.1 Overview of Test Results

All of specimens were failed by forming of net section

Fig. 8 Measurement Points of Connections

failure as shown in Photo 1. Extensive out-of-plane deformations as shown in Photo 2were observed in specimens with thin gusset plate not only in tension but also in compression. Axial load versus axial strain of the brace are shown in Figure 6. Calculated value of connection strength determined by net section fracture is also plotted as dashed line. Specimens with 4 bolts were failed prior to axial strain reaches to 2%. At this time, significant plastic deformation along the braces could not be observed . On the other hand, specimens with 5 bolts which have larger strength compared with specimen with 4 bolts could not be failed during cyclic loading except specimen L-5-6 with gusset plate of 6 mm. Finally, specimen with 5 bolts except L-5-6 showed large deformation capacity exceed 4% which

(a) n=4 (b) n=5

Fig. 9 Relations between Out-of plane Moment and Rotation

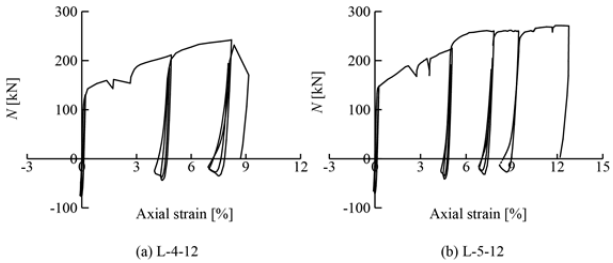

Fig. 10 Load-Local Strain Measured at Net Section Curves

corresponds to approximately more than 5% story drifts in -X-steel braced frame. However, L-5-6 was failed before it reach 2% as is the case with specimens with four bolts.

3.2 Out-of-plane Behavior of Connections

Out-of-plane displacements observed in first compressive loading are shown in Figure 7. Out-of plane displacements were measured at the points described in Figure 8. In the case of specimens with geometric offset of last bolt hole in direction toward the center of brace of 40mm, out-of-plane deformation were occurred starting from point at the intersection of the line connecting with corner of welding with brace axis as shown in Figure 2. In specimens with geometric offset in direction toward the corner of gusset plate, out-of-plane deformation was occurred starting from last bolt. Based on these results, relations between out-of plane bending moment and rotation was obtained as shown in Figure 9. It is confirmed that out-of-plane stiffness of gusset plate connection were increased not only by increasing thickness of plate and geometric offset toward the corner of gusset plate. Especially, by attaching side stiffener, out-of-plane stiffness of connection increased approximately eight times of non-stiffener connection.

3.3 Axial Strains at Net Section

Relations between axial load and axial strain measured at the point beneath the first bolt hole were shown in Figure 10. Axial strains occurred under compression force was not significant. Consequently, Axial strains increases monotonically in tensile direction. It can be concluded that out-of-plane deformation due to the compression force did not lead to significant damage to net section for this test.

Figure 11 shows that axial strains occurred at net section in L-4-6 and L-4-12, when axial force was 50kN (Braces including connection remain elastic) Calculated values which were calculated by considering out-of plane stiffness of gusset plate is also plotted in Figure 9(c). In these figure, distance from edge of web was reset by transforming net section as shown in Figure 9(a). When brace remain elastic, axial strains observed in L-4-6 were slightly larger than that of L-4-12. The calculated values include gusset plate contribution had good correspondence with measured value for both L-4-6 and L-4-12. On the other hand, calculated value ignore the out-of-plane stiffness of gusset plate connection, significantly overestimate the test results

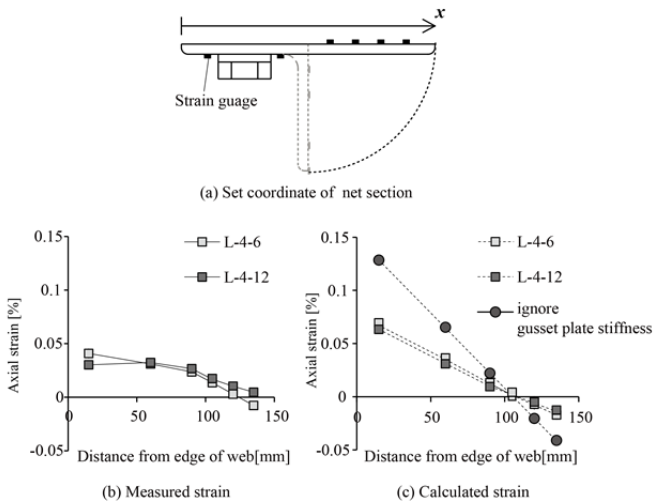

Fig. 11 Axial Strains Measured at Net Section (N=100kN)

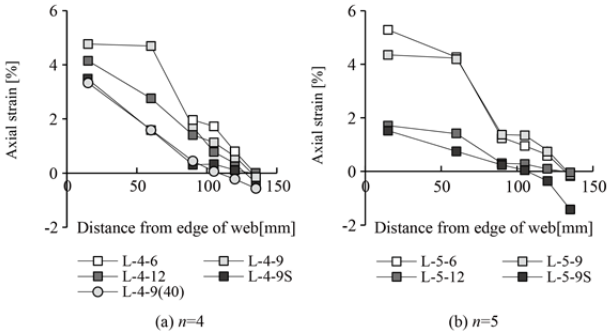

Fig. 12 Axial Strains Measured at Net Section (N=200kN)

This results indicated that gusset plate contribute to the out-of-plane resistance of connection subjected to eccentrically tension loading. Figure 12 shows that strain distribution in net section when it reach 200kN. In plastic region, strain concentration occurred at fracture point, was significant. Magnitude of the strain concentration was increased by out-of-plane stiffness of the gusset plate was reduced. It appears that the decrease of strength capacity was caused by these strain concentration along the web.

3.4 Effect of Out-of-plane Stiffness on Strength and Deformation Capacity

Figure 13 shows measured maximum strength divided by estimated yield strength. These values are plotted as a function of restraint factor k_r defined by following equations In this figure, previous experimental data (Asada, 2012) were also plotted.

$$k_r = \frac{k_{rb}}{k_{ro}} \tag{1}$$

$$k_{ro} = \frac{2EI_b}{l_b} \tag{2}$$

where, k_{ro} : out-of-plane stiffness of connections obtained from test results, I_b: moment inertia of brace, l_b: buckling length of brace As shown in this plots, connection strength

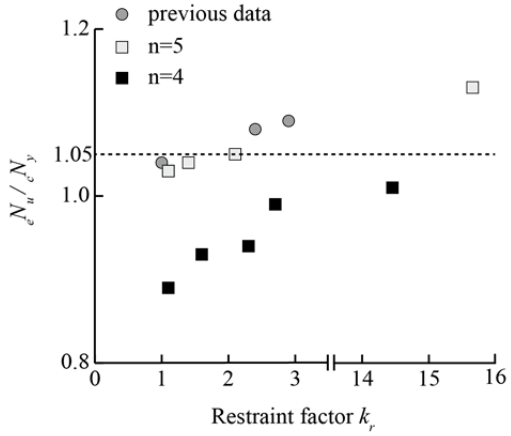

Fig. 13 Relation of Strength Capacity and Restraint Factor

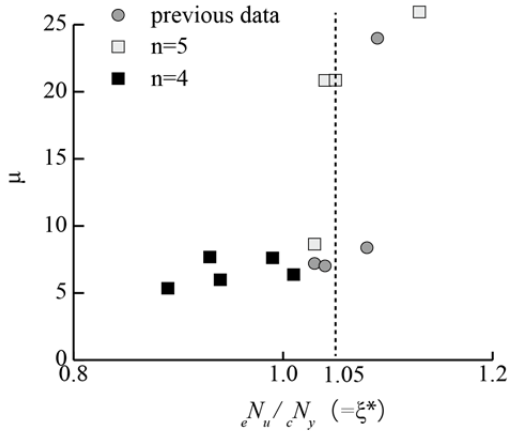
increased as the out of plane stiffness of gusset plate connection get higher in the range of 1.0 to 2.0 of k_r. On the other hand, out-of-plane stiffness had small effect on connection strength when k_r exceed 2.0. Based on these results, plastic deformation capacity is discussed here. Figure 14 shows Relation between deformation capacity represents as ductility factor and cumulative plastic deformation ratio given by following equations, and the ratio of maximum strength to yield strength ξ*.

$$\mu = \frac{\delta_u}{\delta_y} \tag{3}$$

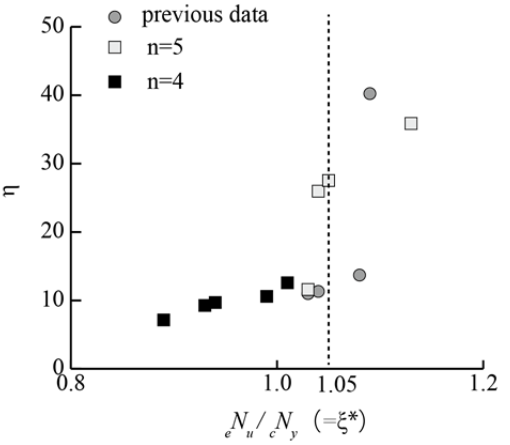
$$\eta = \frac{W_p}{P_y \cdot \delta_y} \tag{4}$$

where, δ_u : axial deformation of brace at maximum strength, δ_y : axial yield deformation based on calculated yield strength of brace, P_y: calculated yield strength of brace. Deformation capacity was also improved by increase of connection strength provided by means of increase of out-of-plane-stiffness. It should be noted that deformation capacity was dramatically improved when ξ * was more than 1.05 which corresponds to minimum requirement of AIJ design provision.



3. CONCLUSIONS

This paper presents the results of cyclic loading tests of single angle brace with large slenderness ratio focusing on the out-of-plane stiffness of gusset plate. Test results were summarized as follows;



Out-of-plane stiffness of gusset plate had effects on strength when failure mode was determined by net section failure.

AIJ design provision overestimated the maximum strengths of specimens with low out-of plane stiffness because magnitude of local strain concentration at fracture point was increased by decrease of gusset plate stiffness

Connection strength capacity was improved by increase

(a) Ductility factor

(b) Cumulative plastic deformation ratio

Fig. 14 Relation of Deformation Capacity and Strength

of out-of-plane stiffness of gusset plate. As a result, deformation capacity of brace was also improved.

Abstract: Slit-dampers are one of the frequently used dampers with many advantages, such as light-weight, easily replaceable, low-cost, and stable hysteresis characteristics. By changing the damper shapes, slit-dampers can be set at different locations in the structures. Most of the current research about slit-dampers focuses on the low-cycle fatigue behavior of dampers with certain shapes. However there is no universal evaluation method of the low-cycle fatigue behavior of slit-dampers with various shapes. As a result, there are no available design guidelines for slit-dampers. The main purpose of this study is to quantitatively evaluate the low-cycle fatigue behavior of slit-dampers with different shapes. In this paper, the first step of this study, cyclic loading tests of slit-dampers with various shapes are reported. Eight series of different shaped slit-damper specimens (flexural yielding type) are made of SN400B steel, which is one of the most common used structural steel in Japan. Constant amplitude cyclic loadings are applied to the specimens in order to obtain the fatigue curve. The effects of each shape parameter on the low-cycle fatigue behavior are evaluated through the tests results.

1. INTRODUCTION

Passive control structural systems with seismic dampers have achieved significant progresses in recent decades (for example: Roeder et al., 1977, Uang et al., 2004). In this type structural system, dampers dissipate most of the earthquake induced energy to minimize damage to the parent structures (Wada et al., 1998). The energy dissipation of dampers can be achieved by different mechanisms: friction, plastification of metals, deformation of viscoelastic solid or liquid, etc. In particular, one of the most popular dampers is the hysteretic dampers usually made of metallic materials. Generally, during moderately severe earthquakes these dampers act as stiff members which reduce structural deformations, while during very severe earthquakes hysteretic dampers dissipate the earthquake input energy (Skinner et al., 1975).

There are many kinds of hysteretic dampers such as steel triangular plate dampers TADAS (Tsai et al., 1993), buckling restrained braces (for example: Maeda et al., 1998), honeycomb dampers (Kobori et al., 1992) and steel slit-dampers (Wada et al., 1997). Among them, steel slit-dampers are known to have stable and large energy dissipation capacity. This kind of dampers is fabricated by simply cutting slits on steel plates, leaving a number of strips in between (Figure 1). All slits are rounded at their ends to reduce stress concentration. High tension bolts are set at the end of the plates to connect the dampers to the parent structures. Each strip behaves as a fixed-ended beam and deform in double curvature. Plastic hinges formed at the end of the strips to dissipate energy under deformation. This kind of device is light-weighted and can be easily set and replaced at various locations in the structures where necessary. By changing the shape of the damper, its stiffness, strength, and energy dissipation capacity can be adjusted to different levels to meet the need of structural design. Moreover, steel slit-dampers are sensitive to small deformation too. Therefore, they are not only effective under large deformation due to major earthquakes. Under long duration earthquake with relatively small deformation amplitude, slit-dampers are also helpful in restraining structural shaking.

Research has been done related to the dampers low cycle fatigue behavior and hysteretic characteristics. Cyclic loading tests were performed; the results demonstrated stable hysteretic behavior and adequate energy dissipation capacity (Chan et al., 2008, etc.). In (Wada et al., 1997) real time speed tests were carried out, which showed that loading speed does not seem to affect the damper's hysteretic characteristics significantly. However, in most of the current research work, only slit-dampers with very limited geometries were studied, while "shape" is one of the most important variables in the design of slit-dampers as well as the structures with slit-dampers inside. As a result, there is no practical design guideline for structures with slit-dampers

which makes it difficult to use this type of device.

For the purpose of building up the design guideline for slit-dampers, it is necessary to clarify how geometric shapes affect the energy dissipation capacity and hysteretic characteristics of slit-dampers. In this paper, preliminary experimental study of slit-dampers of various shapes was carried out. Basic information of the influence of geometries on the behavior of slit-dampers is obtained from the tests.

2. CYCLIC LOADING TESTS OF SLIT-DAMPERS

2.1 Specimen Information

Four different types of slit-damper specimens were loaded in the cyclic loading tests. For each specimen type, 3 specimens were prepared for the tests under different loading histories. All specimens were flexural yielding members where bending moment is the main reason that causes yielding of the dampers.

Figure 1 and Table 1 show the basic information of the specimens. Specimen SLD_1 was taken as the basic model in the tests, while specimens SLD_2~SLD_8 were designed by changing one or several of the shape parameters from specimen No.1. The main parameters in this study include: radius at the end of the slits (R), depth of the strips (B), number of the strips (N), thickness of the damper plate (T), and length of parallel sections of the strips (H). In phase I tests, specimens SLD_1~SLD_4 were loaded till their ultimate states, which will be reported in this paper.

Blast furnace steel plate (SN400B) is used to fabricate the specimens. SN400B steel is one of the structural steel that is commonly used in Japan in recent years in steel buildings. The yield strength is 300MPa while the ultimate strength is 428MPa according to the coupon tests (T=16mm). Figure 2 shows the stress-strain relationship of the material (T=16mm) obtained from coupon tests using JIS-1A test pieces.

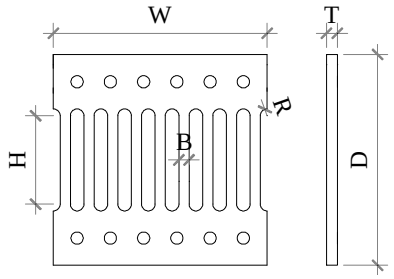

Figure 1 Shape parameters of slit-damper specimens

2.2 Test Setup

Figure 3 shows the test setup details. The specimen was connected to L shape jigs at top and bottom parts through M16 high tension bolts to form the fixed connections. The lower L shape jigs were set up through the reaction jig, with the latter fastened onto the reaction frame to offer horizontal and vertical support. A loading jig connecting the upper L shape jigs and the oil jack (maximum load capacity of 200KN) which was installed horizontally on the reaction frame composed the loading system. Moreover, lateral supports (stiffening systems) consisting of 4 truss members were set at both sides of the specimen to avoid out-of-plane deformation of the whole system. At the same time, this stiffening system was capable to deform following the trail of the specimen under horizontal loading, in other words, to keep the loading jig horizontal during the tests.

2.3 Measuring System

Deformation

Four displacement transducers (LVDT) were set up to measure the shear deformation (δ) of the specimens, which is defined in Eq. (1). Locations of these transducers are shown in Figure 4.

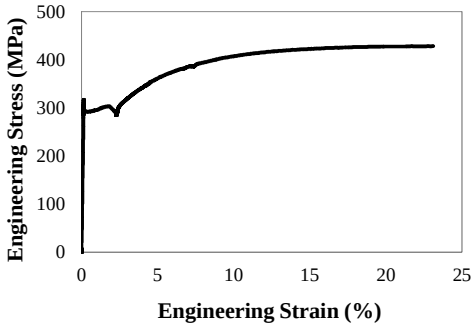

Figure 2 Coupon tests results (T=16mm) (JIS-1A)

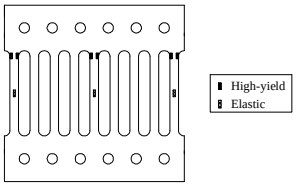

Figure 6 Strain gauge arrangements

$$\delta = \frac{(|\delta_1| + |\delta_2|) - (|\delta_3| + |\delta_4|)}{2} \quad (1)$$

where δ1 and δ2 are the deformation recorded at the top (left & right) of the damper specimens; and δ3 and δ4 are the deformation recorded at the bottom (left & right) of the specimens.

Load

Shear force is recorded through the built-in load cell in the oil jack. Notice that in order to obtain the horizontal force applied to the damper; one displacement transducer (LVDT) was set to record the rotation of oil jack's loading end (Figure 5).

Strain

Figure 6 shows the strain gauge arrangements. High-yield strain gauges, which work effectively under large strain, were attached to the ends of the parallel sections in both sides and the middle strips where significant strain concentration is expected to occur. Elastic strain gauges were attached at the center of the above mentioned strips (front and back sides) to track the axial force in the specimen.

2.4 Loading Histories

The loading history is another variable of this experiment. In order to estimate the fatigue behavior of the slit-dampers, for each type of damper specimen (three specimens), three deformation-controlled cyclic loading histories with different constant amplitudes were employed. The amplitudes were set as $\pm 8mm$, $\pm 24mm$, and $\pm 40mm$.

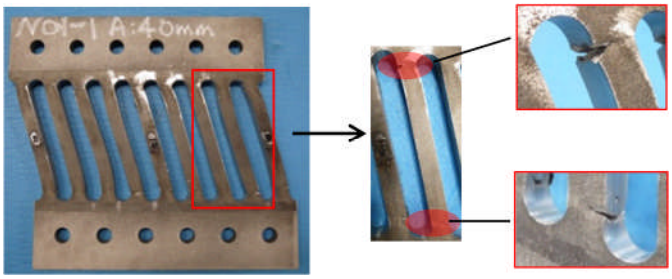

Figure 8 Ductile failure/cracks of SLD_1

3. EXPERIMENTAL RESULTS

3.1 Force-deformation Relationships

Each specimen was loaded till fracture during the tests. As an example, the force history during loading till fracture of SLD_1 is shown Figure 7. It is observed that the maximum force of each cycle decreased rapidly after it dropped below 90% of the maximum value during the whole loading procedure. Therefore, the ultimate states of the slit-dampers were defined to be the point when the maximum force of a certain cycle dropped below 90% of the maximum value. The numbers of loading cycles till the ultimate states of the specimens are listed in Table 2.

Ductile cracks initiated at the end of the parallel sections of each strip close to the rounded toes of the slits during the loading of all specimens. In the wake of loading, those cracks propagated wider and longer, which led to the decrease of the load carrying capacity of the dampers. Figure 8 shows the failure of specimen SLD_1 and its ductile cracks.

The force-deformation relationships from SLD_2 and SLD_3 are shown in Figure 9 as examples, with the 90% maximum force points pointed out. For each type of specimen, the experimental results under 3 different loading histories are shown. The graphs in Figure 9 indicate stable hysteresis loops of all specimens till the ultimate states of the dampers, which are likely to be simplified as bi-linear hysteretic models. The yield point and maximum force of SLD_3 are larger than those of SLD_2 due to large strip

depths.

3.2 Fatigue behavior

In order to investigate the fatigue characteristics of slit-dampers with different shapes, the experiment results are plotted into the log-log graph (Figure 10). The X-axis is the number of loading cycles till ultimate state, and the Y-axis is the full amplitude of each loading history (Manson-Coffin relations) (Manson, 1954, and Coffin et al., 1954). The ultimate number of loading cycles decreases while the deformation amplitude increases. For each type of specimens, linear relations can be found between the plots. However, for the specimens of different geometries, different Manson-Coffin relations are observed. The trend lines of the specimens approximately parallel with each other in this experiment. The steel material all comes from the same lot is considered to be the reason.

The plastic deformation capacity (energy dissipation capacity) of slit-dampers is evaluated by studying the cumulative plastic deformation ratio (η) of the specimen. η is defined as follows (Eq.(2))

$$\eta = \frac{W_p}{Q_p \cdot \delta_p} \tag{2}$$

where W_p is the plastic energy dissipation of the steel slit-damper; where Q_P is the experimental full-plastic shear force of slit-damper, and δ_p is the experimental elastic slit-damper rotation corresponding to Q_P. The values of η are also shown in Table 2. Figure 11 is the comparison of energy dissipation capacity of specimens SLD_1 to SLD_4 in terms of the cumulative plastic deformation ratio. The energy dissipation gets smaller when raising the deformation amplitude.

From Figure 10 and Figure 11, basic information of how shape factors influence the fatigue behavior of steel slit-dampers is obtained.

When the total length of the strip (including the rounded ends) remains unchanged, larger R results in shorter parallel sections of the strips. Being loaded to the same deformation amplitudes, SLD_2 (R=15mm) reached failure earlier than SLD_1 (R=10mm). At the same time, the energy dissipation capacity of SLD_2 is also smaller than that of SLD_1. Strain concentration due to the changing of R seems to be the minor influencing factor in this case.

Specimens with larger depth of the strips (SLD_3) reached failure earlier than the ones with smaller depth of strips (SLD_1) under same loading amplitude and dissipate smaller amount of energy; because the fiber at the edges of the fat strips deforms harder than that of the thin strips.

Slit-dampers with more strips (SLD_4) show worse fatigue behaviors compared to the ones with fewer strips (SLD_1). A part of reason might be the slight slope of the

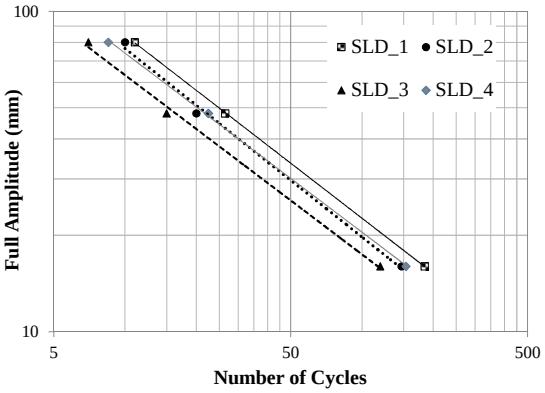

Figure 10 Fatigue life (S-N curve)

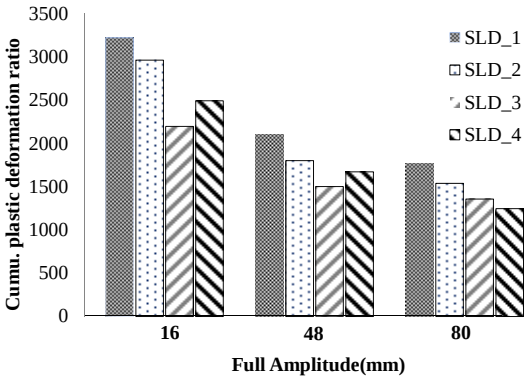

Figure 11 Comparison of energy dissipation capacity

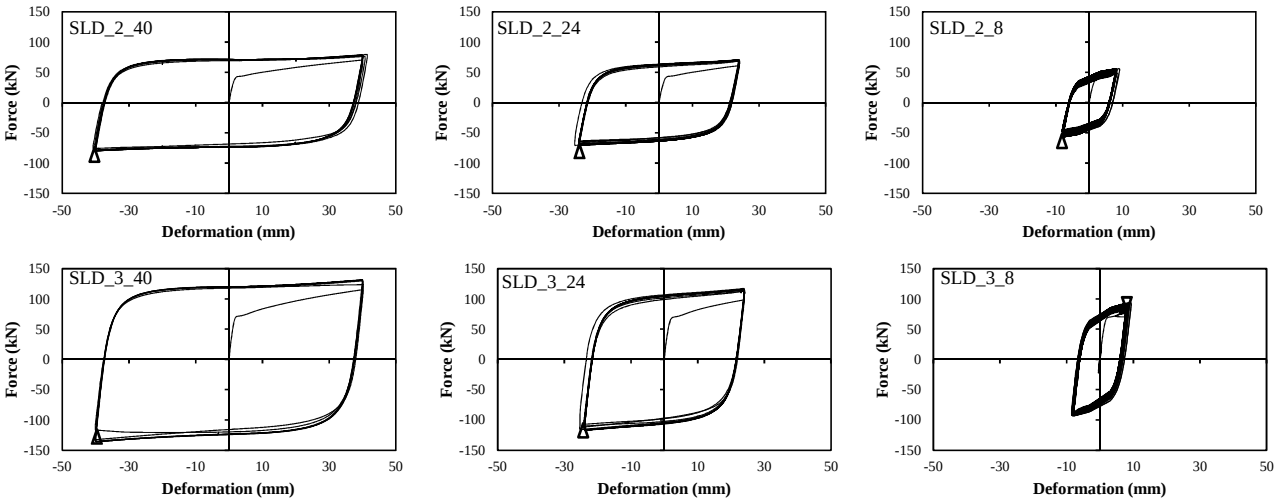

Figure 9 Force-deformation relationships of SLD_2 and SLD_3

loading jig during the tests. The slit-dampers with more strips are wider, which make them more sensitive to the axial force caused by the slight slope of the loading jigs. This phenomenon may also happen at certain locations in real buildings where slit-dampers are installed.

3.3 Local Strain States

To each specimen, 6 high-yield strain gauges were attached to the end of the strips. As an example, the strain histories (first three cycles) at the end of one of the strips' parallel sections from SLD_2 are shown in Figure 12. Under the deformation amplitude of 40mm, the strain recorded in the first loading cycle reached out to 10%, which damaged the strain gauge easily. Therefore, only the data under the amplitude of 24mm and 8mm are shown. The strain under larger loading amplitude grew significantly during the tests, which also showed quick increasing in each cycle. The whole strain histories shifted to the tension side during loading due to the residual strain after plastification.

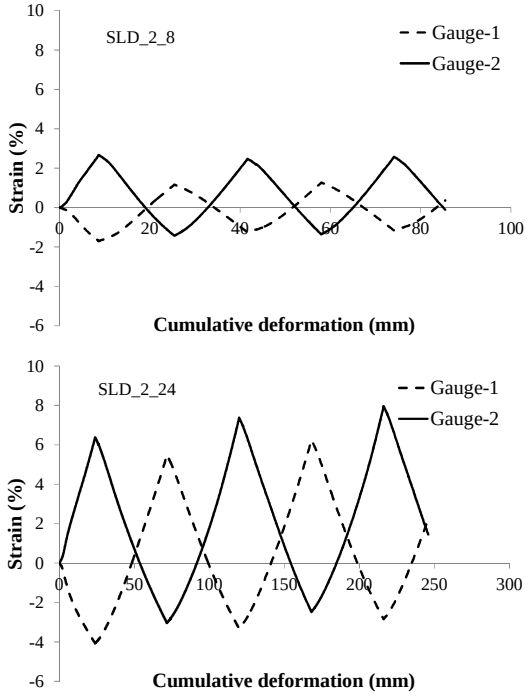

Figure 12 Strain histories of SLD_2 at the end of the strips

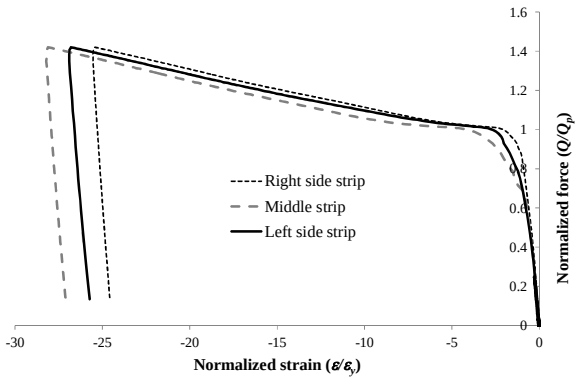

Figure 13 Normalized strain of SLD_1_24mm(1st half cycle)

Figure 13 shows the strain measured through the high-yield strain gauges in the first half loading cycle of specimen SLD_1, with the deformation amplitude of 24mm. The recorded strain is normalized by yield strain when the Y-axis shows the force normalized by the experimental yield force of SLD_1. The strain histories of the right, middle, as well as the left strips in SLD_1 are highly close to each other, which confirm that loading is uniformly distributed between the strips in the slit-damper.

