Preface

It is a signal pleasure to extend an invitation to our 10th International Conference on Urban Earthquake Engineering (10CUEE) being held again this year, 2013, here in Tokyo on March 1st and 2nd. The conference has been convened each March since 2004, under two consecutive five-year Center-of-Excellence programs headquartered at the **Center for Urban Earthquake Engineering (CUEE)** at Tokyo Tech. As is widely known, our current *Global-COE program (August 2008—March 2013)* is entitled "International Urban Earthquake Engineering Center for Mitigating Seismic Mega Risk".

Over the past decade we have aimed not only to promote research to mitigate the seismic "mega"-risk confronting vast present-day metropolises in earthquake-prone regions throughout the world, but also to produce next-generation practitioners and researchers responsible for developing new strategies and practices for seismic risk reduction. We have sponsored the conference each year in the interest of fostering and stimulating intensive information dissemination and technology transfer, while looking to promote and extend an international network that with your help has been directed to the formation of younger researchers through a sustained and now, we believe, truly global collaborative effort.

The Conference this year features state-of-the-art technical presentations on divers topics relevant to Urban Earthquake Engineering, followed by a significant choice of theme-based parallel sessions. Once again there will be a large number of papers related to lessons learned from the catastrophic damage and loss of life occasioned by the *2011 Great East Japan Earthquake and Tsunami* of just two years ago. Having commenced with 66 papers and only 15 overseas participants in March 2004, our Conference this year comprises more than 270 presentations, attracting some 450 participants with nearly 200 overseas guests. As in previous years, 10CUEE is slated this year to include *Special Educational Sessions* and *Best Presentation Awards for Young Researchers*. This year in 2013 about 130 papers are targeted for these Educational Sessions, which, I am convinced, have over the past ten years opened up a new career space for a number of younger researchers. To facilitate participation of this younger cohort, Travel Grants have been awarded once more in 2013 to some forty individuals for participation at 10CUEE.

As 2013 marks the final year of our second five-year program, 10CUEE will be the last conference held under the auspices of this particular Global-COE program. We look forward to continuing to host similar gatherings in future— but on this occasion we shall endeavor to summarize and set in perspective the legacy of our current five-year program, while looking with optimism toward possible ramifications of what has so far been accomplished. We remain confident that the March 2013 event will once again stimulate intensive information dissemination and technology transfer, as well as promote and uphold the now well-established and robust international network of our community. Our hope is that this conference will offer an excellent opportunity for all of us dedicated to Urban Earthquake Engineering to take stock of developments in our joint field.

Kohji Tokimatsu

Global-COE Program Leader and Director of CUEE Tokyo Tech

Table of contents

Paper ID Page

Keynote Lectures

01-377 Exposure Data Development for the Global Earthquake Model: Inventory Data Capture Tools 1
R.T. Eguchi, J. Bevington, Z. Hu and C. Huyck

20-385 Evaluation of Tsunami Force acted on Bridges by Great East Japan Earthquake 7
Kyuichi Maruyama, Yasushi Tanaka, Kenji Kosa, Akira Hosoda, Norimi Mizutani and Tomoaki Nakamura

G-COE Resumé

08-067 Retrofit of Damaged Structures according to Response Control Concept 17
Toru Takeuchi

17-049 Predicting Spatiotemporal Distribution of People for Risk Assessment and Disaster Management 25
Toshihiro Osaragi and Takuya Oki

20-502 Ground-Motion-Induced Damage of Bridges during the 2011 Great East Japan Earthquake..... 31
Kazuhiko Kawashima

Engineering Seismology

01-378 Estimation of Dynamic Behavior of Historical Church in Armenia using Microtremor Survey 41
H. Morikawa, S. Sasano, S. Motoyui, Y. Fujita and A. Mutoh

01-220 Shallow Structure of Taipei Basin Using Receiver Function Technique 47
Che-Min Lin, Kuo-Liang Wen, Tao-Ming Chang and Chun-Hsiang Kuo

01-317 Empirical Site Correction for Ground Motion Simulation 53
K. L. Wen, J. Y. Huang and C. T. Chen

01-363 Use of Airborne Optical and Thermal Imagery for the Detection of Building Damage due to the 2012 61
Tsukuba Tornado, Fumio Yamazaki, Daiki Hanada and Kentaro Suzuki

01-328 Aleatory and Epictemic Uncertainties of Ground-Motion Models. Results from Recent European Projects 69
Fabrice Cotton, Adrian Rodriguez, Ralph Archuleta, Elise Delavaud, Céline Beauval and Mathieu Causse

01-380 Estimation of Mega-Earthquakes Source Models for Strong Motion Prediction: Application for Central Andes 73
Nelson Pulido

Paper ID Page

01-404 Synthesis of Ground Motions of 1999 Taiwan MeiShan Earthquake by Empirical Green's Function Method 79
Huei-Tsyr Chen and Shang-Hong Wei

01-330 Finite Difference Simulation of Long-Period Ground Motion based on Various Source Models of the Anticipated Nankai Trough Megathrust Earthquake 87
Takahiro Maeda, Nobuyuki Morikawa, Shin Aoi and Hiroyuki Fujiwara

01-046 Fundamental Property of Cross Terms of Ground Transfer Function 93
Hiroyuki Goto

20-291 Comparison of ground motion attributes from 2011 Tohoku-Oki mainshock and two subsequent events 99
Tadahiro Kishida, Jonathan P. Stewart, Robert W. Graves, Saburoh Midorikawa, Hiroyuki Miura, Yousef Bozorgnia and Kenneth W. Campbell

01-193 Site Response during Strong Shaking - Estimated from the 2011 Tohoku Earthquake- 107
Kenichi Tsuda

01-231 Preliminary Analysis of Attenuation Relationship for Response Spectra on Bedrock based on Strong Motion Records Including the 2011 Mw9.0 Tohoku Earthquake 113
Hongjun Si, Saburoh Midorikawa, Hideaki Tsutsumi, Changjiang Wu, Toshiyuki Masatsuki, and Akemi Noda

01-360 High Intensity Records Observed in the 2011 Tohoku Earthquake 119
Saburoh Midorikawa, Tomohiro Atsumi, and Hiroyuki Miura

01-410 Strong Motion Pulses Observed during the 2011 Tohoku Earthquake and Their Modeling 125
Atsushi Nozu

20-198 Local Site Effects Observed in Shinagawa and Odawara, Japan, during the 2011 off the Pacific Coast of Tohoku Earthquake 135
Seiji Tsuno, Hiroaki Yamanaka, Saburoh Midorikawa, Hiroyuki Miura, Shin'ichi Sakai, Naoshi Hirata, Hiroe Miyake, Minoru Sakaue and Kazuki Koketsu

01-252 Exploration of Site Characteristics by Microtremor Observations in the Central Area of Thailand 139
N. Poovarodom, A. Jirasakjamroonsri and N. Plalinyot

01-464 Estimation of Deep Subsurface Structures for Prediction of Long-period Ground Motion Characteristics around the Tachikawa Fault 145
Koichiro Saguchi and Hiroaki Yamanaka

01-018 Analysis of HVSR of Microtremor on Different Seismic Site Conditions 151
Chun-Hsiang Kuo, Kuo-Liang Wen, Che-Min Lin, Jyun-Yan Huang and Tao-Ming Chang

01-476 Surface-wave Phase Velocity Inversion using Markov Chain Monte Carlo Method for Estimation of Local Site Amplification 159
Hiroaki Yamanaka

Paper ID Page

01-487 An Evaluation of Subsurface Structure with Inclined Bedrock Using Microtremor Array Exploration 165
Kentaro Motoki, Tetsushi Watanabe, Kenichi Kato, Kojiro Takesue, Hiroaki Yamanaka, Masanori Iiba and Shin Koyama

01-495 Simulation of H/V Spectral Ratios of Microtremors with Directional Dependency 171
Shinichi Matsushima, Florent De Martin, Takanori Hirokawa, Hiroshi Kawase and Francisco J. S Sánchez- Sesma

01-014 Deaggregation of New National Seismic Hazard Maps for Indonesia 175
Achmad Fauzi and Usama Juniansyah Fauzi

01-194 Estimation of Urban Growth Using Time-Series Landsat Satellite Images in Lima, Peru..... 179
Hiroyuki Miura, Saburoh Midorikawa and Masashi Matsuoka

01-362 Web-based Quick Estimation System of Strong Ground Motion Maps Using Observation Records and Engineering Geomorphologic Classification Map..... 187
Masashi Matsuoka, Naotaka Yamamoto and Kazue Wakamatsu

01-401 A Basic Study on the Rapid Prediction of Seismic Ground Motions Using P-waves Observed in Deep Boreholes 195
H. Miyakoshi, S. Tsuno, S. Yamamoto and N. Iwata

20-173 Impact Analysis of the Great East Japan Earthquake by Running Spectrum Analysis of the Newspaper 203
Muneyoshi Numada and Kimiro Meguro

01-384 The Impact of the 2011 Tohoku Tsunami Disaster and Implications to Tsunami-resilient Community 211
Shunichi Koshimura, Satomi Hayashi and Hideomi Gokon

01-051 Comparison of Several Common Transfer Functions for Site Effect Study in Taipei Basin..... 215
Jyun-Yan Huang, Luo-Liang Wen, Chun-Te Chen, Shuen-Chiang Chang and Hsien-Jen Chiang

01-070 A Site-Specific Seismological Model within a Bayesian Updating Framework 223
Alin Radu and Mircea Grigoriu

01-079 Analysis and Study of Site Effect in Kaohsiung and Pingtung area in Taiwan 231
Chiang Hsien-Jen and Wen Kuo-Liang

01-091 Application of Waveform Inversion to Actual Seismic Refraction Data for Retrieving Shallow 2D S-wave Velocity Profile 237
Amrouche Mohamed and Hiroaki Yamanaka

01-204 Reliability of Dispersion Measurement from Microtremors with Seismic Interferometry 241
Kosuke Chimoto and Hiroaki Yamanaka

01-295 Study for Seismic Microzoning in Damascus City, Syria, from Strong Motion Simulation Considering Local Site Amplification 245
Hussam Eldein Zaineh, Hiroaki Yamanaka and Yadab Prasad Dhakal

Paper ID Page

01-318 Improved Method of Data Analysis for the Gravity and Magnetic Exploration System..... 251
Satoshi Tokue, Yumiko Ogura, Hitoshi Morikawa, Shigeo Matsuda, Masayuki Saeki, Takuya Suzuki and Eri Ohzawa

01-364 Estimation of Ground Structure Using Gravity Survey Method around Furukawa, Japan, where was severely damaged by 2011 Tohoku Earthquake 257
Sakkrawit Sripunyaphikhup, Hitoshi Morikawa, Hiroyuki Goto, Masayuki Inatani, Yumiko Ogura, Satoshi Tokure, Xinrui Zhang, Shohei Hamasaki, Masahiro Iwasaki, Masayuki Araki and Sumio Sawada

01-366 The Significance of the Ratio of Power Spectra between Two Sites in the Wavefield of Microtremor..... 261
Xinrui Zhang and Hitoshi Morikawa

01-097 Using Stochastic Finite-Fault Method to Simulate Ground Motion from 2010 Jiashian, Taiwan, Earthquake 267
Fu-Ming Wu, Kuo-Liang Wen, Jyun-Yan Huang and Chun-Te Chen

01-126 Simulation of Stochastic Ground Motion with Site Correction Using Equivalent-Linear Method at Taipei Basin Downhole Arrays..... 273
Saifuddin, Kuo-Liang Wen, Jyun-Yan Huang and Hsien-Jen Chiang

01-188 Long-Period Ground Motion Simulations in the Kanto Basin using Diverse Velocity Models for the Hypothetical Tokai Earthquake..... 281
Yadab P. Dhakal and Hiroaki Yamanaka

01-236 Fundamental Research for Enhancement of Estimation on Earthquake Ground Motion-Development of a Method for Crustal Deformation Analysis Using High-Fidelity Three-Demensional Crustal Structure Model-..... 287
Ryoichiro Agata, Tsuyoshi Ichimura, Mamoru Hyodo, Takane Hori, Kazuro Hirahara and Muneo Hori

01-403 Stochastic Modeling of Bhuj (2001) Earthquake and Synthesis of Seismic Scenarios for the Surat Region, India..... 291
T.P.Thaker and K.S.Rao

Geotechnical Engineering

02-243 Simulation of Liquefaction-Induced Void Redistribution in a Centrifuge Test..... 301
R. W. Boulanger, R. Kamai and K. Ziotopoulou

02-405 Liquefaction Potential Evaluation: Energy-based Method versus Stress-based Method 307
Takaji Kokusho

02-546 Number of Equivalent Cyclic Shear and Effective Duration for Soil Liquefaction in Tokyo Bay Area during the 2011 Great East Japan Earthquake..... 317
Hiroshi Arai

Paper ID Page

02-162 Effect of Grain Size Distributions on Liquefaction Resistance for a Large Number of Loading Cycles 325
Jun Izawa and Yoshitaka Murono

02-234 Comparison between Damage Distribution and Estimated Liquefaction Potential in Chiba City 331
Toru Sekiguchi and Shoichi Nakai

02-359 Dynamic Behavior of a Structure on Desaturated Sand under RElatively Long Shaking..... 335
Jiro Takemura

02-213 Development of Soil Pressures under Lateral Loading 343
Anne Lemnitzer and Albert Luu

02-321 Dynamic Centrifuge Model Test of Building with Embedded Footing on Semi-Rigidly Connected Pile Heads in Liquefiable Soil 353
Sadayuki Ishizaki, Kohji Tokimatsu and Toshiaki Nagao

02-354 Use of Pre-Shaking for Soil-Pile System Identification in Centrifuge Shaking Table Tests ... 359
C. J. Lee, W. Y. Hung, C.H Tsai, T. Chen, Y. C. Tu and M.H. Hsieh

02-103 A Case Study on Multiple Mechanism Model in Three Dimensional Soil-Structure Interaction Analyses 365
Ryo Ueda and Ariyoshi Yamada

02-116 Long-Term Settlement of Holocene Clay Ground after the 2011 Great East Japan Earthquake 371
Naohiro Nigorikawa and Yoshiharu Asaka

02-038 Estimation of Bearing Capacity and Pull-out Resistance of a Pile with or without a Wing Plate in Alternately Cyclic Loading based on Centrifugal Model Tests 379
Hiroko Suzuki , Kei Inamura, Kohji Tokimatsu, Masatoshi Wada and Hideyuki Mano

02-027 Applicability of Equivalent Linear Seismic Response Analysis under Large Earthquakes 385
Nozomu Yoshida

02-322 Effect of Input Motion Characteristics on Seismic Deformation of a River Levee..... 393
Ryosuke Uzuoka, Jorge Shimabukuro and Masumitsu Kuse

02-406 Measurements of Translational and Rotational Dynamic Stiffness for a Model Levee on Peat 399
Edward T. Reinert, Scott J. Brandenberg and Jonathan P. Stewart

02-480 Confining Effect of Bearing Plate and Helix on Sliding Resistance of Reinforced Slope using Steel Pipe Piles 405
Akihiro Takahashi and Yohei Nakamichi

02-365 A Study on the Characteristics of the Ground Surface Deformation Induced by the Reverse Fault Slip 409
Y.Y, Chang, C.J, Lee , W.C, Huang , W.J, Huang and W.Y, Hung

02-207 Methodology for Combining Microtremor Measurements and Simplified Ground Response Analysis 415
Atsushi Mikami

Paper ID Page

02-339 Implicit Stress-Update Algorithm for the Constitutive Model to Describe Cyclic Behavior Based on Finite Deformation Theory 423
Tomohide Takeyama and Shinya Tachibana

02-289 Seismic Earth Pressure and Sidewall Friction acting on Embedded Pile Cap and Pile's Stress..... 429
Shuji Tamura and Takenori Hida

03-163 Evaluation of Collapse and Non-Collapse of Parallel Bridges Affected by Liquefaction and Lateral Spreading..... 439
Benjamin Turner, Scott Brandenberg and Jonathan Stewart

02-064 Numerical Evaluation of Failure Mechanisms of Pile Foundation in Liquefiable Soils 445
Mohammad Reza Salami, Katsuichiro Goda and Subhamoy Bhattacharya

20-415 Liquefaction Induced Ground Deformation Observed at Gohno-ike Pond in Kamisu City during 2011 Great East Japan Earthquake 455
S. Kanemitsu, Y. Tsukamoto and S. Kawabe

02-223 Effects of Drainage and Dewatering on Differential Settlement of Wooden Houses Founded on Liquefiable Soils..... 459
Yasutsugu Suzuki, Kohji Tokimatsu, Takahiko Hidekawa and Naohito Adachi

02-275 Numerical Modeling Issues in Predicting Post-Liquefaction Reconsolidation Strains and Settlements 469
Katerina Ziotopoulou and Ross W. Boulanger

02-340 Modeling of Earthquake Induced Uplift of Tunnels in Liquefiable Soil..... 477
Siau Chen Chian and Kohji Tokimatsu

02-284 Effects of Non-homogeneity on Liquefaction in Stratified Soil Deposits 483
Manika Maharjan and Akihiro Takahashi

02-333 Centrifuge Model Study on the Effect of Shield Tunneling on Adjacent Pile Foundation..... 493
Ittichai Boonsiri, Jiro Takemura and Sakae Seki

02-203 Stress Reduction Effect of Structure due to Basemat Uplift and Soil Yielding..... 499
Takafumi Inoue and Atsushi Mikami

02-117 Evaluating One Dimensional Site Response Analysis using Borehole Arrays..... 505
Georgios Zalachoris and Ellen M. Rathje

02-348 Evaluation of Local Sites Effects in Lima City, Peru from Ground Motion Data..... 515
Selene Quispe, Hiroaki Yamanaka, Hernando Tavera, Fernando Lazares and Zenon Aguilar

02-040 Centrifugal Modeling of Undercut Slopes Subjected to Pseudo-static Loading 523
Mohammad Hossein Khosravi, Jiro Takemura and Thirapong Pipatpongsa

02-118 Pullout Resistance of Geocell Placed as Reinforcement in Gravelly Soil Backfill..... 533
Xinye Han, Takashi Kiyota and Fumio Tatsuoka

02-337 Centrifuge Model Tests on Failure Pattern of Cement Treated Ground 539
Yuki Yoshida, Tomohide Takeyama and Masaki Kitazume

Paper ID Page

50-536 Experimental Investigation on Dewatering and Drainage Methods to Mitigate Liquefaction Damage to Existing Houses 543
Kohji Tokimatsu, Kazushi Tohyama, Hiroko Suzuki and Yasutsugu Suzuki

02-219 Basic Physical Model Test on Seismic Performance of Fill Induced by Suffusion 549
Kazuki Horikoshi, Lin Ke and Akihiro Takahashi

02-249 Criteria for Determining Gmax in Laboratory Element Tests Using Disk Type Piezoelectric Transducers 555
Muhammad Irfan and Taro Uchimura

02-120 Comparison between CPT and SDS Data for Soil Classification in Christchurch 561
Seyed Yasin Mirjafari Miandeh, Rolando P. Orense and Naoaki Suemasa

02-327 Effects of Internal Erosion on Cyclic Resistance of Gap-Graded Cohesionless Soil 567
Lin Ke and Akihiro Takahashi

Lifeline Systems

03-191 Relationships between Damage to Railway Structures and Seismic Intensity in the 2004 Niigata-ken Chuetsu Earthquake and the 2007 Niigata-ken Chuetsu-Oki Earthquake 573
Shuichi Taya and Saburoh Midorikawa

03-132 Experimental Investigation of the Stresses in a Tank Shell Resulting from Uplift during Earthquakes 579
Miguel Ormeno-Godoy, Tam Larkin and Nawawi Chouw

03-054 Evaluation of Gas Distribution Pipelines Network Subjected to Seismic Wave Propagation in Greater Tehran Area, Iran 585
Danesh Nourzadeh, Khosrow Bargi and Shiro Takada

Structural Engineering-Concrete

04-408 Collapse Vulnerability Assessment of Existing Concrete Buildings 591
K.J. Elwood, M. Baradaran Shoraka and T.Y. Yang

04-361 Low Ductility Concrete Wall Test considering Perpendicular Wall Action 599
Carlos Zavala, Patricia Gibu, Luis Lavado, Jenny Taira, Lourdes Cardenas and Luis Ceferino

04-368 CFD Analysis of Wind Pressure on the Complex High-Rising Structure 603
Qiong Xing and Jiang Qian

50-503 Dynamic Analysis of Existing Non-Conforming Concrete Gymnasia with Steel Roof 611
T. Ohmura and S. Hayashi

04-375 FRP-Retrofitted T-Beam-Wide-Column Joints Under Cyclic Loading 619
Kiang Hwee Tan and Aziz Ahmed

04-382 Seismic Performance of Reinforced Concrete Buildings Incorporating Soil-Structure Interaction 625
Wanchai Yodsudjai, Sarawoot Charoensuttikul and Piya Chotickat

Paper ID Page

04-224 Residual Structural Capacity of RC Superstructure of Open-type Wharf Damaged by Earthquake Motion 633
Mitsuyasu Iwanami, Yuichiro Kawabata, Ema Kato and Takahiro Nishida

04-379 Study on Bond Property of Corroded Reinforcing Bar Under Cyclic Loading..... 641
Tomohiro Miki and Takuya Shiomi

04-349 Mechanical Behavior and Strengthening Methods of RC Beams Damaged by Corrosion in Anchorage Part of Rebars..... 647
Koji Matsumoto, Makoto Mori and Junichiro Niwa

04-402 Strategy for Seismic Upgrading of Public Schools 657
Hsiao, F. P.; Hwang, S. J.; Chung, L. L.; Yeh, Y. K.; Jean, W. Y.; Shen, W. C.; Chiou, T. C.; Chow, T. K.; Yang, Y. S. and Chao, Y. F.

04-131 Substructure Pseudo-Dynamic Tests of Reinforce Concrete Frames with Soft-First-Story 661
Hideto Kanno, Naofumi Teramoto, Tetsuya Nishida and Jun Kobayashi

04-013 Earthquake-Resistant Design of Lightly-Reinforced and Low-Rise Concrete Walls..... 667
Julian Carrillo

04-334 Experimental Study on Cracking Strength of Confined Masonry Walls subjected to Shear Force 677
K. Nishimura, Y. Goto and S. Murai

04-324 Calculation of Load-Capacity of RC Beams by Lattice Model Arranged by Experiment Results 685
Yuki Nakata, Ken Watanabe, Tadatomo Watanabe and Junichi Abe

04-045 Three-Dimensional Nonlinear Beam-Truss Model for Non-Planar Reinforced Concrete Walls..... 689
Yuan Lu and Marios Panagiotou

04-048 Influence of Post-Tensioned Ropes on the Dynamic Response of Innovative Mortar-Free Interlocking Structures 699
Majid Ali and Nawawi Chouw

04-094 Shear Behavior of Polypropylene Fiber Reinforced ECC Beams with Reduction of Shear Reinforcements..... 709
Rui Zhang, Koji Matsumoto and Junichiro Niwa

04-096 Shear Behavior of Steel and Synthetic Fiber Reinforced Concrete Beams 717
Pitcha Jongvivatsakul, Koji Matsumoto and Junichiro Niwa

04-119 Behavior of Prestressed Concrete Beams Having Ruptured Strands Strengthened in Flexure by Externally Bonded CFRP Sheets..... 725
Thi Thu Dung Nguyen, Koji Matsumoto, Yuji Sato, Asami Iwasaki and Junichiro Niwa

04-142 Evaluation of Shear Capacity of RC Beams using UFC Permanent Formwork with Different Shear Span to Effective Depth Ratio 731
Puvanai Wirojjanapirom, Koji Matsumoto, Katsuya Kono and Junichiro Niwa

Paper ID Page

04-154 Bond Strength and Bond-Slip Behavior of Steel Reinforcement in High-Performance Fiber-Reinforced Cementitious Composites 737
Matthew J. Bandelt and Sarah L. Billington

04-182 Large-Scale Testing and Analysis of Concrete-Encased Steel Coupling Beams Under Large Ductility Demands 743
Christopher J. Motter, John W. Wallace, David C. Fields, John D. Hooper and Ron Klemencic

04-237 Behavior of Reinforced Concrete Flab Slabs Systems Under Corner and Center Support Failure Scenarios 753
S. Prasad and T. C. Hutchinson

04-281 Seismic Performance and Modeling of Post-Tensioned, Precast Concrete Shear Walls 761
Ahmet Can Tanyeri, Jack P. Moehle and Takuya Nagae

12-033 Effect of Electro-Welded Wire Mesh on the Seismic Vulnerability of Thin RC Shear Walls in Lima, Peru 769
Luis G. Quiroz and Yoshihisa Maruyama

04-505 Shaking Table Test of a Large-scale Self-centering Reinforced Concrete Frame 775
Xilin Lu, Ye Cui, Jingjing Liu, Ying Zhou and Wensheng Lu

04-114 Experimental Investigation of Large Reinforced Concrete Special Moment Resisting Frame Beams 781
Tea Visnjic, Marios Panagiotou, Jack Moehle and Grigoris Antonellis

04-125 Nonlinear Response Assessment and Seismic Retrofit of Reinforced Concrete Buildings..... 791
Jason P. Palacio, Alem J. Pablo, Eric A. Tingatinga and William Mata

04-165 Experimental Evaluation of Out-of-Plane Wall-to-Beam Connections under Cyclic Loading 799
Saman Abdullah, David Naish and Nagi Abo-Shadi

04-228 Seismic Vulnerability Assessment Method of Low-Rise RC Buildings with Masonry Infill Walls 807
Hamood Alwashali and Masaki Maeda

04-233 Process of Collapse for RC Frame Including Shear Column 817
Kazuto Matsukawa, Xiu Liu and Masaki Maeda

04-240 Experimental Study on Reinforced Concrete Frames with Buckling Restrained Braces 825
Yusuke Maida, Zhe Qu, Shoichi Kishiki, Toshio Maegawa, Makoto Hamada, Hiroyasu Sakata and Akira Wada

04-302 Experimental Study on Influence of Bending Radius of Main Tensile Bars on Stress Transmission in Reinforced Cncrete Knee Joints with Prectical Detail 831
Tuvshin Batjarga and Hisato Hotta

10-299 A Study on Structural Performance of CES Shear Walls with Eccentrically Arranged Wall Panel 837
Suguru Suzuki, Hiroshi Kuramoto and Tomoya Matsui

Paper ID Page

04-176 Nonlinear Finite Element Analysis of Reinforced Concrete Structure Considering Multiple Cracking Failure 843
Fangtao Sun, Seizo Tanaka, Muneo Hori, Tsuyoshi Ichimura and Maddegedara Lalith

04-134 Assessment of Seismic Collapse Safety of Reinforced Concrete Frame Buildings Designed by Two Generations of Chinese Seismic Provisions 849
Wenwen Luo, Yingmin Li, Zhe Qu, Hiroyasu Sakata, Heping Zhong and Jun Han

04-197 Effect of Soil-Flexibility on Nonlinear Response of High-Rise Buildings during Collisions Under the El-Centro Earthquake 857
Ayman Abdelhamed and Sayed Mahmoud

Structural Engineering-Steel

05-543 Elastic Local Buckling Strength of Rectangular Hollow Section Column under Biaxial Bending Share 863
Kikuo Ikarashi , Kosuke Sato and Tao Wang

05-130 Method of Small-scale Shaking Table Test overcoming the Scaling Effect 869
Yuko Shimada, Kenta Takahashi and Satoshi Yamada

05-326 Numerical Analysis on Plastic Deformation Capacity of Steel Beam under Verious Loading Histories 875
Satoshi Yamada, Yu Jiao and Shoichi Kishiki

05-298 Effects of Core Plates Local Buckling for Cumulative Deformation Capacity of Buckling Restrained Braces 881
Ryota Matsui and Toru Takeuchi

05-107 Predictive Equations for Modeling Cyclic Buckling and Fracture of Steel Braces 889
Dimitrios Lignos and Emre Karamanci

05-400 Improvement in SSWS Design and Study on the Performance of Steel Frame-SSWS System 899
Yiyi Chen and Ke Ke

05-300 Experimental Study on Buckling-Restrained Steel Plate Shear Walls with Different Aspect Ratios 905
Y. Lu; G.Q. Li; H.J. Jin ; X.L. Liu and F.F. Sun

04-352 Static Test and Numerical Analysis of Composite Concrete Steel-Plate Shear Walls with Binding Bars 915
Deyuan Zhou, Limeng Zhu and Ying Zhou

05-099 Behavior of Steel Tube-Double Steel Plate-Concrete Composite Walls Subjected to Axial Force and Cyclic Loading 923
X. Ji, F. Jiang and J. Qian

Paper ID Page

05-345 Vibration Tests on Single Layer Lattice Domes Subjected to Horizontal Bi-directional Earthquake Motions 933
Tomohiko Kumagai, Takunori Ozawa, Toru Takeuchi and Toshiyuki Ogawa

05-484 Damage Detection for Steel Structures Using the Hilbert-Huang Transform Approach 939
Wen-Ko Hsu and Dung-Jiang Chiou

05-189 Member Damages of High-Rise Building Structures under Severe Earthquakes: Effect of Member Deterioration 945
Yongtao Bai, Akihiko Kawano and Shitaro Matsuo

05-108 Study on Column Behavior in a Full-Scale Steel Building Subjected to Strong Ground Motions on Shaking Table 953
Tran Tuan Nam and Kazuhiko Kasai

05-024 Cyclic Loading Test on RHS Columns under Bi-Directional Horizontal Forces 959
Takanori Ishida, Yuko Shimada and Satoshi Yamada

05-031 Test on Eccentric Beam-to-RHS Column Conecctions 967
Norihito Miki, Yu Jiao, Satoshi Yamada, Shoichi Kishiki and Takashi Hasegawa

05-342 Evaluation of the Composite Beam Stress Subjected to Bending and Axial Force 973
Yoriyuki Matsuda and Kazuhiko Kasai

05-102 Effect of Column Base Behavior on Seismic Performance of Multi-Story Steel Moment Resisting Frames 979
Yao Cui and Satoshi Yamada

05-008 Evaluation of the Response Modification Coefficient Including Collapse Assessment of SCBFs 985
Po-Chien Hsiao, Dawn E. Lehman and Charles W. Roeder

05-092 Seismic Test and Design of Buckling-Restrained Brace Connections Tenth International Conference on Urban Earthquake Engineering 995
Pao-Chun Lin, Keh-Chyuan Tsai, An-Chien Wu and Ming-Chieh Chuang

05-175 Cyclic Loading Tests of Single Angle Brace Focusing on Out-of-plane Stiffness of Gusset Plate 1005
Hayato Asada and Tsuyoshi Tanaka

05-209 Cyclic Loading Tests of Steel Slit-dampers with Various Shapes 1011
Yu Jiao, Yukako Katsuyama and Mamoru Kohno

Structural Engineering-Bridge

06-483 3-D Dynamic Analysis of Bridges in Ultimate States under Earthquakes 1017
Tzu-Ying Lee, Kun-Jun Chung and Yi-Wen Chen

06-288 Fiber Model Analyses of Steel Bridge Circular Columns Considering Local Buckling 1023
Koji Kinoshita

06-465 Development of an Anomalies Detection Method Based on Nonlinearity Expression 1029
Eiichi Sasaki and Nguyen Khac Thanh

Abstract: The Global Earthquake Model represents an open initiative to develop software and tools for assessment of global seismic risk. This paper describes an open-source software suite and protocols for populating a Global Exposure Database of structural information being developed by GEM's Inventory Data Capture Tools (IDCT) risk global component. Several data collection methods are used: remote sensing, direct field observations, and statistically-inferred mapping schemes. Data are collected on pre-earthquake inventory, as well as post-event damage: rudimentary building information from optical satellite or aerial sensors, including building footprints and heights. Field-based observations collected on digital and paper tools by survey teams allow expert users to generate detailed structural information, including structural type, year built, and occupancy. Mapping schemes allow the generation of exposure information for user-defined areas of homogenous urban land use, using sampled field observations. These methods converge to feed GEM's Global Exposure Database and the Earthquake Consequences Database.

1. INTRODUCTION

Over half a million people died in the last decade due to earthquakes, most of these in less-developed countries. However, recent earthquakes in Japan and New Zealand have reminded global populations that despite high levels of development and investment in mitigation strategies, seismic activities still account for major human and economic losses globally. A precursor to negating some of the risk to human life and economic risk, and potentially offsetting the latter through insurance, is having the ability to measure, understand and manage seismic risk. An understanding of physical vulnerability of structures in the built environment requires knowledge of the configuration and characteristics of urban building stock. These data offer valuable baseline information in responding to disasters and to estimate human and financial consequences resulting from the event. Insurance penetration in the most developed countries has led to the use of modeled probabilistic risk assessments to aid risk understanding. However, there are few risk models currently developed and operational in less-developed countries, partly due to a lack of insurance penetration in these regions. Recent years have also seen a trend towards developing open and transparent models to sit alongside the proprietary models widely used in the insurance industry. The latter models can be expensive to use and do not promote understanding of risk at the most fundamental grass-roots level of community risk assessment. Providing the tools for an open-source risk model promotes an understanding of risk in previously un-modeled or poorly-modeled regions, subsequently leading to mitigation and resilience-building activities such as an increased number of insurance products, promotion of building codes and retrofitting activities.

The public-private Global Earthquake Model (GEM) Foundation drives an international effort aimed at the development of state-of-the-art, widely accepted datasets, models and open-source tools/software. With the goal of collaboratively advancing seismic hazard and risk assessment worldwide, these will be made available through the web-based OpenQuake platform, which will be powered by a calculation engine (Silva et al., 2012 and Monelli et al., 2012). Development of a global model of seismic risk through an open, participatory process is at the core of the effort (Pinho, 2012) and international consortia are currently developing the global components of the model. Fig. 1 shows the inter-relationships between the risk global components, which will allow platform-users to generate new exposure data, access existing vulnerability functions and search historical damage surveys and consequences datasets. The hazard global components are aimed at developing methods, datasets and standards for assessing earthquake hazard, by combing data on historic seismic events, active faults, global instrumentation, and ground motion and strain predictions.

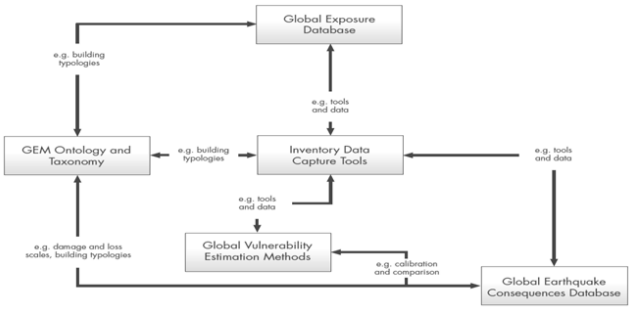

Figure 1 Inter-relationship between the GEM Risk Global Components (GEM, 2011)

The GEM Risk global component is tasked with providing standards for vulnerability estimation (damage, and human and social and economic losses), and also provides a database of physical and socio-economic consequences from past events globally - the Earthquake Consequences Database (ECD). Underpinning this is the Global Exposure Database (GED); a homogeneous database of global building stock that contains spatial, structural and occupancy-related information. The GED stores information on the global building stock using existing datasets and also using customized tools and protocols, whilst adhering to the standards of classification and relationships defined by the Ontology and Taxonomy consortium.

1.1 Inventory Data

A building inventory is a catalogue of the buildings and facilities in each class of a taxonomy, used in loss models to define the exposure to specific hazards, based on insurance exposure data (overview and details of insured properties for an area of interest). This underlying building characterization that serves as input data for which the losses are calculated, and typically requires building characteristics such as type, age, height, occupancy, building value and location (Born and Martin, 2006, Erdik et al., 2010). It is often the case that catastrophe loss models are limited in their ability to provide accurate estimations due to poor estimations of exposure information. This can have a significant impact on the modeled loss or consequences (Coburn and Spence, 1992, Jaiswal et al., 2008), which is apparent by the order of magnitude difference between modeled and actual losses sustained by the insurance industry in several recent natural catastrophes (Conway et al., 2008, Global Reinsurance, 2008)

GEM aims to generate global exposure data for its open-source model through the collection of building inventory information at several geographic scales, from level 0 (country) to level 3 (per-building, Table 1). The GED4GEM consortium is collating global datasets for inventory characterization at levels 0 and 1, including global housing and population data. IDCT is charged with developing the tools and user protocols for collection of inventory data at levels 2 and 3 (regional to per-building precision). A similar set of tools and protocols will also be developed for the collection of earthquake damage information at granularity levels 2 and 3. These data populate the GED and ECD databases, respectively. This paper presents the rationale and workflow of GEM's Inventory Data Capture Tools alongside a description of the tools and methods under development. The three major components of 1) remote sensing, 2) direct field observations, and 3) mapping schemes are presented in context with the wider aims of the GEM Risk global components as the tools underpin much of the analytical ambitions of the model. The method of each tool is described, alongside a status report at time of writing (end of 2012).

Table 1 Geographic Scales of Exposure Data in the GED. IDCT tools will populate levels 2 & 3

Precision level	Source	Grid/Vector	Statistical significance
Level 0	Global (LANDSCAN, PAGER, GRUMP)	30" (~ 1 km)	Country
Level 1	Sub-country database (UN-HABITAT, national census, GEM regional programmes), Urban density, RS (aggregated, < 1 km)	30" (~ 1 km)	Region/municipality
Level 2	Regional sub-country database (Mapping Schemes)	10/15", Vector	Region/municipality
Level 3	Per-building database (remote sensing, ground surveys)	Vector	Single building

2. THE INVENTORY DATA CAPTURE SUITE

Developing a building exposure model requires a combination of expert judgment, established classification typologies and geo-spatial technologies and tools. With this in mind, the IDCT consortium is developing a suite of tools and user protocols that follow a three-pronged workflow - see Fig.2. Firstly, remotely-sensed satellite imagery provides a data source for deriving individual building footprints and larger areas of homogenous urban land use. Second, field teams characterize building attributes using a series of data collection forms for both inventory and post-earthquake damage. Once these characteristics are input into a database, the third component, the Spatial Inventory and Damage Data (SIDD) tool, provides a workbench for the iterative generation of mapping schemes using the homogeneous areas of land use (derived from remote sensing) combined with sampled field data. This workflow produces regional (level 2) and per-building (level 3) inventory datasets. Data from the field tools can also be used to directly populate the Global Exposure Database at level 3. These workflows are described in detail in Fig. 2.

The types of data to be collected are fundamentally defined by the end-user depending on the use case. However, the GEM tools are pre-designed to collect all parameters required to generate new vulnerability functions or calculate risk information using existing vulnerability functions. Data are generated using one or all of the following methods: automatic and manual

remote sensing image interpretation (Section 2.1), direct field observations (Section 2.2), crowdsourced photo interpretation (Section 2.2.3). IDCT offers users a flexible framework allowing data collection missions to be tailored according to the availability of engineering expertise, analysts, hardware or software. All tools described in the user protocols supplied with the GEM tools are open-source, with directions to commonly used commercial software where performance may be greater.

of imagery, image pre-processing, analytical and GIS editing tools are all described in the protocols. All of these software tools and their supporting user guides will be made available as a single download from the OpenQuake site.

Remote sensing tools to extract seismic consequences data are also provided in the IDCT toolset. Analysis of pre- and post-event satellite or aerial imagery can be interpreted by expert users to identify buildings

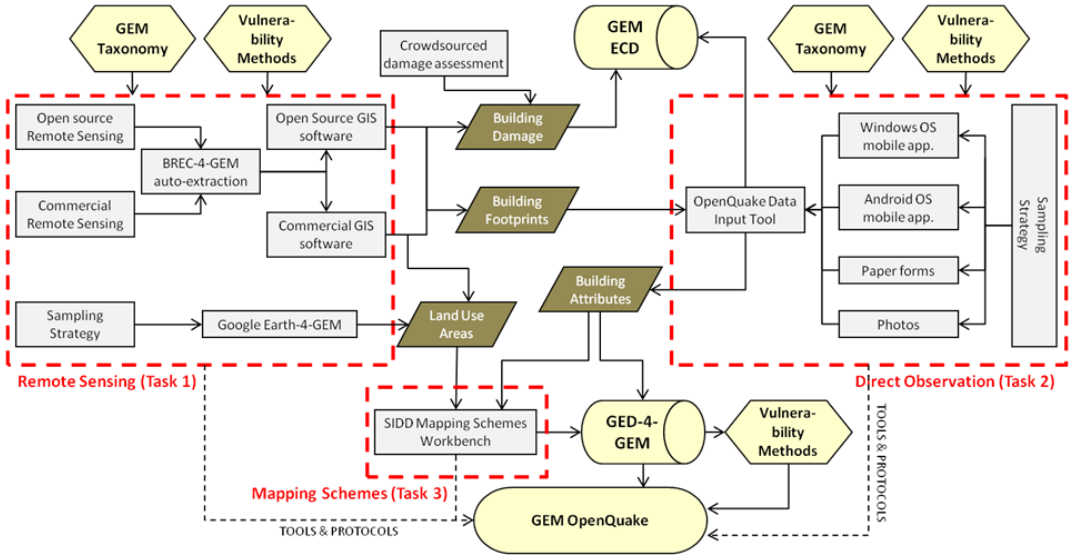

Figure 2 Detailed IDCT Workflow. Major tasks of remote sensing, direct observation and mapping schemes are shown in red. Main data developed are shown in green. Tools are in grey and GEM components external to IDCT are shown in yellow.

2.1 Task 1 – Remote Sensing

Images captured from satellite and aerial sensors have become a staple data source for risk managers in the past decade. The availability of internet tools such as Google Earth has increased the public awareness and general uptake of image processing to extract information on the makeup of urban areas.

IDCT provides a suite of software tools and user guides to enable the extraction of building outlines from imagery for level 3 exposure development, or derivation of areas of homogeneous land use for regional exposure (level 2). These GIS data captured from imagery provide vector location information by delineating in the image the outline of where the building intersects the ground (building "footprint"). Tools to derive height information based on the presence of shadows in imagery are also provided. The IDCT tools are primarily developed in the open-source GIS and Image Analysis package, Quantum GIS (QGIS). The GRASS GIS plug-in is also required, and BREC-4-GEM, a custom toolbar for automatic extraction of building footprints and height data (Gamba et al., 2009), has been developed as an extension to the software (Fig. 3). Two use-case scenarios provide the workflow for the user guides: 1) extraction of building footprints, and 2) delineation of urban land use. Sourcing

that have been collapsed or heavily damaged by earthquakes (e.g., Ghosh et al., 2011).

Automatic change detection techniques are provided to distinguish areas of significant change between these time periods. However, the web interface that facilitates manual identification of damaged buildings provides the main RS consequences toolkit. Based on an interface developed for the Global Earth Observation Catastrophe Assessment Network (GEO-CAN), the Tomnod Disaster Mapper (Barrington et al., 2011) provides pre-and post-event satellite images for assessment by expert image analysts and engineers. Data captured from the RS toolkit can be manually uploaded to GEM's OpenQuake platform and integrated in the GED and ECD.

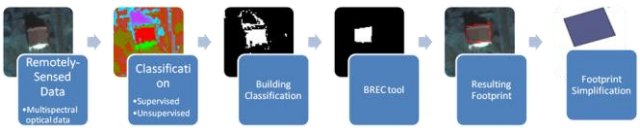

Figure 3 Workflow of BREC automatic footprint extraction tool

2.2 Task 2 – Direct Observation

Remote sensing, while useful for determining location, and potentially height of buildings, has large

uncertainties when manually assessing occupancy, structural type or year built. IDCT therefore fuses the image-based analytics with field observations (Task 2, Fig. 2). A suite of field tools is being developed by the consortium and includes both digital and paper forms for data collection, as well as protocols for collection of location information and field photographs. Digital tools are currently under development for laptop and tablet based hardware. The laptop tool is developed for Windows operating system (OS), while the tablet is being designed to run on the Android OS. The choice of which platform to support was made after extensive user consultation through a questionnaire sent to existing field reconnaissance teams.

The DO field tools are designed to directly incorporate the GEM taxonomy, allowing users to collect information using dropdown forms and pre-loaded options for all attributes to be collected. The tools will have tabbed-functionality to allow maximum ease of use, rather than prescribing a linear data collection process. The DO tools consist of several pre-loaded forms for collection of inventory and damage data. These reflect the GEM taxonomy:

1. Basic building inventory (parameters including, location, structural material type, occupancy, year of construction, lateral-load resisting system and height) – for use in GED
2. Detailed building inventory (to include additional secondary modifiers) - for use in GED
3. Post-event Damage (pre-loaded damage scales for building components) - for use in ECD
4. Interior survey (for when the survey team has access to the inside of the building. To include non-structural elements) - for use in GED and ECD.

The pre-loaded forms in the digital tools also include metadata on location, date, time, surveyor details and additional project information. In addition, templates for paper forms for collecting the same information as in the digital forms are being provided so that the DO capture tools do not discriminate between users based on hardware availability. The DO tools are currently under development in partnership with the UK Earthquake Engineering Field Investigation Team (EEFIT). Other global field reconnaissance teams are also being consulted through the iterative development and testing process, due for completion in early 2012.

2.2.1 Field Photographs

Alongside the digital and paper forms, the user will be provided with information on the types of hardware required to generate geo-tagged photographs. Photographs are an invaluable data source to be collected in field missions for many reasons, including: A photograph may be the best way to describe something (although it may need some accompanying text explaining what is shown in the photograph); if one is in a hurry and there is no time to write detailed notes, a photo can be used to record the moment and notes can be added later (see Data Input section 2.2.3). The protocols provide a 'common sense' approach, recording many parameters, including geo-location, look direction, data and time information, amongst others. It is hoped the protocol can provide best practice on the collection of field photos for both inventory and consequences data capture.

2.2.2 Sampling Strategy

Planning field deployments to collect information for statistical inferring any of the risk parameters relies on having statistically valid samples of observations. IDCT will provide users with a protocol for establishing a custom sampling strategy for each of their field deployments to identify those buildings to survey. The protocol details the following:

- A procedure that allows for variable levels of resources to carry out reconnaissance for a subset of the total population of structures
- A procedure for creating efficient, stratified samples of buildings. By "strata," what is meant here are consecutive ranges of some measurable building features such as building height, distance from population centers, or topographic slope.
- Procedures for extrapolating to the population.
- Procedures to elicit and employ local builder or building-department expertise, for inferring non-visible features from visible ones based on local knowledge.

2.2.3 Data Input (PRIZM)

IDCT provides users with a user-friendly online import tool, currently under development, to manage the collation of field information once teams have returned from their mission(s). This tool is integrated within the OpenQuake online system and will allow the input of photographs, digital forms and manual input of paper forms. A unique linkage system will allow linking of GPS photos to building footprints where users can establish links to photographs for each building surveyed. The photos are then analyzed by engineers and experts who can manually populate the database through visual interpretation of the field footage.

These tools will promote ultimate flexibility for field teams who have limited numbers of trained analysts or engineers, by assigning inexperienced analysts to field photograph collection while engineers can use crowdsourcing as a data input technique through visual interpretation of the field photographs in the online web interface. The system may also in the future allow the public to submit their own GPS photos or for engineers to share their findings or invite fellow scientists to validate their interpretations through the social networking

functionality of OpenQuake. This potential functionality is currently in the design phase.

2.3 Task 3 – Mapping Scheme Design

Mapping schemes are the IDCT tool for generation of regional exposure information (GED level 2), and serve as a way to harness the best-available data for inventory generation at a regional scale. These can often utilize inventory data extracted from individual country- or region-specific research studies (Jaiswal et al., 2008). In the IDCT suite of tools, mapping schemes are generated using the Spatial Inventory and Damage Data (SIDD) tool, a desktop-based workbench for loading, editing, testing and creating mapping schemes - statistical representations of inventory data that are applied to homogenous areas of land use or building type.

The main functions of SIDD are to: 1) receive data from the remote sensing and direct observation tasks; 2) develop mapping schemes or access a library of prebuilt mapping schemes; 3) apply mapping schemes; 4) format and export data to GEM OpenQuake. SIDD serves as a conduit between base data sets derived from both ground observations and remotely sensed sources and a GEM compliant file. Data are loaded into SIDD from the remote sensing module (Task 1, Fig. 2) and the field data collection tool (Task 2, Fig. 2) and processed into a GEM-suitable file. Data from task 1 and/or task 2 are loaded into a local data repository on the user's hard drive. In addition, the user has the option of loading land use data, or delineations of "homogenous land use zones". Zones that are homogenous (areas which are sufficiently similar in terms of attributes such as density and land use) will be characterized by a mapping scheme.

Once data are loaded into SIDD, mapping schemes are identified or created. Mapping schemes are tools for the statistical inference of structural parameters given data from a specific area. Data may be based on regional defaults, expert opinion, survey data, or a combination of these factors. After the mapping schemes are assembled, users apply the mapping scheme and the results output, either as exposure data or consequence data. For the development of inventories, the application of SIDD is likely to be an iterative process with users checking the results carefully and adjusting both geographic and statistical data to develop a final exposure data set that is valid according to the best available combination of field-based and remotely-sensed data. Preliminary testing of the method has revealed users may need to iteratively edit the mapping schemes and base layers before posting the final results (Bevington et al., 2012). The SIDD system is designed as a workbench of tools, rather than a linear process, to facilitate these types of adjustments. Additionally, the protocol will recommend statistical checks to validate the data set.

3. TESTBED SITES

Development of the IDCT tools is ongoing using a number of test sites that have been identified globally. There are four main testing phases: 1) Pilot Study 1 – Tool Development, completed May 2012; 2) Pilot Study 2 – Beta Testing; (inventory), completed July 2012; 3) Pilot Study 3 – Beta Testing (damage) completed July 2012; and 4) Pilot Study 4 – Demonstration, due in 2013.

The tools are currently under development and being demonstrated on imagery and field data collected in Pisco, Peru, Messina, Italy, Bishkek, Kyrgyzstan, Padang and Mataram, Indonesia and Pylos, Greece. Protocols have been updated during these tests, and the validity of the sampling strategy protocol is also tested. The recent earthquakes of Port-au-Prince, Haiti and Christchurch, New Zealand provide valuable imagery and ground-based validation data in which to test the remote sensing and crowdsourced damage assessment techniques. It is currently envisioned that the final demonstration of the full suite of IDCT tools in mid 2013 will focus on the city of Istanbul, Turkey.

4. CONCLUSIONS

One of the most poorly understood areas of disaster risk management is the building stock information that exists in a region. The IDCT component of the Global Earthquake Model is tasked with generating a set of open-source software tools and supplementary user-friendly guides to aid the understanding of seismic risk globally. These tools are aimed at being globally generalizable, with characterization of inventory stock at multiple geographic scales; from regional to per-building capture. Remote sensing plays a major role in the pre-event inventory capture, but also in post-earthquake damage assessment. Emerging methods (e.g. crowdsourcing) and field capture technologies (e.g. tablet-based tools for survey teams) will be used to facilitate a range of domain experience levels. Field tools provide the majority of the inventory characterization, but can be costly to develop for a full assessment of buildings over large areas. The development, application, and validation of mapping schemes are a primary function of the SIDD tool. These tools allow users to generate custom earthquake exposure databases and post-event consequences databases that can be made publically available through GED4GEM and GEMECD. The IDCT tools will be integrated with the GEM's OpenQuake web interface and will be released in 2013.

Acknowledgments:

The authors would like to thank the full IDCT team seismologists, engineers and geographers for their ongoing enthusiasm and commitment to this project. The support of the coordinators and staff at the Global Earthquake Model Foundation has been tremendous throughout. The authors would also like to recognize the support from the GEM Scientific Board and the IDCT internal advisory committee: Fumio

Yamazaki (Chair), Friedemann Wenzel, Hannes Taubenboeck, Ed Parsons and Rowan Douglas.

Abstract: This paper deals with what tsunami force has acted on bridges by Great East Japan Earthquake broken out in March 11, 2011. Almost all data were collected on the bridges in the inundation area. Washed away bridges as well as survived ones were analyzed by the equation proposed by Kosa. Since the velocity of tsunami was a key factor in the equation, the simulation using hydraulic technology was developed and compared with the observed data.

1. INTRODUCTION

Great East Japan Earthquake in March 11, 2011 caused the greatest tsunami we have ever had in one thousand years in Japan. Comparing the damage by the earthquake itself, the damage by the tsunami was much serious for our modern life in the area of eastern Japan.

It was a shocking scene that a lot of bridges near the shore were washed away while very few bridges inland suffered from the earthquake. Since the Great Hanshin Earthquake in 1995, bridge engineers and researchers have been working hard on how to improve the seismic design of bridge structures. The damage of bridge by tsunami was completely out of our concerns because we have never had such damage since modern bridge technology has been introduced in one hundred years.

Right after the earthquake, JSCE has set up a research committee on the tsunami force acting to bridges, consisting of members from various fields such as bridge engineering, concrete engineering, structural engineering and coastal engineering. The authors have been involved in the committee as directive members. This paper is a kind of mid-term report on what we have studied in one and a half years.

2. DAMAGE OF BRIDGES BY TSUNAMI

At the first stage any data of bridges which located in the inundation area from Aomori prefecture in the north to Chiba prefecture in the south were collected by both internet media and on site survey. Fig.1 shows satellite images taken before and after the earthquake.

(a) Before Earthquake (25th June, 2010)

(b) After Earthquake (6th April, 2011)

Figure 1 Satellite Images

Field survey was conducted several times to confirm the details of bridges. Finally, the statistic data are summarized as shown in Table 1. The total number of bridges within the inundation area was 1,793 and the number of washed away bridges was 252, including 28 of railway bridges and 40 of major road bridges.

Table 1 Number of Bridges in the Area of Inundation

Pref.	Iwate	Miyagi	Fukushima	Ibaraki	Chiba	Total
Washed away or moved	78	102	68	2	2	252
Unclear	0	0	8	0	0	8
Survived	427	692	384	30	-	1533
Total	505	794	460	32	2	1793

In order to analyze the damage of bridges, the data of each bridge, such as type, dimension and structural details were collected from authorities who take care of bridges. Currently, the data of more than 400 bridges are collected and the database is now processed. Using the database, some trials have started to categorize bridges by their types and dimensions to see what a key is for resisting tsunami. Fig.2 shows the number of bridges with or without suffering from washed away in comparison with categorized items, such as type of bridge and bridge length. In the figure, only the survived bridges located near the washed away bridges are selected for comparison.

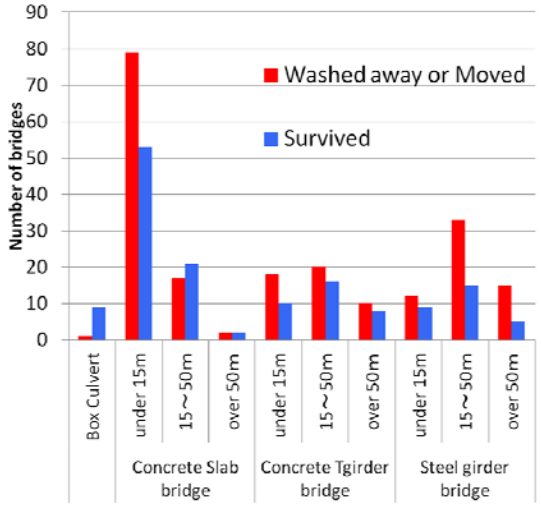

Figure 2 Damage Analysis of Bridge

Fig.2 may not give us a clear tendency on what influences the damage of bridge. This is because no consideration is taken for the velocity and the height of tsunami at the location of bridge.

3. EVALUATION OF BRIDGE RESISTANCE AGAINST TSUNAMI

Kosa (2010), one of the authors, has already started the investigation on the tsunami force acting on bridges after surveying the damage of bridges due to the tsunami of Sumatra Earthquake in 2004. The following discussions are based on his method.

Tsunami force acting to a bridge girder can be treated as a hydro dynamic force indicated by Eq.1, while the resistance of girder is mainly due to self weight computed by Eq.2 or Eq.3. The difference between Eq.2 and 3 lies in the existence of buoyancy judging from the comparison of girder height with tsunami height. Eq.2 should be used when a bridge girder is not submerged at the attack of tsunami, while Eq.3 is for the case of bride girder being submerged and having buoyancy at tsunami.

$$F = \frac{1}{2}\rho_w C_d v^2 A_h \tag{1}$$

$$C_d = \begin{cases} 2.1 - 0.1\cdot(B/D) & (1 < B/D < 8) \\ 1.3 & (8 \le B/D) \end{cases}$$

$$S = \mu W \tag{2}$$

$$S = \mu(W - U) \tag{3}$$

Where, ρ_w is density of water (1030kg/m^3); C_d is the drag coefficient with its value decided based on reference (Japan Road Association, 2002), B and D are width and depth of girder; v is tsunami velocity (6.0m/s is used based on surveys of the Tohoku area); A_h is the projected pressure area of the girder in the horizontal direction; μ is friction coefficient (0.6, based on research by Rabbat et al. (1985)); W is the girder's self weight (kN), and U is buoyancy (kN) as computed by Eq. 4.

$$U = \rho_w g V \tag{4}$$

Where, V is volume of the bridge girder inner the tsunami (m^3).

The ratio of girder resistance (S) to tsunami force (F) is an index to judge whether a bridge girder is washed away or not by tsunami. The indicator β is introduced in this paper as shown in Eq. 5.

$$\beta = \frac{S}{F} \tag{5}$$

When β is smaller than 1.0, a bridge girder has a great possibility of being washed away by a given magnitude of tsunami. Although the velocity of tsunami is most important in this study, observe records of velocity of tsunami are very few at the site of bridge. In this study, some recorded videos throughout the Tohoku area were used for determination of velocity. The average value of velocity is taken as 6.0m/s based on the research by Fu et al. (2012) and this value is used for analysis.

For evaluation of Eq.5 with comparison of the actual behavior of bridge girder, the observed condition of girder is defined as shown in Table 2. Three levels are introduced; Rank A (completely washed away) to Rank C (slightly damaged).

Fig.3 illustrates the computed β values for 37 different types of girders. When β is larger than 1.5, the girders had Rank C damage. When β is smaller than 0.6, the girders suffered the damage of Rank A.

Table 2 Definition of Damage of Bridge Girder

Damage level	Observed condition of superstructure
Rank A	Washed away
Rank B	Moved but not fallen from abutment
Rank C	Slightly damaged

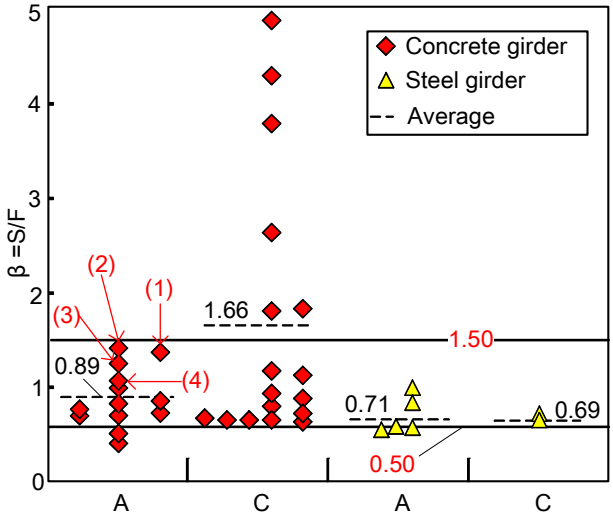

Figure 3 Computed β Values and Damage Level

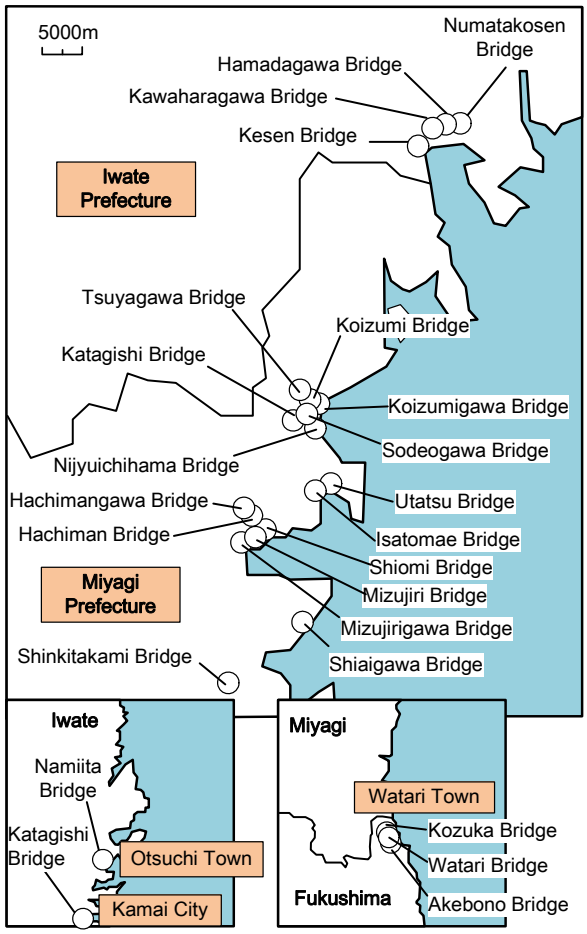

Figure 4 Bridges for Computation of β Value

There exists a gap of β value between Rank A and Rank C, but β could be effective to evaluate how safe a bridge girder is against tsunami. Fig.4 shows the location of bridge used for computation of β values in Fig. 3. For going into further discussion, the types of bridge girder are summarized in Figs.5 and 6. The types of girder shown in Fig.3 have β value of larger than 2.0. In fact, these girders have survived. On the other hand, girders in Fig. 6 having β value of smaller than 0.6 were all washed away by the tsunami on March 11, 2011.

In general, survived girders are made of prestressed concrete having a relatively low height and wider width of cross section. All girders in Fig.5 look flat in shape to compare with girders shown in Fig.6. In addition, the height of pier should play a important role because the velocity of tsunami is a function of tsunami height. The higher the tsunami height is, the faster the tsunami velocity.

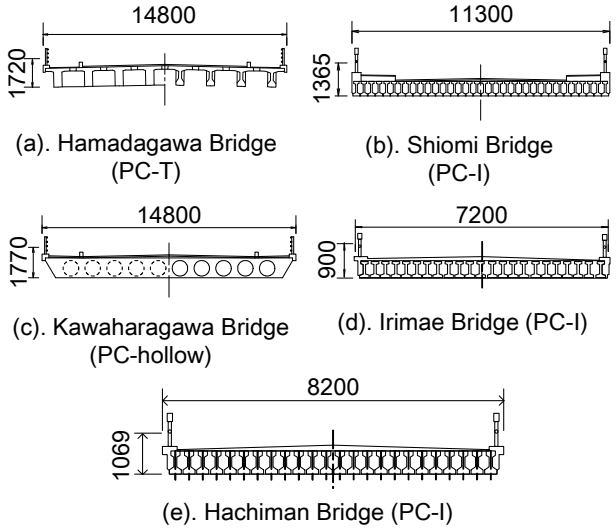

Figure 5 Types of Survived Girder

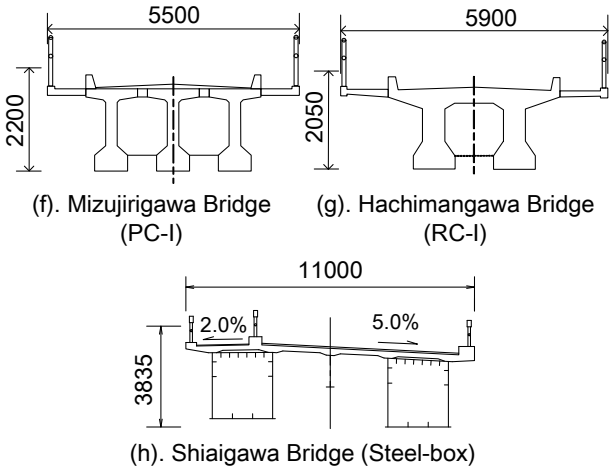

Figure 6 Types of Washed Away Girder

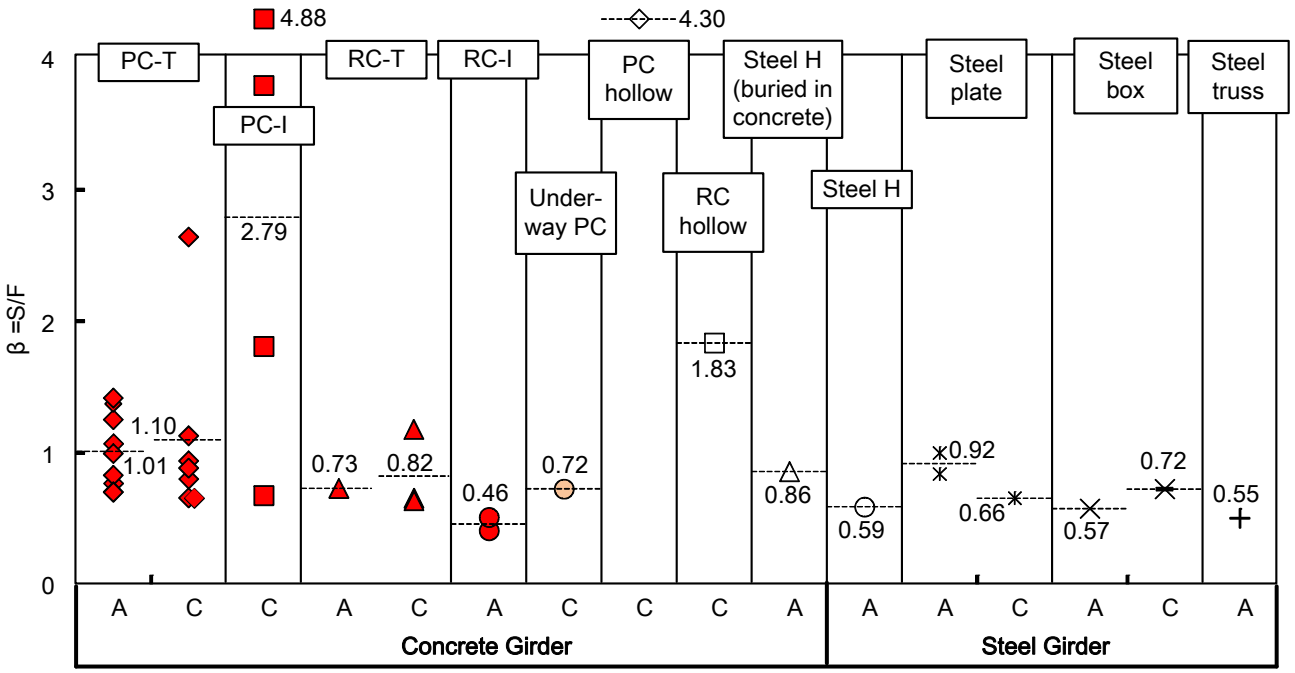

Figure 7 Classification of β by Girder Type

In the previous research works done by Kosa et al. (2010); Zheng et al. (2012), obvious differences are recognized in the value of β for Rank A and Rank C. But Fig.3 shows some discrepancy. As discussed previously the β value of Rank A girders (washed away girders) should be less than 1.0. In fact there observed some girders whose computed β values are larger than 1.0. Similarly some girders categorized in Rank C (slightly damaged girder) show β values being smaller than 1.0.

Bridge girders having β value of larger than 1.0 with actual damage being ranked as A are listed in Table 3. These four are all prestressed concrete girders with cross section of T shape. The relationship between β values and damaged ranks is re-examined by the type of girder as shown in Fig.7. Prestressed concrete T-girders might have undertaken larger tsunami force than that expected by β value.

In general, the reason for such discrepancy might be attributed to the assumption in which the tsunami velocity is constant as 6.0 m/s in this study.

Table 3 Rank A Concrete Bridges with β larger than 1.0

Rank A concrete bridges with β larger than 1.0			
No.	Name	β	Girder Type
(1)	Numatakosen	1.37	PC-T
(2)		1.41	PC-T
(3)	Shimoya	1.25	PC-T
(4)	Kozuka	1.07	PC-T

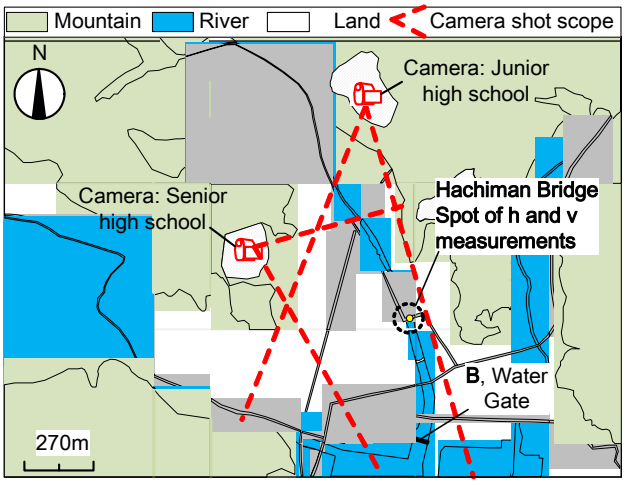

Figure 8 Location of Video Camera

4. CHARACTERISTICS OF TSUNAMI IN THE CITY (SHIZUGAWA)

Japan Meteorological Agent keeps observation of earthquakes and tsunamis constantly at certain points in Japan. The equipments to measure tsunami height and velocity, however, are set in the sea, not inland. The agent does not have any records of tsunami velocity in residential areas. Fortunately, some citizens have taken motion pictures of tsunami in the city by digital cameras.

Based on the motion pictures taken by citizens, the characteristics of tsunami in the city are able to be analyzed. Fig.8 shows the location of video camera in Shizugawa area in Minamisanriku-Chou, Miyagi prefecture. Both cameras were focused on the bridge named Hachiman Bridge. Fig.9 shows the side view of Hachiman Bridge with key reference dimensions. Figs.10 and 11 show static pictures cut out from the recorded motion pictures at 7.05 second and 7.53 second.

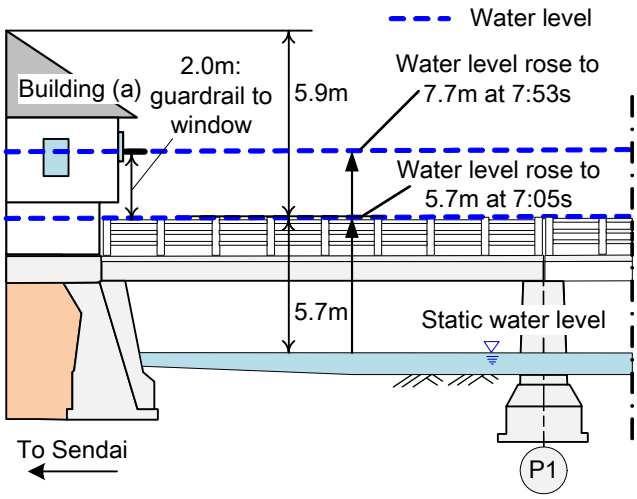

Figure 9 Side View of Hachiman Bridge

In advance of picture analysis, key reference height is estimated as follows;

a) The height from the top of guardrail to static water level: 5.7 m
b) The height from the top of building-(a) to the top of guardrail: 5.9 m
c) The height from the top of guardrail to the window of building-(a) : about 2.0 m

These are shown in Fig.9.

The analysis of tsunami is done in such a way that the surface of tsunami reached the top of guardrail at 7:05 second of motion picture, meaning that the tsunami height was 5.7 m. The surface of tsunami reached the window of a house at 7:53 second, meaning that the tsunami height was 7.7 m. Comparing these two set of data, the rising speed of tsunami can be determined. Motion picture analysis tells that the tsunami height rose with the speed of 3.19 m/min at a time of 4 minutes after the hit of tsunami on Hachiman bridge, and that the tsunami ran up to the maximum 14.8 m high at 7 min. after the hit, at a rising speed of 1.1 m/min. The average rising speed of tsunami height is estimated to be 2.24 m/min. It was relatively low speed, inferring that the wave shape was not the bore type.

There observed much debris flowing in the picture. These are good references to measure the velocity of tsunami. For example, take debris (1) and debris (2) in the motion picture and trace them with a certain time interval shown in the picture. Accurate distance of debris move can be confirmed by both an internet media (Google Earth; Fig 13) and on site survey.

By the above mentioned process, the wave height and velocity of tsunami can be estimated. Based on the analyzed results the relationship between tsunami height and tsunami velocity is obtained and shown in Fig.12. In the figure the assumption that the velocity should be 0 when the tsunami height is 0 is added. When the tsunami began to fall back, the velocity was treated as 0 as well. Before the tsunami reached about 2m, the tsunami velocity rose to about 6 m/s.

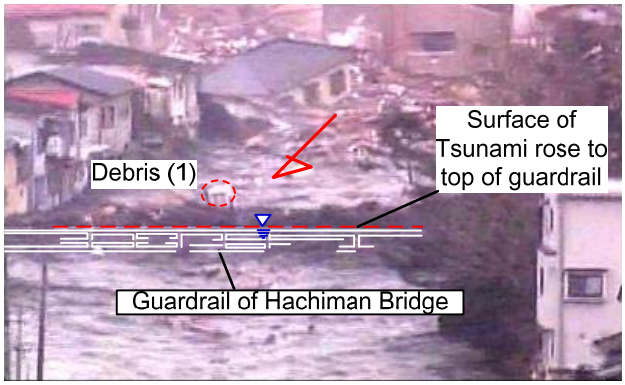

Figure 10 Shot of Tsunami Wave at 7:05s

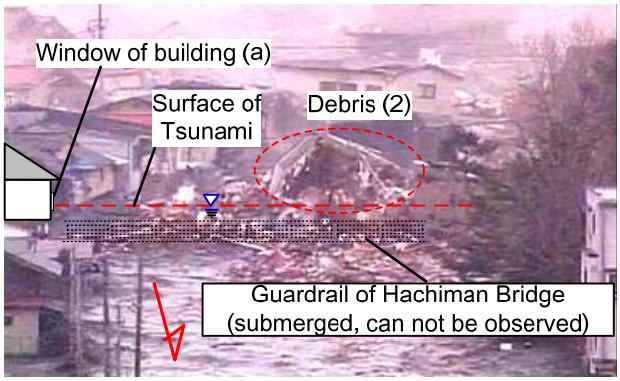

Figure 11 Shot of Tsunami Wave at 7:53s

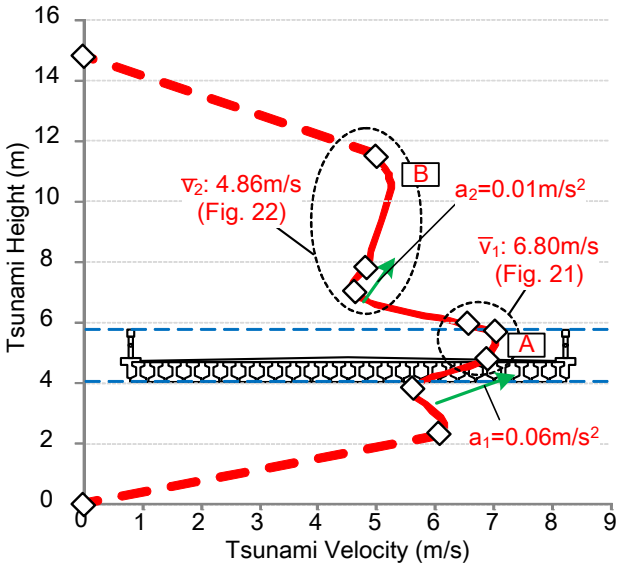

Figure 12 Time-depended Variation of Tsunami Height (Hachiman Bridge)

The velocity of tsunami increased continually before the tsunami hit the bridge girder. The maximum velocity is estimated as 7.02m/s just before the tsunami reached the

bridge girder. When the tsunami ran up to about 6m high, the bridge began to be inundated and the tsunami velocity got to decrease to about 4.86m/s (average of area B in Fig.12). After tsunami height reached about 12m, velocity decreased to 0 gradually.

Fig.12 tells two things. Firstly, the tsunami velocity continuously increases up to the maximum before the tsunami begins to overflow the bridge girder. Secondly, the tsunami velocity decreased suddenly when the bridge girder is inundated. In addition, Hachiman Bridge has a local geographical feature showing that the level of girder is the same as the level of embankment. When the tsunami height rises up to the level of girder, the tsunami would overflow to the land area and that results in the reduc of tsunami energy and velocity

5. RESISTANT MECHANISM OF HACHIMAN BRIDGE GIRDER

In the previous section, the characteristics of tsunami in the city were discussed in details. In particular, the height and the velocity of tsunami at the site of Hachiman Bridge are certainly evaluated. Although Hachiman Bridge has fortunately survived from the tsunami, it must be very important to establish a proper model which is able to explain why Hachiman Bridge was not washed away by the tsunami. As mentioned in section 2, the details of more than 400 bridges in inundation area are collected and arranged in the database. Not only the mechanism for washed away bridges but also that for survived ones is necessary for further discussions on existing bridges in other areas where a huge tsunami is expected to come near future.

Figs 14 and 15 show the possible mechanisms for resistance of Hachiman Bridge against tsunami. Fig.14 represents tsunami wave acts on the girder of bridge, whereas tsunami in Fig.15 acts on the girder like flood in the condition of the girder submerged deeply.

For discussions of these cases, Eq.1 is extended to Eq. 6 as below.

$$F = \frac{1}{2}\rho_w C_d A v^2 + C_m \rho_w AB\frac{dv}{dt} + (\rho_w g h_1 A_1 - \rho_w g h_2 A_2) \qquad (6)$$

Where, C_m is inertia coefficient, assumed to be 1.0; B is bridge width (m); dv/dt is acceleration of tsunami (m/s^2); h_1 and A_1 are the water depth (m) and pressure area (m^2) at the downstream side of girder; h_2 and A_2 are the water depth (m) and pressure area (m^2) at the upstream side of girder.

Eq.6 consists of both hydrodynamic force and hydrostatic force. The mechanism-1 requires both forces, but the mechanism-2 needs only hydrodynamic force because the water head between upstream and downstream of the girder becomes zero. For computation of resistance of the girder, Eq.2 should be used for the mechanism-1 and Eq.3 for the mechanism-2.

Computed results are shown in Fig.16. Either mechanism indicates the survival of girder against the tsunami, but the mechanism-1 gives lower safety.

6. EXPERIMENTAL ANALYSIS

6.1 Experimental Setup and Conditions

A series of hydraulic experiments based on the Froude similarity with a length scale of 1/50 were conducted using a wave flume in the Department of Civil Engineering, Nagoya University, Japan (12.5 m × 2.22 m × 1.0 m). To generate long-period waves, a piston-type wave generator with a maximum stroke of 1.5 m was installed in the flume.