4. CONCLUSIONS

Steel slit-damper is one type of hysteretic dampers that has lots of advantages. In this paper, basic information about the influence of geometries on the behavior of slit-dampers was obtained through cyclic loading tests.

In the future, more experiments are to be carried out to enrich the variables. Together with some numerical analyses, the ultimate objective is to quantitatively evaluate the plastic energy dissipation capacity of steel slit-damper of various shapes under random loading histories.

Abstract: This study is aimed to analyze the ultimate situation of bridges under extreme earthquakes in 3-D space. Since the Vector Form Intrinsic Finite Element (VFIFE) has the superior in managing the engineering problems with material nonlinearity, discontinuity, large deformation, large displacement and arbitrary rigid body motions of deformable bodies, it is selected to be the analysis method in this study. The analysis methods for sliding of structures and fracture of elements are developed to predict the failure process of the bridges in 3-D space. Through numerical simulation of an bridge with a three-span-continuous deck and unseating prevention devices, the ultimate state is demonstrated. The results confirm that the VFIFE is a powerful computation method to simulate the failure behavior of bearings, columns as well as unseating prevention devices and to predict the collapse situation of bridges.

1. INTRODUCTION

In the past extreme earthquakes, such as Kobe earthquake and Chi-Chi earthquake, a number of bridges suffered damage with unseating of the superstructures. Isolated bridges have been extensively used to mitigate the induced seismic forces by a shift of natural period. However, the trade-off is that the deck displacement becomes excessively large when subjected to a ground motion with large intensity or unexpected characteristics. Such a large displacement may increase the hazard of the unseating of decks. Therefore, unseating prevention devices are important for isolated bridges in particular (Kawashima and shoji 2000). Lately, modern bridge seismic design has been developed toward the seismic performance design on whole bridges as well as their elements. Understanding of the performance of the components of bridges, such as bearings, unseating prevention devices, columns, under extreme condition shall be favorable to determine the goal of performance. In this paper, a new nonlinear structural dynamic analysis method is used to simulate the dynamic behavior of the isolated bridges with unseating prevention devices under extreme earthquakes.

The Vector Form Intrinsic Finite Element (VFIFE), a new computational method developed by Ting et al. (2004), is adopted in this study because the VFIFE has the superior in managing the engineering problems with material nonlinearity, discontinuity, large deformation, large displacement and arbitrary rigid body motions of deformable bodies. To simulate the extreme situation of bridges in 3-D space, the analysis methods for sliding of structures and fracture of elements are developed in this study. Numerical simulation of a practical bridge with unseating prevention devices is conducted to predict the failure process. The results present the design concept of the fracture sequence of the structural components. Due to the insufficient strength of the unseating prevention devices, the unseating of decks occurs under an ultimate condition.

2. VECTOR FORM INTRINSIC FINITE ELEMENT

The Vector Form Intrinsic Finite Element has been developed based on theory of physics to simulate failure responses of structural systems due to applied loads. The first step in the VFIFE analysis is to construct a discrete model for a continuous structure by using a lumped-mass idealization. It is noted that all lumped masses are connected by deformable elements without mass. Then applying Newton's Second Law of Motion, the equations of motion are assembled at each mass for all degrees of freedoms. Assume that a structural system consists of a finite number of particles. A particle designated as α has a diagonal mass matrix $\mathbf{M}^{\alpha}$ and a displacement vector $\mathbf{d}^{\alpha}(t)$ at time t. The equations of motion for particle α are written as

$$\mathbf{M}^{\alpha}\ddot{\mathbf{d}}^{\alpha}(t) = \mathbf{P}^{\alpha}(t) - \mathbf{f}^{\alpha}(t) \tag{1}$$

where $\mathbf{P}^{\alpha}$ are the applied forces or equivalent forces acting on this particle; $\mathbf{f}^{\alpha}$ are the total resistance forces or internal resultant forces exerted by all the elements connecting with this particle.

Note that each element without mass in the VFIFE is assumed to be in static equilibrium. Observed from Eq. (1), it is not necessary to assemble the global stiffness matrix for structures with multiple degrees of freedom in the VFIFE analysis. A matrix algebraic operation for the entire system is

waived. Instead, each equation of motion for each particle, Eq. (1), can be individually solved. Since the failure progress of structures involves changes in material properties and structural configuration, discrete time domain analysis is used to solve the equations of motion. The central difference method, an explicit time integration method, is adopted to solve the equations of motion, Eq. (1).

Compared to the traditional finite elements, the feature of the VFIFE is that element internal forces are calculated by deformations of elements through subtracting rigid body motion from total displacements. Therefore, a set of deformation coordinates are defined for each element in each time increment. The VFIFE is capable of dealing with large displacements, deformations and rigid body motion simultaneously.

3. SIMULATION OF ULTIMATE STATES

Bridges may undergo highly nonlinear behavior even structural failure when subjected to strong earthquakes with ground dislocation. In the past large earthquakes, a number of bridges suffered deck unseating, which is high nonlinearity along with rigid body motion. To simulate the collapse mechanism of bridges, the failure mechanism of major bridge components should be taken into account.

The failure components may be high-damping-rubber isolators, unseating prevention devices and plastic hinges of decks and columns. Firstly, isolators are idealized as a bilinear model. Assume that the bearings fracture as the resistance force reaches rupture strength. Once the isolator ruptures, there is no resistance shear force between the superstructure and column other than the friction force in the interface. When the relative displacement between superstructure and column exceeds the unseating prevention length, the superstructure will lose the supporting force provided by the column and then fall down from the column due to the gravity force.

The failure of isolators represents a typical failure mechanism completing material linear and nonlinear hysteretic behavior, fracture, and sliding of structures. The writers have developed the nonlinear elements in VFIFE in the previous study. This paper herein introduces the analytical methods for sliding structures and fracture of elements in VFIFE (Lee et al. 2009, 2010).

3.1 Elements with a Gap or a Hook

Whenever deck unseating failure occurs, local cracking or crushing due to pounding between superstructures can be observed in the sites. To simulate the pounding effect, the pounding force during collision is generally modeled by impact elements. The simplest impact element first developed by Kawashima and Penzien (1979) is a linear elastic spring model simulated by an element with a gap.

The unseating prevention devices are generally with non-working length before they are triggered to function. There are two categories of the unseating prevention devices, compression and tension. The compression device, such as a stopper, is idealized as an element with a gap, whereas the tension device is idealized as an element with a hook. The elements with a gap or a hook in the VIFIFE have been developed for studying the effectiveness of unseating prevention devices. (Lee et al., 2009, 2010)

3.2 Sliding of Structures

After a bearing ruptures, the interface between the superstructure and the column turns to a sliding surface if the relative displacement between the superstructure and the cap beam of column is still within the unseating prevention length. The motion on the sliding surface can be separated into stick and slip phases. When the friction force is smaller than the maximum static friction force, there is no relative motion in the interface, i.e. in stick phase. Once the friction force overcomes the maximum static friction force, relative movement starts in the interface and the friction force converts to dynamic friction force, i.e. in slip phase. In this study, assume that the maximum static friction force is equal to the dynamic friction force, and the dynamic friction coefficient remains constant during sliding.

In the calculation process of the VFIFE, the material properties and structural configuration are assumed to be unchangeable in each time increment. Therefore, the interface should be in either stick phase or slip phase during each incremental time. Before solving the response at next time step $i+1$, the condition at the interface must be determined. In this study shear-balance procedure, which was proposed by Wang et al. (2001) for analyzing sliding structures by state-space approach, is used to determine which phase the interface is in.

The first step is to calculate the friction force in the interface on assumption of stick phase. It is noted that the relative displacement is null in stick phase. The interface is in stick phase if the calculated friction force is less than the dynamic friction force while it is in slip phase if the calculated friction force is equal or larger than the dynamic friction force.

Figure 1 illustrates the motion of the superstructure with mass $\mathbf{M}^p$ and the column with $\mathbf{M}^b$ at time step i and $i+1$. The equations of motion for the two masses in numerical integration equations are

$$\hat{\mathbf{K}}^p \mathbf{d}_{i+1}^p = \hat{\mathbf{P}}_i^p - \mathbf{f}_{Fi} \tag{2}$$

$$\hat{\mathbf{K}}^b \mathbf{d}_{i+1}^b = \hat{\mathbf{P}}_i^b + \mathbf{f}_{Fi} \tag{3}$$

where $\hat{\mathbf{K}}^p, \hat{\mathbf{P}}_i^p$ are the effective stiffness and force, respectively; $\mathbf{f}_{Fi}$ is designated the friction force in the interface. If the interface is in stick phase, the relative displacement $\mathbf{u}_i = \mathbf{d}_i^p - \mathbf{d}_i^b$ between the superstructure and the column at time step i is the same as the relative displacement $\mathbf{u}_{i+1} = \mathbf{d}_{i+1}^p - \mathbf{d}_{i+1}^b$ at time step $i+1$.

$$\mathbf{d}_{i+1}^p - \mathbf{d}_{i+1}^b = \mathbf{d}_i^p - \mathbf{d}_i^b \tag{4}$$

Rearranging and substituting Eqs. (2) and (3) into Eq. (4), the calculated friction force $\mathbf{f}_{Fi}$ is obtained as

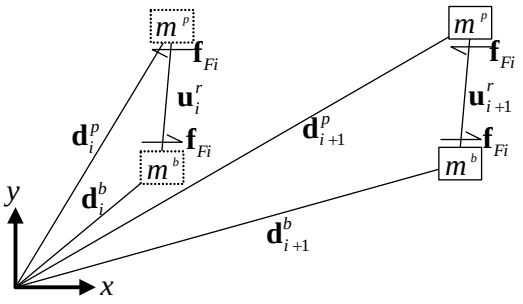

Figure 1 The motion of the superstructure and the column

$$\tilde{\mathbf{f}}_{Fi} = \frac{\hat{\mathbf{K}}^b \hat{\mathbf{P}}_i^p - \hat{\mathbf{K}}^p \hat{\mathbf{P}}_i^b - \hat{\mathbf{K}}^p \hat{\mathbf{K}}^b \left(\mathbf{u}_i^p - \mathbf{u}_i^b \right)}{\hat{\mathbf{K}}^p + \hat{\mathbf{K}}^b} \tag{5}$$

If the calculated friction force $\tilde{\mathbf{f}}_{Fi}$ is less than the dynamic friction force, the assumption of stick phase is correct and the calculated friction force can be used in the next time increment, i.e. $\mathbf{f}_{Fi} = \tilde{\mathbf{f}}_{Fi}$. Otherwise, the interface is in slip phase. The friction force $\mathbf{f}_{Fi}$ must be substituted by dynamic friction force μN, i.e. $\mathbf{f}_{Fi} = \mu N$. The above can be summarized as

$$\begin{cases} \mathbf{f}_{Fi} = \mu N & \text{if } \tilde{\mathbf{f}}_{Fi} \geq \mu N, \text{ slip phase} \\ \mathbf{f}_{Fi} = \tilde{\mathbf{f}}_{Fi} & \text{if } \tilde{\mathbf{f}}_{Fi} < \mu N, \text{ stick phase} \end{cases} \tag{6}$$

3.3 Fracture of Elements

The design principle of isolated bridges is the appropriate utilization of isolators and dampers to shift the main periods of vibration and increase the energy-dissipation capacity of the structures. High-damping-rubber bearings are commonly utilized and can be idealized by a bilinear model. In addition, it has been shown in the past study that the columns of isolated bridges may exhibit nonlinear behavior under extreme earthquakes (Lee and Kawashima 2007). The bilinear model can also be used to idealize reinforced concrete columns and steel columns. It must be carefully managed in constructing the bilinear element of the VFIFE for the loading, unloading and reloading paths. The unseating prevention devices are designed to provide the function against unseating. The unseating prevention devices are generally with non-working length before they are triggered to function. Therefore they are idealized as elements with a hook or/and a gap.

All properties and configuration of elements are assumed to be unchangeable in each time interval $t_i \leq t \leq t_{i+1}$ in the VFIFE. The internal forces are calculated based on the element properties and configuration at the initial time t_i. The deformation coordinates of elements are redefined at the beginning of each time step. Therefore, once an element undergoes nonlinear or discontinuous behavior, all changes are reflected at the beginning of next time step. In this study, the aforementioned elements are considered failure components. Assume that an element fractures as its deformation reaches rupture deformation. At the beginning of each time step it is checked where the element failures or not. Once the element meets the fracture condition, the element and its restoring forces are released from the system.

4. NUMERICAL SIMULATION

A three-span isolated bridge with total length of 3@40 m = 120 m and a width of 12 m, which is supported by two reinforced concrete columns with a height of 12.2 m in each and two abutments, as shown in Figure 2(a), is designed based on the Japan highway bridge design codes. In addition, a three-span bridge with hinge and roller bearings shown in Figure 2(b) is also analyzed to study the failure mechanism. The columns are idealized as a perfect elastoplastic model with a fracture ductility of 21.5 shown in Fig. 3(a). The isolators are idealized as a bilinear elastoplastic model with a fracture shear strain of 500% by general material experiment, as shown in Fig. 3(b). However, in Eastern Japan Great

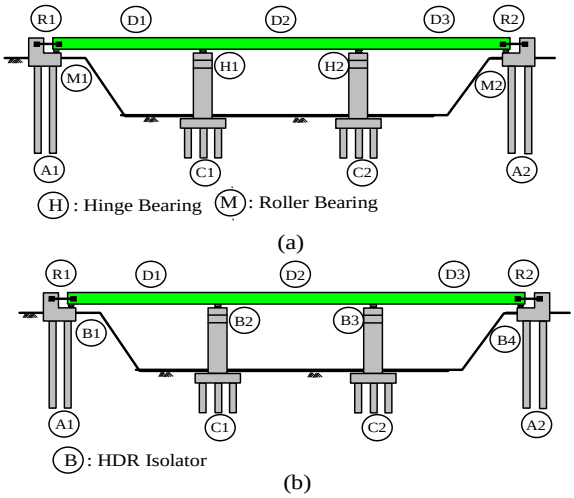

Figure 2 Three-span continuous bridge with unseating prevention devices (a) ridge bearings (b) isolator bearings

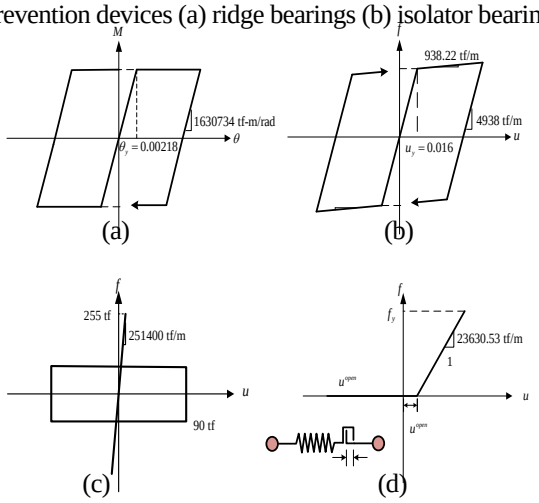

Figure 3 Material properties (a) column (b) isolator (c) hinge bearing (d) steel tendon

Earthquake, isolators failed at the shear strain smaller than 500%. In this study, the dynamic behaviors of bridge with different fracture shear strains of isolators are compared. The hinge bearings and roller bearing are idealized as a linear model with a fracture shear of 168 tf and a friction model, respectively, as shown in Figure 3(c). After hinge bearings rupture, the dynamic friction coefficient at the interface is assumed to be 0.15. The dynamic friction coefficient of roller bearings is assumed to be 0.1.

Steel tendons are installed at each expansion joint as the unseating prevention devices. The tendons are simulated by a tension element with a yielding force of 85.74 tf, an ultimate force of 94.96 tf and a hook of 40 cm shown in Figure 3(d). The pounding effect of two adjacent decks is also considered by using an element with a gap of 28 cm. The unseating prevention length at each column and abutment is 96 cm. In simulation, the bridges are subjected to near-field ground motions recorded at JR Takatori and JMA station, in the 1995 Kobe, Japan earthquake and 1999 Chi-Chi, Taiwan earthquake. The ground acceleration is amplified from 100% to 300% at an increment of 10%.

Through numerical simulation of bridges, the ultimate states are demonstrated and compared. It is interesting to observe that the isolated bridge with 500% of fracture shear strain suffers unseating of the superstructure severer than that with 300% of fracture shear strain. Figure 4 depicts the failure procedure of the bridge with hinge and roller bearings and 0.3 of friction coefficient under 160% of the Chi-Chi earthquake. Figure 5 shows the failure procedure of the isolated bridge with 500% of fracture shear strain and 0.15 of friction coefficient under 220% of JR Takatori ground motion. The first characters H, M, B, C, D and R of the notions denote the hinge bearings, roller bearings, isolators, column, deck and tendon, respectively. It is noted that all the collapse is attributed to column failure because the fracture shear force of the isolators is larger than the fracture force of the columns, in particular, for the isolated bridge with 500% of fracture shear strain. The results show that lager fracture shear strain does not increase the safety of the studied bridges.

5. CONCLUSIONS

Since the VFIFE has the advantages in managing the engineering problems with material nonlinearity, discontinuity, large deformation, large displacement, arbitrary rigid body motions of deformable bodies and even fracture and collapse, it is adopted in this study to predict the ultimate states of bridges under extreme earthquakes in 3-D space. The isolated bridges with different fracture shear strain are analyzed under ground motion amplified from 100% to 300%. The numerical 3-D simulation successfully predicts the failure process of the bridges under extreme earthquakes. The results show that lager fracture shear strain of bearings does not increase the safety of the studied bridges. Also, the results confirm that the VFIFE is a powerful computation method to simulate the failure mechanism of devices and structural elements in 3-D space.

FIBER MODEL ANALYSES OF STEEL BRIDGE CIRCULAR COLUMNS CONSIDERING LOCAL BUCKLING

Koji Kinoshita[1)]

1) Assistant Professor, Dept. of Civil Engineering, Gifu University, Japan

Abstract: One of the most concerned problems for analytical estimation of ultimate strength and ductility of steel bridge columns is the consideration of local buckling. Fiber model analysis method is considered as the most practical analysis method that considers the effects of local buckling in the stress-strain curves. In addition, stress-strain curves with softening behavior to include local buckling were proposed by several researchers. However, accuracy of those models is still relatively low. As a consequence, most bridge designs have been done using fiber model analysis method without consideration of local buckling. In order to improve the analytical response estimation of steel bridge columns, a fiber model analysis method considering local buckling is proposed in this study. In this method, multi fiber elements were used to model the local buckling length to simulate local buckling deformation. The proposed method shows good results not only for estimating peak strength but also post-peak strength compared to previous experimental results. However, improvements can be made to increase the accuracy of the deformation modes.

1. INTRODUCTION

Consideration of local buckling on analytical estimation of ultimate strength and ductility of steel bridge columns is one of the important lessons learned from severe bridge damage in past earthquakes (Figure 1). This local buckling was found in many different forms including variations from different column sections.

In general, fiber model analysis is used for seismic evaluation of steel bridge columns. For steel bridge columns with the consideration of local buckling, there are modeling techniques that include local buckling effects in the stress-strain curves of the plastic hinge zone, where local buckling is occurred.

Although the modeling techniques are not new and many suggestions have been made by previous studies (Ishizawa and Iura, 2005), a common assumption in the analysis of steel bridge columns using fiber model is to ignore the local buckling. The Japanese Standard Specification for Seismic Design of Steel and Composite Structures (JSCE, 2008) permits these structures to be evaluated using the average strain of the plastic hinge zone as an alternative to evaluation peak strength without consideration of local buckling. However, Kakiuchi et al. (2009) concluded that this approach cannot capture the actual behavior and would result to overly conservative evaluation.

The common assumption may be based on two major reasons. First, some of the suggested models do not have hard evidence that they can capture actual behavior because of lack of agreement with experimental results, and second, there are many different forms of local buckling as

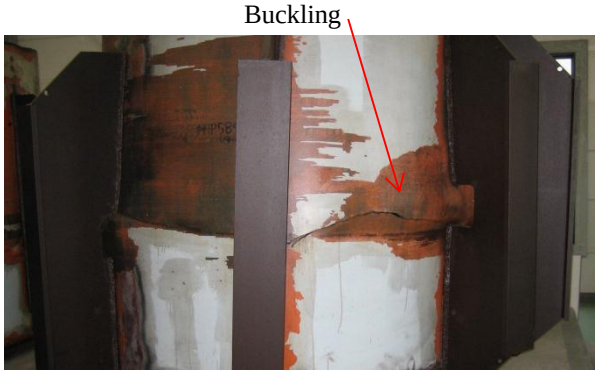

Figure 1 Damaged Steel Bridge Circular Column, Kobe Earthquake, 1995

mentioned above. It is therefore necessary to develop new modeling techniques that can provide not only a better representation for local buckling, but also have good agreement with experimental results.

A recent study on a fiber modeling technique to estimate local buckling of longitudinal bars in RC columns was reported by Ichikawa et al. (2010). The study aimed to directly capture non-linear deformation of local buckling by using fiber elements to model longitudinal bars individually. The study shows a possibility of further extension of the fiber modeling technique. However, there has been no further study to develop fiber modeling technique for steel bridge columns.

The main objective of this study is to propose a fiber model analysis method considering local buckling of steel bridge circular columns. In this method, multi fiber elements are used to model the local buckling length, where the

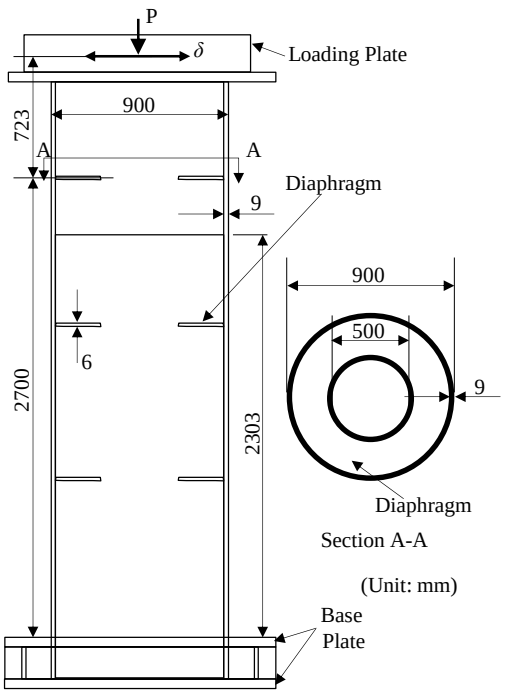

Figure 2 Steel Bridge Circular Column Model (PWRI, 1999)

Table 1 Properties of the Column Model

	Experimental Model
Steel Grade	SS400
Height h (m)	3.423
Thickness t (mm)	9

H_0 (kN)	400.82
δ_y (mm)	10.5
$P/\sigma_y A$	0.199

plastic hinge zone is, to simulate local buckling deformation. This concept is different from previous studies that consider effects of local buckling in the stress-strain curves of the plastic hinge zone. This paper discusses analysis results using the proposed method compared to the previous experimental work.

2. OVERVIEW OF PREVIOUS STEEL BRIDGE CIRCULAR COLUMNS EXPERIMENT (PWRI, 1999)

The geometry and section properties of the steel bridge circular column used in the analyses are shown in Figure 1 and summarized in Table 1. This experimental work was carried out by PWRI (1999).The column was 900mm in diameter with 9mm thickness. The boundary conditions were:

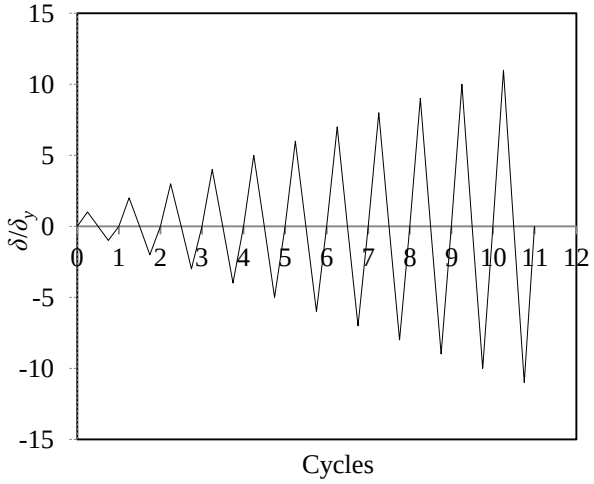

Figure 3 Displacement Controlled Testing Protocol

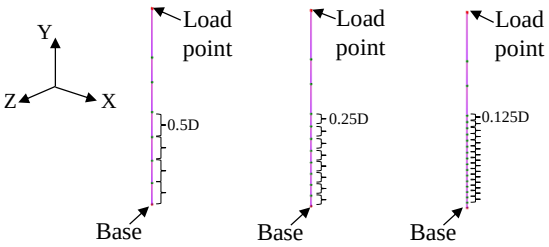
a) fixed column base that was fixed by high tension bolts or pre-stressed steel bars. The base was built-up sections consisting of thick steel plates, and hence was assumed to be rigid.
b) pin connection between the top of the column and loading jacks of each direction.

A displacement-controlled testing on the horizontal direction with a constant axial load was conducted with the loading history, shown in Figure 3, applied to the column. The ratio of the axial force, P, to the value of the yield strength of steel plate, σ_y, multiplied by the section area, A, was approximately 20%. The slenderness parameter, $\bar{\lambda}$, the radius thickness parameter, R_t, the yield horizontal strength, H_0, and the yield horizontal displacement, δ_y, in Table 1 are given as follows:

$$\bar{\lambda} = \frac{2h}{\pi\sqrt{I/A}}\sqrt{\frac{\sigma_y}{E_s}} \quad (1)$$

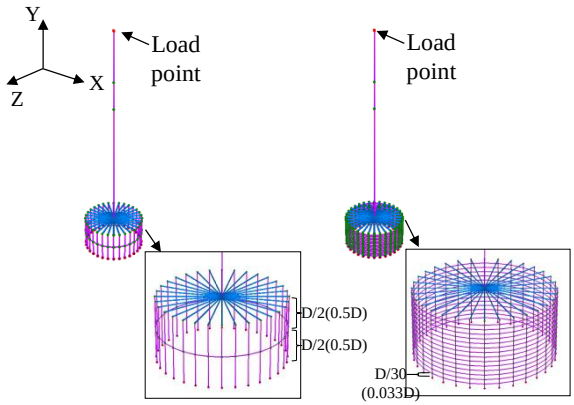
$$R_t = \frac{R}{t}\frac{\sigma_y}{E_s}\sqrt{3(1-\nu_s^2)} \quad (2)$$



$$H_0 = (\sigma_y - P/A)Z/h \quad (3)$$

$$\delta_y = H_0 h^3/3EI \quad (4)$$

The experiment showed that the peak-strength was about 553kN, and local buckling occurred at the bottom plastic hinge zone of the column, which is known as "elephant foot bulge".



3. FIBER MODELING OF STEEL BRIDGE CIRCULAR COLUMNS

In general, the circular column is modeled as a single fiber element that has fine fiber division in the section (Figure 4). However, the local out-of-plane deformation cannot be obtained from single fiber element, because each fiber division calculates only the axial deformation. In the circular column, local out-of-plane bending deformation is created due to local buckling. Because of this, this modeling does not give results for out-of-plane deformation such as local buckling.