Figs. 17 and 18 show the experimental setup. Fig.19 shows the cross-section of a bridge model, which is made of acrylic plates. The cross-sectional dimensions of the bridge model are determined to simulate a superstructure of the Utatsu bridge, Japan, which was damaged in the 2011 Tohoku earthquake tsunami. The length of the bridge model is 0.3 m. The specific weight of the bridge model is lower than that of the prototype due to the limitation of the wave generator. As shown in Figs, 17 and 18, the flume is divided into three 0.31-m-wide sections, which are slightly wider than the length of the bridge model. In a section, a bridge model is put on 0.1-m-high piers to observe whether the bridge model moves or not. In another section, another bridge model is fixed at the same height as the movable bridge model to measure wave force and pressure acting on it. The wave force and pressure are measured using a load cell (Nissho: LMC-3520-50NWP) and pressure transducers (Kyowa: PS-05KCM3Z5P). The position of the pressure transducers is presented in Fig. 19. In the other section, no bridge model is set to measure water surface elevation and flow velocity in the absence of the bridge model. The water surface elevation and the flow velocity are measured using capacitance-type wave gauges (Kenek: CHT6-40) and a propeller-type velocimeter (Kenek: VOT2-100-05N). The cross-shore position of the velocimeter is the same as the seaward edge of the bridge model, and its vertical position is the same as the center of the bridge model.

A single long-period wave was generated toward the bridge models. The offshore still water depth h was set at 0.49 m. The time during which the wave paddle was displaced forward and backward, T, was set at 20.0 s.

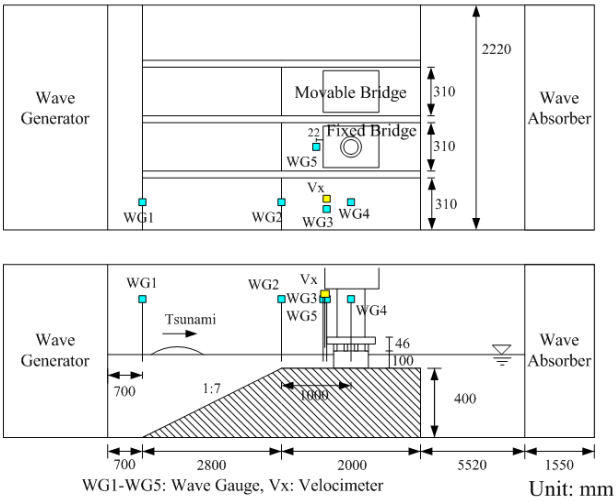

Figure 17 Schematic View of the Experimental Setup

The stroke of the wave paddle S was changed from 1.24 to 1.38 m. In total, five cases were conducted.

Figure 18 Bridge Models

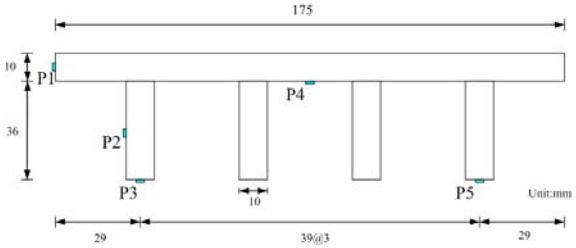

Figure 19 Cross-Section of Bridge Model

6.2 Experimental Results and Discussion

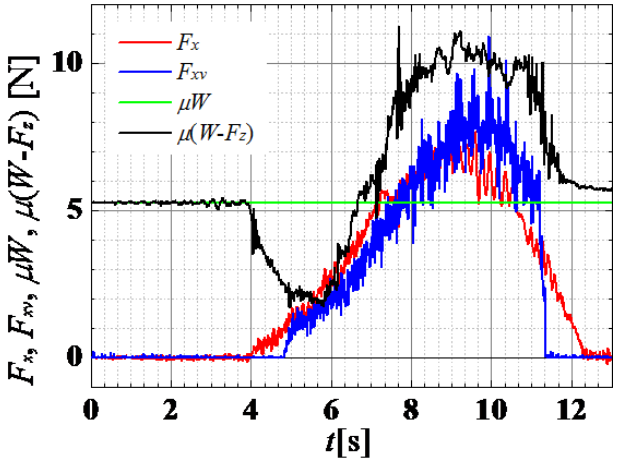

Fig. 20 shows the wave force acting on the fixed bridge model. In the figure, F_x is the horizontal wave force measured using the load cell, and F_{xv} is that estimated by Eq.1

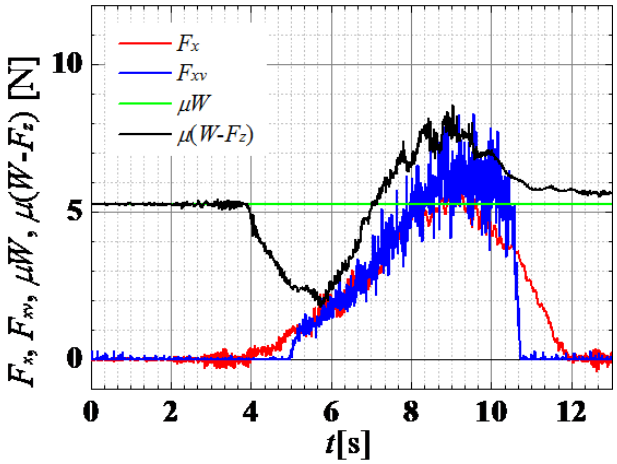
As shown in Fig. 20, the value of F_x gradually increases after the tsunami impinges the bridge model, and reaches its maximum at around 5 s after the impingement. Figure 20 also indicates that although the maximum value of F_{vx} slightly overestimates that of F_x, the time series of F_x is in good agreement with that of F_{xv}. Consequently, the horizontal wave force acting on the bridge model can be evaluated from the flow velocity using Eq. 1.



In Fig. 20, the friction force $\mu\,(W - F_z)$ and its initial value $\mu\,W$ are also presented. Here, W is the weight of the bridge model, F_z is the vertical wave force measured using the load cell, and μ is the static friction velocity, which was determined to be 0.45 by the trial-and-error method. Since a decrease in $\mu\,(W - F_z)$ is equivalent to an increase in F_z, Fig.20 shows that the value of F_z increases after the water surface impinges the bottom of the bridge model. Following that, the value of F_z conversely begins to decrease, and reaches its minimum at the almost same moment as the maximum value of F_x. Because of these changes in F_z, the value of $\mu\,(W - F_z)$ decreases and reaches its minimum shortly before $t = 6$ s. Conversely, it increases and reaches its maximum at around $t = 9$ s.

The bridge model is expected to start moving when the value of F_x exceeds that of $\mu\,(W - F_z)$. In the hydraulic

experiments, it was observed that the bridge model began to move at approximately 2 s after the tsunami impingement in the case of Fig. 20(a), while the bridge model did not move in the case of Fig. 20(b). Fig. 20(a) indicates that the value of F_x slightly exceeds that of $\mu(W - F_z)$ shortly before t = 6 s, suggesting that the bridge model begins to move at this moment. On the other hand, Fig. 20(b) shows that the value of F_x does not reach that of $\mu(W - F_z)$, suggesting no motion of the bridge model. These results are consistent to the observation. Furthermore, a comparison between F_x and μW shows that the value of F_x exceeds that of μW at about t = 8 s in both cases. However, as described earlier, the bridge model began to move at around 2 s after the tsunami impingement for Fig. 20(a), and did not move for Fig. 20(b). This suggests that it is essential to consider the vertical wave force F_z when calculating the static friction force. From these results, it is found that the motion of the bridge model can be assessed using the horizontal wave force F_x and the static friction force $\mu(W - F_z)$.

(a) S = 1.38 m (the bridge moved)

(b) S = 1.24 m (no bridge movement)

Figure 20 Wave Force and Static Friction Force Acting on Fixed Bridge Model

7. NUMERICAL ANALYSIS

To examine whether the motion of a bridge can be evaluated by numerical simulations or not, some numerical experiments were conducted using a three-dimensional coupled fluid-structure-sediment interaction model (Nakamura et al. 2011), which is based on a large-eddy simulation (LES) model that can be applied to tsunami-bridge interaction. Figure 21 shows a schematic view of the computational domain modeled from an experimental setup of Nakao et al. (2010). A bridge model with the dimensions of 80 mm × 200 mm × 20 mm is fixed at a height of 65 mm from the bottom in the hydraulic experiments. In this study, a movable bridge model with the same dimensions is adopted instead of the fixed bridge model. The density of the movable bridge model is changed as 1.0×10^3, 1.5×10^3, 2.0×10^3, and 2.5×10^3 kg/m^3. Toward the movable bridge model, a bore-like flow is generated by the dam break with an initial water height of 250 mm. Detailed explanation of the coupled model can be found in Nakamura et al. (2011).

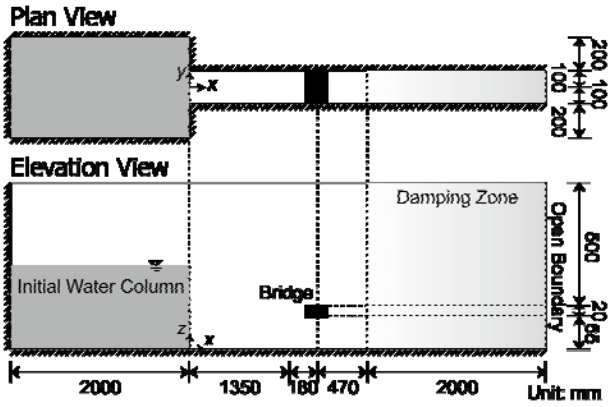


Figure 21 Computational Domain

Figs. 22 and 23 show the bridge motion and the surrounding water surface deformation for the density of the movable bridge model of 1.0×10^3 and 2.0×10^3 kg/m^3. For the light bridge model with the density of 1.0×10^3 kg/m^3, as indicated in Figure 22, the water mass splashes up in front of the bridge model at the impingement of the flow. At this moment, it is observed in Figure 24 that the pressure increases at the front surface of the bridge model. In contrast, the pressure conversely decreases around the bottom surface of the bridge model due to the formation of a vortex, suggesting that an increase in the maximum static friction force acting on it. Figure 22 also shows that no motion of the bridge model is observed until t = 2.2 s. However, although no figure is presented, the horizontal force acting on the bridge model exceeds the maximum static friction force shortly after t = 2.2 s. The bridge model accordingly begins to slide, and finally moves downstream. For the heavy bridge model with the density of 2.0×10^3 kg/m^3, Figure 23 shows that its motion is not observed after the flow is subsided. From these results, it is suggested that the coupled model has the computational capability to simulate the

motion of a bridge. However, a comparison with hydraulic experiments is not conducted in terms of the motion of a bridge. To address the issue, it is recommended that further studies be conducted to verify the validity of the coupled model and clarify the mechanism of the bridge motion.

8. CONCLUSIONS

The research work in the paper covers the field survey of damage of bridges by the tsunami on March 11, 2011, the damage analysis based on database, the characteristic of tsunami after coming up the land, and the hydraulic experiment with development of numerical simulation technique. The followings are concluded.

(1) Internet media is a powerful tool to survey the damage by tsunami in wide area.
(2) More than 200 out of 1793 bridges in the inundation area of east Japan (Tohoku region) were washed away by the tsunami. Comparing survived bridge girders with washed ones, girders with rather shallow cross sections are observed much resistive against tsunami.
(3) Water pressure acted on bridge girder may be evaluated by combination of hydrodynamic and hydrostatic pressures. The location of bridge and the height of pier might influence the condition of girder at the attack of tsunami, whether the girder is submerged or not.
(4) Some characteristics of tsunami coming up in the land are examined by observation of motion pictures taken by citizens. The velocity of tsunami in the land increases linearly as the height of tsunami increases. After the height of tsunami reaches to the girder, the velocity of tsunami around the girder may reduce while the height of tsunami still increases.
(5) Two mechanisms on how girders survive against tsunami could be considered depending upon the condition of girder, whether the girder is submerged or not.
(6) Experimental examination was conducted to see how a girder behaved at the attack of tsunami, and what water pressure acted on a girder. A numerical simulation technique has been developed. However, it needs some more time to establish a reliable simulation model.

RETROFIT OF DAMAGED STRUCTURES ACCORDING TO RESPONSE CONTROL CONCEPT

Toru Takeuchi[1)]

1) Professor, Department of Architecture and Building Engineering, Tokyo Institute of Technology, Japan
ttoru@arch.titech.ac.jp

Abstract: In the Great East Japan Earthquake of 2011, many truss-based structures such as school gymnasia and steel towers were damaged owing to the effect of not only Tsunami but the consequent earthquake shake. Typical failure patterns include buckling and fracture of axial members, and damage around the anchored joints of steel frames of reinforced concrete structures. Conventional retrofit methods that restore the original design pose the risk of an identical failure under similar circumstances. The latest response control techniques that involve avoiding damage to braces and bearings can be applied for overcoming this limitation. In this paper, we discuss a method for retrofitting damaged gymnasia using base-isolation bearings or buckling retrained braces and present examples of the method's real-world application.

1. INTRODUCTION

Many schools in the Iwate, Miyagi, and Ibaragi prefectures were damaged owing to seismic shakes resulting from the Great East Japan Earthquake of 2011 (referred to as the 2011 earthquake, hereinafter) and the Chuetsu-oki Earthquake in 2007. Furthermore, communications and truss towers in electric power plants were damaged. In this paper, we propose a retrofit strategy for these structures based on response control techniques and discuss some examples in depth.

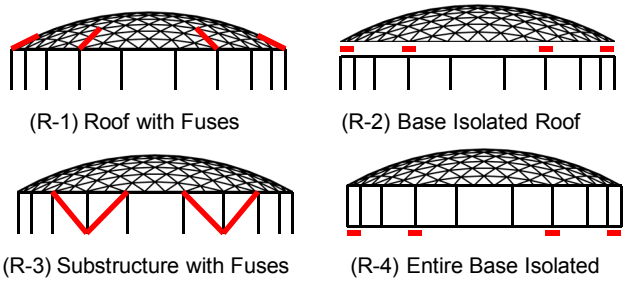

Figure 1 Response Control Concepts for Latticed Roofs

2. RETROFIT USING BASE-ISOLATION BEARINGS

Figure 1 shows a response-control-based method proposed by the Takeuchi et al. (2012.6)[1]. for retrofitting steel roof structures such as domes, latticed shells, and gymnasia. In (R-1), energy-dissipation fuses are installed for protection against the in-plane vibration of the roofs; these are effective in reducing horizontal responses. Here, we use the word "fuse" for elasto-plastic dampers with stable hysteresis, which work as structural elements until their yield strength. In (R-2), base-isolation bearings are installed at the roof's supporting points; these are effective in reducing both horizontal and vertical responses of the roof. Such a system has been installed in several newly constructed structures. (R-3) shows a structure in which energy-dissipating fuses are installed in the substructures and are expected to produce the same effect as that of (R-2). These types of structures are widely used in the construction of stadia and gymnasia. Buckling-restrained braces (BRBs), being in a same situation as those used for multistory buildings, are commonly used as energy-dissipation devices. (R-4) shows a base-isolation system for an entire structure; this structure has been used in the construction of multistory buildings such as airport terminals.

One of the most typical types of damage to school gymnasia due to the 2011 earthquake was failure at the points where steel roof bearings are anchored to concrete

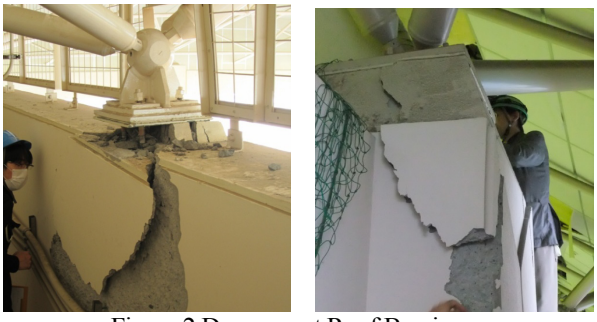

Figure 2 Damages at Roof Bearings

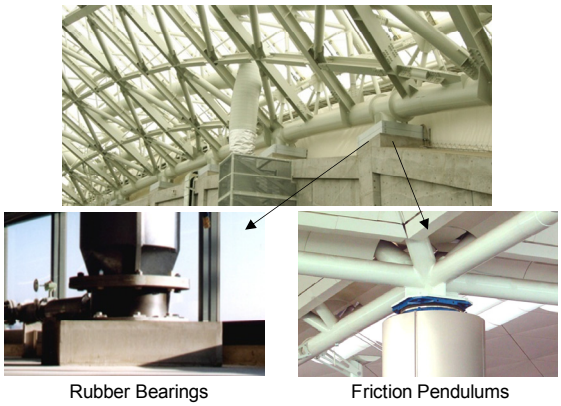

Figure 3 Base Isolation Bearings at Roof Supports

frames[2]. Figure 2 shows damages to gymnasia in the Ibaragi prefecture; in both cases, severe cracking occurred at the beam and column heads, i.e., the points where anchor bolts are fixed. It is assumed that these damages are caused by underestimation of anchor strength against side failure and by the difficulty in estimating the reaction forces on bearings governed by the complex response characteristics of raised shell roofs supported by cantilevered reinforced concrete (RC) walls.

The retrofitting of damaged anchored bearings is difficult. It usually involves covering damaged parts with steel plates, in-filling additional concrete, and fixing with bolts. However, retrofitting often warrants partial reconstruction of beams, columns, exterior walls, and interiors, and the strength and performance of the repaired bearings are usually in line with those of the original design. In cases where the bearings are designed as rollers, they are required to allow for up to 100 mm of displacement because of the cantilevered columns' deformation. Inserting rubber bearings or friction pendulums as base-isolation bearings into roof support points could be an effective, alternative method of retrofitting. Figure 3 shows the examples of cases where base-isolation bearings were inserted into the supporting points of reticulated roofs. Figure 4 shows that the insertion of base isolation bearings into the support points of a latticed roof causes a drastic decrease in the horizontal and vertical components of acceleration along the roof[3]. This result indicates the simplicity and cost-effectiveness of these retrofit methods.

3. RETROFIT USING ENERGY-DISSIPATION FUSES

An easier and more practical retrofit can be achieved by replacing the vertical braces with energy-dissipation members. This concept is shown in Figure 5. Elasto-plastic fuses or viscous dampers can be used as energy-dissipation members; the former are effective in reducing roof displacement, and the latter are effective in reducing roof acceleration. Figure 6 shows the effects of energy-dissipation members on horizontal and vertical accelerations[4]. Increasing the stiffness of the supporting structures increases the response accelerations of raised roofs in the vertical as well as the horizontal directions[5]. As shown in Figure 6 (b), conventional retrofits that involve strengthening the vertical braces can increase the response acceleration along the roof, thus also increasing the risk of damaging the ceiling and any suspended lights. In contrast, response-control retrofit using energy-dissipation fuses or viscous dampers can effectively reduce the roof's response accelerations, as shown in Figure 6 (c) and 6 (d).

In the 2011 earthquake, typical damage patterns such as vertical brace buckling and fractures were widely observed for steel gymnasia. Figure 7 (a) shows the interior of a two-story school gymnasium in Tsukuba, constructed in the early 70s. The first story was constructed using composite, and the second using steel. The roof comprises latticed L-section truss beams supported by steel columns and L-section braces. All vertical braces of this structure underwent severe buckling and fracture, as shown in Figure 7 (b), (c). The ultimate shear strength of the braces allowed for a load equivalent to only 9–14% of the roof's weight and this was inadequate for withstanding the seismic impact of the 2011 earthquake.

(b) Site-welded connections for BRB

Figure 9 Construction of BRB Retrofit

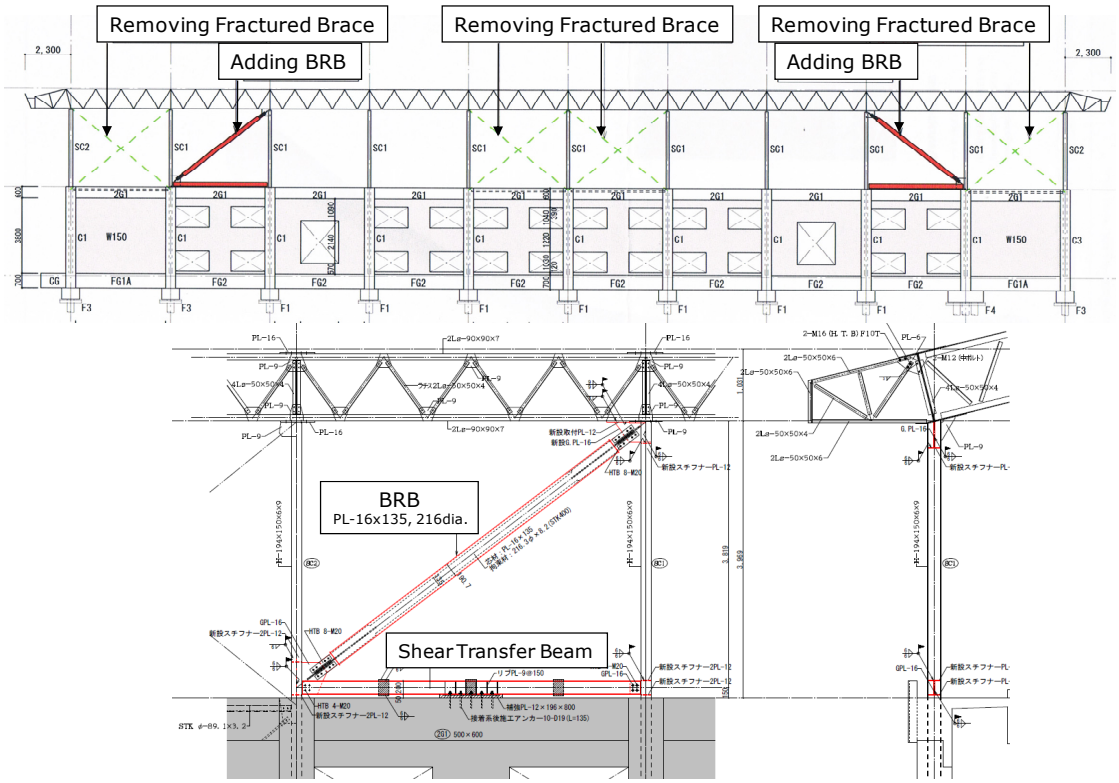

Figure 8 Retrofit of Damaged Gymnasium with BRB

Apart from the vertical braces, a few roof diagonals buckled as well, and many of lighting equipments suspended from the roof fell off. Conventional retrofitting involves the replacement of these braces with wider L-section braces; however, this way, the risk of further buckling due to larger aftershocks remains. To achieve a more robust and damage-tolerant retrofit, we used BRBs instead of L-section braces. Figure 8 shows the longitudinal layout of BRBs. The 24 original braces were replaced with 8 BRBs, which can withstand 557 kN of axial yield forces each and shear forces equivalent to 76–80% of the roof's weight in total. The BRBs are expected to dissipate the impact of seismic inputs larger than those of the 2011 earthquake and prevent severe damage to the roof and the braces themselves. Equivalent seismic indexes, obtained by multiplying the shear force ratio and brace material ductility, are around 211% of the roof's weight. As shown in Figure 8, BRBs were attached by welding gusset plates to the existing frames, and additional shear-force transfer beams were anchored to the RC floor beams.

The retrofit design work was carried out in May 2012, and construction took place between September and December 2012. Figure 9 shows details of the retrofit construction. Figure 9 (a) shows the overall view of the attached BRB, and Figure 9 (b) shows details of the lower and upper connections. The construction was carried out easily, with each BRB attachment taking one day, including site welding and fixture.

Such BRB retrofits are gaining popularity. Figure 10 (a) shows another gymnasium near the border between the Fukushima and Ibaragi prefectures. This gymnasium is a single-story steel construction with a cylindrical shell roof reinforced with vertical braces along the longitudinal

(a) Interior View

(b) BRB Attachement Details

Figure 10 BRB Retrofit in A Junior High School

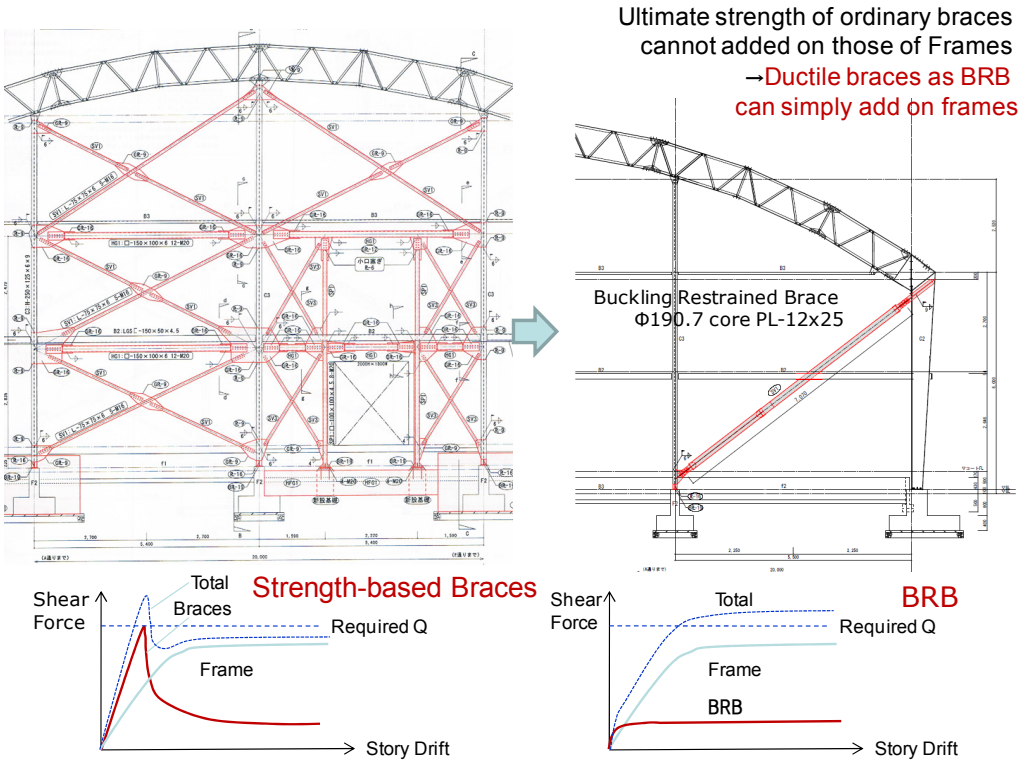

Figure 11 Strength-based Retrofit vs. BRB retrofit

direction. Although the 2011 earthquake did not damage this building, a seismic retrofit was planned because the shear strength of the original braces was equal to only 16% of the roof's weight, which is insufficient against expected future seismic impacts. It was found that the ultimate shear strength in the transverse direction equals 57% of the roof's weight, which is also less than the requirement of 70%. First, the addition of L-section braces was planned under the conventional approach. However, doing so warranted the use of a large number of braces for achieving the 70% shear strength requirement, because the story drift angle at the ultimate shear strength of the latticed frame was expected to be around 2%, and could not be achieved using the additional braces, which reached buckling strength at a 0.13% story drift angle (left part of Figure 11). We proposed, and eventually selected, BRB retrofit as the alternative, because their strength can be added to the original frames directly for maintaining stable hysteresis up to a 3% story drift angle (right part of Figure 11). Consequently, only four additional braces were required. The transverse strength of the BRB-reinforced structure is 91% of the roof's weight, and the expected seismic index, including energy-dissipation effects, touches 230%.

The construction sites are shown in Figure 10 (b). The designed BRBs have a yield strength of around 100 kN and a diameter of 190 mm at the restrainers. These braces are composed of series connections of shorter BRBs and circular section braces, which can pass through the wind-resisting latticed beams, as shown in Figure 9 (c). As in the previous example, gusset plates were welded to the existing frames, and BRBs were fixed using friction bolts.

4. RETROFIT OF TRUSS TOWERS USING BRBs

A similar response control concept with energy-dissipation members can be applied to retrofit various truss structures [1]. Figure 12 shows the layouts of the energy-dissipation members. In (T-1), the devices are installed parallel to the main frame, whereas in (T-2), each chord member is replaced with a corresponding device in each truss column. (T-3) shows another layout for replacing the diagonal members with energy-dissipation members. For arranging such devices in truss frames, the following steps may be followed in general design.

1) For low-stiffness truss structures, the energy-dissipation members should be installed such that they connect two points that are subjected to the largest relative displacement due to expected loads.
2) For high-stiffness truss structures, initially a pushover analysis should be conducted without evaluating buckling, and then, the yielded members should be replaced with energy-dissipation members.

Figure 13 shows the application of the above method to communication towers erected on RC buildings. These communication towers composed of tubular members are designed mainly to withstand wind forces. However, recent studies have indicated that there is a risk of damage to the

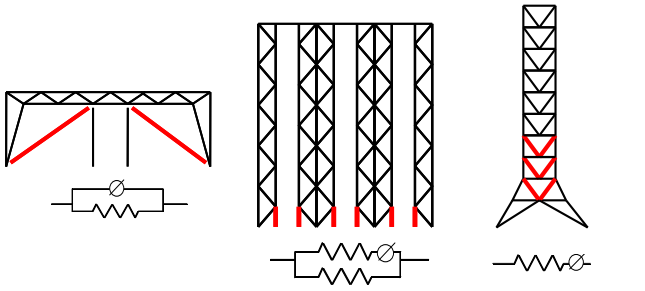

Figure 12 Response Control Concepts for Truss Structures

(a) Fracture of Tubular Members after Buckling

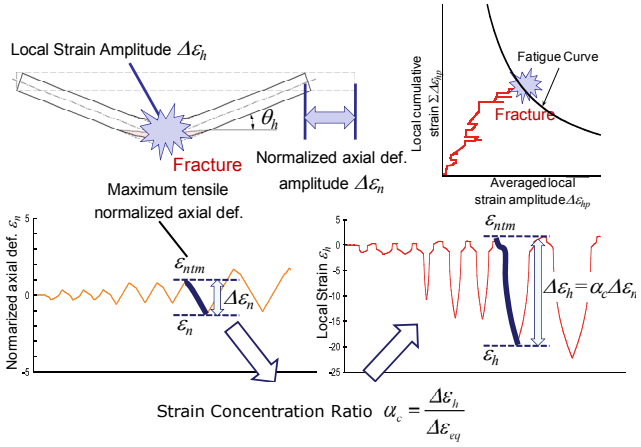
(b) Truss Tower Fractured by Chuetsu-oki Eatrhquake

Figure 14 Fractures of Tubular Members after Buckling

diagonal members and the leg columns owing to expected earthquakes in the Tokai region. The planned retrofit includes the replacement of diagonal members with BRBs and the addition of buckling restrainers around the existing column members. These actions are similar to those taken for (T-2) and (T-3), shown in Figure 12.

Before carrying out the retrofitting, we investigated cumulative deformation capacities of the tubular members post buckling by performing cyclic loading tests on 1:1 size mock scale models of the truss frames [6]. As shown in Figure 14 (a), tubular braces undergo local buckling in addition to and after the entire frame buckles, and fracture soon thereafter because of plastic strain concentration at the point of local buckling. In the 2007 Chuetsu-Oki Earthquake, diagonal tubular members of truss towers at nuclear power plants near the epicenter fractured after buckling, thereby validating the findings of the mock scale model experiment (Figure 14 (b)).

This fracture process can be evaluated using the idea of a strain concentration index α_c [7]. This idea assumes local strain amplitudes by multiplying normalized axial deflections (defined as the ratio of axial deformation to original length) and concentration indexes; fracture is considered to have occurred when the amplitude of the cumulative local strain reaches the low-cycle fatigue curves of the tube material (Figure 15). For evaluating the concentration index α_c,



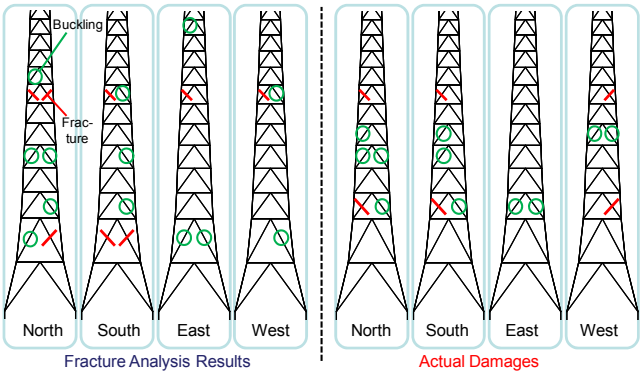


Figure 15 Fracture Prediction by Stress Concentration Index

(b) Fracture Analysis results (c) Actural Damage

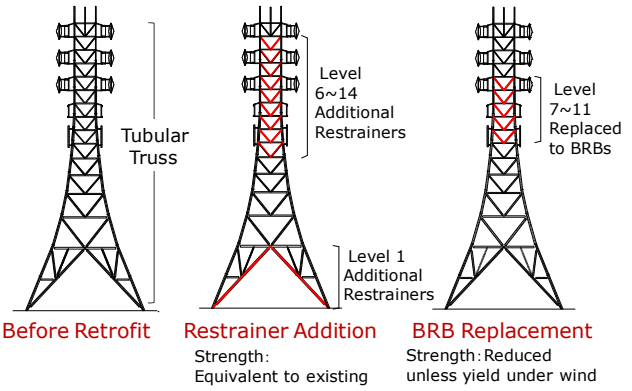
Figure 16 Comparison of Fracture Analysis with Actual Damages

Figure 17 Retrofitted Communication Tower

simple equations for the pre-buckling, post overall buckling, and post local buckling phases have been proposed [7] and can be used for time-history analyses. We evaluated the fractured towers shown in Figure 14 and compared the results with the actual damages shown in Figure 16. The fracture analysis results generally agree with the actual failure pattern; therefore, the assumed fracture mechanisms are considered valid. Because such fractures are caused by partial stress concentration at critical members, an effective retrofit method is to replace these members with stable energy-dissipation members such as BRBs, in which the plastic strain is evenly distributed along the braces. The actual retrofitted communication tower is shown in Figure 17; it involved the use of BRBs.

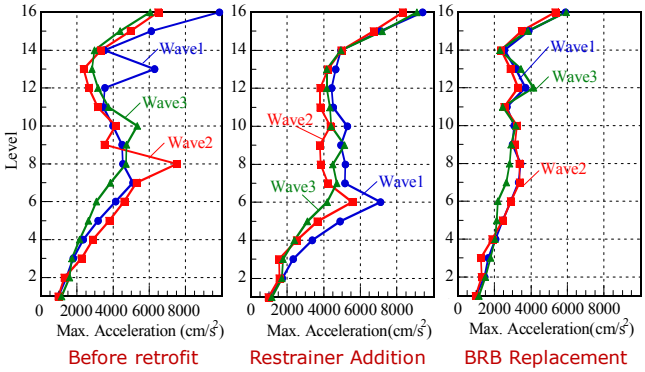
Several retrofit options are compared in Figure 18 (a). One of these is the addition of buckling restrainers around members having insufficient increasing axial strength; the bucking restrainers prevent buckling, thus resulting in increased axial strength (center of Figure 18 (a)). This enhances the structure's seismic responses, and requires additional reinforcement around level 1. The other option is to replace the insufficiently strong members with BRBs (right side of Figure 18 (a)). The analyzed acceleration responses of each of the options are shown in Figure 18 (b). The option involving replacement with BRBs has the minimum response acceleration throughout the height, higher performance, and the lowest construction cost. Consequently, this option was selected and applied to around 50 towers in Tokai religion.

Figure 18 (c) shows the retrofit work for a communication tower in the Mie prefecture. Retrofitting of 20 BRB members could be completed in just six days with three workers, thus proving to be one of the most practical and cost-effective retrofit methods.



5. CONCLUSIVE REMARKS

We proposed the use of and applied the response control concept for the retrofitting of damaged gymnasia and towers with energy-dissipating members.



1) For retrofitting damaged bearings of steel roofs of gymnasia and improving performance, the use of base-isolation bearings is considered to be an effective solution.
2) Replacing the vertical braces of a gymnasia with energy-dissipation members, i.e., BRBs, is also a practical and effective retrofit solution for preventing further damage to braces and roof structures. This concept has already been implemented in several retrofits.
3) Similar concepts are applicable to the retrofitting of truss towers, and have been implemented in several structures.

Abstract: In order to discuss in detail the environment and urban systems, it is necessary to consider not only static physical objects like buildings, but also the spatiotemporal aspects like the distribution of population. This paper aims to construct models that describe the spatiotemporal distribution of population in urban areas. The models are composed of parameters describing the number of persons per unit floor-area of buildings, which varies according to the time fluctuation factors and the location factors, and are calibrated using a person trip survey data and GIS data. We discuss the characteristics of the spatiotemporal distribution of population and the accuracy of the models, and demonstrate that the proposed models can benefit all phases of urban planning which include risk assessment and disaster management.

1. INTRODUCTION

Ordinal modeling techniques of environment and urban systems based only on static physical objects like buildings do not always describe a certain aspects of their realities. Due to human activities and mobility by rapid urban transportation systems, the distribution of population varies according to time (Osaragi, 2009). This is especially true in metropolitan areas. Thus, the next step in modeling of the urban environment is to take population and institutions into account (Aubrecht et al., 2009). In order to consider population in spatial models, it would be a possible means to use spatially referenced demographic data aggregated to census tracts. The problem with census tracts is that they are not regular in size making inter-comparisons very difficult (Aubrecht et al., 2009). Namely, we need a model which enables us to estimate spatiotemporal distribution of population for any places in various size and various shapes.

Accurately estimating population exposure is a key component of catastrophe loss modeling, one element of effective risk analysis and emergency management (Freire and Aubrecht, 2010). Recently, numerous studies have addressed planning for disasters from various approaches, with an emphasis on planning for serious earthquakes. Until now, estimates of human casualties have relied on the static distribution of population provided by the national census and other counts. Thus, the recent-approved studies are based on a seismic intensity map, and only consider resident population from the census data.

However, the actual spatial distribution of transient occupants in any busy metropolitan area changes by the hour, or even by the minute, so static estimates of the population distribution are of limited utility (Osaragi, 2009). Thus, more accurate estimation of population exposure and risk assessment requires moving beyond using simple residence-based census data (Freire and Aubrecht, 2010). An accurate and dynamic view of the population distribution would thus be extremely useful. For detailed analysis such as modeling of hazards and risk exposure there is a need for even more detailed population distribution (Aubrecht et al., 2009).

Concerning methods such as spatial disaggregation of population, the key is to combine such methods with earth observation data and remote sensing techniques in order to achieve fully integrated urban system models (Bracken and Martin, 1989; Sim, 2005; Steinnocher et al., 2006). With the increasingly available census data and remotely sensed data, to discuss their relationship is one of important issue in GIS data integration (Chen, 1998; Chen, 2002). Aubrecht et al. (2009) have demonstrated how disaggregated population data can improve estimation of exposure to earthquake hazard. Also, Freire and Aubrecht (2010) modeled and mapped nighttime and daytime population distribution patterns at high resolution in order to assess the spatiotemporal human exposure to earthquake risk in the Lisbon Metropolitan Area. They combined the population distribution maps with the seismic hazard intensity map to assess potential exposure and produced new daytime and nighttime overall seismic risk map.

In the present study, we construct models which describe the spatiotemporal distribution of transient occupants of the Tokyo Metropolitan area in terms of “When?” (time of day), “Where?” (location or facility), and “How many?” (population). These models employ data of a Person-Trip survey data (PT data) conducted in the Tokyo Metropolitan area in 1998, comprising transient population

data for periods of the day, municipal zones, and building types. Additional information is taken from GIS data about buildings (building type, floor area, spatial distribution), which have recently come to include a wealth of local information from national and local public organizations. These data sets are combined to create a model emulating the spatiotemporal distribution of population in any desired spatial unit of Tokyo. This paper describes our evaluation of the accuracy of the models and examines the spatial units in which they can be applied by searching for the smallest subdivisions of an area for urban planning using traditional Japanese address units (chō-chōme) and geometric cells, and offers basic information in an attempt to suggest new avenues for research.

2. MODEL FOR ESTIMATING SPATIO-TEMPORAL DISTRIBUTION OF POPULATION

2.1 Definition of "Transient Occupants"

"Transient occupants of the metropolitan area" are defined as the union of several sets of individuals: (1) Occupants of all types of buildings (housing, businesses, educational institutions, etc.); (2) occupants outside buildings (pedestrians, cyclists, etc.); and (3) passengers (occupants of trains, automobiles, and other transportation facilities). The spatiotemporal distribution of railroad passengers was discussed in Osaragi (2009), and automobile passengers in Osaragi and Shimada (2009). In this paper, occupants inside buildings and occupants outside buildings are collectively defined as "transient occupants".

2.2 Formulation of Spatiotemporal Distribution Model for Occupants Inside Buildings

First, we consider $y_{ij}(t)$, the number of transient occupants in building type j in zone i at time t. $N_i(t)$, the total number of occupants in zone i at time t, is obtained by summing $y_{ij}(t)$ over all building types j:

$$N_i(t) = \sum_j y_{ij}(t) \quad (1)$$

Next, we consider that $y_{ij}(t)$ is proportional to the scale of the building denoted by x_{ij} [m^2], the total floor area of building type j in zone i. The number of transient occupants $y_{ij}(t)$ can be obtained by multiplying x_{ij} by the density of transient occupants $\gamma_{ij}(t)$ [persons/m^2], which depends not only on the type of building j and time t, but is also highly dependent on the characteristics (advantages) of the location of zone i. Thus, $y_{ij}(t)$ is calculated as follows:

$$y_{ij}(t) = \gamma_{ij}(t)\, x_{ij} \quad (2)$$

Next, we consider $\gamma_{ij}(t)$ can be divided into two parts: the time fluctuation factor $\alpha_j(t)$, which is common to all zones, and the location factor β_{ij}, which is independent from time. Thus, $y_{ij}(t)$ can be expressed as follows:

$$y_{ij}(t) = \alpha_j(t)\, \beta_{ij} x_{ij} \quad (3)$$

Here, if $\alpha_j(t)$ is normalized to 1 as the mean for all times, the location factor β_{ij} can be considered a parameter expressing the mean density of transient occupant in whole day.

Next, we describe β_{ij} using either (i) unique parameter (dummy variable) for each zone i, or (ii) data describing the characteristics of location of zone i, such as the mean time to the nearest station, the number of buildings by scale and the floor area of buildings. A former model that attempts to use unknown but unique parameters b_{ij} of zone i is called a "*descriptive model*" and expressed as follows:

$$\beta_{ij} = b_{ij} \quad (4)$$

On the other hand, the latter model is called a "*predictive model*", in which β_{ij} is described using unknown parameters (b_{j0}, b_{jk}) and an explanatory variable z_{ik} (where k is the suffix of a variable), which includes the mean time to the nearest station in zone i and variables about buildings normalized by dividing by the geographical area of zone i. Hence, we describe the predictive model as follows:

$$\beta_{ij} = \sum_k b_{jk} z_{ik} + b_{j0} \quad (5)$$

The descriptive model is limited in its geographical scope since it is uniquely determined by its zone. However, within the zone itself, the user can "zoom in" to small portions of the zone for fine-scale estimates of the transient occupants there. In contrast, the predictive model can be used anywhere, as long as sufficient GIS data (explanatory variables) have been obtained. It also assists us to understand the degree of influence of explanatory variables on the number of transient occupants.

2.3 Modeling of Occupants outside Buildings

Occupants outside buildings are generally individuals transiting between buildings. This is especially true during the morning and evening rush hours, when most of the occupants outside buildings are transiting between railway stations and buildings. There are also large numbers of transient occupants in the vicinity of large buildings. As a first step toward describing the number of occupants outside buildings, the floor areas of all buildings and the numbers of boarding or disembarking passengers are considered. Specifically, we describe $y_{i*}(t)$, the number of occupants outside buildings in zone i at time t, using the terms of potential E_i for the number of boarding or disembarking passengers, the total floor area of buildings x_{ij}, and the unknown parameters $\gamma_{i*}(t)$ and $\gamma_{ij}(t)$:

$$y_{i^*}(t) = \gamma_{i^*}(t) E_i + \sum_j \gamma_{ij}(t) x_{ij} \quad (6)$$

where $\gamma_{i*}(t)$ is the ratio of transient occupants derived from boarding or disembarking passengers. $\gamma_{ij}(t)$ [persons/m^2] is the density of transient occupants, which depends not only on the type of building j and time t, but is also highly dependent on the characteristics (advantages) of the location of zone i. E_i expresses the decay in the number of passengers with distance from the station, given in the following equation. E_i is calculated by considering not only the stations within zone i, but also other stations close to the zone i.

$$E_i = \sum_l V_l \sum_{m=1}^{n_{il}} \exp[-2d_{iml}] \Big/ \sum_i \sum_{m=1}^{n_{il}} \exp[-2d_{iml}] \ , \quad (7)$$

where V_l is the number of boarding or disembarking passengers per day at station l (extracted from PT data), n_{il} is the number of locations from which station l is the nearest in zone i, d_{iml} is transit (walking) time from location m in zone i to station l.

Next, $\gamma_{i*}(t)$ and $\gamma_{ij}(t)$ are described as follows, using the product of the time fluctuation factor and the location factor:

$$y_{i*}(t) = \alpha_*(t)\beta_{i*}E_i + \sum_j \alpha_{j*}(t)\beta_{ij}x_{ij} \ . \quad (8)$$

$\alpha_*(t)$ can be considered a coefficient distributed in accordance with the number of railway passengers during various time periods throughout the day. The areas around urban stations are considerably more crowded just after the start of business hours, and the vicinities of the stations in outlying suburbs also become crowded at earlier periods corresponding to the respective commuting times into the city. Thus, one would expect time-based fluctuations of $\alpha_*(t)$ to vary greatly between the downtown region and the suburbs. Therefore, zones are classified into 3 areas based on accessibility to the city center using the dummy variable δ_i^p (defined as δ_i^1=1 ($T \le 2$), δ_i^2=1 ($2 < T \le 10$) and δ_i^3=1 ($10 < T$), $\delta_i^1+\delta_i^2+\delta_i^3$=1, using the time T (min) necessary to get from zone i to the Yamanote Line, a ring railway in central Tokyo):

$$y_{i*}(t) = \sum_p \delta_i^p \alpha_*^p(t)\beta_{i*}^p E_i + \sum_j \alpha_j(t)\beta_{ij}x_{ij} \ . \quad (9)$$

A descriptive model describing β_{i*}^p and β_{ij} are created using unknown parameters (b_{i*}^p, b_{ij}), which are unique to zone i.

$$\beta_{i*}^p = b_{i*}^p \ , \quad (10)$$

$$\beta_{ij} = b_{ij} \ . \quad (11)$$

A predictive model describing β_{i*}^p and β_{ij} is created using unknown parameters (b_{*k}^p, b_{*0}^p, b_{jk}, b_{j0}) and explanatory variable z_{ik}, which represents the mean time to the nearest station from buildings in zone i, variables about buildings normalized by dividing by the geographical area of zone i.

$$\beta_{i*}^p = \sum_k b_{*k}^p z_{ik} + b_{*o}^p \ , \quad (12)$$

$$\beta_{ij} = \sum_k b_{jk} z_{ik} + b_{jo} \ . \quad (13)$$

3. IMPLEMENTING THE MODEL

3.1 Pre-processing of Data

The PT data are in text form and not directly linked to the spatial data. Thus, they are address-matched in the GIS data, and the "*zones*", which are the spatial unit for aggregation in the PT data, are constructed in the GIS data. The source of the GIS data used here is *Tokyo City Planning Geographic Information System Data* conducted in the Tokyo Metropolitan area in 1996. The entirety of the Tokyo Metropolis is designated as the region for analysis. The transient occupants of the prefecture are extracted from the PT data for the total of 417 zones (see Figure 1) for each period of the day. Also, the floor area of buildings and number of buildings by size are extracted from the GIS data for each zone.

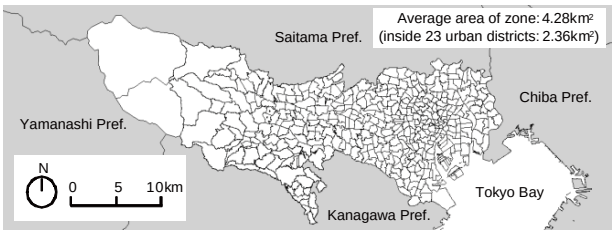

Figure 1 Study Area and Boundaries of Zones

3.2 Calibration of Descriptive Model

3.2.1 Method for estimating parameters of model

A descriptive model is estimated for each building type (14 types, including occupants outside buildings). Figure 2 shows the method for estimating parameters. Since the parameter $\gamma_{ij}(t)$ is divided into two parameters $\alpha_j(t)$ and b_{ij}, they are iteratively estimated by using multiple regression analysis as follows. First, (1) all the values of parameters $\alpha_j(t)$ and b_{ij} are set to 1. Next, (2) create an explanatory variable b_{ij} x_{ij}, and estimate the values of $a_j(t)$ by regression analysis so that the average value of $a_j(t)$ becomes 1. Next, (3) create an explanatory variable $a_j(t)$ x_{ij} using the estimated values of $a_j(t)$, and estimate the values of b_{ij} by regression analysis. Then, (4) check whether the estimated values of parameters $\alpha_j(t)$ and b_{ij} are converged. In case they are not enough converged, repeat the process from (2) to (4).

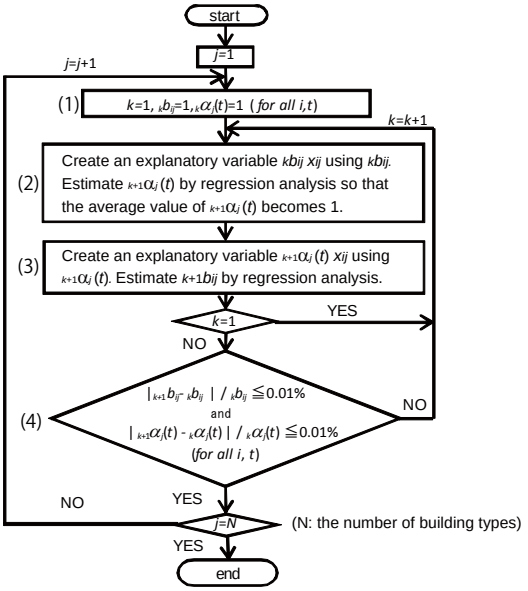

Figure 2 Method for estimating parameters

3.2.2 Model results and observations

Figure 3 shows the estimated values of time fluctuation factor $\alpha_j(t)$ for each building type (the temporal resolution is 1 hour). The fluctuations in $\alpha_j(t)$ vary according to the building types. For instance, the values of residences/ dormitories abruptly decrease between 7:00 and 9:00, and gradually increase from 18:00 to 24:00. I contrast, that of offices/companies/banks is vice versa. The values of other commercial facilities, which include restaurants, show a

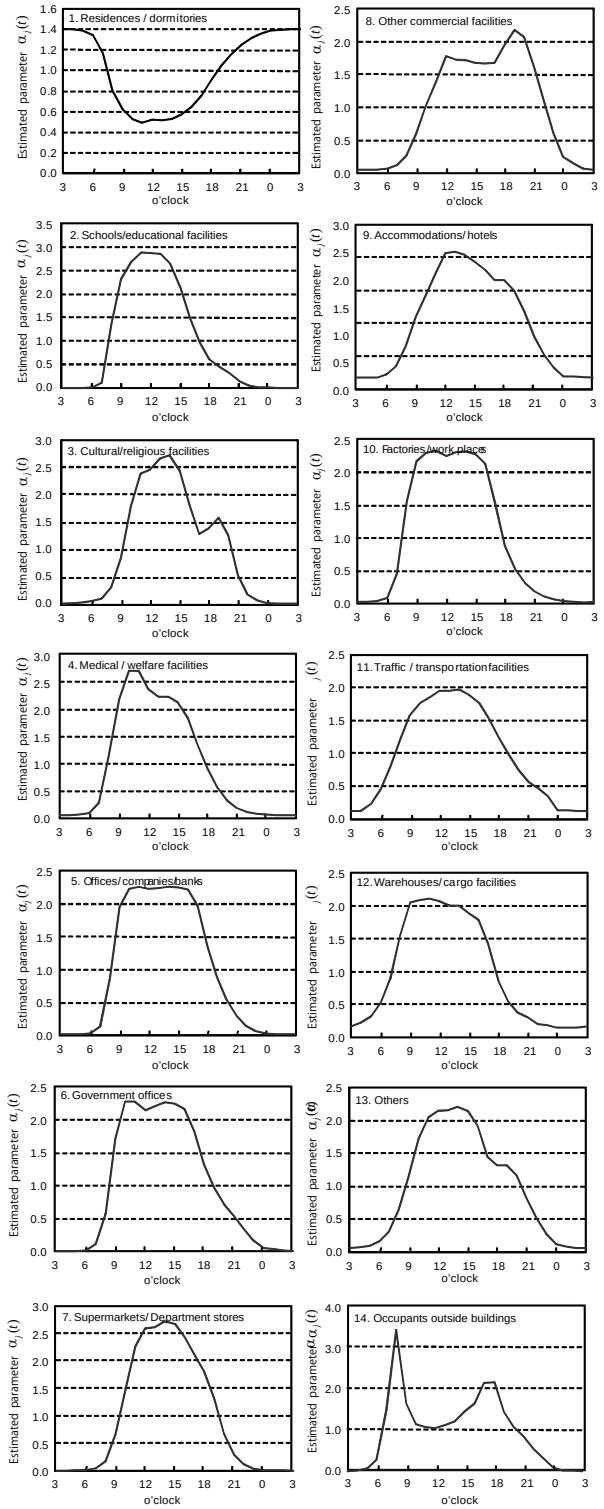

Figure 3 Estimated values of parameters *aj*(*t*)

peak around 19:00. The values of occupants outside buildings show two sharp peaks in the morning and evening, which indicate there are many commuters in the process of traveling to destinations. The values of accommodations/ hotels show only the number of employees and people using facilities (meeting rooms, restaurants, and so on). This is because PT data does not include the guests living outside the study area.

Figure 4 presents the spatiotemporal distributions of density of transient occupants, i.e., the value of $\gamma_{ij}(t)$ (= $\alpha_j(t)$ b_{ij}) for residences/dormitories and offices/companies/banks, which are typical buildings with large number of transient occupants. The time-dependent fluctuation of the transient occupants appears clearly. Some fluctuations of residences/dormitories are even greater in the environs. This indicates that the density of transient occupants is higher in the suburban area than in the city center. The number of individuals leaving these zones increases with time after the early morning, so the transient occupant density falls, as shown in the figure. Correspondingly, the figures for offices/companies/ banks show a low density at 8:00, with no marked difference between regions, but with the passage of time, the density of transient occupants becomes relatively high, especially in zones around Tokyo station. The results for residences/dormitories and for offices/companies/ banks show nearly opposite trends in their distributions, indicating movement between the two building types. The spatial movement between residences and offices is clearly visible here.

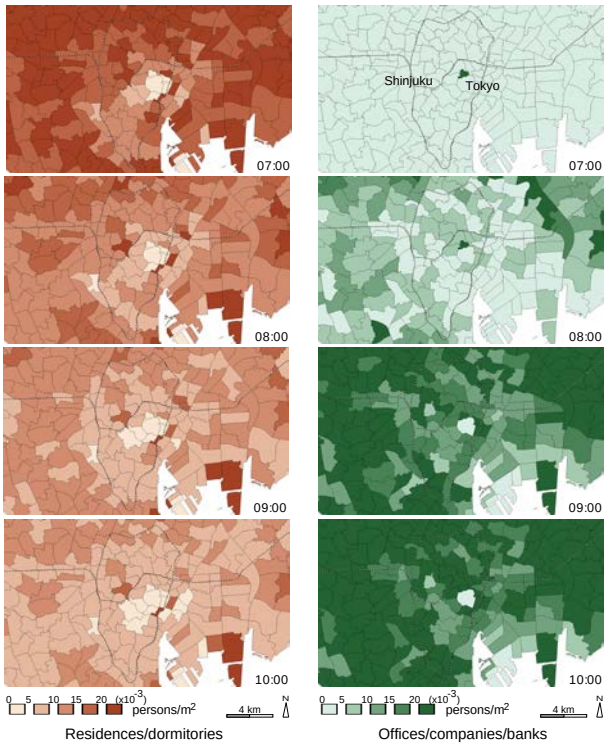

Figure 4 Spatiotemporal distribution of density of transient occupants

3.3 Calibration of Predictive Model

3.3.1 Method for estimating parameters of model

A predictive model is estimated for various types of buildings using building data (floor area, number of buildings of each scale) as explanatory variables describing location factors β_{ij}. However, a residual of the estimate is found along the railway lines, so variables expressing the

railroad service area of railway lines in each zone are incorporated to eliminate that influence.

The parameters are estimated using the method shown in Figure 2. The *t*-values of the parameters and the Akaike Information Criterion (AIC) are calculated in order to evaluate the balance among compatibility and conciseness of the model. The explanatory variables are extracted for every building type and examined to validate whether they are theoretically possible to be used. Table 1 presents the explanatory variables describing location factors, which are statistically significant; only the signs of the estimated parameters are given to simplify the presentation of their influences.

3.3.2 Model results and observations

Table 1 provides the explanatory variables for typical buildings with large numbers of transient occupants. For example, as for the model of residences/dormitories, the coefficient for the number of small-scale detached houses (-80m^2) is positive (+). This indicates that the greater the number of small-scale detached houses in a region, such as in a neighborhood of wooden houses, the greater the density of transient occupants.

Table 1. Variables used in predictive model and their estimated parameters

Objective variable (classification in PT data) The # of occupants	Explanatory variables (classification in GIS data)	
	Building floor area	Significant variables describing local factors and signs of the estimated parameters
Residences/ dormitories	Detached house/ flat/house with shop/house with factory	(+): Detached house(-80m^2), Access time to Yamanote Line, Mita-Tojo Line**, Keikyu-Tokaido Line**, Shinjuku-Ikebukuro Line**, Shinjuku Line** (-): Flat(5000m^2-), Shunjuku2-Sobu-Oshiage- Kameedo Line**, Hibiya-Ginza-Hanzomon Line**, Yamanote Line**
Schools/educational facilities	School	(+):School(400m^2-), Supermarket/Department store(320m^2-) (-): School(-70m^2)
Offices/ companies/banks	Office	(+):Hibiya Line**, Ginza Line** (-): Office(650m^2-), Government office(-80m^2), Time to the nearest station, Oedo Line**
Supermarkets/ Department stores	Supermarket / Department store	(+):Recreational facility*, Detached house(-80m^2) (-):Time to the nearest station
Occupants outside buildings	the # of Passengers	(+):House with shops*, Recreational facility(460m^2-) (-):
	Detached house/ flat/house with shop or factory	(+):Recreational facility(460m^2-), School(400m^2-) (-):
	Office	(+):Hospital(-65m^2) (-): Time to the nearest station

Note: [*] indicates building floor area, [**] indicates dummy variable of railway services area, and variable with the size of floor area indicates the number of buildings in each zone. The sign of the estimated parameter is shown by (+) or (-).

4. VALIDATION OF MODELS

Figures 5 and 6 provide the accuracies of some of the predictions (relationship between actual measurements and model-predicted transient occupants in each zone) of the descriptive model and the predictive model. The results of the descriptive models are markedly consistent with actual measurement (value of PT data). This fact indicates that once we can accurately describe the location factor of each zone, we can obtain extremely precise estimates of the dramatic time-based fluctuations in the number of transient occupants in a city, simply by knowing the floor area of buildings. The results of the predictive model are not as precise as those of the descriptive model. Still, this model shows good accuracy for a simple regressive model.

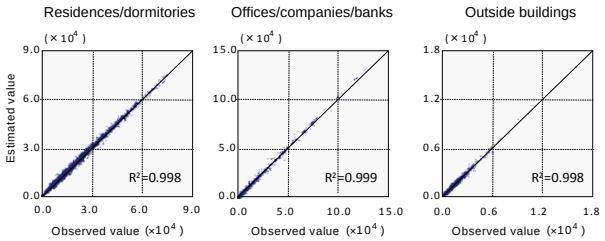

Figure 5 Compatibility of descriptive models

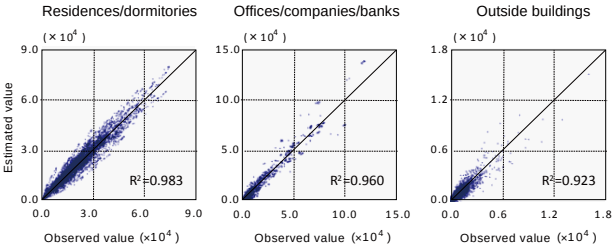

Figure 6 Compatibility of predictive models

Figure 7 shows some results of changes of the mean absolute error and error ratio of the predictive model over time for each building type. In building types prone to higher numbers of transient occupants, such as residences/ dormitories and offices/companies/banks, the mean absolute error is not small enough, but the error ratio is around 0.1. From the viewpoint of the error ratio to the total number of transient occupants, the results show good accuracy in whole day. Buildings with extremely low numbers of transient occupants from the middle of the night to the early morning hours (cultural facilities, etc.) show high error ratios, that is, inferior estimation accuracy. However, the zone totals, comprised of the occupancies of all building types, showed good accuracy in estimates of transient occupant population.

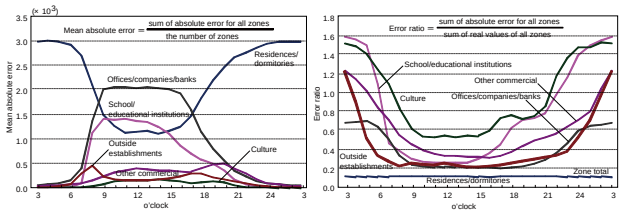

Figure 7 Estimation error of predictive model according to time

5. SUMMARY AND CONCLUSIONS

Models were constructed to estimate the spatiotemporal distribution of transient occupants of the Tokyo Metropolitan area, specific to each type of building in the region, based on information on the scale, type and location features available for buildings in digital maps that have recently become available. These models were successful in visualizing the spatiotemporal fluctuations in transient occupant population while selecting the size of spatial unit by evaluating the estimation error. Future studies by the present authors will examine applications of these models for simulating wide-area rescue activities following a devastating earthquake, behavior of commuters returning home from their offices/ schools on foot, and other topics (Osaragi and Tanaka, 2011).

In order to construct a simulation model for evacuation-efforts following a severe earthquake, we should consider not only the spatiotemporal distribution of occupants remaining in the city, but also of transient occupants, i.e., people who are walking or otherwise in the process of using transportation in the city (Osaragi, 2009; Osaragi and Shimada, 2009). The importance of these kinds of studies lies in its implications for quick emergency response and recovery. For instance, congested streets would impede people from arriving at medical centers or emergency activities, such as firefighting and rescue of persons. In addition, under extreme pedestrian congestion, they might be injured or even accidentally crushed. In the case of a secondary earthquake, the vicinities of large-scale stations already congested with pedestrians, could lead to serious confusion. Hence, we need to consider micro-scale pedestrian flow under such extreme scenarios by using the spatiotemporal database provided in the present study in order to establish emergency and evacuation planning.

The models proposed in the present study were created to offer basic data for a variety of analyses of urban areas, of which disaster mitigation planning is just one example. As Aubrecht et al. (2011) suggested, high-detail spatiotemporal distribution on human activities can be of great value in disaster risk management and simulation, but also in regional and environmental planning as well as geomarketing analysis.

GROUND-MOTION-INDUCED DAMAGE OF BRIDGES DURING THE 2011 GREAT EAST JAPAN EARTHQUAKE

Kazuhiko Kawashima

Professor, Department of Civil Engineering, Tokyo Institute of Technology, Japan
kawashima@kba.biglobe.ne.jp

Abstract: This paper presents damage of bridges during the 2011 Great East Japan earthquake. Effectiveness of recent development of seismic design and implementation of seismic retrofit is evaluated based on comparison of the damage during the 2011 Great East Japan earthquake and the 1978 Miyagi-ken-oki earthquake.

1. INTRODUCTION

The Great East Japan earthquake (M_w9.0) occurred on March 11, 2011 along the Japan Trough in the Pacific Ocean. This was the largest earthquake which ever historically occurred around Japan. The fault zone extended 450km and 200km in the north-south and west-east directions, respectively, as shown in Fig. 1. Extensive damage occurred in a wide region in the east Japan.

A number of strong motion accelerations were recorded in the damaged areas by the National Institute of Earth Science and Disaster Prevention (NIED) and Japan Meteorological Agency (JMA). Most accelerations were recorded at stiff sites as it was the purpose of NIED and JMA to record base-rock accelerations. Fig. 2 shows typical acceleration records along the Pacific Coast. Ground accelerations continued over 200s, and they had at least two wave groups reflecting the fault rupture process. The highest peak ground acceleration of 27.0 m/s^2 was recorded at Tsukidate City. However the high acceleration was resulted from a single pulse with 0.2 second period, therefore response acceleration at 1.0s was only 5.1m/s^2. Consequently damage of bridges and buildings was very minor in Tsukidate City. This clearly shows that only PGA cannot be a reliable index for seismic design.

At soft soil sites in the north Miyagi-ken and south Iwate-ken (refer to Fig. 1), ground accelerations included longer period components leading to higher response accelerations at 0.5-1.5s. For example, response acceleration was over 16 m/s^2 at 0.8 s in Osaki as shown in Fig. 3.

Seismic design code of bridges was extensively enhanced since 1990 (JRA 1990, 1995, 1996, 2002, 2012, Kawashima and Unjoh 1997, Kawashima 2006). Only a combination of the static elastic analysis assuming 0.2-0.3 seismic coefficient and the allowable stress design approach (seismic coefficient method) was used until 1990 (JRA 1964, 1971, 1980). The static elastic method is still in use today but a combination of the inelastic static analysis and the Type I and II design ground motions as shown in Fig. 4 has been the main stream approach in the post-1990 codes. Thus the seismic demand was much enhanced in the post-1990 design codes.

Type I design ground motion represents the ground motions which are induced by an M8 subduction earthquake while Type II design ground motion represents near-field ground motions which are induced by a M7 earthquake. Deterministic ground motions are used in Japan since probabilistic ground motions assuming Poisson's distribution underestimates ground motions when a target earthquake occurs. Zoning coefficient c_z is multiplied to get design ground motion. Zoning map (very high, high, and moderate seismic zones) depends on a probabilistic hazard map, however conservative values are assigned to moderate seismic zone (c_z=0.7) compared to very high seismic zone (c_z=1.0) since seismological information available now is incomplete. Conservative zoning coefficient ($c_Z \geq 0.7$) was very effective to avoid underestimation of design ground motions due to unknown faults in past earthquakes.

Elastic and inelastic dynamic response analyses have been conducted on routine basis for bridges with complex structural response since 1995. Seismic isolation has been implemented since the early 1990s (TRCNLD 1988, PWRI 1992, PWRI 2011, Unjoh et al 2010). This led to extensive implementation of elastomeric bearings, including lead rubber bearings and high damping rubber bearings.

Since the 1980s, over 30,000 reinforced concrete columns in existing bridges with mid-height cutoff of longitudinal steel and insufficient development length have been seismically retrofitted (JRA 1988, 2002).

It is important to note that a number of bridges in a part of the region affected by the 2011 Great East Japan Earthquake (north Miyagi-ken and south Iwate-ken, refer to Fig. 1) suffered extensive damage during the M7.4 1978 Miyagi-ken-oki earthquake (EERI 1978). The 1978 Miyagi-ken-oki earthquake occurred off Sendai. The epicenter was 38.2 N and 142.2 E, and the fault extended 30 km and 80 km in NS and EW directions as shown in Fig. 1. Fig. 5 compares 5% damped response accelerations of records near Kaihoku Bridge in Ishinomaki City during the 1978 Miyagi-ken-oki earthquake and the 2011 Great East Japan earthquake. Since the accelerations were recorded on the surface of shallow soil underlaid by soft rock, the acceleration responses are high at 0.2-0.5s with sharp decrease of response acceleration over

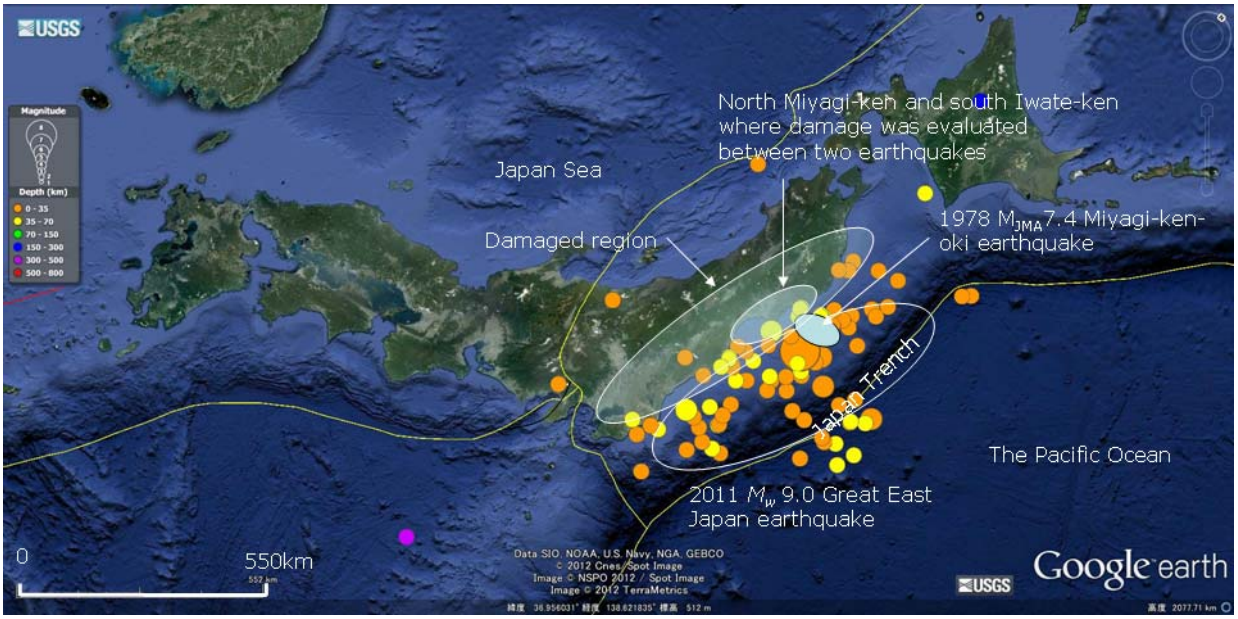

Figure 1 Fault zone of 2011 Great East Japan earthquake, damaged region, and north Miyagi-ken and south Iwate-ken where damage was compared with that from the 1978 Miyagi-ken-oki earthquake

0.5s. Since the ground acceleration near Kaihoku Bridge was one of the few records during the 1978 Miyagi-ken-oki earthquake, the record has been widely used in dynamic response analyses as a typical strong ground acceleration. Thus comparison of records between the two earthquakes is shown here at this site. It is seen that intensity of ground accelerations in terms of response accelerations during the 2011 Great East Japan earthquake was slightly larger than or in the similar level with the one during the 1978 Miyagi-ken-oki earthquake. Note that response accelerations were much larger at 1-2s at soft soil sites than the value shown in Fig. 5. Response accelerations at high intensity areas during the 2011 Great East Japan earthquake were close to but smaller than the Type II design ground motions.

Thus, the 2011 earthquake was a valuable opportunity to evaluate the effectiveness of recent developments of the seismic design codes by comparing damage sustained in the two earthquakes. Comparison was made for damage at north Miyagi-ken and south Iwate-ken where extensive damage occurred during the 1978 Miyagi-ken-oki earthquake (refer to Fig. 1). Damage is described for three bridge categories: (1) bridges designed based on pre-1990 design codes (JRA 1964, 1971, 1980 codes), (2) the first category bridges which had been retrofitted based on post-1990 code (JRA 1990, 1995, 1996, 2002 codes) prior to the 2011 Great east Japan earthquake, and (3) bridges designed based on post-1990 design codes.

In addition to ground shaking induced damage, damage due to tsunami inundation occurred extensively (JSCE 2011, Kawashima et al 2011). However it is not presented in this paper.

2. DAMAGE STATISTICS

Table 1 shows number of national road bridges control by Tohoku Regional Bureau, Ministry of Land, Infrastructure, Transport and Tourism (JSCE 2012, NILIM & PWRI 2011). There were 1,909 bridges consisting of 1,157 bridges on main routes, 415 pedestrian bridges along main routes, and 337 bridges over main routes. Of the 1,909 bridges, 867 bridges (45%) were undamaged, 885 bridges (46%) were damaged by ground shaking, and 154 bridges (8%) were damaged by tsunami. Although it was easily identified that drag of spans, lean of handrails, erosion of abutment backfills and scouring of foundations were developed by tsunami, it was difficult to identify whether cracks of piers and abutments were developed by ground shaking or tsunami. Therefore damage of bridges which were submerged by tsunami at least deck level was counted as damage by tsunami. It should be noted that there was no bridges which collapsed due to ground shaking, while 12 bridges collapsed due to tsunami.

Table 2 classifies deterioration degree of structural performance and serviceability for traffic of 1,572 national road bridges (1,157 bridges on main routes and 415 pedestrian bridges) shown in Table 1. The damage degree and serviceability for traffic were evaluated in accordance with the standard procedure of Guide Specifications for Earthquake Countermeasures - Post Earthquake Countermeasures (JRA 1988, 2008). There were 12 bridges and 13 bridges which were evaluated as A_S rank (collapse or extensive deterioration) and A rank (major damage), respectively, and 29 bridges were completely interrupted for traffic.

Table 1 Number of national road bridges inspected and damaged (JSCE 2012)

Type of bridges	No. of bridges inspected	No. of bridges which could not be inspected	No. of bridges undamaged	No. of bridges damaged by ground shaking	No. of bridges submerged by tsunami
Main bridges	1,157	0	445	619	93
Side pedestrian bridges	415	0	167	190	58
Bridges over main routes	337	3	255	76	3
Total	1,909	3	867	885	154

Table 2: Degree of deterioration of structural damage and serviceability of 1,572 national road bridges (JSCE 2012)

(a) Structural deterioration degree

Damage degree	No. of bridges
A_S: Collapse or extensive deterioration	12 (0.7%)
A: Major damage	13 (0.8%)
B: moderate damage	32 (2.0%)
C: Minor damage	103 (6.6%)
D: No damage	1,412 (89.8%)
Total	1,572 (100%)

(b) Serviceability deterioration

Serviceability	No. of bridges
A: Interrupted	29 (1.8%)
B: Traffic is possible with care	433 (27.5%)
C: No effect	1,110 (70.%)
Total	1,572 (100%)

Table 3: Damage modes of 1,572 national road bridges (JSCE 2012)

Locations	Types of damage	No. of Damage Modes
Overall bridge	Collapse, Offset of superstructures	27 (1.6%)
Superstructures	Cracks and deformation of superstructures	88 (5.1%)
Pavements	Cracks	93 (5.4%)
Expansion joints	Cracks, opening and closure, settlement	173 (10.0%)
Handrail	Lean of handrails by tsunami	149 (8.7%)
Bearings	Failure of bearings and concrete seats	147 (8.6%)
Bearing support	Failure of cap beams under bearings	60 (3.5%)
Unseating prevention devices	Failure of anchor bars or connections	32 (1.9%)
Abutment wall and parapet walls	Cracks or spalling of cover concrete	126 (7.3%)
Side wall of abutments	Cracks or spalling of cover concrete	73 (4.3%)
Backfill of abutments	Settlement	659 (38.4%)
Piers and columns	Cracks or spalling of cover concrete	42 (2.4%)
Scouring of foundations	Scouring due to tsunami	46 (2.7%)
Total		1,715 (100.0%)

Table 3 shows damage modes of 1,572 national road bridges. As there were bridges which suffered more than one mode of damage, the total number of damage mode is over 1,572. Twenty seven bridges collapsed or their spans offset extensively. Common damage mode was settlement of abutment backfills, cracks and spalling of abutment concrete walls, damage of bearings and their supports, and opening and closure of expansion joints. Note that those damage modes are related to permanent tilting of abutments and piers. In particular, as abutments are subjected to dynamic earth pressure from backfill side to bridge side, it often tilts toward bridge side. Lean of handrails and scouring of foundations were developed by tsunami. However no bridges collapsed due to scouring.

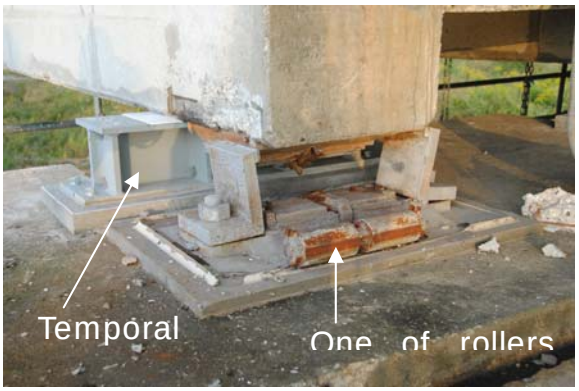
3. PERFORMANCE OF BRIDGES CONSTRUCTED IN ACCORDANCE WITH PRE-1990 CODES

Extensive damage occurred at the bridges which were designed in accordance with pre-1990 design codes and the bridges which had not yet been retrofitted. For example, Fig. 6 shows flexural-shear failure of reinforced concrete piers at Fuji Bridge and Esaki Bridge. The damage was resulted from an overestimated shear capacity and an inadequate development of longitudinal bars at cut-off (Kawashima, Unjoh and Hoshikuma 1995). It was the mandate practice prior to the pre-1980 design codes. This mode of damage occurred extensively during the 1995 Kobe, Japan earthquake (Kawashima and Unjoh 1997). Extensive investigation

(a) Fuji Bridge

(b) Esaki Bridge

Figure 6 Flexure-shear failure of columns due to termination of longitudinal bars with insufficient development (NLIM & PWRI 2011)



was directed to clarify the failure mechanism of such damage, including a series of large scale shake table experiments using E-Defense (Kawashima et al 2011). It should be noted that damage progresses shortly once shear cracks were initiated under this failure mechanism. Seismic retrofit was initiated in the 1980s (Akiyama, Nakajima and Kogure 1990), and it was accelerated after the 1995 Kobe earthquake. Consequently, during the 2011 Great East Japan earthquake, damage due to this mechanism did not occur at the bridges which had been retrofitted.