(a) 0.5D (b) 0.25D (c) 0.125D

Figure 4 Single Fiber Model

(a) D/2 (b) D/30

Figure 5 Proposed Fiber Model

Previous studies tried to consider softening for post-peak behavior in order to assume local buckling in the stress-strain curve of steel plates. However, as mentioned above, this approach may not be able to capture the actual behavior of every steel bridge column because of lack of agreement with experimental results. Moreover, additional calculations based on experimental tests or finite elements analyses are required to consider more accurate stress-strain curve. In fact, some of calculations are complicated.

In the proposed model (Figure 5), the plastic-hinge zone is modeled as multi fiber elements while the general region is modeled as single fiber elements. The out-of-plane bending deformation can be captured directly. Thus, the proposed model takes advantage of the modeling technique that does not need any additional calculations.

A bi-linear stress-strain curve with post yield stiffness, which is assumed as 1% of the Young's Modulus of steel plate, was used to model the steel plates. The yield strength of steel plate, σ_y, is assumed as 308N/mm2, which corresponds to the experimental tests.

4. EFFECT OF MODELING

Different analysis results from the single fiber model case and multi fiber model cases are presented in terms of strength and deformation. The effect of modeling was determined by comparing with the experimental results as the baseline. In addition, the results are also compared with

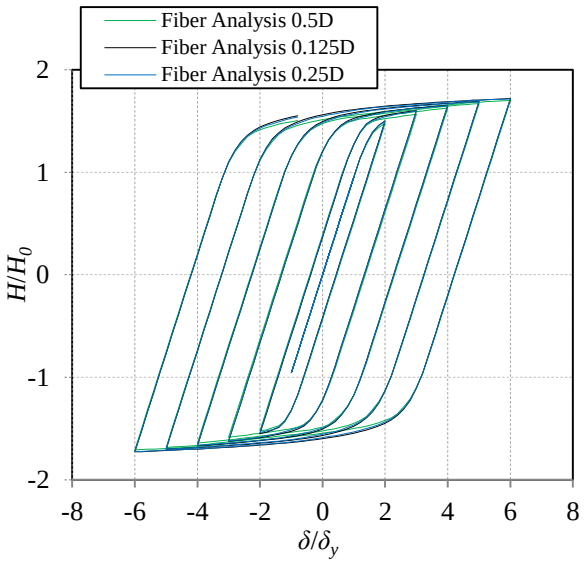


Figure 6 Effect of Element Division on Single Fiber Model

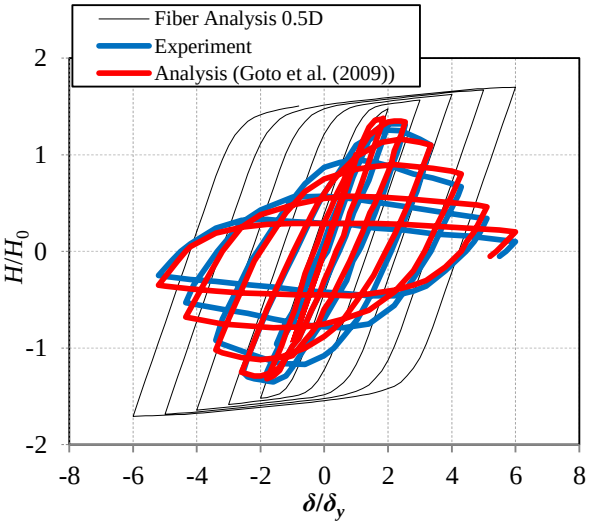

Figure 7 Comparison of Relationship between H/H_0 and δ/δ_y in Experiment and Single Fiber Analysis

the previous analysis results by Goto et al., (2011) that used finite element model.

4.1 Strength

Figures 6 to 9 show the relationship between load and displacement at the loading point. Figure 6 indicates that the effect of element division (see Figures 4(a), (b), (c)) on the single fiber model is not significant. As shown in Figure 7, the discrepancy in this relationship is observed. The single fiber model overestimates not only the peak strength, but also post-peak strength. The peak strength obtained from the single fiber model can be about 1.5 times greater than in the peak strengthfrom the experimental results. This is due to the use of the bi-linear stress-strain curve in the steel plates without consideration of local buckling, which stiffens the plastic hinge zone causing it to allow more load to be carried. This overestimation can have a significant effect during seismic performance evaluation.

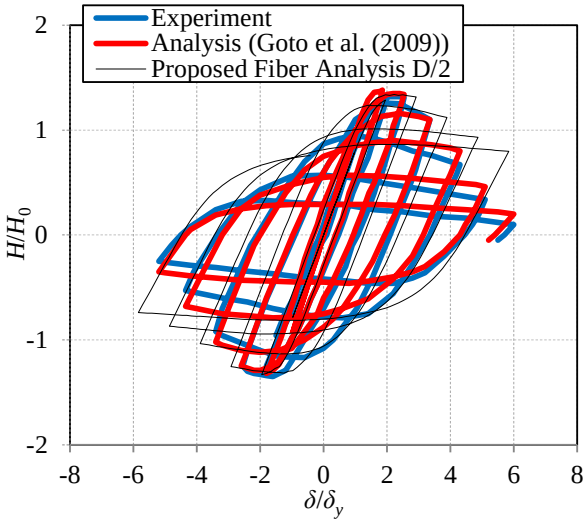

Figure 8 Comparison of Relationship between H/H_0 and δ/δ_y in Experiment and Proposed Fiber Analysis

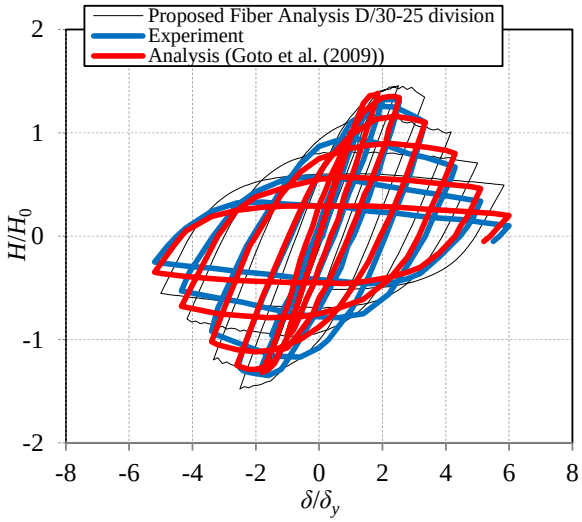

Figure 9 Comparison of Relationship between H/H_0 and δ/δ_y in Experiment and Proposed Fiber Analysis with Fine Element Division in Axial Direction

On the other hand, as shown in Figure 8, the proposed multi-fiber model estimates well the peak strength, and slightly overestimates the post-peak strength, but agrees well with the experimental results compared to the single fiber model. A slight overestimation of the post-peak strength is due to the use of rough fiber element division on the plastic hinge zone. As a follow up, a parametric study has been conducted to study the sensitivity of the division of the fiber elements used on the plastic hinge zone to the results. More specifically, the division of the fiber elements in the axial direction is investigated as shown in Figures 5(a), (b). The division in the circumferential direction is kept the same while the division in the axial direction is varied. Goto et al. (2011) also reported that the FEM analysis using shell elements is excellent in estimating the response of steel bridge frame piers with the circular columns subjected to cyclic loading when a small element division or fine mesh is

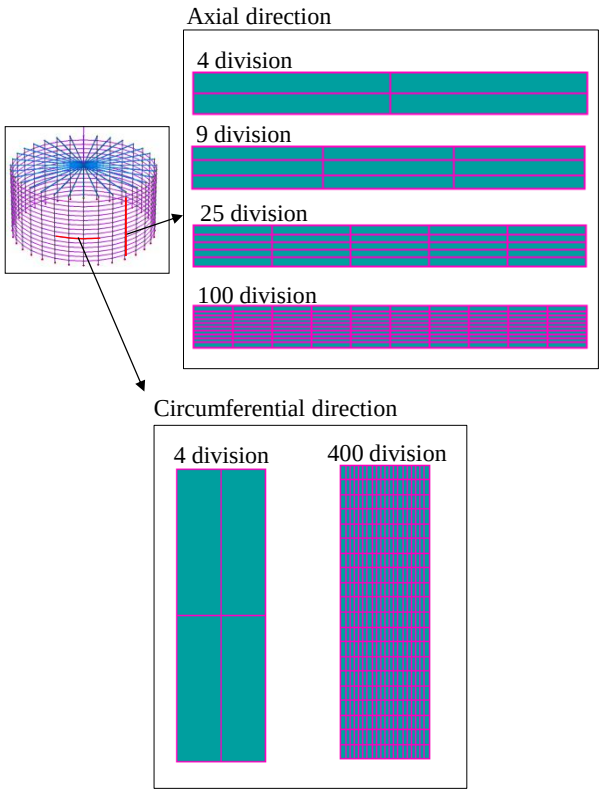

Figure 10 Division of Fiber Section in both the Axial Direction and the Circumferential Direction

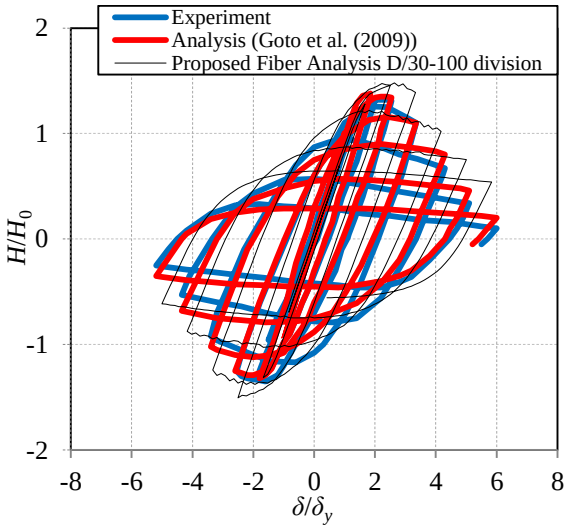

Figure 11 Comparison of Relationship between H/H_0 and δ/δ_y in Experiment and Proposed Fiber Analysis (with 100 Division of Fiber Section)

utilized. Yamaguchi et al. (2005) indicated that the element division on the plastic hinge zone in the axial direction should be less than D/30 and the aspect ratio of the shell element length in the axial direction to the circumferential direction should be less than 1/3 to accurately capture the peak strength when an error of less than 10% is desired. In this study the element division of the plastic hinge zone in the axial direction is under D/30, and the aspect ratio of the length in the axial direction to the circumferential direction

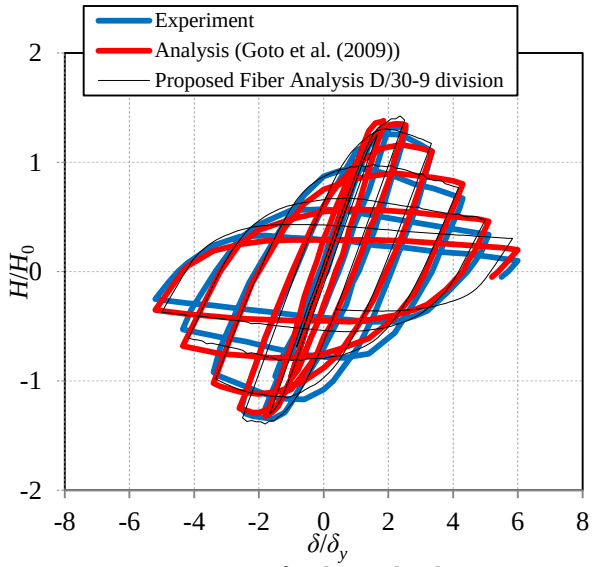

Figure 12 Comparison of Relationship between H/H_0 and δ/δ_y in Experiment and Proposed Fiber Analysis (with 9 Division of Fiber Section)

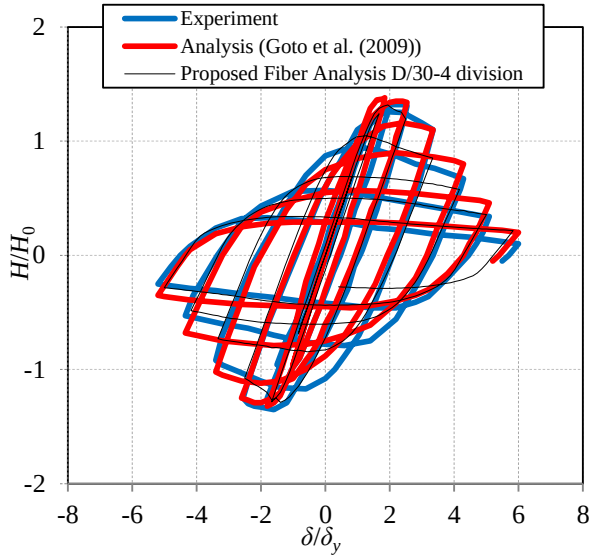

Figure 13 Comparison of Relationship between H/H_0 and δ/δ_y in Experiment and Proposed Fiber Analysis (with 4 Division of Fiber Section)

in the plastic hinge zone is less than 1/3 (see Figure 5(b)). Figure 9 shows that as the element division in the axial direction increases, the post-peak strength decreases and becomes closer to the experiment, but not for the entire history. Therefore, an additional analysis is performed to determine the effect of division of fiber section on the post-peak strength. The division of fiber section was varied from 4-, 9-, 25-, to 100-division as shown in Figure 10. Figures 11to 13 show that as the division of fiber section in the axial direction decreases, the accuracy of the estimated response in terms of peak strength and post-peak strength improves. Thus, it can be concluded that the division of fiber section in the axial direction has significant effect on the post-peak strength. Similarly, the division of the fiber section

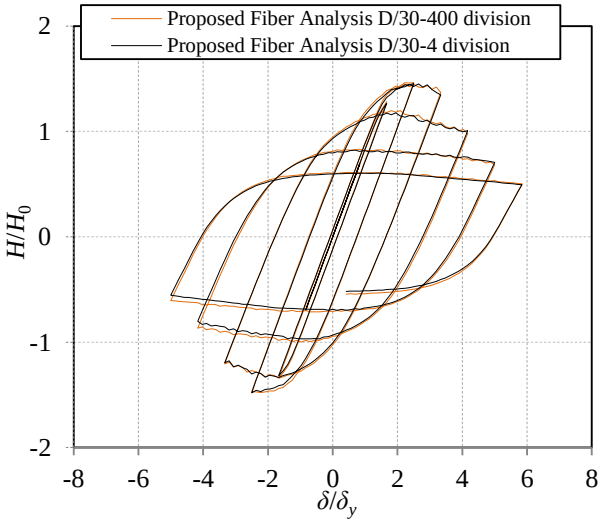

Figure 14 Effect of Division of the Fiber Section in Circumferential Direction

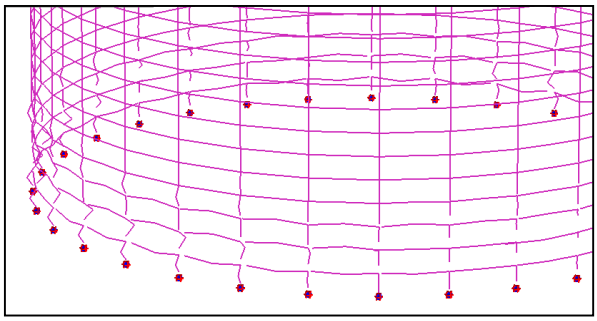

Figure 15 Deformation at Plastic Hinge Zone

in the circumferential direction is investigated. As shown in Figure 14, both the peak strength and post-peak strength are similar regardless of the division of the fiber section in the circumferential direction. Therefore, it can be argued that the proposed method, with adequate division of both fiber element and fiber section in the axial direction, gives good results in estimating not only the peak strength, but also the post peak strength.

4.2 Out-of-Plane Bending Deformation

Figure 15 shows the out-of-plane bending deformation of the plastic hinge zone obtained from the proposed method. As shown, out-of-plane bending deformation due to local bucking occurs in the proposed model. The multi-fiber elements in the plastic hinge zone allow this deformation mode. However, it is also observed that there is a difference in the deformation mode at the plastic hinge zone if compared to the experiment. The proposed model tends to deform toward the inside of the column as opposed to the real deformation observed in experiment. This suggests that some improvements can be made to the modeling of the plastic hinge zone, although estimations of the peak strength and the post-peak strength are good as described in Section **3.1**.

5. CONCLUSIONS

Fiber model analysis techniques used in the analysis of steel bridge circular columns have been discussed in this paper. The effect of modeling on strength was determined by comparing results from single fiber model with multi fiber model proposed in this study. It is shown that peak strength and post-peak strength of the proposed model are comparable to those of the previous experimental work. However, single fiber model is shown to be prone of large error.

The effect of proposed modeling on out-of-plane bending deformation is determined by comparing the deformation from analysis results using the proposed model to the previous experimental results. It is shown that proposed model can be improved to better capture the out-of-plane bending deformation in the plastic hinge zone, where the local buckling occurred.

2) Graduate Student, Department of Civil Engineering, Tokyo Institute of Technology, Japan

Abstract: Real-time evaluation of structural anomalies has long been a challenging subject for structural monitoring systems (SHM). As a new approach to this problem, a method namely Nonlinearity Index is developed to evaluate nonlinearity expression in the relationship between inputs and outputs during real-time behavior of structures. In case anomalies occur in structures, nonlinearity level in input-output relationship is expected to changes abruptly. In this study, the proposed method is demonstrated on seismic simulation data to verify its accuracy and to obtain the characteristics of nonlinearity at the times of failure events. Then its applicability to experimental data is discussed. Results show strong relationship between changes in nonlinearity expression and times and locations when anomalies occur.

1. INTRODUCTION

During their service lives, civil and industrial structures are prone to anomaly/damage. Those damages can be gradual such as fatigue, corrosion or extreme such as earthquakes, blasts. For the sake of safety, especially in the case of earthquake, it is urgent to monitor the health of structures. The development of SHM system has received significant attention in recent years due to its broad applications to civil, mechanical, and aerospace structures. However, ability to real-timely detect anomalies in the structures is still one of the biggest challenging issues for structural health monitoring (SHM) systems. Besides limits in data storage, linearization-based evaluation method is the biggest drawback. For instance, system parameters governing its behavior are estimated from measured data using linear model, whereas actual structures usually behave nonlinear.

Many approaches have been proposed in order to evaluate nonlinearity of the structures. The vibration-based approach is promising because it is nondestructive and the vibration signal of a structure is easily measurable using properly deployed sensors.

In this research, a new method of evaluating nonlinearity, Nonlinearity Index, is developed. It is computed directly from measured data (acceleration, velocity, etc) without linearization. Discussions on the potentiality of using NI in SHM systems are included by demonstrating the proposed Index on simulated and experimental data.

2. DEVELOPMENT OF NONLINEARITY INDEX

It is common knowledge that structural damages modify the dynamical behavior of structures, which can be explored by evaluating the Frequency Response Function (FRF). According to K.Worden and Tomlinson G.R (2001), FRF is estimated as ratio of auto and cross spectral density. In many previous research (Chanpheng T., Sasaki E. et.al 2009, Simon M. and Tomlinson G.R. 1984), whole-length input and output data are used in estimation. However in the case of civil structures, generally, system vibration caused by input only lasts a certain amount of time and dies out afterward due to system attenuation. Thus in this research, data are divided into a certain amount of time (time interval) and FRF is estimated using data in that period to improve accuracy. The size of time interval depends on attenuation property of structures. Moreover, since changes in the structures due to anomalies are instantaneous events, overlap is employed to monitor these. The process of FRF estimation is illustrated in Figure 1.

To evaluate the level of nonlinearity present in FRF, Hilbert transform is often employed. The main characteristic is that FRF of any linear system remain intact under Hilbert transform. In other words, any change in FRF under Hilbert transform suggests anomalies present in the system.

$$FRF'(\omega) = -\frac{1}{\pi i}\int_{-\infty}^{\infty}\frac{FRF(\Omega)}{\Omega-\omega}d\Omega \quad (1)$$

However, implementation of numerical Hilbert transform is not straightforward as due to pole at $\omega=\Omega$ and data truncation. Depend on research purpose and characteristic of data using, many calculation algorithms have been proposed, most commonly Kramers-Kronig (K.Worden and Tomlinson G.R 2001, Tomlinson G.R. 1987) and Matlab hilbert. However, these two methods still leave

numerical errors in the transformed FRF, thus not appropriate to use in evaluating level of nonlinearity. In this research, a new algorithm is proposed with reference of K.Worden and Tomlinson G.R (2001) and proved by test data to have the best result in accuracy and calculation time. Using the characteristic of Hilbert transform, nonlinearity is defined as

$$N = \int_{\omega_2}^{\omega_1} \left| FRF'(\omega) - FRF(\omega) \right| d\omega \qquad (2)$$

$[\omega_1 \ \omega_2]$ is the frequency range where FRF is estimated. Nonlinearity is averaged as Nonlinearity Index (NI) by number of estimated FRF in one time interval $n(\omega)$ to mitigate the effect of time interval's size. $n(\omega)$ can be directly computed from sampling rate and the size of time interval. NI at each time t_i is computed as NI_i. By overlapping time interval as described above, NI is obtained as a function of time, thus make it possible for real-time detection.

$$NI_i = \frac{\int_{\omega_2}^{\omega_1} \left| FRF'(\omega) - FRF(\omega) \right| d\omega}{n(\omega)} \qquad (3)$$

$$n(\omega) = \frac{rF_S}{2} + 1 \qquad (4)$$

Generally, nonlinearity can exist from the beginning (for instance, geometry-wise nonlinear) or newly introduced by anomalies occurring in the system. The former remains constant as long as the system is healthy, therefore by tracking nonlinearity over time, anomalies can be detected.

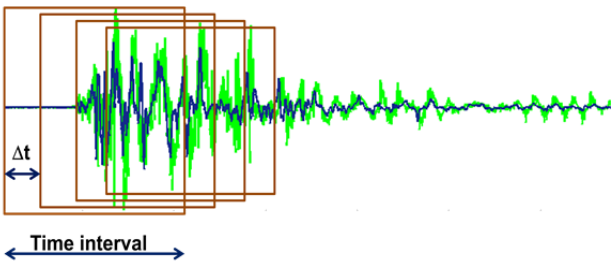

Figure 1 Time interval and overlap

3. METHOD VERIFICATION BY SIMULATING EARTHQUAKE DAMAGE ON A TRUSS BRIDGE

3.1 Simulation Conditions

Simulated model is closely based on the Tokyo Gate Bridge, a large truss bridge of total 2.9 km and 10 spans. This bridge includes three parts, two PC parts (rigid frame) and one steel part (truss). Along with distinguished design in geometry, behavior of this bridge is considered complicated and is an appropriate target of SHM systems. For complex structures like this, conventional linearization approach is not effective in detecting anomalies. Therefore, this bridge is chose in order to verify the proposed NI.

Overall model is shown in Figure 2. Boundary conditions are modified as following to serve the simulation purpose. Simulated model has four bearings, fixed (N1, N4) and moveable (N2, N3) at the main section. As shown in Figure 3, bearings N2 and N3 move along in the bridge's longitudinal and transverse directions by friction of coefficient 0.15 between vertical and horizontal forces. Meanwhile, bearings N1 and N4 are designed as fixed bearings which operate in the same way with N2 and N3 in the longitudinal direction. In the transverse direction, however, a side-block as illustrate in Figure 4 is set up. This side-block allows the bearing to move within 0.01m and fails if contact force reaches 20000kN. In the vertical direction, all bearing is assumed to be fixed.

Apart from two types of nonlinearity above, all material is modeled according to nonlinear constitutive law in order to simulate structure damage caused by material yielding.

Ground motion (acceleration) in 3 directions recorded at JR Takatori station in 1995 Kobe Earthquake with amplitude timed 1.5 is used as input and placed at all pier bottoms. The amplification factor 1.5 is used to assure the bearing failure and bridge collapse to be simulated.

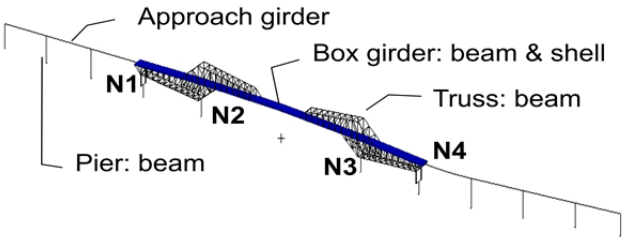

Figure 2 Model overview

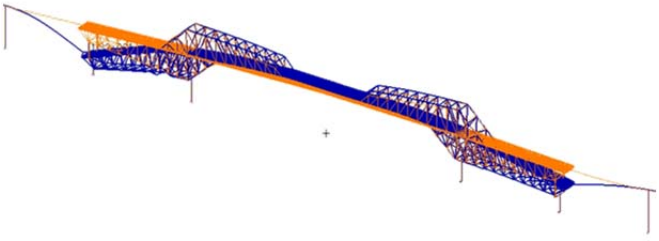

Figure 5 Collapse at left side

Figure 6 Sensor locations

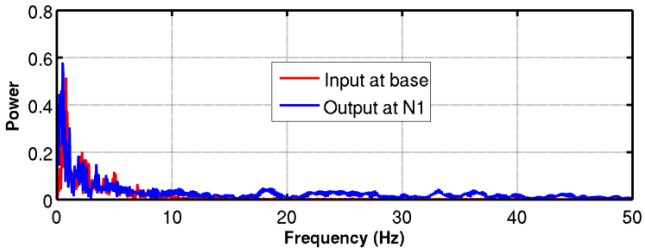

Figure 7 Frequency decomposition

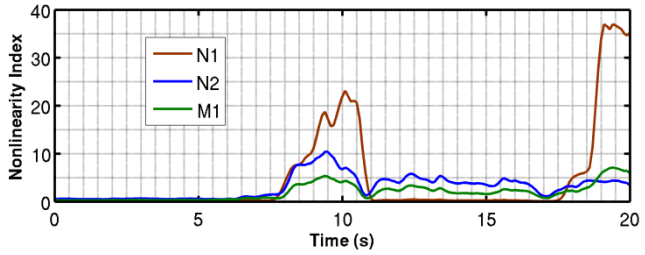

Figure 8 NI between input and bearing N1, N2,M1

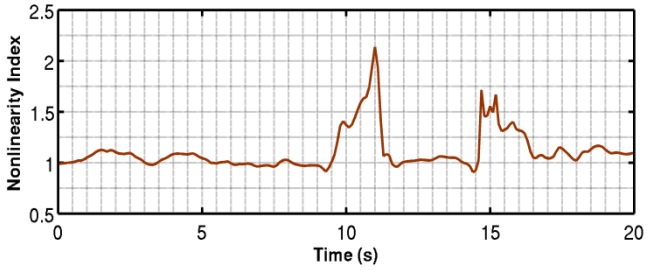

Figure 9 NI between trusses M2 and M3

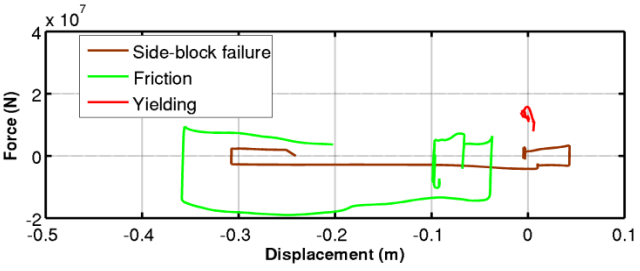

Figure 10 Energy comparison

3.2 Failure

Side-block failures occur at bearing N1 and N4 at 7.5s. After that N1 and N4 lost bearing function while N2 and N3 continue to operate due to friction. Bridge collapses at 17.5s at the side of bearing N1 by gravity of super structures as in Figure 5. Buckling in truss members are observed at the span between N1 and N2 because of this collapse.

3.3 Result evaluation

NI has three components corresponding to input and output (acceleration). However overall result suggests that all components yield similar tendency in term of detecting anomalies, NI in bridge's longitudinal direction is presented here. Figure 6 illustrates locations of sensors used in following evaluation. Frequency range is set as [0 50Hz] based on Figure 7.

Two peaks in NI of bearing N1 in Figure 8 indicate the times of side-block failure and collapse respectively. The first peak is also observed in NI of N2 and M1, which suggests side-block failure in bearing N1 to have impact on whole N1-N2 span. However, after side-block failure, bearing N1 loses bearing function; therefore there is no longer link in movement between N1 and N2. That is why there is no second peak in NI of bearing N2.

Meanwhile, NI of bearing N2 from 11-20s is higher than initial level which proves that friction movement of bearing N2 also causes nonlinearity in the system.

As for material yielding, with same method, yielding times 9s and 14s cannot be clearly observed in NI of M1 due to impact from N1 failures. However, this problem can be overcome by examining NI between two neighbor trusses M2 and M3 as in Figure 9, which also yields at 9s and 11s.

Behavior of NI can be explained assuming nonlinearity expression as a method of energy dissipation which is large (bearing failure) compared to small (local truss yielding). To confirm these assumptions, simulated result about energy dissipation of 3 failure types (side-block N1, friction N2, material yielding M1) is shown in Figure 10. Clearly, energy dissipation by side-block failure or friction is significantly larger than that of material yielding as expected.

4. APPLICABILITY TO MEASURED DATA ON A FOUR-STORY STEEL CONTRUCTED BUILDING COLLAPSE EXPERIMENT

This experiment is conducted to simulate the total collapse under strong earthquakes of a four-story steel constructed building (Figure 11). With Takatori motion as input, loading is divided into 20%, 40%, 60%, and 100% loading. The building collapses at 1F when loading is 100%. NI component in North-South direction (strongest input direction) is presented. Based on Figure 12, frequency range is set as [0 15Hz].

Figure 13 shows the NI between 1F and base according to loading. Clearly, despite input acceleration increases from 20%~60%, level of NI remains constant, which means no major anomaly occurs in the building. Also it is clear that NI is independent to level of input or output. Meanwhile, NI changes abruptly when input acceleration reaches 100%. This agrees with experiment's outcome, where 1F collapses under 100% loading. Even in 100% loading, NI remains constant till 15s despite increase in acceleration. NI starts to rise in 15-20s even with level of acceleration is smaller than previous period. Strain gauge data confirms various yielding in from 15s to 18s while peak at 20s corresponds with total collapse of 1F.

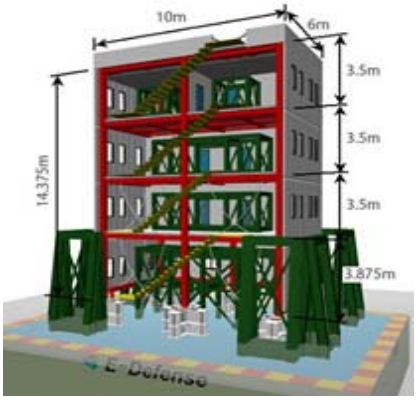

Figure 11 Experiment overview

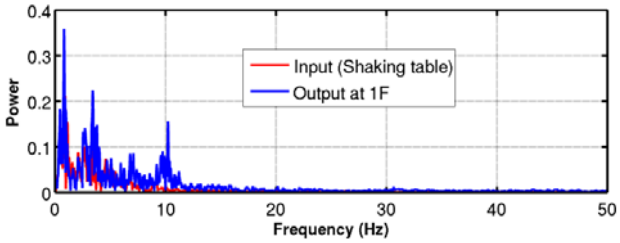

Figure 12 Frequency decomposition

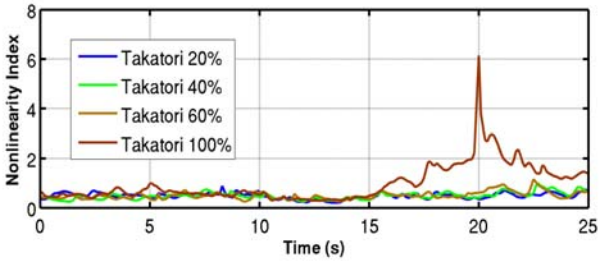

Figure 13 NI between input and 1F

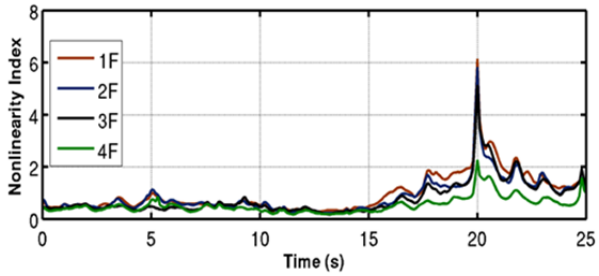

Figure 14 NI between input and 1F

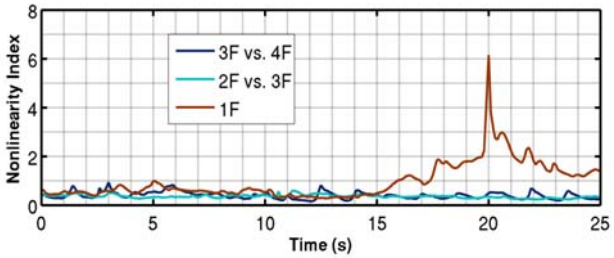

Figure 15 NI between input and 1F

Above results confirm that NI can successfully detect anomalies real-timely and is more sensitive toward anomalies than raw acceleration data.

Figure 14 shows NI for other floors with 100% loading. NI rises in all floors, which seems to be against actual experimental result where upper floors remain undamaged. To see whether those changes in NI come from impact of collapse in 1F or anomalies in upper floors themselves, Figure 15 examines NI between floors. Obviously, level of NI at each output-output is noticeably smaller than failure level, and almost constant, therefore no anomaly detected in upper floors.

5. CONCLUSIONS

By using new method in FRF estimation and numerical Hilbert transform, nonlinearity present in the behavior of the systems is successfully evaluated in order to capture instantaneous changes in the systems. It is demonstrated by simulated and experimental data that NI changes abruptly when anomalies occur in the structures. Since NI is independent of either input or output, it is more sensitive to anomalies than raw data themselves.

Abstract: This paper summarizes our investigation in comparing the performance of a computationally efficient reduced-order model of soil-foundation system of a bridge column, and a high-fidelity three dimensional finite element model. Performance assessment is evaluated at the level of Engineering Demand Parameters, and comparisons are made between the deformation histories of the piles. The study focuses on the interaction between the piles and the surrounding soil media during strong seismic excitations. The high computational cost and the complexity of the full model render finite element models impractical for routine engineering tasks. Consequently, reduced models, which employ the theory of beam on nonlinear Winkler foundations, have become attractive predictive tools in engineering practice. Macroelement models are used for representing the near-field soil-pile interaction effects, including nonlinear soil response, gapping effects, skin friction, as well as far-field radiation damping. Effects of the pile head fixity conditions and properties of the soil strata on the results of the aforementioned models are investigated through parametric sensitivity studies.

1. INTRODUCTION

The existing seismic design guidelines ignore the effects of soil-foundation-structure interaction on the seismic response of ordinary bridges by prescribing either fixed or flexible supports at the boundaries of the bridge superstructure (SDC, 2010; Aviram et al., 2008). Although elimination of soil-foundation system from the numerical model simplifies the analysis and design tasks, it leads to increased uncertainties. The current state of practice compensates for the reduced level of certainty by adopting larger margins of safety, which in turn lead to uneconomical designs. On the other hand, detailed finite element models are aimed to reduce the epistemic uncertainties by integrating elements of superstructure, foundation, and soil into the analysis (Elgamal et al., 2008; Zhang et al., 2003; Jeremic et al., 2002). Nonetheless, tuning the relatively large number of model parameters in order to generate meaningful results is not always a feasible task. Furthermore, the high cost associated with the intensive computational effort is often prohibitive of the adoption of high-fidelity models for routine engineering tasks. As an intermediate alternative, Performance-Based Earthquake Engineering (PBEE) methodologies aim to incorporate the actual nonlinear behavior and energy dissipation characteristics of the soil-foundation system into reduced-order models. As such, they can provide an enhanced understanding of the actual capacities of the bridge at affordable computational costs. However, prior to employing such reduced-order models in everyday engineering practice, their robustness and advantage over existing guidelines needs to be rigorously verified against the output of high-fidelity models and/or experimental data (Dryden and Fenves, 2009; Shin, 2007).

In this study, the outputs of a reduced-order and a three-dimensional finite element model in predicting the Engineering Demand Parameters imposed by seismic excitations on a single pile embedded in homogeneous soil are compared. Brief descriptions of the reduced-order and the finite element models are provided and the key features of each model are emphasized prior to demonstrating the simulation results. The Open System for Earthquake Engineering Simulation (OpenSees) (McKenna, 1997; McKenna and Fenves, 2001) has been used for creating the aforementioned numerical models and for carrying out the nonlinear analysis tasks of the current study. OpenSees is considered a suitable platform for performing PBEE related studies, particularly due to the relatively large number of nonlinear constitutive models as well as solution techniques for nonlinear problems which have been incorporated into its framework since its initial development.

2. MODELING DETAILS

2.1 Modeling the Vertical Propagation of Seismic Waves

Opposite to building structures, which are subjected to uniform strong motion excitation through the base, embedded pile foundations are directly excited by the ground motion at all degrees of freedom. Consequently, the assumption of uniform excitation may not be appropriate in case of significant variation of the ground motion in the vertical direction.

In order to address the spatial variability of the input motion, the dynamic analysis of an embedded pile needs to be performed in two steps. First, a site response analysis is carried out in order to simulate the far-field ground motion and determine if the seismic waves are altered as they propagate in the vertical direction. This is done through the dynamic analysis of a soil column that represents the far field soil domain. In order to achieve the shear-type behavior of soil, four-node plane-strain elements with 2 translational degrees of freedom per node are used and shear-type boundary conditions are imposed on the lateral sides of the representative soil column. Since only the variation of seismic shear waves in the vertical direction is of interest, the Poisson's ratio is set to zero. Therefore, no acceleration is incurred in the vertical direction, i.e., no horizontal propagation of seismic waves occurs and a single element in the horizontal direction would suffice. However, the number of elements in the vertical direction should be chosen such that the characteristics of the propagating waves can be adequately captured. It is often recommended that the element dimension be 1/8 to 1/10 of the wave length, which can be decided from the shear wave velocity and the maximum frequency content of the ground motion. The former depends on the soil shear modulus and density of soil while the latter can be considered not to exceed 25 Hz for most strong motion records. Plane-strain assumption restricts the out-of-plane deformations and mimics the infiniteness of the soil domain in the direction normal to the planes where shear deformations happen. UC San Diego soil models, which are already available in OpenSees, have been used to incorporate nested yield surfaces with elastoplastic constitutive relations for the deviatoric part of the stress and strain tensors. Namely, Pressure Independent Multi Yield Surface (PIMY) and Pressure Dependent Multi Yield Surface (PDMY) material models were used for modeling clay and sand, respectively.

The nodes at the bottom of the soil column are fully and partially restrained in the vertical and horizontal directions, respectively. The partial fixity is achieved by attaching a viscous dashpot to one of the bottom nodes. The dashpot represents the energy absorbing properties of the domain beneath the column of soil, hence, its coefficient is defined in terms of the shear wave velocity and the density of the underlying soil/bedrock. The incoming seismic waves are modeled as a velocity proportional equivalent nodal force at the base of the soil column. The wave and stress field equations which lead to the aforementioned modeling procedure are based on the work done by Lysmer and Kuhlemeyer (1969) for characterizing "absorbing/transmitting boundaries" as described in details by Zhange et al. (2003).

As suggested by the developers of the nonlinear soil models described earlier, in order to develop confinement pressures a gravity analysis under the self weight of soil—while the material is forced to exhibit linear behavior—needs to be completed prior to any seismic analysis. The shear-type boundary conditions on the lateral boundaries provide the necessary constraints for generating the confining pressures. Afterwards, the linearity restriction can be removed for the subsequent gravity and seismic analyses under confining pressures.

In addition to the material nonlinearity, which is the main mechanism for energy dissipation within the plastic range, energy dissipation within the small strain range of deformation is introduced with Rayleigh damping, with Rayleigh coefficients calculated based on a 2% damping ratio corresponding to 0.2 and 20 Hz frequencies. Nodal response (displacement and velocity) along the height of the soil column are recorded to be later used as the input motion for the seismic analysis of the embedded pile.

Excluding the pile from the site response analysis ensures that the far-field effects are isolated from the pile inertia. It is possible to produce similar results by increasing the size of soil domain and integrating the pile and far-field soil in the same model. However, the undesirable increase in the amount of computational efforts—due to the increased number of soil elements—renders this approach disadvantageous.

A source code for performing 1D nonlinear site response analysis in pressure independent material (e.g., clay) is available through OpenSees website. The code was adapted to the current study by amending additional material models.

2.1 Reduced-Order Pile Model (ROM)

The theory of beam on nonlinear Winkler foundation is used for the dynamic analysis of pile. It is essentially assumed that the passive resistance of soil can be modeled with a series of discrete nonlinear springs known as *p-y* springs. The backbone curve of each *p-y* spring is a function of the depth below the surface and is defined due to the relationships recommended by the American Petroleum Institute (API 2000) for clay (Matlock, 1970; Rees and Cox, 1975) and sand (O'Neill and Murchinson 1983). Similarly, skin friction effects are modeled with a series of tangential nonlinear springs referred to as *t-z* springs. A single nonlinear spring (*q-z* spring) at the tip of the pile models end bearing. The present study does not take into account the deteriorative effects of cyclic loading—as described by API recommendations— on the lateral load bearing capacity of soil.

Particular assemblages of the abovementioned nonlinear springs and a number of physical and semi-physical components can incorporate additional

near-field soil-pile interaction effects—such as gapping, drag, and radiation damping—and are referred to as macroelements (Taciroglu et al., 2006; Boulanger et al., 1999). The macroelement described in the work by Boulanger et al. (1999), hereinafter referred to as the *p-y* macroelment, is available in OpenSees and has been adopted for the current study.

The pile is discretized into 15 beam-column elements with three translational and three rotational degrees of freedom per node). Lateral and vertical support is provided by two sets of orthogonal *p-y* macroelement at each node as well as *t-z* springs at the intermediate nodes and a *q-z* spring at the bottom node. The nodal displacement histories form site response analyses of the horizontal component of a strong motion event are applied at the free ends of one set of the orthogonal *p-y* macroelements. It should be noted that no coupling exists between the two orthogonal directions. In other words, the pile response to a component of the ground motion in each direction at a time is identical to its response when the two components are applied simultaneously. However, the ultimate objective of the reduced-order modeling approach is to incorporate the model into three dimensional analyses of bridge structures. Thus, it is essential to develop the model in a manner such that it can lend itself to concurrent application of orthogonal input motions.

2.2 Three-Dimensional Finite Element Model (FEM)

The near field soil is modeled as a 10×10×18 m tub. Eight-node brick elements with 3 translational degrees of freedom per node are used for discretizing the soil domain. The soil domain consists of a total of 5340 brick elements. The side length of the individual elements does not exceed 1 m. The volume of the pile is accounted for as a cylindrical void of 0.6m in diameter. The pile is discretized into 15 beam-column elements at the centerline of the cylindrical void. The translation degrees of freedom of the pile nodes are constrained to the adjacent soil nodes with rigid links. The commercial software GiD (Diaz and Amat 1999) was utilized for the mesh generation. The finite element mesh of the soil tub and the pile-soil connectivity are illustrated in Figures 1 and 2. PIMY and PDMY material models (described in section 2.1) are assigned to the soil elements.

Lysmer_Kuhlemeyer boundary elements (1969) are attached along the base and the lateral planes of the soil tub to mimic the energy dissipation characteristics of the semi-infinite soil domain surrounding the tub. The tub is restrained against vertical motion. The input motion is modeled as equivalent nodal forces applied at the base and the sides of the tube normal in the direction of the ground motion. The nodal forces at each height are proportional to the ground motion velocity, which was obtained from the 1D site response analysis described in section 2.1. In order to generate confinement pressures, a gravity analysis precedes the dynamic analysis (similar to the procedure described in section 2.1.)

3. CASE STUDIES

3.1 Site Response Analysis

The current study addresses the case of a single pile

embedded in a homogeneous layer of soil subjected to the (unidirectional) horizontal component of 1989 Loma Prieta Earthquake (PEER Strong Motion Database, 2000) recorded at Gilroy No.2 station (Figure 3). The ROM was analyzed using the full history of the ground motion. Due to the high computational burden, the analysis of the FEM was carried out using only the strong motion duration (i.e., portion of the ground motion record which corresponds to 5% to 95% of the arias intensity as marked in Figure 3). In order to decide whether truncating the beginning part of the ground motion has significant effects on the analysis results, the analysis for the pile in the stiff clay was repeated using the first 9 seconds of the full ground motion record. Three types of soil materials including soft and stiff clay, as well as loose sand have been considered. The effects of ground water are excluded from the current study. Tables 1 and 2 list the major properties of the three types of soil material used in this study, where ρ, G, c, S_u and ϕ denote mass density, shear modulus, cohesion, undrained shear strength, and friction angel, respectively. The rest of parameters required for defining the PIMY and PDMY material models are chosen based on recommended values available through OpenSees website. The dimension of the soil elements were set to 0.5 m—which was decided according to the most critical case,

i.e., the soft clay material which possesses the smallest shear wave velocity amongst the three materials— in both vertical and horizontal directions.

Table 1. Material Properties for Clay

Material	ρ (ton/m^3)	G (kPa)	c (kPa)	S_u (kPa)
Soft Clay	1.3	1.3×10^4	18	20
Stiff Clay	1.8	1.5×10^5	75	80

Table 2. Material Properties for Sand

Material	ρ (ton/m^3)	G (kPa)	ϕ (degrees)
Loose Sand	1.7	5.5×10^4	29

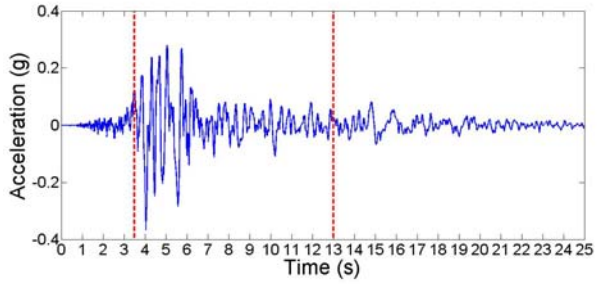

Figure 3. 1980 Loma Prieta Ground Acceleration

The displacement response histories of soil at the pile tip and head elevations due to the site response analysis of a 40 m soil column resting on dense rock are shown in Figure 4. It is observed that the variation of ground motion is more prominent in cohesionless soil (sand) compared to cohesive soil (clay). Qualitative comparison of the displacement records implies that the overall trend of the response history in soft clay slightly deviates from the trends observed for the rest of materials.

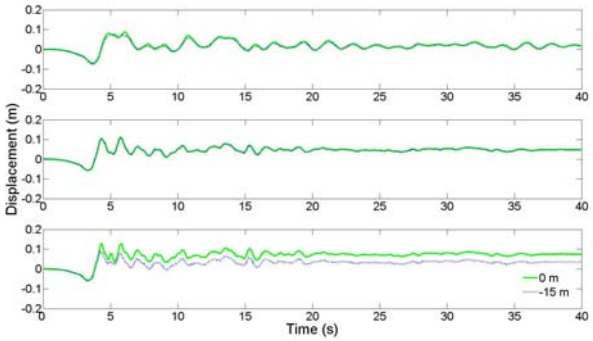

Figure 4. Vertical Variation of Ground Motion in (a) Soft Clay, (b) Stiff Clay, and (c) Loose Sand

It is evident from the stress-strain curves—shown at several representative depths (Figure 5) for soft clay—that the material nonlinearity is mostly concentrated in the lower 10 m of the soil column. Therefore, the 40 m height for the soil column in the site response analysis is an appropriate choice as long as the embedded length of pile falls outside the region of the soil which is highly affected by the boundary conditions at the bottom of the soil column.

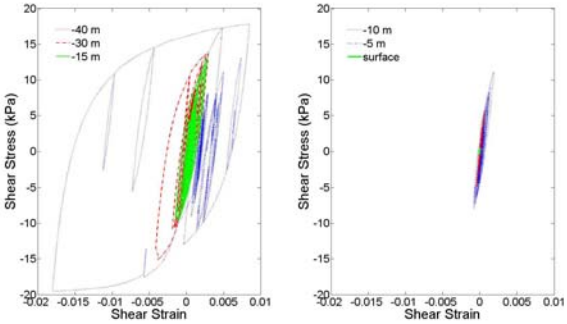

Figure 5. Stress-Strain Curves of Soft Soil

In order to investigate the effect of material nonlinearity on the outcome of site response analysis, the analysis was repeated for soft clay assuming linear elastic relationship for both deviatoric and volumetric parts of the stress and strain tensors during the dynamic analysis, which is initiated from a confined state of material. As illustrated in Figure 6, the upper layers of soil exhibit oscillatory displacement response with peak magnitudes almost twice the peak values observed for the nonlinear clay. The site response analysis results for the nonlinear soil materials are used, henceforth, for the rest of this study.

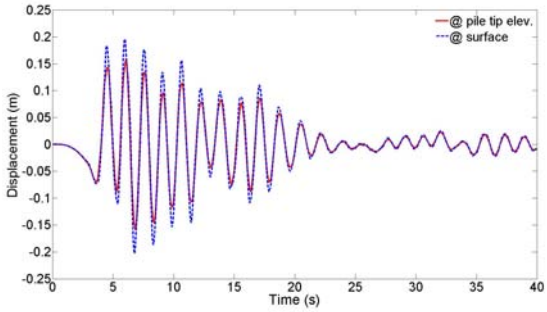

Figure 6. Site Response Analysis Results of Soft Clay using Linear Elastic Material Model

3.2 Pile Response

The pile is fully embedded with an embedded length of 15 meters and a diameter of 0.6 m. A linear elastic material with Young's modulus value, E_c, of 28 MPa and Poisson's ratio, ν, of 0.2 is used for modeling the pile. The pile is restrained against lateral and vertical displacement at top, i.e., pinned-head (PH) condition. Furthermore, all nodes are restrained against torsion. In order to investigate the effect of head fixity on the dynamic response, the analysis was repeated with fixed-head (FH) condition for the pile

embedded in stiff clay. In reality, various degrees of rotational fixity can be achieved, depending on the inertia of pile cap as well as the development length of pile rebars in the pile cap. The degree of restraint against rotation also depends on the number of piles and location of a pile in the bent. We assumed moment of inertial in the longitudinal direction of a bridge is significantly larger than moment of inertia in the transverse direction, thus, a higher degree of fixity is provided against rotation about an axis parallel to the transverse direction of the bridge. Therefore, both pinned and fixed boundary conditions are idealized representations of the actual boundary conditions.

The lateral deformation of pile at four representative depths for the four cases are presented in Figures 7 through 10. As shown in the time history plots, the ROM generates smaller displacements for the PH pile in soft and stiff clay compared to the FEM. The results from the ROM reports spatial variation of displacement along the height of the PH pile in loose sand and FH pile in stiff clay. In general, the pile exhibited smaller displacements in the soft clay material. The effect of neglecting the early portion of the ground motion on the output of the FEM was examined by repeating the analysis for the PH pile in stiff clay. Excluding the beginning portion of the specimen ground motion has resulted in a baseline drift (bias) in the displacement time history at all depths (Figure 11). The most extreme deformed shapes generated by ROM and FEM for all cases are compared side-by-side in Figure 12.

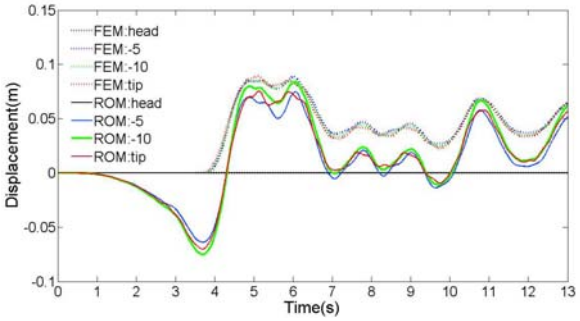

Figure 7. Response History of PH Pile in Soft Clay

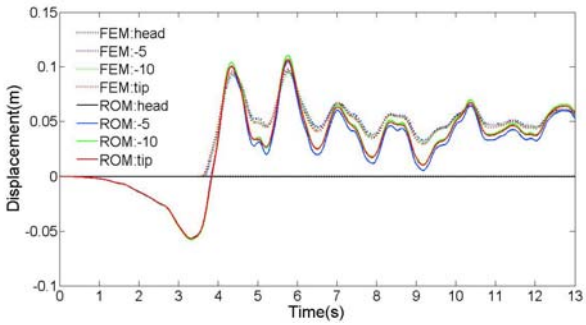

Figure 8. Response History of PH Pile in Stiff Clay

The maximum bending moment demands and their locations are listed in Table 3. The results from the ROM and FEM are in good agreement for the case of loose sand. However, the maximum bending moments generated by the ROM are 25% of the moment obtained through FEM for PH pile embedded in soft clay. This ratio is increased to about 45% for the case of FH pile in stiff clay. Including the first part of the ground motion in the FEM analysis yields 16% reduction in the maximum demand inserted on the pile in stiff clay. The maximum bending moment for the FH pile is incurred at top of the pile. In general, the location of the maximum demand under the PH condition is 2-3 m below the surface in FEM. This location moves further down to 3-4 m below the surface in the ROM. The difference in the location of the maximum moment is also evident from the location of the maximum curvature of the deformed pile profiles displayed in Figure 12 .

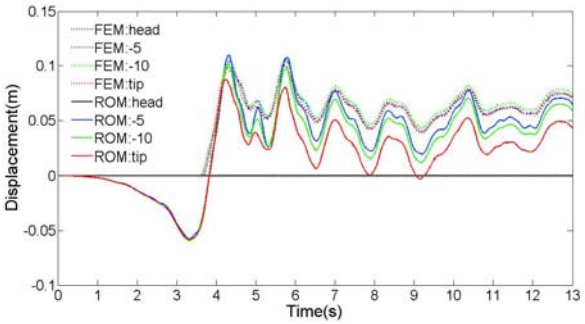

Figure 9. Response History of PH Pile in Loose Sand

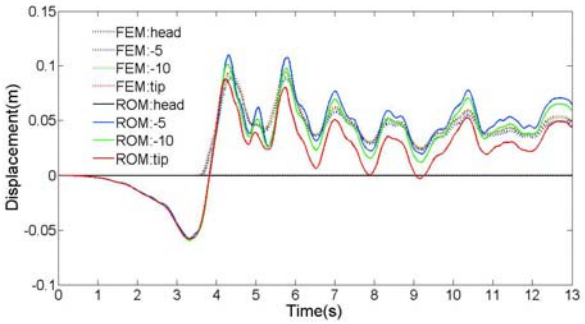

Figure 10. Response History of FH Pile in Stiff Clay

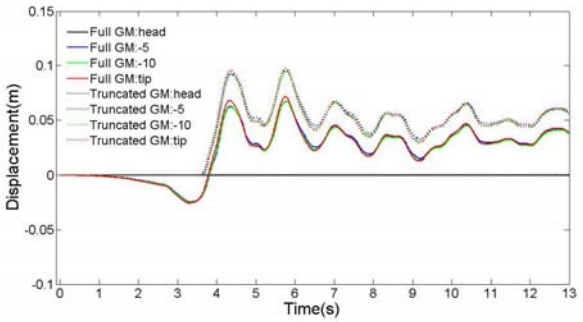

Figure 11. Effect of Neglecting The Early Portion of Ground Motion on the FEM Response of PH Pile in Stiff Clay

As expected, the fixed head condition imposes large bending moment demand on the top. However, the influence

of the fixed head condition on the internal moment becomes less significant in sections away from the top.

4. CONCLUSIONS

The results of employing a reduced-order and a finite element model for the seismic analysis of an elastic pile which is embedded in homogeneous soil are investigated. The effects of soil properties and head fixity on the displacement response history and internal bending moments of the pile are examined. The results indicate that the two modeling approaches yield comparable results for both displacement and bending moment in case of pinned-head pile embedded in loose sand. The two models also generate similar displacement response histories for the pile in clay material. However, significant discrepancies are observed in the bending moment demands predicted by the two models in case of both soft and stiff clay. An investigation of the effect of the arriving portion of the ground motion on the results of FEM revealed their influential effects on the displacement response. Addressing the effects of pile inelastic behavior as well as bidirectional excitations can provide directions for future studies.