Figure 7 Yuriage Bridge

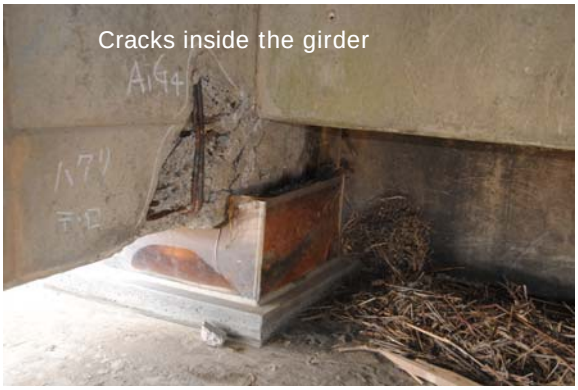
(a) 1978 Miyagi-ken-oki earthquake

(b) 2011 Great East Japan earthquake

Figure 8: Damage of steel roller and pin bearings, Yuriage Bridge

Yuriage Bridge (refer to Fig. 7) suffered extensive damage at reinforced concrete hollow and solid columns, an end of PC concrete girders, and steel pin and roller bearings during the 1978 Miyagi-ken-oki earthquake. Since the damaged columns were repaired and retrofitted by reinforced concrete jacketing, they did not suffer damage again. However steel pin and roller bearings suffered extensive damage again in the similar mode as shown in Fig. 8. It is obvious that steel pin and roller bearings are vulnerable to seismic action, because the stress builds up to failure at a pin bearing, and relative displacement accommodated by a roller bearing is generally only ± 100-200 mm which is much smaller than displacement demand under a strong excitation.

Furthermore, exactly the same end of a PC concrete girder which suffered damage during the 1978 Miyagi-ken-oki earthquake suffered again as shown in Fig. 9. It was a critical zone due to concentration of the seismic force, the dead load reaction and the PC anchor force.



Tennoh Bridge (refer to Fig. 10) built in 1959 suffered extensive damage during the 1978 Miyagi-ken-oki earthquake, and the bridge suffered extensive damage again during the 2011 Great East Japan earthquake at the same members. Fig. 11 (a) an (b) shows failure of a fixed steel bearing and its support during the 1978 Miyagi-ken-oki earthquake. Since detection of the bearing failure under a span was difficult after the earthquake, there was a high risk that this bridge

(a) 1978 Miyagi-ken-oki earthquake

(b) 2011 Great East Japan earthquake

(c) Cracks inside the PC girder

Fig. 9 Damage of a PC girder at the end support, Yuriage Bridge

collapsed due to this damage if a strong aftershock had occurred. Extensive damage of steel bearings occurred again during the 2011 Great east Japan earthquake as shown in Fig. 11(c). Steel bearings are vulnerable because stress builds up to failure in a fixed bearing and relative displacement accommodated by a movable bearing is smaller than displacement demand.

Fig. 12(a) and (b) shows rupture and local buckling of upper and

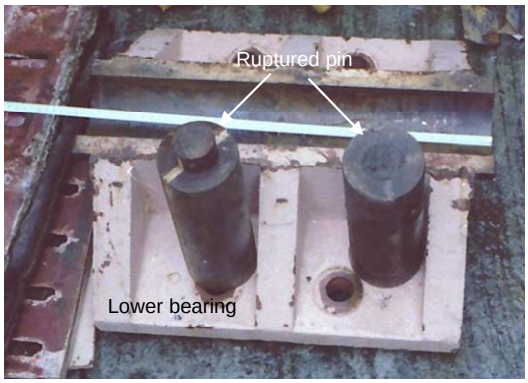
lower braces. Connection of a lower brace to a girder web plate and a diaphragm by a gusset plates was deteriorated due to corrosion of rivets and a gusset plate as shown in Fig. 12(c). Since similar disconnection occurred at several lower braces, it is considered that a large torsion response of the truss bridge occurred due to deterioration of torsional rigidity, and this resulted in extensive rupture and buckling of upper braces. This truss bridge was about to collapse during the earthquake.

(a) Damage of a RC pier during the 1978 Miyagi-ken-oki earthquake

(b) Retrofitted pier did not suffer damage during the 2011 Great East Japan Earthquake

Figure 13 Effect of retrofit, Sendai Bridge



4. PERFORMANCE OF BRIDGES WHICH HAD BEEN RETROFITTED

Damage of bridges which had been retrofitted suffered virtually no damage during the 2011 Great East Japan earthquake. For example, Sendai Bridge which is an extremely important bridge in Sendai City suffered extensive damage at reinforced concrete piers during the 1978 Miyagi-ken-oki earthquake as shown in Fig. 13(a). After the earthquake, the piers were repaired by RC jacket and further retrofitted by fiber reinforced plastic sheet wrapping as shown in Fig. 13(b). Steel bearings were replaced with elastomeric bearings. Consequently the bridge suffered no damage during the 2011 Great East Japan earthquake.

Shin-Iino-Gawa Bridge (refer to Fig. 14) which carries National Road 45 over Kitakami River suffered extensive damage at steel pin and roller bearings as shown in Fig. 15(a) and (b) during the 1978 Miyagi-ken-oki earthquake. The bridge was retrofitted prior to the 2011 Great East Japan earthquake such that 1) several reinforced concrete piers were retrofitted by steel jacketing (refer to Fig. 14), 2) steel bearings were replaced with elastomeric beatings as shown in Fig. 15(c), and 3) nonlinear viscous dampers were installed between a superstructure and a substructure as shown in Fig. 16. As

(c) 2011 Great east Japan Earthquake

Figure 15 Effectiveness of replacement of steel bearings with elastomeric bearings

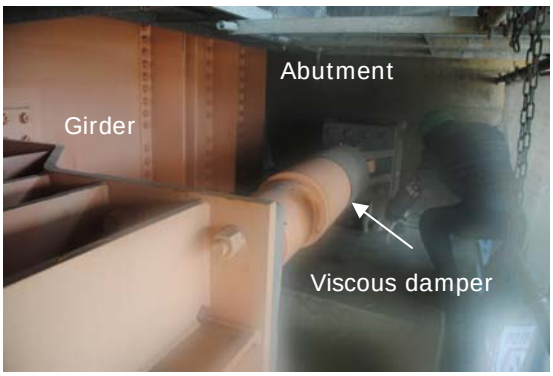

Figure 16 Viscous damper installed as a part of seismic retrofit

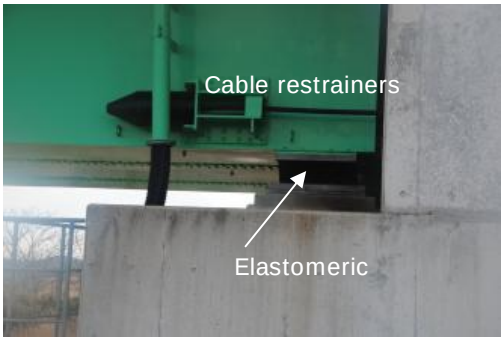
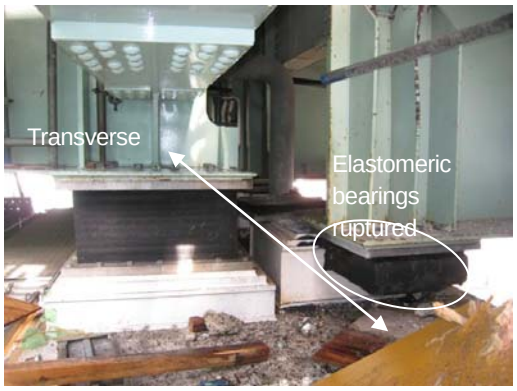


a result, the bridge suffered no damage during the 2011 Great East Japan earthquake.

5. PERFORMANCE OF BRIDGES CONSTRUCTED IN ACCORDANCE WITH THE POST-1990 CODES

Bridges which were designed in accordance with the post-1990 codes suffered essentially no damage during the Great East Japan earthquake. For example, Fig. 17 shows Shin-Tennoh Bridge. The bridge was constructed in 2002 at only 200 m upstream of Tennoh Bridge which suffered extensive damage during the Great East Japan earthquake (refer to Figs. 10-12). Elastomeric bearings and new cable restrainers which satisfy the requirements of the post-1990 design code were set. Shin-Tennoh Bridge suffered no damage.

(a) Spans and columns without damage



(b) Elastomeric bearings and cable restrainers

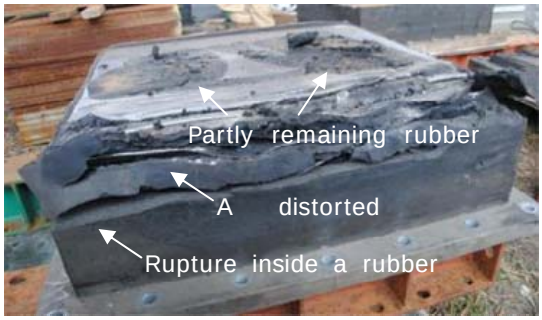


Figure 17 Shin-Tennoh Bridge

(a) Elastomeric bearings which supported the right span ruptured

(b) Rupture of elastomeric bearings

(c) Failure of an elastomeric bearing

(c) drift and settlement of deck

Figure 18 Damage of Sendai-Tobu Viaduct

Since elastomeric bearings are flexible allowing to absorb relative displacement between superstructures and substructures, elastomeric bearings generally performed quite well under the extreme ground motions during 2011 Great East Japan earthquake. However it should be noticed that even elastomeric bearings ruptured in some bridges. For example, elastomeric bearings ruptured at several locations in Sendai-Tobu Viaduct. For example, a deck offset by 0.5m in the transverse direction as shown in Fig. 18(a). Not only rupture occurred inside rubbers layers but also rubber layers were detached from steel shim plates as shown in Fig. 18(b). It is considered that deformation over capacity was developed in the damage bearings.

6. CONCLUSIONS

Ground-motion-induced damage of bridges during the 2011 Great East Japan earthquake was presented. Effectiveness of recent development of seismic design and implementation of seismic retrofit was evaluated based on comparison of the damage developed during the 1978 Miyagi-ken-oki earthquake. Based on the results presented herein, the following conclusions may be deduced:

1) Ground-motion-induced damage of bridges which were built in accordance with the post-1990 design code was very limited during the 2011 Great East Japan earthquake. It was extensively effective for mitigating damage of bridges during the 2011 Great East Japan earthquake to have enhanced the shear and flexural capacity as well as ductility capacity of piers and implemented elastomeric bearings and strengthened unseating prevention devices.

2) Bridges which were built in accordance with the pre-1990 codes and bridges which had not yet been retrofitted suffered extensive damage in a similar mode to the damage which was developed during the 1978 Miyagi-ken-oki earthquake. Prompt and appropriate seismic retrofit is required for those bridges.

morika@enveng.titech.ac.jp

Abstract: Historical Churches in Armenia may have many experiences of earthquake ground motion. Thus, some of them have been damaged partially or severely. We had carried out the microtremor survey at two historical churches, which are Hripsime Church constructed around 7th century and Cathedral at Etchimiadzin around 5th century, to identify the dynamic characteristic. Four sensors are used simultaneously for the observations and vibration modes are estimated from the Fourier amplitudes.

1. INTRODUCTION

Armenia is located at middle between Black Sea and Caspian Sea and in a high seismicity area. The Turkish Anatolian fault, which is a most active fault in the world, reaches to Armenia. Armenia, thus, have experienced often destructive damage by large earthquakes such as 1988 Spitak earthquake. On the other hand, many historical structures, whose ages are more than 1000 years, are still remaining in the country and they face the risk of collapse or severe damage by future earthquakes (eg., Strzygowski, 1918; Cuneo, 1988). It is important for us to forward such the historical structures to next generation without any damage.

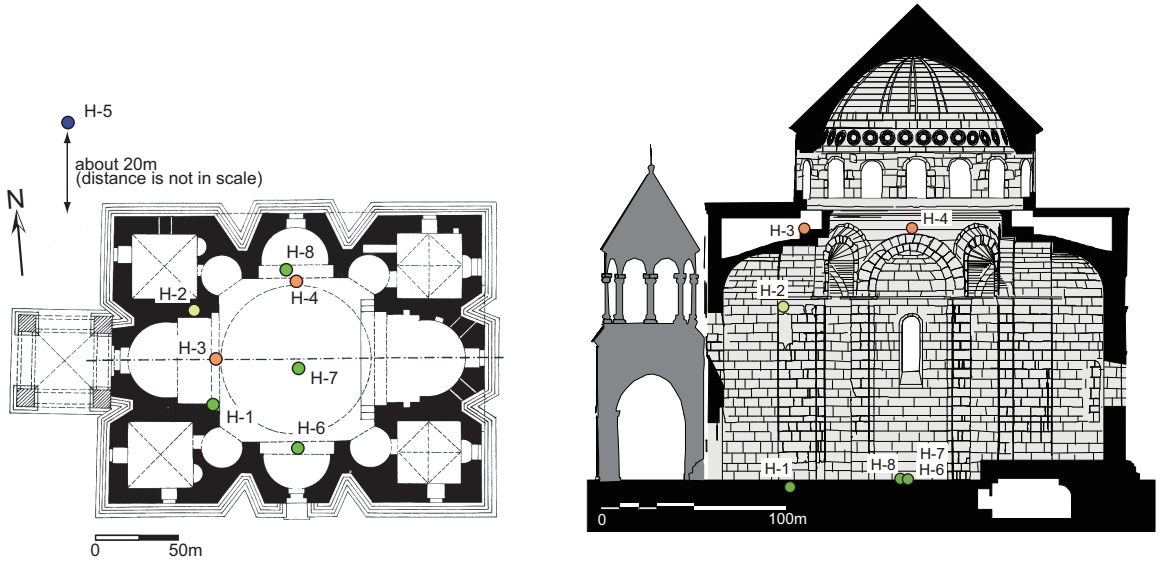
For this propose, a "health diagnosis" of structure is required using a non-destructive technique. Our ultimate goal is to estimate its static and/or dynamic performance through detailed numerical analysis after modelling a target structure numerically. For this kind of approach, it is very important to construct an appropriate model of the structure. This means that dynamic characteristics have to be accurately determined for the structure on the basis of some measured data. To know the dynamic behavior of the structure, microtremor survey is one of useful techniques, because microtremors are generated by natural and/or artificial sources such as sea waves, human activities etc. From the properties of the microtremors, it can be treated as stationary processes though their amplitude is quite small. We have carried out simultaneous measurements of microtremors at some different points in the target structure.

The microtremor survey must be suitable for this situation, because we can measure anytime and anywhere and just put the sensors on the structure without any destruction. Furthermore, the dynamic behaviour of the structure can be obtained directly from the data (eg. Motoki and Seo, 2009). On the other hand, it is very difficult to estimate the non-linear characteristics of the structure because of too small amplitude of microtremors, though its dynamic characteristics may be expected during large earthquake ground motion. However, at least, we can obtain the linear characteristics as most basic parameters for dynamic behaviour.

Preliminary results are shown for the dynamic characteristics of two historical churches in Armenia.

2. OBSERVATIONS

Structures of our target are Hripsime Church and Cathedral at Etchimiadzin, whose main parts were constructed from 5th to 7th century, however, many parts may be reconstructed as needed until now. The detailed history of their reconstruction and renovations are not clear.



For the microtremor observations, we used moving-coil-type velocity sensors and digital data loggers.

The data logger includes amplifier with 256-time gain, anti-alias filter with about 35 Hz cut-off and a client software of NTP (network time protocol) to synchronize NTP server. The logger can digitize analog data with 200 samples per second and 24-bit resolutions. The digitized data are sent to local host computer via network and also stored in the SD card on the system board.

The error of time synchronization to NTP server is less than 3 ms when the system is activating more than one hour, and less than 500 μs when more than three hours. This logger can also record internal circuit noise simultaneously, thus the signal-to-noise ratio (S/N) can be ex-

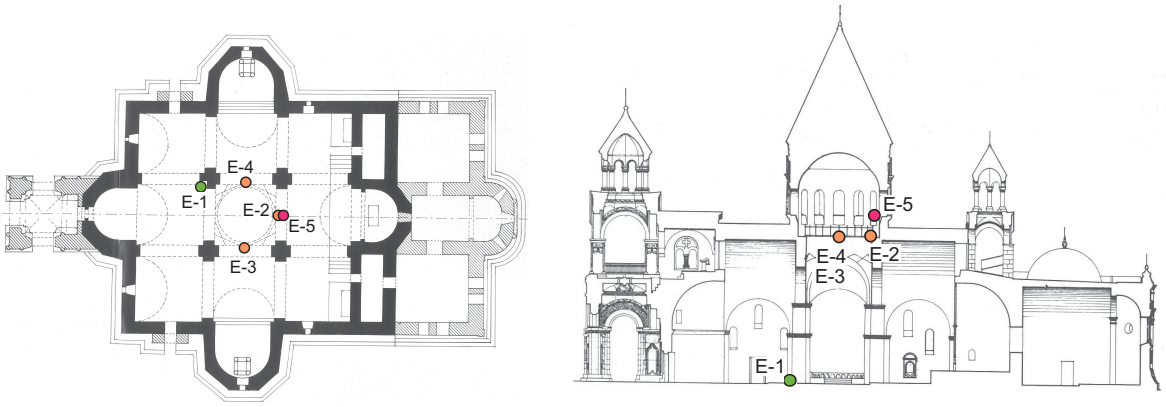
(a) Plan (b) E-W Section

Figure 1 Plan and section of Hripsime Church and sensor locations for the microtremor observation.

tended at least 6dB in frequency range lower than 1Hz.

Natural period of the velocity sensor is about 0.5 s and one chassis includes three components: two orthogonal horizontal and one vertical components.



For the observation, four sets of one sensor and one logger are used simultaneously. A laptop computer is also used as a NTP server to deliver time information to four loggers, and NTP server is synchronized to PPS (pulse per second) signal from GPS (global positioning system) receiver. Before the observation of microtremors for structures, we have observed two signals: one is step responses of each sensor to determine the natural period and damping factor at the site, and the other is total noise of observation system using dummy resistance with same value as coil resistance of sensor, instead of sensor.

Observations were carried out as listed in Table 1 and locations of the sensors for each observation are shown in Figs.1 and 2. The observation systems and sensor settings for observation #1 are shown in Fig.3. Observation #2 was huddle test, which were carried out outside of the church, to compare the responses of sensors.

3. ANALYSIS AND PRELIMINARY RESULTS

3.1 Huddle Test

The instrumental correction are performed for all the data. For this, the record of step responses are used. The step responses are recorded at least 10 times at the site. Optimum values of natural period, T_0, and dumping factor, h, are searched for each observation and sensor, using theoretical shape of step response function for one-degree-

(a) Plan (b) Section

Figure 2 Plan and section of Cathedral at Etchimiadzin and sensor locations for the microtremor observation.

(a) Data loggers and laptop computers: one controls data loggers and other works as an NTP server synchronizing GPS signal.

(b) Sensor at H-1. The sensor is set the basement of column. A small box at left of sensor is dummy resistance for noise measurement.

(c) Sensor at H-3. The sensor is set on a corridor of the drum. Signal cable is connected to the dummy resistance.

Figure 3 Setting of the observation system at Hripsime Church (Observation #1).

(a) Site for huddle test (b) Systems

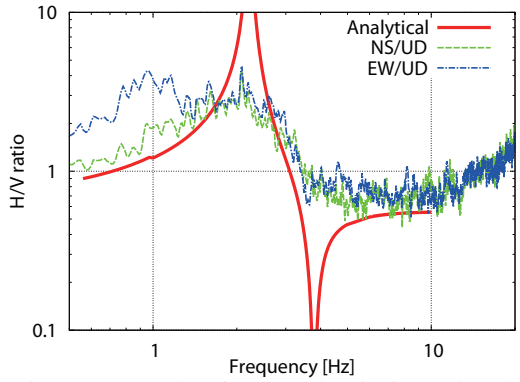
Figure 4 Observation #2 (huddle test).

of-freedom system. Specific T_0 and h for each observation are applied to the instrumental correction and the correction is carried out in the frequency range between 0.05 and 4 seconds.

For the analysis, we apply the Fourier transform to obtain the Fourier amplitudes. 81-second portions are picked up from the data and Fourier amplitudes are calculated, smoothed by Hanning window, and averaged over whole the portions.

To confirm differences of the sensor responses among sensors, we have carried out the huddle test, which is #2 of Table 1. The sensors, thus, are set closely each other as shown in Fig.4. From this test, it is confirmed that the differences among sensor responses can be negligible.

The site for huddle test is outside of Hripsime Church.



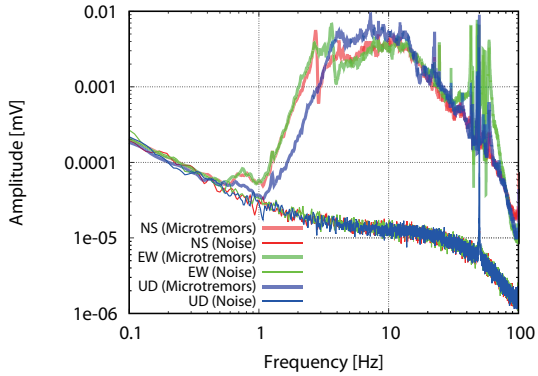


Figure 5 H/V spectral ratio around Hripsime Church and analytical elasticity of Rayleigh wave.

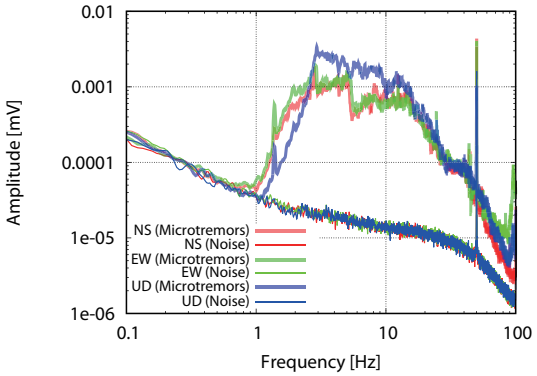

Table 2 An example of velocity structure

Thickness [m]	Density [t/m^3]	V_S [km/s]	V_P [km/s]
48	1.8	0.38	1.9
∞	2.1	1.3	2.5

Thus, we can calculate horizontal-to-vertical (H/V) spectral ratio to estimate the ground structure around Hripsime Church as shown in Fig.5. The shapes of NS/UD and EW/UD are slightly different around 1 Hz, though a peak

(a) Hripsime Church (H-1)

(b) Cathedral at Etchimiadzin (E-1)

Figure 6 Examples of signal and noise level during observation.

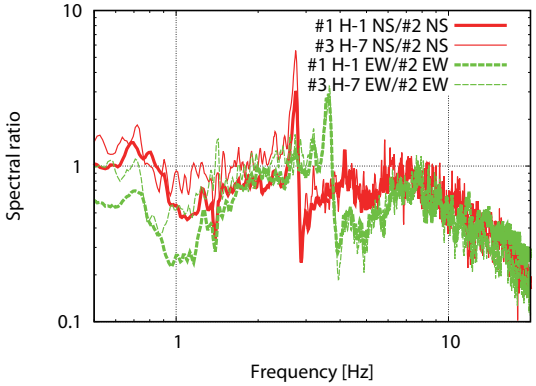

Figure 7 Spectral ratio between ground level (#1 and #3) of the church and outside (#2).

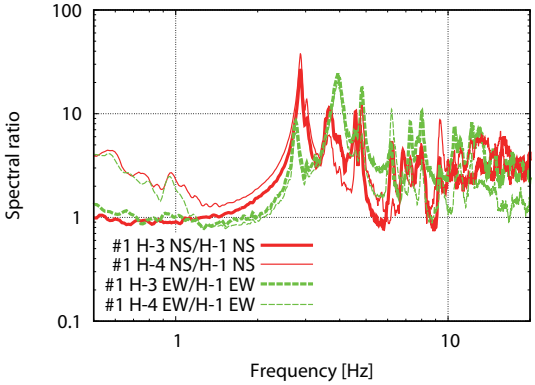

Figure 8 Spectral ratio between corridor of drum (H-3 and H-4) and ground level (H-1) from #1.

is found around 2 Hz. Since the phase velocity is not available because of no array observation, it is difficult to find appropriate velocity model. Table 2 is a very simple example of velocity structure with two layers to explain the observed H/V spectral ratio. We just consider the peak around 2 Hz to fit the analytical ellipticity of Rayleigh wave.

3.2 Signal and Noise Level

The power of microtremors are generally very small and the ground condition at the target site seems to be good. Thus, the noise level of observation system is very important. The data logger can observe simultaneously the circuit noise and remove it as post-processing. However, we had to use very long signal cables to connect between sensors and loggers because of the situation of the church. Furthermore, the moving-coil-type velocity sensor is very high impedance system. This means that the long signal cables can be a good antenna of noise and signal must be contaminated by noise.

To observe the signal and noise level, we record data using dummy resistance instead of sensor. The value of resistance is same as coil resistance of sensor. The dummy resistance can be found in Fig.3. Fig.6 shows the Fourier amplitudes of the signal and noise. The signal without any instrumental correction and noise are compared in observed voltage. Sharp peak is shown at 50 Hz, which is hum noise caused by electric power supply and noise less than 10 Hz shows a typical feature of 1/f noise.

Since the natural period of sensor is 0.5 second (2 Hz), the response sensitivity is decreased less than 2 Hz. In general, the microtremor level is very small around 1 Hz, thus, the signal level becomes lower than noise level. However, the frequency range higher than 1 Hz can recognize the signal. From this, we discuss the frequency range between 1 and 20 Hz and the instrumental correction is performed for the signal in this range.

3.3 Dynamic Behaviour of Hripsime Church

Fourier amplitudes show distinguishing shape on the ground floor of the church, which can be shown as the response for rocking-sway motion. In this observation, we did not carry out simultaneous observation outside and inside of church. The spectral ratios, however, are calculated using the data obtained through observation #1, #2, and #3. Fig.7 shows the spectral ratio for ground level of the church to outside. Although dates of observations of #1 and #3 are different, the shapes of spectral ratios are very similar mutually, especially, at 2.7 Hz for NS component and 3.6 Hz for EW component. Furthermore, the ratios between outside and other places on ground floor, that is, H-1, H-6, and H-8 are very similar. This suggests that the church vibrate rigidly and may include rocking-sway motion, whose natural frequencies depend on direction.

Fig.8 shows the spectral ratios of same directions between corridor of drum and ground level. These data are obtained simultaneously. The peaks for ratio of NS and EW components locate about 2.9 Hz and 3.7 Hz, respec-

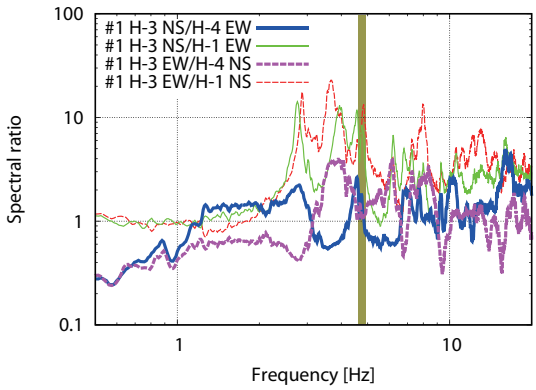

Figure 9 Spectral ratio between NS and EW at different and same level (#1).

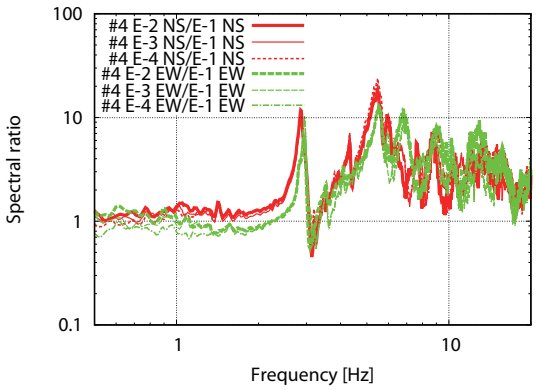

Figure 10 Spectral ratio between corridor of drum (H-2, H-3, and H-4) and ground level (H-1) from #4.

Table 3 Summary of vibration modes (Hripsime Church)

Mode	Frequency [Hz]	Note
1st	2.9	Translatory motion in NS
2nd	3.7	Translatory motion in EW
3rd	4.8	Torsional motion

tively. It is noted that the level of peaks at 2.9 Hz and 3.7 Hz are different. The peaks at 2.9 Hz predominate for NS component and 3.7 Hz for EW component. This means that the first and second mode of the vibrations are translatory motion to NS and EW directions, respectively. The structure is not perfect system, thus, the modes may leak to other modes. This may be a reason for the small peaks for EW component at 2.7 Hz and NS component at 3.6 Hz.

First and second modes of the vibration are clear to determine as shown in Fig.8, however, detection of third mode is slightly difficult. The third mode is assumed as torsional motion of drum and dome. If the torsional motion predominates, the ratios of NS/EW between drum level and ground level must show a peak with same level and the ratios of NS/EW at different sites on drum level must be almost one. Fig.9 shows the spectral ratios: the thin lines stands for the ratios between drum level and ground level, and thick lines for the ratios between NS and EW of different sites on drum level. Solid and dashed lines show the NS/EW and EW/NS, respectively.

To search the above described conditions, we can find the shaded area of Fig.9 around 4.8 Hz. In this area, the thick lines take almost one and peak levels of thin lines are not so different. This frequency corresponds to the third peak of Fig.8. From this, it is suggested that the torsional mode of church is about 4.8 Hz.

The first to third modes of Hripsime Church are summarized in Table 3.

3.4 Dynamic Behaviour of Cathedral at Etchimiadzin

Same analysis as Hripsime Church is applied to the data of Cathedral at Etchimiadzin. The spectral ratios between drum level and ground level in same direction are shown in Fig.10. It seems to be difficult from this figure to discuss the mode shape, because of less difference between different directions. Though large peaks appear at 2.9 Hz and 5.5 Hz for NS and EW components, differences are found at 4.3 Hz and 6.0 Hz for only NS component and at 6.8 Hz for only EW component.

First mode must be at 2.9 Hz and some other mode can be at 5.5 Hz, however, it is difficult to determine other mode at 4.3, 6.0, and 6.8 Hz in this time. Thus, discussion of phase must be necessary for appropriate detection of mode.

4. CONCLUSIONS

We have carried out microtremor observations at two historical structures in Armenia, which are Hripsime Church and Cathedral at Etchimiadzin, to determine their dynamic behaviours. The observation was performed at four sites simultaneously using velocity sensors with three component.

From the discussion of Fourier amplitudes, first three modes are detected for Hripsime Church: we found translatory motion in NS direction at 2.9 Hz, translatory motion in EW direction at 3.7 Hz, and torsional motion at 4.8 Hz. On the other hand, it is very difficult to determine the mode for Cathedral at Etchimiadzin. We can find just candidate of the mode at some frequencies such as 2.9 Hz and 5.5 Hz.

These properties are obtained from discussion of only the Fourier amplitudes. To confirm and improve the reliability of mode detections, we have to discuss phase in the future.

Abstract: Receiver Function is a conventional technique for studying the structure of crust and upper mantle beneath the seismometer. In this study, we apply the Receiver Function technique on the high-frequency acceleration seismograms recorded by TSMIP stations of CWB to estimate the shallow S-wave velocity structure in Taipei Basin. The results show the feasibility of the high-frequency Receiver Function technique for estimating shallow structures.
The Taipei basin is a triangular alluvium basin with the complex Tertiary basement and the weak Quaternary alluvium. The site effects of the basin amplifying and extending the seismic waves result in the major seismic disasters in Taipei. From the variations of receiver function waveforms with respect to azimuth, the complex structure beneath the stations can be concluded, such as a dipping plane or large lateral velocity heterogeneity. The averaged Receiver Function of each station we calculated discreetly exhibit the converted waves reflected the main shallow interfaces. The waveforms and arrival times varied with the local sites of stations. After the forward modeling and inversions of receiver functions, the depths and shapes of the Tertiary basement and other main interfaces inside the Taipei basin were estimated and generally agree with that of previous studies.

1. INTRODUCTION

Taipei Basin, including the Taipei City, the capital of Taiwan, and the New Taipei City, located in the northern Taiwan is the metropolitan areas with the highest population density. The basin was filled with thick and soft Quaternary deposits which amplified the incident seismic waveforms (Wen and Peng, 1998). The site effects of the basin structure have caused several seismic disasters in the Taipei Basin. The building collapses caused by the 1999 Chi-Chi earthquake (M_L 7.3) and 2002/3/31 east coast earthquake (M_L 6.8) were the significant examples recently. According to widely distributed 30 drilling wells and 300 shallow reflection seismic lines, the Tertiary basement and the Quaternary strata above the basement were described (Teng et al., 2001; Wang et al., 2004). However, the structures of some major interfaces affecting the propagation of seismic wave in the basin are still unclear. For reducing the earthquake hazards in the future, the complete and detailed S-wave velocity structure under the Taipei Basin is essential to conduct site-effect estimations, theoretical simulations of strong motion, and seismic hazard assessments.

Teleseismic receiver function method has been developed to provide local information on S-wave velocity discontinuities beneath the recording station (Langston, 1979; Owen et al., 1984; Ammon et al., 1990; Ammon, 1991). The method is excellent at clearly showing the Ps converted phases used to estimate the depth of the discontinuities even if seismograms are contaminated by noise and scattering waves. The receiver functions of stations distributing over a region are efficient to estimate their three dimensional structures. Because the largest S-wave velocity discontinuity generally coincides with the Moho, the method was popularly used to study the structures from the lower crust to the upper mantle. However, if the site is filled by sediments, the sediment-bedrock interface becomes a major velocity discontinuity. The waveforms from these receiver functions are dominantly controlled by the sedimentary structures within the first few seconds after the direct P arrival. Information from the deeper structure may be masked by multiples from this large near-surface discontinuity (Zelt and Ellis, 1998). As a result, the sensitivity of the receiver functions to variations in both the velocity and thickness of the surface layer becomes dramatically increased. Julià et al. (2004) inverted the seismic velocities and densities for the sedimentary cover in the New Madrid Seismic Zone. The whole thicknesses of the Cenozoic and Cretaceous sediments within the depth of one kilometer are respectively estimated by performing an inversion of receiver functions computed at individual broadband station. Zheng et al. (2005) applied the receiver function method to image the sedimentary structure of the Bohai Bay Basin in Eastern China. The sedimentary cover with the depth about 2-12 km in the basin were well estimated. The aim of this study is to apply the receiver function technique on the high-frequency acceleration seismograms recorded by Taiwan Strong Motion Instrumentation Program (TSMIP) stations of Central

Weather Bureau (CWB) to estimate the shallow S-wave velocity structure in Taipei Basin.

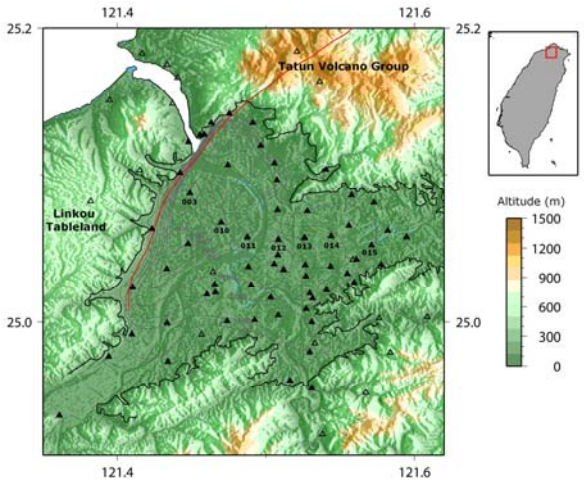

Figure 1 Topography of the Taipei Basin. The thick black lines are the boundaries of the Taipei Basin. The depth contours of the Tertiary basement in the basin are shown by the gray lines (Wang et al., 2004). The thick red line is the Sanchiao Fault indicated as an active fault. The TSMIP stations are shown as triangles in which the filled ones are the stations we used in the study. The stations we mentioned in the article are marked with a number which is the station name without the heading "TAP" below the station

2. GEOLOGIC BACKGROUND

Taipei Basin is a triangular basin with about 20 km length of the side (Fig. 1). The basin is bounded by the Pleistocene Tatun Volcano groups in the north, Western foothills in the southeast, and Linko tableland in the west. The elevation of topography around the basin varies between sea level and about 1100 m. Four young formations are found sitting flat above the basement which is at most 700 m deep (Teng et al. 2001). During the Pliocene and the Pleistocene age, gravels and conglomerates were widely deposited in the Linkou area which was a delta fan produced by reverse faulting activities. About 400 thousand years ago, the area became a tensile environment and resulted in that the Hsinchuang fault altered its sense of movement and became a normal fault, now rename as Sanchiao fault. The normal faulting activities of the Sanchiao fault caused the sinking of the Taipei basin and took shape the basin. Thus, the deepest part of the basin is along the NW border, where the Sanchiao fault is located.

Four newly deposited unconsolidated strata were overlying the basement because of the geohistory of the Taipei Basin. The top near-surface layer, called the Sungshan Formation, dominates the site effects because of its loose sand and silt content (Wen et al. 1995). The Chingmei Formation beneath the Sungshan Formation is mainly composed of gravels and overlies the sand-and-silt Wuku Formation. The fourth Quaternary stratum is the gravel-rich Banchiao Formation overlay on the Tertiary Basement. Based on the data of drilling wells and shallow reflection seismic lines, the two major discontinuities in the basin, the bottom of the Songshan Formation (Fig. 2) and the basement (Fig. 1), were respectively figured. The Songshan Formation is relatively thin (about 50 m) with very low S-wave-velocity. The deepest of the Tertiary Basement is about 700–1000 m along the western border of the Taipei Basin. Table 1 shows the P- and S-wave velocities and depths of the strata in the Taipei Basin (Wang et al., 2004).

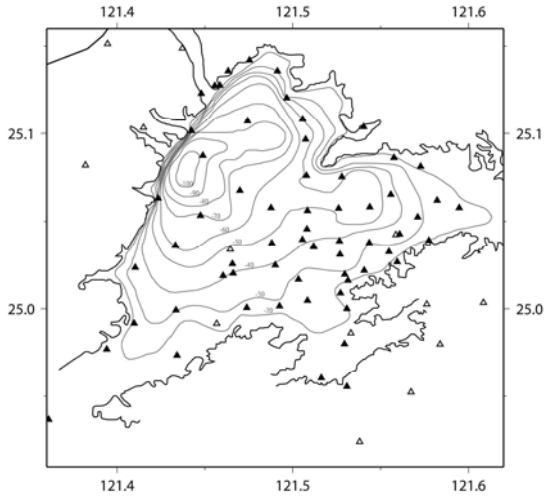

Figure 2 Depth contours of the Sungshan Formation which is the topmost strata of the Taipei Basin (Wang et al., 2004). The TSMIP stations are shown as triangles in which the filled ones are the stations we used in the study

Table 1 P- and S-wave velocities and depths of the strata in the Taipei Basin (Wang et al., 2004)

Stratum	Depth (m)		P-wave (km/sec)	S-wave (km/sec)
	NW	SE		
Sungshan Formation	0-20	0-15	450	170
	20-50	15-35	1500	230
	50-100	35-50	1600	340
Chingmei Formation	100-160	50-100	1800	450
Wuku Formation	160-320	100-200	2000	600?
Banchiao Formation	320-700?	200-300	2200	880?
Tertiary Basement	-	-	3000	1500?

3. ANALYSIS OF RECEIVER FUNCTION

In the Taipei Basin, the dense TSMIP stations provide a large number of excellent seismic data for our study. The instruments installed at the stations are all tri-axial accelerometer (Liu et al., 1999). Sixty-four TSMIP stations located in the Taipei Basin were chosen (Fig. 1). The period of the database is from 1992 to 2009. The earthquakes we used are all local ones occurred within or around the Taiwan Island. Each waveform was visually inspected to eliminate

recordings with low signal-to-noise ratios, anomalous glitches, and calibration issues. The pickings of the P- and S-wave arrivals were also reviewed. We commutated the receiver functions of the seismograms in acceleration rather than velocity used for teleseismic receiver function. In the commutation of receiver functions, the width a = 50 of the Gaussian low-pass filter and the water level c = 0.05 were applied. Figure 3a shows all receiver functions of the TAP010 in order of back-azimuth. Because most earthquakes located in the seismic zone of eastern Taiwan and Western Foothills, the back-azimuth just cover the range from 110° to 220°. Most receiver functions of TAP010 exhibits two apparent converted phases at 0.6 and 1.0 second. In the receiver functions, the systematic variation of converted phase waveforms versus ray back azimuth and the appearance of seismic energy on both the radial and transverse components both reflect the existence of the dipping velocity discontinuity.

After the selection the receiver functions with similar and reasonable waveform, the average receiver functions for each station were calculated. The average of seventeen receiver functions for TAP010 (Fig. 3) enhances the converted phases and reduce the inharmonic arrivals. The average receiver functions of seven TSMIP stations (marked in Fig. 1) located on an E-W direction line in the Taipei Basin are drawn in Fig. 4. The difference of receiver functions between stations is obvious, but the similar converted phase can be observed at most stations with different arrival times. The stations located on the western side where the basin is deeper show later arrival times, and the stations located on the eastern side where the basin is shallower show earlier arrival times. The converted phases with the arrival times less than 1.5 second should produced by the shallow velocity discontinuity within the basin. The variation of arrival times versus location proves the shape of basin affect the high-frequency receiver function. The receiver function technique is effective to analyze the strong motion data observed in the Taipei Basin.

In the study, Genetic Algorithms (GA) was applied to search for the S-wave velocity model with the best fitness between observed and synthetic receiver function. GA searching is a powerful global optimization method. The algorithm consists of selection, crossover, and mutation of individuals in a population; it can search both globally and locally for an optimal solution (Goldberg, 1989). According to the Table 1 (Wang et al., 2004), we assumed a model with six layers covering a half space for the GA searching. The P- and S- velocities of the layers were fixed to avoid the trade-off between the velocity and thickness of layers. We estimated the thickness of each stratum based on the assumption that all the strata in the basin are homogeneous. The searching range of S-wave velocity model was shown by the blue dash lines in Fig. 5a. The full GA process included conducting fifty GA searches. Each GA search was terminated at the 500th generation. The population size of each generation was fifty. Therefore, the total number of repetitions for forward modeling was 1,250,000.

Figure 5a shows the results of the GA searching for the station TAP010. The results of GA searching display the effective convergence of the wide searching ranges for thickness. The synthetic receiver function corresponding to the best model fit the observed one well (Fig. 5b). The phases converted at the four major interfaces under the Taipei Basin were identified. The inverted S-wave velocity model of TAP010 slightly overestimates the depth of the Tertiary Basement in previously study (Fig. 1). The high contrast of the basement produces the converted phase observed at 1 second. The biggest phase observed at 0.6 second converts at the bottom of the Wuku Formation with the depth of about 200 m. The bottom of the Sungshan and Chingmei Formation produced the small converted phases respectively at 0.3 and 0.4 second.

The blue dash lines show the searching range of the S-wave velocity in the GA searching. The black bold line is the S-wave velocity model with the best fitness of the GA searching. The lines with various colors are the best twenty models. (b) is the comparison between the observed average receiver function (black line) and the synthetic one (red line) with the best fitness based on the GA searching

4. STRUCTURES OF TAIPEI BASIN

The above-mentioned analysis process of receiver function was applied to the sixty-four TSMIP stations in the Taipei Basin. The average receiver functions were calculated and modeled to estimate the 1D S-wave velocity models for the stations. Because the velocities of layers were fixed, the depths of the major interfaces were easily identified. We combined the 1D models of all the stations widely distributed in the basin to delineate the 3D structures of the strata. Figure 6 are the depth contour maps of the four major interfaces under the Taipei Basin delineated based on the synthetics of the receiver functions. The thickness of the topmost Sungshan Formation is between 80 m in southeast and 120 m in northwest. The distribution of the strata we estimated agrees with the result of the drilling and seismic surveys (Fig. 2), but there are two noticeable differences between Fig. 6a and Fig. 2. The deepest range we estimated in the northwest is larger than that of Fig. 2 (Wang et al., 2004). The bottom of the Sungshan Formation in Sungshan area in Fig. 2 is the deepest part of the eastern half with a shape of extended platform in the depth of about 50 m. Our result controlled by the receiver function of TAP014 in the same area exhibits much deeper depth. The deep-hole shape under TAP014 is abnormal and may result from the multiple and close phases (Fig. 4).

Although the TSMIP stations are not dense enough to figure out the deep shape of the Tertiary Basement along the northwestern border in the basin, several stations located in the area, including TAP003, TAP016 and TAP094, exhibit the depth of more than 600 m for the basement. The Tertiary Basement we delineated (Fig. 6d) shows similar trend with the Fig. 2 (Wang et al., 2004). The basement gradually dips from southeast to northwest. The deepest part along the northwest border form a sharp graben because the normal faulting activities. We also delineated the bottom of the Chingmei and Wuku Formations. The distributions for the two layers both agree with the estimation of Wang et al. (2004) (Table 1). According to the shapes of the four major interfaces, the gradual change of the sedimentary environment can be presumed.

5. CONCLUSIONS

The receiver function technique has applied on the high-frequency acceleration seismograms recorded by TSMIP stations of CWB to estimate the shallow S-wave velocity structure in the Taipei Basin. The averaged receiver function of each station exhibit apparent converted phases reflected the major shallow interfaces under the basin. After the forward modeling of GA searching, we delineated the brief 3D structures of the four Quaternary strata under the Taipei basin. The thicknesses and shapes of the interfaces we estimated are all comparable with that of the previous drilling and seismic survey. The results proved that the high-frequency receiver function is feasible to figure out the shallow discontinuity with high velocity contrast. The technique will provide another tool to study the shallow sedimentary structures which is essential to conduct site-effect estimations, theoretical simulations of strong motion, and seismic hazard assessments.

Because the shallow structures are usually more complex, the high-frequency receiver function is easy to be contaminated by not only the artificial noise but also the non-horizontal and inhomogeneous layers. Besides, the receiver function analysis theoretically requires near-vertical incidence plane waves to elucidate the structure directly beneath a seismic station. We suggest that the high-frequency receiver function should apply on the seismic station with a lot of data. The original seismic waveforms and receiver functions should be carefully inspected and selected for the waveform with real converted phases of velocity discontinuities. The sufficient data will help conclude the systemic receiver functions to estimate the structures we are interesting in.

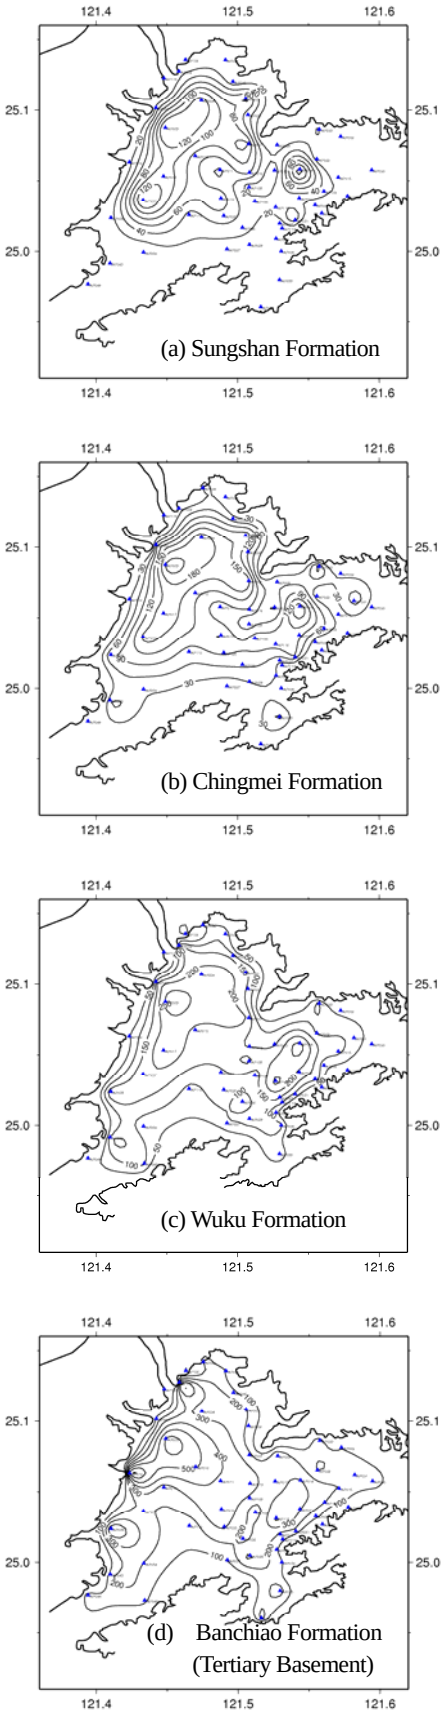

Figure 6 Depth contour (meter) maps of the four major interfaces under the Taipei Basin estimated based on the synthetics of the receiver functions for the TSMIP stations shown respectively by the triangles

Abstract: The site response is not easy to consider for ground motion estimation especially in the basin area. Where 1D, 2D, or 3D basin response need to be considered in the simulation. In this study, we try to use empirical site correction term for the ground motion simulation in the Taipei basin. The method of the stochastic point-source modeling is used to simulate the rock site ground motion in the Taipei basin area. Empirical site corrections are calculated by the spectral ratios between observed earthquake record and stochastic point-source modeled for rock site. The empirical site correction model is then used to simulate four target earthquake ground motions on the soft soil sites within the Taipei basin. The 1999 Chi-Chi, Taiwan earthquake had surface rupture occurred and were simulated by finite-fault modeling. Residual between the observed and simulated ground motions are discussed in the time and frequency domains, and also compared with that from the ground motion prediction equation method which engineer application usually used.

1. INTRODUCTION

An earthquake record observed on a seismic station should include the effects from source, path, and local site. In many earthquakes, sit effect shown an important part of these three effects, for instance, 1985 Michoacan, Mexico earthquake and 1999 Chi-Chi, Taiwan earthquake. Anderson et al. (1996) indicated that the top soft alluvium layer will acted an important role for site effects. For this reason, study the site effects is critical on seismic hazard mitigation for the future earthquakes.

Recently, numerical simulation of strong ground motion is widely used in engineering analyses for the regions with less earthquake data (Beresnev and Atkinson 1998; Sokolov et al. 2001). For soft soil basin, many studies already worked on real basin by 3D ground motion simulation (Lee et al. 2008; Miksat et al. 2010). But, mostly, it still limited in lower frequency response which can not directly used for engineering and hazard mitigation problem.

The method of the stochastic point-source modeling is used in this study to simulate the rock site ground motion in the Taipei basin area. Empirical site corrections are calculated by the spectral ratios between observed earthquake records and stochastic point-source modeled for rock site. The empirical site correction model is then used to simulate the ground motions of other events, not used in the previous empirical site correction analysis, for the soil sites within the Taipei basin. Also, we try the same empirical site correction model for the 1999 Chi-Chi, Taiwan earthquake ground motion by finite-fault modeling for the larger earthquake magnitude than the events used for calculating the site correction function. Residuals between the observed and simulated ground motions are discussed in the time and frequency domains, and also compared with that from the ground motion prediction equation (GMPE) method which engineer usually used.

2. DATA AND METHOD

Stochastic method included both point source and finite-fault modeling for different magnitude events in this study. The point source model use the code SMSIM developed by Boore (2009), and the finite-fault method involves discretization of the fault plane into smaller sub-faults, each of which is assigned a ω-square spectrum. The stochastic finite-fault method was incorporated in the code EXSIM (Motazedian and Atkinson 2005; Assatourians and Atkinson 2007; Boore 2009).

The method consists of two steps. First, earthquakes with magnitude less than 6 and focal

depth less than 40 km are selected to do the stochastic point source modeling of the rock site response. Totally, 203 earthquakes recorded by the stations in the Taipei basin area from 1991 to 2009 are used to generate the site correction functions for the soft soil site within the Taipei basin (Figure 1). Compared the observation and simulation records for the class B stations outside the Taipei basin can generate the rock site correction function for the ground motion simulation of rock site. Table 1 lists parameters used for the rock site simulation by SMSIM code are followed D'Amico et al. (2012). The empirical site correction function for each soft soil station within the Taipei basin is calculated from the observation record to the rock site simulation for that soil site. Based on the many earthquakes results, the average site correction function can be used as final empirical site correction function for that station. The empirical site correction function also can be used to study the site effects of the Taipei basin.

Then, another 4 events (red stars in Figure 1), which are not used in the previous empirical site correction analysis, are used as a validation test for this ground motion simulation. It included 3 earthquakes with magnitude from 5.5 to 6.2 by stochastic point source modeling method and the 1999 Chi-Chi, Taiwan 7.6 earthquake by the finite-fault modeling method. Parameters used for the Chi-Chi earthquake simulation by EXSIM code that are referred to D'Amico et al. (2012) (Table 2). Source parameters following Chang et al. (2000) and slip distribution useing the result from Ma et al. (2001). The simulation and observation records are compared to see whether the empirical site correction model suitable or not. The biases in frequency and time domains are defined as the logarithm of the ratio of the observed to simulated Fourier spectra and peak ground accelerations over all sites shown in Eq. (1) and Eq. (2) as follow:.

$$\mathrm{DSDP} = \sum_{0.2}^{10}\left(\left|\log_{10}\left(\frac{\mathrm{FASo}}{\mathrm{FASs}}\right)\right| \times \mathrm{df}\right) \quad (1)$$

$$\sigma_{\mathrm{lnErr}} = \sqrt{\frac{1}{\mathrm{N}}\sum_{i=1}^{\mathrm{N}}(\mathrm{Residual}_i)^2} \quad (2)$$

$$\mathrm{Residual} = ln\mathrm{PGA_o} - ln\mathrm{PGAs} \quad (3)$$

where subscript represent observation data and *s* represent simulation data.

One of the main factors that affect the GMPE method is existence of the site effects. Therefore, it is necessary to take account of the site effects in applying the attenuation relationship for ground motion prediction. In this study, we used two-step method to predict the best results of PGA shake map.

First step, we got the PGA of each site by PGA attenuation relationship (Jean and Loh 2001; Jean et al. 2006), which follows the model proposed by Campbell (1981). The attenuation equation can be expressed as follow:

$$Y_{att}=0.00369e^{1.75377M}[R+0.12220e^{0.78315M}]^{-2.05644}$$
$$\sigma_{\mathrm{lnErr}} = 0.78 \quad (4)$$

where Y_{att} is predicted PGA value and R is the closest distance to the source.

Second step, the site correction of each station can be simplified by the following equation:

$$ln(PGA_{obs})_S = C_0 + C_1 \times ln(Y_{att})_S \quad (5)$$

where PGA_{obs} is the observed PGA value, and Y_{att} is the predicted PGA value obtained from the attenuation relationship law. In Eq. (5), the values of C_0 and C_1 are the site-dependent parameters for corrections on site effects

3. EMPIRICAL SITE EFFECTS

Due to the site effects in the Taipei basin are not easy to identify from theoretical analysis, maybe it needs to consider 2D or 3D basin responses. In this study, the empirical site effects are calculated from the spectra ratios of the observation with respect to the synthetic motions which did not consider the basin structure. For each station within the Taipei basin, we calculated the average spectral ratio to represent the site correction function for that station. Figure 2 shows the general transfer functions for stations within the Taipei basin with different site classifications. The site classification of the strong motion stations are referred from the Engineering Geological Database for TSMIP (EGDT, Kuo et al. 2012).

Figure 3 represents the contour of the dominant frequency in the Taipei basin from the empirical site correction functions. The distribution of the dominant frequencies shows that the areas near the basin edge have a higher dominant frequency, but within the basin have two low dominant frequency zones. The dominant frequency distribution correlated with the soil layer thickness, and the low dominant frequency zone occurs over the deepest part of the soil layer.

Previous survey (Wen and Peng 1998) indicated the top soft soil layer, the Sungshan

formation, within the Taipei basin react to the site effects at low frequency and it also shown the same result in the study. Figure 4 presents the contour of the empirical site functions at 0.5 and 2.0 Hz in the Taipei basin. It is very clearly to show that the high amplification hot spots occurred in two areas, the western and eastern part of the Taipei basin, for 0.5 Hz response. These areas are also the deepest parts of the Sungshan formation. This amplification should be due to the wave resonated within the soft soil layer. But the high amplification area for 2.0 Hz response change to basin edge areas except the western part of deep alluvium part.

4. SIMULATION OF THE TARGET EARTHQUAKES

The empirical site correction model is then used to simulate four target earthquake ground motions on the soft soil site within the Taipei basin. Residual between the observed and simulated ground motions are discussed in the time and frequency domains, and also compared with that from the attenuation equation (GMPE) method which engineer usually used.

4.1 Simulation of Moderate Events

Due to the empirical site correction function for each station was calculated from the earthquakes with magnitude less than 6.0 and focal depth less than 40 km. In the validation, we selected three moderate events with M_w 5.5, 5.6, and 6.2, but one with focal depth of 76 km. Figure 5 shows an example of the frequency and time domain results of the station TAP007 for the June 9, 2003 earthquake. In this figure, the black lines are observation data, blue lines are the simulations on rock site condition, and red lines are the simulation results after applied the site correction functions. The bias in the spectrum (DSPD) reduce from 3.7093 (rock site) to 2.1834 (after site correction). Compare the peak ground acceleration distribution of simulation and observation for the same event, he residual map (Figure 6) shows most area had a good PGA prediction, only the southern part has a little under estimate. One thing need to point out that the observed PGA in the residual calculation does not filter any frequency band in this study.

The same earthquake also predicted the PGA distribution based on the GMPE method. First, using the rock site attenuation equation calculated the PGA in Taipei basin based on the magnitude and distance; then done the site correction for each station following the two steps method (Jean et al. 2006; Wen et al. 2009). Figure 7 shows the PGA results from different methods include rock site condition and after site correction. Black closes are the observed PGA. Blue triangles are the stochastic point source results for rock site (not consider the soft basin) and red triangles are the results added empirical site correction function for each station. Residure (σ_{lnErr}) of the June 9, 2003 earthquake reduce from 0.979 to 0.389 after applied the empirical site correction function. Dash line indicated the GMPE of Jean et al. (2006), and σ_{lnErr} = 1.325; but it reduce to 0.336 after second step of the site correction shown in circles.

Another shallow earthquake of September 10, 2000 also shows the same characteristics. σ_{lnErr} reduce from 1.1 to 0.487 for stochastic simulation, and from 1.458 to 0.456 for GMPE method. The results for March 24, 1995 earthquake with focal depth 76 km still shown the σ_{lnErr} reduction effect, but the values are all greater than other two shallow events. The magnitude of this event is Mw5.6 that is around the same with other two events and in the database range for analysis empirical site correction function. So, the simulation results not so good as others should due to the different site responses for shallow and deep earthquakes found in Taipei basin (Sokolov et al. 2009). The bias in frequency domain (DSPD) for the deep event is 3.10 also greater than 1.83 and 2.12 of the two shallow events. GMPEs for shallow and deep earthquakes also found are different by many studies. This also can explain the larger bias for PGA of the 1995 deep event than those two shallow events for the GMPE results in the time domain.

4.2 Simulation of the 1999 Chi-Chi Earthquake

Due to the 1999 Chi-Chi, Taiwan earthquake, magnitude Mw=7.6, occurred along with a surface fault rupture. The stochastic ground motion simulation needs to use finite fault model (EXSIM). Figure 8 shows an example of the simulated results of station TAP003. From all the simulation time histories we can draw the PGA contour and compared with the observation. The residual map of the PGA simulation is displayed in Figure 9. We have a satisfactory prediction in the most area of basin but there has one underestimates occurred in western part and a large part overestimated in the eastern part of the basin. These mismatches may due to the large magnitude earthquake did not used in calculation of the empirical site correction function or the source spectrum did not exactly simulated by the finite fault model. So, DSPD (Figure 10) reach to 4.06 which is

greater than previous three moderate magnitude earthquakes. The PGA simulation seems had a good result compare to the results of three moderate events. σ_{lnErr} = 0.472 for EXSIM of rock site simulation and reduce to 0.304 after applied empirical site correction for each station. For GMPE simulation, σ_{lnErr} = 0.76 for rock site direct calculated from attenuation equation and reduce to 0.387 after site correction.

5. DISCUSIONS AND CONCLUSIONS

The stochastic point source model which has been calibrated on rock sites was used to obtain the site transfer function for each soil site within the Taipei basin. The empirical site correction function for each soil station was calculated from average the results of 203 magnitude less than 6.0 and depth less than 40 km earthquakes. Then, the ground motion simulation can be performed for moderate magnitude earthquakes by the stochastic point source simulation to rock basement and added the empirical site correction to get the final ground motion simulation. The biases of the stochastic simulation results compared with observation are around the same compared with the GMPE simulation.

For the 1999 Chi-Chi, Taiwan earthquake with surface rupture and large magnitude (Mw=7.6), the stochastic finite fault model was used and the empirical site correction function still used that from the previous analysis. Although the spectrum bias is larger than that of the moderate magnitude earthquake simulations, the PGA from EXSIM included the site correction function still show a good simulation with σ_{lnErr} = 0.304 which is even better than GMPE result of σ_{lnErr} = 0.387 after site correction. This shows the ground motion prediction already can go more high frequency from seismology method. The simulation results in the time domain will have around the same biases compared to the results from GMPE method which engineering usually used. Specially, the simulation results from this kind ground motion simulation method not only can predict the PGA as GMPE method done but also can have time history with the spectrum under limited bias or uncertainty.

The bias analysis in this study suggested more detail works need to be done. Hope it will reduce the uncertainty of the ground motion simulation for different magnitude earthquake. More accurate ground motion prediction can provide a good reference for the future seismic hazard mitigation. The empirical site transfer function was calculated from the ratio between observation and simulation earthquake records. Effects from the magnitude level for source effects, ground motion level for nonlinear site effects, and focal depth for propagation path or direction should be considered in the future study.

Abstract: On May 6, 2012, a strong tornado attacked Tsukuba City, Ibaraki Prefecture, Japan. It has caused heavy property losses in a concentrated area. An early detection of building damage is very important for quick response after an occurrence of natural disasters. Aerial visible images are widely used to detect building damage because they can cover a wide area quickly with very high spatial resolution. However, these images cannot be taken without sunlight, which could generate a "blank time" if a disaster occurs in the nighttime. On the other hand, aerial thermal-infrared images can be taken both in the daytime and nighttime without depending on sunlight although it has an inferior spatial resolution compared with aerial visible images. It is considered to be possible to detect building damage from the temperature distribution of an urban surface. In this study, detection of building damage and debris is carried out from aerial thermal-infrared images taken over Tsukuba City on May 8, 2012, both at daytime and nighttime. Spatial characteristics of temperature distribution, such as non-uniformity, are considered to grasp building damage and debris.

1. INTRODUCTION

On May 6, 2012, three powerful tornados were generated in Tochigi and Ibaraki Prefectures, Japan, almost at the same time. These tornados caused severe property losses and some casualties although in narrow areas, such as Tsukuba City. This event was considered to be a good case to test the capability of airborne remote sensing in damage detection, especially using visible and thermal infrared imagery (van Aardt *et al.*, 2011).

Remote sensing is widely used especially for the sites where the access from the ground is limited and the damage distribution covers wide areas (Rathje and Adams, 2008; Eguchi *et al.*, 2008; Dell' Acqua and Gamba, 2012). Various platforms and sensors have been developed recently for satellite remote sensing and its spatial resolution has been improved significantly (Joyce *et al.*, 2009), Airborne remote sensing, however, still has advantages over satellite remote sensing in spatial resolution, immediacy and applicability in cloudy conditions by flying under high-altitude clouds.

Damage detection using visible imagery is simple and common. However, visible imagery cannot be taken in the nighttime, and thus "blank time" may occur in emergency response after a disaster strikes. On the other hand, thermal infrared (TIR) imagery can be taken both in the daytime and nighttime without depending on sunlight. Yamazaki *et al.* (2009) confirmed that clear edges of buildings, roads, and vegetation can be extracted from aerial TIR images of urban areas. Hanada and Yamazaki (2012) recently used ASTER's TIR images for grasping flooded areas by tsunamis caused by the March 11, 2011 Tohoku, Japan earthquake. Satellite TIR imagery, however, has low spatial resolution, e.g. 90 m for ASTER and 60 m for Landsat-7. Hence, its application to small-scale damage is difficult. However, airborne TIR imagery has much higher spatial-resolution, say order of 2 to 3 m, and hence, it can be used for damage detection of individual buildings, especially at nighttime when visible sensors cannot be used.

In this study, we acquired visible and TIR images from a helicopter two days after the tornado in Tsukuba City. The TIR images taken at daytime and nighttime were compared with the visible image at daytime. Visual damage inspection was first carried out by the authors using the daytime visible image for a hard-hit area of the city. The TIR images were then compared with the result of the damage inspection. The temperature distribution from the TIR images was further investigated by employing building footprints from the visible image and GIS. The temperature distribution within a footprint was compared with the damage grade of the building and the capability of aerial TIR images in damage detection was studied.

2. THE MAY 6, 2012 TORNADO IN TSUKUBA

A strong tornado was generated in Joso City, Ibaraki Prefecture, on May 6, 2012 at 12:35. It caused significant damages along its path with 17 km in length and 500 m in width until its end at Tsukuba City (**Figure 1**). The moving speed of the tornado was about 60 km/h (passing 17 km in 18 min) based on the analysis of meteorological Radar by Japan Meteorological Agency (JMA, 2012). JMA judged the Fujita scale of the tornado as F2 (the average wind speed of 50-69 m/s in 7 s) based on their field survey after it passed

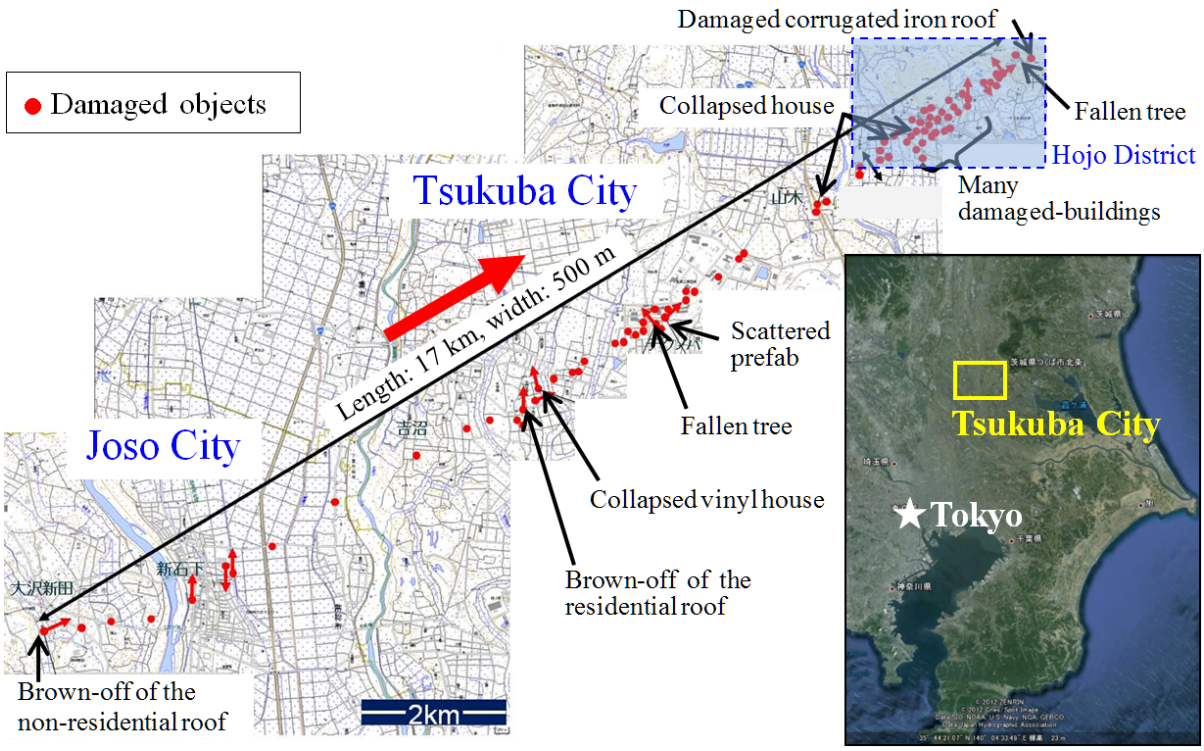

Figure 1 Detail map of the tornado's path and resultant damages, modified from JMA (2012).

by. However, it was changed to F3 (the average wind speed of 70-92 m/s in 5 s) in June 8, 2012 because the resultant damages were found to be so severe; for example, one wood-frame house was overturned upside-down with its concrete base.

This event is ranked as one of the strongest and most damaging tornados in Japan. By this tornado, one person was killed and 37 people were injured as of May 9, 2012, and 1093 buildings were damaged as of August 31, 2012 only in Tsukuba (Tsukuba City, 2012). In the recent years, the number of strong tornados is increasing in Japan, probably due to the climate change. Prediction of the occurrence time and location of a tornado is still very difficult because its time-span is short and its affecting area is small. However, enhancement of tornado prediction, its early warning and rapid response are strongly desired to reduce human casualties due to tornados.

We conducted a field survey of Hojo district, Tsukuba City, to obtain ground truth data from 14:00 to 16:00 on May 8, 2012, almost at the same time of our daytime's aerial image acquisition. Typical damages by the tornado were blown-off of building roofs, broken windows, and falling-down of trees and electric poles. Since these types of damages, other than the damage to building walls, can generally be observed from vertical imagery, we thought this is a good opportunity to test the capability of aerial TIR imagery for building damage assessment as well as that of optical imagery. We surveyed the hard-hit area and took ground photos of severely damaged buildings with their GPS location data.

The route of our field survey in Hojo district on May 8, 2012 was shown by the blue line in **Figure 2a**. We walked around the hard-hit area with digital cameras and hand-held GPSs. The weather condition of the day was cloudy with the maximum air temperature 24.8 ^{o}C, and minimum air temperature 13.4 ^{o}C.

Typical damage scenes are shown in **Figure 2** (**b-i**). Many buildings were collapsed or brown off their roofs, and these were covered by blue sheet (**b**). Trees were uprooted, and a wooden house was overturned upside-down with its concrete base (**e**). The Fujita scale was changed to F3 by this damage. Many objects were covered with mud because the tornado hit the area with rain (**f**). This might affect the surface temperature. Debris and mud on roads were mostly cleaned up already at the time of our field survey although some still remained. Recovery efforts were very fast because the tornado damage was localized. Restoration of electric poles and cables were going on with many trucks and workers (**i**).

3. VISIBLE AND TIR IMAGES USED AND ANALYSIS METHOD

In this study, the detection of building damage was carried out for the tornado that hit Tsukuba City. As a study area, Hojo district, a northern part of Tsukuba City, was selected where the most serious damage was observed by the tornado (**Figures 1** and **2**). Assessment of building damage was carried out using by TIR and visible images

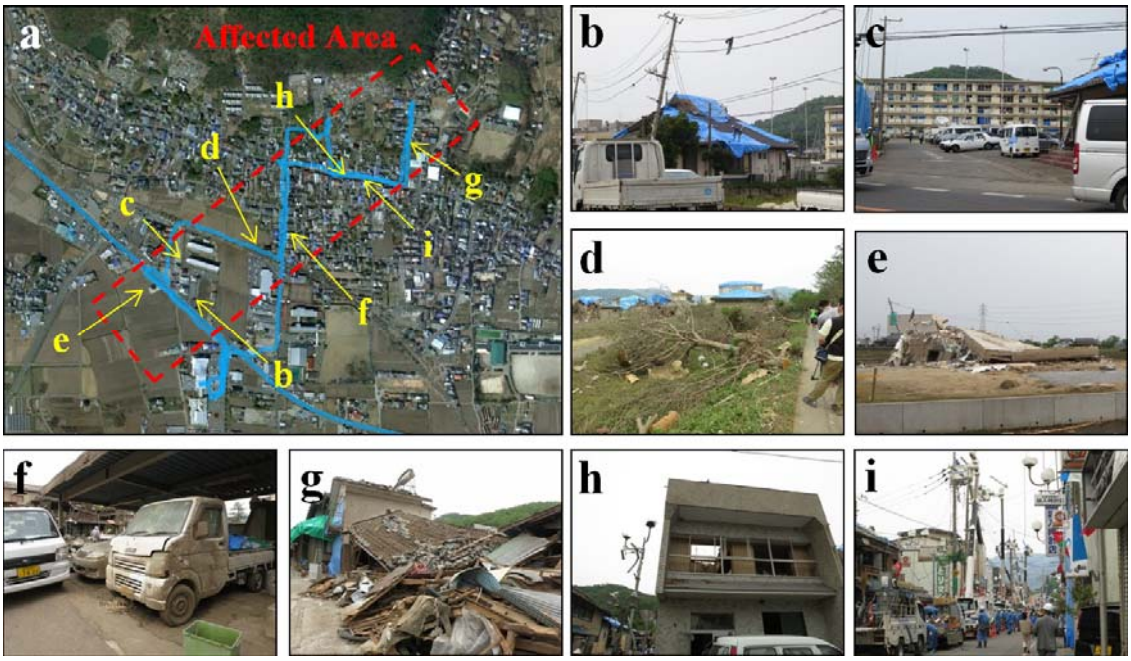

Figure 2 (a) The area of field survey in Hojo district, Tsukuba City and photo shooting locations, (b) Blue-sheet on the roof, (c) Damage on the side wall of an apartment building, (d) Fallen trees along street, (e) Overturned wooden house with its concrete base, (f) Cars stained with tornado's mud water, (g) Buildings that reduced to debris, (h) Brown-off of the roof (the sky is seen from the window), (i) Restoration work of electric poles and cables.

taken from a helicopter of SKYMAP co. by our request after the tornado. **Figure 3** (**a, c**) show a part of the post-event visible and TIR images taken at daytime (about 14:00) on May 8, 2012 while (**d**) shows a part of the TIR image taken at nighttime (about 19:30) on the day.

These images were taken from a small helicopter from the height of 460 m. The visible image with 0.25 m pixel size was created by mosaicing high-definition television (HDTV) scenes from a SONY handy video camera. The thermal-infrared (TIR) images with 1.54 m pixel size were mosaiced from ones taken by a TIR camera (NEC TS7302). Building footprints were created on a GIS system from the daytime aerial visible image by the present authors in order to use them in damage assessment for individual buildings.

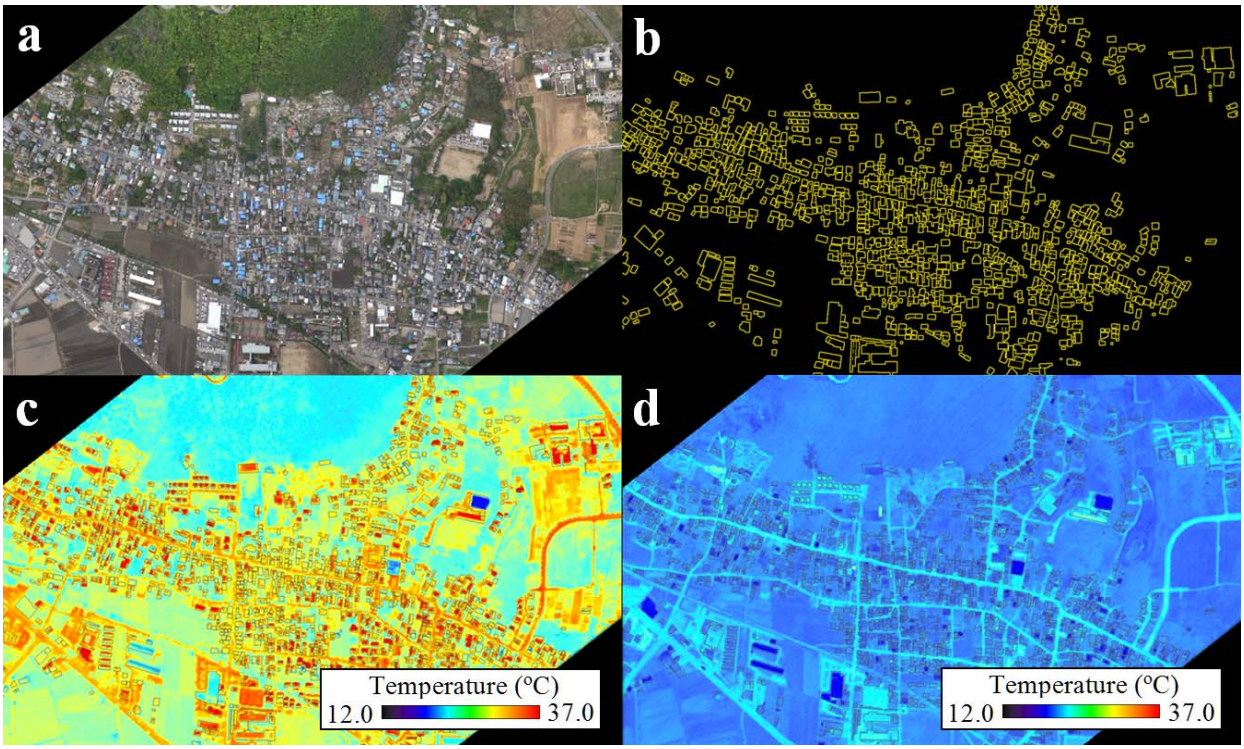
The damage assessment was carried out in the following steps; Firstly building footprints were manually created from the daytime aerial visible image and an existing Zenrin digital map on ArcGIS software (**Figure 3b**). Then, damage status of each building was detected visually from the daytime aerial visible image based on the building damage classification shown in **Figure 4**. This classification was applied here, modified from the floor damage criteria by the Cabinet Office of Japan (2009), which is recommended to use when evaluating the monetary loss of residential structures for local governments. In the classification, the damage level of each wooden house is judged by 5 grades: such as no to slight (G0-G1), minor (G2), moderate (G3), major damage (G4) and collapse (G5). We employed the method based on the damaged percentage of a roof (*R*) since it is suitable to apply to vertical aerial images.

The damage level of each building was also estimated from the temperature distribution obtained from the daytime and nighttime TIR images. The average temperature and its slope angle within a building footprint were calculated and they were compared with the damage grade. The slope angle was calculated for a 3x3-pixels window (ArcGIS Resource Center, 2011). A large slope angle means a large difference in temperature between adjacent pixels while a small slope angle indicates a small difference. We considered that a severer building damage level might lead to higher variability in temperature distribution within a footprint. The average temperature within each footprint was also calculated for the daytime and nighttime TIR images using ArcGIS software. An open DXF file was generated by ArcGIS and a histogram of the average temperature for each building was made for each damage grade.