Abstract: Although it is clear that live load provides additional gravity load and dynamic force effects due to its sprung nature, the significance of these effects on the seismic response of a bridge still remains unclear. Therefore, implications of live load on the seismic response of a bridge need to be understood especially since traffic congestion has become a new normal in most major cities in the world. The main objective of this study is to investigate and obtain insight into the effect of vehicle-bridge interaction during earthquakes. The study consists of experimental and analytical work. An experimental test program was conducted that includes multiple shake table testing of a 2/5-scale model of a three-span horizontally curved steel girder bridge loaded with a series of six representative trucks. From the experimental data, a numerical model has been validated to be used in the analytical study. This model has also been used to study the effect of number of vehicles placed along the length of the bridge model. It is shown that the maximum column displacements vary in the range of approximately 15% when the number of vehicles is varied from one to six and that adverse behavior occurs with fewer vehicles.

1. INTRODUCTION

Although earthquake reconnaissance reports have shown that live load is present during earthquake events, design procedures for earthquake-resistant bridges in most countries do not require the simultaneous presence of live load and earthquake load to be considered. This decision is based on two major assumptions. First, it is unlikely that the full design live load will be on the bridge at the time of the design earthquake, and second, the seismic response of a bridge is dominated by its dead load and live load inertial effects are negligible by comparison. However for bridges in urban and metropolitan areas where congestion is a frequent occurrence, some fraction of the design live load (usually taken as 50%) is now recommended to be included with the dead load when computing gravity load effects (AASHTO, 2012). But this recommendation applies only to gravity load effects and not to inertial effects.

The omission of inertial effects in design is the result of a prevailing attitude that the suspension system of a heavy vehicle acts in a manner similar to a tuned mass damper and reduces the motion in the bridge. It is therefore believed to be conservative to ignore these effects. But in fact little is understood about the dynamic interaction between heavy vehicles and bridge systems during strong shaking and there is no hard evidence that the tuned mass damper model is universally applicable. It is equally possible that the added weight increases the inertial loads in the bridge and the corresponding displacements and forces.

An experimental shake table study was carried out in the Large-Scale Structures Laboratory at University of Nevada, Reno to obtain insights on the vehicle-structure interaction during earthquake shakings. Although the experimental study was useful to calibrate and validate the numerical model, this only represents one case of the problem. There are still possibilities for various different cases that may occur. Therefore, a set of analytical parameter studies were devised. In this paper, the effect of the number of vehicles present on the bridge is presented.

2. LITERATURE REVIEW

Currently, very little research has been conducted to resolve the live load issue. Previous work has shown that live load can either have a beneficial or an adverse effect on the structure during earthquake shaking. However, there are still uncertainties about the reason why this is so and there has been no large-scale experimental work to investigate the effects of live load on the seismic response of bridges prior to this experiment.

An earlier study by Sugiyama *et al.* (1990) used a single degree-of-freedom vehicle system that can model rolling in the transverse direction and pitching in the longitudinal

direction, but the properties are not given. The bridge was idealized as a nine-mass system with transverse and rotation inertia connected by linear springs and damper elements. A vibration test is reported on an existing steel girder bridge with and without trucks in the longitudinal and transverse directions to verify the results. In the test, two large trucks were parked facing the same direction on a portion of an existing off ramp whose girders were vibrated with an electro-hydraulic exciter. The bridge was tested with the vehicles empty and loaded to various capacities. The results show that the dynamic effect of the vehicle is more dominant in the transverse direction and the vehicle tends to reduce the response of the bridge. They also mentioned that as the exciting force level increases, the effects of nonlinearity become more apparent since the dynamic characteristics of the vehicle itself are nonlinear. These results are corroborated by Kameda *et al.* (1992) who used a 5 degree-of-freedom model in their study. These authors state that the vehicle tends to increase the bridge response when the vehicle is in the in-phase mode with the bridge and decrease the bridge response when it is in the out-of-phase mode. Moreover, they also concluded that the ratio of the fundamental frequencies of the bridge and the vehicle plays an important role for the response of the bridge.

Furthermore, another study of seismic response of a bridge with live load was done by Kawatani *et al.* (2007). They analyzed the seismic response of a steel plate girder bridge under vehicle loadings during earthquakes. The vehicles were modeled with 12 degree-of-freedom that took sway, yaw, bounce, pitch, and roll into account. The observations from the numerical analysis showed that heavy vehicles acting as a dynamic system can reduce the seismic response of bridges under a ground motion with low frequency characteristics, but the vehicles have the opposite effect and slightly amplify the seismic response of the bridge under high frequency ground motions.

Kawashima *et al.* (1994) and Otsuka *et al.* (1999) performed a series of study to determine the effect of live load on a bridge when combined with seismic load. The study modeled a two-span simply supported girder bridge with a mix of ordinary cars, modeled as additional dead load, and large trucks, each modeled with 5 degree-of-freedom. The bridge was only analyzed in the transverse direction because it was estimated that the deck response would be significantly affected by the rolling of the large trucks. The studies found that the displacement response of the girders increased by 10% when the live load was included; ductility demand at the bottom of the column also increased by 10% with live load on the bridge. This study concluded that this was not enough of an effect to be significant and safety factors can be modified to take this effect into account if they are not already sufficient enough. It was also concluded that the increase in response was due to the increase of weight, however, the effect of the large trucks was not just to increase the dead weight, and they also behaved as a mass damper.

Scott (2010) developed a simplified modeling approach for dynamic analyses to account for combined live load and seismic load. It is shown that for short-span bridges, the displacement responses are mainly due to the fundamental bridge mode. In addition, for long-span bridges, vehicle speed has small influence on the displacement and acceleration responses of the bridge.

A recent study on the effects of live load a highway bridge under moderate earthquake in the horizontal and vertical directions was reported by Kim *et al.* (2011). The study concluded that the seismic responses of the bridge are amplified when the vehicle is considered as merely additional gravity load or mass and the amplification is dependent on the relationship between the fundamental frequency of the bridge and the response spectra of the ground motion. However, when the vehicle is considered as dynamic or mass-spring-damper system, which is more realistic, the dynamic effect of the vehicle is greater than its gravity load addition effect and thus it reduces the seismic response. In addition, the study also showed that the effect of moving vehicle as compared to stationary vehicle is negligible. Therefore, it is sufficient to model the vehicle as stationary for this purpose.

The presence of multiple vehicles on a bridge can be seen as a series of mass damper placed on a structure. Therefore, the effects of vehicles on the bridge may be observed as if multiple mass dampers, not necessarily tuned, on a structure. Some articles have discussed the effects of multiple tuned mass dampers (MTMD) on structure (Xu and Igusa, 1992; Abé and Fujino, 1994; Park and Reed, 2001). The results show that MTMD system is slightly more effective in reducing the seismic demand since it operates in a broader range of frequency. Another possibility to explain the effect of vehicles on the bridge is that the suspension system behaves as passive nonlinear energy sinks. The concept of nonlinear energy sinks (NES) is similar to a tuned mass damper but the stiffness of the secondary system is nonlinear which makes it become load dependent but can dissipate the energy more efficiently. This has been shown to reduce the demand in the structure subjected to seismic loading (Wierschem *et al.*, 2011; Wierschem *et al.*, 2012). The nonlinear nature of the vehicle suspension system can be thought as NES in this sense.

3. OVERVIEW OF BRIDGE MODEL AND REPRESENTATIVE VEHICLE IN EXPERIMENT

A three-span, curved bridge model was tested on the NEES Shake Table Array in the Large-Scale Structures Laboratory at University of Nevada, Reno. This 0.4-scale model has a steel plate girder superstructure, single-column reinforced concrete substructures, and seat-type abutments, as shown in Figure 1. Overall dimensions of the bridge model are shown in Table 1 below.

The bridge model has a total length of 145 ft [44.196 m], a total width of 12 ft [3.658 m], and subtended angle of 104° as shown in Figures 1 and 2. Each bent has a single circular column. The column height is 7 ft - 8 in [2.337 m] with a diameter of 24 in [0.61 m]. The superstructure is a

three-span, three-girder steel bridge with concrete deck. The detail of the superstructure and the column can be seen in Figure 2. The superstructure is supported by fixed (rotation-only) pot bearings at the bent locations and sliding bearings at the abutments. Moreover, shear keys are provided at the abutments to restrain movement in the radial direction during small amplitude earthquakes, but are designed to fail at higher events to protect the abutment foundations against damage.

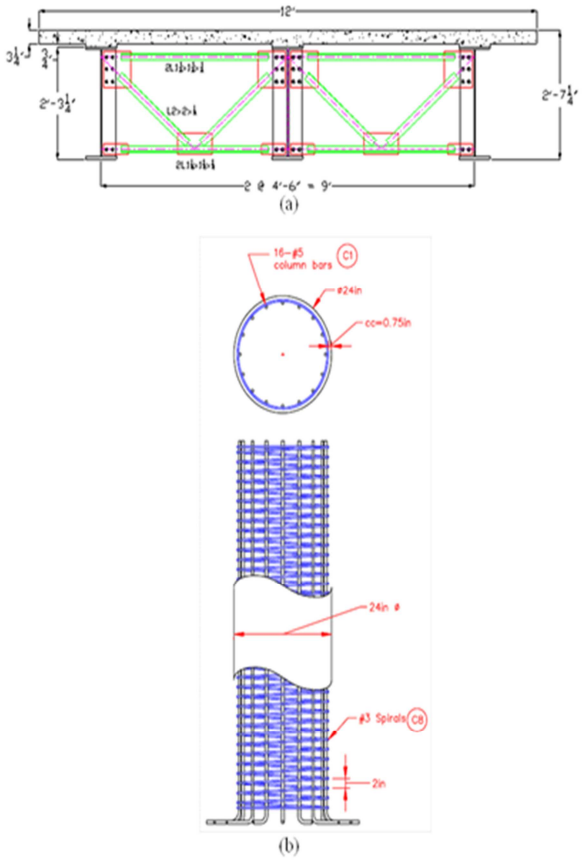

Figure 2 Typical (a) Superstructure and (b) Column Details

Table 1 Summary of Bridge Geometry

Parameter	Prototype	Model
Total Length	362.5'-0"	145'-0"
Span Lengths	105'-0", 152'-6", 105'-0"	42'-0", 61'-0", 42'-0"
Radius at Centerline	200'-0"	80'-0"
Subtended Angle	104° (1.8 rad)	104° (1.8 rad)
Total Width	30'-0"	12'-0"
Girder Spacing	11'-3"	4'-6"
Total Superstructure Depth	6'-6⅛"	2'-7¼"
Column Height	19'-2"	7'-8"
Column Diameter	5'-0"	2'-0"

The prototype bridge was designed for a site in Seismic Zone 3 (AASHTO, 2012) with a 1,000-year spectral acceleration at 1.0 second (S1) of 0.4 g. Under this Design Earthquake (DE), the bridge is expected to be damaged but not collapse. The record selected as the input motion for the experimental studies was the Sylmar record from the 1994 Northridge Earthquake near Los Angeles, scaled to have the same spectral acceleration at 1.0 second. A scale factor of 0.475 was therefore applied to both the NS and EW time histories of ground acceleration from this station.

The starting point for selection of the test vehicle was the H-20 truck, which is a two-axle vehicle weighing 40 kip [178 kN] (8 kip [35.6 kN] on the front axle and 32 kip [142.4 kN] on the rear axle) with a 14 ft [4.267 m] wheel base. For a 0.4-scale model, the model truck would have a wheel base of 5.6 ft [1.707 m], a width of 2.4 ft [0.732 m], and weigh 6.4 kip [28.48 kN]. Since such a vehicle would most likely have to be custom-built and thus not economically feasible, the decision was made to select from commercially available vehicles. The closest vehicle to match the modeling requirements and constraints of the experimental setup was found to be the Ford F-250. The overall dimensions and weight ratings of this vehicle are presented in Table 2. If six vehicles were placed on the bridge, the mass ratio was found to be approximately 20%. Although the similitude requirements are not fully satisfied, the dynamic properties of the chosen vehicle can produce similar effects to those of the target vehicle.

Table 2 Ford F-250 Dimensions and Weight Ratings

Parameter	Value
Overall Length	247 in [6.274 m]
Overall Width	68 in [1.727 m]
Overall Height	80 in [2.032 m]
Wheel Base Length	156 in [3.962 m]
Ground Clearance	7.9 in [0.201 m]
Curb Weight	6.7 kip [29.815 kN]
Gross Vehicle Weight Rating	10 kip [44.500 kN]
Max. Allowable Payload	2.3 kip [10.235 kN]

4. OVERVIEW OF NUMERICAL MODEL IN ANALYSIS

In the finite element model developed for SAP2000, the superstructure is modeled with shell elements, the substructure with frame elements, and column plastic hinges with fiber elements. The abutment towers used in the experiment are also included in the model as shown in Figure 3 below.

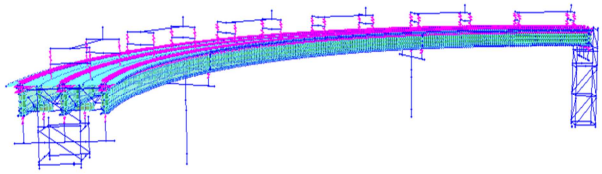

Figure 3 Finite Element Model of Bridge with Vehicles

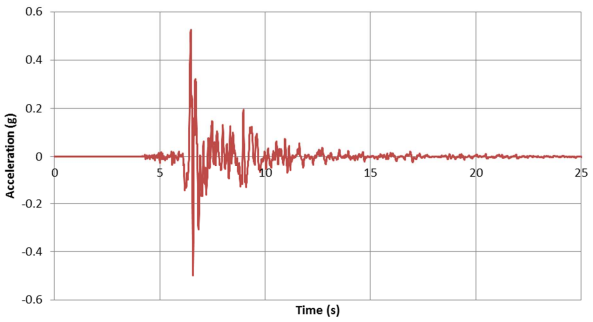
Two different boundary conditions were modeled to represent the sacrificial shear keys at the abutments in their intact and failed states, as follows:

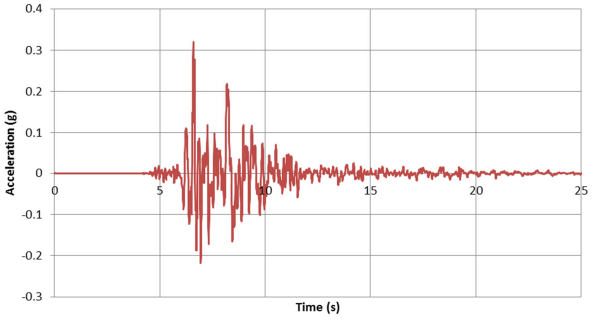
1. Intact shear keys located in the inner bay of the abutment cross frames allowing tangential movement but restraining radial displacement, i.e. tangentially free, radially restrained condition (TFRR).
2. Failed shear keys that provided no restraint at the abutments in any direction, i.e., free condition (Free).

In addition, no vertical restraint was imposed at the abutments which were therefore free to uplift as necessary. Pinned bearings were assigned to each girder over the bents, which allowed rotation about any axis but restrained displacement in both horizontal and vertical directions.



In the numerical model, the vehicle is modeled as a 16 degree-of-freedom, mass-spring-damper system, as shown in Figure 3. The mass is distributed in the suspension and axle levels and each spring or damper represents the stiffness or damping at suspension or axle/tire levels. This model is an expansion of the vehicle model that was used by Kim *et al.* (2005). The properties of the vehicle were obtained from single truck experiments carried out previously on one of the shake tables at the University of Nevada, Reno. The results of these experiments gave stiffness and damping values in the vertical, transverse, and longitudinal directions both for an empty and fully loaded vehicle. Table 3 summarizes the properties of the fully loaded vehicle, which is used in the numerical model.

5. EARTHQUAKE INPUT MOTION



As previously mentioned, the bridge model was subjected to Sylmar record of the 1994 Northridge Earthquake scaled accordingly to match the design spectrum at the period of 1 s. The acceleration histories used as the input motion for the analytical study were the average of the table accelerations in the longitudinal and transverse directions, as measured in the laboratory. The observed accelerations for each table were found to be within reasonable agreement with each other and all four tables were deemed to be moving synchronously. Averaging to obtain input motions for the analytical studies was therefore considered appropriate. In addition, filtering and base-line correction were also applied to obtain the final input acceleration histories. These are shown for the longitudinal and transverse directions of the 100% design earthquake (DE) run in Figures 4a and 4b, respectively.

Table 3 Fully Loaded Vehicle Dynamic Properties

	Direction	Suspension Level			Tire Level		
		Stiffness (kip/in)	Damping (kip.s/in)	Damping Ratio (%)	Stiffness (kip/in)	Damping (kip.s/in)	Damping Ratio (%)
Front	Vertical	0.459	0.037	25.92	3.48	0.000	0.00
	Transverse	1000	0.000	0.00	1.73	0.000	0.00
	Longitudinal	1000	0.000	0.00	0.56	0.000	0.00
Rear	Vertical	0.718	0.041	19.89	3.48	0.000	0.00
	Transverse	1000	0.000	0.00	1.73	0.000	0.00

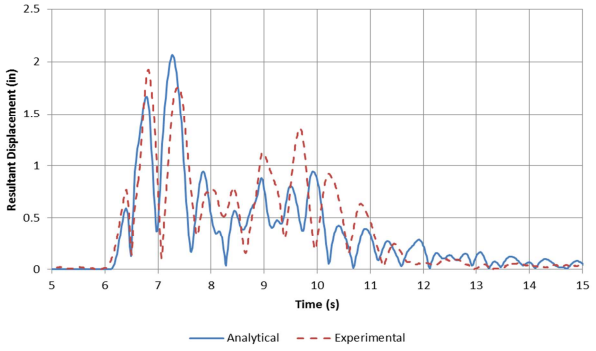
(b)

Figure 4 Input Acceleration Histories in (a) Longitudinal and (b) Transverse Directions for 100% DE Run



6. NUMERICAL MODEL VALIDATION

Analysis results for the 100% DE are presented below. For this earthquake, the boundary conditions at the abutments were taken to be 'free' since the shear keys failed during the 75% DE run for the experiment without live load, and during the 100% DE run for the case with live load. During the course of the experiment, it was observed that live load had a beneficial effect on the seismic response of the bridge model and that column damage was less with live load than without. In order to represent the different levels of inelasticity in the column with and without live load, different EI modifiers were used in the numerical model for these two cases. For 100% DE, the modifier with and without live load was taken to be 60% and 30% respectively.

Figures 5a and 5b show comparisons between the analytical and experimental results for resultant displacement histories under 100% DE for the north and south columns, respectively. It is seen that the analytical results for peak values have good agreement in magnitude to the experimental results. The agreement later in the record is not as favorable and indicates further refinements to the bridge and vehicle models can be done. Nonetheless, the numerical model developed can provide good estimation of the peak displacement as a measure of the seismic demand in the structure.

(a)

(b)

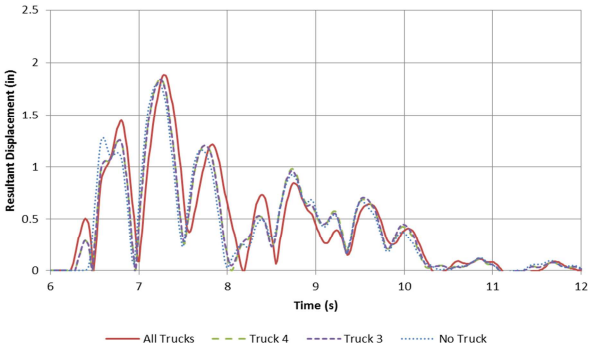


Figure 5 Analytical and Experimental (a) North and (b) South Column Resultant Displacement Histories Comparison under 100% DE

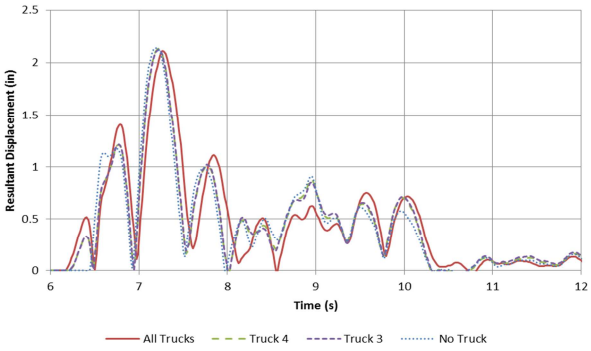
Some of the results from the experimental study suggested that live load gave beneficial effects for this particular bridge model and earthquake excitation (Wibowo *et al.*, 2012). The presence of live load was shown to impede the cracks or damage in the columns and reduce the movement of the structure. These could be due to the vehicles acted as multiple mass dampers and/or the vehicle suspension acted as nonlinear energy sinks, as mentioned earlier, besides some experimental differences between the experiment cases with and without live load.



7. PARAMETER STUDY RESULTS

As previously mentioned, this parameter study tries to investigate the effect of varying the number of vehicles on the deck to the seismic response of the bridge. The trucks are numbered 1 through 6 starting from the north end of the bridge. The displacement histories obtained analytically from several cases are presented herein.

Two cases of one vehicle present were analyzed. One is only Truck 3 and another is only Truck 4 present. Figures 6a and 6b show the resultant displacement histories at the top of north and south bents during 100% DE. It is observed that when only one vehicle is present, the displacement of the north column is slightly reduced while the displacement of the south column is slightly increased compared to when all six trucks are present.

(b)

Figure 10 (a) North and (b) South Column Resultant Displacement Histories for Five-Vehicle Case

For two vehicles present, two cases are presented. One case is when Trucks 4 and 6 are present and another when Trucks 3 and 4 are present. The resultant displacement histories for these cases are presented in Figure 7. Trucks 3 and 4 are the ones closest to the center span of the bridge. When two vehicles are placed on the middle, the resultant displacement demand is increased compared to when all six trucks are present. However, the opposite observation is true when only Trucks 4 and 6 are present, which in this case the resultant displacement demand is decreased.

When comparing two cases of three vehicles present, which are Trucks 1, 3, 5 and Trucks 2, 4, 6 cases, it is shown that the latter case gives the greatest maximum resultant displacement demand of all cases. The maximum resultant displacements were found to be 2.02 in [5.13 cm] and 2.26 in [5.74 cm] for the north and south bents, respectively. The resultant displacement histories at the top north and south bents for these cases are shown in Figure 8.

While the greatest maximum resultant displacement was found in the case where three vehicles are present, the least maximum resultant displacement was found in the case where four vehicles are present. As depicted in Figure 9, the least maximum bent displacements were obtained when Trucks 1, 2, 5, and 6 are present, which were found to be 1.75 in [4.45 cm] for north bent and 1.93 in [4.90 cm] for south bent. Trucks 1 and 2 are located on the north end of the bridge while Trucks 5 and 6 are located on the south end of the bridge. Moreover, when four vehicles were grouped on one side of the bridge such as the case when Trucks 3, 4, 5, and 6 are present, the displacement of the columns is very close to the case when all six trucks are present.

Table 4 Comparison of Maximum Displacements from Various Cases

Truck(s)	Mass Ratio	Max. Disp. (in)		Disp. Ratio	
		North Bent	South Bent	North Bent	South Bent
3	0.031	1.842	2.127	0.976	1.007
4		1.853	2.135	0.982	1.011
3,4	0.063	1.957	2.245	1.037	1.063
4,6		1.833	2.112	0.972	1.000
1,3,5	0.094	1.873	2.088	0.993	0.988
2,4,6		2.021	2.263	1.071	1.071
1,2,5,6	0.125	1.754	1.929	1.930	0.913
3,4,5,6		1.907	2.200	1.011	1.041
1,2,3,5,6	0.157	1.842	2.038	0.976	0.965
1,2,3,4,5		1.939	2.158	1.028	1.021
1,2,3,4,5,6	0.188	1.887	2.112	1.000	1.000

The resultant displacement histories from cases where five vehicles are present are shown in Figure 10. Similarly, two cases were investigated. One is when Trucks 1, 2, 3, 4, and 5 are present and another is when Trucks 1, 2, 3, 5, and 6 are present. From these two cases, the displacement of the columns was found to have little difference than the case when all six trucks are present.

Table 4 presents the comparison of the maximum resultant displacements at the top of north and south bents obtained from various different cases. The mass ratio is the ratio of the mass of the vehicle(s) to the total mass of the structure and it ranges from 3.1% to 18.8%. The displacement ratio is the ratio of maximum displacement of a particular case to the maximum displacement when all trucks are present.

From the results presented, it is shown that the maximum displacement varies in the range of approximately 15% when the number of vehicles is changed from one, two, three, four, five, and six. Moreover, this shows that the presence of live load alters the dynamic behavior of the structure and the problem is not merely an additional gravity load. For cases of the same mass ratio, the seismic response of the structure can be different depending on the placement of the vehicles.

8. CONCLUDING REMARKS

From the data presented in this paper, several observations can be made:

1. The developed numerical model has been validated and is shown to have good agreements with the experiment results.
2. The beneficial effects observed in the experiment results could be due to multiple mass dampers and nonlinear energy sinks effects.
3. The change in the maximum displacement demand at the top of the bents ranges up to approximately 15% when the number of vehicles is varied from one to six.

In addition, more parameter studies are currently ongoing to better understand the behavior of vehicle-bridge interaction during earthquakes and to obtain the limits of when live load gives beneficial and adverse effects.

Abstract: As highway bridges approach their design life, concerns of the influence of aging on their seismic performance increase. In particular, a large number of highway bridges still utilize steel bearings that have been shown to be susceptible to failure in the past. This paper presents the results from a numerical study used to investigate the lateral response of a typical highway bridge with steel bearings under various ground motions. Previous finite element results and theoretical findings are used to develop hysteretic models of the bearing behavior in each orthogonal direction considering the effects of corrosion and axial load level. Nonlinear time history analyses are conducted for a suite of bidirectional ground motions and the longitudinal and transverse displacements are compared to allowable displacement levels representing potential failure modes. The results provide information on expected maximum lateral displacements in bridges with steel bearings and potential need for retrofit or rehabilitation.

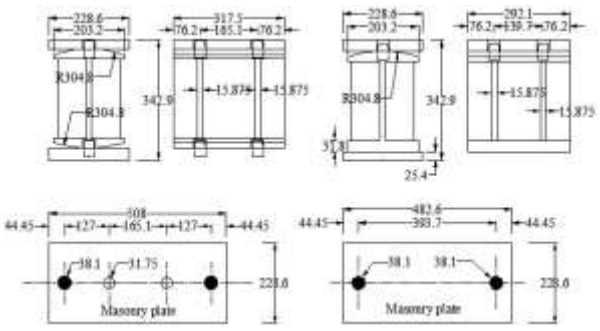
1. BACKGROUND

Failures of highway bridges during past seismic events have been associated with the use of steel bridge bearings. Many older bridges, particularly those located in the Central and Eastern United States, continue to use steel bearings as a mechanism for transferring load from the superstructure to the substructure while also accommodating displacements and rotations caused by thermal changes and vehicular motion. The continued use of older steel bearings combined with moderate to high seismic regions in the Central and Eastern United States (i.e. New Madrid Seismic Zone and Charleston South Carolina Seismic Zone) result in the potential for bridge damage, loss of evacuation routes, and economic impact from an earthquake (Nielson and DesRoches 2008). Given the vital role highway bridges play in transportation networks, there is increased concern regarding seismic performance given their deteriorated in-situ condition (Padgett and DesRoches 2008).

Steel bearings are assemblages of steel components in various geometric forms that utilize rolling and sliding mechanisms between steel surfaces to permit small translations and rotations (Chen and Duan 2003). These bearings often can regain their original positions after small perturbations due to the restoring mechanism associated with their geometric form. However, these bearings are not designed to accommodate large displacements and rotations that can result from a seismic event and knowledge of their behavior under earthquake loads, even in a pristine condition, is limited.

Lack of routine maintenance, such as regular painting and lubricating of the contact surfaces can lead to severe corrosion in steel bearings. Corrosion can result in material loss, section reduction, and decreased stiffness of steel components (Kayser and Nowak 1989). As a result, corrosion can significantly alter the mechanical mechanisms that steel bearings depend on to function properly. Also, debris and corrosion products can accumulate between contact surfaces causing locking of the bearing and interfering with the rolling and sliding mechanism. Locking can then lead to unanticipated and unfavorable lateral forces in the bearing. It has been observed that locking has caused unseating of spans and toppling of the steel bearings due to excessive lateral forces even under only vehicular braking action (Splitstone et al. 2010).

In a seismic event, highway bridges are subjected to large loads and have demonstrated poor performance in the past (Bruneau et al. 1996; Housner and Thiel 1995; and Mitchell et al. 1995). A variety of failure modes for steel bearings has been observed during past earthquakes such as lateral instability, bearing connection fracture, steel component fracture (i.e. keeper plate and stopper), and strength failure (i.e. anchorage failure). Common highway bridge failures owing to failure of steel bearings during an earthquake include damaged piers, unseated or collapsed spans, localized buckling of steel girders, and rupture of end diaphragms.



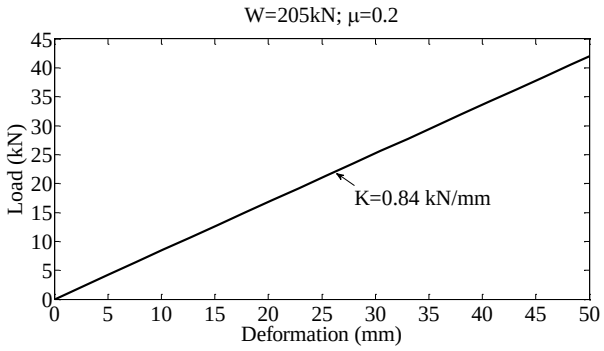
Past studies of the seismic response of steel bridge bearings and their influence on the performance of bridges under earthquakes are limited due to a multitude

of reasons. The most obvious reason is that in regions of frequent seismic activity, most highway bridges have been upgraded or retrofitted with elastomeric or other types of seismic bearings. In addition due to the secondary role they play, steel bearings are often overlooked in the seismic research of bridges (Mander et al. 1996). Yet, an accurate account of the seismic behavior of steel bearings is crucial in assessing the true seismic performance of an in-situ bridge, particularly one that has deteriorated significantly due to corrosion.

In this study a set of hysteretic models is proposed for steel bridge bearings based on the results of a previous finite element study of the cyclic behavior of corroded steel bridge bearings (Fan and McCormick 2011; Fan and McCormick 2012). The hysteretic models are implemented in a model of a simply supported bridge to investigate the maximum lateral displacements of steel bearings under a suite of ground motions. Aging effects are also examined by looking into the influence of friction on the overall seismic response of the bridge. The influence of the superstructure weight on the lateral response of the bridge also is studied.

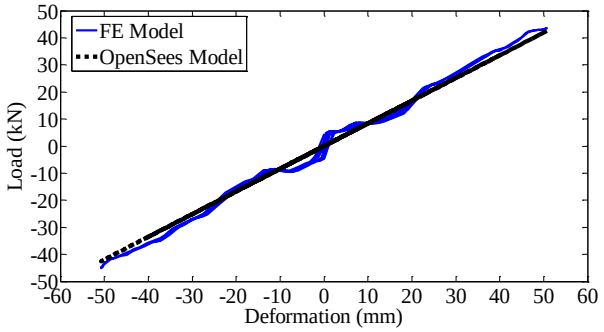
2. HYSTERETIC MODELS OF STEEL BEARINGS

The lateral response of steel bearings in the two orthogonal directions, longitudinal and transverse, is of concern. A previous finite element study (Fan and McCormick 2012) simulated both the longitudinal and transverse behavior for two prevalent rocker (expansion) and bolster (fixed) bearing types (Figure 1). The rocker bearing, also known as an expansion bearing, permits both longitudinal translation and rotation about the transverse axis while the bolster bearing, also known as a fixed bearing, only accommodates rotation about the transverse axis. From the finite element results, the hysteretic models are created using a combination of existing material models (e.g. Steel01, ElasticPPGap, and Hysteretic) in the Open System for Earthquake Engineering Simulation (OpenSEES 2012).



(a) Rocker Bearing (b) Bolster Bearing

Figure 1 Configuration and Dimensions (mm) of the Bearings

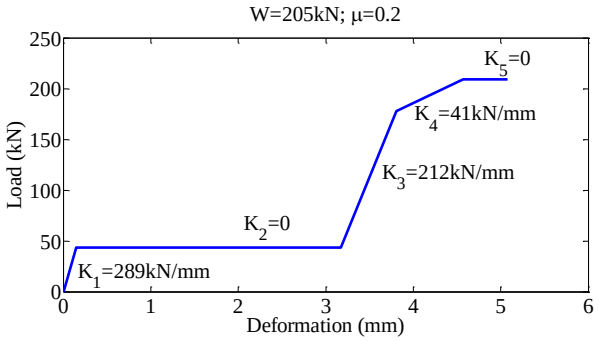


2.1 Rocker bearing models

The results of the finite element study show that the rocker bearing exhibits a constant longitudinal stiffness. A theoretical derivation by Fan and McCormick (2012) reached the same conclusion and determined that this behavior was associated with the rolling mechanism along the rocker bearing's cylindrical contact surface. As a result of this constant longitudinal stiffness, the load-displacement relationship in the longitudinal direction displays a linear behavior that can be mathematically described by Eq. (1). This behavior is captured well using the elastic material model available in the OpenSEES (Figure 2). However, the linear behavior is only applicable until the displacement capacity of the bearing is reached. For the rocker bearing considered in this study, a displacement capacity of 64 mm is assumed. Previous studies also revealed that the rolling mechanism of the rocker bearing is influenced by the axial load and geometry of the rocker body, not by the sliding friction coefficient (Fan and McCormick 2012). This finding suggests that section reduction due to corrosion can influence a rocker bearings longitudinal response.

$$H = W\frac{2R-h}{h^2}u \qquad (1)$$

(a) Model Based on FEM Findings



(b) Validation of the Proposed Model

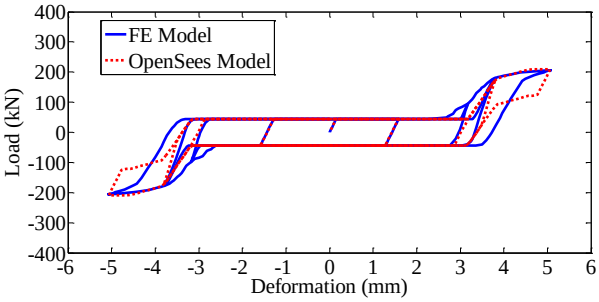


Figure 2 Longitudinal Model for the Rocker Bearing

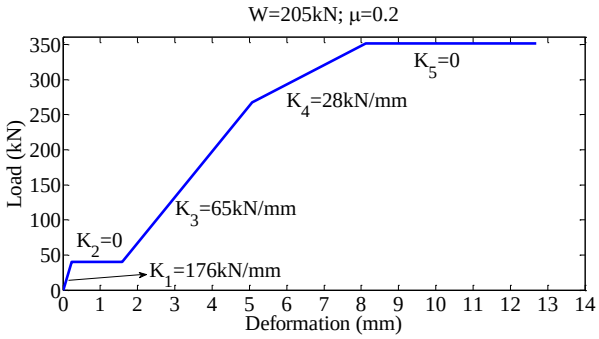
In the transverse direction, the rocker bearing is designed to be rigid under service loads, such as thermal action and vehicular forces. However, the rocker bearing

is predisposed to experience instability under large lateral forces due to the nature of the rocker bearing assemblage. The previous finite element study indicates a limited sliding behavior and then instability as lateral displacements or loads increase (Fan and McCormick 2012). The sliding behavior is attributed to the gap between holes in the masonry plate and sole plate and the pintles in the bearing body that prevent lateral translation at the top and bottom rocker bearing contact surfaces. A slight elongation of the sliding plateau is observed in the finite element study from the accumulation of plastic shear deformation in the pintles. The load-deformation behavior under transverse loading captures both the observed sliding and the loss of stiffness with continued displacement (Figure 3). The OpenSEES model captures the observed behavior from the finite model well, but cannot account for the increase in the sliding plateau due to plastic deformation of the pintles and shows some small differences in the unloading behavior. However, these differences are minor. Toppling of the rocker bearing is not explicitly accounted for, but is assumed to occur when the transverse displacement reaches 5 mm.

(a) Model Based on FEM Findings



(b) Validation of the Proposed Model

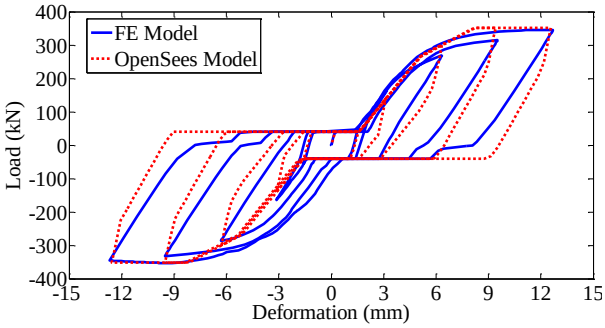


Figure 3 Transverse Model for the Rocker Bearing

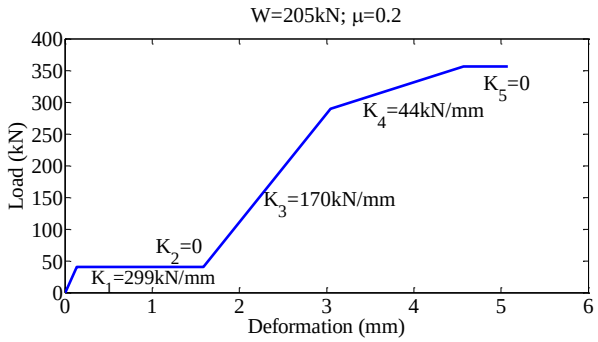
2.2 Bolster bearing models

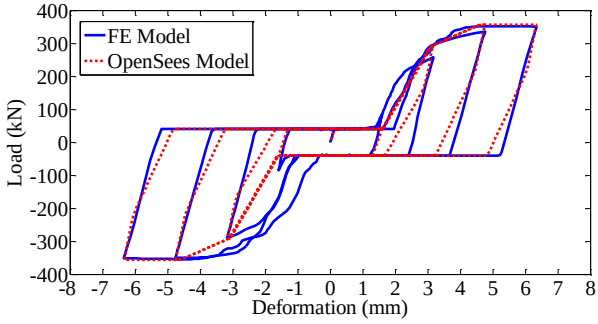
The behavior of the bolster bearing is highly nonlinear in both the longitudinal and transverse directions. This nonlinear behavior depends on the transfer of load through contact, friction, and anchorage elements. From the finite element study, it is found that the bolster bearing has a larger displacement capacity in the longitudinal direction as compared to the transverse direction. This displacement capacity is due to the fact that under longitudinal displacement the bearing bends about its weak axis and the anchor rods provide only a single line of resistance at the centroid of the bearing. Conversely under transverse displacements, bending occurs about the strong axis of the bearing body and the two anchor rods form a couple moment to resist overturning leading to a much stiffer response. The overall behavior in both directions consists of an initial elastic response until the friction coefficient is overcome causing rigid sliding. Once the available sliding distance associated with the oversize of the pintles holes is overcome, a hardening response is observed until loss of stiffness and failure. The adopted hysteretic models in OpenSEES shows similar behavior in the two orthogonal directions while accounting for the difference in the stiffness as illustrated in Figure 4 and 5.

(a) Model Based on FEM Findings



(b) Validation of the Proposed Model

Figure 4 Longitudinal Model for the Bolster Bearing



The rigid sliding portion at the initial loading stage in the model for both the longitudinal and transverse behavior is a result of the clearance that exists between the pintle hole and the pintle. Rocking and prying dominate the deformation mode of the bolster bearing and dictate the failure pattern as illustrated by the hardening portion in the OpenSEES models. Degradation of the bearing after reaching its ultimate strength is not explicitly addressed in the current models. Instead, a failure criterion is defined using allowable displacements. For the longitudinal behavior of the considered bolster bearings, the allowable displacement is assumed to be 13 mm, while 6.4 mm is used for the transverse behavior.

As shown in Figures 4 and 5, the proposed OpenSEES models for the bolster bearing agree well with

the finite element results with only minor differences at certain loading and unloading regions. The examples shown in the figures for the bearing models are all derived for an axial load of 205 kN and a friction coefficient of 0.2. Considering different bridge configurations and various corrosion levels, both the axial load and friction behavior are subject to change. Nevertheless, similar procedures are applied to generate and update the current bearing models to account for these differences based on the finite element study by Fan and McCormick (2012).

Figure 5 Transverse Model for the Bolster Bearing

3. MODEL DESCRIPTION

3.1 Bridge Model

The rocker and bolster bearings modeled in this study are based on those from a typical steel girder highway bridge found in the Central and Eastern United States. These bearings are similar to other steel bearings used throughout the world and function based on similar mechanisms to accommodate thermal expansion and vehicular loads. The highway bridge has four continuous spans of varying lengths and a composite superstructure consisting of concrete slabs and wide-flange steel girders. As a result of the configuration of the bridge, the steel bearings that support the outside girders sustain different axial loads than those supporting the interior girders. However to simplify the study, a simply supported single span bridge resembling the main span of the highway bridge is modeled. One pair of rocker and bolster bearings is located at each end of the span, respectively. The simply supported bridge has a net span of 17.83 m and a width of 9.14 m. The weight of the superstructure accounts for both the concrete slab and two steel girders.

To better understand the potential behavior of the bearings under varying earthquake loads and deteriorated conditions, several assumptions are made in modeling the bridge. First, the bridge superstructure is idealized as rigid with mass being assigned to the center of the block. Also, the interaction between the abutment and the superstructure is ignored for the purpose of investigating the maximum displacement of the bridge under earthquake loads. Third, the bearings on each end of the span are lumped together such that the rigid superstructure is supported at the four corners. A detailed illustration of the bridge model is provided in Fig. 6.

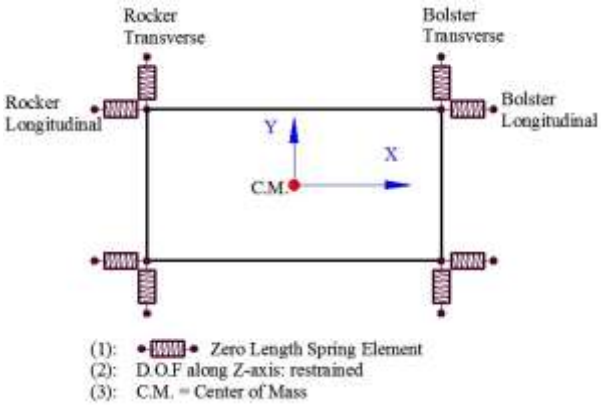

Figure 6 Schematic of the Bridge Model

3.2 Ground Motion Information

Since the bearings being considered are typically found in the Central and Eastern United States, ten pairs of ground motion accelerations representing a 2% probability of exceedance in 50 years for the Boston, MA area are used to evaluate the behavior. Each pair of ground motions has two orthogonal components, one normal to the fault and another parallel to the fault. For all nonlinear time history analyses, the normal component is applied along the longitudinal direction of the bridge while the parallel component is applied in the transverse direction allowing the effects of bi-directional motion to be evaluated. A detailed description of the ground motions is provided in Table 1 while the response spectra for the set of ground motions are shown in Fig. 7. Figure 7 suggests that the ground motions in each orthogonal direction have almost identical response spectrum. The mean peak pseudo acceleration occurs at a period of roughly 0.12 seconds for both components. The normal component produces a mean peak pseudo acceleration of approximately 0.13g while the parallel component has a mean peak pseudo acceleration of 0.11g. This suggests that the ground motion set is insensitive to directivity effects.

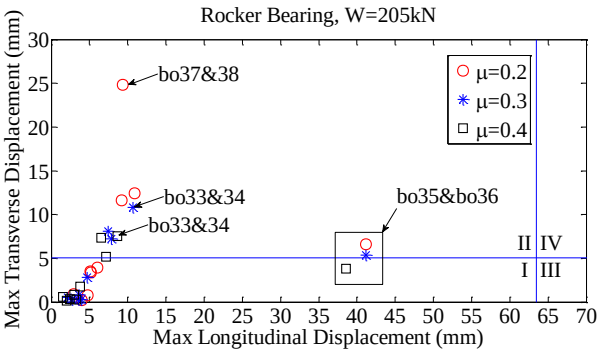
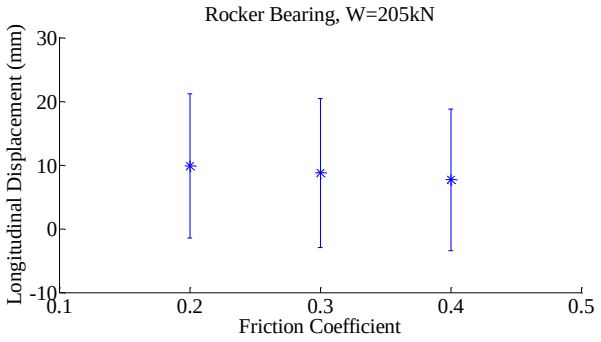
4. INVESTIGATION OF BEARING DISPLACEMENTS UNDER SEISMIC LOADS

To consider the behavior of the overall bridge structure under seismic loads, the lateral displacements of the bearings in the longitudinal and transverse directions are evaluated through nonlinear time history analyses using OpenSEES. The developed models for the bearing behavior in the longitudinal and transverse directions are applied to the zero length spring elements shown in Figure 6. In evaluating the behavior of the bearings, the assumed displacement capacities are taken into account by noting those ground motions that cause lateral or transverse displacements that exceed these limits suggesting potential failure of the bearings.



The effect of aging and deterioration of the bearings also is investigated by considering changes in the friction behavior at the contact interfaces where sliding and rolling occur. In addition, the effect of different axial loads on the bearings is taken as another parameter since the axial load level sustained by the bearings also affects the frictional force generated at the sliding interfaces in the bearings. The findings provide a better understanding of how aging affects the performance of the steel bearings and overall bridge under seismic loads. This method can then be used to better assess potential threats to in-situ bridges and aid in the development of cost effective strategies to ensure the continued safety of older steel girder bridges relying on steel bearings in seismic regions.

4.1 Effect of Friction Coefficient



Figures 8 and 9 provide details on the effect that the friction coefficient has on the seismic response of the bridge in terms of the longitudinal and transverse bearing displacements. The bearing models are derived as discussed in Section 2 using the finite element analyses considering friction coefficients of 0.2, 0.3, and 0.4 (Fan and McCormick 2012). Since bidirectional ground motion pairs are applied simultaneously through the nonlinear time history analysis, displacement interaction diagrams are created for both the rocker and bolster bearing to provide a means of better understanding the bidirectional response under seismic loads.

The displacement interaction diagram is divided into four zones based on the assumed allowable displacements in the two orthogonal loading directions. If the displacement pair falls within Zone I, then the bearing under consideration functions well under the input ground motion pair. When the displacement pair is in Zone II, the considered bearing fails in the transverse direction due to instability for the rocker bearing or due to excessive displacement of the bolster bearing. If the displacement pair falls within Zone III, the failure is due to large displacements in the longitudinal direction. Zone IV is where the displacement capacity of the bearing is surpassed in both the longitudinal and transverse directions.

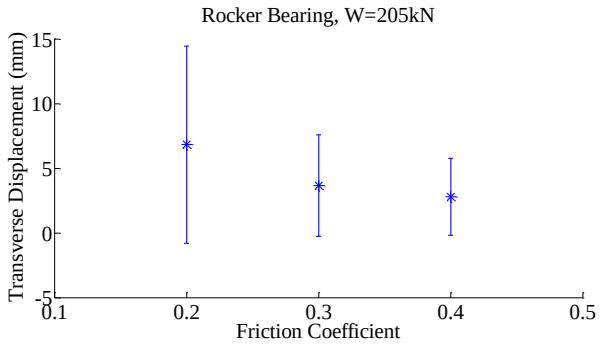


Figure 8(a) shows a clear trend in the displacement of the rocker bearing with respect to the friction coefficient. As the friction coefficient increases from 0.2 to 0.4, the maximum transverse displacement decreases from 25 mm to 7.5 mm for all considered ground motions, while the maximum longitudinal displacement remains at approximately 41 mm for all levels of the friction coefficient. The ground motion pair that results in the maximum transverse displacement varies for the different levels of friction coefficient. The responsible ground motion pair changes from bo37&38 to bo33&34 as the friction coefficient is increased from 0.2 and 0.3 to 0.4. However, the maximum longitudinal displacement for all three friction coefficient levels is caused by the same ground motion pair, bo35&36. This pair has the largest PGA of 1.5g for the normal component that is applied in the longitudinal direction of the bridge.

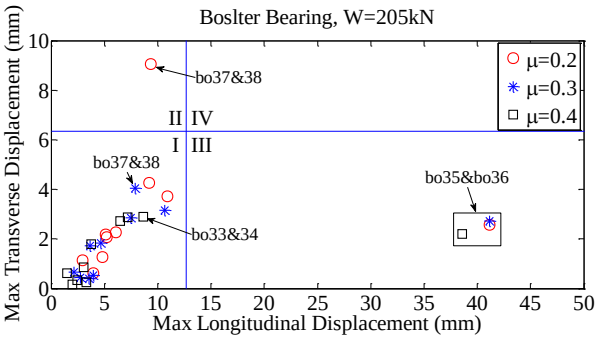
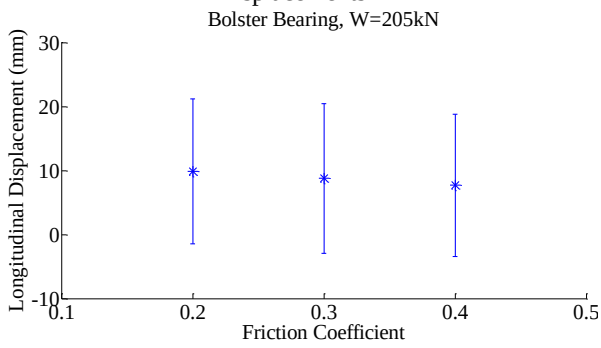
(a) Interaction of Longitudinal and Transverse Displacements

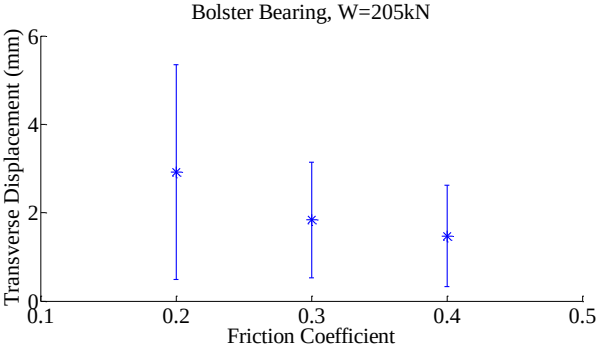


(b) Longitudinal Displacement, Mean ± 1σ



(c) Transverse Displacement, Mean ± 1σ

Figure 8 Effect of Friction on the Displacement Response of the Rocker Bearing under Seismic Loads



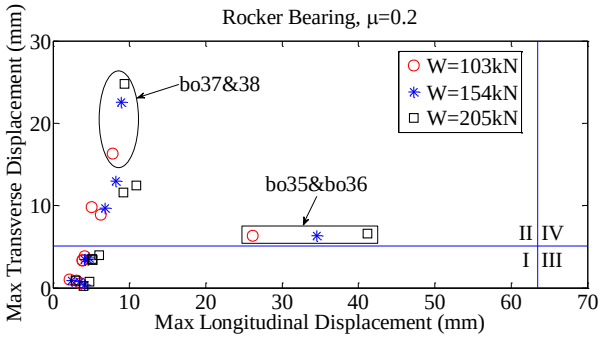
The displacement pairs for all ground motions fall within Zone I and II. This finding indicates that the rocker bearing has adequate displacement capacity in the longitudinal direction and failure is more likely to occur due to instability in the transverse direction. As a result, rehabilitation and retrofit techniques should focus on the transverse response of rocker bearings. Figures 8(b) and (c) also clearly shows that the longitudinal displacement of the rocker bearing is negligibly affected by changes in the friction coefficient, which is due to the fact that rolling is the dominant deformation mode, not sliding. However, the transverse displacement is influenced by the value of the friction coefficient showing more dispersed and larger displacements for lower friction coefficients suggesting that aging will have a greater effect on the transverse response of rocker bearings.

(a) Interaction of Longitudinal and Transverse Displacements

(b) Longitudinal Displacement, Mean ± 1σ

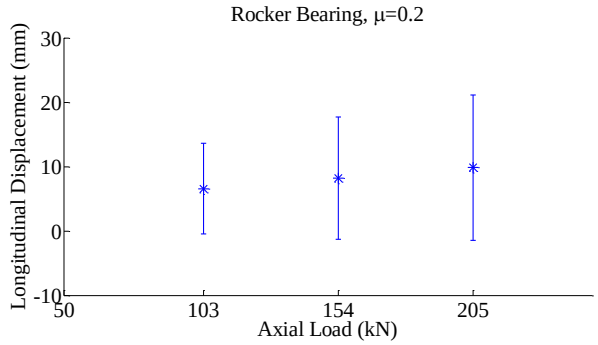
(c) Transverse Displacement, Mean ± 1σ

Figure 9 Effect of Friction on the Displacement Response of the Bolster Bearing under Seismic Loads



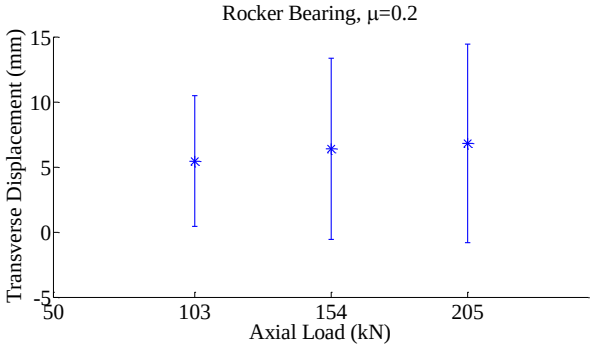
For the bolster bearing, Figure 9(a) shows that an increase in the friction coefficient from 0.2 to 0.4 leads to a decrease from 9 mm to 2.9 mm in the maximum transverse displacement. Conversely, insignificant decreases are observed for the maximum longitudinal displacement as the friction coefficient increases. Additionally, the maximum transverse displacement is caused by two different ground motion pairs depending on the friction coefficient (bo33&34 and bo37&38), while the maximum longitudinal displacement for all friction coefficient values is caused by the same ground motion pair (bo35&36). Unlike the rocker bearing, the analysis of the bolster bearing shows potential failure in both the transverse and longitudinal directions with displacement pairs found in Zone I, II, and III.

Figure 9(b) and (c) reveal a decreasing trend for the mean maximum displacement for both the longitudinal and transverse directions as the friction coefficient increases. This trend is less obvious for the longitudinal response. The transverse response also has a more dispersed displacement distribution at lower friction coefficient values compared to the longitudinal response. These findings suggest that aging may have a greater effect on the response of fixed bearings and that retrofit and rehabilitation methods need to consider both the transverse and longitudinal response.



A close examination of Figures 8 and 9 reveals that the longitudinal responses for the rocker and bolster bearing are of similar magnitudes for each ground motion pair. On the contrary, the transverse responses for the rocker and bolster bearing have significant discrepancies in displacement magnitudes under the same ground motion pair with the rocker bearing showing approximately three times larger displacements. This observation suggests a twisting of the bridge about the vertical (Z-axis) axis caused by the bidirectional motion and different stiffness of the bolster and rocker bearing in the transverse and longitudinal directions, respectively. The lower magnitude in displacement for the bolster bearing is a result of its higher transverse stiffness than that of the rocker bearing.

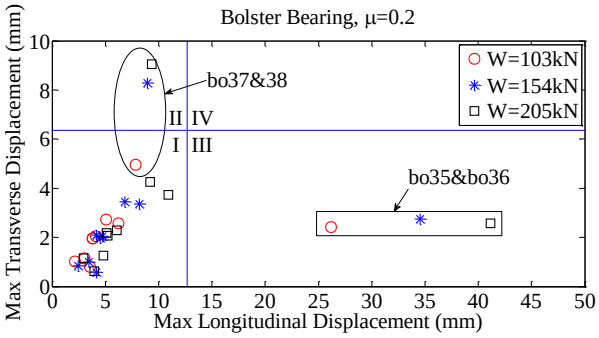
4.2 Effect of Axial Load



The effect that the axial load level sustained by the bearings has on the seismic response of the bridge under bi-directional earthquake loads also is investigated to account for different bridge configurations and span lengths. Figures 10 and 11 provide the findings considering three common levels of axial load in an individual bearing: 103 kN, 154 kN, and 205 kN. The behavior of the bearings at these axial load levels is achieved by varying the overall mass of the bridge segment considered in the OpenSEES model and modifying the parameters of the bearing model to represent the behavior found through the previous finite element analysis of the rocker and bolster bearings under the specified axial loads (103 kN, 154 kN, 205 kN) with a constant friction coefficient of 0.2 (Fan and McCormick 2012).