4. RESULTS OF DAMAGE EXTRACTION

4.1 Visual Damage Assessment from the Post-event Visible Image

Figure 4 shows the result of our visual damage inspection from the daytime aerial visible image. It is seen that the grades G3-G5 buildings were located along the path of the tornado. The path of the tornado was clearly seen from the visible image, and the center line was drawn as shown in **Figure 5**. The parallel lines were also drawn up to 200 m from the center line to the both sides in 20 m interval. The damage ratio for each distance class was calculated and shown also in **Figure 5**. It is observed that the collapsed



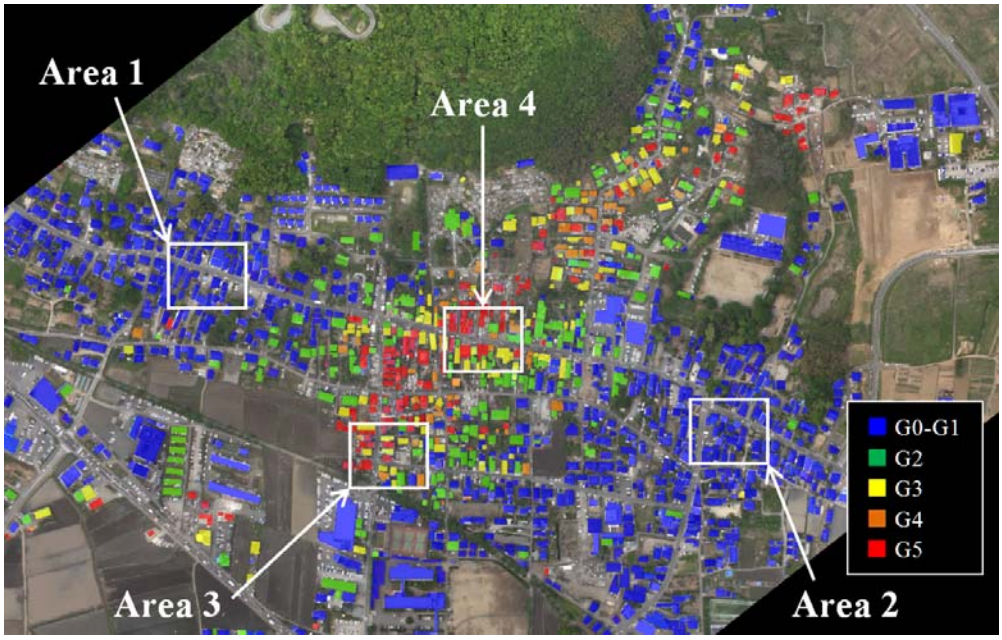


Figure 3 (**a**) Visible image of Hojo district in Tsukuba City at daytime, (**b**) building footprints created from (a), (**c**) TIR image at daytime, and (**d**) TIR image at nighttime on May 8, 2012 taken from helicopter.

Damage Level	G2	G3	G4	G5
Roof damage ratio $R = \frac{Damaged\ Roof}{Roof}$				
	0%<R≤20%	20%≤R<50%	50%≤R<70%	R≥70%

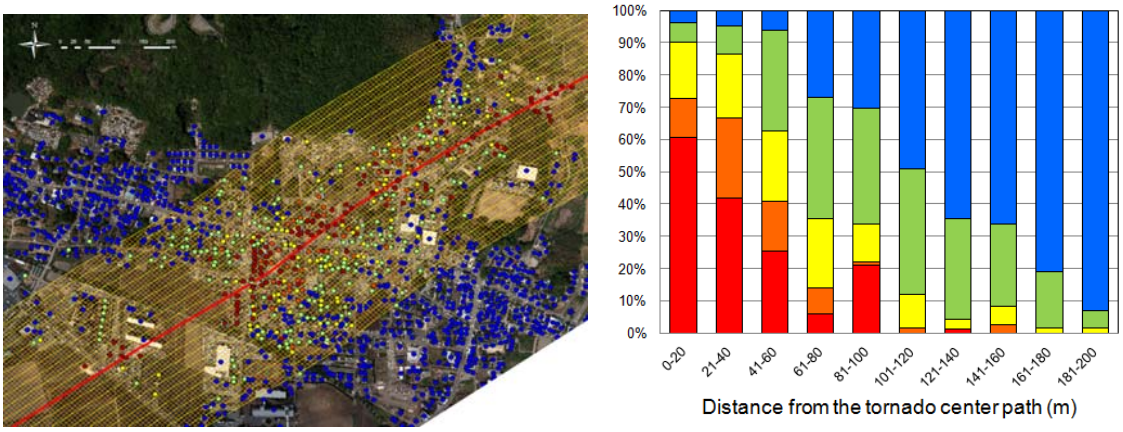

Figure 5 The center path of the tornado detected from our visual inspection and its parallel lines within 200 m (left) and the damage ratio of buildings for 20 m interval from the center path (right)

Table 2 Comparison of the result by our visual inspection on the daytime optical image and that from field observation by Tsukuba Fire Department for 730 buildings within 200 m from the tornado path in Hojo district

Visual Inspection \ Field Survey	G5	G4, G3	G2	G1, G0	User's Accuracy
G5	82	17	6	8	72.6%
G4, G3	27	56	40	22	38.6%
G2	9	34	100	39	54.9%
G1, G0	0	15	102	172	59.5%
Producer's Accuracy	69.5%	45.9%	40.3%	71.4%	Overall Acurracy 56.2%

buildings (G5) were located mostly within 60 m from the center path of the tornado. No collapsed building was found outside of the 100 m lines from the center path. Almost no damaged buildings were seen outside of the 200 m lines from the center path. The damage due to the tornado was concentrated in a narrow range although tornado paths are unpredictable.

In our visual damage inspection, some buildings were judged as no damage although some damages on their side surfaces were seen in our field survey, i.e. the apartment building in **Figure 2c**, because the damage was judged only from the roof condition of the vertical visible image. This might be the reason of the difference between our inspection result with the damage assessment result by Tsukuba Fire Department from the ground, as shown in **Table 2**. The damage assessment in their field survey was conducted by looking from outside, and thus damages to side walls and facade could mostly be seen. G3 and G4 were grouped as one class because their results did not distinguish these two.

It is seen from the table that the user's accuracy and producer's accuracy are almost the same level in this area, which indicates that both vertical photos and ground survey have weakness; the former sees only a top view while the latter mostly a side view of a building. In case of building damage due to tornados, damages to roofs prevail and hence vertical areal images are suitable to detect damages. On the contrary, damages due to earthquakes are more difficult to extract from vertical aerial images since damages to side walls are usually significant.

In this study, our visual inspection result was used as the reference data for the aerial TIR images since the both data were acquired from the same vertical view angle, where only the damage condition or the temperature of the roof was seen.

4.2 Temperature Characteristics of Non-damaged Areas from Daytime and Nighttime TIR Images

The characteristics of the TIR images at non-damaged areas were discussed first. **Figure 6** shows the locations of two target non-damaged areas in **Figure 4**. **Figure 7** shows the surface temperature within the building footprints from the daytime and nighttime TIR images, superimposed on the visible image. From the daytime roof temperature distributions in **Figure 7** (**a**, **c**), the roofs mostly show high temperature although some low temperature roofs exist. From the nighttime roof temperature distributions in **Figure 7** (**b**, **d**), the buildings showing high temperature at daytime are still in relatively higher temperature at nighttime. It is observed that the roof temperature within a footprint of a non-damaged building is mostly uniformly distributed but the effects of surrounding vegetation, shadow and footprint's inaccuracy can be observed around the outline.

Figure 8 shows the slope angle of the surface

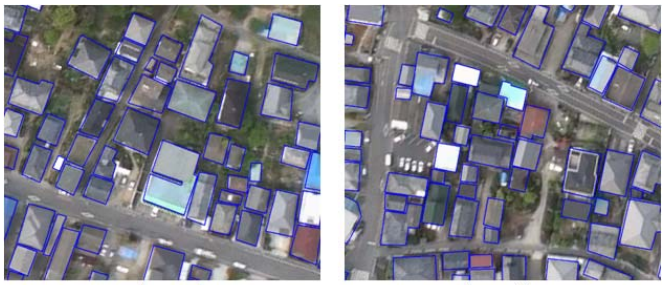

Figure 6 Target areas of non-damage in Figure 4

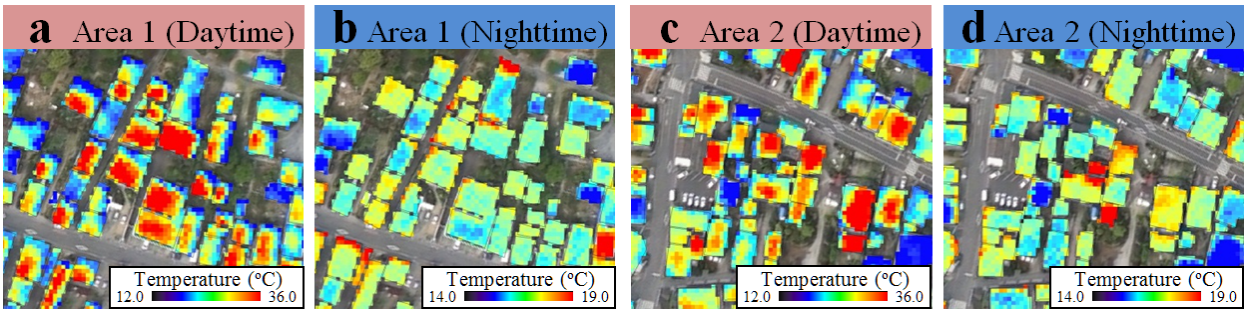

Figure 7 Temperature within building footprints for non-damage areas, **a**, **c**: Daytime, **b**, **d**: Nighttime

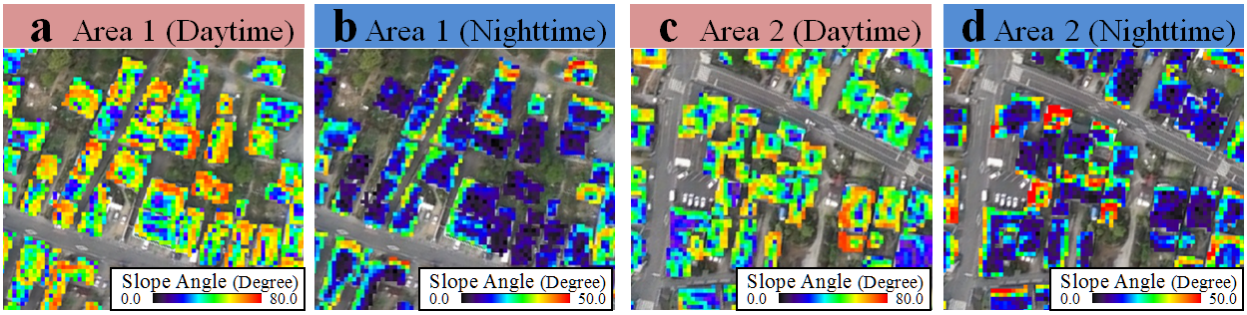

Figure 8 Slope angle of the temperature within building footprints in Figure 7, **a**, **c**: Daytime, **b**, **d**: Nighttime

temperature within the footprints. In calculation of the slope angle, the temperature of the adjacent pixels affected the result although the angle is shown only within the footprints. In the daytime slope angles in **Figures 8** (**a**, **c**), high temperature roofs show generally larger slope angles because the temperature difference with their surroundings is large due to the difference of surface materials. In the nighttime slope angles in **Figure 8** (**b**, **d**), the slope angles within some building outlines are displayed red color affected by surrounding road or vegetation. However most building roofs are in low temperature with uniform distribution, and thus their temperature changes within their outlines are small.

4.3 Temperature Characteristics of Heavily-damaged Areas from Daytime and Nighttime TIR Images

Next the characteristics of the TIR images at heavily-damaged areas were discussed. **Figure 9** show the locations of two target heavily-damaged areas in **Figure 4**. **Figure 10** shows the surface temperature within the building footprints from the daytime and nighttime TIR images, superimposed on the visible image. From the daytime roof temperature distributions in **Figure 9** (**a**, **c**), damaged roofs mostly show low temperature because they were covered by blue sheet or reduced to debris. The nighttime roof temperature distributions in **Figure 9** (**b**, **d**) also exhibit low values. The temperature distributions for heavily-damaged buildings are seen to be somewhat different from those of non-damaged ones both at daytime and nighttime, but this observation is highly affected by the material, color and orientation of the roof, shadow and surrounding conditions.

Figure 11 shows the slope angle of the surface temperature within the footprints. In the daytime slope angles in **Figure 11** (**a**, **c**), many buildings show small values as in purple to blue colors. It is also observed that the pixels with large angles are few probably because buildings were reduced debris and it spread in and outside of the original building footprints. Many materials were mixed up by building collapse and thus many objects became a

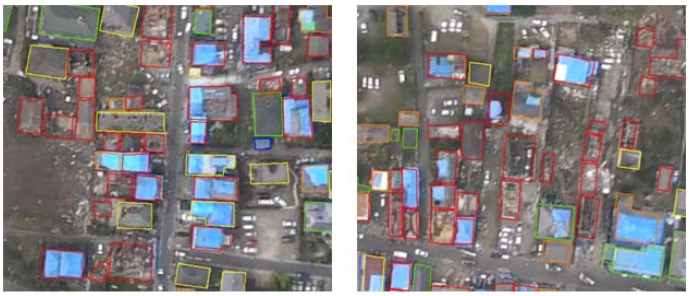

Figure 9 Target areas of heavy-damage in Figure 4

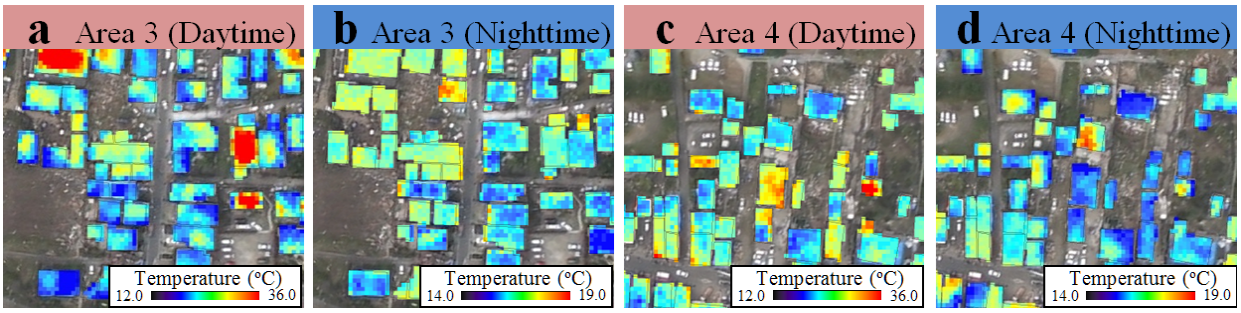

Figure 10 Temperature within building footprints for heavy-damage areas, **a**, **c**: Daytime, **b**, **d**: Nighttime

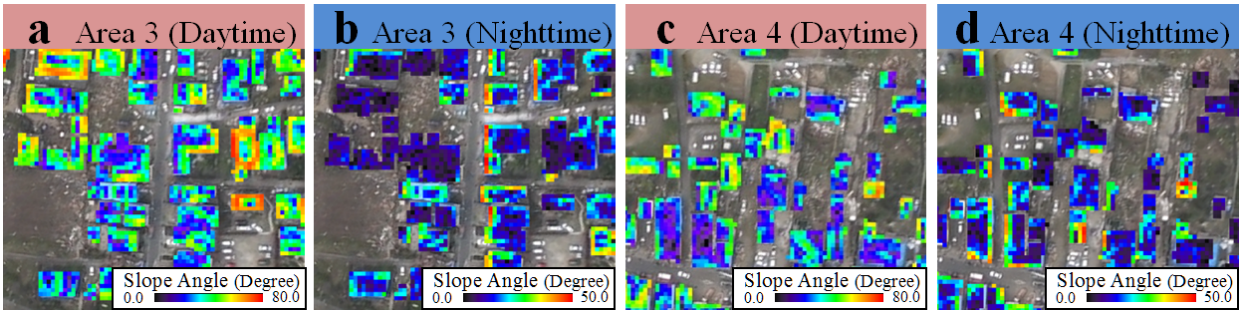

Figure 11 Slope angle of the temperature within building footprints in Figure 10, **a**, **c**: Daytime, **b**, **d**: Nighttime

mixed-pixel (mixel) condition for the low resolution TIR images (1.54 m). This characteristic is remarkable especially for the upper left building group in **Figure 11b**. Most footprint areas show small changes as in dark blue color. It can be seen in the visible image of Area 3 that the spread debris in the area became the similar condition as soil. This kind of debris spread was also observed in our field survey, and hence there is possibility to use this more uniform temperature distribution with the surroundings in early damage detection from TIR images.

4.4 Distribution of Average Temperature within Footprint for Each Damage Level

Figure 12 shows the cumulative distributions of the average temperature within building footprints for each damage level. Here, buildings other than in Hojo district were also counted. From the daytime graph, the average roof temperatures for non-damaged buildings are seen to be widely distributed in the range from 20 to 40 ^{o}C. On the contrary, those for damaged buildings are displayed in a narrower range from 24 to 35 ^{o}C and the range gets small as the damage level gets higher. For collapsed buildings (G5), the average temperature becomes in the range from 25 to 33 ^{o}C. This is because that the roofs were lost and the footprint areas were covered by the mixture of various materials like debris and mud. If we can use a much higher-resolution TIR image, a wider temperature distribution can be seen in more detail. But at this time, the resolution of our TIR images are 1.54 m, and thus most debris became in a mixel condition and the temperature distributions became flat. The histogram for damaged buildings at daytime tends to be in a narrow range and the average values were decreased for 2 or 3 ^{o}C.

From the nighttime graph, the average temperatures for most buildings are seen in narrower ranges, around 17 ^{o}C, compared with the daytime graph, as typically observed for collapsed buildings (G5). The cumulative distributions for damaged buildings at nighttime also tend to be in narrower ranges, the same as the daytime case. This kind of temperature characteristics in aerial TIR images may be used

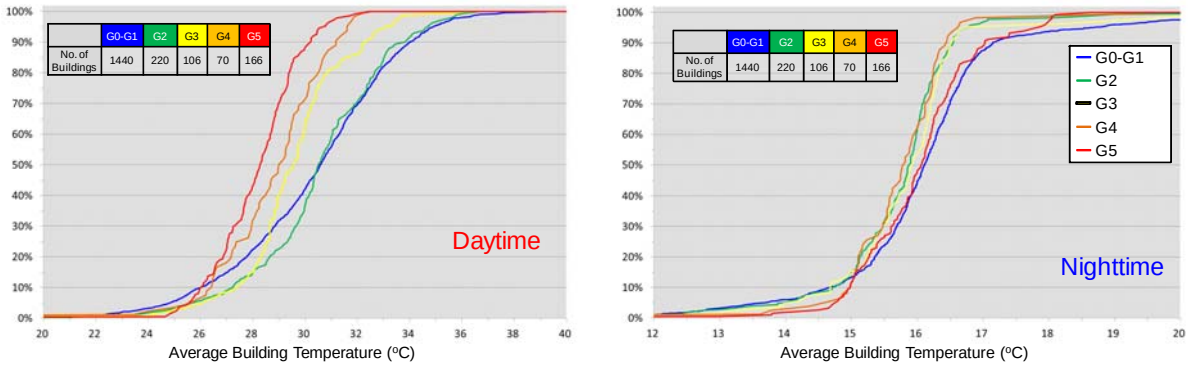

Figure 12 Cumulative distributions of average temperature within footprint for each damage level

in early damage detection in the future although more examples for various conditions should be tested.

5. CONCLUSIONS

In this study, aerial thermal infrared images were used to grasp building damages caused by the tornado that hit Tsukuba City on May 6, 2012. We acquired visible and TIR images over Hojo district of the city from a helicopter two days after the tornado struck. First building footprint data were created manually from the acquired visible image and the existing GIS map. Visual damage inspection was then carried out using the daytime visible image for the hard-hit area. The TIR images were then compared with the result of the damage inspection. The temperature distribution within the footprints was further investigated on a GIS.

From the average temperature distribution within non-damaged and damaged building footprints, non-damaged buildings showed higher temperatures with a larger range than those of damaged buildings. This observation may be explained by the fact that due to the collapse of roofs, the sunlight did not reach the roof locations and thus the temperature there was generally reduced. The change of temperature within each footprint was also evaluated using the slope angle of the temperature. But the slope angle was also strongly affected by the temperature itself, and hence a clear trend was not found.

From the distributions of the average temperature within building footprints for five damage levels, that for the collapsed level was distributed in a narrower range than that for non-damaged one's both at daytime and nighttime. The temperature distribution was seen to become flat as the damage level goes up. This is due to the mixed-pixel of debris and others around the original footprint, especially for the low spatial-resolution TIR images used in this study.

We tested the aerial TIR images after the tornado in this study because TIR imagery can be obtained even at nighttime and thus is possible to reduce "blank time" after a disaster strikes. However, due to the limitation of its spatial resolution, about 1.5 m in the current example, it was not so easy to detect small damage to individual buildings. Another important drawback of TIR imagery is that it is highly affected by the roof material, color and its orientation as well as the surrounding condition and the weather and air-temperature. Hence, more case studies are necessary in the future to utilize aerial TIR imagery for early damage detection after a disaster strike, especially at nighttime.

Abstract: The goal of this presentation is to present work performed recently in Europe to better understand strong ground motions and evaluate epistemic and aleatory uncertainties of ground-motion models. The methodologies used to select and weight empirical ground motion models used to build the new European seismic-hazard map (Shared FP7 project Delavaud et al., 2012) will first be presented. This methodology aims to build a logic tree which capture the epistemic uncertainty related to the prediction of ground-motions in Europe. This analysis has taken into account experts opinions but we also the use of new data-driven selection methods (e.g. Beauval et al., 2012). The random ground-motion-prediction variability of the chosen empirical models strongly influences the seismic hazard curve computation, in particular for long return periods. One of the key challenges of seismology is to be able to calibrate and analyze the physical factors that control the ground-motion variability. In a second part, I then will present new strategies to better understand the controlling factors of this variability. The exponential growth of seismological near-field records provides the opportunity to separate the source, propagation, and site factors controlling the ground-motion variability (Al-Atik et al., 2010; Rodriguez et al., 2011, 2013). Our results suggest that moderate earthquakes are more 'variable' for a given magnitude than large ones. Our data analysis shows that some stations are also showing larger variability ground motion than others, and that ground motion might be more variable at short distances than at large distances. We suggest (Cotton et al., 2013) that the between-event ground-motion variability gives an upper boundary to the earthquake stress-drop variability. This quantification of stress-drop variability offers a new way to calibrate future earthquakes aground-motion simulations.

1. INTRODUCTION

For seismically active areas, the estimation of ground motions is conducted through statistical analyses of existing ground motion data, that is, the development of ground motion prediction equations (GMPE).

Given the large amount of existing ground-motion prediction equations (GMPEs), the selection of the appropriate set of GMPEs capable of reflecting the center, body, and range of observed ground motion in large regions is a major challenge and potential source for unintended differences in hazard estimates between regions. The methodologies used to select and weight empirical ground motion models used to build the new European seismic-hazard map (Shared FP7 project Delavaud et al., 2012) will then be presented. This methodology aims to build a logic tree which captures the epistemic uncertainty related to the prediction of ground-motions in Europe. This analysis has taken into account experts opinions but we also the use of new data-driven selection methods (e.g. Beauval et al., 2012).

The random ground-motion-prediction variability of the chosen empirical models strongly influences the seismic hazard curve computation, in particular for long return periods. In a second part, I then will present new strategies to better understand the controlling factors of this "aleatory" variability. New strong-motions databases provide the opportunity to separate the source, propagation, and site factors controlling the ground-motion variability (Al-Atik et al., 2010; Rodriguez et al., 2011, 2012). We also suggest (Cotton et al., 2012) that the observed between-event ground-motion variability may offer a new way to calibrate future earthquakes and ground-motion simulations.

2. GROUND-MOTION LOGIC TREE FOR PSHA IN EUROPE

A new pan-European compilation of well-calibrated strong- and weak-motion records has first been built. This new database incorporates well-calibrated waveforms from key earthquake databases from other region of the world (to complement the European data coverage in the near-field and high magnitude range).

The Seismic Hazard Harmonization in Europe (SHARE) project, which began in June 2009, aims at establishing new standards for probabilistic seismic hazard assessment in the Euro- Mediterranean region. In this context, a logic tree for ground-motion prediction in Europe has been constructed. Ground-motion prediction équations (GMPEs) and weights have been determined so that the logic tree captures epistemic uncertainty in ground-motion prediction for six different tectonic regimes in Europe. This strategy, described in Delavaud et al. (2012) has the

particularity of combining two complementary and independent approaches: expert judgment and data testing. A set of six experts was asked to weight pre-selected GMPEs while the ability of these GMPEs to predict available data was evaluated with the method of Scherbaum et al. (Bull Seismol Soc Am 99:3234–3247, 2009). Results of both approaches were taken into account to commonly select the smallest set of GMPEs to capture the uncertainty in ground-motion prediction in Europe. For stable continental regions, two models, both from eastern North America, have been selected for shields, and three GMPEs from active shallow crustal regions have been added for continental crust. For subduction zones, four models, all non-European, have been chosen. Finally, for active shallow crustal regions, we selected four models each of them from a different host region but only two of them were kept for long periods. In most cases, a common agreement has been also reached for the weights. In case of divergence, a sensitivity analysis of the weights on the seismic hazard has been conducted, showing that once the GMPEs have been selected, the associated set of weights has a smaller influence on the hazard.

Based on the results of both the expert judgment and the testing, a consensus set of GMPEs was determined for each tectonic regime. Models supported by the empirical data testing and the experts' choices (first category) were selected while the models that were not supported by the data testing and not chosen by the experts (fourth category) have been rejected. For the rest of the models (second and third categories), discussions were held between the experts and ground-motion modeling group to decide on their rejection or selection. Weights were also determined but different propositions were retained for sensitivity analyses.

This task involved roughly a dozen institutions with the goal, in a limited amount of time (18 months), to commonly define a logic tree that would capture the center, body, and range of ground motion.T he principal idea that guided our strategy was to gather as much knowledge as possible from independent sources and different methods. Based on the characteristics of the available GMPEs determined by Douglas (2011), we first identified the best candidates using the rejection criteria of Cotton et al. (2006) and Bommer et al. (2010). Afterward, expert judgment highlighted the sets of GMPEs that were, according to the experts, capable of capturing epistemic uncertainties, while testing using observational data showed GMPEs capable of closely predicting past ground motions.

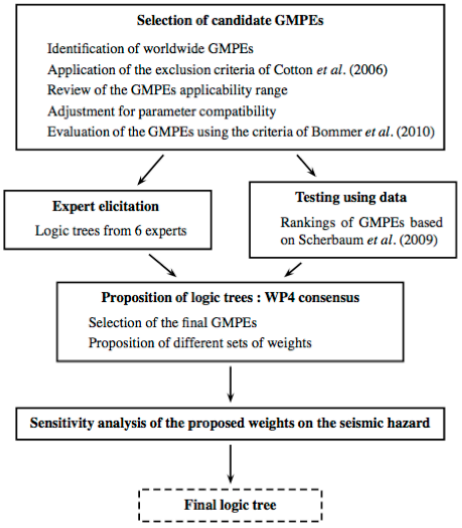

Figure 1. Methods used to capture epistemic uncertainties of GMPE's: expert elicitation and data-testing. Adapted from Delavaud et al. (2012)

From this experience, we have learnt lessons and identified weaknesses in our methodology. First, a great effort should be dedicated to the collection of data and meta-data in order to get as much information as possible from the GMPE testing. In our case, data were not sufficient to cover the center, body, and range of ground motions in Europe. Secondly, the procedure for the selection and weighting of GMPEs by experts should be clearly defined. Within the SHARE project, most experts required more guidance and information (e.g., What do weights represent? How will they be used afterward?). Selecting GMPEs and assigning weights is still not an obvious task, although Scherbaum and Kühn (2011) have recently proposed a method. To build a logic tree is not to give a quality measure to each candidate GMPE independently from the others but rather to identify the set of models that together, with a certain weighting, can capture the perceived epistemic uncertainty. In the context of the SHARE project that covers a large area, the set of GMPEs had to be the smallest one. The robustness of the proposed logic tree is a crucial property. For ASCR, the SHARE GMPE selection is in agreement with the data testing of Delavaud et al. (2012) who used an independent dataset to rank candidate GMPEs for Europe and Middle East. Regular updates of the logic tree should be planned to take new data and new GMPEs into account

2. TOWARD BETTER ESTIMATION OF GROUND-MOTION VARIBILITY (sigma).

2.1 Can sigma be reduced ?

With the aim of assessing the seismic hazard at a given site, one of the key steps includes the assessment of the ground motion expected from a future earthquake. For this, most seismic hazard studies make use of ground motion models (GMPEs), derived from existing seismic motion databases. In this framework, the random variability associated to the ground motion predictions ("sigma")

strongly influences the seismic hazard curve computation, in particular for long return periods.

Over the past 40 years, despite an increase in the number of available records, an improvement of processing tools and the increased complexity of the equations, the values of « sigma » have remained and the source, propagation, or site factors controlling sigma are still poorly understood. Since the GMPEs are derived using data recorded on multiple sites during earthquakes generated from different seismic sources, the difficulty lies on quantifying the influence of individual components on the overall uncertainty.

In traditional Probabilistic Seismic Hazard Assessment (PSHA), the underlying assumption is that the ground-motion uncertainty computed by a GMPE from a global data set (e.g., a dataset that includes various sites and various earthquakes from multiple sources) is the same as the variability at a single site. This is known as the "ergodic" assumption. For site-specific PSHA, additional information on site response can be used to improve the prediction of the GMPE at the site. In this case, the ergodic sigma must also be reduced to reflect this additional information. This reduction can only be accomplished with an adequate understanding of the factors that control ground motion variability.

Given the recent improvements in the number of available good quality ground motion recordings, and in particular the increased number of well recorded ground motions available at single sites from multiple occurrence of earthquakes in the same region, the possibility of removing (partially or fully) the ergodic assumption from the hazard assessment practice, and therefore of reducing the variability of ground motion, has become more and more concrete, at least in some areas of the world. Recently, much research has been devoted to the comparison between the "sigma" associated to ground motions from regional GMPEs based on regressions over large databases and either, the "sigma" associated to a given seismic station ("single station sigma") or the "sigma" associated to an individual seismic source ("single source sigma"). The main conclusion of these studies is that the sigma related to an individual seismic station is, for most stations, smaller than the one associated to the overall database. [e.g. Atkinson 2006, Rodriguez-Marek et al. 2011].

These results are highly motivating since they show that sigma values may be refined and that we now have the opportunity to understand the physical factors that control ground-motions variabilities. Ground-motion variability is usually divided into between-events variability and within-event variability. The presentation will describe and discuss some recent results and analysis performed on these two variability components.

2.2 Evaluation of the within-event (site-corrected) variability using data from various tectonic régions

The mean ground-motion residual at a station represents the site term. Quantification of site terms permits a more elaborate treatment of the ground motion uncertainty: the within-event component is split into a site-to-site and an event and site corrected (PhiSS) components.

In a recent study (Rodriguez-Marek et al., 2013) we estimate the PhiSS for five databases from different regions worldwide (California, Switzerland, Taiwan, Turkey, and Japan). We investigate the potential dependency of PhiSS on region, Vs30, distance and magnitude. The results show that the variability of PhiSS across the different regions is small when compared with the within-event standard deviation. In other words the variability in the ergodic among regions is significantly larger than the variability of among regions. This is one of the most striking results of this study: the value of single-station sigma (within appears to be largely region-independent. The average value of PhiSS is 0.45, with relatively small variation across spectral periods. The values of PhisSS show no specific trend with Vs30. Records at shorter distance show a higher PhiSS value; however, there is a potential that this is due to the scarcity of data at shorter distances. We observe (Rodriguez et al;, 2013) that PhiSS are larger for smaller magnitude earthquakes. This trend mimics the trend observed for the ergodic in various GMPEs. The larger values for small magnitudes can also be a reflection of a poorer constrain of metadata for these earthquakes, or can be due to the lack of data at larger magnitudes.

Estimates of single station sigma show considerable variability in the values of single-station sigma at different stations, and, in particular, that some stations are more variable then others. Investigation on the physical causes (e.g. geology, geophysics parameters) of such a large variability is actually carried out using simulations. Preliminary results (Maufroy et al., in preparation) show that topographic effects may play an important role to explain these larger values.

2.3. Between-event variability and sigma of stress-drop

Stress drop is a fundamental parameter in the description of earthquake source scaling properties. As we use ground-motion simulations to guide our understanding of earthquake hazard, it is imperative to know what standard deviation (sigma) should be used for the stress drop distribution. The ground-motion simulations should certainly not use a distribution with a sigma larger than is necessary.

The between-events residual represents average source effects (averaged over all azimuths) and reflects the influence of factors such as stress drop and variation of slip in space and time that are not captured by the inclusion of magnitude, style of faulting, and source depth.Two points confirm the link between stress-drop and between-event ground-motion variability. The between-events variability decreases when magnitude increases. This could be due to a higher stress drop variability of small earthquakes as suggested by Oth et al. (2010) or a reduced quality of the characterization (depth, distance, magnitude) of small earthquakes. Moreover the between-event variability is smaller for datasets that include earthquakes of a similar tectonic region, which also suggest a stress-drop control.

Using the theory of stationary Gaussian random functions and a simple source Brune's model we then have shown in a recent paper (Cotton et al., 2013) that there is proportionality between PGA and the stress-drop. According to this relation, the observed between-event PGA variability is a way to evaluate an upper bound of the stress-drop variability for a given region.

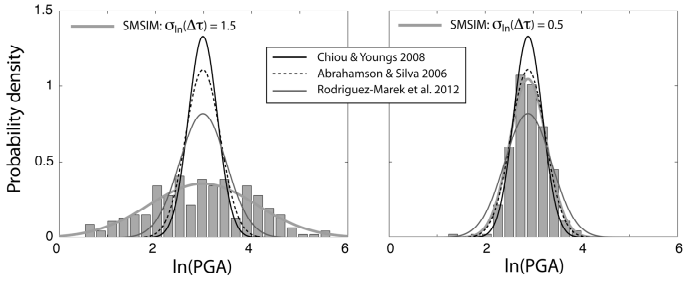

Figure 2. The result of computing PGA with two different values of variability on the natural log of stress drop. Histograms are from 200 runs with a lognormal distribution of stress drop with sigma of 1.5 (typical value from seismic results) and 0.5 (typical value inferred from GMPEs). As expected the GMPE's produce a good fit to the histogram because the inferred sigma (see text) was deduced from the GMPEs. Adapted from Cotton et al. (2013)

We show that stress-drop variability derived from the observed between-event ground-motion variability is much lower than those derived from source parameter studies, i,e., those based on corner frequency analysis. The variability of the stress drop analyzed trough source studies has always about a factor of 10-30 around the mean. We show that the standard deviation (sigma) of seismically determined stress drops is about 3-4 times larger than the sigma of the inferred stress drop based on ground motion prediction equations (GMPEs). This inconsistency does not make sense. Is the seismically derived variability real, or is it a consequence of the method for determining the stress drop? We suggest that stress-drop, determined by corner frequency, has greater uncertainty than that implied by the ground-motion data.

3. CONCLUSIONS

Recent improvements in the number of available good quality ground motion recordings allow to reduce the epistemic uncertainty of ground-motion models and refine the ground-motion aleatory variability.

To complement the expert opinions, testing of the candidate GMPEs against empirical data provides key informations to evaluate the applicability of candidate models by evaluating their probability to have generated the available data. Expert judgment and data testing are complementary and independent approaches that have been adopted to build the ground-motion logic tree used to define the new PSHA map of Europe (SHARE-GEM project).

The amazing quality of new networks and datasets (e.g. Knet and Kiknet networks in Japan) gives also the unique opportunity to identify the components of ground motion variability at a single site that are repeatable rather than purely random (e.g. the site response), so these can be removed from the aleatory variability and transferred to the quantification of epistemic uncertainty. Our results suggest that moderate earthquakes are more 'variable' for a given magnitude than large ones. Our data analysis shows that some stations are also showing larger variability ground motion than others, and that ground motion might be more variable at short distances than at large distances. We suggest (Cotton et al., 2013) that the between-event ground-motion variability gives an upper boundary to the earthquake stress-drop variability.

A better knowledge of ground-motion variability is then critical both for empirical ground-motions model developments (e.g. GMPE's) but also help to calibrate the variability of key simulations parameters (e.g. stress-drop).

ESTIMATION OF MEGA-EARTHQUAKES SOURCE MODELS FOR STRONG MOTION PREDICTION: APPLICATION FOR CENTRAL ANDES

Nelson Pulido

Senior Researcher, National Research Institute for Earth Science and Disaster Prevention, Japan. nelson@bosai.go.jp

Abstract: The recent 2011 Tohoku-oki earthquake occurred in a region where giant megathrust earthquakes were not expected. This earthquake proved the difficulty to assess seismic hazard mainly based on information from historical earthquakes. In this study we propose a methodology to estimate the slip distribution of megathrust earthquakes based on a model of interseismic coupling (ISC) distribution in subduction margins as well as information of historical earthquakes, and apply the method to the Central Andes region in Peru. The slip model obtained from geodetic data represents the large scale features of asperities within the megathrust, which is appropriate for simulation of long period waves and tsunami modelling. For the simulation of a broadband strong ground motion it becomes necessary to introduce small scale heterogeneities to the source slip to be able to simulate high frequency ground motions. To achieve this purpose we propose "broadband" source models constructed by adding the slip model inferred from the geodetic data, and short wavelength slip distributions obtained from a Von Karman PSD function with random phases. Using these slip models and assuming several hypocenter locations we calculate a set of strong ground motions within Lima and incorporate site effects obtained from microtremors array surveys.

1. INTRODUCTION

Recent mega-earthquakes in Sumatra (2004), Chile (2010) and Japan (2011) have highlighted the enormous hazard associated with these giant subduction events. In particular the 2011 Tohoku-oki earthquake proved the difficulty to assess seismic hazard mainly based on information from historical earthquakes. Due to the limited span of earthquake catalogues, other source of information such as geological or geodetic data might be considered for hazard assessment of future mega-earthquakes. In recent years the development of GPS and SAR interferometry is making possible to measure the strain build up associated with plate convergence in many earthquake prone regions around the world (Chlieh et al., 2008, and Perfettini et al. 2010). Recent studies have suggested that subducting plates are either locked or creeping aseismically, and that a patchwork of locked or coupled regions during the interseismic period may be related with asperities of earthquakes (Moreno et al. 2010). In this study we propose a methodology for seismic hazard estimation of megathrust earthquakes based on a model of interseismic coupling (ISC) distribution of subduction zones as well as information of historical earthquakes, and apply the method to the Central Andes region in Peru. Central Peru, North of the Nazca ridge, has been repeatedly affected by large earthquakes such as the 28 October 1746 which is reportedly the worst earthquake Lima has experienced since its foundation. Intensity reports as well as a tsunami record suggest a moment magnitude of ~8.8 for this earthquake (Dorbath et al. 1990). The 1746 earthquake was followed by a long period of quiescence until a sequence of magnitude 7-8 earthquakes in the 20th century starting with the 1940 earthquake up to the M8.1 Pisco earthquake in 2007 (Sladen et al., 2010) (Figure 1A). We use this information combined with an interseismic coupling model of Central Andes to elaborate a scenario for a megathrust earthquake that could likely affect the Lima metropolitan region.

2. SCENARIO EARTHQUAKES

2.1 Interseismic coupling (ISC and scenario earthquake

A model of interseismic coupling (ISC) for Central Andes (Chlieh et al 2011) indicates the existence of two strongly coupled regions, the first one off-shore Lima and the second one off-shore Pisco city (Figure 1B). Assuming an interseismic period of 265 years since the last megathrust earthquake that stroke Central Andes in 1746, up to 2010, we obtained a slip deficit equivalent to an earthquake with a moment magnitude of 8.9 (Figure 1C).

2.2 Broadband slip scenario earthquake

The geodetic slip model (GSM) obtained from the ISC, has a maximum slip of approximately 15 m, the source dimensions are approximately 500 km along strike and 160 km along dip, and the grid spacing is 20 km (Figure 2A). The moment magnitude, calculated using a rigidity of 39GPa is 8.9. The GSM is characterized by a smooth distribution of asperities (Figure 2A). This model is appropriate for the simulation of long period seismic waves

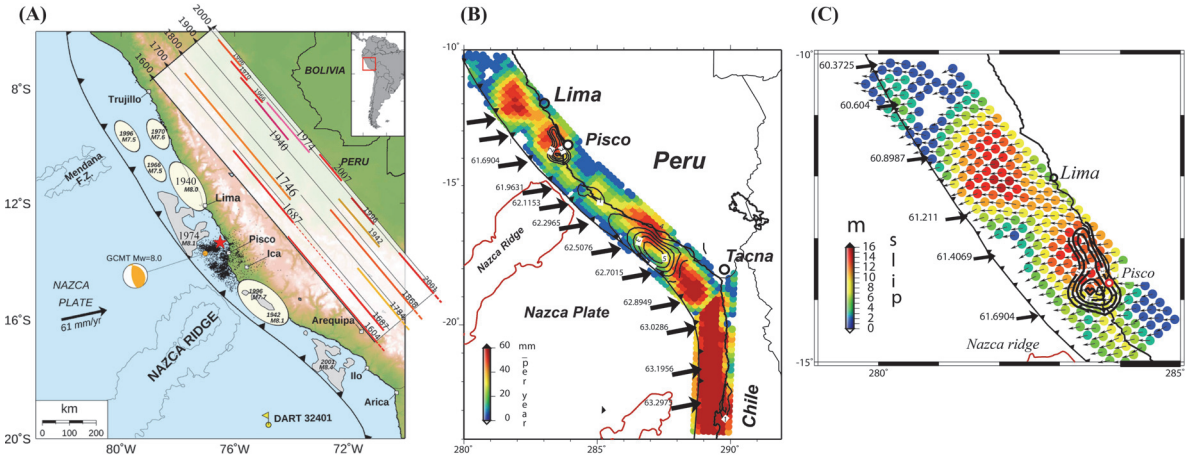

Figure 1. A) Historical earthquakes along the Nazca subduction zone in Peru (Sladen et al. 2010). B) Slip deficit rate model in Peru and northern Chile obtained from geodetic measurements (Chlieh et al. 2010). C) Slip distribution of a scenario earthquake for the subduction zone off-Lima, obtained by combining the slip deficit rate in (B) with an interseismic period of 265 years since the 1746 earthquake. The slip contours of the 2007 Pisco earthquake are shown in black

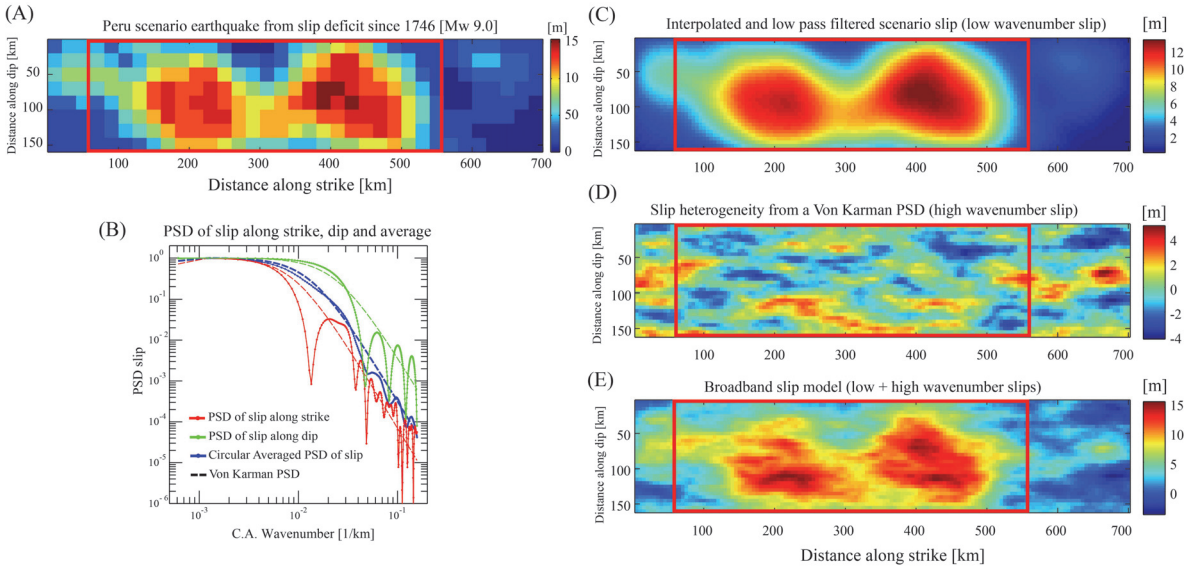

Figure 2 A) Slip distribution of the Central Andes scenario earthquake from ISC model. B) PSD of slip along strike (red), dip (green) and circular average (blue). Dashed lines correspond to the best fit Von Karman PSD function to the PSD of slip. C) Interpolated (to a 5 km grid spacing) and low-pass wavenumber filtered slip in A). Red boxes indicate the assumed source area for the slip scenarios.

as well as for tsunami modelling. However for the simulation of a broadband strong ground motion it becomes necessary to introduce small scale complexities to the source slip to be able to simulate high frequency ground motions. To achieve this purpose we propose a "broadband" source model in which large scale features of the model are constructed from the GSM, and the short wavelength slip distribution is obtained from spatially correlated random noise. To obtain the parameters of this short wavelength slip we first calculate the power spectrum density (PSD) of our GSM, along the strike and dip directions (red and green lines in Figure 2B), as well as for a circular average (blue line in Figure 2B), and then fit a Von Karman PSD function to the observed spectra,

$$P(k_s, k_d) = \frac{k_s k_d}{\left[1 + a_s^2 k_s^2 + a_d^2 k_d^2\right]^{H+1}} \qquad (1)$$

where k_s and k_d are wavenumbers along strike and dip, a_s and a_d are the autocorrelation distances along strike and dip, and H is the Hurst exponent defining the spectral decay. Our fit to the PSD of the GSM yielded values of 110 km^{-1}, 40 km^{-1}, and 1 for a_s, a_d and H respectively (dashed lines in Figure 2B). To calculate a "broadband" slip we first interpolate the original GSM to a smaller grid interval, and apply a low-pass filter for wavenumbers smaller than a crossover wavenumber (k_{cross}) equal to 0.05, to get a long wavelength slip distribution (Figure 2C). Then we generate a correlated random slip model by using the aforementioned Von Karman PSD function (eq. No.1) using a random phase,

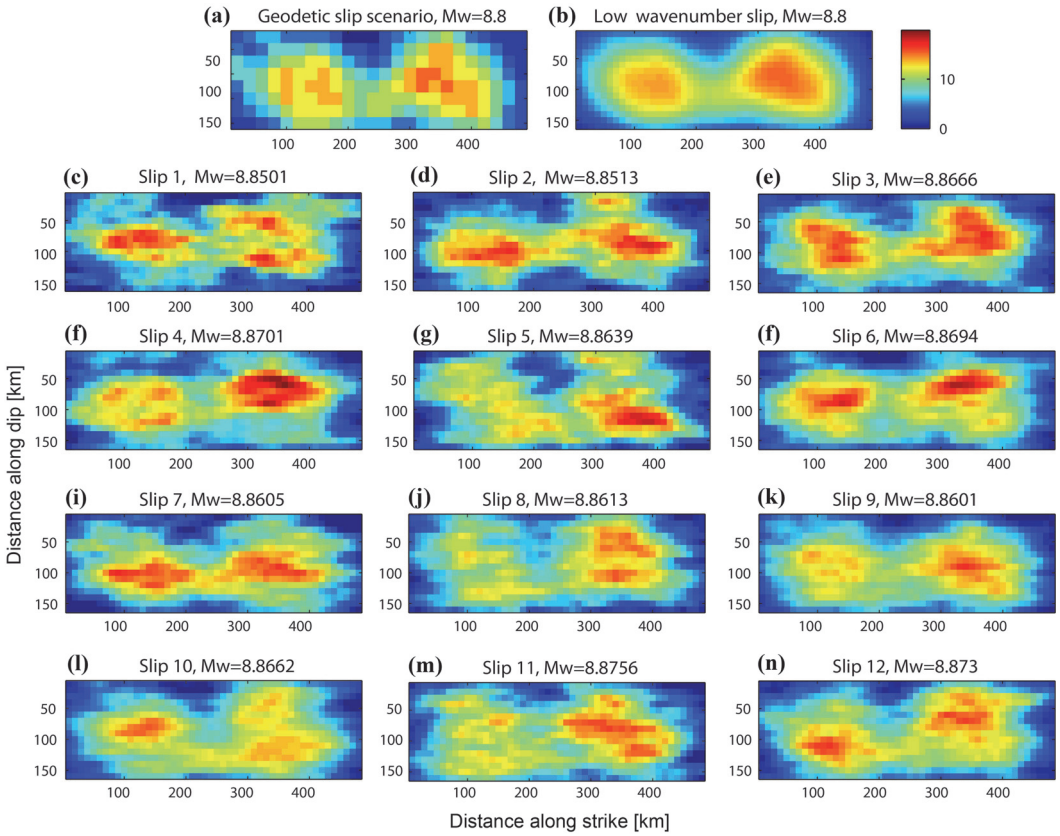

Figure 3 a) Slip scenario obtained from ISC model. b) Interpolated and low-pass wavenumber filtered slip model in a). c) to n) Broadband slip scenarios for 12 random realizations of short wavelength slip.

and apply a high-pass filter for wavenumbers above k_{cross} (Figure 2D). Finally we add the long and short wavelength slips to get a broadband wavelength slip (Figure 2E). The k_{cross} value was selected to approximately correspond to the size of the long wavelength asperity (125 km) (Figure 2C), which is about 5 times the corner wavenumber of GSM.

2.3 Broadband slip realizations

In order to obtain several broadband slips to be used for the strong motion simulations in Central Andes region, we compute a number of short wavelength slip models realizations. For this purpose we generate 12 sets of normally distributed random numbers with mean 0 and standard deviation 1 for the same source area used for the GSM, calculate their FFT in the wavenumber domain along strike and dip, multiply their spectral amplitude by the square root of the Von Karman PSD function of slip (eq. 1), and get them back to the spatial domain. We finally obtained 12 broadband slip realizations (Figures 3c to 3n). For the Central Andes strong motion simulations we have selected a subfault size of 10km.

3. STRONG MOTION SIMULATIONS

3.1 Strong motion simulation

To perform the strong motion simulations we follow the finite fault hybrid method of Pulido and Kubo (2004), and use the 12 broadband slip source models obtained previously. We assumed 9 different locations of starting points of the rupture (Figure 4A). Main parameters for the simulations are the stress drop, moment and rise time distributions across the fault plane, as well as the rupture velocity. We calculated the stress drop distributions for all the broadband slips following Ripperger and Mai. (2004). Rise times of subfaults are assumed to be proportional to the square root of slip. The rupture velocity is assumed to be 72% of the average S-wave velocity at the source, and we added a 5% fluctuation to enhance high frequency radiation. Maximum frequency f_{max} is set to 10Hz , and we use a Q value obtained for the Lima region ($Q=80f^{0.63}$) (Quispe, 2011). For the simulation of low frequency waveforms we used a 1D velocity model obtained for the Lima region (Dorbath et al. 1991). The simulation domain covers all Lima metropolitan region, spanning an area of 50 km by 55 km (white rectangle in Figure 4A), and a grid spacing of 5 km. We calculated the ew, ns and ud components of broadband frequency strong ground motions at every grid point (169 points) for a seismic bedrock condition (Vs=3454 m/s), for all slip models and assumed hypocenters. This yielded a total of 108 fault rupture scenarios and more than 50 thousand synthetic accelerograms. We added site amplifications up to the engineering bedrock (~400 m/s) by performing the convolution between the seismic bedrock waveforms with the soil transfer functions at every grid point. Site amplifications were obtained from 8 array microtremors surveys performed at representative geotechnical zones within Lima. (Calderón et al., 2012). In order to include soil amplifications for the shallowest soil we used an empirical

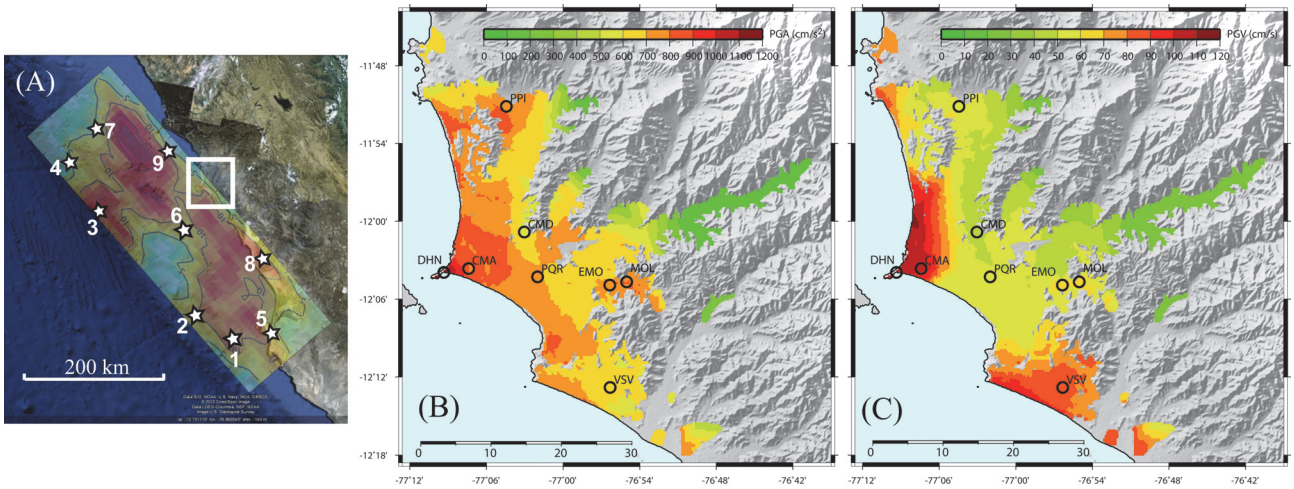

Figure 4 A) Scenario slip No.5 (Figure. 3g) and all assumed hypocenter locations for the rupture scenarios (stars). The simulation region in Lima is indicated by a white rectangle. B) Average of simulated PGA distributions in Lima for slip No.5 and all assumed hypocenters in A). These results include soil amplification. C) Same as A) but for the simulated PGV.

equation relating the soil amplification and the average S-wave velocity for the shallowest 10m of soil (Vs10) (Calderón, 2012). This information allowed us to calculate the PGA and PGV values at a grid spacing of approximately 250m.

3.3 Strong motion simulation results in Lima

In Figures 4B and 4C we can observe the PGA and PGV distributions for the slip model that yielded the largest ground motion amplitudes among the 12 broadband slip models considered (slip No.5, Figure 3g), averaged for all assumed rupture starting points scenarios. We can observe that the largest values of PGA are above 1000 cm/s^2 at Callao, La Punta (DHN). Large values of PGA were also obtained in Puente Piedra Province (800 cm/s^2) (PPI). These large values of PGA are closely related with the large amplifications for the shallower soil at these sites. The PGV distribution on the other hand displays the largest values for Callao (above 100 cm/s), followed by large PGV values in Villa El Salvador district (above 80 cm/s) (VSV). These large values of PGV are also closely related with the very large soil amplifications observed at Callao for periods around 1s, and at Villa El Salvador for periods around 0.8s to 1.5s (Calderon et al. 2012).

3.4 Comparison with records from the 1974 and 1966 earthquakes

The damaging earthquakes of 1966 (Mw8.0) and 1974 (Mw8.0) that occurred in the subduction zone off-shore Lima (Figure. 1a) were recorded by a strong motion station at Parque de la Reserva (PQR) in central Lima (Figure 4). At the same location we calculated broadband strong motions for all scenarios, by including site amplifications obtained from results of a microtremor array survey at this site (Calderon et al. 2012). In Figure 5A we may observe several simulated accelerograms at PQR in blue colors, and the observed strong motion records during the 1974 earthquake (red) and 1966 earthquake (orange) for the NS component. In dark blue we display the simulated accelerogram obtained from slip No. 5 and hypocenter No.1. This scenario generates a PGA at PQR similar to the average value of PGA for slip No. 5 (Figure 4B). The waveform in blue corresponds to slip No.7 and hypocenter No.1, which generates a PGA value comparable to the average PGA for all 108 rupture scenarios considered in this study. The waveform in light blue corresponds to the previous scenario but for a seismic bedrock outcrop condition. We can observe that the PGA amplitudes of the scenarios are about 2~3 times larger than the values observed at PQR during the 1966 and 1974 earthquakes. We can also observe that the simulated PGA values for a seismic bedrock outcrop condition (Figure 5A, 5B, light blue), are about 2~3 times smaller than the simulations that incorporate site amplifications (Figure 5A, 5B, blue). A similar observation can be made from the comparison of simulated and observed PGV amplitudes at PQR (Figure 5B).

In Figure 6A and 6B we can observe the acceleration and velocity response spectra for all the waveforms detailed in Figure 5. Here we can observe that the spectral amplitudes of the simulated waveforms are as large as 4 times the values observed during the 1974 and 1966 earthquakes at PQR. Another interesting feature is that all the simulated spectra for our scenarios at PQR have a large spectral peak at a period around 0.35s, which is also a clear feature of the observed acceleration and velocity spectra from the 1974 and 1966 earthquakes (Figure 6A and 6B). These results and the observation of a large amplification at this period in the transfer function at PQR (Calderon et al. 2012), strongly suggest that this large spectral peak is due to site effects. Other interesting feature can be observed at the velocity response spectra for periods longer than 5s. At this range the spectral amplitudes for all scenarios are similar, which may suggest that they might be largely influenced by the source characteristics, as the soil transfer function at PQR above 5s displays no amplification (Calderon et al. 2012)

3. CONCLUSIONS

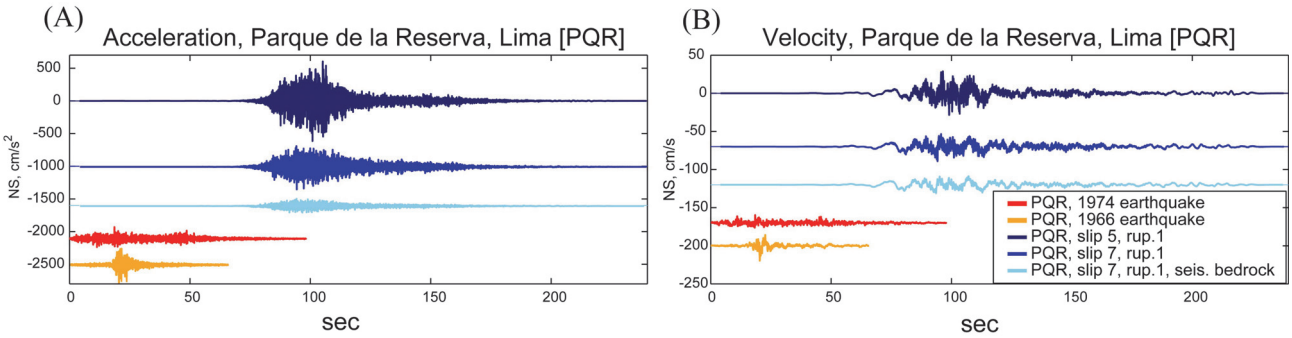

Figure 5 A) Simulated accelerograms at PQR, for slip No.5 and hypocenter No.1 (dark blue), slip No.7 and hypocenter No.1 (blue), and slip No.7 and hypocenter No.1 for a seismic bedrock soil condition (light blue). The accelerograms in red and orange correspond to records at PQR from the 1974 and 1966 Lima earthquakes. B) Same as in A) but for velocity.

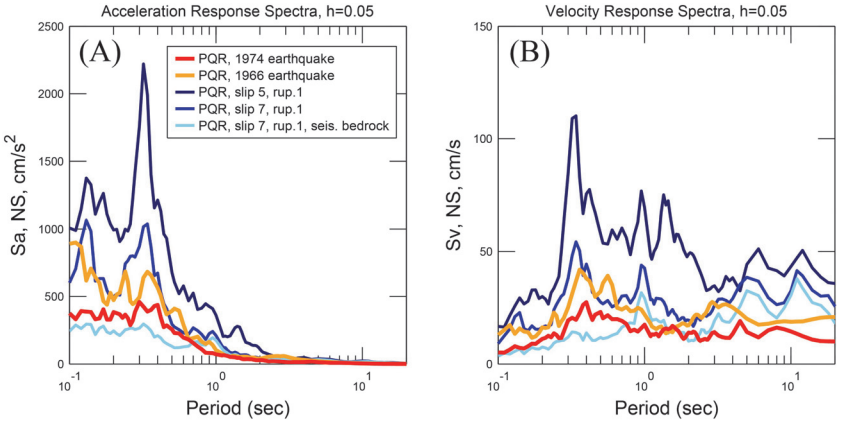

Figure. 6 A) Acceleration response spectra of the simulated NS accelerograms at PQR, for slip No.5 and hypocenter No.1 (dark blue), slip No.7 and hypocenter No.1 (blue), and slip No.7 and hypocenter No.1 for a seismic bedrock soil condition (light blue). The response spectra in red and orange correspond to records at PQR from the 1974 and 1966 Lima earthquakes. B) Same as in A) but for velocity response spectra.

We have developed a methodology for the estimation of slip scenarios for a future megathrust earthquake originated from the convergence between the Nazca plate and the South American plate. This methodology is based on estimations of interseismic coupling at the megathrust obtained from space geodesy measurements as well as information of historical earthquakes.

Our results show that the Central Andes region in Peru has the potential of generating an earthquake with moment magnitude of 8.9, a peak slip of 15 m and a source area of approximately 500 km along strike and 165 km along dip. We constructed 12 broadband slip source scenarios by adding this long wavelength slip model obtained from geodetic data, with 12 short wavelength slips obtained from a Von Karman PSD function of slip. We calculated the EW, NS and UD components of strong ground motions at Lima for the 12 scenario slips by including 9 possible hypocenter locations for each slip model. Our simulations incorporate site amplifications obtained by microtremors array surveys conducted at the representative geotechnical zones in metropolitan Lima as well as site amplifications based on the average of S-waves for the shallowest 10m of soil. Our simulation results display values of PGA and PGV above 1000 cm/s^2 and 80 cm/s in Lima, for the slip model producing the largest ground motions averaged for all hypocenters locations. Our results indicate that the simulated PGA and PGV in Lima are in average 2~3 times larger than the values observed in PQR, central Lima, during the 1974 and 1966 earthquakes. The observed records and our simulations at PQR indicate a large short period site amplification at 0.35s. Simulated spectral values at PQR at this period are as large as 4 times the values observed during the 1974 and 1966 earthquakes.

Abstract: The probability for MeiShan fault in Taiwan to generate an earthquake of magnitude 7.1 is 9.75% within next 10 years as reported in 2010. Applying empirical Green's function (EGF) method, the forward analysis was adopted to synthesize the observed motion of target event and in this study, the target event that we synthesized is MeiShan earthquake (Mw= 5.85) which occurred on Oct. 22, 1999 using the small event (Mw= 4.05) of the main fault occurred on Oct.28 1999. The results show that EGF method can simulate the observed motions at the rock site (CHY41) very well, while the agreement is not so good for the alluvium site (CHY38 and others). For the nonlinear responses of a three-degree-of-freedom model considered, the synthesized motions render smaller responses than the observed motions and the spike in the ground motion seems to affect the displacement significantly.

1. INTRODUCTION

An accurate broadband scenario earthquake motions for a target city or region is of primary importance to develop effective countermeasures to reduce its future earthquake damages. Through years, the methods proposed can be classified into three categories: theoretical Green's function method, empirical Green's function method and empirical method basing on statistical information. Although the numerical computation of 3D theoretical Green's function using computer has been developed, the inability to obtain enough geophysical and geotechnical properties along the path of wave propagation from source to site makes the application of theoretical Green's function method difficult. On the other hand, the empirical Green's function (EGF) method proposed by Hartzell (1978) uses the small earthquakes as Green's function to synthesize large earthquakes. Revisions have been made by Irikura (1983,1986) and others. The advantages of EGF method are that the effects of propagation path and local site conditions are included and the broadband estimation of strong ground motions can be made as long as the small earthquake records from aftershocks exhibit the accurate broadband frequency range. As a result, the EGF method now becomes a popular approach for generating the scenario earthquakes.

In Taiwan, MeiShan fault is located in the Chiayi County and passes through the campus of National Chung-Cheng University. In 1906 this fault generated an earthquake of magnitude 7.1 which killed more than 1000 people. On January 21, 2010, The National Science Council of Taiwan announced that the probability for this fault to generate an earthquake of magnitude 7.1 is 9.75% within next 10 years and 44.92% within next 50 years. Thus, the generation of scenario earthquake motions over Chiayi area from MeiShan fault becomes a critical task. In this paper the EGF method obeying an ω^{-2} spectral scaling is adopted to simulate the main target event of MeiShan earthquake (Mw= 5.85) occurred on Oct. 22, 1999 using the aftershock (Mw= 4.05) records occurred on Oct.24 1999 as empirical Green's function. The comparisons of the observed and synthesized motions will also be made using the nonlinear responses of a three-story reinforced concrete building.

2. EMPIRICAL GREEN'S FUNCTION METHOD

For EGF method used this study we adopted the formulation by Irikura (1986) which is based on a scaling law of fault parameters for large and small events (Kanamori and Anderson, 1975) and the ω^{-2} source spectra (Aki, 1967). The fault of target event is divided into some subfaults first, and each subfault is deemed as a point source (Fig. 1). For EGF method the record of small event such as foreshock or aftershock which occurred in the area of the main fault is treated as the waveform for each subfault, known as empirical Green's function, and is then stacked to simulate the waveform generated by the main fault, as shown in Eq. (1).

$$U(t) = \sum_{i=1}^{N} \sum_{j=1}^{N} \frac{r}{r_{ij}} \{F(t) * (C \cdot u(t))\} \qquad (1)$$

where U(t) is the synthesized waveform for the large event, F(t) a filtering function to adjust a difference in slip time function between the large event and small event, u(t) the waveform of small earthquake, r is the hypocentral distance of the small earthquake and r_{ij} is the distance from each subfault to the site, C the ratio of stress drop between target and small events, N the source dimension of target event and small event and * the convolution. The values of C and N are obtained from Eqs. (2) and (3).

$$N = \sqrt{\frac{U_0}{u_0} \cdot \frac{a_0}{A_0}} \qquad (2)$$

$$C = \frac{1}{N}\frac{A_0}{a_0} \qquad (3)$$

where U_0 and u_0 are the constant levels of amplitude of the displacement spectra of large and small events, respectively, and A_0 and a_0 the constant levels of amplitude of the acceleration spectra of large and small events, respectively. Figure 2 is the illustration of spectral ratios of target and small events.

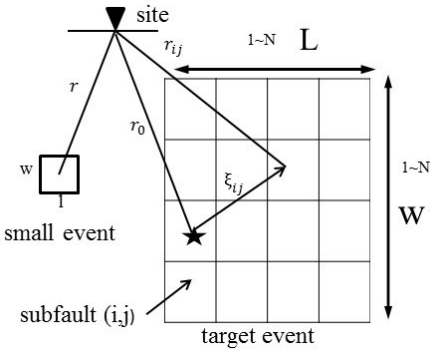

Figure 1 Geometric Relation between Fault and Observation Site

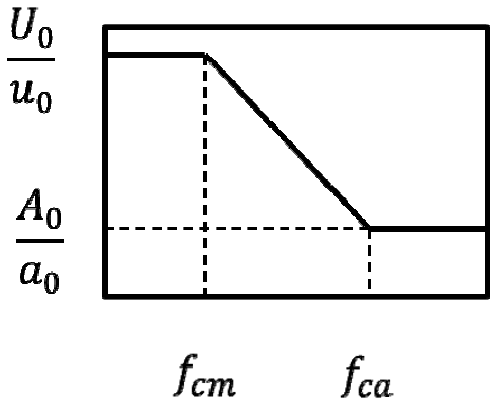

Figure 2 Illustration of Spectra Ratio of Target and Small Events

For F(t) we chose the form by Nakamura et al. given in the recipe issued by The Headquarters for Earthquake Research, Japan (2008), as shown in Fig. 3, and the interested readers can refer to that reference for the detailed formulation of this slip-velocity time function and the definition of the relevant parameters.

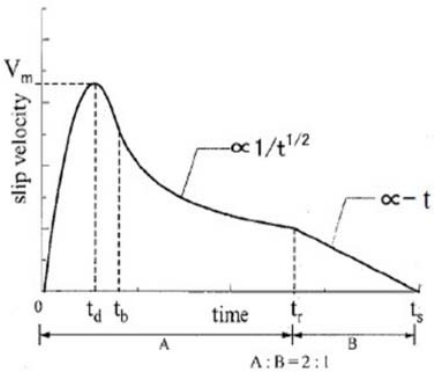

Figure 3 Slip-velocity time function (from recipe)

3. SYNTHESIS OF GROUND MOTIONS FOR 1999 MeiShan earthquake

In this study, the target event that we simulated is MeiShan earthquake (Mw= 5.85) which occurred on Oct. 22, 1999 and the small event (Mw= 4.05) of the main fault occurred on Oct.24 1999 was used as the empirical Green's function. In this study four stations labeled as CHY 09, CHY38, CHY39 and CHY 41 were selected where only CHY 41 can be classified as rock site and Fig. 4 shows the locations of these stations relative to the epicenter of the earthquake. In the syntheses of motions of main event, the forward analysis was conducted for the EW component of the records for a frequency range between 0.2Hz and 10Hz and the fault mechanism is the one which can render good agreement for the waveforms of all stations. The C and N values obtained using Eqs. (2) and (3) from the data set are 1.02 and 8, respectively. Additional parameters used for the synthesis are depicted in Table 1. In this paper the discussions will be given only for CHY38 and CHY41.

Figure 4 Locations of Stations Considered in Synthesizing the Main Events

Table 1 Parameters Used for the Synthesis

length:	9.6 km
width:	9.6 km
dip angle:	68.03°
rake angle:	71.16°
strike angle:	356.56°
Stress drop (average)	2.08E+06 Pa
Stress drop (background)	0.75E+06 Pa
Stress drop (asperity)	1.42E+07 Pa

Figure 5 and Figure 6 show the waveforms of small events for CHY 038 and CHY 041, respectively. Based on the several trials, the final fault model adopted is as shown in Fig. 7 where the black region is treated as inactive region which is based on the observation that most of the aftershocks occurred on the left side and the red star and colored region are the hypocenter and asperity. Shown in Figures 8 and 9 are the observed waveforms, synthesized waveforms and their Fourier amplitude spectra, respectively. From Figure 8, it can be seen that the agreement between the observed and synthesized motions at CHY41 are good. From Figure 9, the large spike in the observed motion at CHY38 can not be reproduced in the synthesized motion; however, if we neglect this, the waveforms of the observed and synthesized motions are basically similar and that maybe the reason why their Fourier amplitude spectra agree well.

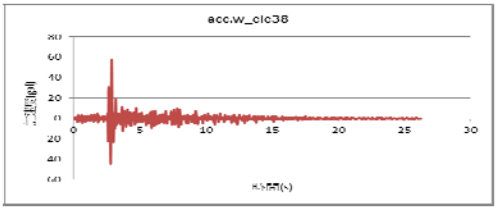

Figure 5 Waveform of Small Event at CHY38

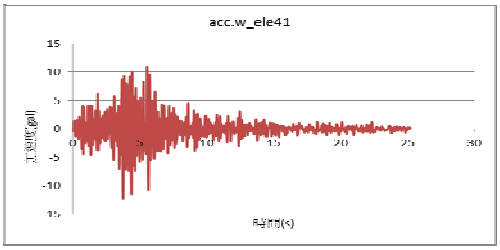

Figure 6 Waveform of Small Event at CHY41

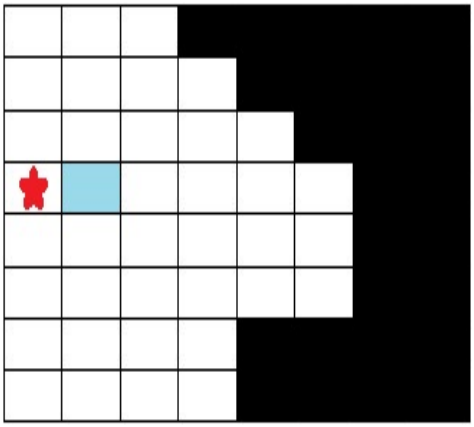

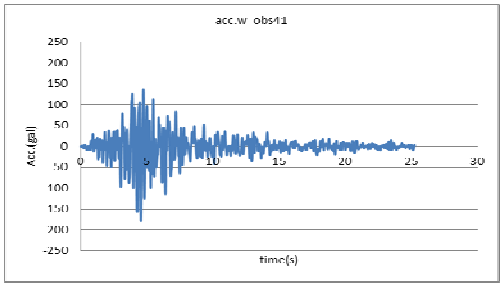

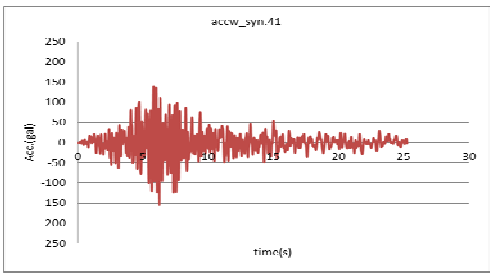

Figure 7 Fault Model for Synthesizing the Main Events

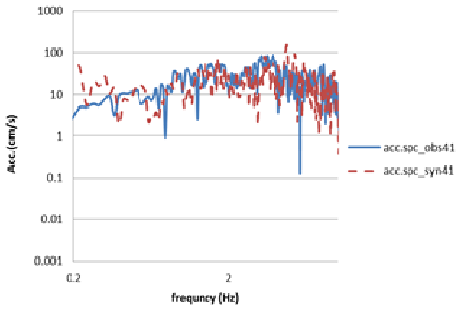

Figure 8 Observed Waveform, Synthesized Waveform and Fourier Spectra at CHY41

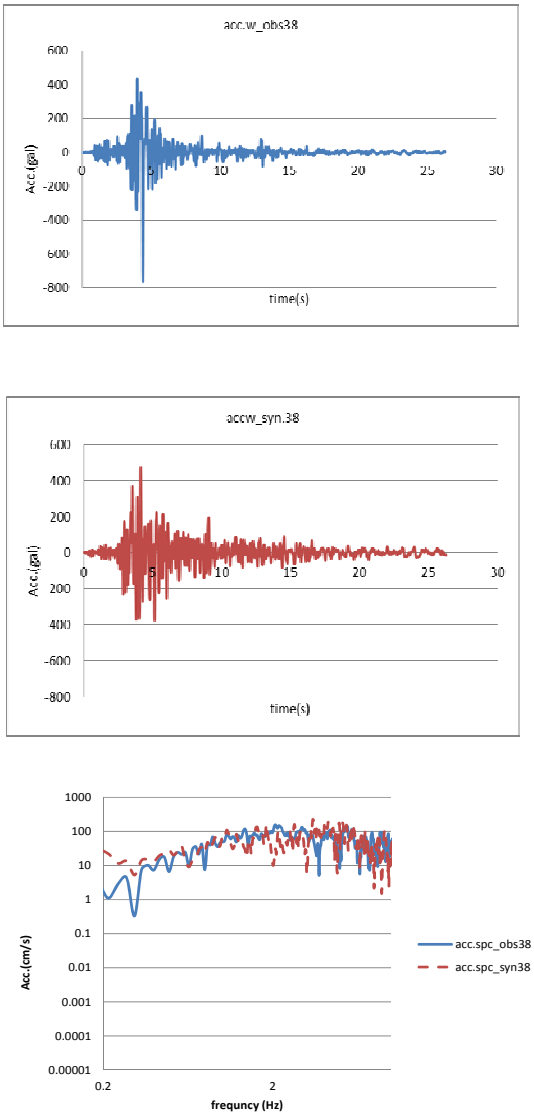

Figure 9 Observed Waveform, Synthesized Waveform and Fourier Spectra at CHY38

In order to further investigate the conformability of the observed and synthesized waveforms, a hypothetical three-story reinforced concrete building modeled as a three-degree-of-freedom lumped mass system, also known as stick model, was adopted. In this model, the masses are m_1= 1.69x10^4 kg, m_2= 1.581x10^4 kg and m_3= 1.412x10^4 kg and the stiffness of sticks of the stories is k_1= 1.512x10^7 N/m, , k_2= 2.012x10^7 N/m and k_3= 2.012x10^7 N/m. The nonlinear behavior of stick of each story assumes to follow the Takeda model (Takeda, 1970). The story drifts corresponding to crack for each stick are d_1= 6.3mm, d_2= 4.9mm and d_3= 4.2mm, and those corresponding to yielding are D_1= 21.8mm, D_2= 18.9mm and D_3= 17.2mm. Shown in Figure 10 are the time-history responses of acceleration, displacement and the story-shear and story-drift relation for each floor of the structure at CHY41. Generally the responses computed using synthesized waveform as input are smaller than those computed using observed waveform as input; however, the system under the action of both motions remains elastic. Figure 11 depicts the time-history responses of acceleration, displacement and the story-shear and story-drift relation for each floor of the structure at CHY38. Again, generally the responses subjected to synthesized motions are smaller those subjected to observed motions, especially for displacement responses. For the responses subjected to observed motion, the spike-like responses can be observed, while those are not shown for those subjected to synthesized motion. A point should be noted that for the observed motion it exhibits a spike which causes larger story drifts on all floors and forces the system to enter the plastic deformation significantly, leading to the more cycles in the hysteresis loop of the stick of first floor. However, if the structure at CHY38 is subjected to the synthesized motion, only slight plastic deformations can be seen on the first and second floor

4. CONCLUSIONS

In this study, the target event that we simulated is MeiShan earthquake (Mw= 5.85) which occurred on Oct. 22, 1999 using the small event (Mw= 4.05) of the main fault occurred on Oct.28 1999 as the empirical Green's function. Applying EGF method, the forward analysis was adopted to synthesize the observed motion The results show that EGF method can simulate the observed motions at the rock site (CHY41) very well, while the agreement is not so good for the alluvium site (CHY38 and others). The nonlinear responses of a three-degree-of-freedom lumped mass model were computed to further investigate the conformability of the observed and synthesized motions. For the model considered, the synthesized motions render smaller responses than the observed motions and the spike in the ground motion seems to affect the displacement significantly. Finally the hybrid approach will be adopted to generate scenario earthquakes in Chiayi area in the future.