(a) Interaction of Longitudinal and Transverse Displacements

(b) Longitudinal Displacement, Mean ± 1σ



(c) Transverse Displacement, Mean ± 1σ

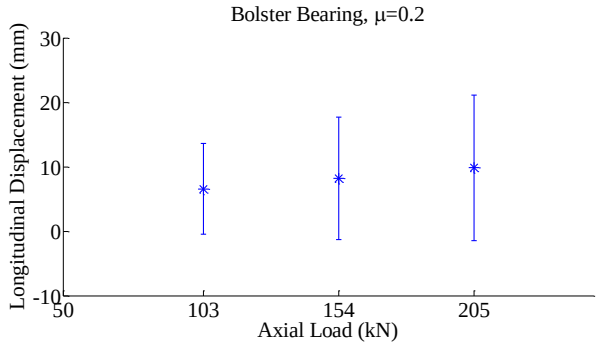


Figure 10 Effect of Axial Load on the Displacement Response of the Rocker Bearing under Seismic Loads

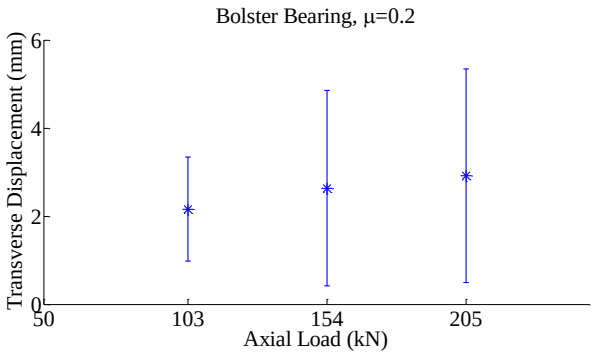
Figure 10(a) shows that for the maximum longitudinal and transverse displacements of the rocker bearing are dependent on the axial load level or mass of the bridge. The maximum longitudinal displacement increases from 26 mm to 35 mm to 41 mm as the axial load is increased from 103 kN to 154 kN to 205 kN, respectively. The ground motion pair, bo35&bo36, causes the largest longitudinal displacement for the three considered axial load levels. The maximum transverse displacement increases from 16 mm to 22 mm to 25 mm as the axial load level is raised from 103 kN to 154 kN to 205 kN, respectively. Again, a single ground motion pair, bo37&38, causes the maximum transverse displacement for all of the axial load levels. However, it is a different ground motion pair than that causing the maximum



longitudinal displacement. This finding is different than the behavior observed when varying the friction coefficient where different ground motion pairs resulted in the maximum displacements for the different friction levels. These findings are consistent with basic structural dynamics since larger axial loads on the bearings indicate a heavier superstructure and thus greater inertial forces under the same ground motion input resulting in greater displacements in the bearings. In addition, all of the displacement pairs are located in Zone I and II, suggesting that the rocker bearings are more susceptible to failure in the transverse direction. Figure 10(b) and (c) shows a similar trend for the longitudinal and transverse displacements. At higher axial loads the maximum displacements for all ground motion pairs is more dispersed and has a larger mean value.

(a) Interaction of Longitudinal and Transverse Displacements

(b) Longitudinal Displacement, Mean ± 1σ

(c) Transverse Displacement, Mean ± 1σ

Figure 11 Effect of Axial Load on the Displacement Response of the Bolster Bearing under Seismic Loads

Fig. 11 provides the response of the bolster bearing under the considered suite of bidirectional ground motions. As the axial load level increases both the longitudinal and transverse displacements increase. The maximum longitudinal displacement increases from 26 mm to 35 mm to 41 mm and the transverse displacement increases from 5 mm to 8 mm to 9 mm when the axial load increases from 103 kN to 154 kN to 205 kN. The responsible ground motion pairs causing the maximum longitudinal and transverse displacement are bo35&36 and bo37&38 under all three axial load levels, respectively. As a result of the limited displacement capacity of the bolster bearing in both loading directions, the displacement pairs are scattered throughout Zone I, II, and III indicating that the bolster bearing has potential to fail in either the longitudinal or transverse direction given the considered suite of ground motions. Fig. 11(b) and (c) reveal that a higher axial load level generates a more dispersed distribution of maximum displacements with a larger mean value for both the longitudinal and transverse responses of the bridge.

A comparison of the data points between Figures 10(a) and 11(a) suggests that under the same ground motion pair, the longitudinal displacement in the rocker bearing is the same as that in the bolster bearing, while the transverse displacement differs. This again suggests that twisting of the rigid bridge deck about a vertical axis is occurring due to the difference in the stiffness of the two bearing types in the transverse direction.

5. CONCLUSIONS

To assess the seismic performance of older highway bridges utilizing steel bearings, credible models for the behavior of steel bearings under both the longitudinal and transverse displacements are needed. Due to the fact that steel bearings are designed solely for gravity loads and are susceptible to corrosion, their effect on the seismic response of highway bridges is of concern. In this study, a set of hysteretic models are developed for two types of steel bearings, rocker and bolster bearings, considering the influence of the friction coefficient and axial load. The friction coefficient is considered to account for potential deterioration of the steel bearing components as a result of corrosion over time. The axial load effect also is investigated to account for the influence of the bridge mass on the initial stiffness, sliding resistance, and critical load for instability. These hysteretic models are incorporated into a simply supported bridge model in OpenSEES to examine its response under a suite of ground motions through nonlinear time history analyses. The maximum longitudinal and transverse displacements are used to determine the influence of the various parameters on the response of the bridge. Allowable displacements are defined for the bearings based on potential failure modes in each orthogonal direction.

The results suggest that larger friction coefficients

can lead to a reduction in the maximum displacement sustained in the transverse loading direction for the rocker bearing and in the two orthogonal loading directions for the bolster bearing. Larger friction coefficients also lead to a less dispersed distribution of maximum displacements and smaller maximum displacements for the suite of ground motions considered. The effect of the friction coefficient is rather limited for the longitudinal response of the rocker bearing.

The findings with respect to the axial load level show that an increase in axial load leads to greater displacements for both the rocker and bolster bearing in the longitudinal and transverse loading directions. Additionally, larger dispersions in the distribution of the maximum displacements are observed for higher axial loads.

For the suite of ground motions, the observed failure modes for the rocker bearing are due to transverse displacement of the bearing. The rocker bearing shows adequate displacement capacity in the longitudinal direction. Moreover, the bolster bearing exhibits possible failure in both the longitudinal and transverse direction due to excessive displacement. This finding suggests that retrofit and rehabilitation of bridges utilizing steel bearings should focus on minimizing displacements in the transverse direction and strengthening bolster bearings in both orthogonal directions.

The conclusions reached in this study are based on a simplified and idealized bridge model for a simply supported single span bridge neglecting the interaction between the abutment and the deck. However, the findings give a general understanding of the influence of aging and bidirectional motion on the response of bridges utilizing typical steel bearings. The overall finding suggests that the presence of steel bearings can lead to damage under moderate ground motions and either retrofit or replacement of steel bearings is suggested for highway bridges in regions of low to moderate seismicity.

Abstract: This paper describes the development and testing of a new pre-tensioned bridge bent system that includes 1) precast components to reduce construction time, 2) unbonded pre-tensioned strands in the columns to minimize post-earthquake residual displacements, and 3) Hybrid Fiber Reinforced Concrete (HyFRC) located in the plastic-hinge regions to reduce spalling, and delay bar buckling and bar fracture.

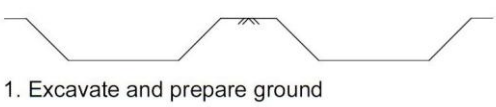
Quasi-static, cyclic tests were conducted previously on two subassemblies that represented a column-to-footing connection and a beam-to-column connection. Those specimens contained conventional concrete in the plastic hinge region. Those tests showed that bents built with this technology would likely re-center better than conventional bents, but the columns experienced bar buckling and bar fracture at lower drift ratios than observed in previously tested RC specimens without the pre-tensioning. To address this concern, the system was modified to include HyFRC shells in the plastic-hinge regions. The performance of this modified system was then first investigated with a series of shake-table tests on a single column. That testing showed that the specimen was able to re-center up to a peak drift ratio of 5.5%. It also showed that the HyFRC shell delayed spalling, bar buckling, and bar fracture. To allow direct comparison, under identical conditions, of specimens with and without the HyFRC shell, quasi-static test of the new system was conducted in December 2012.

1. INTRODUCTION

Reinforced concrete bridge construction techniques in seismic regions have changed little since the mid-1970s, when ductile details were first introduced. Nearly all bridge bents (intermediate supports) in seismic regions are now constructed of cast-in-place reinforced concrete using those ductile details. Such bridges have served well in the past, but to meet current design expectations, they need to be improved in three main areas: 1) speed of construction, 2) seismic resilience and 3) durability.

New structural systems and construction methods are needed to make improvements in these three areas. One approach for reducing construction-related delays is to precast structural elements off-site and then assemble them rapidly once they arrive on site. Post-earthquake residual displacements can be reduced by prestressing the precast bridge columns. The prestressing is designed to bring the system to its original plumb position when lateral load is removed. Durability of the system can be enhanced by the selection of high-performance materials to improve the system structural performance and minimize corrosion. Precasting also has other benefits, such as improved worker safety and higher construction quality.

This paper describes a new unbonded, pre-tensioned precast bent system developed to meet the current design expectations. Different connection systems are used at the column-to-foundation and at the cap beam-to-column interfaces, because the conditions at each location have unique constraints and opportunities. Both connections are pre-tensioned. The connections were tested quasi-statically for seismic performance using conventional concrete in the plastic hinge region. In June 2012, an improved pre-tensioned system with Hybrid Fiber Reinforced Concrete (HyFRC), in the plastic hinge region, was tested on the shake table at the Richmond Field Station Earthquake Simulation Laboratory of the University of California at Berkeley. A quasi-static version of the improved system is being tested in December 2012.

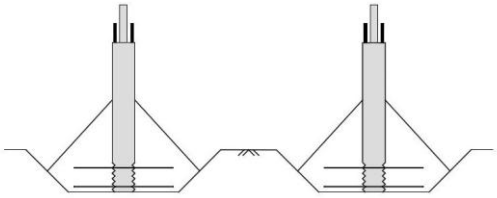


2. PRE-TENSIONED BRIDGE BENT SYSTEM

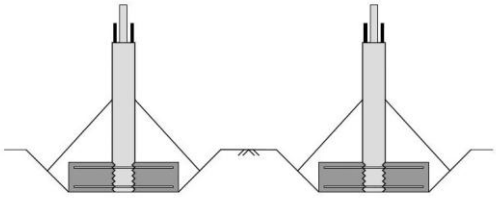
2.1 System Overview

The new system is an outgrowth of concept development and experimental research on a fully precast bent system at the University of Washington (Stueck et al. 2007, 2009, Pang et al. 2008, 2010, Cohagen et al. 2008, and Haraldsson et al. 2012a, 2012b).

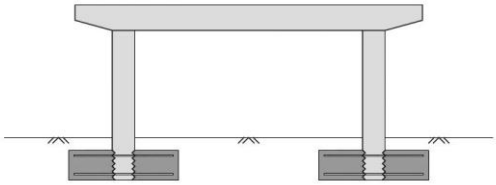
Figure 1 shows the construction sequence for the new pre-tensioned bent system. Once the footing has been



excavated (Step 1), top and bottom reinforcement is placed (Step 2). The precast pre-tensioned column is then brought to site, plumbed, leveled and braced (Step 3). The footing can then be cast-in-place (Step 4). Alternatively, the precast column can be plumbed and leveled before the footing reinforcement is placed. The final step is to connect the column to the cap-beam (Step 5). In comparison with conventional cast-in-place system, the primary advantage of this system is that a footing and a column can be built in little more time than is needed to cast the footing alone. A main time-saving factor in the bent construction is the presence of the precast cap-beam (Marsh et al. 2011, Weinert 2011). By precasting the cap-beam, time needed to complete various tasks, such as shoring, rebar placement, casting and curing, are relieved.



1. Excavate and prepare ground



2. Place Rebars (and formwork)

3. Position and brace precast column

4. Cast footing

5. Position precast cross-beam and grout projecting column segment and bars

Figure 1. Construction Sequence

The pre-tensioned bent system concept is shown in Figure 2.

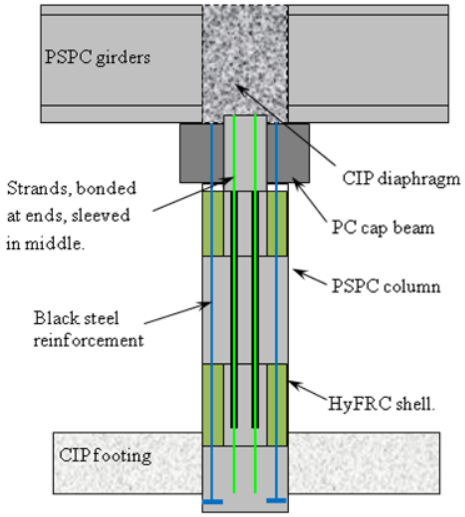


Figure 2. Pre-Tensioned Bridge Bent System

In this system, bridge elements are precast off-site and assembled rapidly on-site. To facilitate rapid construction, the precast column is connected to a cast-in-place spread footing with a "socket" connection (Haraldsson et al. 2012a, 2012b). At the top, the column is connected to a precast cap-beam using a modified grouted bar connection (Davis et al. 2012a, 2012b). The connection concepts are described further in subsections 2.2 and 2.3.

To increase resilience and durability, the column is precast with pre-tensioning that is bonded within the connections and unbonded within the clear height of the bent. The prestressing strands are designed to remain elastic to a specific drift target, and they are intended to bring the bent system back to its original plumb position following an earthquake. The purpose of debonding the strands over the clear height of the column is to distribute strains during the earthquake. To dissipate energy, bonded mild reinforcement crossed the crack planes located at the beam-to-column and column-to-foundation interfaces. In order to delay spalling and buckling of the longitudinal bars, plastic hinge regions were made more ductile with prefabricated elements made of Hybrid Fiber Reinforced Concrete (HyFRC) composite material (Kumar et al. 2011). For fabrication reasons, those elements were cast in the form of cylindrical pipes that were subsequently filled with conventional concrete.

2.2 Column-to-Footing Connection: Socket Connection

The system uses a socket connection to connect the precast column to the cast-in-place spread footing (Haraldsson et al. 2012a, 2012b).

The construction process for this connection is simple, as shown in Figure 1. The location of the footing is excavated, and the precast column is brought in, plumbed and braced. Then, the footing reinforcement is put in place and the concrete is cast around the column. Alternatively, the footing reinforcement could be placed before the column is set.

The precast column has an intentionally roughened exterior surface where it is to be embedded in the cast-in-place footing. The column bars are terminated with mechanical anchors instead of being bent out into the spread footing to facilitate handling and to improve the flow of internal forces. The prestressing strands are bonded within the embedded portion of the column.

2.3 Colum-to-Cap Beam Connection: Grouted Bar Connection

At the top of the column, the socket connection concept could not be used easily with a precast beam. Thus, a new connection was developed, based on the concept of grouted bars, to incorporate bonded prestressing strands as well. It can be seen in Figure 3.

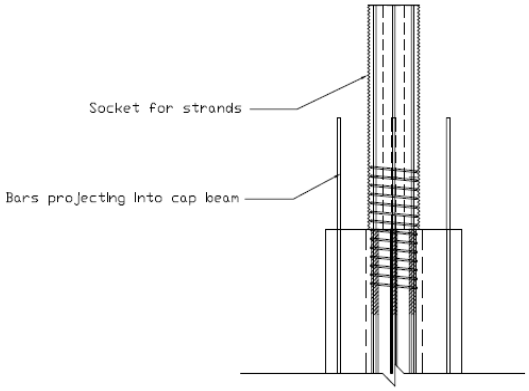

Figure 3. Hybrid Grouted Bar Socket Connection

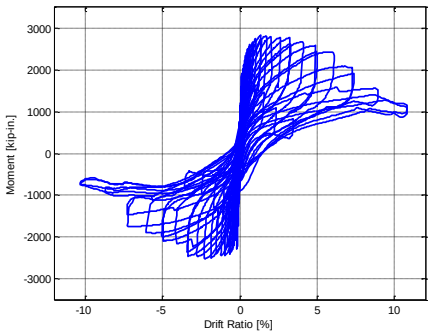
The grouted bar connection was a modification of the one developed by Pang et al. (2008, 2010). In Pang's connection, large bars extend from the column and are grouted into matching ducts in the cap beam. Their large diameter means that few are needed, so large ducts can be used and fit-up is easy. In the modified version, a central section of column with a reduced diameter extends beyond the body of the column and is grouted into a large central duct. This section contains the prestressing strands and allows the bonding to be completed within the depth of the cap-beam, thereby maximizing the unbonded length of strand. The shoulder on the column provides a temporary erection support for the cap-beam. Mild reinforcement is also connected as in Pang's system and provides energy dissipation by cyclic yielding under seismic loading.

2.4 Constructability

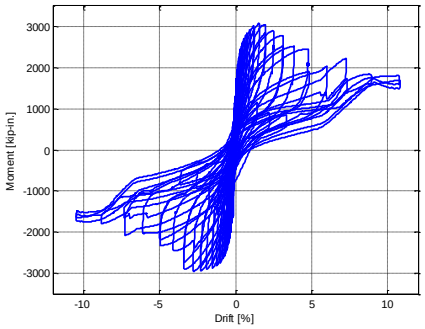
The parent system of the pre-tensioned system (i.e., the non-prestressed precast bent system) was recently deployed in Washington State as part of the construction of a bridge over Interstate-5 (Khaleghi et al. 2012). The bridge had two spans, tall abutments on the ends and a center pier of four columns. Even though the columns were light enough to be lifted in one pick, the columns were fabricated in several pieces to verify the constructability of a segmental version of the system for future applications.

The precast columns were connected to the cast-in-place spread footings using the socket connection. No major problems were encountered and alignment was relatively straight forward (Haraldsson et al. 2012b). At the top, the precast columns were connected to the precast cap-beam using a Large-bar connection (Pang et al. 2008, 2012). The cap-beam was in two segments because of weight constraints. The placement of each cap-beam segment was a quick operation and it took less than 30 minutes per segment.



The pre-tensioned bent system relies essentially on same connections as the precast bent system. Thus, it is expected that the system is both easily and rapidly assembled together on site. The prestressing and fabrication of the HyFRC are performed simultaneously in the precast plant and so are taken off the critical path.

3. QUASI-STATIC TESTS



Davis et al. (2012a, 2012b) report the details of the experimental program and the measured response of a pre-tensioned column-to-cap beam and a column-to-spread footing connection using conventional concrete in the plastic hinge region.

Two 42% scale cantilever subassemblies were tested at the University of Washington Structural Laboratory. The specimens had columns that were 508-mm (20-in.) in diameter (representing 1.22-m [4-ft] diameter prototype column) and 1.52-m (60-in.) high, resulting in a span-to-depth ratio of 3.0. Both test columns had the same octagonal cross section with a 508-mm (20-in.) diameter from flat face to flat face. The number and configuration of bonded reinforcing bars and unbonded strand was identical for both columns. Six D-13 (No. 4) bars were used in a circular pattern with a 438-mm (17.25-in.) diameter and six 10-mm (0.375-in.) diameter epoxy-coated strands were used in a circular pattern in the column center. Each strand was jacked to a stress of 1241 MPa (180 ksi) and after taking into account all losses, the resulting strand stress was estimated to be 1124 MPa (163 ksi), providing the system a total prestressing force of 369 kN (83 kips).

Under cyclic load, both specimens hinged above the connection region and had nearly identical force-displacement curves and damage progression, as shown in Figure 4. They showed good re-centering capability (less than 1% drift residual after being cycled to 10% drift), but spalling and bar buckling were initiated at drift ratios lower than those typically achieved in non-prestressed specimens (e.g., Pang et al. 2008, 2010, and Haraldsson et al. 2012a, 2012b). Even though they experienced early damage, both specimens maintained 80% of their peak lateral strengths up to a drift ratio of 5%.

a) Column-to-Footing Connection

b) Column-to-Bap Beam Connection

Figure 4. Moment-Drift Ratio Response for a) Bottom Connection and b) Top Connection

To delay bar buckling and fracture, the system was modified by including Hybrid Fiber Reinforced Concrete (HyFRC) in the plastic hinge region. HyFRC has been shown to exhibit superior durability and cracking resistance (Yi and Ostertag 2004, Grupp et al. 2007, Ostertag et al. 2007, and Jen et al. 2011). At the time of writing (December 2012), an identical column-to-footing specimen with HyFRC shell in the plastic hinge region is being tested (Finnsson 2012).

4. SHAKE-TABLE TEST OF ISOLATED COLUMN

In June 2012, shake-table tests were performed at the Richmond Field Station Earthquake Simulation Laboratory of the University of California, Berkeley to evaluate the damage susceptibility and re-centering capability of new resilient columns. The following discussion describes the unbonded, pre-tensioned precast column using HyFRC in the plastic hinge regions. A reference column (a typical Caltrans design) for the new designs is scheduled to be tested in late December 2012.

4.1 Connection Specimen

A cantilever unbonded, pre-tensioned precast column was designed and fabricated for the shake-table test. The full-scale prototype was assumed to be a 1.2-m (4-ft) diameter column. The specimen represented the column-to-foundation connection at a 33% scale with an aspect ratio of 6.0.

Figure 5 shows the details of the scaled test specimen. The final design resulted in eight D-13 (No. 4) bars (A_s = 1.6 in^2, ρ_l = 0.75%) and eight 10-mm (3/8-in.) diameter prestressing strands (A_p = 439 mm^2 [0.68 in^2], ρ_p = 0.32%). Epoxy-coated strands were used to improve bond and minimize corrosion. Each strand was jacked to a stress of 1117 MPa (162 ksi) that resulted in an effective stress of 986 MPa (143 ksi), thus providing a total prestressing force of 431 kN (97 kips). The strands were designed to have first yield at 3.0% drift. The transverse reinforcement consisted of 4-gauge spiral at 32-mm pitch (ρ_s = 0.88%). The column cross-section was octagonal to facilitate fabrication. The HyFRC shell height in the plastic hinge region was 711 mm (28 in.) with a wall thickness of 71 mm (2.8 in.). The shell extended 102 mm (4 in.) into the spread footing to avoid cold joint opening at the column-to-foundation interface, therefore leaving a length of 1.5 times the column diameter extending up the column.

4.2 Experimental Setup

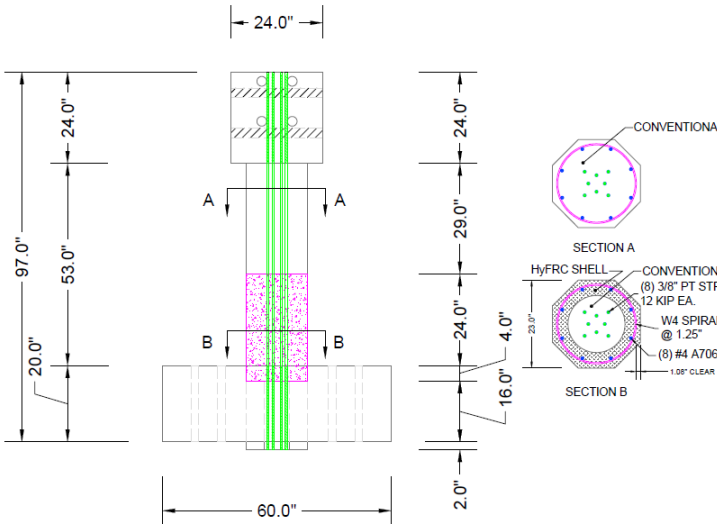


Figure 5. Scaled Colum-to-Foundation Connection

Figure 6 shows the test setup. The specimen was placed on the shake table, leveled with shims and post-tensioned to the top of underlying tri-axial load cells. On top of the column were three mass blocks (each of size 3.048 m [120 in.] x 3.048 m [120 in.] x 0.356 m [14 in.]) that provided approximately 240 kN (54 kips) dead load. To support the mass blocks on top of the column, steel brackets were post-tensioned to the top of the column (via a "load stub") in two orthogonal directions.

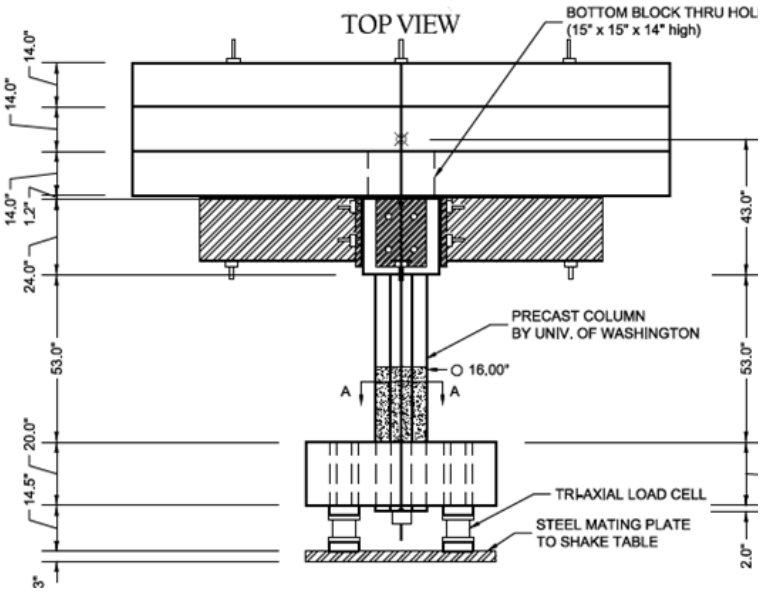

Figure 6. Experimental Test Setup

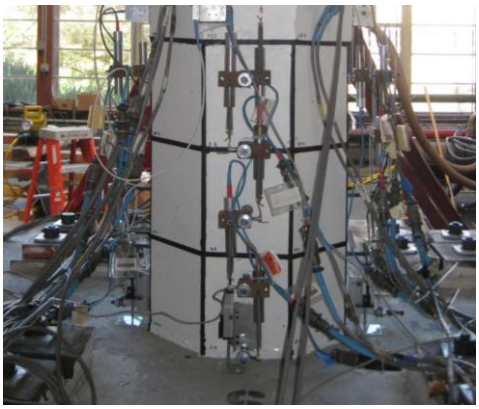

Figure 7. Column at the Start of the Test Program

4.3 Testing Protocol

The test protocol consisted of eight ground motions, applied in order of ascending intensity. The ground motions were selected on the basis of how they displaced the reference column in a nonlinear time-history analysis. Table 1 summarizes target drifts and ductility demands for the reference column. Before each earthquake test, low-amplitude white noise tests were performed to detect any change in natural period and damping as damage accumulated. Table 1 shows that the intensity level was increased in six stages. The first level was intended to keep the specimens below first yield, while the other levels would push the specimens beyond yield.

Table 1. Target Drift and Ductility Demand for the Reference column

EQ No.	EQ. Name	Drift Ratio (%)	Ductility Demand (-)
1	Coalinga, 1983	< 0.47	-
2	Imperial Valley, 1979	2.1	2.0
3	Morgan Hill, 1984	2.1	2.0

5	Northridge, 1994	4.2	4.0
6	Northridge, 1994	6.3	6.0
7	Kobe, Japan 1995	8.4	8.0
8	Kobe, Japan 1995	10.5	10.0

4.4 Damage Progression

Figure 7 shows the pre-tensioned test specimen prior to the shake table tests.

During the shake-table testing, the table was not set down for inspection after every ground motion. The table was first set down after Earthquake 2 (2.1% target drift). The column was plumb and hairline cracks (<0.1 mm) were found in the bottom 406 mm (16 in.) of the column.