Abstract: Evaluation of long-period ground motions for many possible scenarios is important to understand a possible range of long-period ground motions. To understand a variation of long-period ground motion caused by uncertainty of source model, we performed a finite difference simulation using 55 source models of the anticipated Nankai Trough megathrust earthquake in southwest Japan. The source models were constructed by assuming various possible source parameters including rupture area, asperity location, and hypocenter. We also included the scenario which contains large slip area near the trough following the lesson we learned from the 2011 Tohoku-oki earthquake. Simulated velocity response spectra have large variation by a factor of a few hundred depending on different rupture area. Among the source models with same rupture area, simulated velocity waveforms vary greatly according to the hypocenter location. The simulated waveforms of the scenarios including large slip near the trough show significantly large amplitude and long duration at some sedimentary basins. T he amplitude and duration of these waveforms decrease by applying a boxcar-like slip velocity function to the large slip area near the trough instead of the Kostrov-like function.

1. INTRODUCTION

Megathrust earthquakes in the Nankai Trough in southwest Japan have been occurring with an interval of 100-200 years. Mainly, there are two patterns of Nankai Trough earthquake; one is the series of smaller earthquakes in short time period and second is the single larger event ruptured at once. The most recent example of the first case is the series of earthquake in 1944 Tonankai earthquake (M7.9) and in 1946 Nankai earthquake (M8.0). The most recent example of the second case is the 1707 Hoei earthquake (M8.4).

For improving seismic hazard assessment to prepare for the anticipated Nankai Trough earthquake, it is important to understand a possible range of ground motion caused by uncertainty of source model. In this study, we evaluate long-period ground motions of the Nankai Trough earthquake, which will cause damage to high-rise and large-scale structures, using many scenarios with various possible parameters including rupture area, asperity location, and hypocenter. In the possible parameters, we also include the scenario; the large slip near the trough following the lesson from the 2011 Tohoku-oki earthquake. The long-period ground motions are simulated by the finite difference method using characterized source model and recently developed three-dimensional velocity structure model of Japan.

2. SEISMIC SOURCE MODEL

We use a characterized source model in the long-period ground motion simulation. The characterized source model is defined by three kinds of parameters: outer, inner, and extra fault parameters. These parameters are determined based on a 'recipe' for predicting strong ground motion (Irikura and Miyake, 2001). Although the 'recipe' for the crustal earthquake has been validated using observed records of many earthquakes, that for the subduction-zone earthquake, especially for megathrust earthquakes, has been validated using insufficient data. We should note that the ground-motion simulation results may be modified after improving the 'recipe' for the subduction-zone earthquake.

The outer fault parameters define an overall character of the source model. At first we define source areas of the anticipated Nankai Trough earthquakes (Figure 1). An occurrence pattern of the Nankai Trough earthquakes is assumed that respective earthquakes occur independently or that multiple earthquakes occur in a correlated manner. As for the respective earthquakes, we define source areas of the Nankai earthquake (ANNKI), the Tonankai earthquake (ATNKI), and the hypothetical Tokai earthquake (ATOKI) based on the model reported by Earthquake Research Committee (2001). We also model the Hyuga-nada (AHGND) area as a source area, since Furumura et al. (2011) pointed out that a source area of the 1707 Hoei

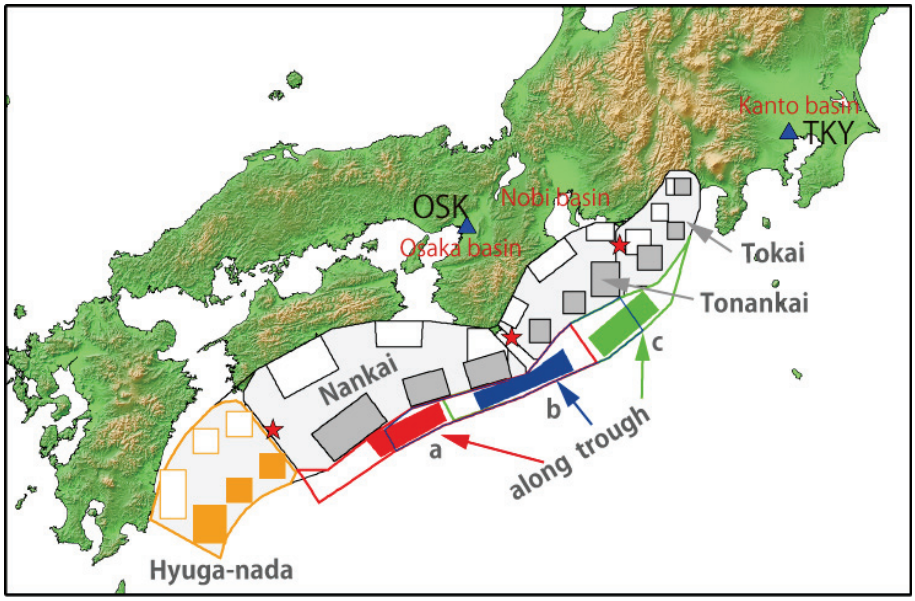

Figure 1 Characterized source models for the Nankai Trough earthquakes. Grey regions are the source area of the Nankai, Tonankai, and hypothetical Tokai earthquakes. Orange region is a source area of Hyuga-nada. Red, blue and green regions are source areas along the trough. Solid and open squares in the source area are asperities of shallower and deeper cases, respectively. Red stars are the hypocenters. Blue triangles are the sites for comparing simulation results.

earthquake extends to this area. In addition, we assume the large slip area along the trough following the lesson from the 2011 Tohoku-oki earthquake and model three source areas along the trough (Figure 1; ATRGHa-c). We model source areas for the case of correlated occurrence as a combination of the respective source area. These are the Nankai-Tonankai area (ANNI1), the Tonankai-hypothetical Tokai area (ANNI2), the Nankai -Tonankai-hypothetical Tokai area (ANNI3), the Nankai -Tonankai-hypothetical Tokai area with along the trough area (ANNI4a-c), and the Nankai-Tonankai-hypothetical Tokai area with the Hyuga-nada area (ANNI5). We estimate the rupture area S for each source area by taking into account geometry of plate interface and then calculate seismic moment M_0 and average slip D by assuming an average stress drop $\Delta\sigma$ of 3.0 MPa and rigidity of 40.4 GPa.

As for the inner fault parameters, combined area of asperities (a large slip areas) S_a and average slip of asperities D_a are derived by a scaling relationship to the seismic moment proposed by Murotani et al. (2008); S_a=0.2S and D_a=2.2D. The number of asperity for the ANNKI, ATNKI, ATOKI, and AHGND is three and their area ratio is 2:1:1, while the number of asperity for ATRGHa-c is one. We assume two kinds of asperity location; deeper and shallower cases. As for the case of correlated occurrence, we assume that the asperity area is similar to the respective earthquake and calculate average slip and seismic moment with respect to a total rupture area. Source parameters are shown in Table 1. We use a slip velocity time function approximated from dynamic rupture simulation proposed by Nakamura and Miyatake (2000).

The extra fault parameters define propagation pattern of rupture. We assume three hypocenters; west (boundary of the Nankai and Hyuga-nada areas), center (boundary of Nankai and Tonankai areas), and east (boundary of the Tonankai and Tokai areas). The rupture propagates radially from the hypocenter at a constant rupture velocity (2.7km/s). The rupture in each asperity starts from a point at the moment the rupture front reaches the point.

3. LONG-PERIOD GROUND MOTION SIMULATION

We simulate long-period ground motions using a three dimensional (3-D) finite difference (FD) method with discontinuous grids (Aoi and Fujiwara, 1999; Aoi et al., 2004). To accommodate details of 3-D subsurface structure into the FD model, we used discontinuous grids that consist of a fine grid spacing of 200 m in horizontal and of 100m in vertical for regions shallower than 8 km that contain low-velocity sedimentary layers, and a three times coarser grid spacing for deeper region (8 ~ 70 km). The total number of grid points is about 2 billion. The 3-D velocity structure model used in the FD simulation is the Japan integrated velocity structure model (Koketsu et al., 2008), which includes basin, crust, plate and oceanic structures. The lowest S-wave velocity is 500m/s in the structure model and thus the FD simulation is valid for period more than 2 second. However the characterized source model used in the FD simulation does not contain short period component, and thus we consider that the FD simulation is valid for period more than about 5 second. Inelastic attenuation is introduced in the same way as in Graves (1996) and we assume a reference period for Q-value of 5 second.

4. RESULTS

We simulate long-period ground motions for 55 scenarios. Figures 2 compares the simulated ground velocity for scenarios ANNI3, ANNI4a-c, and ANNI5 with different hypocenter and asperity location at Osaka (OSK) and Shinjuku in Tokyo (TKY). Among these scenarios, the hypocenter has a greater impact on waveforms, followed by the asperity location, and then the rupture area. S waves from deeper asperities of the Nankai area and later phases from the along trough 'a' area have significant influence at OSK. Later phases from the along trough 'b' and 'c' areas elongate a duration of long-period ground motion at TKY.

Figure 3 compares the simulated velocity response spectra for all simulated scenarios. These spectra have large scattering by a factor of few hundred. The spectra of scenarios ANNI3, ANNI4a-c, and ANNI5 at OSK and TKY have scattering by a factor of 4-10 and 2-4, respectively. The scattering at TKY is small because TKY locates on the forward rupture direction of the hypothetical Tokai area in the scenarios. Because the difference of seismic moment between the scenarios ANNI3, ANNI4a-c, and ANNI5 is small by a factor of two (Table 1), the large scattering indicates the hypocenter and asperity location have greater effect on simulation results than the rupture area.

5. DISCUSSION AND CONCLUSIONS

Figure 4 shows histograms and cumulative frequency distribution of simulated peak ground velocity (PGV) and simulated velocity response spectra (Sv) at period of 5 and 10 seconds. The histograms show contribution of the rupture area. The scenarios with wider rupture areas (colored bars) have larger PGV and Sv than those with smaller rupture areas (grey bars). In particular, the scenarios ANNI4a generate significantly large PGV and Sv at OSK. The cumulative frequency distributions show contribution of hypocenter and asperity location. The scenarios with western hypocenter (red symbols) generate large PGV and Sv at OSK and TKY.

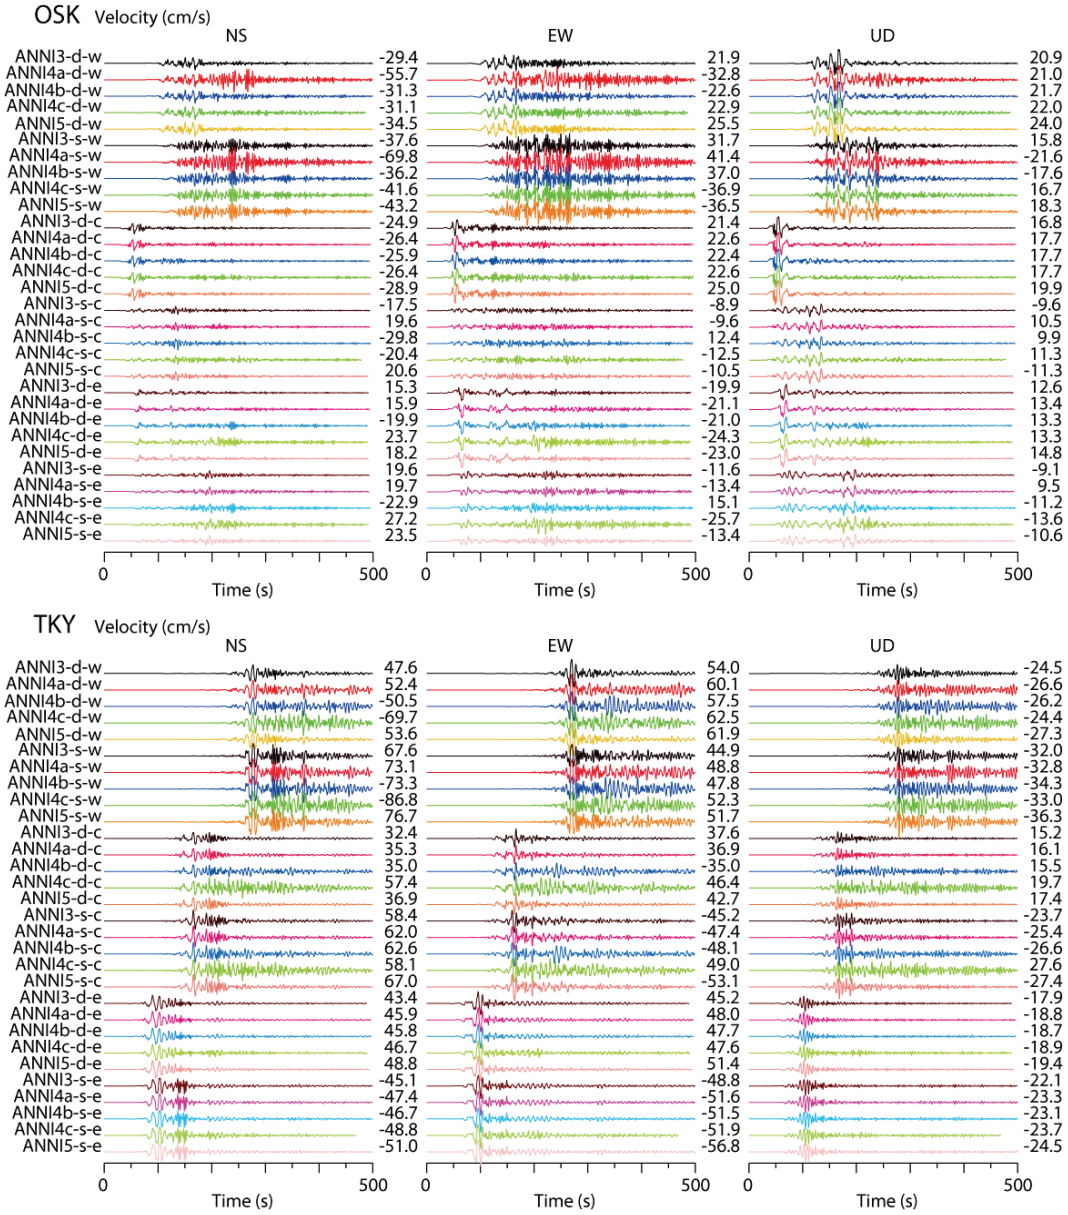

Figure 2 Results of the 3-D FD simulation for 30 scenarios at (a) OSK, (b) TKY. Scenario name shown in the left means [source area]-[asperity location (deep, shallow)]-[hypocenter (west, center, east)]. The numbers on the right indicate the peak amplitude in cm/s.

To assess a character of PGV and Sv distribution (Figure 4), we make PGV and Sv maps showing maximum, median (second quartile), interquartile range (iqr: the difference between the third and first quartiles), and maximum scenario using simulation results of 55 scenarios (Figure 5). These maps show a possible range of long-period ground motions from the anticipated Nankai Trough earthquakes. Large maximum and median values on accretionary prism suggest that the accretionary prism greatly contributes to the generation and propagation of long-period ground motions. The maximum scenario maps show that the scenarios ANNI5 with deep asperity contribute maximum values in the left half area in the map, especially in PGV and Sv 10s. These are the effect of long-period S wave from the Nankai area. In the maximum scenario maps of Sv 5s, the red and green areas distribute in land area wider than PGV and Sv 10s indicating greater effect of the along trough area on Sv 5s values.

In the maximum value maps, the Sv 5s values are larger than Sv 10s values at the Osaka and Nobi basins, while the Sv 10s values are larger than Sv 5s values at the Kanto basin. The Osaka and Nobi basins have large difference between the maximum and median values and have small iqr. This feature indicates that these basins are greatly influenced by a few specific scenarios as shown in Figure 4. However, the Kanto basin has relatively large median values and iqr. This indicates that the long-period ground motions in Kanto basin are generally large among the simulated scenarios.

In the FD simulation, we use a Kostrov-like slip velocity time function proposed by Nakamura and Miyatake (2000). However, applying this function to the interpolate

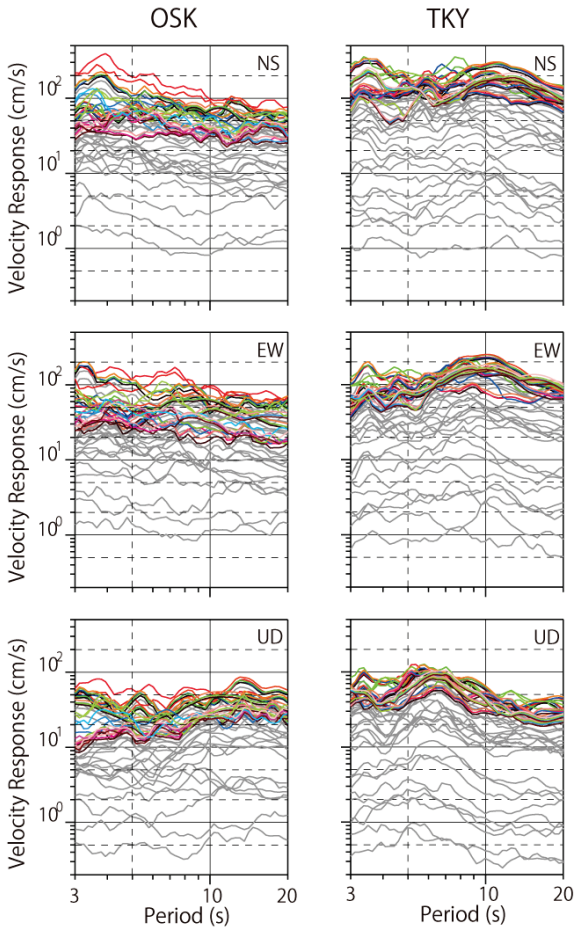

Figure 3 Velocity response spectra (h=0.05) of the 3-D FD simulation results for 55 scenarios at OSK and TKY. Color of the lines corresponds to scenarios shown in Figure 2. Grey lines correspond to other smaller scenarios.

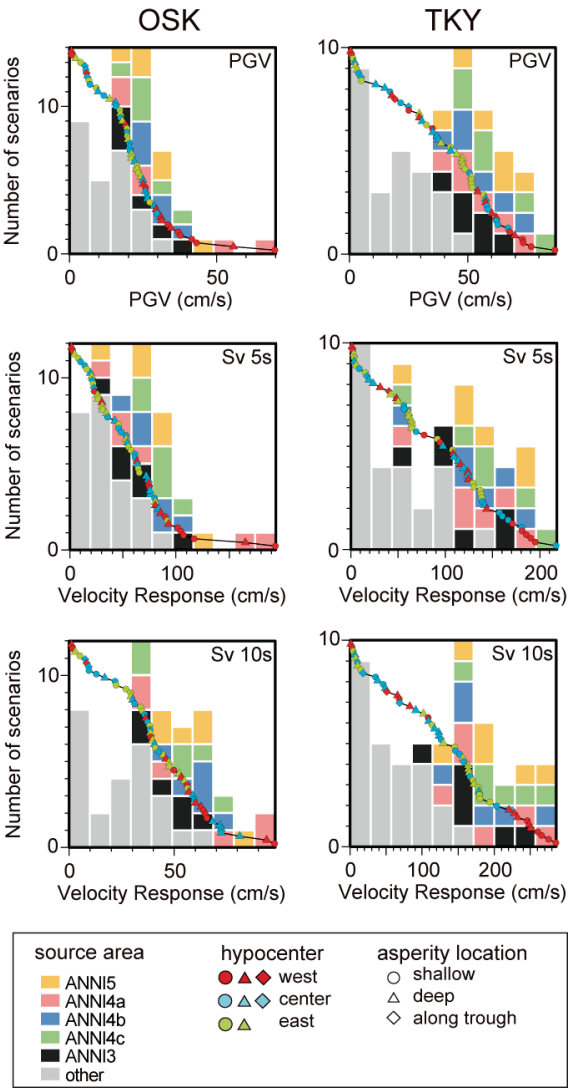

Figure 4 Histograms and cumulative frequency distribution of peak ground velocity (PGV) and velocity response spectra (Sv) at period of 5 and 10 seconds for 55 scenarios at OSK and TKY. earthquakes is a contentious issue, especially in a shallow source area. To assess a contribution of source time function, we apply a boxcar like time function to the along trough area. The simulation result shows that PGV values decrease by a factor of two (Figure 6). This indicates that the significant large amplitudes at OSK as shown in Figure 4 are controlled by selection of the slip velocity function. Selection of appropriate source time function is important and it is a future task.

FUNDAMENTAL PROPERTY OF CROSS TERMS OF GROUND TRANSFER FUNCTION

Hiroyuki Goto[1)]

1) Assistant Professor, Disaster Prevention Research Institute, Kyoto University, Japan
goto@catfish.dpri.kyoto-u.ac.jp

Abstract: Normalized energy density (NED) is one of the essential quantities for a ground transfer function of a 1D layered structure model. This quantity is regarded as a type of norm for the power of the ground transfer function. The cross term of the functions is defined as an extension of the NED. The cross term is physically defined as the correlation coefficient between the two ground transfer functions. The cross term detects the harmony of two transfer functions; a finite value is obtained only in the case where peak frequencies coincide. The properties of the cross term is analytically proved for a two-layered case and numerically shown for three- and four-layered cases.

1. INTRODUCTION

The elastic wave propagations inside an elastic material are a fundamental topic for understanding certain aspects of engineering and scientific issues. For example, in seismology, earthquake engineering, and exploration geophysics, seismic wave propagation through the crust structure is regarded as elastic wave propagation; this property has been discussed based on elastic wave theory (e.g., Aki and Richards, 2002; Kennett 2002).

As the seismic waves radiating from an earthquake source travel through the crust structure, they are amplified, attenuated and elongated the duration owing to reflection, refraction, and scattering. Then, the wave arrives at the ground surface layer. In earthquake engineering, the amplification of the seismic wave owing to the ground surface layer, which is a deposit of soil overlying the basement, is an important issue to be addressed for earthquake disaster mitigation, e.g., seismic microzonation (Borcherdt, 1970).

Because the material velocity generally decreases in the shallower part of the underground, the incident angle of the wave can be assumed to be vertical at the engineering basement that consists of about 400-700 m/s of S-wave velocity material. This process highlights the importance of determining how to quantify a ground transfer function, which is a frequency-dependent amplification factor of a seismic wave from the basement to the ground surface. The ground transfer function has been evaluated based on elastic wave theory. Numerous approaches incorporating an inelastic attenuation, nonlinear behavior of soil, etc., are available, e.g., the Haskell matrix method by Haskell (1960), SHAKE by Schnabel et al. (1972), and DYNEQ by Yoshida and Suetomi (1996). Several researchers have applied them to discuss the ground motion observations during actual earthquakes (e.g., Suetomi and Yoshida, 1998).

Recently, Goto et al. (2011a) suggested a conserved quantity named normalized energy density (NED) in the ground surface layer. The NED is an interesting property of the ground transfer function; the frequency average of the power only depends on the impedance ratio between the uppermost surface layer and the basement, but does not depend on the physical property between them. This provides a potential constrain to the parameter space in evaluating the ground transfer function; for instance, the NED allows a direct estimation of the total damping of the ground surface layer (Goto et al., 2011b).

From this definition, the NED is regarded as a type of norm of the ground transfer function. In this article, more general discussion similar to the NED is presented, focusing on the cross term of the different transfer functions.

2. NORMALIZED ENERGY DENSITY

Normalized energy density (NED) is a quantity defined in reference to a multilayered structure that consists of n horizontal layers (#1-n) over a half space basement #0, as shown in Figure 1. The S-wave velocity of Layer #k is β_k, the density is ρ_k, and the thickness is h_k. When 2D SH waves vertically propagate into the layers through the interface between layer #n and basement #0, the NED for layer #k is defined as follows (Goto et al., 2011a):

$$\mathrm{NED}_k = \lim_{\Omega\to\infty} \frac{1}{\Omega} \int_0^{\Omega} \rho_k \beta_k \left| \frac{A_k(\omega)}{A_0(\omega)} \right|^2 d\omega \qquad (1)$$

where A_0 is a Fourier amplitude of the upgoing wave through the basement #0 and A_k is a Fourier amplitude of the upgoing wave through the layer #k. ω is the angular

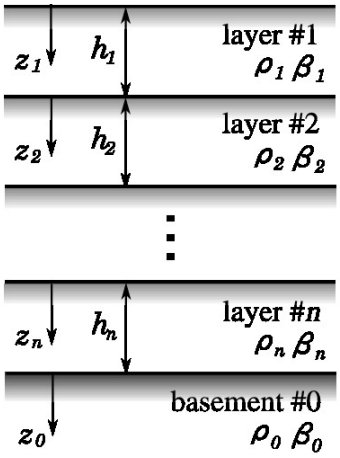

Figure 1 Model of multilayered structure in definition of NED.

frequency. The integration is only applied to a positive value of ω instead of the original definition (Goto et al., 2011a), wherein both the negative and positive sides are integrated. This is permitted because the integrand is an even function when $|A_k/A_0|$ is causal.

A ground transfer function of the structure is usually defined by $H=2A_1/A_0$. The NED for layer #1 can be represented by the transfer function as

$$\mathrm{NED}_1 = \lim_{\Omega\to\infty} \frac{1}{\Omega} \int_0^{\Omega} \frac{\rho_1\beta_1}{4} \left|H(\omega)\right|^2 d\omega \tag{2}$$

Because the amplitude ratio A_k/A_0 depends on only the physical parameters of each layer and basement, the NED is evaluated from the physical parameters independent of the property of the incident waves.

The NED is proven to be constant, $\mathrm{NED}=\rho_0\beta_0$, through the layer #1-n and basement #0, analytically for a two-layered case and numerically for the case of more than three layers (Goto et al., 2011a). This means that the NED is a conserved quantity through the layered structure and is evaluated without a detailed physical property when a transfer function and an impedance $\rho_1\beta_1$, in the uppermost layer are available.

To generalize the discussion, a particular model of the structure is represented by a complex function $a(\omega)$ incorporating the impedance ratio $R_a=\rho_1\beta_1/\rho_0\beta_0$, as

$$a(\omega) = \sqrt{R_a}\,\frac{A_1(\omega)}{A_0(\omega)} \tag{3}$$

a depends on a physical property of the structure, and satisfies the following relation,

$$\langle a^* a\rangle \equiv \lim_{\Omega\to\infty} \frac{1}{\Omega} \int_0^{\Omega} a^* a\, d\omega = 1 \tag{4}$$

where a^* denotes a complex conjugate of a. Equation (4) is equivalent to $\mathrm{NED}_1=\rho_0\beta_0$ that is the property of the NED.

3. CROSS TERMS OF TWO DIFFERENT TRANSFER FUNCTIONS

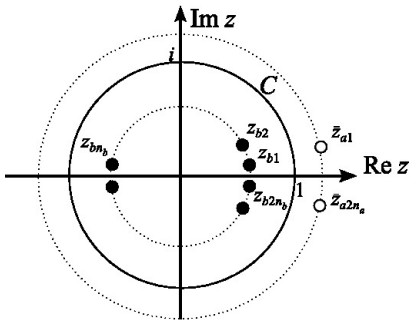

Figure 2 Unit circle C and poles $\bar{z}_{ak}$ and z_{bl} on a complex plane.

3.1 Two-layered case

Let a and b to be the functions representing the model of layered structures; both satisfy the principle defined by Eq.(4). Here, a cross term of a and b is defined as follows:

$$\langle a^* b\rangle \equiv \lim_{\Omega\to\infty} \frac{1}{\Omega} \int_0^{\Omega} a^* b\, d\omega \tag{5}$$

In the case of $a=b$, the cross term is equal to 1 by definition. For a two-layered case, a and b are explicitly evaluated as,

$$a = \frac{\sqrt{R_a}}{\cos(\omega h_a/\beta_a) + iR_a \sin(\omega h_a/\beta_a)} \tag{6}$$

$$b = \frac{\sqrt{R_b}}{\cos(\omega h_b/\beta_b) + iR_b \sin(\omega h_b/\beta_b)} \tag{7}$$

where R_a and R_b are the impedance ratios of the layer to the basement. h_a and h_b are the thicknesses of the layers, and β_a and β_b are the S-wave velocities of the layer. i denotes an imaginary unit.

Here, a complex value $z=\exp(i\omega h/\beta)$ with a unit absolute value is defined. If one supposes that h_a/β_a and h_b/β_b are represented by a product of h/β and some non-negative integer, n_a and n_b, then this assumption limits the ratio of h_a/β_a and h_b/β_b to being a rational number. In the case represented in this paper, the following representations are available:

$$\begin{cases} \cos(\omega h_a/\beta_a) = \frac{1}{2}(z^{n_a} + z^{-n_a}) \\ \sin(\omega h_a/\beta_a) = \frac{1}{2i}(z^{n_a} - z^{-n_a}) \end{cases} \tag{8}$$

$$\begin{cases} \cos(\omega h_b/\beta_b) = \frac{1}{2}(z^{n_b} + z^{-n_b}) \\ \sin(\omega h_b/\beta_b) = \frac{1}{2i}(z^{n_b} - z^{-n_b}) \end{cases} \tag{9}$$

and a and b are rewritten by z as follows:

$$a = \frac{\frac{2\sqrt{R_a}}{1+R_a} z^{n_a}}{z^{2n_a} + \frac{1-R_a}{1+R_a}}, \qquad b = \frac{\frac{2\sqrt{R_b}}{1+R_b} z^{n_b}}{z^{2n_b} + \frac{1-R_b}{1+R_b}}. \tag{10}$$

z is located on a unit circle on the complex plane and moves counterclockwise as ω increases. This means that z and a function of z are periodic with a period of $2\pi\beta/h$. In the case, the integration in Eq.(5) is modified into a complex integration along the unit circle C.

$$\langle a^* b\rangle \equiv \frac{1}{2\pi i} \oint_C a^* b z^{-1}\, d\omega \tag{11}$$

The representation is allowed to evaluate the integral based on the residue theorem. The integrand $a^* b z^{-1}$ is represented by

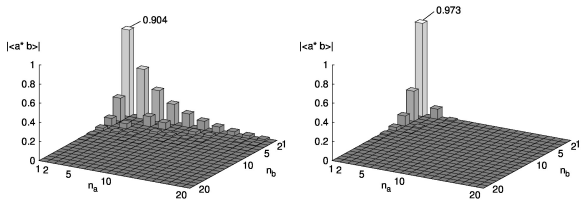

Figure 3 Absolute values of cross term $\langle a^* b \rangle$ with respect to n_a and n_b for case $\{R_a, R_b\}=\{0.5, 0.2\}$ (left) and case $\{R_a, R_b\}=\{0.5, 0.8\}$ (right).

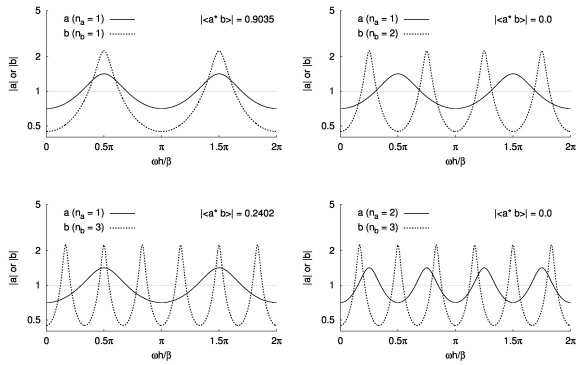

Figure 4 Absolute values of a and b associated with $\omega h/\beta$ for case $\{R_a, R_b\}=\{0.5, 0.2\}$. Each panel corresponds to $\{n_a, n_b\}=\{1, 1\}$ (top left), $\{1, 2\}$ (top right), $\{1, 3\}$ (bottom left), and $\{2, 3\}$ (bottom right).

$$a^* b z^{-1} = \frac{\frac{2\sqrt{R_a}}{1-R_a}\frac{2\sqrt{R_b}}{1+R_b} z^{n_a+n_b-1}}{\left[z^{2n_a}+\frac{1+R_a}{1-R_a}\right]\left[z^{2n_b}+\frac{1-R_b}{1+R_b}\right]}. \quad (12)$$

and the poles are located at

$$\bar{z}_{ak} = \left(\frac{1+R_a}{1-R_a}\right)^{1/2n_a} e^{(2k-1)\pi i/2n_a} \quad k\in\{1,\ldots,2n_a\} \quad (13)$$

$$z_{bl} = \left(\frac{1-R_b}{1+R_b}\right)^{1/2n_b} e^{(2l-1)\pi i/2n_b} \quad l\in\{1,\ldots,2n_b\} \quad (14)$$

Because R_a and R_b are the physical positive values, $\bar{z}_{ak}$ is located outside of the unit circle, as shown in Fig.2.

Based on the residue theorem, the cross term is evaluated from a sum of the residues corresponding to z_{bl}.

$$\langle a^* b \rangle = \sum_{l=1}^{2n_b} \underset{z=z_{bl}}{\mathrm{Res}} [a^* b z^{-1}] \quad (15)$$

where the residue is represented, as follows:

$$\underset{z=z_{bl}}{\mathrm{Res}} [a^* b z^{-1}] = \frac{-\frac{2\sqrt{R_a}}{1-R_a}\frac{\sqrt{R_b}}{2n_b(1+R_b)} z_{bl}^{n_a+n_b}}{z_{bl}^{2n_a}+\frac{1+R_a}{1-R_a}}. \quad (16)$$

From the definition, z_{bl+nb} for l=1,…,n_b is equal to $-z_{bl}$ (see Fig.2). This suggests that z_{bl}^{2na} is equal to z_{bl+nb}^{2na}. z_{bl+nb}^{na+nb} is also equal to $-z_{bl}^{na+nb}$ when n_a+n_b is an odd value. Thus, the cross term vanishes in cases where n_a+n_b=odd.

For high values of n_a and n_b, the limit to the value of the cross term $\langle a^* b \rangle$ becomes zero. A detailed description is in Goto (2013). If n_a and n_b are regarded to be infinite values when the ratio of h_a/β_a and h_b/β_b is not a rational number, the cross term is also vanished in this case. Only for a pair of low values of n_a and n_b, does the term provide a finite value.

Figure 3 shows the absolute values of the cross term $\langle a^* b \rangle$ with respect to a set of n_a and n_b values for cases of R_a=0.5, R_b=0.2, and R_a=0.5, R_b=0.8. Each value is calculated based on Eq.(15), whereas the value of a pair that n_a and n_b are not coprime are set as zero. For example, the pair of n_a=n_b=5 gives the same cross term with the pair of n_a=n_b=1, whereas the non-coprime pair is not essential in discussing the convergence for the large n_a and n_b. It should be referred to the corresponding value for n_a=n_b=1. In either case, the cross term becomes zero when n_a+n_b=odd as analytically proved, and the other values monotonically decrease depending on n_a and n_b. This also implies the cross terms are not zero for low values of n_a and n_b.

Figure 4 shows the absolute values of a and b associated with $\omega h/\beta$ for a case R_a=0.5 and R_b=0.2, and each panel corresponds to the pairs of $\{n_a, n_b\}=\{1, 1\}$, $\{1, 2\}$, $\{1, 3\}$, and $\{2, 3\}$. The cross terms $\left|\langle a^* b \rangle\right|$ are evaluated as 0.9035, 0.0, 0.2402, and 0.0, respectively. When n_a and n_b are odd, the peak values of both $|a|$ and $|b|$ appear at 0.5π and 1.5π. n_a+n_b=odd is equivalent to the case where n_a and n_b are odd when n_a and n_b are coprime. Thus, the condition n_a+n_b=odd has the clear physical meaning that peak values of $|a|$ and $|b|$ appear at the same angular frequency. This suggests that $\langle a^* b \rangle$ quantifies a harmony between two different layered structure.

3.2 Multilayered case

The cross term $\langle a^* b \rangle$ is also available for multilayered cases. However, the analytical approach introduced in the two-layered case is not easily applicable. Some of the numerical simulations are performed to discuss the properties of the cross term.

As discussed in the two-layered case, the cross term strongly depends on the values of n_a and n_b, which correspond to the harmony of peak frequencies. Because the variables are not defined for the general multilayered case, a hypothetical model for n_a and n_b is constructed from a particular model. Let h_{ak} and β_{ak} to be a thickness and the S-wave velocity of a kth layer in model a. A thickness h_{bk} for the hypothetical model b is calculated from a pair of n_a and n_b:

$$h_{bk} = h_{ak}\frac{\beta_{bk}}{\beta_{ak}}\frac{n_b}{n_a} \quad (17)$$

This is consistent with the definition of n_a and n_b in the two-layered case.

For the three- and four-layered cases, a Monte Carlo simulation is performed. First, fifty sets of layered models \$a\$ are generated from random numbers within the range 10-700m/s for S-wave velocity, 1000-2000kg/m^3 for the density of every layer, and 1000-2000kg/m^3 for the density of the basement. The S-wave velocity of the basement is set at an impedance ratio equal to 0.5. The total thickness of the layers is generated within the range of 1-50m and then divided into layers with a random thickness. Fifty additional sets of layered model candidates are also generated under the same condition as model a, except for the layer thickness. The S-wave velocity of the basement is set such that the impedance ratio is equal to 0.2. Then, the layer thickness of

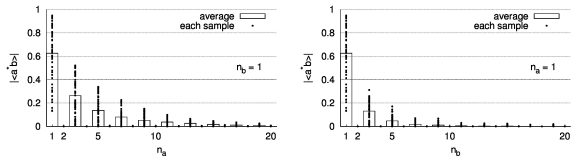

Figure 5 Absolute values of cross terms $\langle a^* b \rangle$ for three-layered case ($\{R_a, R_b\}=\{0.5, 0.2\}$) with respect to n_a (n_b=1) (left) and n_b (n_a=1) (right).

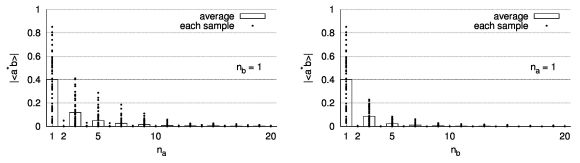

Figure 6 Absolute values of cross terms $\langle a^* b \rangle$ for four-layered case ($\{R_a, R_b\}=\{0.5, 0.2\}$) with respect to n_a (n_b=1) (left) and n_b (n_a=1) (right).

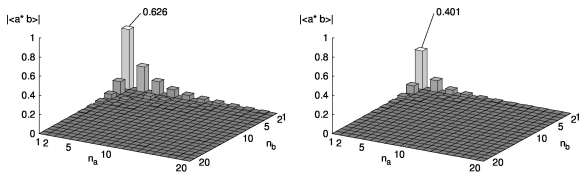

Figure 7 Average over absolute values of the cross term $\langle a^* b \rangle$ with respect to n_a and n_b for three-layered case (left), and four-layered case (right).

each of the fifty model candidates are scaled via the relation in Eq.(17) for a given pair of n_a and n_b, and construct the model *b*. The cross terms are calculated between the fifty pairs of *a* and *b* by varying n_a and n_b for each pair. The integrations are approximated by numerical integration every $0.1s^{-1}$$ up to $1.0\times6s^{-1}$.

Figures 5 and 6 show the absolute values of the cross term for the three- and four-layered cases, respectively. Each panel corresponds to the case n_b=1 and n_a=1. Fifty samples are indicated as the points, and the average over the samples is also plotted via a bar chart. The impedance ratio of the uppermost layer to the basement is constant, 0.5 in model *a* and 0.2 in model *b*, whereas the variation among the samples are observed. The variation decreases as n_a or n_b increases. Similar to the two-layered case, the cross term is significantly small when n_a+n_b is odd.

Figure 7 shows the averages over fifty samples of absolute values of the cross term for three- and four-layered cases, respectively. The results are similar to the results for the two-layered case (Fig.3); the values almost vanish when n_a+n_b is odd, and they monotonically decrease depending on n_a and n_b, although the values are the averages over all the samples.

4. DISCUSIONS AND CONCLUSIONS

Let the transfer functions for a model *a* and model *b* be denoted as H_a and H_b. The cross term of the transfer functions is proportional to $\langle a^* b \rangle$ as

$$\langle H_a{}^* H_b \rangle = \frac{4}{\sqrt{R_a R_b}} \langle a^* b \rangle \tag{18}$$

This indicates that the properties of the cross terms discussed in Sections 3 are transferrable to the properties of the cross terms between the transfer functions with a factor depending on the impedance ratios R_a and R_b. $H_a{}^* H_b$ is a cross spectrum between the observed signals on the ground surface when the incident wave contains a constant power in frequency, such as that of white noise (e.g., Zerva, 2009). This implies that the frequency average of the *normalized* cross spectrum must obey the property described in Sections 3.

When the values of the transfer function in each frequency are regarded as a set of samples, Pearson's correlation coefficient between the transfer functions can be defined as

$$C_{ab} \equiv \frac{\langle \left(H_a - \langle H_a \rangle\right)^* \left(H_b - \langle H_b \rangle\right) \rangle}{\sqrt{\langle \left|H_a - \langle H_a \rangle\right|^2 \rangle \langle \left|H_b - \langle H_b \rangle\right|^2 \rangle}} \tag{19}$$

Because the correlation coefficient is invariant, it gives the same value when it is defined by *a* and *b*.

$$C_{ab} = \frac{\langle \left(a - \langle a \rangle\right)^* \left(b - \langle b \rangle\right) \rangle}{\sqrt{\langle \left|a - \langle a \rangle\right|^2 \rangle \langle \left|b - \langle b \rangle\right|^2 \rangle}} \tag{20}$$

Using the property of the NED represented by Eq.(4), $\langle |a|^2 \rangle$ and $\langle |b|^2 \rangle$ are identically 1. When the average of *a* and *b* is supposed to be zero, as described in Goto (2013), the correlation coefficient C_{ab} is equal to the cross term of *a* and *b*.

$$C_{ab} = \langle a^* b \rangle \tag{21}$$

This provides a clear physical meaning of the cross term as being the correlation coefficient between the transfer functions.

The cross term of ground transfer functions is defined as an extension of the NED. The cross term gives a finite value only in cases where peak frequencies coincide. This finding suggests that the cross term detects the harmony of two transfer functions. The properties are analytically proved for a two-layered case, and numerically shown for three- and four-layered cases. The cross term physically implies the correlation coefficient between the two ground transfer functions.

Although the explicit application of the findings regarding the cross terms is not clear at this time, the essential property of the transfer function will provide some new insights for the transfer functions; for instance, the correlation coefficients are not equivalent to the average of the cross term within the finite frequency range, whereas they are deeply linked as the frequency range broaden.

Abstract: The M_w 9.0 Tohoku-oki Japan earthquake and many of its subsequent aftershocks and triggered events were very well recorded, providing opportunity for detailed study of source, path, and site effects. In previous work, we utilized mainshock data to demonstrate faster attenuation with distance in backarc than in forearc regions, positive event terms for high frequency intensity measures for multiple ground motion prediction models, and minimal scaling of site amplification with V_{s30} at high frequencies. In this paper, we consider two subsequent events, one M_w 6.7 on the plate interface that ruptured in the mainshock and one M_w 6.3 inland from the volcanic front, to examine if similar ground motion features are apparent from these data sets. We continue to find evidence for the divergence in attenuation rate in forearc and backarc regions, despite the fact that the events are located on opposite sides of the volcanic front. The site response for these events does not appear to follow previously observed patterns for Japan, being relatively similar to V_{s30}-scaling in active crustal regions generally.

1. INTRODUCTION

The M_w 9.0 Tohoku-oki earthquake occurred on March 11 2011 along the plate boundary off the Pacific Coast of Japan. In prior work (Stewart et al., 2013), we reviewed the mainshock source solutions and selected a representative source model for engineering application; we described the uniform ground motion processing applied to approximately 2000 available triaxial accelerograms; and we described the results of data analysis to investigate source, path and site effects. For short period ground motion intensity measures, we found faster attenuation with distance in backarc than in forearc regions, positive event terms for multiple ground motion prediction models at short periods, and minimal scaling of site amplification with V_{s30}. Many of these effects disappeared at long periods.

Many of these observations are of substantial practical significance for ground motion prediction, and therefore there is interest in seeing if they are repeatable. This paper represents a first step in this direction. We select two well recorded events that occurred subsequent to the mainshock, one M_w 6.7 on the same plate interface that ruptured in the mainshock and one M_w 6.3 inland from the volcanic front. Identical data processing procedures are applied to these recordings as were used for the mainshock. Our objective is to see if similar ground motion features are apparent from these data sets as were found from the mainshock.

2. SELECTED EVENTS AND AVAILABLE DATA

We selected two events from the Japan Meteorological Assoc. (JMA) web site (http://www.seisvol.kishou.go.jp/eq/sourceprocess/). Attributes of the two events are given in Table 1. We refer to the 12 March 2011 event as 'crustal' and the 23 June 2011 event as 'interface.' As shown in Figure 1, the crustal event occurred in the backarc region. It had a reverse-slip mechanism and a shallow focal depth (8 km). The interface event occurred near the northwest corner of the mainshock fault plane (Fig. 1). It had a reverse-slip mechanism along a 17 deg. westward dipping fault plane and a focal depth of 36 km, which are consistent with rupture along the plate interface. In addition, this event is located close to the 03-11-2011 M_w 7.4 aftershock (Fig 1), which is also inferred to have rupture at the plate interface.

Table 1. Attributes of selected events

Date	M_w	Top-Ctr Lat, Long	Depth to top (km)	Length, width (km)	Strike / dip (°)
3/2011	6.3	37.051, 138.532	4.4	12, 12	26 / 32
6/2011	6.7	39.982, 142.588	36	18, 12	185/17

There are hundreds of well recorded events following the Tohoku mainshock. Our reasons for selecting these specific events were:

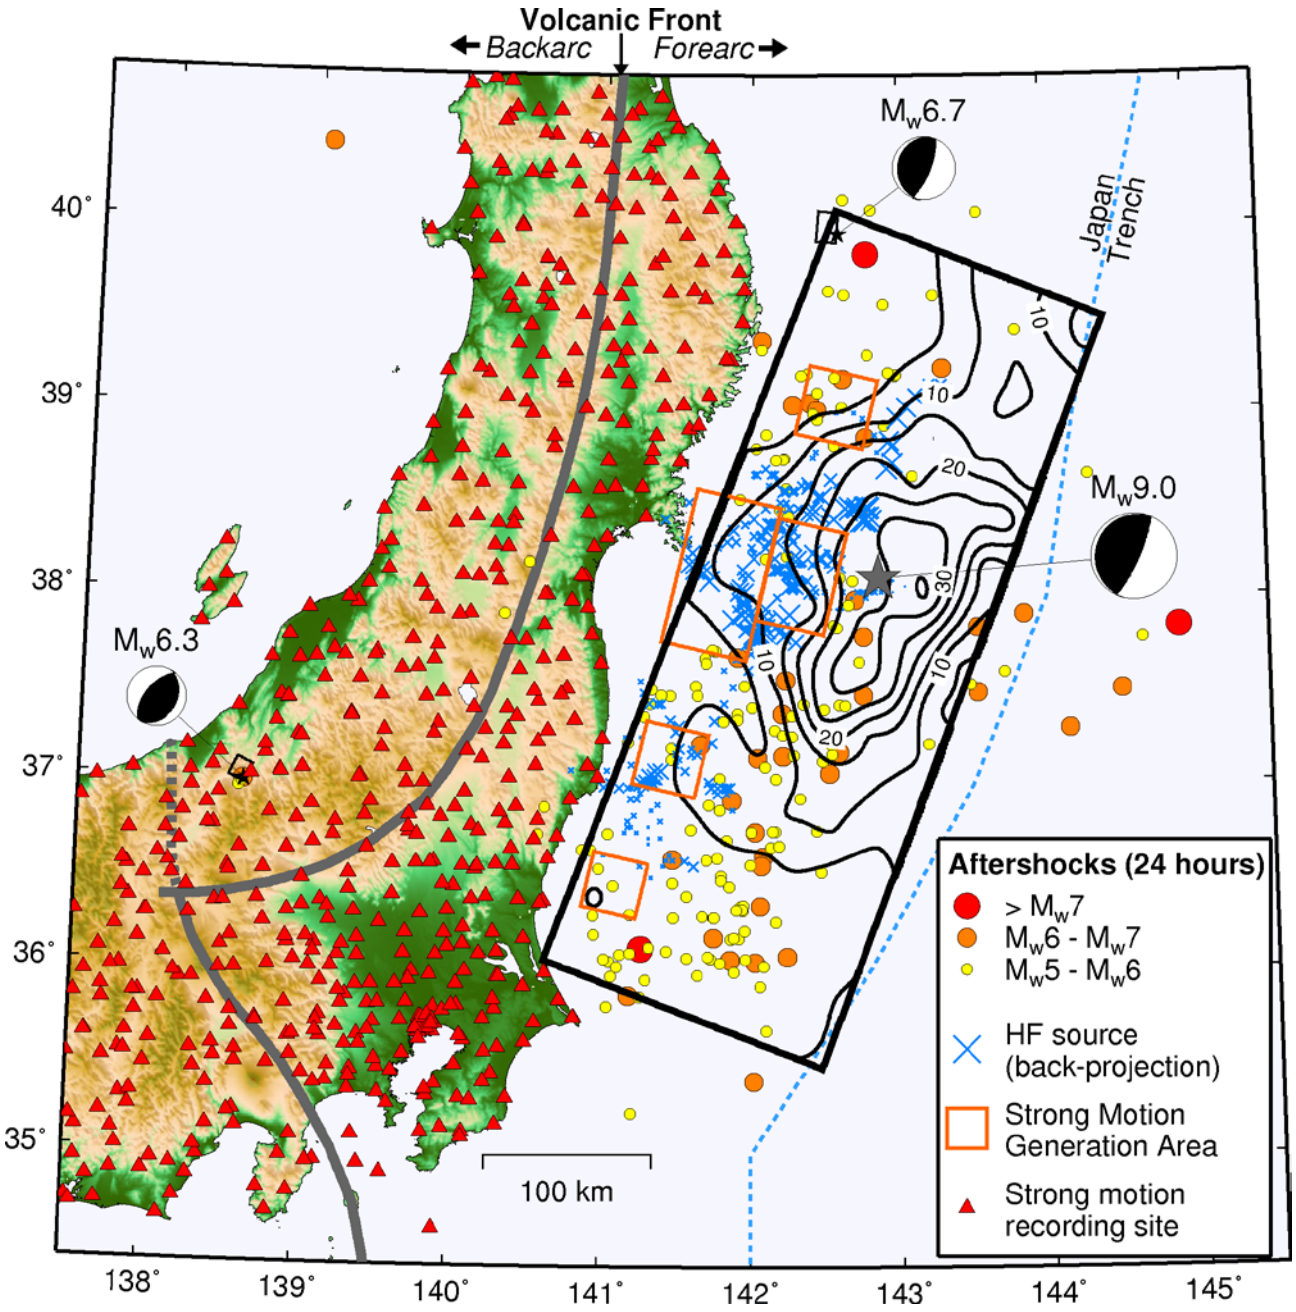

Figure 1. Map view showing surface projections of two selected triggered events for this study (Mw 6.3 crustal event and Mw 6.7 interface event) along with various attributes of mainshock fault model selected by Stewart et al. (2013), which is derived from Yokota et al. (2011). Mainshock fault attributes shown are the Strong Motion Generation Areas of Kurahashi and Irikura (2011) (orange rectangles) and the high-frequency back-projection source locations of Meng et al. (2011) (blue crosses). Contours indicate slip (m) for the Yokota et al. rupture model. Colored circles show aftershocks within the first 24 hours following the mainshock. Dashed blue line indicates location of Japan Trench and the gray star is the JMA epicenter of the mainshock. The red triangles denote the locations of some of the strong motion recording sites considered in our analysis (additional stations were considered beyond the limits of the map).

1. *Location relative to plate boundary.* We sought events on, and inboard from, the plate boundary. This was to see if the forearc/backarc path effects are similar for waves travelling principally in a forearc-to-backarc direction (source to instruments) or vice-versa. We are also interested in event-term trends for these earthquakes relative to the mainshock.
2. *Recordings*. We sought events with numerous uniformly processed recordings using standard Pacific Earthquake Engineering Research (PEER) procedures (Darragh et al., 2004; Chiou et al., 2008) as of 12/2012. The crustal & interface events produced 520 & 472 records.
3. *Magnitude*. We sought events with similar magnitudes.

For the crustal event, we took the fault plane solution of Nagumo (2012). We examined several other fault plane solutions for this event from the JMA web site (http://www.seisvol.kishou.go.jp/eq/sourceprocess/event/201103120359near.pdf, last accessed Dec 2012) and NIED web site (http://cais.gsi.go.jp/YOCHIREN/report/kaihou86/07_04.pdf, last accessed Dec 2012). The Nagumo model was selected because its fault plane solution is most clearly documented. For the interface event, we take the only available fault plane solution, which is from the JMA web site (http://www.seisvol.kishou.go.jp/eq/sourceprocess/ event/20110623near.pdf, last accessed Jan 2013). Both of the selected fault planes are shown in Figure 1.

For both events, we obtained available ground motion records from the Knet and Kik-net arrays at the NIED web site (http://www.kyoshin.bosai.go.jp/kyoshin/, last accessed Dec 2012). A total of 554 and 641 three-component uncorrected digital accelerograms were selected for the crustal and interface events, respectively. Sponsored by the PEER center, those motions were processed by Pacific Engineering and Analysis following PEER/NGA protocols (Darragh et al., 2004; Chiou et al., 2008), which include selection of record-specific corner frequencies to optimize the usable frequency range. For Kik-net sites, only data from the ground surface stations are considered.

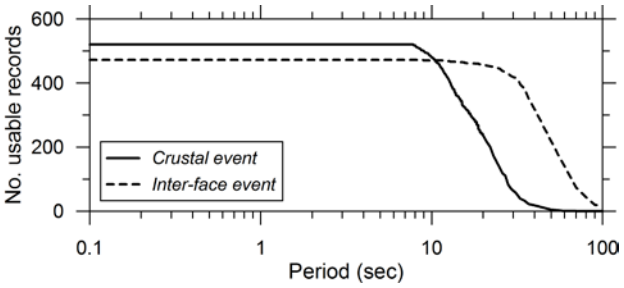

Figure 2. Number of usable two-component horizontal records as function of spectral period for the two data sets

The most important filter is the low-cut filter, which removes low frequency noise effects. We take the minimum usable frequency as $1.25 \times f_{HP}$, where f_{HP} is the high-pass (equivalent to low-cut) corner frequency used in the processing. Using the filtered records, we computed the intensity measures of peak acceleration (PGA), peak velocity (PGV), and pseudo-acceleration response spectra at a range of periods between 0.01 and 10.0 sec. Figure 2 presents the number of usable recordings as a function of period. A usable recording for period T is defined as having both horizontal components with $T < 1/(1.25\ f_{HP})$. The data set is seen to fall off for periods beyond about 10-30 sec.

3. DATA ANALYSIS

3.1 Analysis Procedures

The data analysis follows the same procedures described in Stewart et al. (2013), and hence is described here only briefly. Essentially, we compute total residuals (data minus model in natural log units) using an applicable ground motion prediction equation (GMPE). In this case, we use the Zhao et al. (2006) GMPE. Event terms are computed using the mean of total residuals for conditions where distance attenuation bias is judged to not significantly contaminate the results. Distance attenuation trends are evaluated from the trends of residuals with distance.

A second set of residuals is computed as the difference between data and the GMPE for rock conditions (described in Stewart et al., 2013). These residuals are used to evaluate the scaling of ground motions with the time averaged shear wave velocity in the upper 30 m of the site (V_{s30}).

3.2 Distance Attenuation

Figure 3 shows RotD50 values (i.e, median of single-azimuthal ground motions; Boore, 2010) for PGA, 0.1 s, 1.0 s, and 3.0 s pseudo-acceleration (PSA) at 5% damping versus rupture distance. Also shown in Figure 3a are medians (μ) and medians ± one intra-event standard deviation (ϕ_{ln}) for the ZEA (Zhao et al.) 2006 GMPE for the site category having $V_{s30} \approx 300$ m/s. Figure 4 shows total residuals versus rupture distance. Forearc and backarc sites are distinguished in both Figures 3 and 4.

Several significant trends are evident from Figure 3 and 4. The crustal event occurs in the backarc region and produced backarc recordings from nearly zero distance to large distance. Forearc recordings begin at about 80 km. As shown by the binned median residuals, the forearc recordings have an upward shift relative to the backarc, which is consistent with previously observed trends of faster distance attenuation in backarc than forearc regions (Ghofrani and Atkinson, 2011). This is generally consistent with what we saw with the Tohoku mainshock, but interestingly in this case, the waves are crossing the volcanic front in opposite directions.

The interface event has forearc recordings starting at around 60 km and backarc recordings beginning at about 120 km. Backarc residuals have a clear downward shift relative to the forearc, which is the same trend observed with the Tohoku mainshock data (Ghofrani and Atkinson, 2011; Skarlatoudis and Papazachos, 2012; Stewart et al 2013). Hence, the apparent differences in anelastic attenuation rate in forearc and backarc regions appear to be stable across events and source locations (relative to volcanic front).

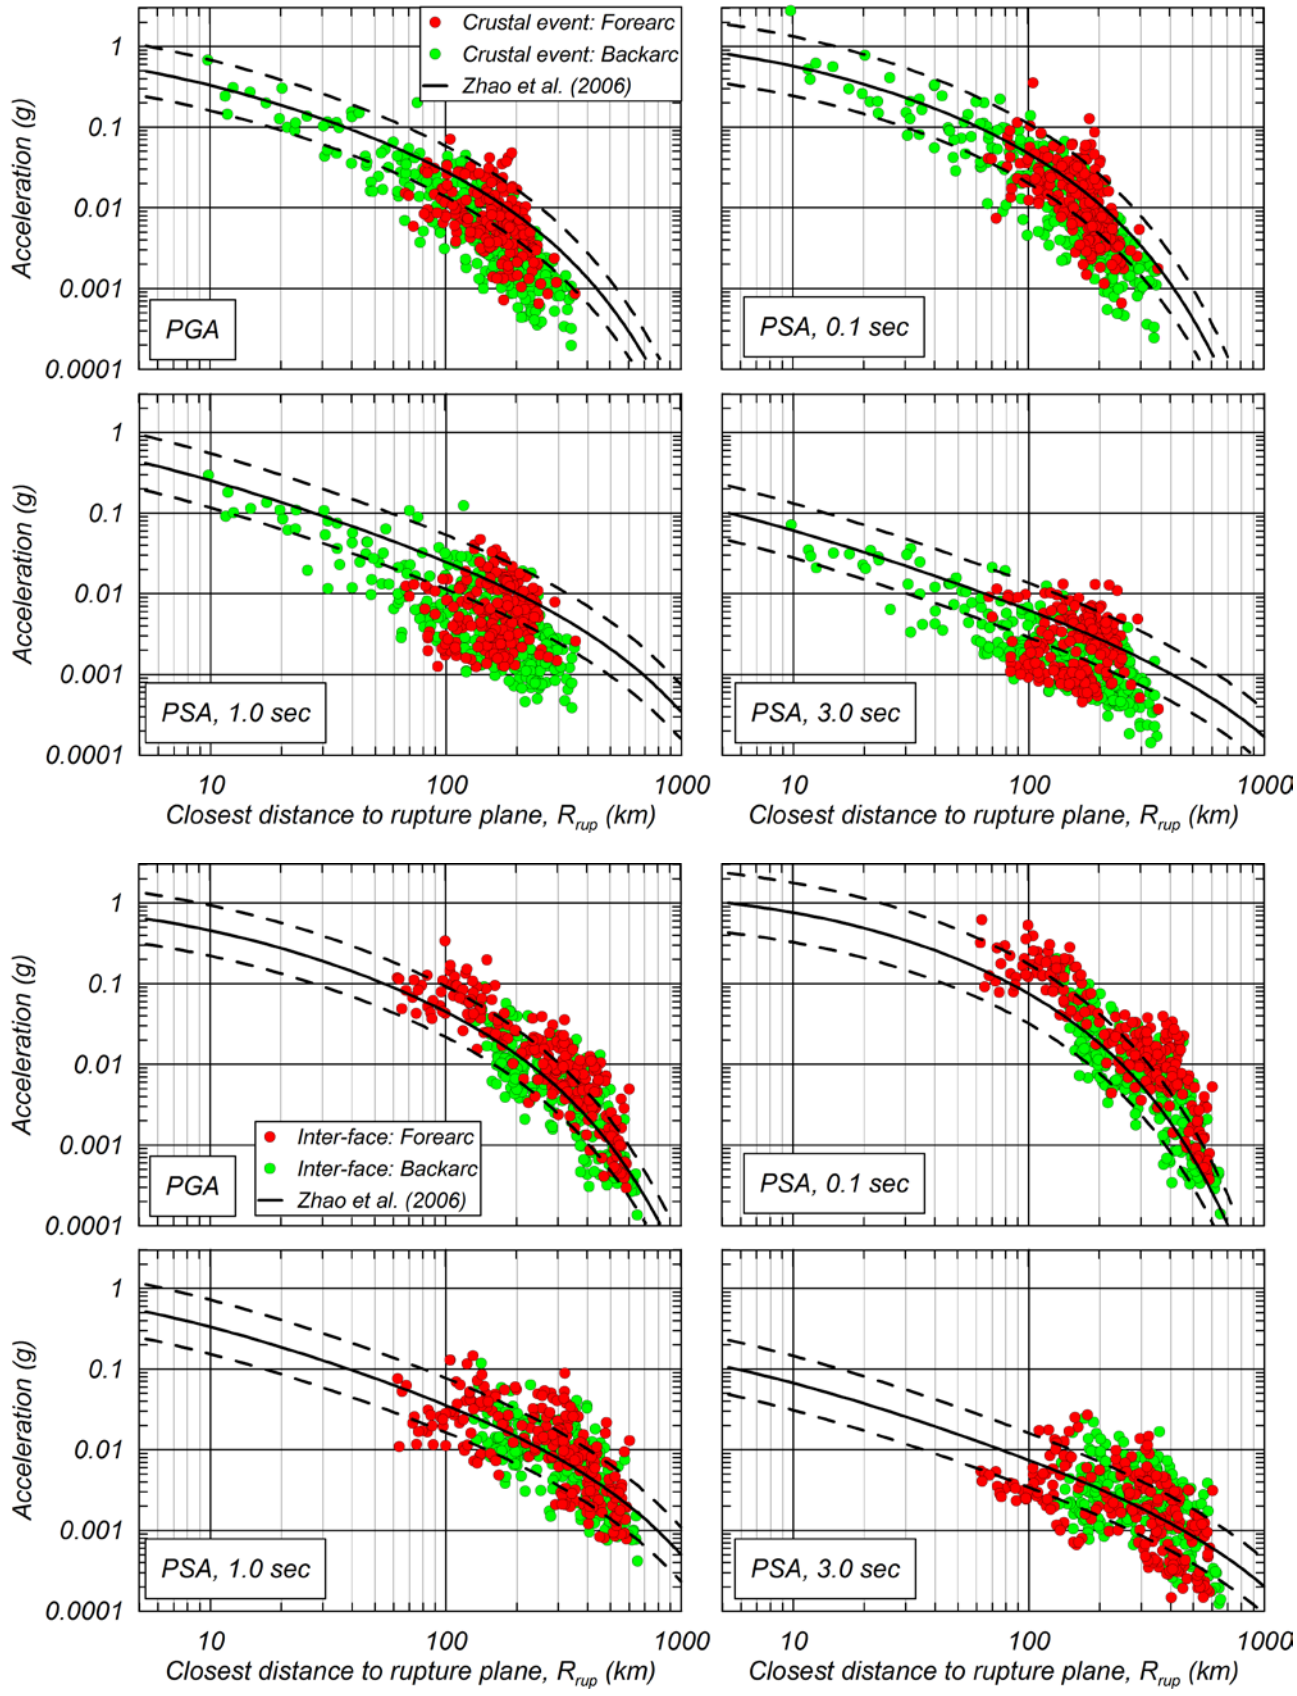

Figure 3. Ground motion intensity measures plotted against distance for crustal (top) and interface (bottom) triggered events. Backarc and forearc records shown with separate symbols. Zhao et al. 2006 GMPE shown for soil site condition.

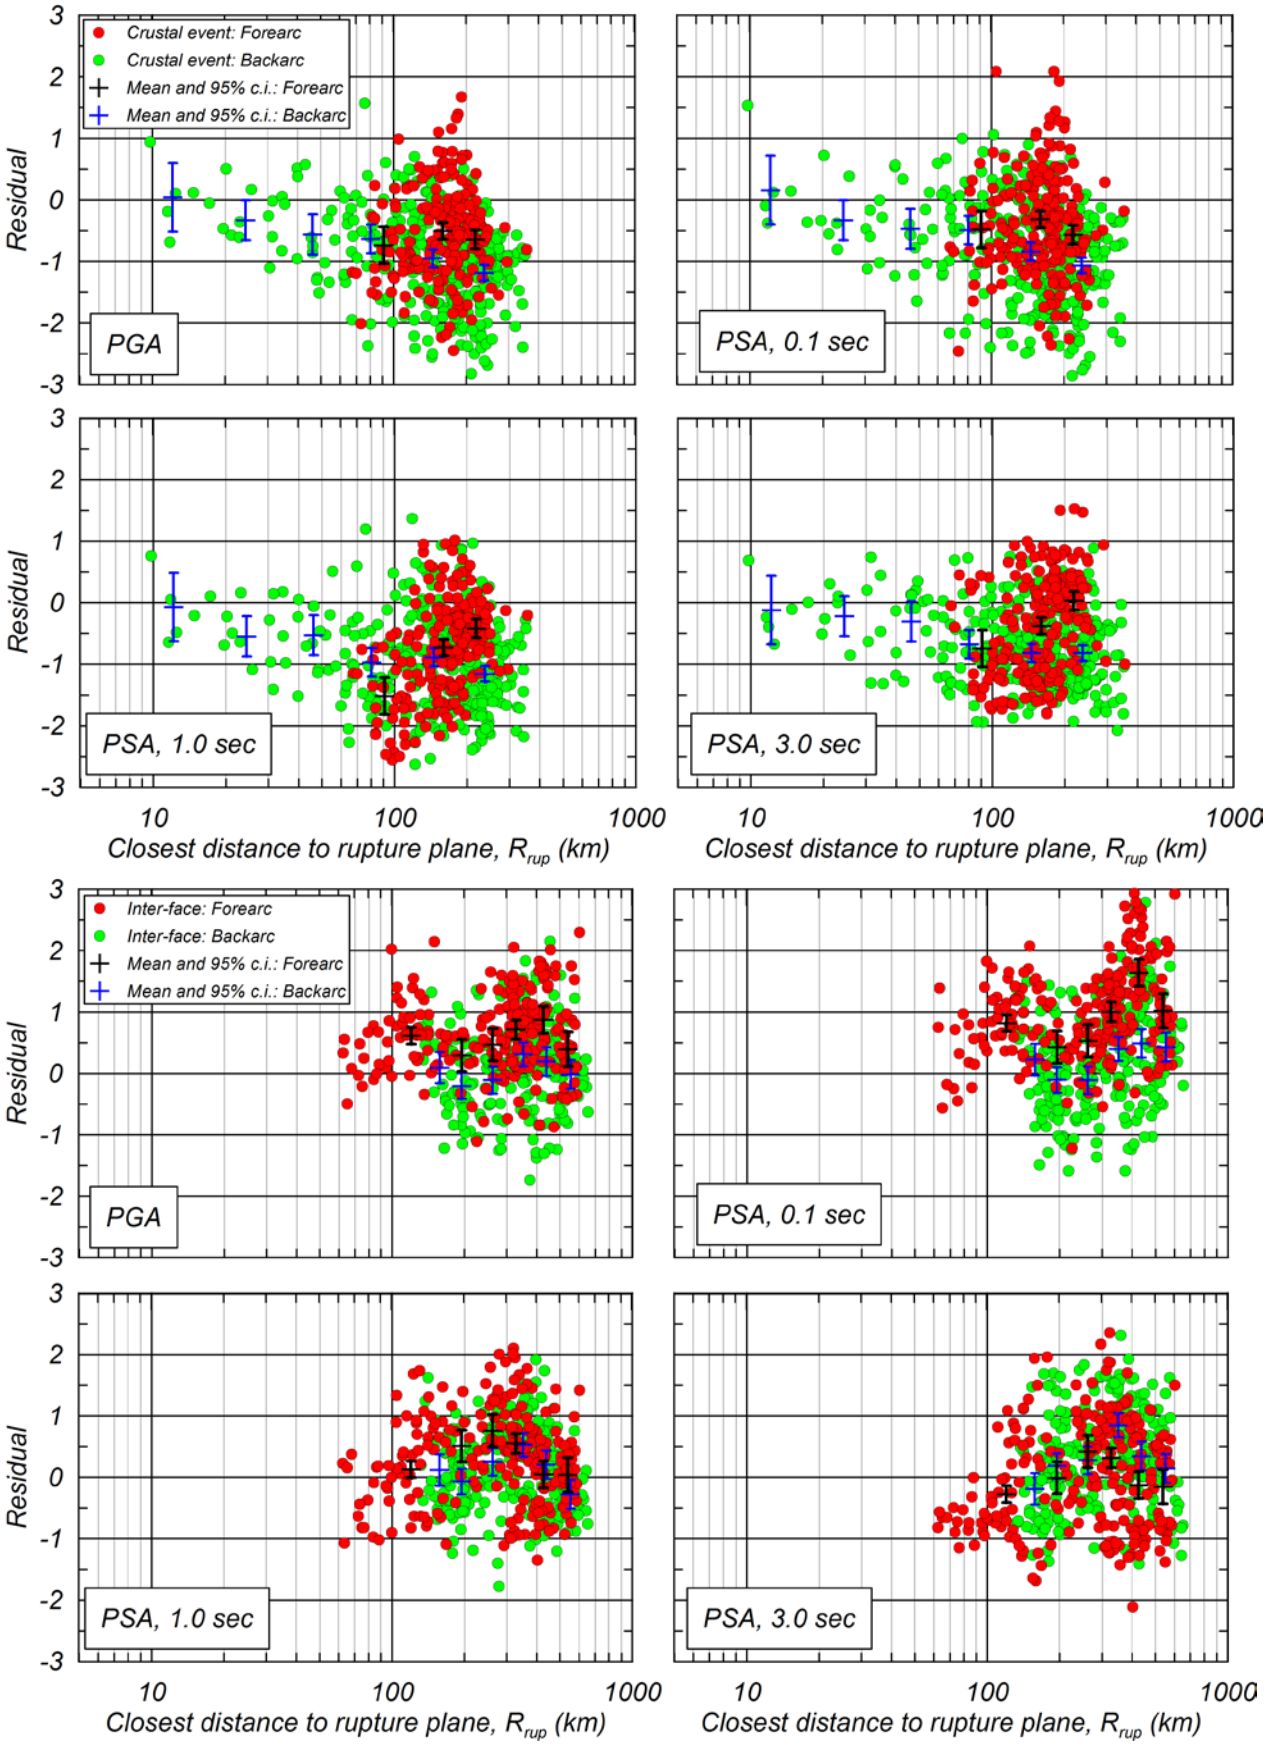

Figure 4. Distance-dependence of total residuals for crustal (top) and interface (bottom) events relative to ZEA 2006 GMPE.

3.3 Event Terms

As shown in Figure 4, in most cases the residuals are not centered at zero ordinate, indicating systematic misfits of the GMPE relative to the data. Since the events are well recorded, this bias is practically equivalent to an event term as would be calculated from a mixed-effects regression (e.g., Abrahamson and Youngs, 1992). Non-zero event terms (η) are typical; what is of interest is to see if the event terms are consistent with event-to-event scatter (represented by event term standard deviation τ) as observed from previous earthquakes. Figure 5 shows event terms, calculated using the following data for the two earthquakes:

1. For the crustal event, we use a combination of backarc recordings with closest distance (R_{rup}) < 70 km and forearc to R_{rup} < 250 km. We include the close-distance backarc records because the distance attenuation is dominated by geometric spreading in that region.
2. For the interface event, we use forearc recordings with R_{rup} < 250 km.

Event terms are taken as median residuals for the ZEA 2006 GMPE as a function of spectral period. Also shown in Figure 5 are the $\pm$ τ model (inter-event standard deviation) from ZEA 2006. We note that the mainshock and interface event terms have a similar trend with period, whereas the crustal event is different because of an increase at long period. One possible explanation for this is stronger surface waves excited by the shallow crustal event compared to the lack of surface waves for the relatively deep interface event. These surface waves would be more pronounced at the longer periods due to the higher attenuation of shorter periods in the shallow crust. Analyses of additional events are needed to determine whether these effects are accidental or systematic.

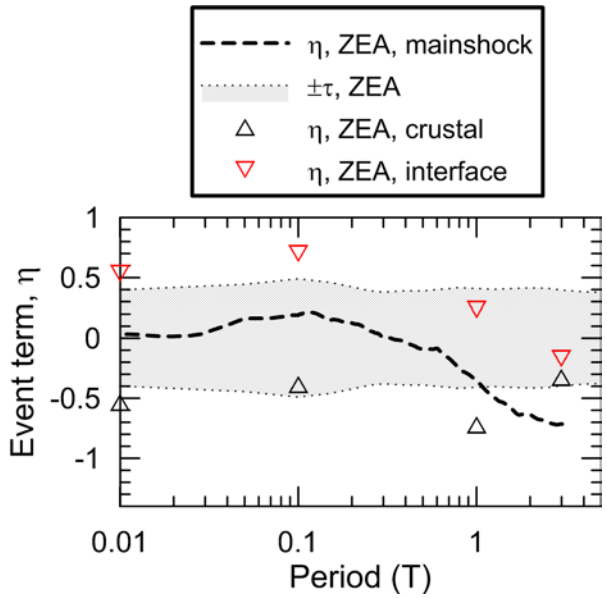

Fig. 5. Estimated event terms of Tohoku-oki mainshock and two triggered events relative to the ZEA 2006 GMPE. Also shown is the ZEA inter-event standard deviation (τ).

3.4 Site Response

A meaningful analysis of site effects from these data sets is complicated by the significant distance attenuation misfits identified in Section 3.2, which cause large non-zero residuals for reasons unrelated to site response. Accordingly, for the analysis of site effects, we use the subset of data used for event term computations (described in Section 3.3), for which distance attenuation trends are relatively well-matched by the ZEA GMPE. We use intra-event reference site residuals, which are total reference site residuals corrected to zero mean through subtraction of the event term (details in Stewart et al. 2013).

Figure 6 shows the trends of ZEA 2006 reference site residuals for the crustal event against V_{s30} for the intensity measures of PGA and PSA at 0.1, 1.0, and 3.0 sec. A log-linear regression is also shown.

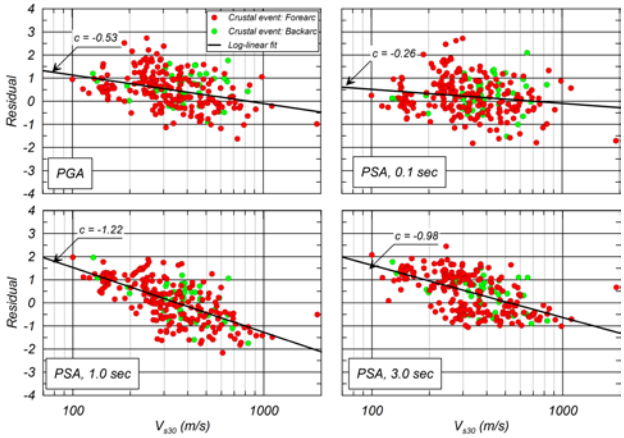

Fig. 6. Reference rock residuals of crustal event using ZEA 2006 GMPE for rock site conditions, showing scaling of site factors with V_{s30}.

Figure 7 shows the slopes of the fit lines (denoted as c) for both events against trends presented previously for the Tohoku mainshock and a representative model for active crustal regions (ACRs; Choi and Stewart, 2005). The slopes from these events differ from those for the mainshock at short periods, having stronger V_{s30} scaling. These differences may be influenced by nonlinearity.

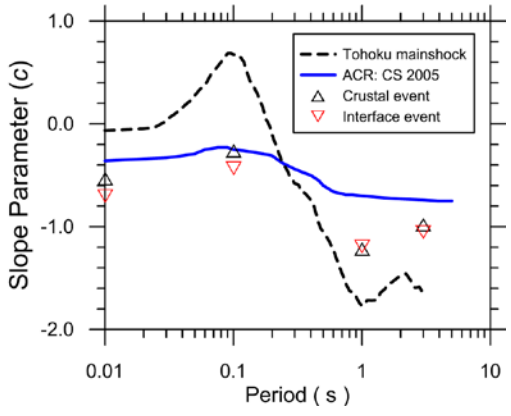

Fig. 7. V_{s30}-scaling of rock residuals (c parameter) from mainshock, subsequent events, and ACR model

4. CONCLUSIONS

In a separate paper investigating the attributes of the Tohoku-oki mainshock data (Stewart et al., 2013), we found important attributes of the ground motions that have substantial practical importance for seismic hazard analysis. Among those attributes were: (*i*) faster anelastic attenuation in the backarc region as compared to the forearc region; (*ii*) positive event terms at short periods that decrease as period increases; and (*iii*) scaling of site amplification with V_{s30} that is substantially reduced from that in active crustal regions at short periods but enhanced at long periods (weaker and stronger V_{s30}-scaling, respectively). We note here that the analysis of site effects from the Tohoku mainshock did not consider nonlinearities.

In this paper, we examine the repeatability of these effects using an admittedly small data set of two events subsequent to the mainshock – one a crustal event in the backarc region and one occurring at the plate interface on the mainshock fault plane. Both events are well recorded and the data was uniformly processed using standard PEER procedures in the same manner as the mainshock data.