The column was next inspected after Earthquake 4 (4.2% target drift). The column re-centered back to its original plumb position. Cracks propagated around the column but very little cracking occurred higher than 406 mm (16 in.) above the interface. The largest residual crack measured 0.76 mm (0.03 in.) approximately 203 mm (8 in.) above the interface. Noticeable spalling was observed after Earthquake 4 (4.2% target drift). No separation between the column and the spread footing was noticed. In Earthquake 5 (4.2% target drift) new spalling occurred 102 mm (4 in.) above the interface on the whole north side of the column (north, northwest, northeast). A level placed on the column showed that the column was still re-centering to its original position, confirming visual observation.

Cracking and spalling became more pronounced after Earthquake 6 (6.3% target drift). A very visible dominant crack formed 102 mm (4 in.) above the interface, and was seen opening and closing during the whole test. The column continued to be plumb when it was at rest. After Earthquake 7 (8.3% target drift), the column appeared to have residual drift. For the first time a hairline crack was noticed at the cold joint (located 610 mm [24 in.] above the interface) between the HyFRC shell and the conventional concrete. Earthquake 8 (10.4% target drift) was the last record that the column was subjected to. During the shaking, two fracture sounds were heard. A spiral fracture became visible through spalling crack (the spalling was held together by the steel fibers) on the north face of the column approximately 152

mm (6 in.) above the interface. The other fractured spiral or longitudinal bar could not be located. Bar buckling was observed 203 mm (8 in.) above the interface on the northeast face of the column. Spalling increased around the perimeter of the column but was held in by the steel and plastic fibers in the HyFRC shell. Residual drift was apparent. Figure 8 shows the specimen after the test program.

Figure 8. Column at the End of the Testing

4.5 Column Drift Response

The specimen was subjected to all eight ground motions without failing. Table 2 summarizes peak drifts and residual drifts measured in any direction. The table shows the column re-centered almost perfectly through Earthquake 6 (6.3% target drift), as found by the visual observations. The column had been expected to re-center perfectly when displaced less than 3.0% peak drift, because up to that displacement the strand stress remained below yield, as shown by the strand strain gages (first yield detected in Earthquake 4). Nevertheless, the column continued to re-center past first yield.

Table 2. Column Drift Response Results

EQ No.	Ref. Col Target Drift Ratio (%)	Pre-T Col. Meas. Drift Ratio (%)	Pre-T Col. Res. Drift Ratio (%)
1	< 0.47	0.4	0.00
2	2.1	1.7	0.06
3	2.1	2.1	0.01

5	4.2	5.2	0.19
6	6.3	5.5	0.06
7	8.4	8.7	1.07
8	10.5	5.9	0.52

5. SUMMARY

This paper presents a new bridge bent system that is rapidly constructible and provides excellent seismic performance. The rapid construction features are achieved by precasting the elements and by using innovative connections and erection procedures. The superior seismic performance is obtained through the use of unbonded prestressing in the column.

The constructability of the new system has been demonstrated. The new system is an outgrowth from an already developed non-prestressed precast bridge bent system that has been implemented in a bridge construction in Washington State. At the bottom, a precast column is connected to a cast-in-place foundation using a socket connection. At the top, the precast column in connected to a precast cap-beam using a modified grouted bar connection. The seismic performance has been tested in three stages.

In the first stage, quasi-static tests were conducted on two, 42% scale sub-assemblies that used conventional concrete in the plastic hinge region, and represented the system's bottom and top connections. The specimens behaved almost identically and maintained 80% of their peak lateral strength up to a drift ratio of 5%. Furthermore, they showed the system is able to re-center to its original plumb position (1% residual drift after being displaced to 10% peak drift). However, initial spalling, bar buckling and bar fracture were observed at a lower drifts than observed in previously in non-prestressed specimens (Davis et al. 2012a, 2012b).

The system was improved by including Hybrid Fiber Reinforced Concrete (HyFRC) in the plastic hinge region. The HyFRC composite is expected to delay premature spalling, bar buckling and bar fracture (Kumar et al. 2011). In the second stage, completed in July 2012, a 33% scaled shake-table test was conducted on a column that contained HyFRC in the plastic hinge region. The column was subjected to eight different earthquakes with six different intensity levels. During shake table testing, the column was seen to rock about a crack 4-5 in. above the column-to-footing interface. The column showed a excellent re-centering through the first six earthquakes (no residual drift up to 5.5% peak drift, and 1% residual drift after the extreme peak drift of 8.7%).

In the third stage, in December 2012, quasi-static testing was conducted on the system with HyFRC in the plastic hinge region to permit direct comparison, under identical loading conditions, the effect of the HyFRC on the system. Ideally this step would have been conducted before the shake table testing, but the schedule was controlled by the availability of test facilities.

6. CONCLUSIONS

The following conclusions were drawn from the study:

- Response of both quasi-static test specimens and shake table test specimens were controlled by column properties. Essentially no damage occurred in the connection region.

- In the first stage, the unloading curves of quasi-static tests specimens (with conventional concrete in the plastic hinge region) showed that pre-tensioned specimens are likely to re-center, and have lower residual drifts (specimens returned to 1% residual after being displaced laterally to a drift ratio of 10%), than previously tested non-prestressed specimens (Pang et al. 2008, 2010, Haraldsson et al. 2012a, 2012b). In the second stage, the measured response of the shake table specimens showed that re-centers after being displaced laterally up to 5.5% drift. At that time, prestressing strands had already yielded, as intended.
- The pre-tensioned quasi-static tests suffered spalling and bar buckling at a lower drift ratios than did in previously tested non-prestressed specimens. The pre-tensioned system was modified by including Hybrid Fiber Reinforced Concrete (HyFRC) in the plastic hinge region and tested first in series of shake table tests in the UC Berkeley Earthquake Simulation Laboratory. Currently (December 2012), the effect of the HyFRC on the plastic hinge region is being evaluated through a direct quasi-static test comparison.
- The presence of prestressing in the column is not expected to affect the constructability of the connections. The system relies essentially on the same connection as its parent system that is already developed and implemented in practice (i.e., precast bent system).

Abstract: The NEES-Soft Project, whose full title is "Seismic Risk Reduction for Soft-Story Woodframe buildings," is a five-university, multi-industry, NSF-funded project that has the objectives of (1) enabling performance-based seismic retrofit (PBSR) for at-risk soft-story woodframe buildings; and (2) experimentally validating the U.S. Federal Emergency Management Agency (FEMA) P-807 retrofit methodology. This paper focuses on the development, refinement, and future full-scale experimental validation of the Performance Based Seismic Retrofit (PBSR) methodology, which is an extension of the Direct Displacement Design (DDD) applied during the NEESWood project, but with the ability to include torsion which is often present in these soft-story structures. The PBSR approach decouples the translational and torsional response and allows the analyst to decide what portion of the allowable target story drift may be due to torsion with the remainder of the allowable target drift coming from translation. This illustrative example of a four-story building retrofit includes design of a steel cantilevered columns retrofit option, initial validationo of PBSR approach using nonlinear time history analysis, and shake table testing program at U.C. San Diego. A variety of retrofits will be considered in the testing but only one retrofit approach (steel cantilevered columns) is presented in this paper. Nonlinear time history analysis provides initial validation of the PBSR approach and plans for shake table testing at U.C. San Diego for the four-story building are discussed .

1. INTRODUCTION

The NEES-Soft Project, whose full title is "Seismic Risk Reduction for Soft-Story Woodframe buildings," is a five-university, multi-industry, NSF-funded project that has the objectives of (1) enabling performance-based seismic retrofit (PBSR) for at-risk soft-story woodframe buildings; and (2) experimentally validating the U.S. Federal Emergency Management Agency (FEMA) P-807 retrofit procedure. A soft-story building is a building that has one or more stories with significantly less stiffness (and strength) than the stories above or below. This condition usually occurs at the bottom story of a multi-story building and is often the result of large openings that are used for main building entrances or parking garages. Figure 1 shows a typical soft-story building in San Francisco, California. It is estimated that there are thousands of these buildings in San Francisco alone and many more throughout California and the United States. These buildings were generally built before 1970 and many as early as the 1920's, which means that they used construction practices not considered acceptable by today's codified standards. For example, many of these buildings do not have wood structural panels but rather rely on plaster on wood lathe, horizontal wood siding made up of dimension lumber planks, and diagonal bracing for shear resistance. These archaic assemblies require significant wall lengths in order to supply the necessary lateral capacity. The wall lengths available for soft-story buildings are, in general, too short at the bottom story, thereby resulting in a soft-story. The soft-story condition is exacerbated by the poor performance of these archaic assemblies, making it difficult to retrofit in many cases. In addition, as the buildings have undergone remodeling over the years, more and either additional layers of what are considered non-structural finishes by today's engineering standards have been added, or some portions of the assemblies replaced further complicating the analysis and retrofit of these buildings.

In order to better understand the seismic behavior of soft-story woodframe buildings, the NEES-Soft project

consists of numerous tasks ranging from numerical analysis and model development, hybrid testing, and full-scale shake table tests for validation of the methods developed within the project. This paper focuses on (1) the performance-based seismic retrofit (PBSR) approach with application to a four-story apartment building; and (2) explanation of the shake table test program at NEES@UCSD wherein the same four-story building will be tested.

Figure 1. Example of a soft-story woodframe building in San Francisco, California (Photo: M. Gershfeld)

2. PERFORMANCE-BASED SEISMIC RETROFIT

Displacement-based design was originally proposed by Priestley (1998) and later modified by Filiatrault and Folz (2002) for wood structures. Pang and Rosowsky (2009) proposed the direct displacement design (DDD) method by employing modal analysis of the structure and used the code-specified acceleration response spectral values in order to calculate the displacement at each story. Later, Pang et al. (2009) proposed a simplified procedure for applying the DDD method by modeling the structure with an equivalent single degree of freedom system and Wang et al. (2010) further refined the procedure.

The current DDD methodology (Pang et al., 2009) determines the required lateral stiffnesses over the height of the building such that the building meets the target displacement. This method serves as the basis for a direct displacement retrofit (DDR) procedure and can be used to retrofit symmetric buildings (i.e., no torsional moment due to seismic force) or irregular buildings that after retrofit would have negligible asymmetry (eliminating torsion by reducing the in-plane eccentricity) (Bahmani and van de Lindt, 2012). The proposed Performance-Based Seismic Retrofit (PBSR) in this study can be used to retrofit existing buildings such that all stories meet the performance criteria (not necessarily meeting the exact target drift because of the constraints formed by the existing design) and it can be used to retrofit buildings that are weak (and soft) in both translation and rotation.

In the PBSR approach being developed in the NEES-Soft Project, the DDD method is employed to design the retrofits such that the building meets the performance criteria communicated by the owner or stakeholders for different seismic hazard levels. The first step is identifying the target story drift and corresponding seismic intensity at which that drift is not to be exceeded for the specific building; then, in the second step, the DDD method is employed to determine the distribution of lateral and torsional stiffness for each story such that the target performance requirements (story drifts limits) are satisfied 50% of the time (i.e., a non-exceedance probability of 50%).

3. DIRECT DISPLACEMENT RETROFIT (DDR)

The DDR method proposed in this paper can be used to design buildings with horizontal irregularities (torsionally unbalanced) by distributing the stiffness of the structure vertically, along its height, and horizontally, in the plane of each story, such that the target displacement of each horizontal line of the resistance can be achieved under a specific seismic intensity, taking into account the nonlinear behavior of the structure. In order to simplify the DDR procedure, the structure can be modeled as a single degree of freedom (SDOF) system. Figure 2 presents an equivalent SDOF system for an N-story building. It can be seen that the total displacement measured at the center of mass of the story is a summation of displacement due to translation ($\Delta^{Tns.}$) and displacement due to torsion ($\Delta^{Tor.}$). The superscripts "*Tns.*" and "*Tor.*" are corresponding to translational and torsional displacements, respectively. The effective mass (W_{eff}) and lateral force distribution factors (C_v) can be calculated based on the approach used in Pang et al. (2009). The fundamental translational period of the building can be obtained from the displacement response spectrum that is developed based on the design spectral acceleration maps (ASCE7, 2010) and should be modified to take into account the effect of equivalent damping in the system as shown in Figure 3.

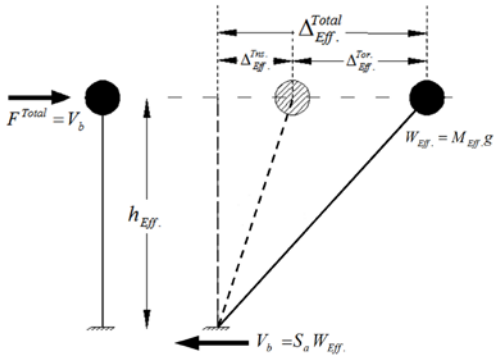

Figure 2. Equivalent SDOF model of multi-story building

Having the fundamental period of the building, the effective lateral stiffness, and consequently the distribution of the stiffness for lateral load resisting system at each story, can be obtained. The last step is locating the lateral load resisting systems (i.e., shearwalls or other retrofit assemblies in woodframe buildings) such that the design satisfies the initial assumption that is made regarding the contribution of torsion to the total displacement.

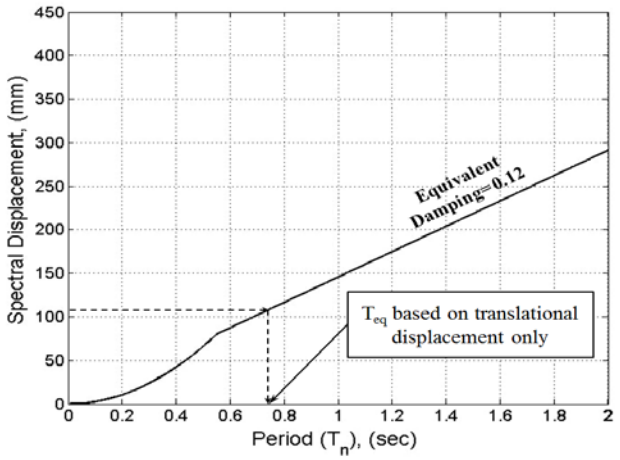

Figure 3. Displacement response spectrum

Retrofit Techniques

In this study, steel cantilever columns were used to retrofit the first story (soft story) and standard wood shearwalls with different nail patterns were used to retrofit the upper stories. The required lateral stiffness of each story was calculated based on the DDR method and using the secant stiffness of standard wood shearwalls and steel cantilever columns at the target displacement of the retrofit design (assuming that all walls along a common wall line experience the same displacement). For the steel frame, the initial stiffness of each column is given by (using DDR method):

$$K_{\sec ant} = \frac{(1-r)\Delta_Y + r\,\Delta_{T\arg et}}{\Delta_{T\arg et}} K_{in.} \quad (1)$$

where, $K_{in.}$ is the initial stiffness of a cantilevered column and r is the ratio of the secondary stiffness to the initial stiffness in a bilinear spring model. Δ_y is the lateral displacement associated with the yield strength (F_y) of at which point the initial stiffness reduces to secondary stiffness. Having the stiffness of each column, the initial stiffness of the frame can be calculated and the best cantilevered column design can be selected by using the lateral stiffness of two-column inverted moment frames with infinitely rigid beam (Equation 2). In this study, the grade beam was considered much stiffer than the columns and thus the columns were treated as inverted moment frames (IMF). The initial stiffness of each IMF is given by:

$$K_{in.} = \frac{6EI_c}{L_c^3} \quad (2)$$

where, I_c is the second moment of inertia of each column about its strong axis and L_c is the height of the frame. The secant stiffness corresponding to target drifts of 0.5% to 4% for 11.9 mm think OSB wood shearwall connected to framing member by 10d common nails is tabulated in Table 1.

Table 1. Secant stiffness for standard wood shearwall

		Secant Stiffness, K_s (kN/mm per m)				
		Wall Drift				
	Edge/Field Nail Spacing (mm)	0.50%	1.0%	2.0%	3.0%	4.0%
Standard Wood Shearwall	51/304	1.570	1.100	0.657	0.385	0.244
	76/304	1.214	0.786	0.448	0.256	0.159
	102/304	0.955	0.611	0.340	0.194	0.121
	152/304	0.684	0.422	0.231	0.132	0.082

4. FOUR-STORY FULL-SCALE SHAKE TABLE TESTING

A four-story woodframe building with a footprint of 11.6 m × 7.3 m (38 ft × 24 ft) and total height of 9.8 m (32 ft) was designed based on the proposed DDD method for nonlinear structures and its response was verified using the SAP2000© software. A solid model of the building is presented in Figure 4.

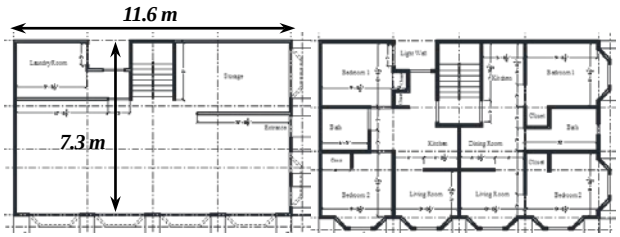

Figure 4. Solid model of soft-story woodframed building to be tested at NEES@UCSD.

Figure 5 presents the ground and typical floor plans of the building. At ground level (level 1), the building has four parking bays, a laundry room, and storage space; Levels 2-4 consist of two 2-bedroom apartments per story. The bold lines represent the lateral load resisting elements (i.e., wood shearwalls in this case) at each story. It should be noted that the ground floor has fewer shearwalls than the upper stories and their horizontal distribution at ground floor is highly

unsymmetrical which makes the building vertically and horizontally irregular. Figure 6 presents the CDF of peak story drifts when the building is subjected to a suite of 22 earthquakes along its long direction scaled for San Francisco, which verifies that the first story is, in fact, soft and weak and would collapse at a spectral acceleration well below MCE. In fact, there is a 98% probability that a 2% story drift will be exceeded. If 7% story drift is taken as a conservative collapse estimate, there is approximately a 70% probability of collapse for the un-retrofitted building at MCE level. Furthermore, the configurations of shearwalls in both ground and upper floors are not symmetric about the center of mass of the building; hence, the building was classified as an unsymmetric structure with severe torsion.

The eccentricity ratios in x- and y-directions at the ground floor are e_x/L_x = 27.8% and e_y/L_y = 34%, respectively. The in-plane eccentricity ratios in x- and y-directions at the upper stories are e_x/L_x = 12.9% and e_y/L_y = 18.2%, respectively. It should be noted that the location of centers of rigidity were calculated assuming that the relative stiffness ratio of all shearwalls remain constant during the analysis. Hysteretic models for horizontal wood siding and gypsum wall board were used to model exterior and interior walls for the non-retrofitted building. The results from a multi-record analysis shows that the building is weak in both translation and torsion, hence structural retrofit is required.

a) Ground floor plan b) Typical floor plan

Figure 5. Floor plans for the four-story building

Using the proposed DDR procedure, the building was retrofitted such that it would perform well during MCE level earthquakes in the San Francisco area, specifically to satisfy the desired performance criteria which is represented here as not exceeding a 2% story drift for half of the MCE level earthquake motions. In order to determine the contribution of torsion to the total displacement, the effective (i.e., equivalent) eccentricity of the building in the y-direction was calculated and divided by the width of the floor (i.e, L_y). The result was that, for all stories, 20% of the total displacement was due to rotation and the remainder was due to translation. Therefore, the building was designed for 80% of the target drift (i.e., 1.6%) and was checked to ensure that each story has enough torsional stiffness to limit the torsional displacement to 20% of the target drift (i.e., 0.4%). The equivalent damping ratio for all wood shearwalls was assumed to be 12% (i.e., 80% of 15% damping ratio proposed by Filiatrault and Folz, 2002). The fundamental period of the equivalent SDOF system was determined using response spectra for 12% damping and consequently the spatial distribution of lateral load resisting elements at each floor was calculated. A distributed load of 2.4 kN/m^2 (50 psf) was assigned to all floors and 1.9 kN/m^2 (40 psf) to the roof. Table 2 presents the design parameters and the distribution of the lateral and torsional stiffnesses of the building calculated based on the proposed DDR procedure. It can be seen that the torsional stiffness at all stories is greater than the required torsional stiffness which limits torsional displacements to be less than $\Delta^{Tor.}$. Ten inverted steel columns where used at the first story to retrofit the building. 11.9 (15/32") think wood shearwalls with nail patterns of 76/304 mm (3"/12"), 102/304 mm (4"/12") and 152/304 mm (6"/12") were used to retrofit the 2nd, 3rd and 4th stories, respectively. Each upper story needed about 14.6 m (48 ft.) of wood shearwall except the 4th story which required only 8.5 m (28 ft.) of wood shearwall.

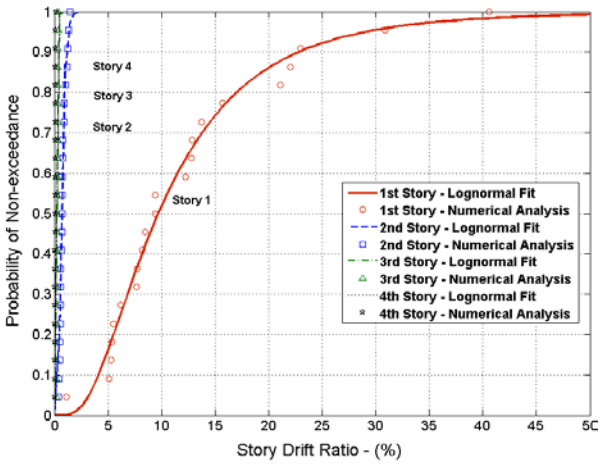

Figure 6. CDF of the peak drifts of the un-retrofitted four-story woodframe apartment building

Table 2. Summary of DDR method with torsion

	3	222 (50)	12.9	18.2	1.6	0.4	0.33		1.66 (9.31)	1.62 (9.08)	8.90 (49.9)	7.24 (40.6)	7.28 (40.8)	OK
	4	178 (40)	12.9	18.2	1.6	0.4	0.35				4.60 (25.8)	2.94 (16.5)	2.98 (16.7)	OK

Verification Using Non-linear Time History Analysis

The four-story building was modeled using the SAP2000© software and a detailed finite element time-history analysis was conducted to verify the performance of the building subjected to 22 far field earthquake records (FEMA P695, 2009) scaled to a seismic intensity corresponding to MCE level in San Francisco, California. The fundamental period of the building and the corresponding spectral acceleration were T_n = 0.45 seconds and S_a = 1.5g (5% damped), respectively. It should be noted that the effective period is a

combination of the first torsional and translational mode shapes of the building.

Figure 7 presents the rank-ordered peak story drifts from time history analysis, providing the probability of exceedance versus story drift of the building under the 22 far-field earthquakes scaled to 1.5g spectral acceleration. It can be seen that the story drift ratio corresponding to 50% probability of non-exceedance at the third story is 2.04% which is very close to the target drift of 2.00% giving only 2.0% error. The inter-story drift ratios at the 1st, 2nd, and 4th stories are all less than 2.00% which meets the desired performance criteria.

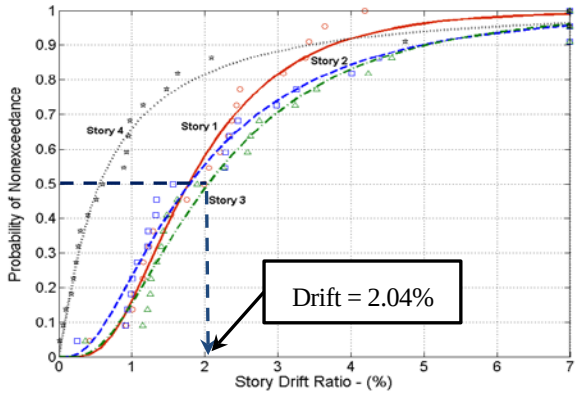

Figure 7. Probability of non-exeedance of 2% inter-story drift under 22 far-field earthquakes scaled to MCE level earthquake in San Francisco, California.

5. SUMMARY AND CONCLUSIONS

This paper provided a brief introduction to the NEES-Soft Project and focused on the performance-based seismic retrofit procedure entitled Direct Displacement Retrofit (DDR). This procedure is based on previously developed DDD methods. The four-story woodframe apartment building scheduled to be tested on the outdoor shake table at NEES@UCSD in the summer of 2013 was introduced and used to highlight the DDR procedure proposed in this paper. This building is a soft-story multi-family residential building that will be retrofitted using four different techniques as part of the test program. Numerical analysis of the steel cantilevered column retrofit was described in this paper. The DDR procedure appears to work well for buildings with extreme vertical and horizontal irregularities, making it a general enough to be used for woodframe systems and even other systems.

PERFORMANCE-BASED SEISMIC DESIGN FOR WOOD HOUSES USING EQUIVALENT LINEARIZATION METHOD

Hiroshi Isoda[1)] and Shu Nagaoka[2)]

1) Professor, Department of Architecture, Faculty of Engineering, Shinshu University, Japan
2) Graduate Student, Department of Architecture, Faculty of Engineering, Shinshu University, Japan
hisoda@shinshu-u.ac.jp, 11ta327b@shinshu-u

Abstract: Performance-based seismic design is a developing design methodology in the modern seismic design and research community and has already been applied to the building standard law and enforcement in Japan. However, the application to wood houses, which represents the vast majority of the residential building stock, is still under early stage of development, mainly due to a lack of understanding of the dynamic response.
This paper discusses the application of performance-based seismic design to wood houses through an equivalent linearization method. In the first part of the paper, the fundamentals of the equivalent linearization for wood houses are outlined. Thereafter, a description of the system parameters required for its application is descried. For the purpose of evaluating these parameters for wood houses, non-linear time history analyses for predicting the response and evaluating the energy dissipation of wood houses under from moderate to severe earthquakes are presented. As the result of numerical studies, equivalent period of non-linear system and equivalent viscous damping with pinching behavior are summarized. As application examples, peak displacements are compared with the displacement calculated from both non-linear time history analysis and proposed equivalent linearization method.

1. INTRODUCTION

The building code of Japan has been changed from current prescriptive and the traditional force-based design into performance-based approach in 2000 in order to newly compile a highly flexible Building Standard Law of Japan (The Build Center of Japan 2004). Several key papers laid the foundation for the standard and code development of performance-based seismic design (PBSD) including in timber-based building .

In that decade, PBSD has been developed all over the world. As for the timber-based structure in the late 1990's and early 2000's, the CUREE-Caltech Woodframe Project in the U.S. focusing on the improvement of woodframe codes and standards through a detailed and robust experimental, numerical and documentation effort to examine current practices in the design and construction of woodframe buildings has been started. Several useful papers laid the foundation for the development of PBSD in the project. The NEESWOOD project which has started since 2006 sought to develop a performance-based seismic design philosophy for mid-rise woodframe buildings through an extensive siries of numerical simulations and full-scale system-level experiments (Filiatrault et al, 2010; van de Lindt et al, 2010) as well as numerical modeling (Christovasilis, 2010; Pei and van de Lindt, 2010). .

This paper discusses the application of performance-based seismic design to wood houses through an equivalent linearization method. In the first part of the paper, the fundamentals of the equivalent linearization for this study are outlined. Thereafter, a description of the system parameters such as an equivalent elastic period and damping required for its application is descried. For the purpose of evaluating these parameters for wood houses, non-linear time history analyses for predicting the response and evaluating the energy dissipation of wood houses under from moderate to severe earthquakes are presented. As the result of numerical studies, equivalent period of non-linear system and equivalent viscous damping with pinching behavior are summarized. As application examples, peak displacements are compared with what calculated from both non-linear time history analysis and proposed equivalent linearization method.

2. FUNDAMENTAL OF DISPLACEMENT-BASED DESIGN PROCEDURE

2.1 Key Equation for Target Displacement

Since interstory drift is a key parameter for the control of damage and collapse in timber-based structure, it is rational to examine a procedure wherein displacements are considered at the beginning of the seismic design process. The fundamental components of this procedure, known as the direct-displacement method (Priestley 1993) are discussed. In Japan, mainly for steel construction including in the structure with dampers, some equations to evaluate

equivalent stiffness and equivalent viscous damping at a target drift have been proposed (Nakashima 1999). A following equation (Kasai 2003) is now discussing in this paper.

$$S_d(T_e, h_{eq}) = \frac{T_e}{2\pi}\overline{S_{pv}}(T_0 - T_e) \times D_h(h_{eq}) \quad (1)$$

Where T_e=equivalent elastic period of the structure at the target displacement S_d, $\overline{S_{pv}}$=the average of pseudo velocity from T_o to T_e and D_h=damping reduction factor. $D_h = \sqrt{(1+25h_0)/(1+25h_{eq})}$