We find the variable anelastic attenuation rates to be repeatable, even though one of the considered events occurred on the backarc side of the volcanic front. This is perhaps our most significant finding in this paper. The interface event terms follow a similar form to those from the mainshock, whereas the crustal event shows a different pattern at long periods, but we cannot draw statistically significant inferences from so few earthquakes. The V_{s30}-scaling from these events was much stronger at short periods than had been observed in the mainshock, but relatively consistent at long periods. The differences at short period may be a result of nonlinearity, but further study will be required to understand these differences.

SITE RESPONSE DURING STRONG SHAKING – ESTIMATED FROM THE 2011 TOHOKU EARTHQUAKE-

Kenichi Tsuda

1) Researcher, Institute of Technology, Shimizu Corporation, Japan
kenichi.tsuda@shimz.co.jp

Abstract: The 2011 Tohoku earthquake, largest earthquake recorded in Japan (Mw 9.0) produced large ground motions and brought severe damage on broad area. Kanto area, more than 300 km away from the hypocenter, experienced severe damage from large ground motions amplified by the deep sedimentary basin. Also these amplified ground motions produced nonlinear soil behavior causing the liquefaction.

In order to get better understandings for the nonlinear soil behavior, the precise comparison of site response between during strong shaking like the main event of this earthquake and during moderate or weak ground shaking. I have used the data from seismograph arrays densely deployed on the Kanto area. The arrays include K-NET, KiK-net and other strong motions arrays etc. I compared the site response by using moderate sized event (Tsuda *et al.*, 2010) and the site response computed from this earthquake incorporated the finite faults effects based on the source model obtained by Asano and Iwata (2012) with four strong motion generation areas (SMGA). The comparison of site response could lead to the better understandings of how site response has been changed dependent of level of ground motions.

1. INTRODUCTION

The observed ground motions are constituted by three different factors: seismic source (source effects), wave propagation through heterogeneous earth's interior (path effects), and local geological conditions (site effects). This relationship can be represented by the following equation;

$$O(t) = S(t) * P(t) * G(t) \qquad (1)$$

where * is the convolution operator, O(t) is the observed records, S(t) means the source effects of earthquake ruptures, P(t) means the path effects of wave propagation through the heterogeneous earth's interior, and G(t) means the site response close to the stations. This basic equation has been used to estimate site response based on the observed records.

The off-coast of Tohoku earthquake (Tohoku-Oki earthquake) with moment magnitude M_w 9 is one of the largest earthquakes in Japan that has been well recorded in the near vicinity of the source area (Aoi *et al*, 2012). The source area extends to almost 500 km along the latitude and 200km along dip (*e.g.*, Simons, *et al.*, 2011; Suzuki *et al.*, 2011). Figure 1 shows the observed waveforms along the coast line (Asano and Iwata, 2012). As seen, four distinct wave packets are recognized. The observed records of this event are also characterized by the longer duration of strong shaking. One site recorded a JMA intensity value of 7 (maximum value of this scale) and 28 sites recorded values of 6+. The observed PGA values from K-NET and KiK-net showed large accelerations for many sites (19 sites showed PGA larger than 1 g) and strong motion duration longer than 80 s (time interval between 5% and 95% of the Arias intensity).

Some records observed on the deep sediment sites showed different types of nonlinear soil behavior, going from traditional high frequency deamplification to liquefaction (Bonilla *et al.*, 2011). Some of these sites are located far fromw the faults area, such as the Chiba and Tokyo prefectures. For example, Fujikawa (2011) reported that boil sand or liquefaction could be seen for some sites around the eastern area of Tokyo located on soft soil.

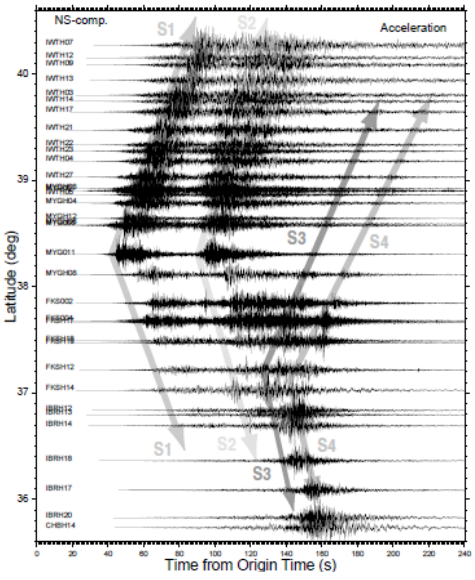

Figure 1 Record section of the NS component of acceleration according to the latitude. Each waveform is normalized by its maximum amplitude. Arrows indicate the distinctive wave packets seen on the records (Asano and Iwata, 2012)

Also the report compiled by the Shimizu corporation (2011) showed that the location with being seen the liquefaction during or after the mainshock of Tohoku-earthquake are very broad. Since then, many researchers have analyzed the observed data to understand the phenomena and tried to reproduce the records based on various kinds of assumption. However, observed records themselves already include the source and path effects. This means the separation of source and path effects are necessary to estimate site response during strong shaking.

In this study, we have tried to estimate the site response during strong shaking after separating source and path effects. The resultant site responses have been compared to those obtained by using the weak motion data i.e., linear case. This comparison indicates that how the site response changed during the strong shaking.

2. DATA

Among the sites with observed records showing nonlinear soil behavior, the K-NET station CHB024 is picked in this study as a target site. This site is located in the Chiba prefecture and faces Tokyo Bay. Even though this site located on the deep sedimentary basin is more than 300 km away from the hypocenter of this earthquake, the observed records showed the striking features of nonlinear soil behavior have been seen mentioned as Bonilla *et al.* (2011). The observed waveforms of the two horizontal components are shown in Figure 2 (a).

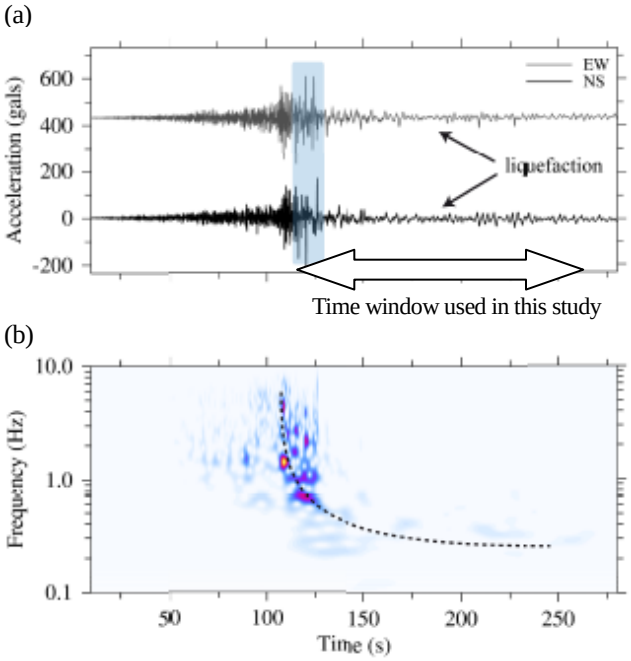

Figure 2 Observed records at the station of CHB024 (a) acceleration time histories of horizontal components (b) energy spectral density as a function of time (Bonilla *et al.*, 2011)

The shaded area shows strong cyclic mobility and looks start liquefaction after that phase. Bonilla *et al.* (2011) investigated the Stockwell transform to estimate how the frequency contents have been changed during strong shaking. Figure 2 (b) shows the results and apparent frequency shift to the lower side could be seen after the phase corresponding to the shaded area in Figure 2(a). In this study, the time window of 150sec showing Figure 2(a) that corresponds to the S-wave portion and includes the onset of nonlinear soil behavior is used to estimate site response for strong shaking. Two horizontal components are used and vectorial summed for each frequency after Fourier amplitude spectra are calculated. As for the estimation of site response for weak motion, the data obtained by the moderate sized events are used with the time window of 10 sec for S waves (Tsuda *et al*., 2010 and Hayakawa *et al.*, 2010).

3. METHOD OF ESTIMATING SITE RESPONSE

In order to estimate site response, we have to separate the source and path effects from observed records. However, separation of those effects is sometimes difficult. Usually the way to separation is based on the spectral inversion analysis (Iwata and Irikura, 1988; Yamanaka *et al.*, 1998), however, the site response is the relative values to the reference site and the selection of the reference is always the issues for this analysis. For this problem, Tsuda *et al.* (2006) proposed the method of spectral inversion method independent of the selection of reference site. Explaining the detail concept for this spectral inversion analysis applied in this study is beyond this study, we explain briefly how the site response is estimated for the weak motion (linear case) and strong motion (nonlinear case).

3.1 Site Response for the Weak Motion

In a frequency domain, the observed records representing the equation (1) can be rewritten as a multiplication:

$$|A(f)| = |S(f)|\,|Site(f)|\,R^{-1}\,e^{-\pi f R / Q(f)\beta} \qquad (2)$$

where f is frequency, $|A(f)|$ is the acceleration amplitude spectrum of the recorded ground motion, $|S(f)|$ is the source spectrum, $Q(f)$ is the quality factor, which is assumed to be frequency dependent, $|Site(f)|$ is the site response amplitude, R is the distance from source to site, and β is the average shear wave velocity of the medium (3.7 km/s, Yamanaka *et al.*, 1998). Following equation 3 uses Boatwright's (1978) representation of a source spectrum (Brune, 1970), in which the amplitude of the source spectrum has a nonlinear dependence on the corner frequency:

$$|S(f)| = C\,M_o(2\pi f)^2 \cdot f_c^2 / (f^4 + f_c^4)^{0.5} \qquad (3)$$

where

$$C = (G_0 \cdot F^{rad}) / (4\pi\rho V_S^3) \qquad (4)$$

C depends on the radiation parameter of the source: F^{rad} is

the effects of this radiation pattern coefficients on site response estimation will be discussed, the material parameters for source area (3200 [kg/m³] for density: ρ and 4.46 km/s for shear wave velocity: V_S, Fukuyama *et al.*, 1998) and the free surface effect G_o is included.

Tsuda *et al.* (2010) applied the idea of Tsuda *et al.* (2006) to estimate site response by using the data for moderate sized events surrounding the Kanto area. Hayakawa *et al.* (2010) updated those site responses especially for the longer period. They incorporated the effects of radiation pattern (focal mechanism) into the estimation of site response especially for the lower frequency range (< 0.5 Hz) based on the same data set by Tsuda *et al.* (2010). They assumed the theoretical radiation calculated by the focal mechanism determined by the National Research Institute for Earth Science and Disaster Prevention (Fukuyama *et al.*, 1998).

The site responses for the weak motion are combined the results of Hayawaka *et al.* (2010) for lower than 0.5 Hz and Tsuda *et al.* (2010) for higher than 0.5 Hz. The site response for weak motion at CHB024 site is shown in Figure 3.

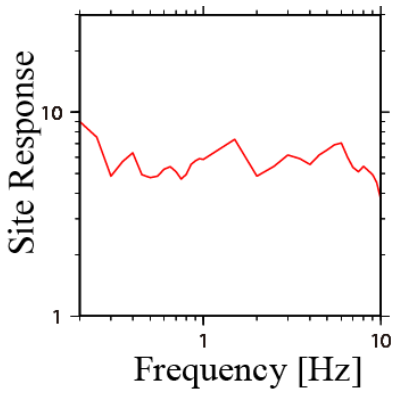

Figure 3 Estimated site responses for weak motion at CHB024 site.

3.2 Site Response for the Strong Motion

The idea of spectral inversion analysis is based on the point-source approximation *i.e.*, the fault finiteness is not incorporated. Tsuda and Steidl (2006) have tried to estimate site response during strong shaking for two large events, 2003 (Mw 7.0) and 2005 (Mw 7.2) Miyagi-Oki earthquakes. They incorporated the fault finiteness by incorporating the effects of radiation pattern for low frequency range. This study follows the similar procedures based on the source model for the Tohoku-Oki earthquake.

The number of source model for this earthquake has been already proposed based on the various kinds of data. Asano and Iwata also proposed the source model composed of four strong motion generation areas (SMGA) using the empirical Green's function method. The location of SMGA and the hypocenters of empirical Green's function and hypocenter of the main shock are shown in Figure 4.They used two moderate sized events as the empirical Green's functions with frequency range of 0.1 – 10.0 Hz. They estimated the source parameters, such as the spatial dimensions, stress drop, rise times, rupture starting points inside SMGA and velocity of rupture propagation for each SMGA.

Table 1 Source Parameters for each SMGA (Asano and Iwata, 2012)

	SMGA1	SMGA2	SMGA3	SMGA4
Strike [deg]	195	195	198	203
Dip [deg]	13	13	17	20
Area [km^2]	1296.0	1296.0	1225.0	1225.0
Seismic Moment [Nm]	4.57E+20	5.33E+20	3.07E+20	1.16E+20
Stress Drop [Mpa]	23.9	27.8	17.5	6.6
Average Slip [m]	5.2	6.1	3.7	1.4
Corner Frequency [Hz]	0.0815	0.0814	0.0838	0.0838

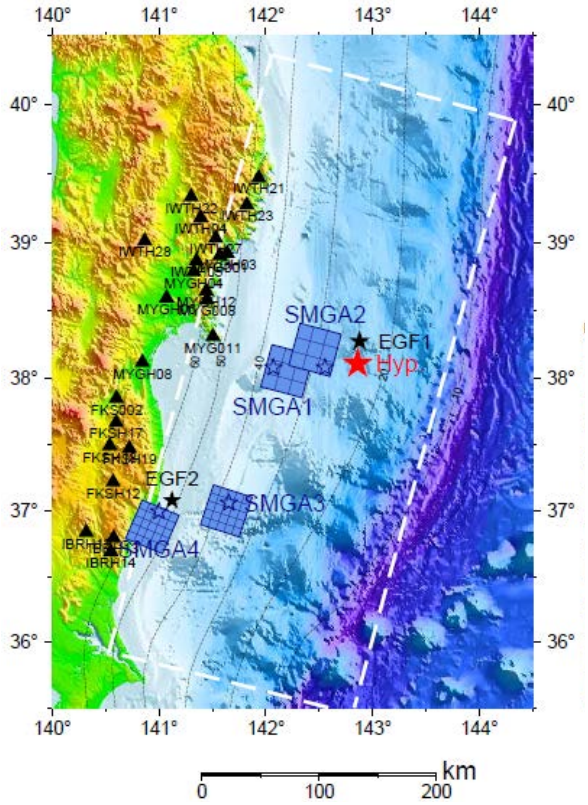

Figure 4 Source model by Asano and Iwata (2012) composed of four SMGAs. The blue open stars denote the rupture starting points of each SMGA. The broken rectangle indicates the fault plane of the 2011 Tohoku-Oki earthquake by Suzuki *et al.* (2011).

The source parameters determined by Asano and Iwata are listed on Table 1. The corner frequency is calculated based on the following relations (Brune, 1970)

$$f_c = 0.37\ Vs\ (16\ \Delta\sigma / 7\ M_o)^{(1/3)} \quad (5)$$

where $\Delta\sigma$ is the stress drop and M_o is the seismic moment for each SMGA, respectively. Each value is used on the Table 1. Vs is the shear wave velocity around the source area (4.46 km/s).

The source spectrum (Equation 3) is calculated for each SMGA. They summed to make the source spectrum for the whole mainshock. The observed waveform (Figure 2) of this site has only one wave packet unlike the sites close to the fault plane (Figure 1). This feature leads to the summation of source spectrum for each spectrum without any correction based on any features, such as the distance to the site, size of each SMGA, and seismic moment ratio etc. As for the radiation pattern coefficient, the theoretical values (Aki and Richards, 2002) are considered in the 0.1-0.5 Hz and the isotropic radiation (radiation pattern coefficient is 0.63, Boore and Boatwright, 1984) are used higher than 0.5 Hz. The focal mechanism for each SMGA to calculate the radiation pattern coefficient is listed on Table 1. The rake angle is set 90° because of its type of earthquake and assumed to be constant for whole area of SMGA .

The path effects represented by the quality factor Q(f) used the results by Tsuda *et al.* (2010) as a function of frequency:

$$Q(f) = 107f^{0.52} \quad (6)$$

The hypocentral distances in equation (2) assumed the distance between rupture starting points for each asperity (blue open stars in each SMGA of figure 5) and the site. After correction of source, path effects and geometrical spreading to the observed amplitude spectrum |A(f)|, the site responses are estimated as follows:

$$|Site(f)| = R|A(f)| / (|S(f)|\ e^{-\pi f R / Q(f)\beta}) \quad (7)$$

The source spectrum summed for four SMGA corresponds to the area of radiating for strong motion not from the entire area. On the contrary, the seismic waves observed at site include the waves look radiated from the entire area. This leads to the underestimation of source spectrum. Thus, the source spectrum in Equation 7 is corrected by the ratio of seismic moment based on the values determined by NIED (Fukuyama *et al.*, 1998) in this study.

4. Results

In Figure 5(a), the site response for the strong motion is shown. The site response for the weak motion is also plotted to compare it. The ratio of site response between strong motion/weak motion is shown in Figure 5(b). As seen on the figure, the site response for the strong motion showing apparent deamplification compare to the weak motion especially above 0.5 Hz. As for the lower frequency range, the data used to estimate site response for weak motion might be contaminated by the noise. On the contrary, the predominant frequencies around 1.5 Hz in weak motion looks shifting to lower than 1 Hz of site response for strong motion.

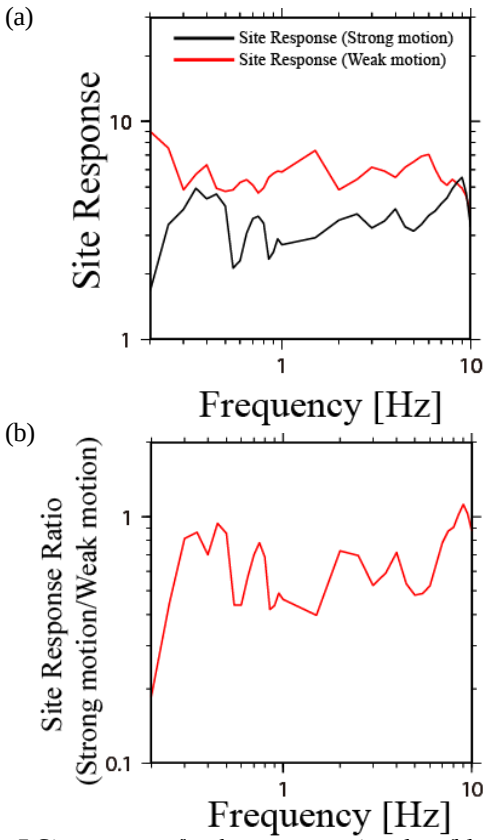

Figure 5 Site response for the strong motion data (black line) and weak motion data (red line) (a) and site response ratio between weak motion and strong motion (b).

5. Summary

The site responses for strong motions of the mainshock of the 2011 Tohoku earthquake have been compared to those for moderate sized events on the CHB024 site. The observed record for this site shows distinct nonlinear soil behavior during the mainshock. The source and path effects are corrected based on the previous studies including the focal mechanism and quality factors. The site responses for the weak motion include the effects of radiation pattern especially in lower frequency range.

The comparison of site response shows the clear deamplification and shift of lower frequency range of predominant frequencies of site response. The estimation of site response for strong motion are based on some assumptions such as how the rupture directivity are incorporated how source spectrum for each SMGA are summed, quality factor or total moment values for the main

shock etc. These assumptions should be validated for the better estimation of site response for strong motion and will be discussed in the future. The investigation of the conditions for how site responses have been changed as a function of soil conditions, ground motion parameters such as PGA, PGV or Arias Intensity etc is the next step. And the compilations of these conditions are very useful for the ground motion prediction for future large events on the sites of soft soil such as CHB024 site.

Abstract: During the 2011 off the Pacific coast of Tohoku Earthquake (refer as the 2011 Tohoku earthquake), an abundant of strong ground motion records has been derived. This provides us opportunity to develop a GMPE to be applicable to a M9 class earthquake. In this study, we updated the database of strong ground motion on hard rock to include the records from the Tohoku earthquake and the main aftershocks and induced earthquakes. The new data are mainly derived from the observation stations of KiK-net and are estimated on hard rock with a shear-wave speed over 2 km/sec. Based on the new database, we updated the GMPE for response spectra on hard rock. The feature and the validity of the GMPE are discussed.

1. INTRODUCTION

During the 2011 M_w9.0 off the Pacific coast of Tohoku Earthquake (refer as the Tohoku earthquake hereafter), an abundant of strong ground motion records has been derived. This is the first time that the strong motion recordings from a M9 class earthquake have been derived at over thousands stations. Based on the analysis of the data, it is indicated that the attenuation characteristics of the peak ground motion for a M9 class earthquake may be different from those for a M8 or smaller earthquakes (e.g., Si et al., 2011a, b). This implies that for the prediction of strong ground motion for a M9 class earthquake, the data from the 2011 Tohoku earthquake should be included to the database used in the development of the ground motion prediction equation (GMPE).

On the other hand, so far, a database of strong ground motion on hard rock has been constructed, and preliminarily a GMPE has been developed based on the database (Si et al., 2011c). Since the largest earthquake included in the current database is M_w8.3, it is necessary to include the data from the Tohoku earthquake.

In this study, we updated the database to include the records from the Tohoku earthquake and its main aftershocks and induced earthquakes. Based on the database, we updated the GMPE for response spectra on hard rock. In this paper, the preliminary results of the updated database and GMPE will be presented.

2. DATA

2.1 Outline of the database

The strong ground motion records from 7 earthquakes including the 2011 Tohoku earthquake are collected and added to the database established by Si et al. (2011c). Among these earthquakes, there are 3 crustal earthquakes, 3 inter-plate earthquakes, and 1 intra-plate earthquake. Totally, there are 14 crustal earthquakes, 11 inter-plate earthquakes, and 9 intra-plate earthquakes in the database. Table 1 show the earthquakes used in this study. Figure 1 shows the histogram of the earthquake type and the plot of moment magnitude versus the focal depth.

In the database, the distance definitions are fault distance (FD) and the equivalent hypocentral distance (EHD), both measured from the fault plane for each earthquake. The moment magnitudes are adopted from the global CMT resolution. The range of M_w is from 5.5 to 9.1.

Figure 2 shows the distribution of M_w and FD of the records in the database. From the figure, it can be confirmed that the near-field data are also included in the database.

All the data added in this study are recorded at stations of KiK-net operated by National Research Institute for Earth Science and Disaster Prevention (NIED). Response spectrum is defined as GMRotI50 proposed by Boore et al. (2006) for horizontal components, and response spectra for vertical components. The updated database for response spectra on hard rock is consists of the records derived at

2.2 Estimation of ground motion on hard rock

As the same as in Si et al. (2011c), the new data added to the database were selected to be recorded at stations where the underground seismograph is located on the hard rock with a Vs≧2km/s. The strong motion observation system of KiK-net is a vertical array in which the seismographs are installed both on the ground surface and on the bottom of the borehole. By taking the advantage of the vertical array, firstly the parameters of the soil profile in the borehole are identified by fitting the transfer function defined as the ratio of the Fourier spectra of the seismic wave recorded on ground surface and the bottom of the borehole, then the strong motions on bedrock are directly estimated based on the records on ground surface and the theoretic amplification factor calculated based on the identified soil profile. All the data from KiK-net are derived by using this method.

3. REGRESSION ANALYSIS

3.1 Regression analysis for distance dependency

We performed a two-step regression analysis. In the first step, the regression model shown in Eq.(1) fits to the data to remove the distance dependency by determining the regression coefficients, including the event term b (T).

$$\log SA(T) = b(T) + g(X) - kX + \varepsilon(T)$$
$$g(X) = \begin{cases} -\log(X + C); D \le 30km \\ 0.6\log(1.7D + C) - 1.6\log(X + C); D > 30km \ \& \ X \ge 1.7D \end{cases}$$
$$C = 0.0055 \cdot 10^{0.5M_w}, T < 0.3s$$
$$= 0.0028 \cdot 10^{0.5M_w}, T \ge 0.6s$$
$$k = 0.003, T < 0.3s$$
$$= 0.002, T \ge 0.6s \qquad (1)$$

Where, SA(T) shows GMTRotI50, an average response spectra proposed by Boore et al. (2006) for horizontal components, and response spectra for vertical components. X show fault distance (FD) or equivalent hypocentral distance (EHD). D shows the focal depth.

Function of g(X) shows modeling for different attenuation rates for shallow and deep earthquake originally proposed by Midorikawa and Ohtake (2002).

C shows the saturation of strong motion in short-distance when using fault distance, and k shows the coefficient for anelastic attenuation. Here, since no sufficient data to determine the coefficient of C and k based on regression method, we adopt the values of PGA and PGV in Si and Midorikawa (1999) for short- and long-period, respectively (See Eq. (1)). At the transition periods, interpolation between short- and long-period is used.

When fitting the data, following weighting schemes are used: 8 for distance ≤ 25km; 4 for ≤50km; 2 for ≤ 100km. Figure 3 shows examples of the fit of strong motion data and the regression model. The same operation is applied to all the dataset.

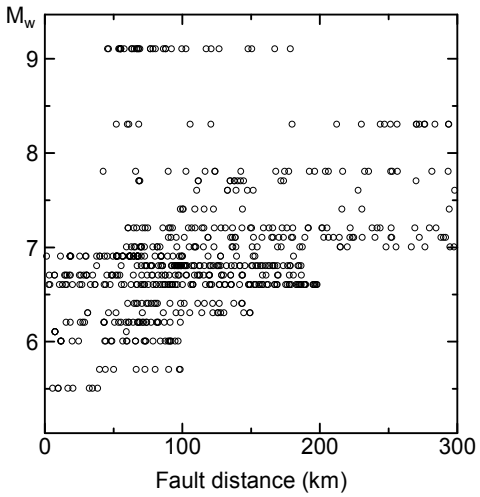

Figure 2 Distribution of Mw vs. fault distance

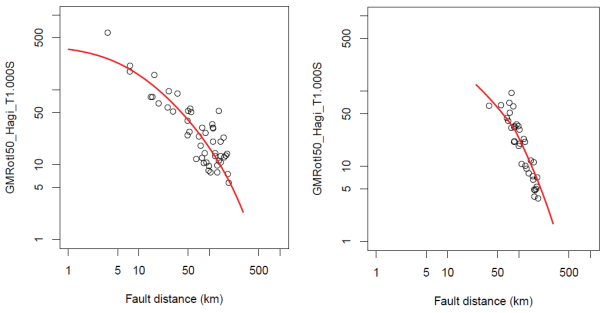

Figure 3 Example of fitting of the regression model and the observation data at period of 1.0 s. (No.12 (left) and 13 (right) earthquakes in Table 1)

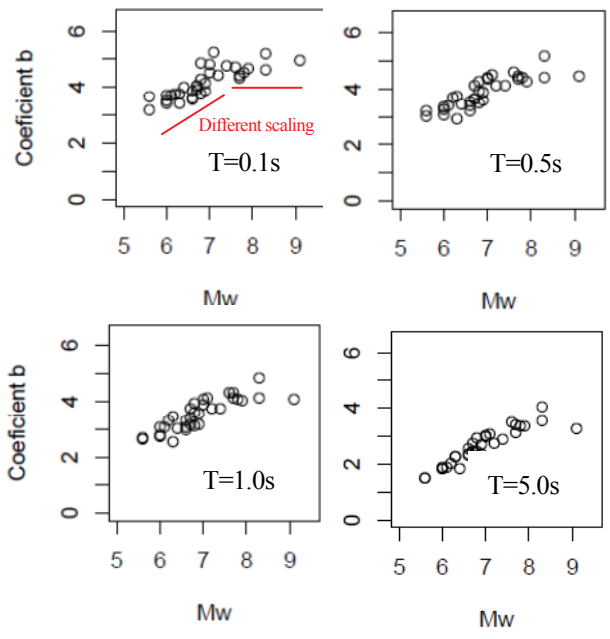

Figure 4 Plots of coefficient b (T) versus M_w

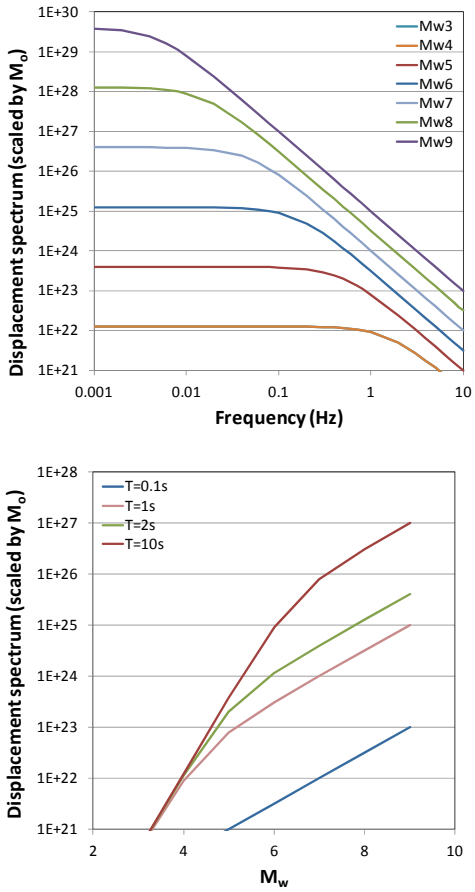

Figure 5 illustration of scaling law for source spectra. (upper: far-field displacement spectra; lower: amplitude of the displacement spectra at different periods versus M_w.)

3.2 Regression model for b (T)

The results for b (T) are plotted Versus M_w in Figure 4. From the Figure, it can be confirmed that b (T) are strongly correlated with M_w until M_w 7 or 8. For the earthquakes with larger M_w, the scaling becomes weak. This phenomenon has been interpreted by the saturation of ground motion (especially relatively short-period ground motion) with large M_w (cf., Si et al., 2011a, b). For long-period ground motion, in addition to the saturation for M_w, the difference in scaling of M_w inferred based on the seismic source spectra, as shown in Figure 5, should also be considered (e.g., Fukushima and Midorikawa, 1993). In Figure 5, for the case T=10s and $M_w \geqq 6$, the scaling of M_w can be represented by two straight lines with different slops.

In order to model the feature described above, regression model for b (T) adopted in this study is shown in Eq. (2). In the equation, $a_1(T)$ and $a_2(T)$ are the straight lines showing different scaling with M_w. M_w of the inflection point between the two straight lines is decided based on data and the results by Si et al. (2011a, b).

$$b(T) = \begin{cases} a_1(T)M_w + \sum d_i(T)S_i + h(T)D + \varepsilon_1(T) \\ M \leq 8.3 or M \leq 7.5 if T \geq 2s \\ a_2(T)M_w + \sum d_i(T)S_i + h(T)D + \varepsilon_2(T) \\ M > 8.3 or M > 7.5 if T \geq 2s \end{cases} \quad (2)$$

Where, D shows the focal depth. S_i is a category variable, showing the earthquake type defined as crustal, inter- and intra-plate earthquake, the same as that used in Si and Midorikawa (1999).

In the regression analysis, a weighted multi-variable least square method is used. The weighting schemes are as follows: 8 for earthquakes with No. of records ≥ 30; 4 for ≥ 20; 2 for ≥ 10. For the periods shorter than 5s, all data are used in the analysis. For the periods longer than 5s, only the earthquakes with M_w over 6 are used.

Since the focal depth maybe correlated with earthquake type, in this study, the coefficient for focal depth h (T) are firstly determined based on the data for inter- and intra-plate earthquake separately. Then, if both the results are derived successfully, the average values are used. Finally h (T) is simplified by a straight line in logx-y plane.

4. RESULTS

Figure 6 shows the coefficients derived in this study. From the figure, a_1 (T) increase with period T; a_2 (T) is zero for the case of FD, showing the saturation with M_w. For EHD, a_2 (T) are almost the same non-zero values for only long-period (T≧2s). The coefficients for earthquake type, d_i (T), generally decrease with T for intra-plate earthquakes. This seems to meet the consensus of the feature for an intra-plate earthquake. The coefficient of focal depth, h (T), varies in the range of 0.011 to -0.002, corresponding to the periods from 0.1s-10s. This also show reasonable tendency by comparing with the previous studies.

Figure 6 also shows the comparison of the coefficient of M_w, a_1 (T), derived in this study and those in the other recent studies. From the figure, the results in this study show similar tendency with the others, e.g., Uchiyama and Midorikawa (2006), Kanno et al. (2006). This implied that, the results in this study are reasonable.

Figure 7 shows the prediction by the GMPE derived in this study. Figure 8 shows the ratio of V/H based on the prediction. Figure 9 shows the standard deviation for the GMPE. The prediction for response spectra are calculated under the following condition: a crustal event, at a fault distance of 50km; M_w of the target earthquakes are 6, 7 and 8. From the results, it can be confirmed that, (1) the amplitudes increase with M_w; (2) amplitudes for intra-plate earthquake generally larger than those from crustal and inter-plate earthquake; (3) The ratios of V/H are generally consistent with the past study but show M_w dependency for longer periods; (4) the standard deviations are around 0.3 in ten-based logarithm.

In order to check the validity of the GMPE proposed in this study, the observation data on hard rock which not included in the database used in the development of GMPE are used in the comparison with the prediction. Figure 10 shows the results for the data from the 1999 M_w7.62 Chi-Chi earthquake. The data are adopted from NGA database (NGA flatfile, 2008). Vs30 of the station of ILA063 is about 1.0 km/s. From the figure, it can be confirmed that the observation is well consistent with the prediction.

5. CONCLUSIONS

In this study, we updated the database of response spectra on hard rock including the recording from the 2011 Tohoku earthquake. Based on the database, we derived a new GMPE for response spectra on bedrock. The standard deviation is relatively small. Comparison with the observation data in NGA database shows a good agreement. This implied that our model is reasonable.

Abstract: The Tohoku earthquake produced many strong motion records. Peak ground accelerations higher than 1 g are observed at 32 sites. Among the 32 records, spike-like wave forms are seen in 18 records, which may be due to cyclic mobility of sandy soils. Peak ground velocities higher than 70 cm/s are observed at 34 sites with softer site class. The records whose velocity response amplitude (h=0.05) is higher than 300 cm/s are observed at 34 sites. The spectra of the records are larger than high intensity records observed in the 1995 Kobe and 1994 Northridge earthquakes.

1. INTRODUCTION

The 2011 Off the Pacific Coast of Tohoku earthquake (hereafter Tohoku earthquake) of Mw 9.0 hit northeastern Japan. From the Tohoku earthquake, several thousands of strong motion records were obtained owing to dense strong motion observation networks in Japan. These records will provide valuable insight on ground motion characteristics of gigantic earthquakes. The characteristics of the observed records, however, have not fully examined because the number of the records are too large. Among the records, there are many intensive records such as those with peak acceleration of over 1g. In this paper, we select the high intensity records and introduce their features.

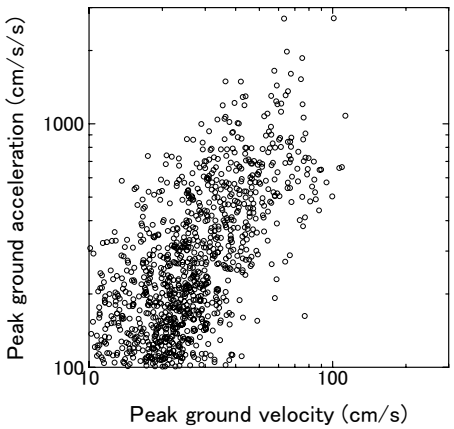
2. COLLECTION OF RECORDS

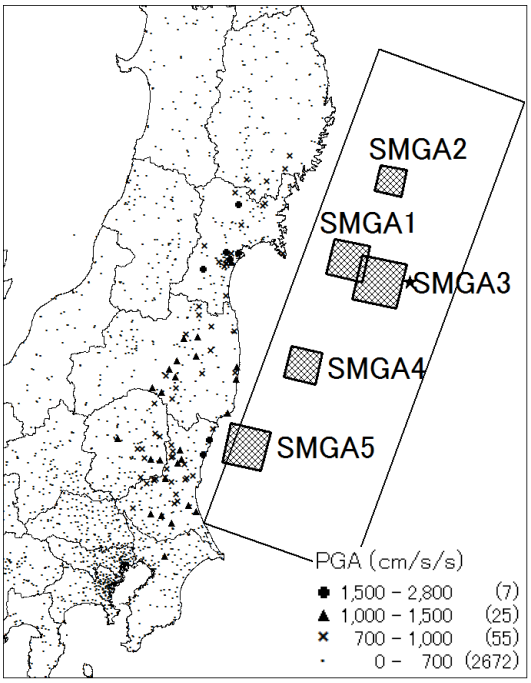
The Tohoku earthquake produced many strong motion records. In Japan, many nation-wide strong motion networks have been developed such as K-NET (about 1,000 sites) and KiK-net (about 700 sites) by National Research Institute for Earth Science and Disaster Prevention (NIED) , the JMA-net (about 600 sites) by Japan Meteorological Agency (JMA), the Prefectures-net (about 2,800 sites) by each prefectural office and the MLIT-net (about 700 sites) by Ministry of Land, Infrastructure and Transport (MLIT) (Midorikawa, 2005).

About 1,200 K-NET and KiK-net records were made available soon after the earthquake (NIED, 2011). JMA released about 400 records from their net together with about 500 records from the Prefectures-net (JMA, 2011; Japan Meteorological Business Support Center, 2012). Another 500 data from the Prefectures-net were made available from other sources such as SK-net (SK-net, 2011). MLIT released about 150 records from their net (MLIT, 2011). The Building Research Institute (BRI), the Port and Airport Research Institute (PARI) and Tohoku Institute of Technology also released their records (BRI, 2011; PARI, 2011, Kamiyama et al., 2012).

We collected and compiled the records on ground from these sources. Some of the data had errors or noises and abandoned. The total number of the compiled records is about 2,800. Figure 1 shows the peak groud accelerations and velocities of the compiled records.

For site classification, the average shear-wave velocity to 30m depth, V_{s30}, is calculated at K-NET, KiK-net and other sites where the PS logging data is available. As about half of the sites have no logging data, V_{s30} is estimated based on geomorphologic categories by using correlations developed to link geomorphologic units to V_{s30} by Matsuoka et al. (2006). The sites are classified into four NEHRP site classes; B, C, D and E which correspond to V_{s30} of 760 to 1500 m/s, 360 to 760 m/s, 180 to 360 m/s and less than 180 m/s, respectively.





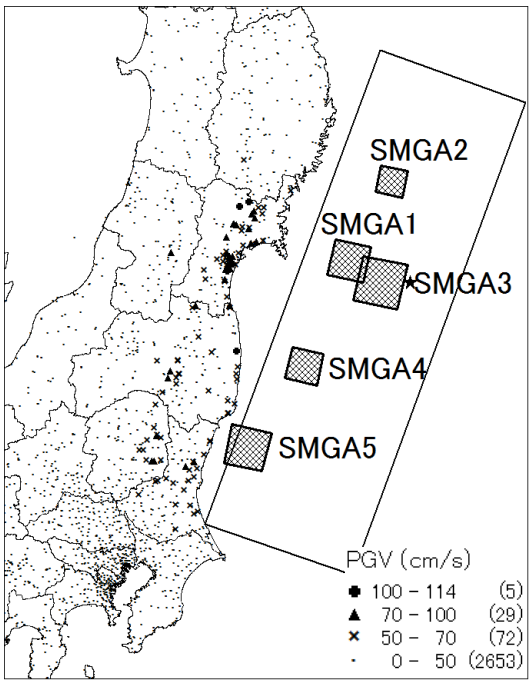


Figure 1 Peak Ground Accelerations and Velocities of Data

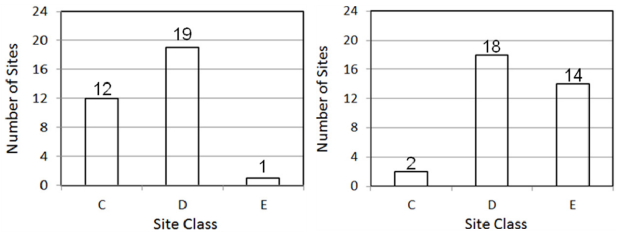
3. PEAK VALUES OF HIGH INTENSITY RECORDS

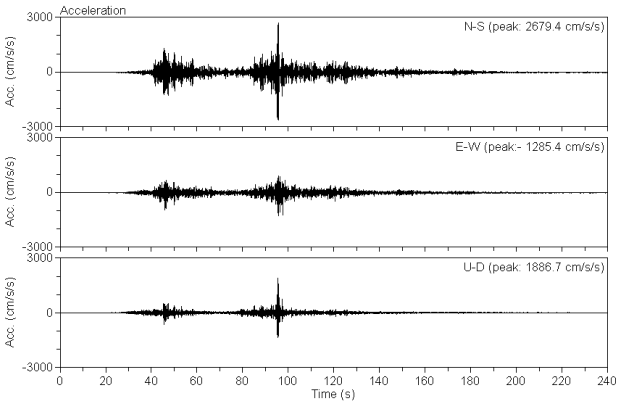
Among the records, peak ground accelerations higher than 2 g and 1 g are observed at 2 sites and 32 sites, respectively. Peak ground velocities higher than 100 cm/s and 70 cm/s are observed at 5 sites and 34 sites, respectively. Locations of the sites are shown in Figs. 2. The figures also show the fault plane of the earthquake derived from long period data by Koketsu et al. (2011) and strong motion generation areas derived from shorter period strong motions by Irikura and Kurahashi (2012).

(a) High Acceleration Data



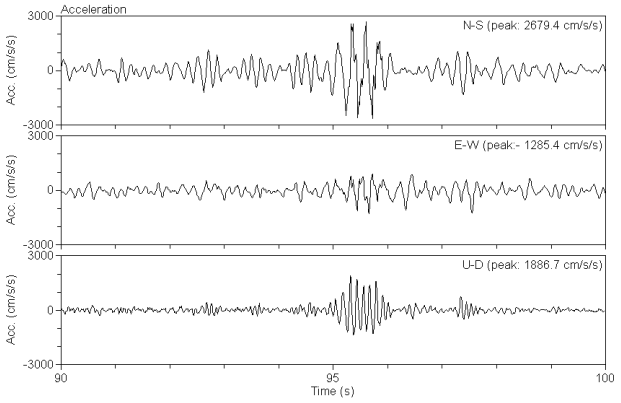
(b) High Velocity Data

Figures 2 Locations of High Intensity Records



Higher accelerations and velocities are observed in Miyagi, Fukushima, Ibaragi and Tochigi prefectures, and the number of sites with higher velocities are larger in Miyagi prefecture and smaller in Ibaragi prefecture in comparison with that with higher acceleration. Figures 3 show the distributions of the site class of the sites where observed acceleration and velocity are higher than 1 g and 70cm/s, respectively. For higher acceleration records, the site class is distributes mostly at C (stiff site) or D (intermediate site), but in D or E (soft site) for higher velocity records.

The maximum peak acceleration observed is about 2.8 g at K-NET Tsukidate, Miyagi prefecture. The acceleration time history of the record is shown in Figs. 4. The waveform is composed of two distinct phases producing long duration of strong shaking. In the second phase, pulse-like high accelerations appear in the north-south and vertical components. Such high acceleration pulses are not observed at the surrounding sites.



(a) High Acceleration Data (b) High Velocity Data

Figures 3 Distribution of Site Class

(a) Total View of Record

(b) Close-up of Main Part

Figures 4 Acceleration Time Histories at K-NET Tsukidate

Figure 5 shows the orbit of the high-pass-filtered displacement in the vertical (NS-UD) plane, showing an arc-like shape. This suggests that the foundation of the instrument caused combination of sway and rocking motions. The high acceleration at K-NET Tsukidate may be due to partial uplifting of the foundation of the instrument, as has been discussed by Motosaka and Tsamba (2011), and may not necessarily indicate actual ground acceleration.

The arc-like orbit results that the ratio of the period of the horizontal motion to that of the vertical motion is two. Therefore, if the wave forms of horizontal and vertical components are similar and the ratio of the periods is two, the record will be affected by partial uplifting of the foundation. Of the 32 records with over 1g acceleration, nine records have such features. In many cases, the horizontal periods are 0.2 to 0.4 sec.

Figures 6 show the acceleration time history of the record at Kawasaki town, Miyagi prefecture where the peak ground acceleration of 2.7 g is observed. The wave form is spike-like and suggests the effect of cyclic mobility of sandy soils. Of the 32 records with over 1g acceleration, 18 records have such spike-like feature. The boring data are available for 7 records of the 18 records. As shown in Fig. 7, sandy soils such as silt, sand or sandy gravel are found at the sites. Thus, among the 32 records with acceleration higher than 1 g, 27 records might be affected by partial uplifting of the foundation or cyclic mobility of sandy soils. The remaining five records have peak acceleration smaller than 1.3 g.

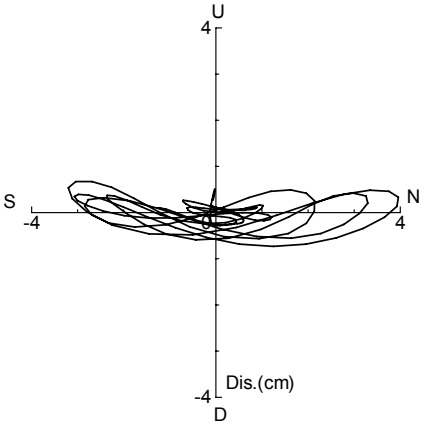


Figure 5 Displacement Orbit of K-NET Tsukidate Record

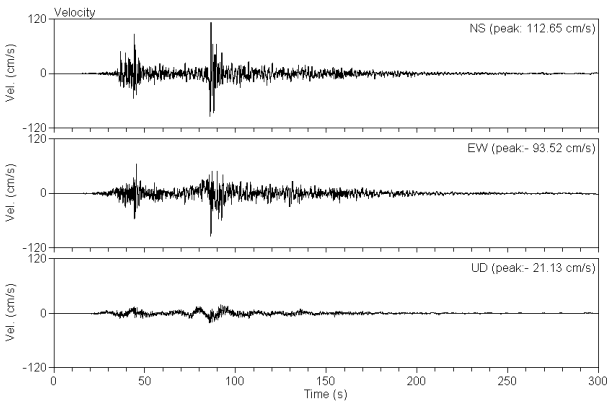

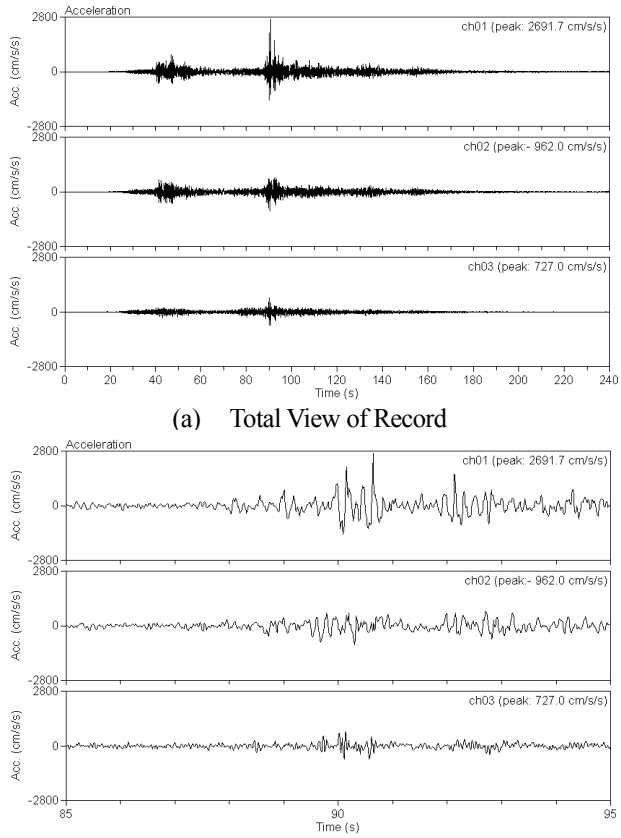

Figure 8 Velocity Time History at Shichigo J. H. School

(a) Total View of Record

(b) Close-up of Main Part

Figures 6 Acceleration Time Histories at Kawasaki Town

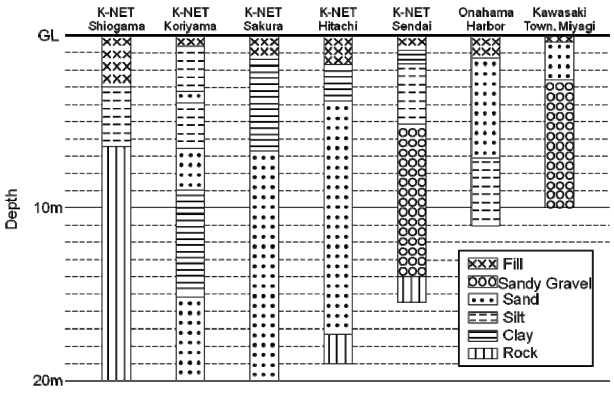

Figure 7 Boring Data at Strong Motion Sites

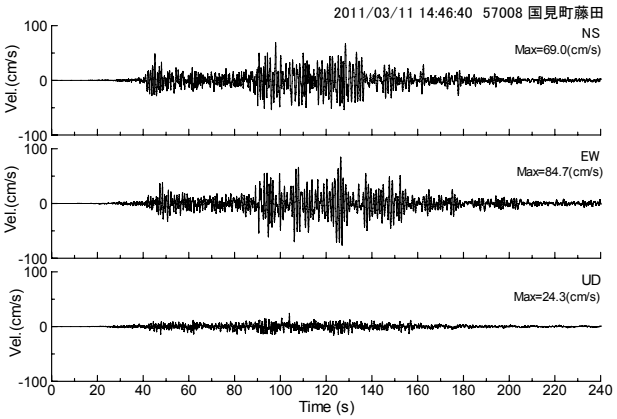

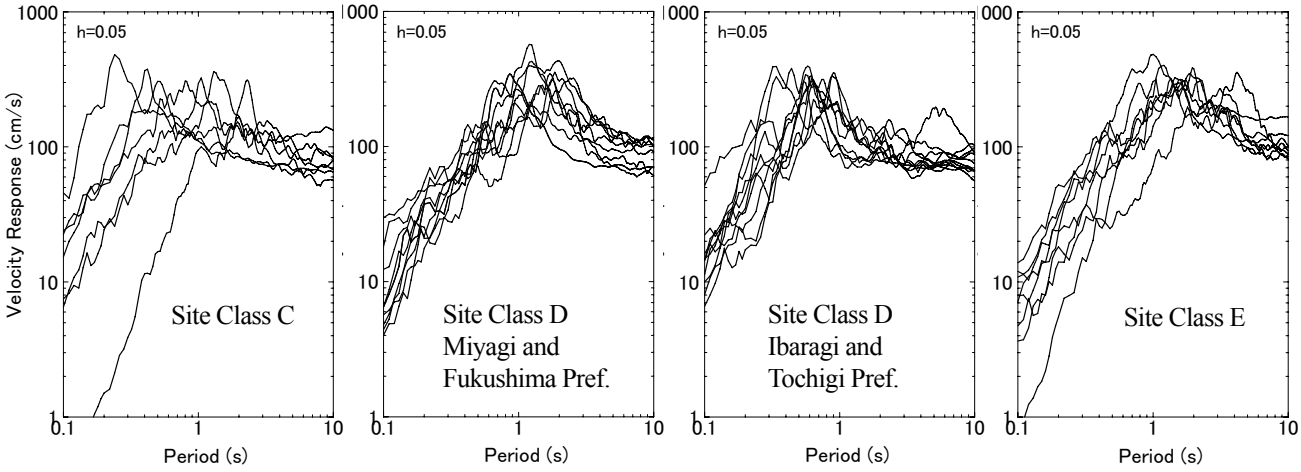

Figure 9 Velocity Time History at Kunimi Town

Figures 10 Two-dimensional Velocity Response Spectra (h=0.05) of High Intensity Records

The maximum peak velocity observed is about 110 cm/s at the Shichigo junior high school in Sendai city. The velocity time history of the record is shown in Fig. 8. The duration of strong shaking is short. On the other hand, the records with longer duration are also observed. Figure 9 show the velocity time history of the record at Kunimi town, Fukushima prefecture. The peak velocity is about 85 cm/s and the duration of strong shaking seems more than 1 minute. The long duration might be because that the site is close to several strong motion generation areas (SMGAs) as shown in Figs. 1 and strong shakings from different SMGAs continuously arrived at the site.

3. SPECTRA OF HIGH INTENSITY RECORDS

The records whose two-dimensional horizontal velocity response spectrum (h=0.05) has the amplitude higher than 300 cm/s are also selected. The number of the selected records is 34. Figures 10 show the two-dimensional velocity response spectra of the selected records for different site classes; C, D and E. No record is selected at site class B.

At site class C (stiff site), the spectra are rather constant with period, but show peaks at periods of 1 to 2 sec. at site class E (soft site). At site class D (intermediate site) where many records are available, the spectra observed at the northern area (Miyagi and Fukushima prefecture) and the southern area (Ibaragi and Tochigi prefectures) are separately shown in the figure. The spectra at the northern and southern areas tend to have peaks at periods of 1 to 2 sec. and at periods of 0.5 to 1 sec., respectively. This suggest that the SMAG at the northern part might generate longer period motion than that at the southern part.

The maximum velocity response amplitude observed is about 600 cm/s at Kunimi town. At the site, the Kunimi town office building with three storied RC structure was damaged and demolished. Figure 11 shows the two-dimensional velocity response spectrum (h=0.05) at Kunimi town. The spectrum has a sharp peak at period of 1.2 sec. with amplitude of 570 cm/s.

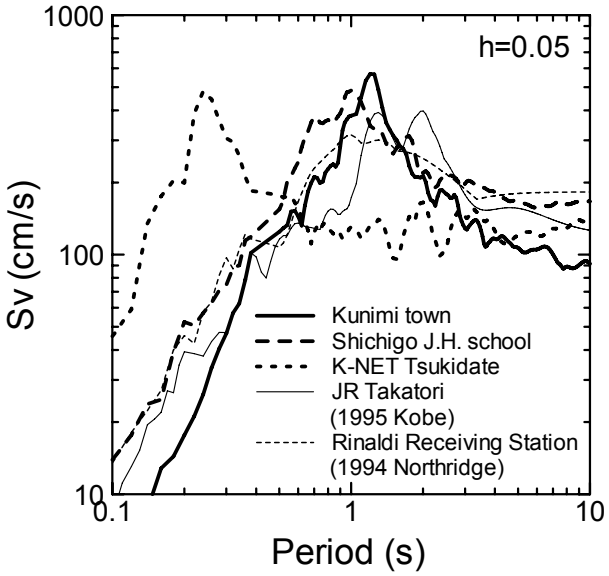

Figure 11 Comparison of Two-dimensional Velocity Response Spectra of High Intensity Records in the 2011 Tohoku, 1995 Kobe and 1994 Northridge Earthquakes

The figure also shows the spectra of the records with maximum peak acceleration and velocity; K-NET Tsukidate and Shichigo junior high school. The spectrum at Shichigo is similar with that at Kunimi but the spectrum at K-NET Tsukidate is much smaller at periods longer than 0.5 sec. The observed building damage around the sites was that some wooden houses were collapsed at Kunimi town (Itagaki et al., 2011) and building damage was very small at K-NET Tsukidate (Midorikawa and Miura, 2011). The observed damage seems to be consistent with the spectra.

For comparison, the spectra of high intensity records in past damage earthquakes such as the JR Takatori record in the 1995 Kobe earthquake and the Rinaldi Receiving Station in the 1994 Northridge earthquake are shown in the figure. The spectra at Kunimi town and Shichigo are larger than those at Takatori and Rinaldi. It is confirmed that very high intensity records have been obtained in the Tohoku earthquake.

4. CONCLUDING REMARKS

The Tohoku earthquake produced many strong motion records. Peak ground accelerations higher than 1 g are observed at 32 sites. Among the 32 records, spike-like wave forms are seen in 18 records, which may be due to cyclic mobility of sandy soils. Peak ground velocities higher than 70 cm/s are observed at 34 sites with softer site class. The records whose velocity response spectrum (h=0.05) has the amplitude higher than 300 cm/s are observed at 34 sites. The maximum velocity response amplitude is about 570 cm/s at Kunimi town. The spectra are larger than high intensity records observed in the 1995 Kobe and 1994 Northridge earthquakes.

Abstract: The 2011 Tohoku, Japan, earthquake is obviously the first M9 earthquake which was recorded by dense strong motion networks such as K-NET, etc. From engineering point of view, the most striking feature of strong ground motions of the earthquake is the generation of strong-motion pulses in the frequency range from 0.2 to 1 Hz observed at many sites along the coast of Miyagi through Ibaraki Prefecture. It is significantly important to consider the generation of such pulses in the strong-motion prediction for mega earthquakes, especially when the prediction is aimed at seismic design of structures. To model strong motion pulses from the Tohoku earthquake, a source model including nine subevents with relatively small size (on the order of several kilometers) was developed for the earthquake. The sizes of the subevents were determined so that the width of the pulses can be reproduced appropriately. The agreement between the observed and calculated ground motions was quite satisfactory, especially for velocity waveforms. Strong ground motions from the same earthquake have been modeled using a source model with SMGAs with a size of tens of kilometers. However, the relatively small width of the observed pulses requires smaller subevents. The author redefines the small subevents as SPGAs.

1. INTRODUCTION

The 2011 Tohoku, Japan, earthquake is obviously the first M9 earthquake which was recorded by dense strong motion networks such as K-NET (Kinoshita, 1998) and KiK-net (Aoi et al., 2000), etc. From engineering point of view, the most striking feature of strong ground motions of the earthquake is the generation of strong-motion pulses in the frequency range from 0.2 to 1 Hz observed at many sites along the coast of Miyagi through Ibaraki Prefecture. It is significantly important to consider the generation of such pulses in the strong-motion prediction for mega earthquakes, especially when the prediction is aimed at seismic design of structures. In this study, to model strong motion pulses from the Tohoku earthquake, a source model including nine subevents with relatively small size (on the order of several kilometers) was developed for the earthquake. The sizes of the subevents were determined so that the width of the pulses can be reproduced appropriately. The agreement between the observed and calculated ground motions was quite satisfactory, especially for velocity waveforms.

The small subevents used in the present study is, in essence, equivalent to the "super asperities" proposed by Matsushima and Kawase (2006), because their source model is aimed at explaining strong motion pulses from the 1978 Miyagi-ken oki earthquake (M_w7.6). The author, however, redefines the subevents as SPGAs (Strong-motion Pulse Generation Areas), because the definition of "asperity" itself is currently somewhat ambiguous.

2. WHAT ARE STONG MOTION PULSES?

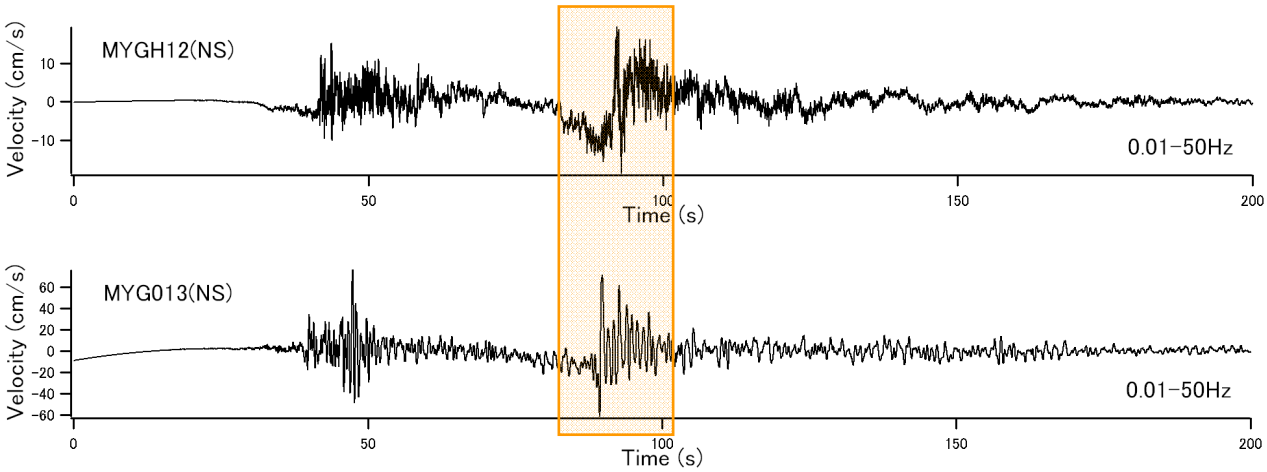

Figure 1 (top) shows the broadband (0.01-50 Hz) velocity waveforms observed at two strong motion stations located in Miyagi Prefecture during the 2011 Tohoku, Japan, earthquake. The broadband velocity waveforms can be regarded as the superposition of very low-frequency ground motion, which presumably came from the large slip area (e.g., Suzuki et al., 2011; Koketsu et al., 2011), plus the large-amplitude short-period pulses. The most typical short-period pulses are indicated by the hatches.

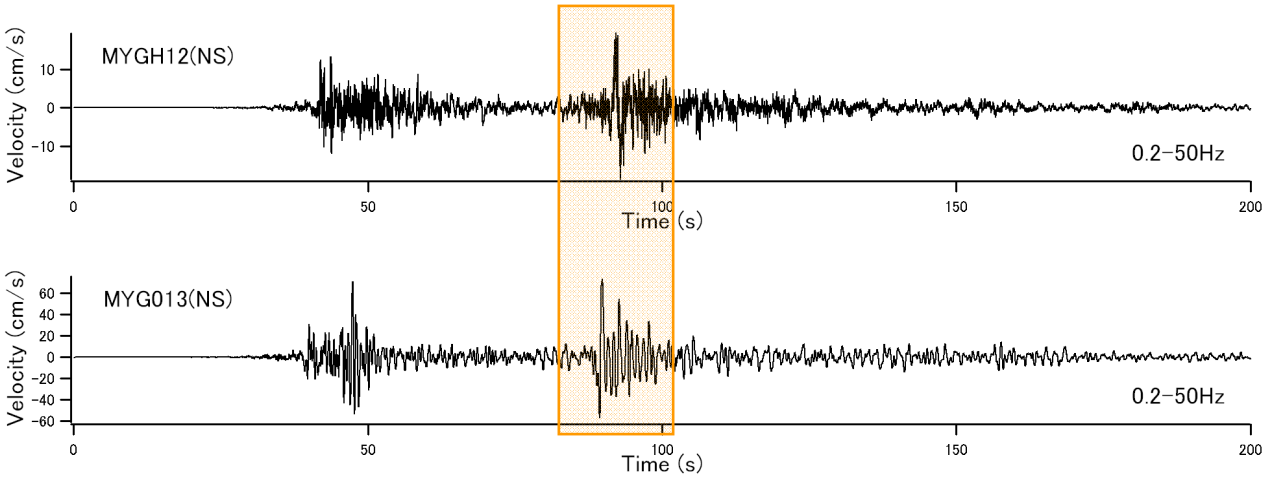
If we remove low-frequency components lower than 0.2 Hz, which are less important for the majority of engineered structures, from the broadband waveforms, the result is the velocity waveforms (0.2-50 Hz) shown in Figure 1 (middle). It can be seen that the short-period pulses dominate the waveforms in this frequency range.

Furthermore, if we remove high-frequency components higher than 1 Hz, which are again less important for many types of structures including port structures, the result is the velocity waveforms (0.2-1 Hz) shown in Figure 1 (bottom). It can be recognized that the velocity waveforms in this frequency range are dominated by distinctive, almost discrete pulses.



Strong ground motions in this frequency range have significant effects on a wide range of structures including port structures and tall buildings. In addition, the report of Sakai et al. (2002) indicates the importance of this frequency range even for general buildings. Therefore, when we try to

0.01-50 Hz (broadband)

↓ **remove low frequency components lower than 0.2Hz**

0.2-50 Hz

↓ **remove high frequency components higher than 1Hz**

0.2-1Hz

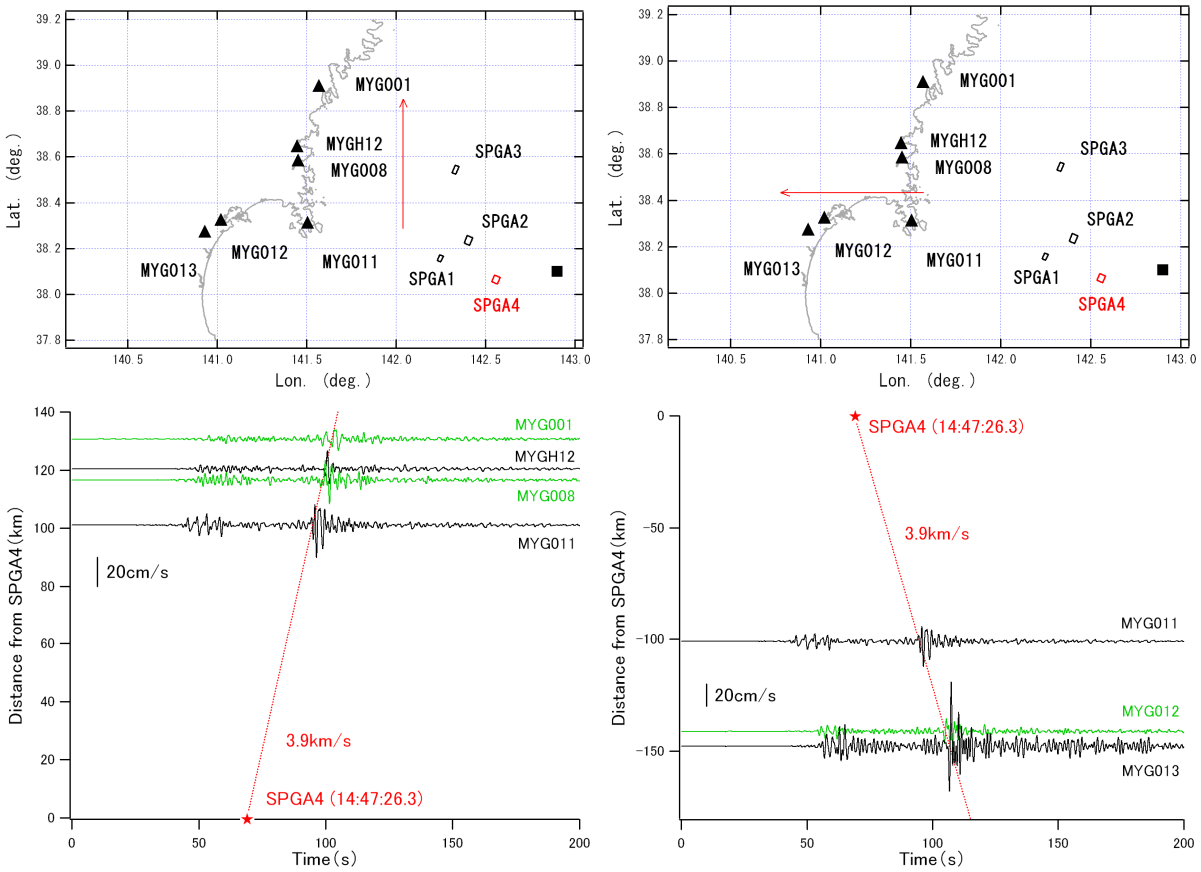

Figure 2 Propagation of strong motion pulses from south to north (left) and from east to west (right)

construct a source model for mega-thrust earthquakes, we should pay special attention to the characteristics of strong ground motions in this frequency range.

The importance of the pulses in Figure 1 (bottom) is that they appear in the frequency range relevant to structural damage. Thus, they are referred to as the "strong motion pulses" in this article.

Strong motion pulses were observed not only at these two stations but also at many other stations. They almost dominate velocity waveforms at Sendai City, Miyagi Prefecture (e.g., Figure 5 of Ohno et al., 2012). These pulses might also have been responsible for damage to bridges in the same region (e.g., Takahashi, 2012). Similar pulses were observed in other regions in Japan including Fukushima and Ibaraki Prefectures during the 2011 Tohoku earthquake. The author's primary intention in this study is to construct a source model which can explain such pulses.

3. PROPAGATION OF STRONG MOTION PULSES

If we paste up records from neighboring stations, we can clearly observe the propagation of strong motion pulses. For example, Figure 2 shows the propagation of the most significant strong motion pulse for this event, from south to north (left) and from east to west (right).

In the paste-ups, the bottom axis indicates the time from the initial rupture at the hypocenter. In the left panel, the pulse propagates from MYG011 to the north, which indicates that the source of the pulse is located at least south of MYG011. In the right panel, the pulse propagates from MYG011 to the west, towards Sendai City. At MYG013, the pulse is amplified due to the site effects (Nozu and Nagao, 2005).

In the paste-ups, the left axis indicates the distance from SPGA4, which is estimated to be a subevent which generated the pulse (see Chapter 4). The red dotted line indicates the theoretical arrival time for the assumed rupture time of SPGA4 at 14:47:26.3 and the assumed S-wave velocity of 3.9 km/s. These assumptions are found to be consistent with the arrival times of the pulse at these stations.

4. MODELING OF STRONG MOTION PULSES

4.1 Method Used to Calculate Strong Ground Motions

In this study, forward modeling approach was used to develop a source model that can explain strong motion pulses. For any candidate source model, strong ground motions were calculated based on site amplification and phase characteristics (Kowada et al., 1998; Nozu et al., 2006; Nozu and Sugano, 2008), which can take into

account the effect of sediments both on Fourier amplitude and Fourier phase of strong ground motions. Outline of the method can be described as follows.

The first step is to evaluate ground motions from a small event (Green's function). The Fourier amplitude of the Green's function is evaluated as a product of the source spectrum |S(f)|, the path effect |P(f)| and the site amplification factor |G(f)|. The source spectrum is assumed to follow the ω^{-2} model (Aki, 1967). As for the path effect, geometrical spreading and nonelastic attenuation are considered (Boore, 1983). As for the site amplification factor, the empirical site amplification factor is used. As for the Fourier phase of the Green's function, the Fourier phase of an actual record at the site of interest is used. Thus, we can obtain a time domain Green's function which incorporates the effects of sediments both on Fourier amplitude and Fourier phase. The Green's function in the frequency domain can be written as follows:

$$|S(f)|\ |P(f)|\ |G(f)|\ O_s(f)\ /\ |O_s(f)|_p, \qquad (1)$$

where $O_s(f)$ is the Fourier transform of an actual record at the site of interest and $|O_s(f)|_p$ is its Parzen-windowed amplitude (band width of 0.05 Hz is used). If several records are available at the site, it is recommended to choose an event which has a similar incident angle and a similar backazimuth with the target event. The second step is to superpose Green's functions to obtain strong ground motions from a large event (or a subevent of a large event) in the same way as the EGF method (e.g., Miyake et al., 2003). The resultant synthetic ground motions basically follow the ω^{-2} model.

For the particular application to the Tohoku earthquake, the Q value estimated for the region (Satoh and Tatsumi, 2002) and the site amplification factors estimated based on spectral inversion technique (e.g., Nozu and Nagao, 2005; Nozu et al., 2006) were used. Some of the small events used to determine the Fourier phase of the Green's functions are shown in Figure 3.

At two sites MYGH10 and FKS001, where the effect of soil nonlinearity was anticipated, the Green's functions were corrected for multiple nonlinear effects based on the simplified formula proposed by Nozu and Morikawa (2004) with nonlinear parameters (ν_1, ν_2)=(0.80, 0.008) for MYGH10 and (0.90, 0.005) for FKS001.

4.2 Off Miyagi Prefecture

The forward modeling was started with off Miyagi prefecture. Figure 4 shows the observed ground velocities at three strong motion stations MYG011, MYGH12 and MYGH06 located in Miyagi prefecture. As already pointed out by many researchers (e.g., Kurahashi and Irikura, 2011), strong ground motions in Miyagi prefecture include two distinctive wave packets, indicating contributions from at least two subevents. Then, as already done by other researchers (e.g., Asano and Iwata, 2011), the locations and the rupture times of the subevents were determined based on the arrival times of the S waves corresponding to different wave packets (indicated by vertical red bars in Figure 4). The estimated locations on the fault plane are indicated as SPGA1 and SPGA4 in Figures 3 and 5. The estimated location of SPGA1 was close to the hypocenter of the 1978 off Miyagi prefecture earthquake (M7.4).

Then, assuming rectangular SPGAs which involve the estimated locations as local rupture starting points, the parameters for the SPGAs were determined through forward modeling approach. The estimated parameters include the length, the width, the seismic moment of the SPGAs as well as the relative locations of the SPGAs with respect to the rupture starting points. In the forward modeling approach, the parameters were determined so that the velocity waveforms in the strong motion stations in the frequency range from 0.2-1 Hz are reproduced as accurately as possible. Throughout the study, the rupture velocity was fixed to 3.0 km/s and the rise time was fixed to the width of the SPGA divided by the rupture velocity and multiplied by 0.25.

The estimated parameters for SPGA1 and SPGA4 are listed in Table 1. The resultant waveforms, i.e., the synthetic waveforms with contributions from two SPGAs namely, SPGA1 and SPGA4 are compared with the observed waveforms in Figure 6. The agreement between the observed and synthetic waveforms is basically satisfactory. In particular, the amplitude and the width of S-wave pulses are reproduced very well, indicating that the estimated seismic moment and the size of the SPGAs are appropriate (although different assumption on the rupture velocity may lead to different estimation of the size). In Figure 6, however, some phases included in the observed waveforms are not included in the synthetic waveforms as indicated by crosses. To improve the results, two more SPGAs, namely, SPGA2 and SPGA3 were introduced (Figures 3 and 5). The synthetic waveforms with contributions from four SPGAs agree quite well with the observed waveforms as shown in Figure 7.

4.3 Off Fukushima Prefecture

At stations around the border of Miyagi and Fukushima Prefectures such as MYGH10 and FKS001, the contributions from four SPGAs off Miyagi prefecture can almost explain the observed waveforms as shown in Figure 8. At stations further south, however, the contributions from the SPGAs off Miyagi prefecture alone cannot explain the observed waveforms as shown in Figure 9. In particular, three distinctive pulses are present in the observed waveforms as indicated by crosses, which do not appear in the synthetics. The locations and the rupture times of three SPGAs corresponding to these pulses were estimated based on the arrival times of the S-waves. The estimated locations of the three SPGAs, namely, SPGA5, SPGA6 and

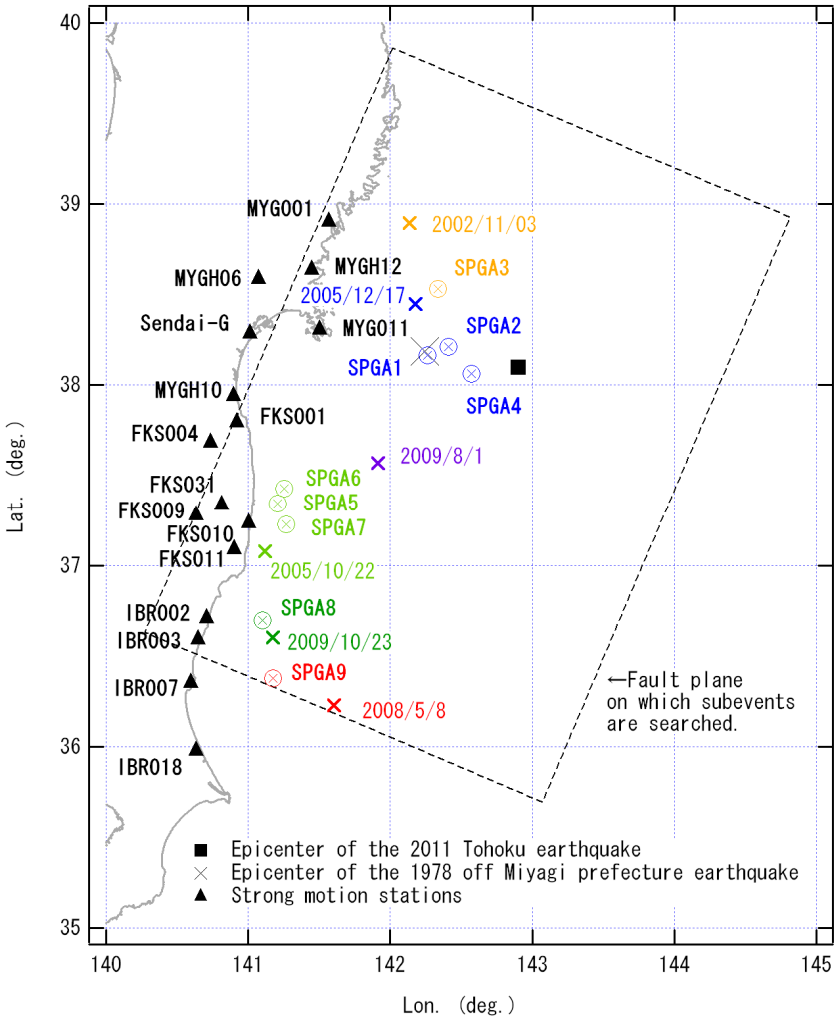

Figure 3 The proposed source model composed of nine SPGAs. The triangles indicate strong motion stations. The crosses indicate epicenters of small events used to determine phase characteristics.

Table 1 Parameters for the proposed SPGA model

	Rupture time (h:m:s)	Length (km)	Width (km)	Area (km^2)	M_0 (Nm)	Rise time (s)

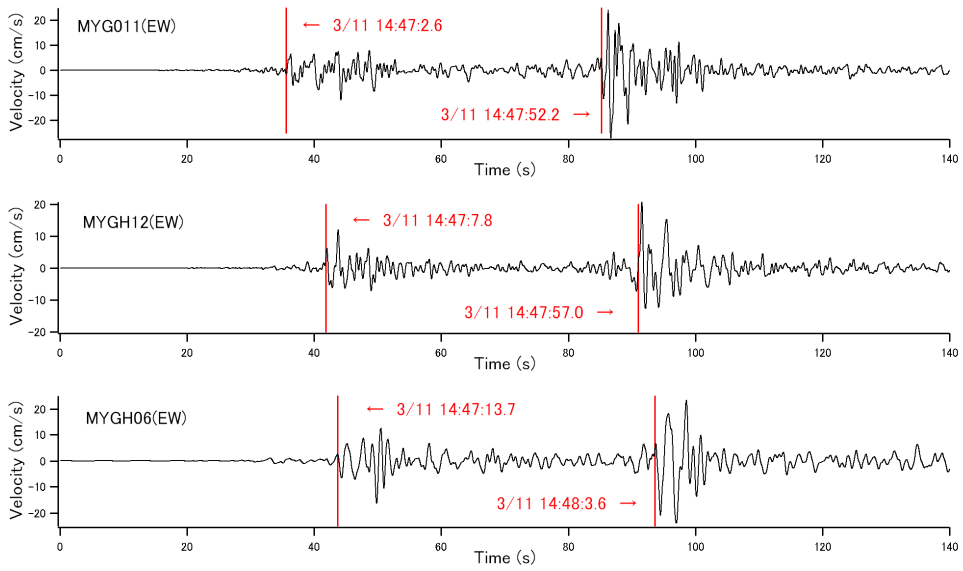

Figure 4 Observed ground velocities at MYG011, MYGH12 and MYGH06 (EW components; Borehole records are shown for MYGH12 and MYGH06)

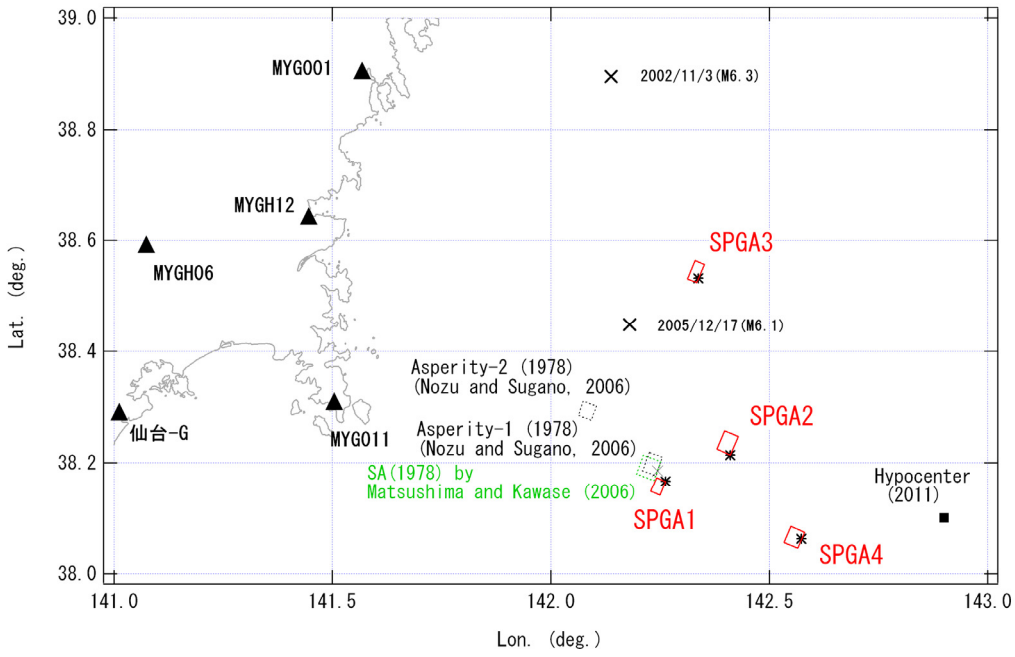

Figure 5 Detailed locations of four SPGAs off Miyagi Prefecture

SPGA7 were close to the coast of Fukushima Prefecture as shown in Figure 3 and Figure 10 (left). The parameters for the SPGAs were determined through forward modeling. The resultant parameters are given in Table 1. The synthetic waveforms with contributions from three SPGAs off Fukushima Prefecture are compared with the observed waveforms in Figure 11. The agreement between the observed and synthetic waveforms is satisfactory.

4.4 Off Ibaraki Prefecture

A similar analysis was conducted for strong motion stations in Ibaraki Prefecture and two more SPGAs, namely, SPGA8 and SPGA9 were identified as shown in Figure 10 (right) and Table 1.

5. DISCUSSION

One important character of the source model developed here is that the size of the subevent is significantly smaller than the “asperities” or “SMGAs” conventionally assumed for a mega-thrust earthquake. In fact, the dimension of the SPGAs used in our analysis was around several kilo meters, while other authors (e.g., Kurahashi and Irikura, 2011; Asano and Iwata, 2011) propose “SMGAs” with a dimension of several tens of

kilo meters for the same event. It should be noted that the small size of the subevents used in this study is a natural reduction from the fact that, at many sites along the coast of Tohoku, strong motion pulses were observed and their pulse widths were around one to several seconds. As is well known, the duration of rupture of a subevent is related to the pulse width. If the dimension of a subevent is around several tens of kilo meters, then the pulse width will be more than 10 s and will not agree with the observed width. This is the reason why small subevents are needed to accurately reproduce strong ground motions in the frequency range from 0.2-1 Hz, which is of great importance from engineering point of view. Different assumptions on the rupture velocity may lead to different estimation of the size, but it will not significantly affect this conclusion.

Although the primary objective of the present source model is to explain strong ground motions in the frequency range from 0.2-1 Hz, it is basically applicable to higher frequencies. Figure 12 shows the comparison of the observed and synthetic Fourier spectra (0.2-10 Hz) at selected sites. Figure 13 shows the comparison of the observed and synthetic velocity envelopes (0.2-10 Hz) at the same sites. In these figures, the synthetic waveforms were calculated considering nine SPGAs. Basically, the agreement between the observed and synthetic Fourier spectra and velocity envelopes is satisfactory. Thus, the present model is basically applicable to high frequencies up to 10 Hz. In particular, the agreement in Fourier amplitude in Figure 12 indicates that strong ground motions from subevents of a mega-thrust earthquake follow the ω^{-2} model (Aki, 1967), because the simulation method used in this study is based on the ω^{-2} model.

6. CONCLUDING REMARKS

From engineering point of view, the most striking feature of strong ground motions of the 2011 Tohoku

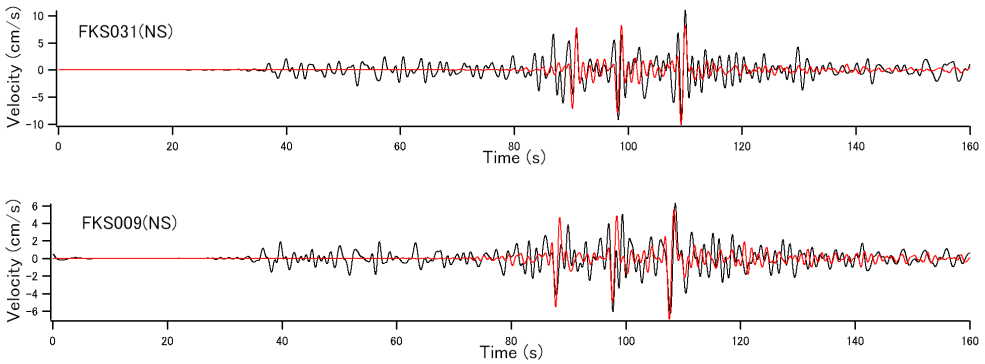

Figure 11 Observed (black) and synthetic (red) velocity waveforms (0.2-1 Hz). Contributions from three SPGAs off Fukushima Prefecture are considered in the synthetic waveforms.

earthquake is the generation of pulses in the frequency range from 0.2 to 1 Hz observed at many sites along the coast of Miyagi through Ibaraki Prefecture. It is significantly important to consider the generation of such pulses in the strong-motion prediction for mega earthquakes, especially when the prediction is aimed at seismic design of structures.

To model strong motion pulses from the Tohoku earthquake, a source model with rectangular subevents was developed for the earthquake. The locations of the subevents were determined from the arrival times. The sizes of the subevents were determined so that the width of the pulses can be reproduced appropriately.

The constructed source model involves 9 subevents with relatively small size (on the order of several kilometers), located off-the-coast of Miyagi through off-the-coast of Ibaraki. The strong ground motions from the source model were calculated based on site amplification and phase characteristics (Nozu et al., 2006). The agreement between the observed and calculated ground motions was quite satisfactory, especially for velocity waveforms (0.2-1.0 Hz) including near-source pulses.

Strong ground motions from the same earthquake have been modeled using a source model with SMGAs with a size of tens of kilometers (e.g., Kurahashi and Irikura, 2011; Asano and Iwata, 2011). However, the relatively small width of the observed pulses requires smaller subevents.

The small subevents used in the present study is, in essence, equivalent to the "super asperities" proposed by Matsushima and Kawase (2006), because their source model is aimed at explaining strong motion pulses from the 1978 Miyagi-ken oki earthquake (M_w7.6). The author, however, redefines the subevents as SPGAs (Strong-motion Pulse Generation Areas), because the definition of "asperity" itself is currently somewhat ambiguous.

The observed strong motion pulses require a very high moment rate within a small area. The future work should be aimed at revealing the dynamics of SPGAs.

Abstract: Strong ground motions were locally observed in Shinagawa to Kawasaki and in Odawara, Japan, during the 2011 off the Pacific coast of Tohoku Earthquake (Mw 9.0). Velocity responses for periods of 2 and 3 seconds at the northern area of the Haneda airport, Shinagawa were larger than 100 cm/sec and those at the center of the Ashigara Valley, Odawara were larger than 200 cm/sec. To comprehend the wave packets in which earthquake ground motions for periods of 2 and 3 seconds were largely excited, we applied the time-frequency analysis to seismic records observed in these areas. The ground motions in Shinagawa were dominated for periods of 1.5 to 5 seconds in main phases. On the other hand, the ground motions in the Ashigara Valley were dominated for periods of 1.5 to 3.5 seconds in main phases. In the Ashigara Valley, seismic records in the bed rock are obtained. Also, a S-wave velocity structure in the valley is already estimated by the previous study. After the 1-D analysis of earthquake motions, we concluded that the large velocity responses were amplified by the local site effects due to the deep S-wave velocity structures in the Ashigara Valley.

1. INTRODUCTION

During the 2011 off the Pacific coast of Tohoku Earthquake (Mw 9.0), strong ground motions of more than 30 cm/sec were observed at plenty of sites in the Tokyo Metropolitan Area which is located around 150 km far from the seismic fault. Also, long-period ground motions for more than 2 seconds were observed throughout the Kanto Region (Tsuno et al., 2012). Seismic records for this giant earthquake were obtained at more than 1000 stations in the Kanto Region by several seismic observation networks, such as MeSO-net, K-NET, KiK-net, SK-net and so on. Especially, MeSO-net (Sakai and Hirata, 2009) installed with an interval distance of about 5 km has high densely covered the Tokyo Metropolitan Area with more than about 250 stations. In this paper, we focused on earthquake ground motions in Shinagawa and Odawara where the local site effects were clearly observed. We evaluated the earthquake ground motions observed in these specific areas, by the pseudo velocity response spectra (h=5%) and the time-frequency analyses.

2. GROUND MOTIONS OBSERVED IN THE KANTO REGION, DURING THE 2011 OFF THE PACIFIC COAST OF TOHOKU EARTHQUAKE

2.1 Data Used in this Study

In this study, we used seismic records in the Kanto Region obtained at about 1150 stations which are maintained by 21 institutes, as shown in Figure 1.

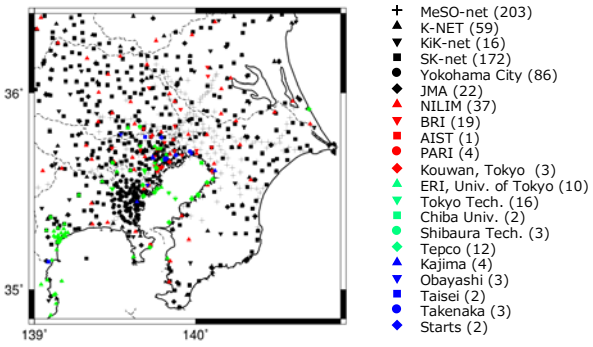

Figure 1 Locations of seismic stations used in this study. Legend shows institutions maintained stations and the number of stations.

2.2 Distributions of Pseudo Velocity Response for Periods of 2 and 3 Seconds in the Kanto Region

Distributions of pseudo velocity responses (h=5%) for periods of 2 and 3 seconds in the Kanto Region during the 2011 off the Pacific coast of Tohoku Earthquake (Mw 9.0) are shown in Figure 2 and Figure 3, respectively. Here, pseudo velocity response spectra were calculated by the geometric mean of those for NS and EW components. The complex distributions of earthquake ground motions in the Kanto Region were shown by velocity responses for periods of 2 and 3 seconds, using seismic records of the main shock observed at seismic stations of about 1150. In the Kanto Region, velocity responses for periods of 2 and 3 seconds were significantly large over 100 cm/sec in Shinagawa to Kawasaki and the Ashigara Valley, Odarawa, except in the southern area of Kasumigaura near the southern edge of the seismic fault. Especially, in the Ashigara Vellay despite of the long distance of about 200km far from the seismic fault, velocity responses for a period of 3 seconds exceeded 200 cm/sec at a certain site.

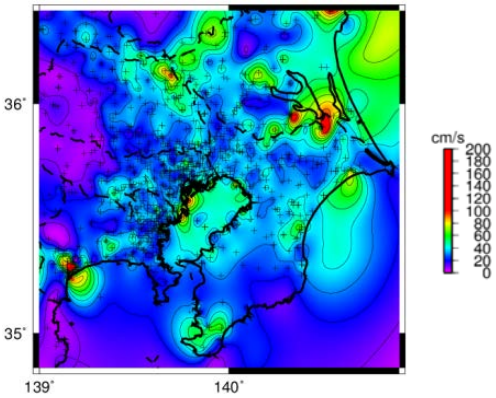

Figure 2 Distributions of pseudo velocity response (h=5%) for a period of 2 seconds observed in the Kanto Region.

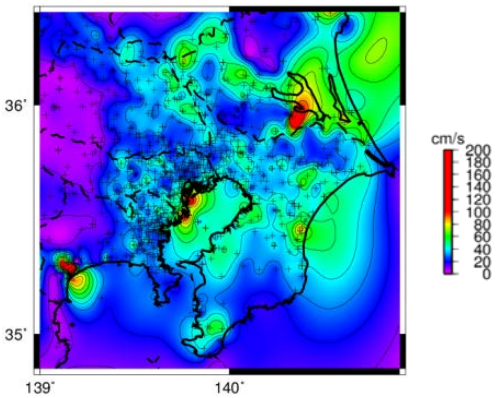

Figure 3 Distributions of pseudo velocity response (h=5%) for a period of 3 seconds observed in the Kanto Region.

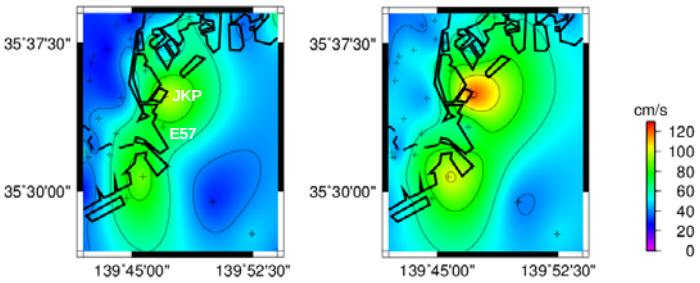

3. LOCAL SITE EFFECTS OBSERVED IN SHINAGAWA AND ODAWARA

3.1 Local Site Effect Observed in Shinagawa

Distributions of pseudo velocity responses (h=5%) for periods of 2 and 3 seconds observed in Shinagawa to Kawasaki are shown in Figure 4. Pseudo velocity responses for a period of 3 seconds at JKP, which is located at the northern area of Haneda airport, exceeded 100 cm/sec. Also, pseudo velocity responses for a period of 3 second at E57, which is located near Haneda airport, were larger than 50 cm/sec. On the other hand, pseudo velocity responses for periods of 2 and 3 seconds at the inland from the Tokyo Bay were less than 50 cm/sec. The significant difference of earthquake ground motions at the Tokyo Bay Area and the inland, in spite of the same distance from the seismic fault, indicated that the local site effects play an important role to evaluate strong ground motions.

Velocities processed by integration of accelerations and high pass filter with a cutoff period of 50 seconds for JKP and E57 are shown in Figure 5. Pseudo response velocity spectra (h=5%) for JKP and E57 are shown in Figure 6. Main phases of S-waves at JKP and E57 arrived at around 100 seconds after arrivals of P-waves. Ground motions of more than 2 cm/sec last for 400 seconds after arrivals of S-waves at JKP, which the continuous recording system has been installed. Large velocity responses were dominated for periods of 1.5 to 5 seconds, in spite of the long distance of about 150 km from the seismic fault. Especially, velocity responses exceeded 100 cm/sec for periods of 2 to 3.5 seconds. Note that velocity responses for NS component at both JKP and E57 were larger than those for EW component.

Also, we applied the time-frequency analysis by STFT (Short-Time Fourier Transform) to velocity waveforms for NS and EW components observed at JKP (Figure 7). We used a Gaussian time window of 20 seconds for STFT. Strong ground motions for periods of 1.5 to 5 seconds are lasting in main phases of S-waves for about 40 seconds.

3.2 Local Site Effect Observed in Odawara

Distributions of pseudo velocity responses (h=5%) for periods of 2 and 3 seconds observed in the Ashigara Valley, Odawara are shown in Figure 8. Pseudo velocity responses for a period of 3 seconds at NRD, which is located at the center of the Ashigara Valley, exceeded 200 cm/sec. Also, pseudo velocity responses for a period of 3 seconds in the valley were larger than 75 cm/sec. On the other hand, pseudo velocity responses for periods of 2 and 3 seconds at KHZ, which is located at the rock site outside the valley, were less than 50 cm/sec. The strong ground motions observed in the Ashigara Valley might be amplified by the local site effects due to the soft-soil sedimentary deposits.

Velocities processed by integration of accelerations and high pass filter with a cutoff period of 50 seconds for NRD and CTS are shown in Figure 9. Pseudo response velocity spectra (h=5%) for NRD and CTS are shown in Figure 10. Main phases of S-waves at NRD and CTS arrived at around 100 seconds after arrivals of P-waves. Ground motions of more than 2 cm/sec last for 200 seconds after arrivals of S-waves at NRD. Large velocity responses were dominated for periods of 1.5 to 3.5 seconds, in spite of the long distance of about 200km from the seismic fault. Especially, velocity responses at NRD exceeded 200 cm/sec for periods of 2 to 3 seconds. Note that velocity responses for NS component at the both sites were larger than those for EW component.

Also, we applied the time-frequency analysis by STFT to velocity waveforms for NS and EW components observed at JKP (Figure 11). We used a Gaussian time window of 20 seconds for STFT. Strong ground motions for periods of 1.5 to 3.5 seconds are lasting in main phases of S-waves for about 40 seconds.

4. DISCUSSION

In the Ashigara Valley, large velocity responses for periods of 2 and 3 seconds observed at NRD might be amplified by the local site effects due to the deep velocity structures. To explain that, we removed site amplifications from earthquake ground motions observed at NRD by the multi-reflection theory assumed a vertical input of SH-waves and then, we compared the waveforms on the basement simulated at NRD to ground motions observed at the rock site of KHZ. When we removed the site amplifications from earthquake ground motions, we used the S-wave velocity structure at NRD (Kanno et al., 1999) estimated by the SPAC method, as shown in Figure 12. The earthquake motions simulated at NRD reproduced well those observed at KHZ (See Figure 13). The validity of the S-wave velocity structure proposed at NRD is demonstrated and also, the result indicates that the large velocity responses for periods of 2 and 3 seconds were amplified by the local site effects due to the deep S-wave velocity structures in the Ashigara Valley.

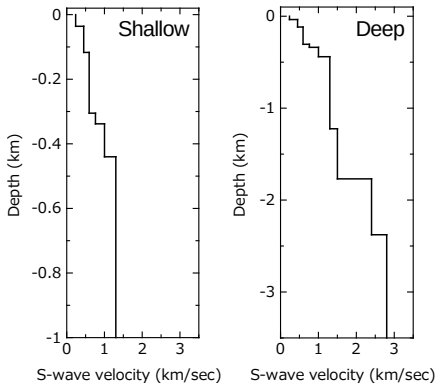

Figure 12 S-wave velocity structure at NRD proposed by Kanno et al., 1999.

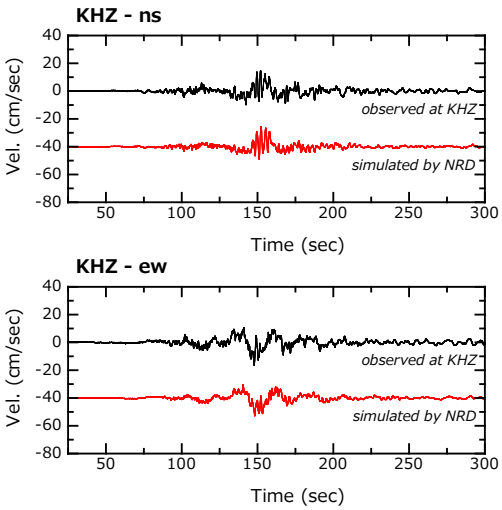

Figure 13 Comparisons of velocities on the basement simulated by the 1-D analysis to those observed at the rock site of KHZ. Results for NS and EW components are shown in the upper and the bottom, respectively.

5. CONCLUSIONS

In this study, we evaluated the strong ground motions for periods of 2 and 3 seconds locally observed in Shinagawa to Kawasaki along the Tokyo Bay and in the Ashigara Valley, Odawara, Japan, during the 2011 off the Pacific coast of Tohoku Earthquake (Mw 9.0). In Shinagawa to Kawasaki, velocity responses for a period of 3 seconds over 100 cm/sec were dominated in main phases for about 40 seconds. And also, in the center of the Ashigara Valley, velocity responses for a period of 3 seconds over 200 cm/sec were dominated in main phases for about 40 seconds. In the Ashigara Valley, earthquake motions simulated by the 1-D analysis at the sedimentary site were in good agreement with those observed at the rock site. Therefore, we concluded that the large velocity responses for periods of 2 and 3 seconds were amplified by the local site effects due to the deep S-wave velocity structures in the Ashigara Valley.

Abstract: This paper presents results of extensive microtremor surveys in the central area of Thailand. The studied area is a large flat plain underlain by alluvial and deltaic sediments of the Chaophraya Basin. Field investigations were conducted for 126 sites distributed almost evenly in the studied area. The Horizontal-to-Vertical spectral ratio (H/V) method was used to estimate predominant period and the Spatial Autocorrelation (SPAC) method to determine shear wave velocity profile from phase velocity dispersion curve and inversion analysis. Site classifications based on the predominant period and the average shear wave velocity are presented and discussed. The area along the Gulf of Thailand and the south-east part exhibit very low average shear wave velocity from the surface to 30-m depth (V_{S30}) of 70 m/s and long predominant period (Tp) of 1.1 second, while high V_{S30} of 550 m/s and short Tp of 0.2 second are found in the north, west and east parts which are boundary of the plain. From a number of site characteristic data, relations among average shear wave velocity at different depth and predominant period are examined.

1. INTRODUCTION

Several observations from past earthquakes have revealed that seismic waves could be remarkably modified by local site conditions. Therefore, evaluation of site effects from site characteristics have been considered as a main issue to specify appropriate ground motions for earthquake resistant design of structures. Some common practices for site characterization given in design codes inferred from dynamic properties of a site include average shear wave velocity from the surface to 30-m depth (since NEHRP 1994) andS site predominant period (Japan Road Association, 1990).

Conventional seismic methods for surveying shear wave velocity have crucial disadvantages as they are costly, time consuming and difficult to conduct in urban areas. Alternatively, observations by microtremor have been proposed as an efficient tool to evaluate site effects from several advantages such as economical, environmentally friendly for urban areas and effective for low or moderate seismicity.

The central area of Thailand which covers the capital city, Bangkok, and the vicinity provinces is founded on deltaic sediments of main rivers of the country. The area, with a population of over ten million, is located about 120 to 300 km from low to moderate seismicity faults and over 400 km from the highly active Sumatra subduction zone. Site effects in this area have been regularly observed from distant earthquakes. Although the new seismic regulation for Thailand (DPT 2009) after the recent Probabilistic Seismic Hazard Assessment (PSHA) studies (Ornthammarath et. al. 2010, Palasri and Ruangrassamee 2010) have included the site effects into seismic consideration, there have been very few investigations of site classification in the country. From the current limited information, this study aims to quantitatively investigate site characteristics of subsoils using economical and practical technique of microtremor observations in order to provide sufficient data for site characterization in the central area of Thailand. The technique of single point observation with Horizontal-to-Vertical spectral ratio (H/V) method to estimate the predominant period and the technique of array observation with Spatial Autocorrelation (SPAC) technique for exploration of shear wave velocity profile down to about 90 m were conducted. Following the prior work (Poovarodom and Plalinyot 2013), this paper presents results of investigation for 126 sites in approximately 150 km (north-south) by 250 km (east-west) area. Discussions on relations among the obtained results such as the shear wave velocity at different depth and the predominant period are provided.

2. MICROTREMOR OBSERVATION TECHNIQUES

Microtremor observations have been raised up as an efficient tool for evaluating site effects. This technique has several advantages; economical, environment friendly for urban area and effective for low or moderate seismicity area.

In this study, the microtremor measurements, which can be readily conducted on the ground surface without making a borehole, are conducted for extensive surveys in the studied area to provide site characteristics useful for ground motion evaluation. Two techniques were employed, the Horizontal-to-Vertical spectral ratio (H/V) method to estimate the predominant period and the Spatial Autocorrelation (SPAC) technique for exploration of shear wave velocity profile.

2.1 Horizontal to Vertical Spectral Ratio Method (H/V spectral ratio)

Nakamura (1989) proposed this technique to interpret records of microtremors for the dominant period of subsoil sediments and also the estimated amplification level. In this method, the ratios of horizontal to vertical Fourier Spectra of microtremors are used to eliminate the source effect. This technique requires the horizontal and vertical component of microtremors measured at a single station only. The H/V spectrum plots are obtained by taking the ratio of the Fourier Spectra of the horizontal to the Fourier Spectra of the vertical component, as shown in equation 1.

$$\text{H/V spectrum} = \frac{\sqrt{F_{NS} \times F_{EW}}}{F_{UD}} \tag{1}$$

where F_{NS}, F_{EW} and F_{UD} are the Fourier amplitude spectra in the north-south, east-west and up-down directions, respectively. The peak of the H/V spectrum plot is interpreted as predominant period and amplification ratio. In spite of the wide popularity of the H/V spectral ratio method, there exists inconsistency of the assumption used in this method with theory. Nakamura's method assumes that microtremors are composed of body waves and thus is theoretically inconsistent with the results that show that microtremors are composed of surface waves. However, a number of researches have experienced that the H/V spectral ratio can be utilized to estimate the predominant period of a site, and it has broadly been applied to evaluate site effect and seismic microzonation.

2.2 Spatial Autocorrelation Method (SPAC method)

This technique was proposed by Aki (1957) based on the relationship between the temporal and spatial spectra of waves to obtain phase velocity dispersion curve. The basis of SPAC method is to simultaneously record the vertical component of microtremors for several positions to obtain Rayleigh wave samples propagating from a wide range of azimuthal angles. The coherency spectrum can then be computed for any pair of sensor in the array to evaluate the correlation among them to determine phase velocity characteristic which is dispersive. The coherencies for all measurement pairs having the same spatial distance are then azimuthally averaged to provide the spatial autocorrelation coefficients of inter-station distance r, $\rho(\omega, r)$. By assuming that, the wave energy propagates with only one velocity at each frequency, ω, it can be shown that the spatial autocorrelation coefficient for a circular array is given by (Aki, 1957, Okada, 2003):

$$\rho(\omega, r) = J_0\left(\frac{\omega r}{c(\omega)}\right) \tag{2}$$

where J_0 is the Bessel function of the first kind with the zero-th order and $c(\omega)$ is the (dispersive) phase velocity at frequency ω for the Rayleigh waves with the fundamental mode. From the dispersion relation of phase velocity and frequency, the results from field observations are then compared with those derived theoretically from a horizontally layered earth model by iteration procedure. The results of best-fit shear wave velocity–depth profile can be determined from the inversion analysis, in which this study applies the technique developed by Yokoi (2005) which employs the combination of Down Hill Simplex Method with Very Fast Simulated Annealing.

3. FIELD OBSERVATIONS AND DATA ANALYSIS

3.1 Area of Study

The investigated area is located within latitudes 13° 10' N to 14° 40' N and longitudes 99° 40' E to 101° 20' E, covering Bangkok and the vicinity provinces named Ratchaburi in the west, Phra Nakhorn Si Ayutthaya in the north, Samut Sakhon and Samut Prakan in the south, and Nakhon Nayok and Chachoengsao in the east. The area lies on a large alluvial plain of delta area where four main rivers, Chaopraya, Tha Chin, Mae Klong and Bang Pakong, empty into the Gulf of Thailand in the south. Figure 1 shows the investigated area where 126 observation sites are distributed almost evenly inside.

Figure 1 Area of Study

The plain consists of thick soft clay in which the thickness increases gradually from the north to the south, and more sharply near the edge of the basin in the west and east direction (AIT 1981). Generally, the thickness of soft clay with very low shear strength is 15 to 20 meters at the central area. The depth of bedrock is estimated to be in an order of 500 meters or deeper, but there is no sufficient information available.

3.2 Microtremor Observation

The vibration measuring system used in this work consists of a 24-bit seismic recorder and four units of tri-axial velocity sensor with a natural period of 2 seconds. The arrangement of sensors for SPAC observation was selected as equilateral triangular array where one unit is placed at the center of circular and the other three are on the perimeter allowing simultaneously record of six pairs of observation with two different radiuses, i.e. r and $\sqrt{3}r$. The array sizes consist of small radius of 10 m to large radius of 50 m. For each observation, data were collected for 20 minutes with sampling frequency of 200 Hz. The data of one station measurement were analyzed for H/V spectrum ratio and the data of array measurement were used for SPAC analysis. The maximum depth for inversion analysis was set to 90 m which is approximately equal to the maximum distance between the two sensors.

4. RSULTS AND DISCUSSIONS

4.1 Predominant Period

From H/V spectral plot, the identified period at the spectral peak is interpreted as the predominant period, T_P. It is noted that, due to limitation of the sensor, the peak for period longer than 2 second was not identified in this study. T_P values are found in a range of 0.2 to 1.1 second. Figure 2 presents a map of variation of T_P where solid line and number indicate contour line of area having approximately the same T_P. The sites with longest T_P are located in the south-east part which contains the deepest layer of soft soil. Area along the Gulf of Thailand and in Bangkok metropolitan also exhibit considerably long T_P, longer than 0.8 second. T_P decreases toward the north, east and a west direction as soil becomes stiffer around the edge of the basin.

4.2 Shear Wave Velocity

The results of shear wave velocity are presented as the average shear wave velocity from the surface to 30-m depth (V_{S30}) and they are shown as a contour map in Figure 3. V_{S30} varies considerably in the area, from 70 to 550 m/s. The sites with lowest V_{S30} are located in the south-east part which is the same area of longest T_P. Area along the Gulf of Thailand and central of Bangkok exhibits low V_{S30} which is also consistent with distribution of thick soft clay. As soil becomes stiffer toward the edge of the studied area, V_{S30} increased and the hardest soil sites in this study are located near the boundary of the plain.

Variations of shear wave velocity are illustrated as 2D cross-sectional profiles in Figure 4 and 5 for north-to-south and west-to-east directions, respectively. In these figures, color lines represent constant average shear wave velocity of 100, 150, 200, 250 and 300 m/s for different sites. The depth of the level for a specific average value is shown in the vertical axis. Shear wave velocity profile for each site is also shown in these figures. From Figure 4, depth of any specific value of the average shear wave velocity increases from the north to the south indicating that shear wave velocity at the same depth becomes lower toward the southern part. In Figure 5, high average shear wave velocities are found in shallow layers of the area near the edge, in Ratchaburi and Chachoensao. Profiles of shear wave velocities drop sharply after the boundary. Shallow shear wave velocities are almost invariant at the central area. Deep shear wave velocities tend to decrease in Samutprakarn where V_{S30} is minimum.

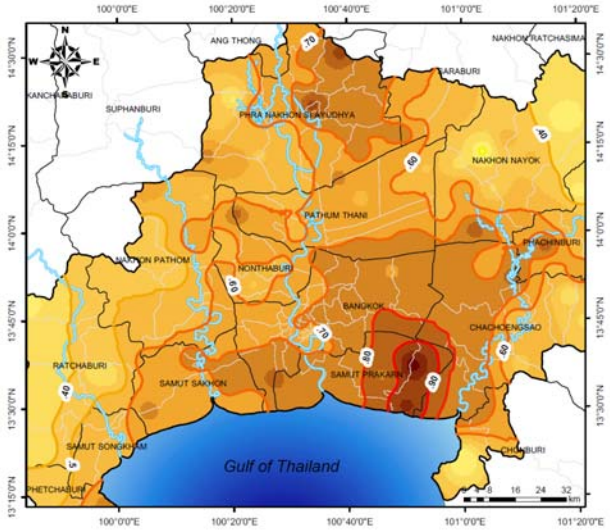

Figure 2 Contour Map of T_P

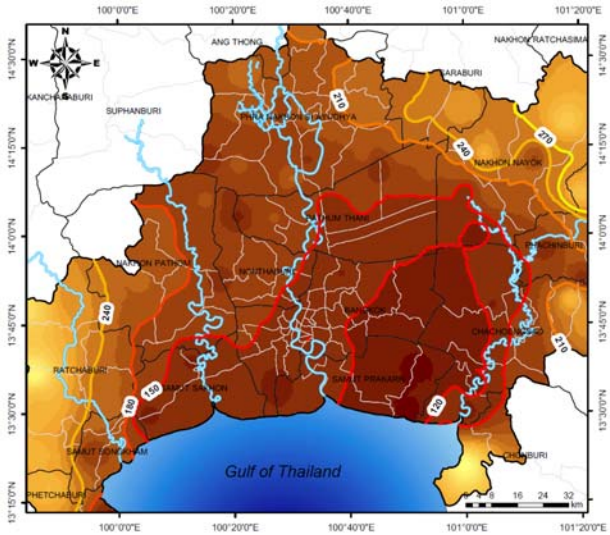

Figure 3 Contour Map of V_{S30}

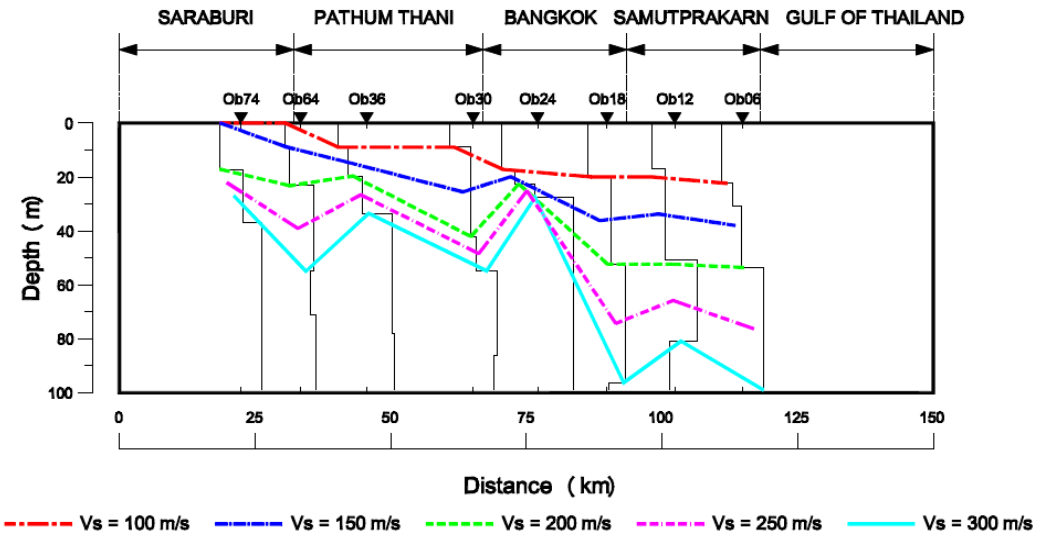

Figure 4 Cross-Sectional Profile of Shear Wave Velocity (North-to-South direction)

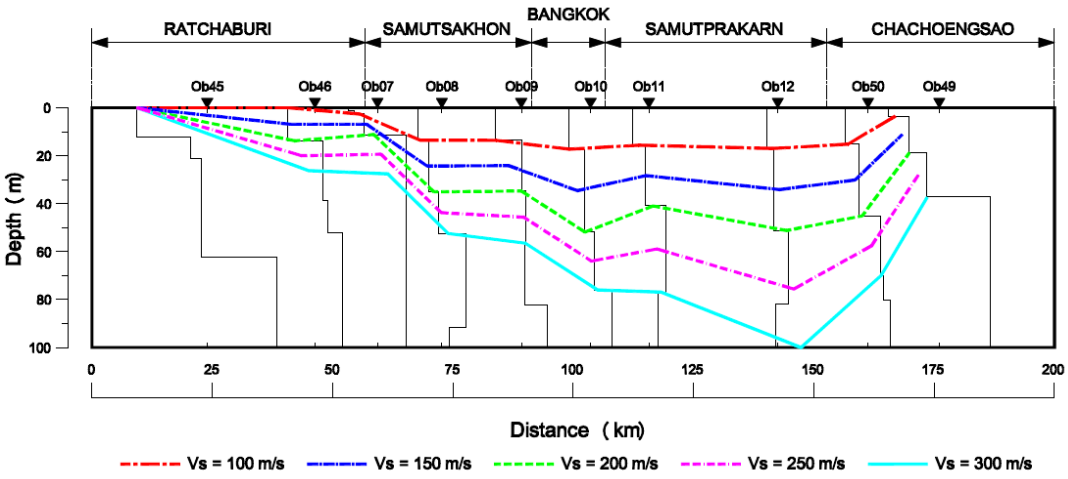

Figure 5 Cross-Sectional Profile of Shear Wave Velocity (West-to-East direction)

4.3 Relations among V_S and *Tp*

From a number of site characteristic data presented in the preceding sections, relations among average shear wave velocity at different depth V_{SD} and predominant period are discussed. In the following discussion, the statistical correlation among the average shear wave velocity from the surface to 10, 30, 60 and 90-m depth (V_{S10}, V_{S30}, V_{S60} and V_{S90}) together with *Tp* are examined by regression analysis. First, the consistency of V_{SD} is investigated by considering relations of V_{SD} with V_{S30}. The generalized relation among V_{SD} and V_{S30} is written as a form in Eq. (1).

$$V_{SD} = \alpha_1 (V_{S30})^{\beta_1} \tag{1}$$

Eq. (1) can be used for the regression analysis to determine the coefficient α_1 and β_1 by re-written in a form of linear relationship as:

$$y = a + \beta x \tag{2}$$

In which $y = \log(V_{SD})$, $a = \log(\alpha_1)$, $x = \log(V_{S30})$ and $\beta = \beta_1$. The plots of Eq. (2) can provide the interception a at $x = 0$ and slope β of the straight line by minimizing the standard error of estimate between the measured and the predicted values. Figure 6 presents the plot of $x = \log(V_{S30})$ and $y = \log(V_{SD})$, and the results of regression analyses are shown for α_1, β_1 and the coefficient of determination, R^2 in Table 1.

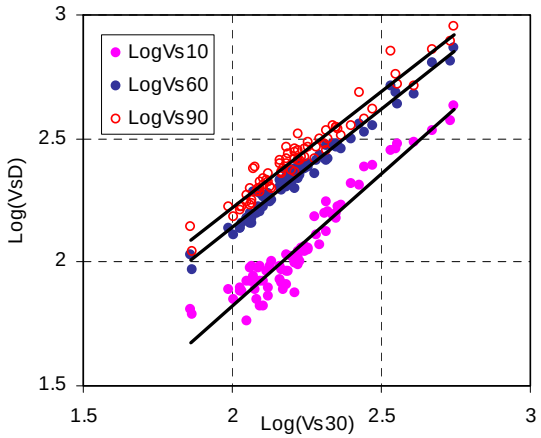

Figure 6 Relations among V_{S30} with V_{S10}, V_{S60} and V_{S90}

Table 1 Regression Analysis Results of V_{S10}, V_{S60} and V_{S90}

	α_1	β_1	R^2
V_{S10}	0.569	1.035	0.851
V_{S60}	1.635	0.961	0.971
V_{S90}	2.174	0.939	0.941

From the above regression results, the exponent of Eq. (1) is almost unity indicating that the relations between V_{S30} and V_{SD} are nearly in linear proportion. In addition, high correlations among V_{S30} with V_{S60} and V_{S90} are obtained from their considerably large R^2 while it is lower for correlations between V_{S30} and V_{S10}. This can be inferred that V_{S30} may represent deeper shear wave velocity profile for this area quite well. However shallow average shear wave velocity of V_{S10} may not appropriately represent deeper velocity structures in the case of thick deposits as in this area.

Similar regression analyses are conducted for determination of correlation among the average shear wave velocity at different depth and the predominant periods obtained in this study. The relations among V_{SD} and the predominant frequency (1/ Tp) can be written in Eq. (3). The results of regression analysis are presented in Figure 7 and Table 2.

$$V_{SD} = \alpha_2 (1/T_P)^{\beta_2} \qquad (3)$$

The relations between V_{SD} and (1/ Tp) are also close to linear function. Moreover their correlations are considerable, especially for deep V_{SD}. However, lower correlation with V_{S10} is observed. These observations address the applicability of H/V spectral ratio technique that the information of deep ground structure could be appropriately achieved but not that of the uppermost layers.

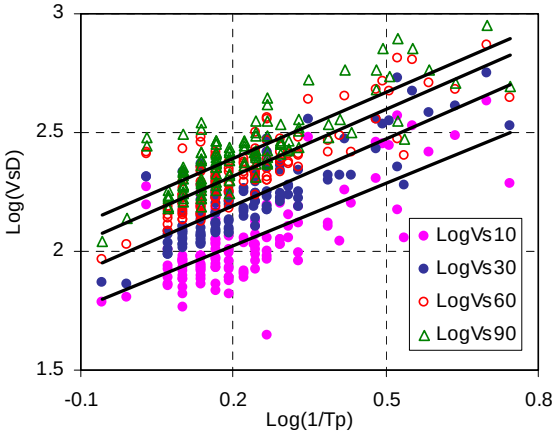

Figure 7 Relations among (1/ TP) with V_{S10}, V_{S30}, V_{S60} and V_{S90}

Table 2 Regression Analysis Results of (1/ Tp) and V_{S10}, V_{S30}, V_{S60}, V_{S90}

	α_2	β_2	R^2
V_{S10}	70.4	0.880	0.471
V_{S30}	100.7	0.934	0.658
V_{S60}	135.2	0.934	0.687
V_{S90}	160.6	0.930	0.689

5. CONCLUDING REMARKS

Site characterizations in the central area of Thailand by microtremor observation are reported in this paper. From 126 observation sites, shear wave velocities, by SPAC method, and predominant periods, by H/V spectral ratio method, are presented and discussed. The area along the Gulf of Thailand and the south-east part of the studied area exhibit very low V_{S30} of 70 m/s and long predominant period of 1.1 second while high V_{S30} of 550 m/s and short predominant period of 0.2 second are found near the boundary of the Chaophraya basin.

The relations among the average shear wave velocity at different depth, from 10 m to 90 m, and the predominant periods at site are examined. It was shown that shallow shear wave velocities to 10 m depth, influenced by the top layer of weathered soil, were not reasonably correlated with deep shear wave velocities. Higher correlations were observed among V_{S30} and deeper shear wave velocities. In addition, the predominant periods were found to be more correlated with deep average shear wave velocity by higher value of the coefficient of determination than average shear wave velocity at 10 m depth.

Abstract: Tachikawa fault is one of the most activity faults in the Tokyo metropolitan area and when large earthquake will occur by this fault in the near future, it is expected that large economic and human loss will happen around this area. However, three dimensional subsurface structural model is not clear still enough for the estimation of the strong ground motions in this area. In this study, we estimated the three dimensional subsurface structural model using the receiver function method from the obtained records of the K-NET, KiK-NET and SK-net. We calculated the receiver functions from 20 to 50 seismic records obtained at the 60 stations, and we identified the subsurface structural model using inversion based on the simulated annealing method. We constructed the three-dimensional subsurface structural model in this area obtained from P-wave and S-wave velocity profiles of thick sediments at each station. Moreover, we calculated Radial/Vertical spectral ratios with this three dimensional model. The results indicate that the characteristics of the calculated predominant period display good agreement with the observed one during the 2011 off the Pacific coast of Tohoku Earthquake.

1. INTRODUCTION

Since the 2011 off the Pacific coast of Tohoku Earthquake, there have been increased seismic activities in the Tokyo metropolitan area. Tachikawa fault is one of the most activity faults in the Tokyo metropolitan area and when large earthquake will occur by this fault in the near future, it is expected that large economic and human loss will happen around this area. Therefore it is required to estimate the strong ground motions accurately in this area. However, three-dimensional subsurface structure including detailed fault geometry is not clear still enough for the prediction of the strong ground motions in this area.

In this study, we estimated the three-dimensional subsurface structural model using the receiver function method (Langston 1979, Kobayashi et al., 1998) from the obtained records of the K-NET and KiK-NET of National Research Institute for Earth Science and Disaster Prevention (NIED), and SK-net provided by the Tokyo metropolitan area comprehensive network. We calculated the receiver functions from 20 to 50 seismic records obtained at the 60 stations, and we identified the subsurface structural model using inversion based on the simulated annealing method. We constructed the three dimensional subsurface structural model in this area obtained from P-wave and S-wave velocity profiles of thick sediments at each station. Moreover, we calculated Radial/Vertical spectral ratios with this three dimensional model. Finally, we discuss the long-period ground motion characteristics during the 2011 off the Pacific coast of Tohoku Earthquake around the Tachikawa fault based on a constructed three-dimensional subsurface structural model.

2. SPATIAL DISTRIBUTION OF PS-P TIME BY THE RECEIVER FUNCTION METHOD

Tachikawa fault zone located about 20km western of Tokyo metropolitan, and a total length of this fault zone is about 33km consists with Naguri and Tachikawa fault as shown in Figure 1. Many seismic records was observed at seismic stations (K-NET, KiK-NET and S K-net) around those faults. Figure .1 also shows distribution of the depth up to the seismic basement based on "Long-period ground motion hazard maps" (Headquarters for Earthquake Research Promotion 2009). The seismic basement became deep gradually from west to east from this distribution, and it is not confirmed that the geometry of a subsurface structure are change drastically around the Tachikawa fault.

In this study, we calculated the receiver functions from the seismic records obtained at the 60 stations as shown in Figure 1. Seismic records was used at each station from 20 to 50 records in the 70 earthquakes (over Mj = 4.5) within 100km of the epicentral distance as shown in Figure 2. In the calculation of the receiver function at each station, we used the first 5 seconds from the onset of the P-wave in these records. A band-pass filter with a frequency range from 1.0 to 5.0Hz was applied during the calculations. An example of the resultant receiver function at TKYH02 (KiK-NET) is

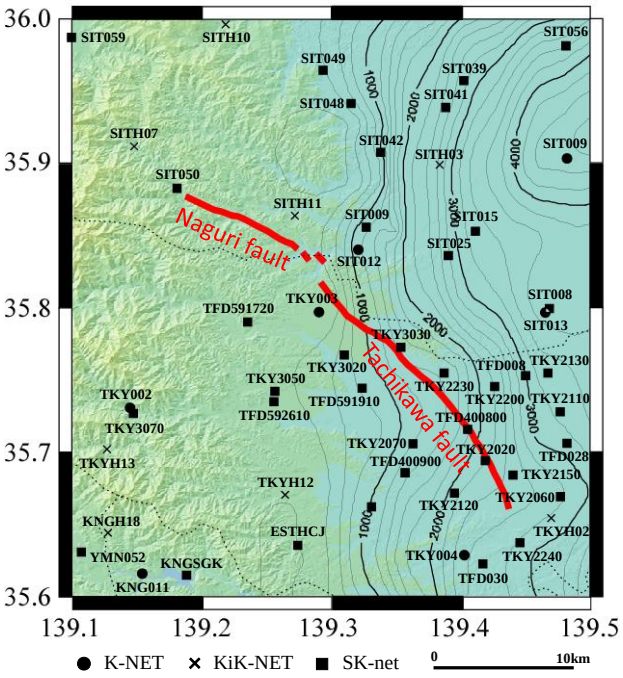

Figure 1 Seismic stations around the Tachikawa fault zone

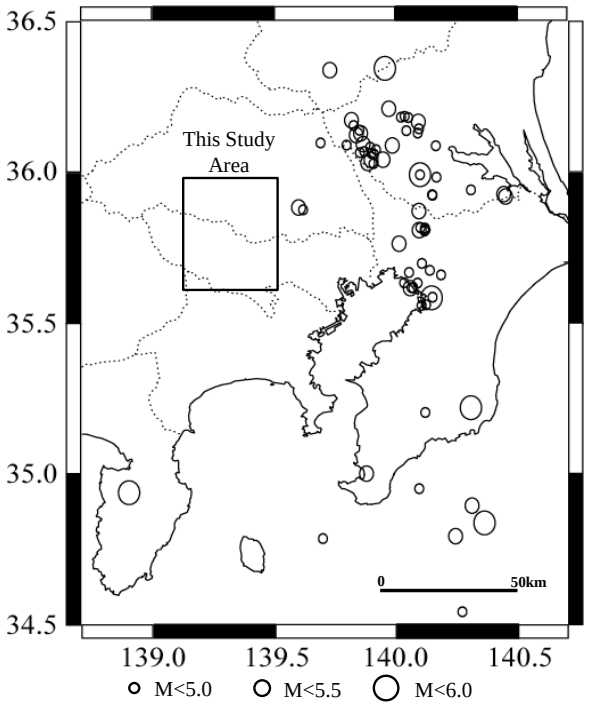

Figure 2 Epicenter of the earthquakes that was used for the receiver function method analysis

shown in Figure 3. PS-P time is indicating 1.3 seconds in the observed receiver functions as shown in Figure 3.

Figure 4 shows the distribution of PS-P time at all seismic observation stations obtained from the analysis of the receiver function method. We found that PS-P time is significantly different across the Tachikawa fault as shown in Figure 4. PS-P time has become longer in the eastern part of the Tachikawa fault although that has become shorter in the western part of the Tachikawa fault. Therefore, it will be assumed that there are thick sedimentary layers in the eastern part of the fault although there are not sedimentary layers in the western part of the fault.

Figure 5 shows the distribution of a difference between observation and theoretical PS-P time. A theoretical PS-P time obtained from the receiver functions calculated with the subsurface structural model base on "Long-period ground motion hazard maps", and the theoretical receiver functions are calculated by the method of Haskell (1962). It is almost the same as the theoretical and observed PS-P time at the stations on the eastern part of the Tachikawa fault (i.e. TKY2200, TFD400800) as shown in Figure 5. The observed PS-P time is shorter than the theoretical one at the station on the western part of the Tachikawa fault, especially TKY2070.

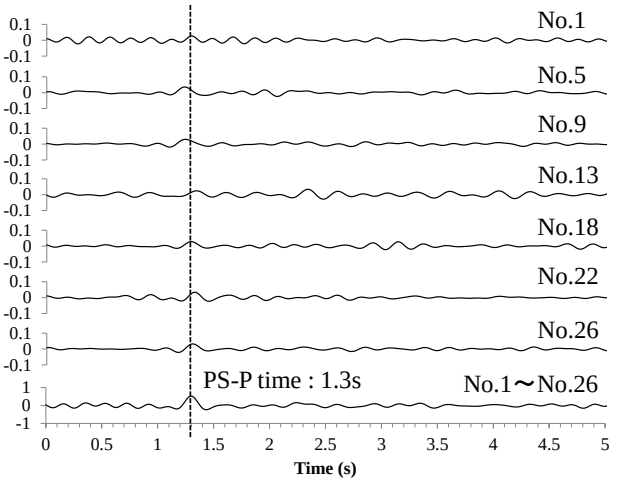

Figure 3 Receiver functions at TKYH02 (KiK-net)

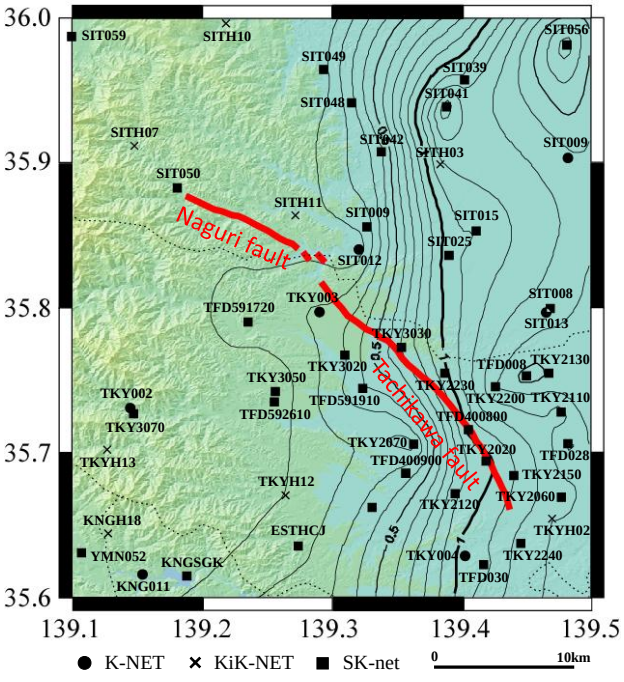

Figure 4 Distribution of the P-SP time obtained from the receiver function method analysis

Thus, it is considered that sedimentary layers are very thin than the subsurface structural model based on "Long-period seismic hazard map". Further, around the Naguri fault, it is possible that the sedimentary layers in the southern part are thicker than the northern part of the fault.

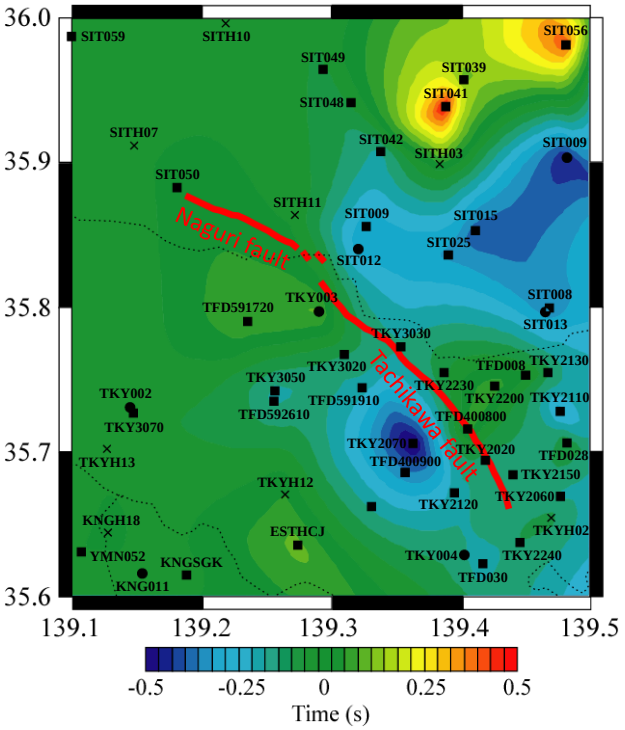

Figure 5 Distribution of the time difference between the observed P-SP time and the theoretical one based on "Long-period seismic hazard map"

3. IDENTIFICATION OF SUBSURFACE STRUCTURE BY SIMULATED ANNEALING

We identified the subsurface structural model at each seismic observation station from the receiver function calculated from the observed record using the simulated annealing method (Ingber 1989, Yamanaka 2001).

We identified the layer thickness (H) in the search range set of the 1-200% of the initial value because the trade-off occurs between the layer thickness and P and S-wave velocity. Initial subsurface structural model at each station based on "long-period seismic hazard map" was used in the inversion. Evaluation function in the identification of subsurface structure is defined as the following equation (Kurose and Yamanaka 2006).

$$E_m = \frac{1}{N}\sum_{n=1}^{N}\left|\frac{R.F.^{C}(t_n) - R.F.^{O}(t_n)}{\sigma(t_n)}\right| \qquad (1)$$

Where $R.F.^{C}(t_n)$ is the theoretical receiver function, $R.F.^{O}(t_n)$ is the observed receiver function, $\sigma(t_n)$ is the standard deviation of the observed receiver function $R.F.^{O}(t_n)$ at time t_n and N is the number of data, respectively.

Figure 6 shows a comparison between the receiver function (Obs.) observed at TKYH02 (KiK-NET) and the inverted receiver function (Inv.) as an example of the identified result. In addition, receiver function (Ini.) calculated with the underground structure model by "Long-Period Ground Motion Hazard Maps" as an initial model is also shown in Figure .6. The receiver function with identification results is good agreement with the observed receiver function, and it is indicated that the layer thickness of individual layers are inverted very well.

Figure 7 shows examples of the P and S-wave velocity profiles at TFD400800 and TKY2070 (SK-net) obtained from inversion. Velocity profiles are mainly approximated by 4 sedimentary layers and seismic basement with P-wave velocity of 5.5km/s and S-wave velocity of 3.2km/s around the Tachikawa fault zone. The thickness of the sedimentary layers at TKY2070 and TFD400800 which are located in the western part and eastern part of the Tachikawa fault was 0.3km and 2.1km, respectively. Therefore, it is indicated that a basement depth in those profiles at down-thrown side of the fault is larger than that at up-thrown side with a difference of about 1.8km. On the other hand, it is estimated that the seismic basement of the Naguri fault dropped toward to the southwest with a difference of about 0.3km according to inverted subsurface structures at SITH11 (KiK-NET) and TFD591720 (SK-net).

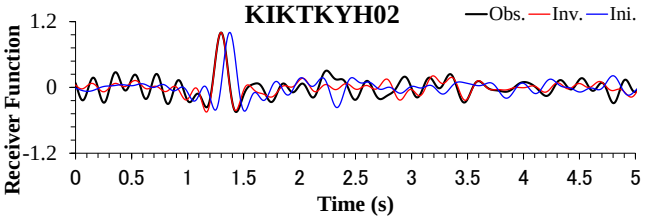

Figure 6 Identified receiver function obtained from the inversion using the simulated annealing method at TKYH02 (KiK-net)

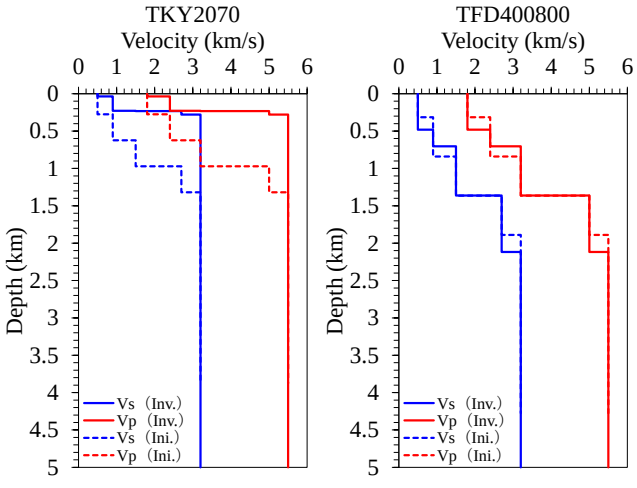

Figure 7 Identified subsurface structural models obtained from the inversion using the simulated annealing method (Left:TKY2070 (Sk-net), Right: TFD400800 (Sk-net))

4. THREE-DIMENSIONAL SUBSURFACE STRUCTURE NEAR THE TACHIKAWA FAULT ZONE AREA

We constructed the three-dimensional subsurface structural model near the Tachikawa fault zone obtained from P-wave and S-wave velocity profiles of thick sediments at each station. Figure 8 shows distribution of depth to the top of the seismic basement (Vp=5.5km/s, Vs=3.2km/s) in the three- dimensional subsurface structural model around the Tachikawa fault zone obtained from the inversion using the receiver functions. It is indicated that the seismic basement is steeply inclined around the Tachikawa fault as shown in Figure 8.

Figure 9 shows the ratio of the depth of the upper of the seismic basement between the inverted three-dimensional subsurface structural model to the "Long-period ground motion hazard maps" model shown in Figure 1. Near the Tachikawa fault, it is indicated that the seismic basement evaluated by this study has become shallow in the southwestern part of the fault as shown in Figure 9. In addition, around the Naguri fault, it is denoted that the seismic basement evaluated by this study has become deep in the southern part of the fault. The seismic basement obtained from inversion display good agreement with the "Long-period ground motion hazard maps" model in the western part of Tokyo metropolitan area and the southern part of Saitama prefecture as shown in this figure.

5. LONG-PERIOD GROUND MOTION CHARACTERISTICS AROUND THE TACHIKAWA FAULT DURING THE 2011 OFF THE PACIFIC COAST OF TOHOKU EARTHQUAKE

Tsuno et al. (2012) evaluated the characteristics of the long-period ground motions and site amplifications in the Kanto plain including Tokyo metropolitan area by the main shock and aftershocks of the 2011 off the Pacific coast of Tohoku Earthquake. Here, we discuss the corresponding with the sedimentary layers thickness of the inverted three-dimensional subsurface structural model and the predominant period of the Fourier spectrum which were observed during the main shock around the Tachikawa fault zone area.

Figure 10 shows the distribution of the predominant period of the Fourier spectrum with the horizontal component which synthetic two components around the Tachikawa fault zone. Figure 10 also shows distribution of the depth up to the seismic basement based on inverted three-dimensional subsurface structural model using receiver functions. It should be noted that our target period range is from 0.5 to 10 seconds. The distribution of predominant periods observed at the eastern part of the Tachikawa fault is about 3 to 4 seconds as shown in Figure 10. The distribution of predominant periods observed at the western part of the Tachikawa fault is around 1 second. It seems that the distribution of predominant period doesn't display good agreement with the depth of the upper seismic basement.

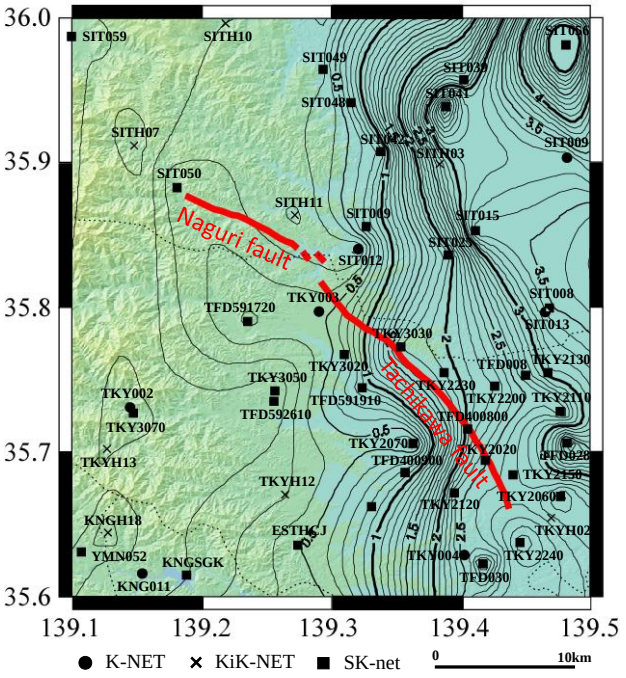

Figure 8 Distribution of depth to the top of the seismic basement (Vp=5.5km/s, Vs=3.2km/s) in the three- dimensional subsurface structural model

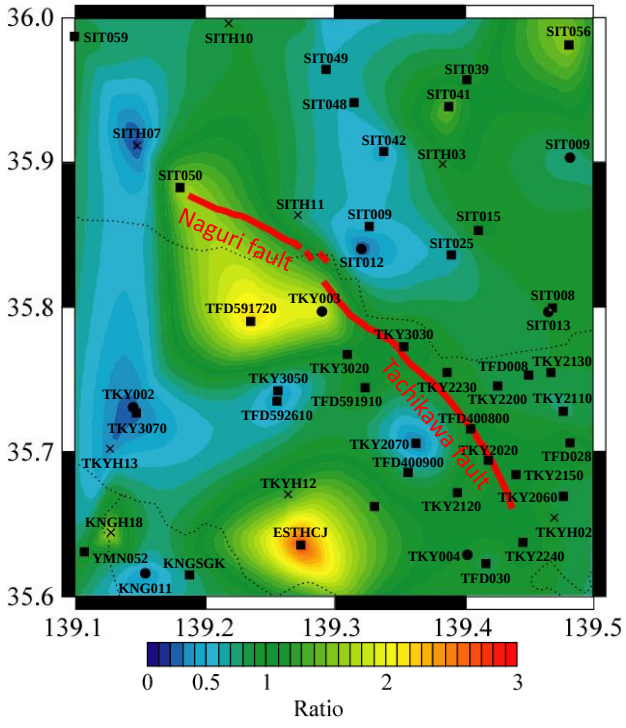

Figure 9 Distribution of the ratio of the depth of the upper seismic basement between the inverted three-dimensional subsurface structural model to the "Long-period ground motion hazard maps" model shown in Figure 1

Figure 11 shows the distribution of the predominant period of the Radial/Vertical spectral ratios around the Tachikawa fault zone. The distribution of predominant

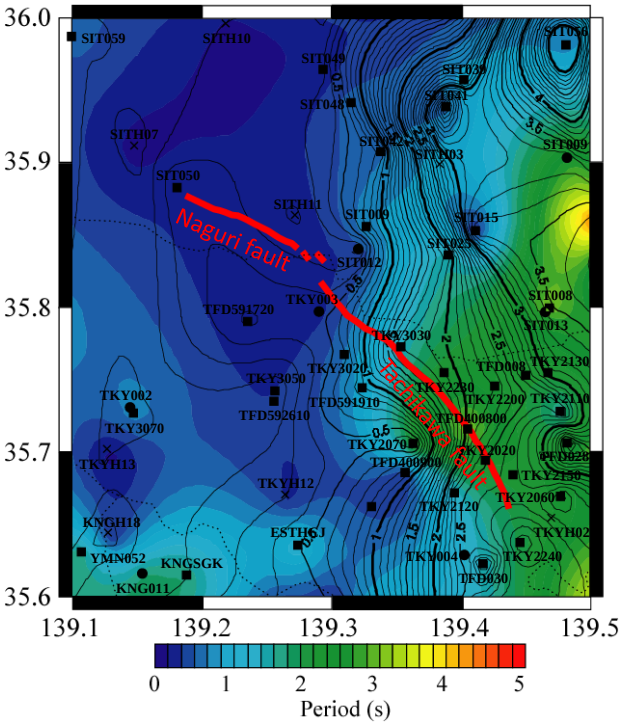

Figure 10 Distribution of the predominant periods of the Fourier spectrum with the horizontal component

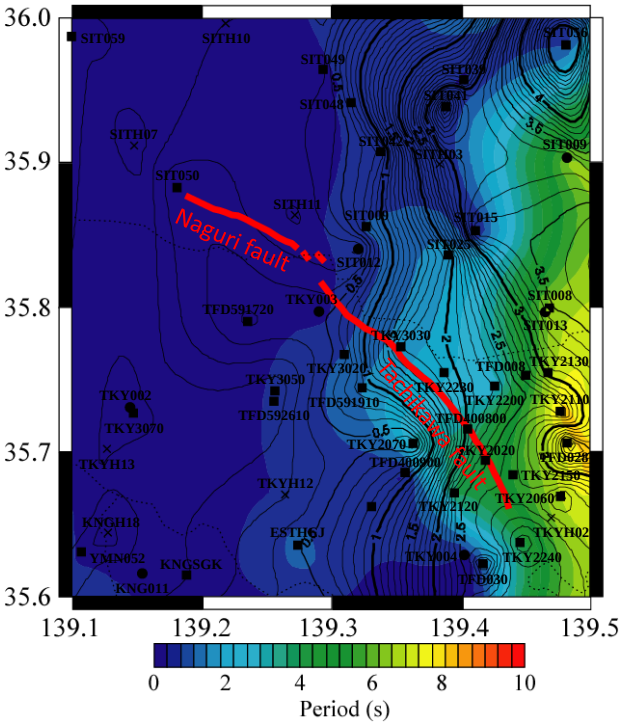

Figure 11 Distribution of the predominant periods of the Radial/Vertical spectral ratios

periods observed at the eastern part of the Tachikawa fault is about 5 to 8 seconds as shown in Figure 11. The distribution of predominant periods observed at the western part of the Tachikawa fault is about 2 second or less. Therefore, the difference has appeared clearly across the fault, it seems that the distribution of predominant period display good agreement with the depth of the upper seismic basement near the Tachikawa fault. In addition, it is corresponds that long period ground motions are remarkable at the region having thick sedimentary layers, especially northern part of the Yokohama city.

Moreover, we calculated the Radial/Vertical spectral ratios with inverted three-dimensional subsurface structural model as shown in Figure 12. The results indicate that the characteristics of the calculated predominant period of the Radial/Vertical spectral ratios near the Tachikawa fault display good agreement with the observed one during the main shock. However, the characteristics of the calculated predominant period of the Radial/Vertical spectral ratios in the northeastern part of this model don't display good agreement with the observed one. Therefore, It was suggested that the further investigation for the subsurface structures is required.

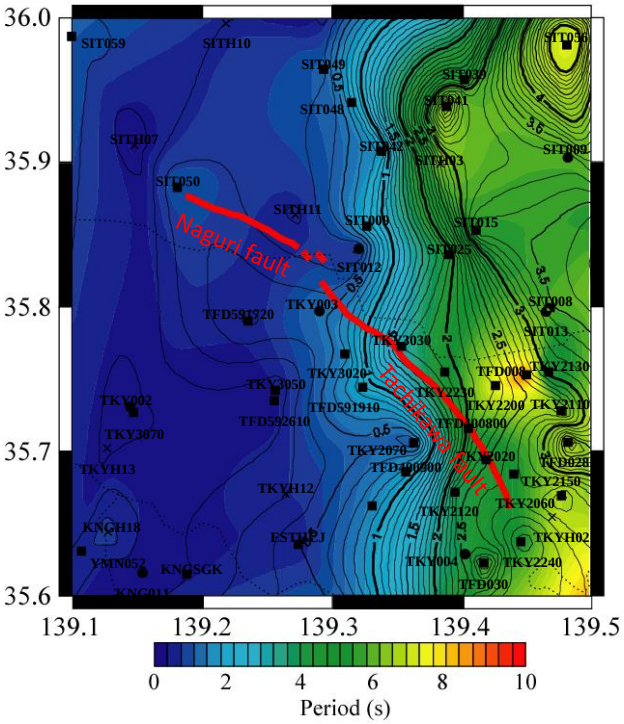

Figure 12 Distribution of the predominant periods of the the Radial/Vertical spectral ratios obtained from the inverted three-dimensional subsurface structural model

6. CONCLUSIONS

In this study, we estimated the three-dimensional subsurface structural model around the Tachikawa fault zone using the receiver function method. We identified the subsurface structural model using inversion based on the simulated annealing method, and we constructed the three-dimensional subsurface structural model in this area obtained from P-wave and S-wave velocity profiles of thick sediments at each station. Moreover, we calculated Radial/Vertical spectral ratios with this three dimensional model. The results indicate that the characteristics of the calculated predominant period display good agreement with

the observed one near the Tachikawa fault during the 2011 off the Pacific coast of Tohoku Earthquake.

Abstract: Single station of microtremor measurements were employed at stations of Taiwan Strong Motion Instrumentation Program (TSMIP) in the Taipei area (TAP) and thus the Horizontal to Vertical Spectral Ratio (HVSR) of microtremor can be derived after a standard data processing. In addition, the Engineering Geological Database for TSMIP (EGDT), including logging data such as P- and S-wave velocities, N values, specific gravity, and various soil parameters, is constructed and the Vs30-based seismic site conditions at those stations were assessed (Kuo et al., 2012). Since both of the microtremor measurements and S-wave velocity profiles are available at 60 TSMIP stations in the Taipei area, the properties of HVSR of microtremor on different seismic site conditions are studied as well as an experimental correlation of the sedimentary depths from boreholes, the dominate frequencies from microtremorôs HVSR, and the average S-wave velocities of deposits. Remarkable properties of microtremorôs HVSR including dominate frequency, falling frequency, and amplification are learned in this study to help us discriminate between different site conditions. A quick approach of the site classification according to the criteria of National Earthquake Hazard Reduction Program (NEHRP) is proposed via HVSR of microtremor.

1. INTRODUCTION

Seismic waves are usually amplified by local unconsolidated sediments at specific frequencies during strong motions, that is, the so called site effect, a significant issue in seismology, earthquake engineering, and seismic hazard assessment. The fact of different seismic site conditions can cause varied site effects, was recognized more than hundred years ago (Milne, 1898). It was noted that ñIt is an easy matter to select two stations within 1000 feet of each other where the average range of horizontal motion at the one station shall be five times, and even ten times, greater than it is at the otherò. This showed the site effect could be evident at two nearby stations.

Microtremors (also called microseism, ambient noise, or seismic noise) are caused by various natural and artificial signals, such as winds, tides, rains, traffics, and mechanical vibrations. Those signals always exist and thus the time of measurements is very short in comparison with that for earthquakes. After Nakamura (1989) proposed the single station HVSR method, microtremor became a popular tool to assess site response, i.e., resonance frequency and amplification factor at a specific site. Several studies (Delgado et al., 2000; Dinesh et al., 2010; García-Jerez et al, 2006; Parolai et al., 2002) developed relations between thickness of sedimental layers and resonant frequency of microtremor, which then can be used to estimate the thickness of sediments in whole study region; otherwise, S-wave velocity was estimated by a developed empirical relation with depth.

Prior to the present study of developing HVSR models on different seismic site conditions, a reliable site classification is the fundamental. The Engineering Geological Database for TSMIP is constructed by the National Center for Research on Earthquake Engineering (NCREE) and the Central Weather Bureau (CWB), including logging data at more than 400 stations, Vs30 and the site classification of the drilled stations also have been accomplished (Kuo et al., 2011; 2012) according to the criteria of NEHRP (BSSC, 2001). This study focused on the Taipei area due to the various site conditions and abundant related studies for developing HVSR models. The site classification and Vs30 at 11 stations of class B, 20 stations of class C, 32 stations of class D, and 5 stations of class E sites were available in TAP from the EGDT as shown in Figure 1 (Kuo et al., 2012). Microtremor measurements were employed at most of those stations for the development of the HVSR model on different seismic site conditions.

Since most of the velocity profiles of EGDT are less than 35 m, additional deeper velocity profiles were required to evaluate the empirical correlation between depth of sediments and dominate frequency of microtremorôs HVSR. The Strong Motion Downhole Array and the Broadband Downhole Seismic Network in the Taipei Basin were installed by the Central Geological Survey and the Institute of Earth Science of Academia Sinica from 1991 and 2005, respectively. Both S-wave velocity profiles and microtremor measurements were available at several stations of the downhole arrays and the depths are from 80 m to 292 m (Wen and Yeh, 1996, 1998; Wen et al., 1995; Huang et al., 2008).

HVSR of microtremor at different geological zones were usually grouped into different categories according to the shapes of HVSR (Tuladhar et al., 2004), and sometimes a representative velocity profile may be available in a zone (Rodríguez and Midorikawa, 2004). Since enough stations with seismic site conditions from EGDT are known and the HVSR are also available, we can therefore evaluate the correlations between HVSR of microtremor and seismic site conditions in the Taipei area.

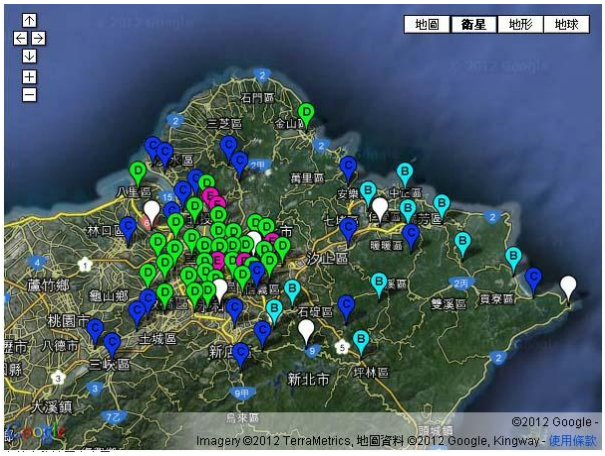

Figure 1 The site classification of EGDT (Kuo et al., 2012) in the Taipei area displayed in the Google Maps. The aqua marks with a letter B mean the class B sites; the blue marks with a letter C mean the class C sites; the green marks with a letter D mean the class D sites; the fuchsia marks with a letter E mean the class E sites; the white marks without any letter mean no borehole at the station.

2. LOCAL GEOLOGY AND DATA ACQUISITION

2.1 Geology in the Taipei Area

The Taipei area contains the triangular Taipei Basin with a region of about 20 km across, as well as the surrounding Tatun volcanic region (Pleistocene), Linkou area (Pleistocene), and Western Foothills (Miocene) in the North, the West, and the Southeastern, respectively.

Inside the Taipei Basin are four Quaternary sedimentary formations covering on the Tertiary bedrocks. Taipei City is the capital of Taiwan, located in the Taipei Basin, subject severe damages during large earthquakes, like Hualien earthquake in 1986, Chi-Chi earthquake in 1999, and Hualien earthquake in 2002, due to significant site effect (Wen et al., 1995; Wen and Peng, 1998). The relevant Sungshan Formation is the topmost layer composed mainly of soft silty clays and silty sands and believed the major cause of the seismic wave amplification. Below the Sungshan Formation are the Chingmei, Wuku, and Banchiao Formations in order. The thickness contours of the Sungshan Formation and the depth of Tertiary bedrocks were indicated by Wang et al. (2004), as well as the seismic velocities of the sedimentary layers. The average shear-wave velocity of Sungshan Formation throughout the whole basin is around 170-340 m/s. The largest depth of the bedrock is in the northwest of the basin and may be shallower than 50 m around the basin edge.

2.2 Microtremor Measurements and Data Processing

Two types of instruments were used in this study, SAMTAC-801B (recorder) and VSE311C (sensor) manufactured by Tokyo Sokushin, and the alternative K2 with an EpiSensor made by Kinemetrics. Sampling rate is 200 point per second and the recording period is 18 minutes. The appropriate location for our microtremor measurements was on the side of stations to ensure the geological conditions are identical to the stations and boreholes. The instrumental response was eliminated in the procedure of HVSR. Microtremor at a number of 60 stations was measured up to now and the distribution was shown in Figure 2 as triangles, including 10 of class B, 17 of class C, 28 of class D, and 5 of class E. Of cause, those stations have Vs30 and were classified as in Figure 1.

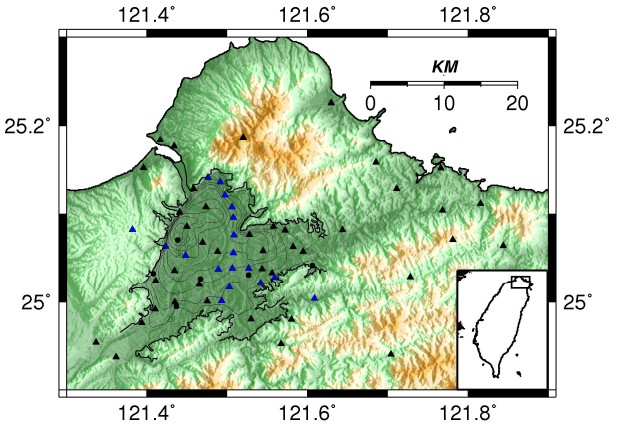

Figure 2 The distribution of the stations contain the microtremor measurements. The triangles are stations from EGDT; the circles are stations of downhole arrays with larger depths. S-wave velocity profiles are available in all of those stations displayed here. The blue stations indicate two profiles of HVSR in N-S and E-W directions across the Taipei Basin.

Multi-windows with 8192 points of each was used to cut the microtremor recordings, and 6% cosine taper was implemented at both ends of each window. The recordings

must be checked and the windows contaminated by unusual noise can be deleted in advance; however the number of selected windows should be more than 20. A geometric mean horizontal Fourier spectrum was calculated, smoothed 5 times using three points approach and then divided by the smoothed vertical Fourier spectrum. After averaging the HVSR of each window, the mean HVSR at one station was derived.

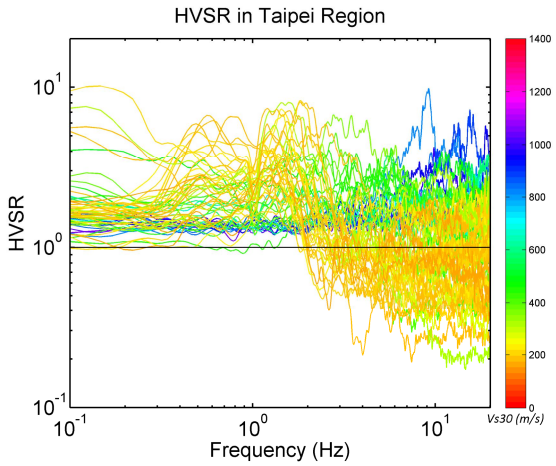

Figure 3 HVSR at the 60 strong motion stations of TAP from the EGDT with different Vs30. The resonance peaks with larger Vs30 seems at the higher frequency; on the other hand, the resonance peaks with smaller Vs30 were located at lower frequency.

3. HVSR OF DIFFERENT SITE CLASSES

The Taipei area was selected as the preliminary research area for the noteworthy site effects in the basin, varied site conditions in whole region, and sufficient reference materials. These advantages, particularly abundant velocity profiles from logging measurements are significant for the qualitative and quantitative analyses in developing the new models of HVSR and new technique on site assessment using microtremor.

HVSR at the 60 strong motion stations were derived (Figure 3) following the standard data processing introduced in the above section and plotted in different colors according to the Vs30 at each station. The dominate frequencies of HVSR increase as the Vs30 become higher. However, the amplification factors of HVSR of different Vs30 are very similar. The amplification factors of the dominate frequency lower than 2 Hz are almost equal to those of higher than 9 Hz, and the others between 2 and 9 Hz are smaller.

Moreover, we categorized these HVSR curves into classes of B, C, D, and E according to the site classification of Kuo et al. (2012) (Figure 4). Stations of class B, the Vs30 is between 760 and 1500 m/s, situated on hard rocks or sometimes covered with a thin regolith and therefore the dominant frequencies of HVSR are unremarkable or relatively higher with strong amplification. The stations of class C, which are situated on soft rocks or stiff soils, have more obvious amplification at comparatively lower resonant frequency than the class B. The HVSR curves of classes D and E are amplified at relatively lower dominant frequencies.

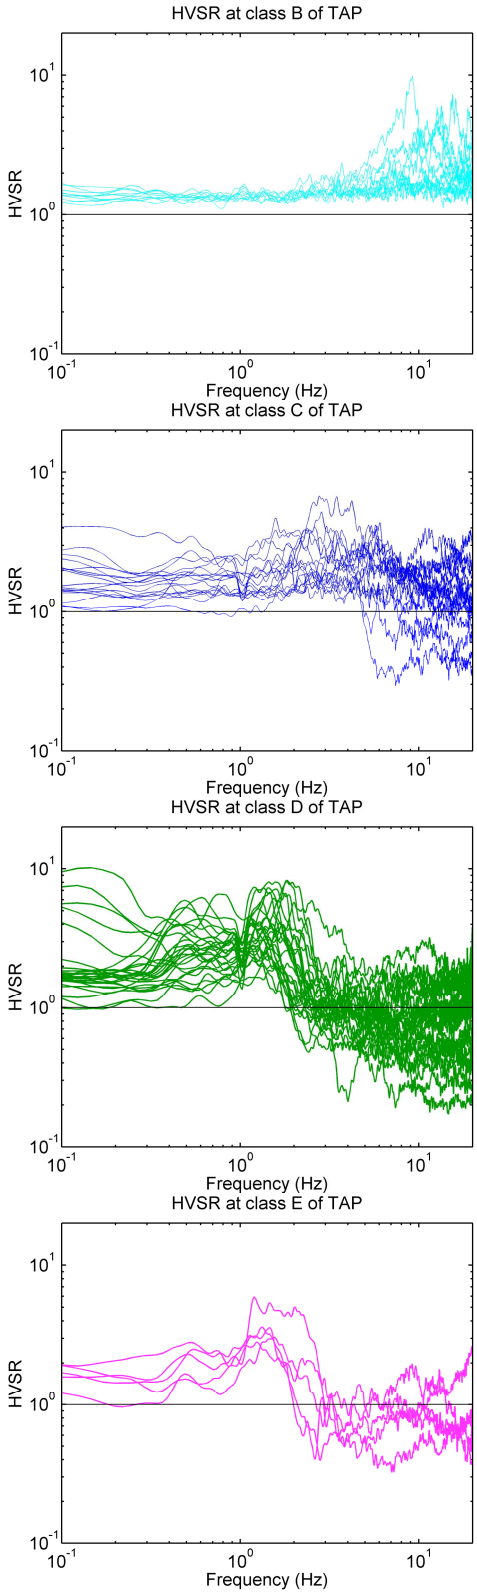

Figure 4 The categorized HVSR curves according to the site classification of Kuo et al. (2012). From top to bottom is class B, class C, class D, and class E.

Figure 5 shows the average HVSR of four classes, the difference of shape and dominant frequency are very clear. The dominant frequency increased with Vs30, except for class D and E. The HVSR in the two classes, in terms of shapes, the dominant frequencies, the double peaks, and the amplification factors are quite similar that it often difficult to group them into two specific classes. We speculated that the similarity is because the thickness of sediments at sites of D and E is mostly greater than 30 meters so Vs30 can not tell the differences from the HVSR. Since dominant frequency is related to the thickness of sediments rather than the variation of velocities, the distinction in two classes are not prominently seen. The other possible reason is the Vs30 of the 5 stations are close to the boundary of class D and E (180 m/s), so that the difference between the HVSR of the two classes is not notable.

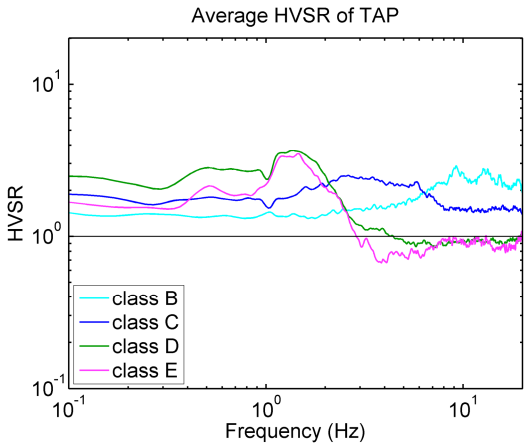

Figure 5 Averaged HVSR of class B, C, D, and E. Different dominant frequencies were very clear except for class D and E.

Additionally, Figure 4 shows a notable phenomenon, that is, deamplication, in the relative high frequencies. We therefore called the threshold of the deamplification as ñfalling frequencyò, at which the deamplication starts to occur. This could be found in all HVSR curves of class D, class E, and several of class C. The occurrence of ñfalling frequencyò is another important property of HVSR found in this study which could also be used to distinguish site classes. The falling frequency of microtremorôs HVSR always occurs at a site covered with soft sediments. The signal of microtremor tends to resonate within the covering sedimental layer and then Rayleigh waves are generated. The effect of Rayleigh waves in the vertical component become relatively larger and thus the spectral ratio of horizontal to vertical fall into values less than one on those frequencies, i.e. Rayleigh waves become dominant in microtremor on the higher frequency band. It can be found in all stations of class D and E, as well as several stations of class C. In contrast, the HVSR larger than one because of the lack of Rayleigh waves at hard rock sites. Consequently, the phenomenon of falling frequency is very clear in the average HVSR of D and E in Figure 5. Otherwise, the falling frequency of class E is lower than that of class D, possibly due to lower S-wave velocity of sediments. Maybe this criterion can be used as an index for distinguishing sites into classes D and E. This needs, however, further validation.

4. THE EMPIRICAL CORRELATION BETWEEN DOMINATE FREQUENCY AND THICKNESS OF SEDIMENTS

The well-known empirical correlation (Equation 1) of thickness of sediments (H), S-wave velocities (Vs), and dominant frequency (F) has been widely used in estimations of depths of bedrocks (e.g., Wooley and Street, 2002).

$$H = Vs / 4F \tag{1}$$

However, the empirical equation has some divergence owing to the difference in local geology. We used the drilling profiles of EGDT and refer to some other velocity profiles of deep boreholes in the Taipei Basin, estimating the relation between resonant frequency and the depth of bedrock by least-square method. The data (red circles) as well as the estimated result (blue curve) are shown in Figure 6. S-wave velocity is larger than 600 m/s and an obvious boundary exists above the indentified bedrock. The correlation coefficient (R) is as high as 0.92. The experimental correlation is $H = 64.02 \times F^{-0.92}$ as shown in Figure 6. The exponent of dominant frequency is -0.92, very near to the value of -1 in Equation (1). The coefficient 64.02 therefore can be seen as a quarter of the average Vs of a particular depth that causes the resonance peak and thus the average Vs of the sediments in the Taipei area is about 256 m/s, agree well with the average S-wave velocity of the first sedimentary layer, i.e. the Sungshan Formation.

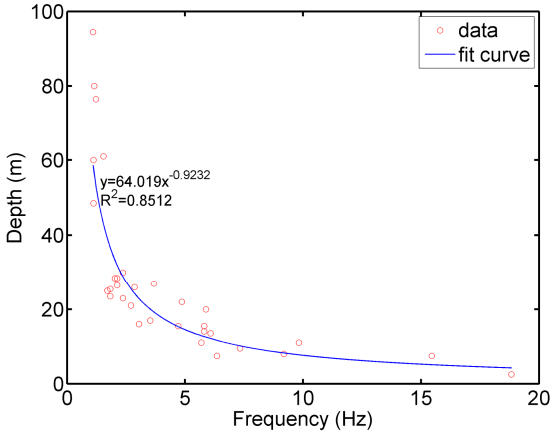

Figure 6 The open red circles are data points and blue curve is the result of regression using least-square method in the Taipei area. The correlation coefficient is 0.92.

As we can see in Figure 4 and 5, almost all of the HVSR at those stations of class D and E with two resonant peaks, which indicates two strong subsurface interfaces

(engineering and geological bedrocks) inside the Taipei Basin. The dominate frequency used for the regressed equation is the one at higher frequency of class D and E. For those stations of class B and C, only one or non-obvious peak can be found. We speculate the higher peak was caused by the interface between the first soft layer and the bedrock. The first soft layer is the Sungshan Formation inside the basin and a regolith in the surrounding mountain areas. Furthermore, the discrepancies between the empirical correlation and the result from borehole become larger and the depth usually underestimated at the lower frequency in Figure 6. This might because the average S-wave velocity increased with the extended sedimentary thickness.

5. DISCUSSIONS

Figure 7 shows the HVSR in the NS and EW profiles across the Taipei Basin. The stations were marked as blue triangles in Figure 2, ten stations contained in the N-S direction and nine in the W-E direction from top to bottom in Figure 7. TAP001 is the co-station of the profiles. We can see different fluctuations of the resonant peaks of those HVSR in the two profiles. In the N-S profile, the dominate frequencies of the 3rd to 8th stations are lower than the first two and last two stations. In the W-E profile, the dominate frequency of the 3rd station is the lowest. Roughly speaking, the fluctuation of HVSR in W-E is much larger than in the N-S direction. This means the variation of the depth of the Sungshan Formation in the W-E profile is larger than in the N-S profile. According to the depth contour of the Sungshan Formation drawn by Wang et al. (2004), the depth variation is about 30 m in the N-S profile; however, more than 50 m in the E-W profile. In the N-S profile, TAP094 is grouped into class C; TAP096, TAP005, and TAP001 are grouped into class E; the others are class D. As for the W-E profile, TAP052 and TAP089 are grouped into class C; TAP001 is grouped into class E; TAP071 is grouped into class B; the others are class D (Kuo et al., 2012).

In addition to logging (Kuo et al., 2011, 2012), surface geology (Lee et al., 2001), elevation (Chiou et al., 2008), and slope (Allen and Wald, 2009), H/V response spectral ratios of earthquakes were usually used by studies of site classification (Phung et al., 2006; Zhao et al., 2006; Ghasemi et al., 2009). Zhao et al. (2006) found the 5% damping average response spectral ratios of the horizontal to vertical components of earthquakes for all site classes were not strongly affected by magnitude, hypocentral distance, and focal depth, so that an site classification index (SI) from the empirical H/V response spectral ratios was designed for the site classification of K-net in Japan. Ghasemi et al. (2009) utilized an improved SI for the site classification of the strong motion stations in Iran because surface geology and Vs30 are not available at most of the stations. Actually, Phung et al. (2006) applied the 5% damping average response spectrum of the horizontal component normalized with respect to average PGA on stations without known site classification. Although the HVSR of response spectra were also tested in the study, it resulted in lower accuracy than the normalized horizontal response spectra. They developed the scheme based on the 87 station for which the site conditions are known by surface geology from Lee et al. (2001); however, it was indicated that many stations were misclassified in Lee et al.ôs (2001) result according to the measured velocity profiles of logging data (Kuo et al., 2011, 2012).

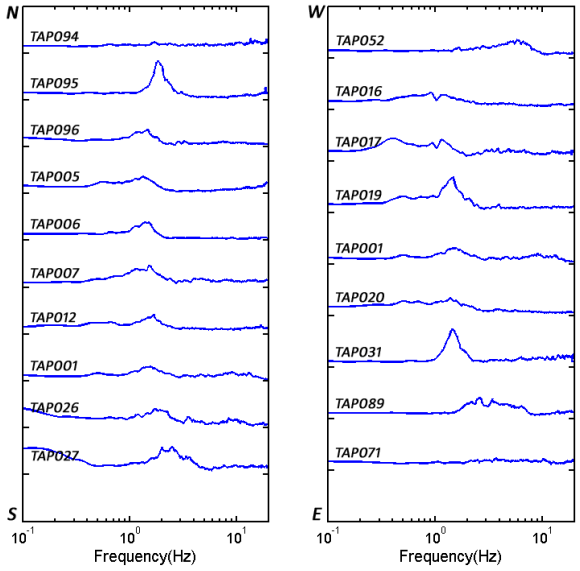

Figure 7 The HVSR in the NS (left) and EW (right) profiles across the Taipei Basin in Figure 2. Ten stations are contained in the N-S direction and nine stations are in the W-E direction. TAP001 is the co-station of the profiles.

Since the exact site classification is available at a large number of stations in the Taipei area, a reliable empirical horizontal to vertical spectral ratio method can be developed. Otherwise, an approach which can eliminate the effects of source, path, and soil nonlinearity to decrease the uncertainty is desirable. Therefore, we propose the technique recognizing features of microtremorôs HVSR of different site classes. The process of horizontal to vertical spectral ratio can eliminate source and path effects, and microtremor is not subject to soil nonlinearity.

Spearmanôs rank correlation coefficient was exploited to calculate SI for each site class at a particular site (Ghasemi et al., 2009). We therefore employed the absolute value of the same correlation coefficient in this study as in the following.

$$SI_k = \left| 1 - 6 \sum \frac{d_i^2}{n(n^2-1)} \right| \qquad (2)$$

Where subscript K means the Kth site class (i.e. B, C, D, and E in the present study), d_i is the difference between each rank of corresponding values of X_k and Y at a particular frequency of i. X_k is the average HVSR for the Kth site class,

Y is the mean HVSR shown in Figure 5 for the site of interest, and n is the number of frequencies. SI_k equals unity when the ranks of corresponding values of HVSR for a site of interest is identical to the mean HVSR of a particular site class, that is, a perfect positive correlation between X_k and Y, or it is less than one.

As described in the paragraphs above and shown in Figure 5, we are aware of the properties of dominate frequency, falling frequency, and amplification, and thus those indices were considered as weighting factors with given values between 0 and 1 afterwards. The geometric mean of SI_k multiplied by the other three weighting factor is the finial site classification index, which is also between zero and unity. After calculating each finial site classification index for a site of interest, the site class with the largest SI was assigned to the site of interest.

Table 1 The site classifications in the Taipei area by the logging data from EGDT (Kuo et al., 2012) and using HVSR method in this study.

HVSR \ EGDT	B	C	D	E	Total
B	9	0	0	0	9
C	1	15	0	0	16
D	0	2	28	3	33
E	0	0	0	2	2
Total	10	17	28	5	60

Table 2 The site classifications in the Taipei area by the logging data from EGDT (Kuo et al., 2012) and from other studies (Chiou et al., 2008; Lee et al., 2008; Allen and Wald, 2009).

Chiou \ EGDT	B	C	D	E	Total
B	2	0	0	0	2
C	4	8	4	0	16
D	0	5	15	4	24
E	0	0	0	0	0
Total	6	13	19	4	42

Lee \ EGDT	B	C	D	E	Total
B	10	8	1	0	19
C	1	12	4	1	18
D	0	0	19	2	21
E	0	0	8	2	10
Total	11	20	32	5	68

Wald \ EGDT	B	C	D	E	Total
B	0	2	0	0	2
C	9	13	7	2	31
D	2	5	25	3	35
E	0	0	0	0	0
Total	11	20	32	5	68

Using this approach a result of site classification was obtained, and is better than that only considering the similarity of shapes for HVSR. The percentage of classifying a site into the correct class is increased from 65% (considering only similarity of HVSR) to 90% (further considering the weighting factors of dominate frequency, falling frequency, and amplification) as shown in Table 1. Afterwards, the site classifications in the same area were acquired from the other studies (Chiou et al., 2008; Lee and Tsai, 2008; Allen and Wald, 2009) as listed in Table 2. In Table 1 and 2, the site classification of EGDT is according to the Vs30 calculated from measured S-wave velocity profiles of strong motion stations, and then categorized them into each class on the basis of NEHRPôs criteria. Actually, the other three studies in Table 2 also consulted parts of the EGDT, that is, some site conditions were known by them in advance of their studies. The percentages of correct site classifications in comparison with the EGDT are 59.5%, 63.2%, and 55.9% for Chiou et al. (2008), Lee and Tsai (2008), and Allen and Wald (2009), respectively. No site was classified into class E in the results of Chiou and Wald which used the evaluated correlations between Vs30 and elevation or slope. This might imply the use of only the surface parameters like elevation and slope can not tell sites of class E owing to almost identical surface geological conditions of class D and E. On the other hand, the developed HVSR method met the difficulty in telling the soft soil classes though, a certain level of the identification ability is owned since the subsurface information is brought by the microtremor we used.

6. CONCLUSIONS

The approach of using HVSR can eliminate the effects of source, path; otherwise, soil nonlinearity is no more a problem in the utilization of microtremor instead of earthquakes, and thus pure site effect is obtained theoretically. This study is evaluating the correlation between site classes and HVSR and then qualitative analysis of HVSR was also achieved. The S-wave velocity information of EGDT is a very important foundation and criterion for this study. Various site conditions of stations and enough microtremor measurements in the Taipei area are also essential.

Even though the previous studies consulted and directly use the Vs30 from parts stations of the EGDT, the accuracy of the classifications are still lower than only using the similarity of HVSR. Stations of class B are situated on hard rocks or sometimes covered with a thin regolith so that the dominant frequencies are unremarkable or relatively higher with strong amplification. The HVSR curves of classes D and E are amplified at relatively lower dominant frequencies with two resonant peaks. The HVSR with two peaks are all inside the Taipei Basin that we speculate they are caused by engineering and geological bedrocks. The higher velocity in the first layer than class D and E as well as lower subsurface velocity than class B may be the reason that the amplification factor of class C usually lower than the others.

The similarity of HVSR between class D and E makes the classification of a soft soil site into a suitable class of D or E more difficult than distinguishing a soft soil site from a hard rock site. However, the present result of this study is better than the others. From the fluctuation of the two profiles in Figure 7, we know the depth variation in the W-E profile is larger than in the N-S profile. The empirical

correction of sedimentary depth and dominate frequency will be adopted to calculate the depth of bedrock at each stations in the near future.

SURFACE-WAVE PHASE VELOCITY INVERSION USING MARKOV CHAIN MONTE CARLO METHOD FOR ESTIMATION OF LOCAL SITE AMPLIFICATION

Hiroaki Yamanaka

Professor, Dept. Environmental Science and Technology, Tokyo Institute of Technology, Japan
yamanaka@depe.titech.ac.jp

Abstract: In this study, an applicability of Markov Chain Monte Carlo method in surface-wave phase velocity inversion is examined. Numerical examinations were conducted using synthetic phase velocity of Rayleigh wave in a layered model of a deep sedimentary basin. The Metropolis-Hasting procedure was used to sample the model space, and final inverted model is derived from averaging S-wave velocity and thickness for the sampled models. The inverted model was similar to the true model with regardless of observed standard deviations of the phase velocity. We also estimated resolutions for the model parameters using their standard deviations of the sampled models, and shows that the resolution depends on the standard deviations of the synthetic phase velocity. We also evaluated variations of one-dimensional amplifications using the sampled models for the phase velocity with different standard deviations. The dominant periods and their amplitudes do not depend on the observed errors of the phase velocity, while amplification factors at high frequency are different from each other. We applied the method to actual phase velocity data obtained in a microtremor exploration in the Kanto basin. These numerical experiments and the actual application clearly indicate a high applicability of the method in the phase velocity inversion. The averaged amplification factors for the sampled models show a smoothed spectral shape without any peaks at periods less than one second, while the amplitudes at the predominant period are common for most of the sampled models.

1. INTRODUCTION

It is known that S-wave velocity distribution in depth is one of the crucial factors to estimate the effects of surface geology on seismic motion during an earthquake. Various kinds of geophysical exploration techniques have been developed to know S-wave velocity profile in shallow and deep soils. One of the most inexpensive explorations is the technique using microtremors. In particular microtremor array exploration is capable to provide a 1D S-wave velocity profile from records of microtremors in an array deployed on the surface. Because of the easy field operations, this technique is widely used in geophysical explorations for evaluation of the local site effects in various kinds of soil conditions (e.g., Okada, 2003).

The microtremor array technique is principally based on estimation of phase velocity of surface wave (mainly Rayleigh waves) and its inversion to a 1D S-wave velocity profile. Frequency–wave number spectral analysis and spatial autocorrelation method have been used in retrieving Rayleigh-wave phase velocity from array records of vertical microtremors (Okada, 2003). Least square approaches are traditionally used in phase velocity inversion in microtremor array exploration. It is well known that the least square methods have some difficulties in practical applications, such as numerical instability and trapping at local minimum models. In particular, the existence of local minimum solution leads to the dependence of final solution to initial model assumed in advance. This practical difficulty in the phase velocity inversions can be solved with an application of heuristic approaches. The heuristic approaches in the inversions are one of Monte Carlo methods, but models with small misfit are effectively searched using various kinds of the algorithms. One of the typical approaches is genetic algorithms and simulated annealing (e.g., Yamanaka, 2005). Since these methods do not use the derivatives of misfit function to be minimized, a chance for trapping of solution at local minimum models is smaller than those in the conventional least square methods. Therefore these methods have been widely applied in actual inversions of surface-wave phase velocity in actual microtremor exploration work (e.g., Yamanaka et al., 2000). One of the disadvantages of these heuristic inversions is difficulty in estimation of model resolution.

In this study Markov Chain Monte Carlo method is applied in surface wave phase velocity inversion for the microtremor exploration. I first explained the computational procedure of the method. Then, the applicability of the method is examined using synthetic phase velocity data of Rayleigh wave. I finally applied the method to actual

Rayleigh wave phase velocity data from the microtremor explorations in the Tokyo basin. I also discuss variation of amplification factors using sampled models to know the effects of model uncertainty.

2. MCMC METHOD

The Markov Chain Monte Carlo method is one of numerical statistic approaches where the probability density function for the target distribution is numerically estimated using random sampling of parameters. It is significantly difficult to sample randomly wide parameter spaces with conventional Monte Carlo methods. The MCMC method is however capable to sample a complex function having many unknown parameters with reasonable computational cost with an assumption of stationary Markov chain condition. The method is originally used for numerical estimation of probability density functions of arbitrary functions, and applied in various kinds of science and technologies (e.g., Gilk et al., 1996).

The MCMC methods reply on the Bayes theorem. According to the theorem, the probability density function p(**m/d**) of model parameters, m, with given data, **d**, is derived from

$$p(\mathbf{m}\,|\,\mathbf{d}) = p(\mathbf{d}\,|\,\mathbf{m})p(\mathbf{m})/\,p(\mathbf{d}) \qquad (1)$$

Here p(**m**) is a prior distribution of the model parameters, and p(**d**) is the distribution of the data. p(**d**|**m**) is a conditional probability density function of **d** for given **m**, and corresponds to a likelihood function. p(**m**|**d**) is called posterior distribution of the model parameters. Because we usually have the data before the inversions, the probability distribution of data p(**d**) is constant. Then equation (1) is written in the form,

$$p(\mathbf{m}\,|\,\mathbf{d}) \propto p(\mathbf{d}\,|\,\mathbf{m})p(\mathbf{m}) \qquad (2)$$

This equation shows how the distribution of the model parameters is modified after having the data. The likelihood function in our inversion of the surface-wave phase velocity can be expressed by

$$p(\mathbf{d}\,|\,\mathbf{m}) = L(\mathbf{m}) = \exp\left[-E(\mathbf{m})\right] \qquad (3)$$

where E(**m**) is a misfit function defined using the least-squared differences between the observed phase velocity, $C^o(T_i)$, and the calculated phase velocities, $C^c(T_i)$, as

$$E(\mathbf{m}) = \sum_i \left[\frac{C^o(T_i) - C^c(T_i)}{\sigma(T_i)}\right]^2 \qquad (4)$$

Here $\sigma(T_i)$ is a standard deviation of the observed phase velocity at a period of T_i. When we do not have a prior information on model parameters, p(**m**) is a uniform distribution. The equation (3) can be simplified as

$$p(\mathbf{m}\,|\,\mathbf{d}) \propto p(\mathbf{d}\,|\,\mathbf{m}) = \exp\left[-E(\mathbf{m})\right] \qquad (5)$$

The distribution of the model parameters can be estimated from this equation using the misfit function. It is noted that the inversion based on this approach does not provide the best model that fits the observed phase velocity with the minimum errors, but a distribution of the model parameters. Therefore we can estimate an accuracy of the model parameters together with the model parameters which can be the average of the models of the distribution. It is not usually an easy task to evaluate the distribution by drawing samples of model parameters.

One of the ways for this evaluation is through a Markov chain as its stationary distribution. Markov chain is known as sampling state where the sampling result only depends on the current model, and does not depend on history of the sampling. Assuming the Markov chain, the sampling results converge to the distribution of the parameters. We apply the numerical procedure based on Metropolis-Hasting algorithm (Hastings, 1970) to construct a Markov chain for estimation of the stationary distribution of the equation (5).

The sampling process with the MCMC method in a finite length of iterations more or less depends on initial model assumed. It is known that the MCMC algorithms can generate a stationary sampling after long-term iterations. Therefore some of the sampled data must be rejected before it reaches a stationary state of a Markov chain. The term for the rejection of the data sampled before the stationary sate is called burn-in period. In order to determine the burn-in period for extracting the stationary part of the sampled data, I used a convergence criteria by Geweke (1992). From the sampled data with enough many iterations, the average (g_1) and standard deviation (σ_1) for the first n data are calculated. I also calculated those (g_2 and σ_2) for the m data from the end of the iteration. Then Z-value is calculated as

$$Z = (g_1 - g_2)\big/\sqrt{\sigma_1 - \sigma_2} \qquad (6)$$

It is indicated that the sampling is convergent with a significant level of 5%, if the Z-value is less than 1.96 (Geweke, 1992). In this study, n and m are set to be 10% and 50 % of the number of the sampled data after deleting the data in the burn-in period

3. NUMERICAL TESTS

The inversion based on the MCMC method is examined using synthetic phase velocity for Rayleigh wave. In particular we focus on the phase velocity inversion for profiling an S-wave velocity profile of deep sedimentary layers of a large basin.

The S-wave velocity model shown in Figure 1 and Table 1 are used to generate synthetic phase velocity data for fundamental Rayleigh waves in the numerical test. This is one of typical S-wave velocity models of the deep sedimentary basin, such as Kanto basin in Japan (e.g., Yamanaka and Yamada, 2006). I calculated fundamental Rayleigh-wave phase velocity for the model at periods from 0.1 to 2Hz. Then the phase velocity is contaminated with random noises whose are generated by adding a uniform random value having amplitude of 5% of the phase velocity. The standard deviation for the synthetic phase velocity is also assumed to be 10 % of the assumed phase velocity. The resultant phase velocity is also displayed in Figure 1. The S-wave velocity and the thickness for each layer in the 4-layer model are optimized in the inversion of the phase velocity. P-wave velocity is given from S-wave velocity using an empirical relationship by Kitsunezaki et al (1996).

The density for each layer is given in advance.

An initial model is randomly generated within the search limits in Table 1. Then, the initial model is modified through the MCMC sampling. Figure 2 shows the variations of the S-wave velocity and thickness of each layer. The parameters for the initial 5000 models are different from the true values showing a dependency on the initial model assumed. Then, the parameters for the first and second layers seem to converge around the true values showing a stationary state of the Markov chain. The other parameters vary gradually to the true values, and converge after 70000 iterations.

The Z-values are calculated for different burn-in periods as can seen in Figure 3. The Z-values in the figure indicates the maximum value among the Z-values for all of the parameters. The Z-value rapidly decreases beyond the burn-in period of 70000 models, and it becomes less than 2.0 after 80000 models were removed as the burn-in period. Therefore, we can use the models beyond this burn-in period to evaluate the distribution of the model parameters.

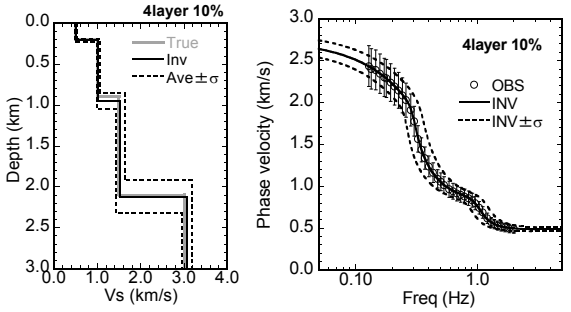

Figure 1. True and inverted S-wave velocity models (left) and synthetic Rayleigh wave phase velocity (right) for the true model with phase velocity for the inverted model.

Table 1 Model parameters and search limits for numerical test.

Vs (km/s)		Thickness (km)		Density (g/cm^3)
True	Search limits	true	Search limits	
0.5	0.2-1.6	0.2	0.02-1.4	1.8
1.0	0.4-1.8	0.7	0.05-1.6	1.9
1.5	0.6-2.5	1.2	0.1-2.	2.0
3.0	2.2-3.5	-	-	2.3

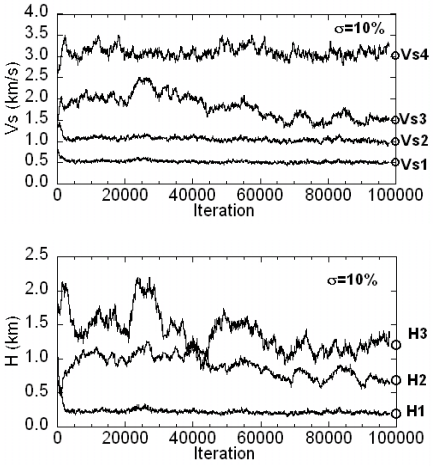

Figure 2. Variation of S-wave velocity and thickness from MCMC sampling for synthetic phase velocity in Fig.1.

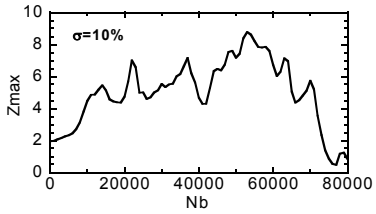

Figure 3. Relationship between Z-values and burn-in period.

The distributions of the S-wave velocities and the thicknesses are evaluated for the sampled models after the burn-in processing as shown in Figure 4. The average values and the standard deviations for the parameters are also shown in the figure. The distribution of the S-wave velocity and the thickness for the top layer are very narrow and sharp indicating a high resolution, while those for the deep part are wider distribution than those for the top layer. The relatively low resolution is due to the lack of the phase velocity at periods lower than 0.1 Hz. However, the distributions of all the parameters are enough to determine the final inverted model. The inverted model shown by a broken line in Figure 1 was derived from averaging the parameters of all the models sampled with the MCMC method. The two models are quite similar, though a slight differences of the depth to the interface at a depth of about 1km. Since we assumed the small standard deviation for the observed data, the standard deviation of the estimated parameters is also very small. The phase velocities for the inverted model are also compared with the observed data in Figure 1. The observed phase velocities at all the periods are well explained by the theoretical phase velocity.

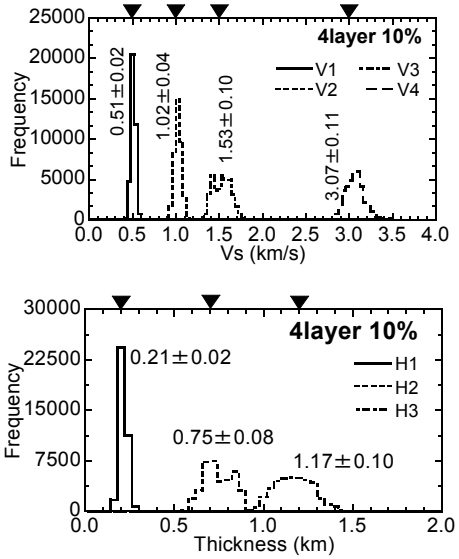

Figure 4. Distributions of S-wave velocity (left) and thickness (right) from sampled models.

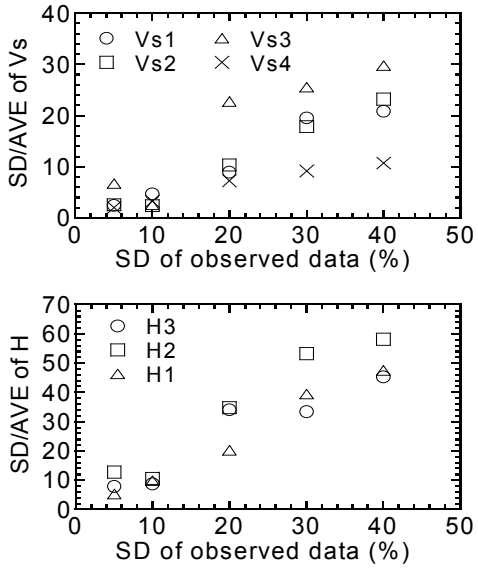

Figure 5. Relationship between standard deviations of observed phase velocity and coefficient of variations of S-wave velocity and thickness of the sampled data.

It is well known in the least-squares inversion theory that the errors in the observation determine the accuracy of the parameters. Here we investigate the effects of the observational errors assumed on the variations of the parameters. First we generated the synthetic Rayleigh waves with the different standard deviations from 5 to 40 % in the similar manner explained above. Then the similar samplings were conducted for each synthetic data. Figure 5 displays the relationships between the standard deviations for the observed phase velocity and parameters for the sampled models. It is noted that each value is normalized with its average to obtain variation coefficients. The coefficients for the parameters in the shallow part are more affected by the observational errors than the deep part. This figure also indicates that the observed phase velocity must be obtained with an accuracy of 30 % for an estimation of S-wave velocity in the top layers with an accuracy of 10 %. Similarly we can see that high accuracy phase velocity data are needed for estimating the thickness with the same accuracy. This numerical test clearly indicates the advantage of the inversion based on the MCMC method for estimation of not only an inverted profile but also its accuracy from a probability distribution of the model parameters.

4. VARIATIONS OF AMPLIFICATIONS

Once we estimated the variation of the parameters for the inverted S-wave profile, the variation of the amplification factors can be also obtained numerically. Here I calculated 1D amplification factors for the vertically propagating S-waves in the 1D models sampled in the MCMC method. Q-value is assumed to be Vs/10. Figure 6 shows averaged amplification factors with ±their standard deviation. The amplitudes and peak periods for the fundamental mode are very stable with small standard deviations. However, the variations at periods shorter than 1 second are large. The variations for the amplification factors at the predominant period are less influenced with the observational errors of the phase velocity than those for the high frequencies. This indicates that the amplification factors at the predominant periods are well constrained with the phase velocity from the microtremor explorations.

Similar calculations of the amplifications were conducted using the sampled models for the phase velocities with the different observational errors. Figure 7 shows the averaged amplification factors for the sampled models. The amplifications at the fundamental modes at a period of about 6 seconds are very similar to each others. This indicates again that the fundamental peak is well estimated from the phase velocity, although the observational errors for the phase velocity are large. On the other hands, the peaks of the amplification factors with large errors become small at periods shorter than 1 second. In particular the amplifications for the errors of 40 % have no dominant peaks at periods less than 1 second. Since the amplifications for the models from inversions of the phase velocity with large errors have peaks at different periods except for the fundamental modes, the averaged amplifications are smoothed in the averaging process at short period ranges. This suggests the difficulties for the estimation of accurate amplifications at short periods from long-period microtremor phase velocity.

The relationship between the standard deviation of the observed phase velocities and the coefficient of variations for the predominant peak period and the maximum amplitudes are shown in Figure 8. It can be seen that the peak period and the maximum amplitudes are insensitive to the observation errors. Since the maximum amplitude of the amplification factors is mainly controlled by the impedance contrast between the top layer and the basement, the low values of the variation coefficients are due to the high accuracy of S-wave velocity in the shallow part of the models.

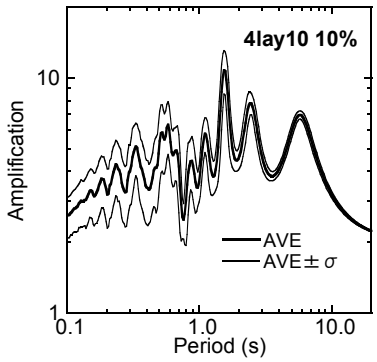

Figure 6. Average and average+-standard deviation for one-dimensional amplification factors calculated for the sampled models in inversion of phase velocity in Fig.1.

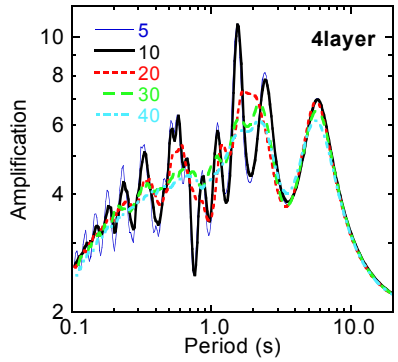

Figure 7. Average one-dimensional amplification factors calculated for sampled models in inversion of phase velocity with different standard deviations of phase velocity from 5 to 40% in Fig.1.

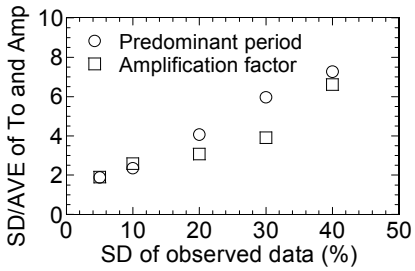

Figure 8. Relationship between standard deviations of observed phase velocity and coefficient of variations of predominant period and maximum amplitude of 1D amplification factors for the sampled data.

5. APPLICATION TO ACTUAL PHASE VELOCITY

I apply the MCMC inversion method to Rayleigh wave phase velocity from actual microtremor array exploration in the Kanto basin. Here, the phase velocity at ASO in Yamanaka et al. (2000) was used as shown in Figure 9. They inverted the observed phase velocity with a genetic algorithm to derive a 1D S-wave velocity profile that is also shown in Figure 9.

The MCMC inversion was conducted assuming a 4-layer model. The inverted S-wave velocity profile is derived from averaging the parameters for all the sampled models after the burn-in operation. The inverted profile is almost the same as that from the genetic inversion. The comparison between the observed and the theoretical phase velocities can be seen in Figure 9. The distributions of the S-wave velocities and the thicknesses for the sampled models are shown in Figure 10. The parameters for the top layer are well resolved with the narrow distributions. The S-wave velocity for the second layer is also inverted with a high accuracy, while the distribution of its thickness is broad showing a low resolution. Furthermore the parameters for the third layer and basements distribute in wide ranges. The lack of the phase velocity data at periods more than 4 seconds is the main reasons for the low resolutions of the parameters of the third layer.

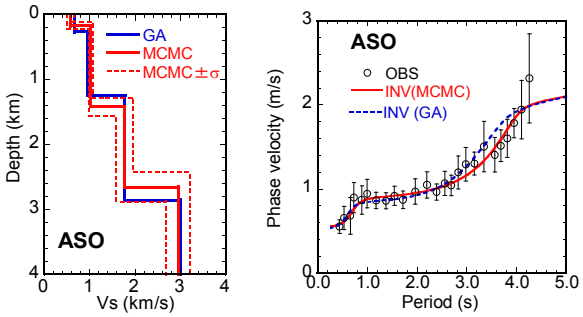

Figure 9.Comparison of inverted results from previous study and this study. Left is S-wave velocity profiles and right is phase velocities for the inverted models with observed ones.

The sampled models from the inversion of the phase velocity at ASO were used to know the variation of the amplification factors. Figure 11 shows the averaged amplification factor with standard deviation. Similar to the numerical experiments, the amplifications at the dominant period are very accurately estimated with a small standard deviation. However, short period amplifications show large variations. Because peaks for the higher mode are dominant at different periods for the sampled models, the amplification factors become smoothed without any trough and peaks. Figure 11 also shows the amplification factor for the best model from conventional inversion based on GA. The amplification factors at longer than 5 seconds including peak at the fundamental period for the model from the genetic inversion are very similar to those for the averaged one from the MCMC inversion. However, they are not the same at some periods shorter than 1 second. It is noted that the amplification is underestimated for the model from the GA due to its spectral trough.

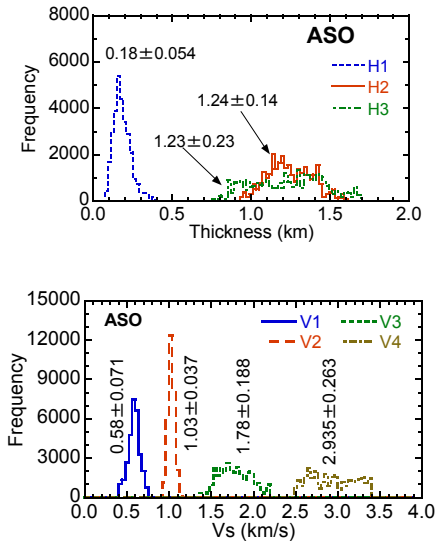

Figure 10. Distributions of S-wave velocity (left) and thickness (right) from sampled models by MCMC inversion of the observed phase velocity at ASO in Figure 9.

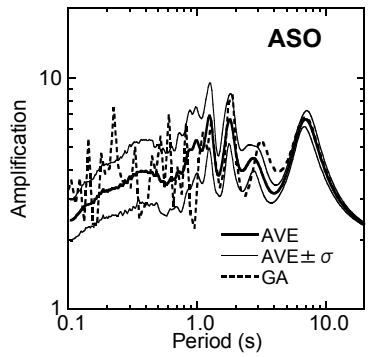

Figure 11. Average and average±standard deviation for one-dimensional amplification factors calculated for the sampled models in inversion of phase velocity at ASO in Fig.9, shown by thick and thin lines. Broken line shows amplification factors for the model derived with hybrid heuristic inversion of the observed phase velocity.

6. CONCLUSIONS

I applied the Markov Chain Monte Carlo method to surface wave phase velocity inversion. The numerical test of the method was conducted using the synthetic Rayleigh wave phase velocity data. The method can evaluate not only an inverted S-wave velocity profile, but also probabilistic distributions of the model parameters from which we can understand model resolutions. This can be addressed as one of the powerful advantages for the method. Since the MCMC inversion method requires only the calculation of the misfit function just like genetic algorithms and simulated annealing, this method is also very robust during computations. I also apply this method to the observed phase velocity data from actual microtremor explorations in the Kanto basin. The results of the inversion clearly indicated a high resolution of the S-wave velocity and the thickness for the shallow part and a low resolution for the deep part, because of the absence of phase velocity at long-periods. Using the sampled models the variations of the 1D amplification factors were estimated. The averaged amplification factors for the sampled models show a smoothed spectral shape without any peaks at periods less than one second, while the amplitudes at the predominant period are common for most of the sampled models.

Abstract: In this study, we conducted microtremor array exploration at a site with inclined bedrock to deduce S-wave velocity in shallow soil. The S-wave velocity of the 1st layer and the depth to engineering bedrock evaluated from microtremor array exploration are consistent with the results of measurement-while-drilling, surface wave exploration method and H/V spectra of microtremors. In order to estimate the effect of bedrock inclination on the phase velocity, 2D model was constructed from aligning the 1D profiles. The difference between the phase velocities from FEM analysis with the 1D and 2D models can be recognized in the long period range.

1. INTRODUCTION

An amplification factor at an inclined bedrock site is significantly influenced by laterally propagating seismic waves (e.g. Watanabe, *et al.* 2011). The damage was concentrated in near Kego fault during the 2005 west off Fukuoka prefecture earthquake, and it was interpreted that the amplification was affected by irregular shallow subsurface structure (Motoki *et al.* 2006). Not only a subsurface structure at a site but also ones around a site are required for a precise estimation of amplification factor at an inclined bedrock site.

Microtremor array explorations have been made use of an estimation of amplification factor of subsurface geology for application to an earthquake resistant design (e.g. Fukumoto and Mimachi 2006) and to a damaged area during a disastrous earthquake (e.g. Asano *et al.* 2009). Microtremor array exploration can be regarded as one of the most useful methods to obtain a number of subsurface structures because of the high mobility and the high cost performance of it.

S-wave velocity profiles based on microtremor measurements are evaluated with a stratified media. In that analysis, microtremors are assumed to consist of Rayleigh wave, and 1D model is applied to an inversion (e.g. Yamanaka and Ishida 1995). Therefore, the point is applicability of Rayleigh wave for 1D model at a site with inclined bedrock.

As pointed out by previous studies on an applicability of 1D model for microtremor array exploration, body wave and higher mode Rayleigh wave are dominated around the points near highly irregular subsurface structure, and the phase velocities at these points cannot be reproduced only with 1D model, consequently (Nakagawa and Nakai 2010 Uebayashi *et al.* 2009, Sato *et al.* 2006). Although subsurface structures are inversed with 2D or 3D model ideally, it is too difficult to apply to a practical engineering. It can be considered that it is important to reveal applicability of 1D model through a field test.

In this study, we demonstrate applicability of 1D model in microtremor array exploration by comparing with the results of measurement-while-drilling, surface wave exploration and H/V spectra of microtremors at a site of irregular subsurface structure. We investigate the influence of the irregular subsurface structure on the phase velocities with numerical analysis.

2. TARGET SITE AND MEASUREMENTS

We selected the site where the the shape of the upper boundary of engineering bedrock by a sounding technique, measurement-while-drilling (hereafter MWD, Nishi *et al.*, 1997) was regarded as an irregular site. The MWD can produce a continuous soil resistance index, called Np value corresponding to N value by standard penetration test (hereafter SPT). This site was leveled in mountainous area and

the outside of a site is a slope face. Figure 1 shows the contour map of the depth to 25 of Np value and N value and microtremor measurement points.

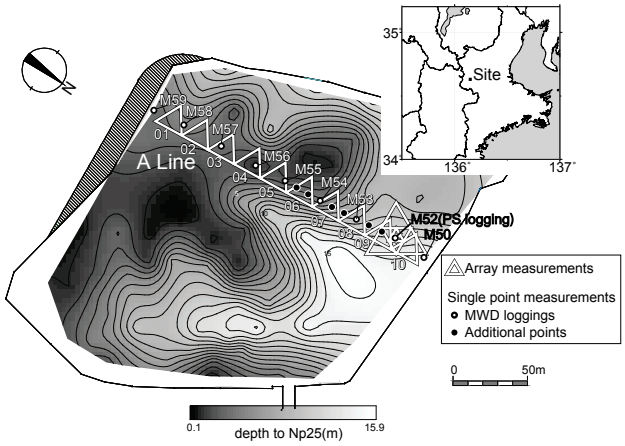

Figure 1 Contour Map of Np25 Estimated by MWD and the Arrangement of Microtremor Measurements

We deployed 10 sets of microtremor array measurements aligning along A line in Figure 1 where the soil deposits are thick in the northern part and thin in the southern part. We measured another one of microtremor array nearby the hole conducted PS logging, M52 in Figure 1. In addition to microtremor array measurements, we carried out microtremor measurements using a single three-component sensor at the MWD logging points and the additional points interpolating the steep area of the shape of the bedrock. The surface wave exploration using an artificial source (Hayashi *et al*., 2001) was also conducted along A line in Figure 1.

We installed 7 vertical accelerometers at the vertexes of 2 equilateral triangles with sides of 10m and 20m long and the center of them for a set of microtremor array measurement. In the aligning array, a vertex of adjacent arrays is located at the same point as a vertex and 10 sets consist of the continuous measurement. In the array at M52, we had 3 turns, which consisted of equilateral triangles with sides of 2.5m, 5m, 10m, 20m and 40m long.

The surface wave exploration consisted of recordings taken with 24 sensors with a sampling interval of 2m. A sinker of 20kg weight was used for an artificial source. The source was set at 5m, 10m and 15m far from the sensors to the north side.

The P- and S-wave velocities at the depths from GL-1m to GL-26m with an interval of 1m are evaluated by PS logging at M52 using the downhole method.

Figure 2 shows the results of PS logging, MWD and SPT at M52. The Np values by MWD are consistent with the N values by SPT. It can be found that the Np values quickly change at the depth where the Np values are 25 and 150, and those depths correspond to the geological boundary among the bank, the strongly weathering granite and the weathering granite. The S-wave velocity of the first layer is estimated 200m/s by PS logging. The engineering bedrock of which S-wave velocity is 460 m/s appears at the 17.5m depth, that corresponds to the depth to 150 of the Np value and the upper boundary of the weathering granite. The granite of which S-wave velocity is 2200m/s at the about 23.5m depth causes the high contrast surface with the weathering granite. The depths of granite were not estimated by MWD logging because of the strength of the percussion drill.

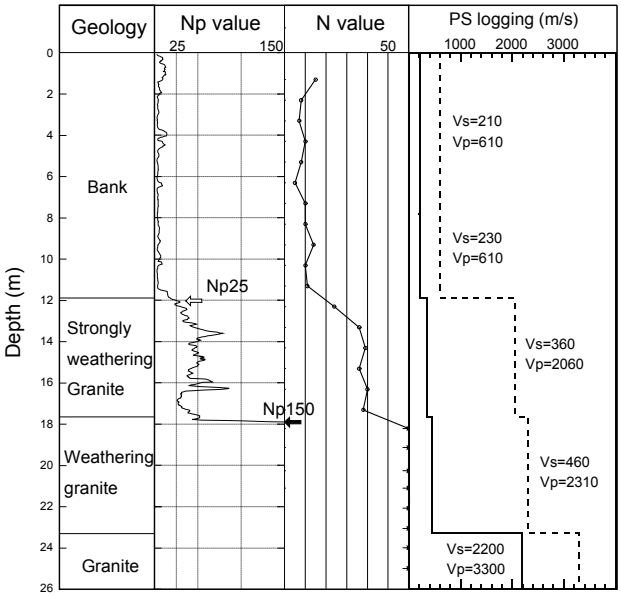

Figure 2 Comparison of the Results of the PS logging, the MWD and SPT at the Point M52 Shown in Figure 1

3. RESULTS OF MICROTREMOR MEASUREMENTS

3.1 Data Processing

More than 10 segments which had a 20.48 second each were picked up from the microtremor record as samples for Fourier analysis avoiding the noise inferred from the amplitude. SPAC method (Aki 1957) was adopted to evaluate the phase velocity. The logarithmic Parzen window suggested by Konno and Ohmachi (1995) was applied to smooth spectra. The normal dispersion part in the phase velocities were used for an inversion.

3.2 Phase velocity

Figure 3 shows comparison of the phase velocities between evaluated from microtremor records and theoretically calculated with the model shown in Figure 2. The evaluated phase velocity is consistent with the calculated one. Therefore, we use this model as a reference model in an inversion.

Figure 4 shows the phase velocity evaluated from the continuous array measurements from 01 to 10. The phase velocity at the point 04 is the fastest of all 10 points and the value of the phase velocity is gradually decreasing being distant from the point 04. This feature qualitatively approximates to the distribution of the thickness of the 1st layer shown in Figure 1 and it can be considered that the differ-

ence of the depth to the bedrock reflects the transition of the phase velocities.

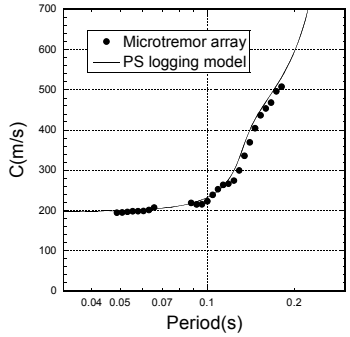

Figure 3 Comparison of Phase Velocities at M52 between Evaluated by Microtremor Array Measument and Calculated for Fundamentarl Mode Rayleigh Wave with the PS Logging Model Shown in Figure 2

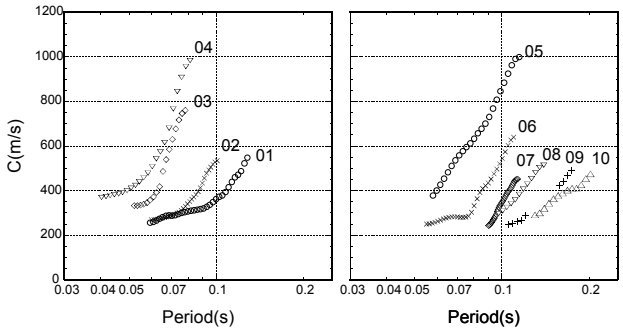

Figure 4 Transition of Phase Velocities Evaluated by Continuous Array Measurements

4. ESTIMATION OF SUBSURFACE STRUCTURE ON INCLINED BEDROCK

4.1 Subsurface Structure Inverted with 1D Model

In this chapter, S wave velocity profiles are deduced from the observed phase velocities. The phase velocities are averaged to divide logarithmically equal frequency axis. Since 1 turn of the measurement with a equilateral triangles with sides of 10m and 20m long was carried out and the phase velocity was picked up only from the part showing normal dispersion, .available frequency ranges are restricted. As Suzuki and Yamanaka (2010) pointed out, it is difficult to avoid trade-off relation between thickness and S-wave velocity of shallow layer in an inversion using only a phase velocity, especially for the restricted frequency range. This study focuses on the shape of the bedrock, and it is important to stabilize the thickness of shallow layer. Therefore, we apply a restricted inversion model that the 2 unknown parameters are the depth to the last layer and the S-wave velocity of the 1st layer. The reference model is referred to the result of the PS logging shown in Figure 2 and is set to 4 layer model that the 1st layer (Vs=210m/s) and 2nd layer (Vs=230 m/s) were arranged into 1 layer. In the inversion model, S-wave velocities of other layers are fixed to the reference model and thicknesses of shallow layers are changed proportionally. When the S-wave velocity of the 1st layer is faster than that of the 2nd layer, the S-wave velocity of 2nd layer is made equal to that of 1st layer. The P-wave velocity is calculated by the empirical relation reported by Kitsunezaki *et al*., (1990).

We adopt Genetic Algorithm as a heuristic search method, and objective function is following.

$$misfit = \sum \left| \frac{O(f) - C(f)}{O(f)} \right| \tag{1}$$

O(f) and C(f) are respectively observed phase velocity and calculated phase velocity assumed the fundamental mode of Rayleigh wave. Population, maximum generation and crossover rate are set to 15, 40 and 0.9, respectively. 20 times calculation with the different seed for random numbers, and the final result is averaged of the solutions within allowable error of 2 percents of the minimum misfit.

4.2 Comparison among the Result of Subsurface Structures Including Other Exploration Method

Figure 5 shows the result of the each exploration performed in this study. First, we focus on the comparison of the S-wave velocity of the 1st layer. Near the ground surface, the S-wave velocity evaluated by surface wave exploration can be considered more credible than other explorations because of the numbers of densely arranged sensors and the apparent active source. The velocities of the 1st layer were estimated more than 300 m/s at the point 04 and about 200 m/s in the northern part. The results of microtremor array exploration and surface wave exploration are consistent with each other.

Next, we focus on the depth of the engineering bedrock. The depth of the geological boundary by MWD can be considered the most credible, because the result of the other exploration include trade-off relation between thickness and S-wave velocity, and the percussion drill for MWD directly contacted to the material. The transitions of the Np value are indicated by thin line. The depths of the engineering bedrock correspond to the depth of Np 150 as shown in Figure 2 and are plotted in Figure 5(b).

The depths of 410 m/s in S-wave velocity by surface wave exploration are regarded as a depth of the engineering bedrock paying attention to the phase velocity that are equivalent to those calculated from 4 layer models by microtremors. The depths are drawn only shallower than 15m, because of low sensitivity in deeper than 15m due to the small artificial source.

The depths of the engineering bedrock by microtremors are deeper in the northern part than the center and the southern part, and this shape is similar to the depth by Np 150. Except for the both end of the measurement line, the depths of the bedrock by all explorations are consistent with each other. The depths estimated by microtremors are relatively deep in the norther part from 150m and the southern part to the 50m comparing with the results of other 3 explorations. The both outsides of the measurement site are steep slope face, and this irregularity has a possibility to affect to the

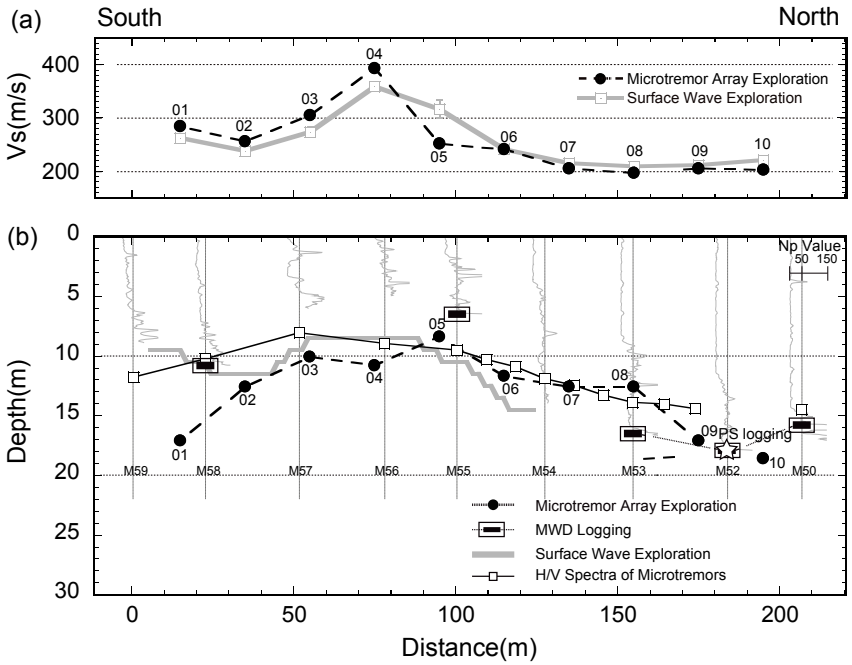

Figure 5 Comparison of the Results among Microtremor Array Exploration, Surface Wave Exploration, MWD Logging and H/V Spectra of Microtremors. (a) S-wave Velocity of 1st Layer, (b) Depth to Engineering Bedrock

phase velocity. Nakagawa and Nakai (2010) concluded that the contamination to the phase velocity due to the structural irregularity appeared near the steep slope. Uebayashi *et al*. (2009) pointed out that the deeper basement is estimated by microtremors comparing to the result of the borehole, because the complexity of the wavefield due to the irregular subsurface structure decrease the value of SPAC coefficient. The depth near the both end of the measurement line evaluated by microtremors can be overestimated, taking their expertise into account.

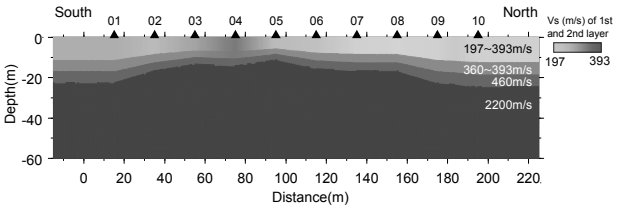

Figure 6 Constructed 2D Model with 1D Model Evaluated by Microtremor Array Exploration

5. INFLUENCE OF INCLINED BEDROCK TO PHASE VELOCITY

Even though the result of microtremor array exploration is consistent with the results of other explorations as shown in Figure 5, a problem of influence due to the irregularity of the subsurface structure is still remained. In order to consider this influence, we construct 2D model by interpolating 1D models of subsurface structure and examine the difference between the phase velocities through simulated with 1D and 2D models.

Figure 6 shows 2D model constructed interpolating the S-wave velocities of 1st and 2nd layers and the depth of the layer boundaries linearly. The outside of the model is set to strata, and the boundary conditions are set to viscous boundary at the bottom and energy transmitting boundary at the lateral ends. The damping rate is set to 0.02. The excitation is set to the fundamental mode Rayleigh wave into the both lateral ends. The phase velocities are derived from the average of the velocities calculated from coherence of vertical motions at 3m, 5m and 10m far from the center.

Figure 7 shows the phase velocities obtained with 1D and 2D model at the points of 01, 04 and 06. The phase velocities at the point 01 and 04 with incident into north end of 2D model and at the point 06 with incident into south end are similar to those with 1D model. On the contrary, the phase velocities with incident with opposite end to above case appear unstable and the obvious discrepancy from the result with 1D model in the long period range. This feature cannot be recognized in the short period range. Since the phase velocity in the short period range is affected by the S-wave velocity near the ground surface, it is confirmed that the S-wave velocity in shallow soil above the inclined bedrock can be estimated by the phase velocity. Furthermore, good agreement in Figure 5 (a) supports this conclusion.

Turbulence of the phase velocity in the long period range appears when the surface wave propagates from deeper area to shallower area in the depth of the bedrock boundary. This feature can be regarded as the turbulence due to the contamination by the body wave and higher mode Rayleigh wave (Nakagawa and Nakai, 2010).

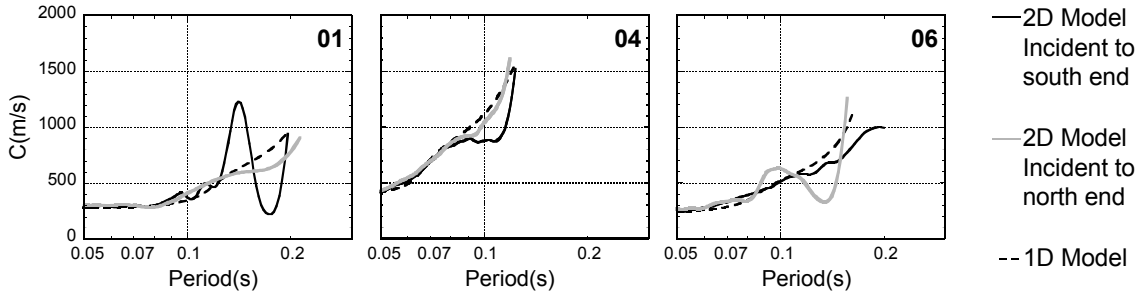

Figure 7 Comparison of the Phase Velocities Numerically Calculated with 2D model Shown in Figure 5 and 1D Model

In order to consider the influence of the irregularity of the subsurface geology on the turbulence in the phase velocity, we estimate the phase velocities with the cut models shown in Figure 8. Model I and II are set up for simulation extent to limit 30m and 15m far from point 01 to the north side, respectively. We simulated the case of the incidence from the south end of the model.

Figure 9 shows the phase velocities calculated with model I and II. The phase velocities in the shorter period range than 0.12 second are similar to each other. On the contrary, it can be recognized that the calculated phase velocity is approximated to the result of 1D model with the more limited model. This suggests that a spatial extent related with phase velocity depends on a period. Therefore, microtremor array exploration can be applied to deduction of the subsurface structure with 1D model even at an inclined bedrock site, paying attention to the period range for an inversion.

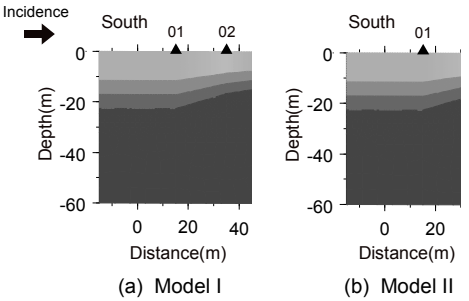

Figure 8 2D Model Limited Area for Numerical Simulation

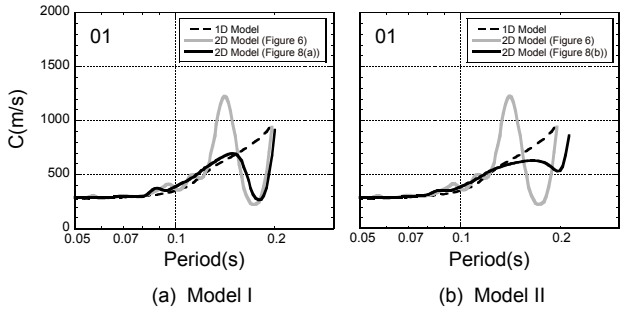

Figure 9 Phase Velocities Calculated with Limited Model

6. CONCLUSIONS

We conducted mictrotremor array exploration at an inclined bedrock site where had been leveled in mountainous area. The structure of the inclined bedrock was deduced by 10 subsurface structures evaluated with 1D model. The following features were found in this research.

1. The S-wave velocities near the ground surface evaulated by microtremor array are consistent with the result of the surface wave exploration.

2. The depths of the engineering bedrock evaluated by microtremor array are consistent with the result of the MWD, the H/V of microtremors and the surface wave exploration.

3. The phase velocity calculated by numerical analysis with 2D model is similar to the phase velocity calculated with 1D model in the short period range.

4. On the contrary, the difference of the numerical phase velocities between 1D model and 2D model can be recognized in the long period range. The turbulence of the phase velocity with 2D model is appeared in the case of the surface wave propagating from deep area to shallow area in the engineering bedrock.

5. It is required that we pay attention to the period range to apply an inversion, while a conventional inversion technique with 1D model is applied to an inclined bedrock site.

Abstract: The authors have proposed a new theory to calculate the Horizontal-to-Vertical (H/V) spectral ratio of microtremors assuming that the wave field is completely diffuse which is not limited to horizontally flat-layered 1D structures and have attempted to apply the theory to understand the observed microtremor data. For a sufficiently flat, horizontally layered structure, we can easily calculate the theoretical Green's function for that 1D model but for a laterally heterogeneous underground structure, such as the case of Uji campus where significant directional dependency of microtremor H/V spectral ratios were observed, a numerical approach is needed to interpret the H/V spectral ratios. We performed numerical analyses by Spectral Element Method using point source in both the 1D and 2D models to examine the effect of the 2D basin structure on the H/V spectral ratio of microtremors. As a result, we found that the 2D basin structure clearly changes the characteristics of the H/V spectral ratio in both perpendicular and parallel directions relative to the basin edge and we have succeeded to simulate qualitatively the difference between the two orthogonal horizontal components as a result of directional dependence as seen in the observed H/V spectral ratio of microtremors at Uji campus.

1. INTRODUCTION

The authors have proposed a new theory to calculate the Horizontal-to-Vertical (H/V) spectral ratio of microtremors assuming that the wave field is completely diffuse (Sánchez-Sesma *et al*., 2011), based on the diffuse field theory (Perton *et al*., 2009) and have attempted to apply the theory to understand the observed microtremor data. It is anticipated that this new theory can be applied to understand the subsurface velocity structure as well as the condition of lateral heterogeneity, since the new theory to calculate the H/V spectral ratio of mircrotremors is not limited to horizontally flat-layered 1D structures.

As observational evidence of non 1D microtremor H/V spectral ratios, we have discovered significant directional dependency at a site in Uji campus, Kyoto University, Japan, where the bedrock depth varies from east to west from 250m to 420m within the distance of 1km. This directional dependence can be considered to be the result of 2D subsurface structure (Hirokawa *et al*., 2011).

For a sufficiently flat, horizontally layered structure, we can easily calculate the theoretical Green's function for that 1D model but for a laterally heterogeneous underground structure, such as the case of Uji campus, a numerical approach is needed to interpret the H/V spectral ratios. We performed numerical analyses by Spectral Element Method (SEM) using point source in both 1D and 2D models to examine the effect of the 2D basin structure on the H/V spectral ratio of microtremors.

2. THE EFFECT OF 2D BASIN STRUCTURE

Microtremor measurements were made at four sites in Uji campus (Hirokawa *et al*., 2010) and the H/V spectral ratios showed significant directional depencency as shown in Figure 1. The H/V spectral ratios for each observed data for NS and EW components are computed separately without averaging the two horizontal components as done in conventional H/V spectral ratio studies. From these figures, we can see that for every site except for site A the amplitude of the peak ratio of NS/UD is about 4.0, larger than that of EW/UD, which is about 2.5 and that the peak frequency of NS/UD ratio is 0.5Hz, slightly smaller than that of EW/UD, which is about 0.6Hz (Hirokawa *et al*., 2011).

At Uji campus, previous surveys and research by

Koizumi *et al*. (2002) show that the bedrock is dipping east to west from the Obaku fault that runs in the north south direction several hundreds of meters east of the campus. In this study we assume a 2D structure which the bedrock depth varies from 250m to 420m within a distance of 1km and construct a 2D one-layered basin structure shown in Figure 2.

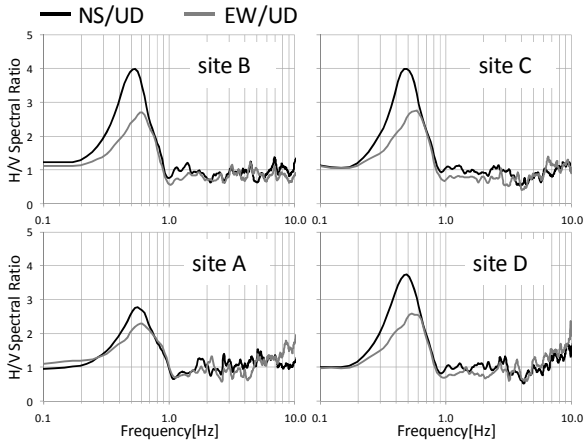

Figure 1 Average NS/UD and EW/UD spectral ratios of June 21st, 2010, observed at four sites in Uji campus of Kyoto University (Matsushima *et al*., 2012).

Figure 2 Top 500m of the section of the 2D basin structure (after Hirokawa *et al*., 2011)

3. THEORY

It has been recently derived that the H/V spectral ratios of microtremors corresponds to the square root of the ratio of the sum of the corresponding imaginary parts of horizontal displacements for horizontal unit harmonic loads and the imaginary part of vertical displacement for a vertically applied unit harmonic load (Sánchez-Sesma *et al*., 2011).

Theoretical energy density at a given point $\mathbf{x_A}$ can be written as Eq. (1) and since it is proportional to $\langle u_1^2 \rangle = \langle H_1^2 \rangle$, the H/V spectral ratio can be written as Eq. (2). From Eqs. (1) and (2), theoretical H/V spectral ratio can be derived as Eq. (3).

$$E(\mathbf{x_A}) = \rho\omega^2 \langle u_m(\mathbf{x_A}) u_m^*(\mathbf{x_A}) \rangle = -2\pi\mu E_S k^{-1} \times \mathrm{Im}[G_{mm}(\mathbf{x_A}, \mathbf{x_A})] \quad (1)$$

$$\frac{H(\omega)}{V(\omega)} = \sqrt{\frac{E_1(\mathbf{x},\omega) + E_2(\mathbf{x},\omega)}{E_3(\mathbf{x},\omega)}} \quad (2)$$

$$\frac{H(\omega)}{V(\omega)} = \sqrt{\frac{\mathrm{Im}[G_{11}(\mathbf{x},\mathbf{x};\omega)] + \mathrm{Im}[G_{22}(\mathbf{x},\mathbf{x};\omega)]}{\mathrm{Im}[G_{33}(\mathbf{x},\mathbf{x};\omega)]}} \quad (3)$$

In an equipartitioned field, it will be valid even if we take only one horizontal component of Eq. (3), so the directional H/V spectral ratio can be derived as Eq. (4).

$$\frac{H_m(\omega)}{V(\omega)} = \sqrt{\frac{\mathrm{Im}[G_{mm}(\mathbf{x},\mathbf{x};\omega)]}{\mathrm{Im}[G_{33}(\mathbf{x},\mathbf{x};\omega)]}} \left[m = 1,2\right] \quad (4)$$

This shows that with our new theory, we can calculate the H/V spectral ratio of mircrotremors in two orthogonal horizontal components separately meaning that it is not limited to horizontally flat-layered 1D structures.

4. SIMULATION OF H/V SPECTRAL RATIO

In order to take into account of the 2D or 3D subsurface structure, we need to incorporate a numerical approach for Green's function calculation. In this study we use the 3D Spectral Element Method (SEM) code ÉFISPEC3D (De Martin, 2011), to study cases of laterally heterogeneous elastic layers over a half-space.

4.1 Flat Layered Velocity Model

For calibration purposes, we first checked that numerical calculations by SEM give the same results as theoretical ones. We assume a flat-layered model with a single layer over half-space, equivalent to velocity model at site C. The characteristics of the 3D SEM calculation are listed in Table 1 and the velocity model for the flat-layered case is listed in Table 2. For simplicity, we used here a one layer model. Figure 3a displays the schematic image of the velocity model of the one layer 1D model. Figure 4a shows the mesh of the model for the one layer 1D model. It is a mesh composed by structured hexahedra designed to be accurate (i.e., without numerical dispersion) with seven Gauss–Lobatto–Legendre (GLL) nodes per wavelength at 5 Hz (we use polynomials of order 6 to sample the wave field; therefore, each hexahedron contains 7 x 7 x 7 = 343 GLL nodes). The bedrock is meshed with hexahedra of size 396m and the layer is meshed with hexahedra of size 132m. A mesh tripling is used inside the bedrock to refine the mesh just below the layer. We apply a unit load to the surface of the model at the target position and retrieve the imaginary part of the Green's function from the response at the same position. We note that the unit load is applied as a spatial Dirac positioned at a GLL node common to four hexahedra.

Figure 5 shows the comparison of theoretical and numerical results for the 1D velocity model shown in Table 2 and Figure 3a. Figure 5a is the imaginary part of Green's function for horizontal (dark gray) and vertical (light gray) components. The dotted and solid lines are results of the 3D SEM and 1D theory, respectively. The SEM results shows very good match to the theoretical ones. Figure 4b is the H/V spectral ratio derived from the imaginary part of Green's function shown in Figure 4a. Since the imaginary part of Green's function show good match, the H/V spectral ratio also shows very good match, naturally.

Table 1 Characteristics of the three-dimensional SEM calculation

Parameter	One layer 1D	One layer 2D basin
Model size	Length 40km Width 40km Depth 40km	Length 16km Width 16km Depth 10km
Minimum Element Size	132m	
Total Elements	1,693,366	289,069
Order of polynomial's shape function	6	
Maximum Frequency	5 Hz	
Minimal number of GLL nodes at 5 Hz	7	
Time Increment	0.0035 s	
Time Step	58000	
Total Duration	20.0 s	

Table 2 One layer one-dimensional velocity model equivalent of site C for testing SEM calculation

	Thickness [m]	P wave velocity [m/s]	S wave velocity [m/s]	Density [kg/m^3]	$Q_{s,p}$
1	390	1,985	661	1,930	9999
bedrock	-	5,083	2,348	2,600	9999

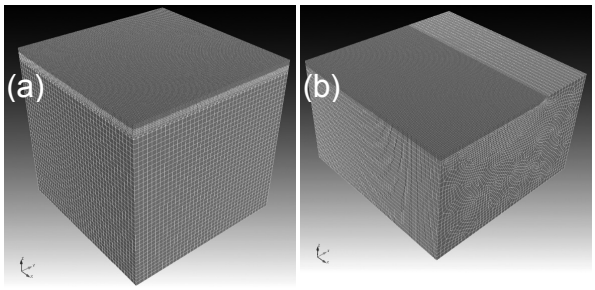

Figure 4 Mesh of the model for (a) one layer one-dimensional velocity model and (b) one layer two-dimensional basin model for three-dimensional SEM calculation

4.2 Layered 2D Velocity Model

Now we consider a laterally heterogeneous velocity structure. We use a 2D velocity model and calculate the 3D wave field. The 2D velocity model consists of one layer over half-space that gradually gets shallow from west to east and eventually pinches out as shown in Figure 3b. The maximum depth of the 2D basin in the model is 420m. The parameters of the model are listed in Table 3. The mesh used

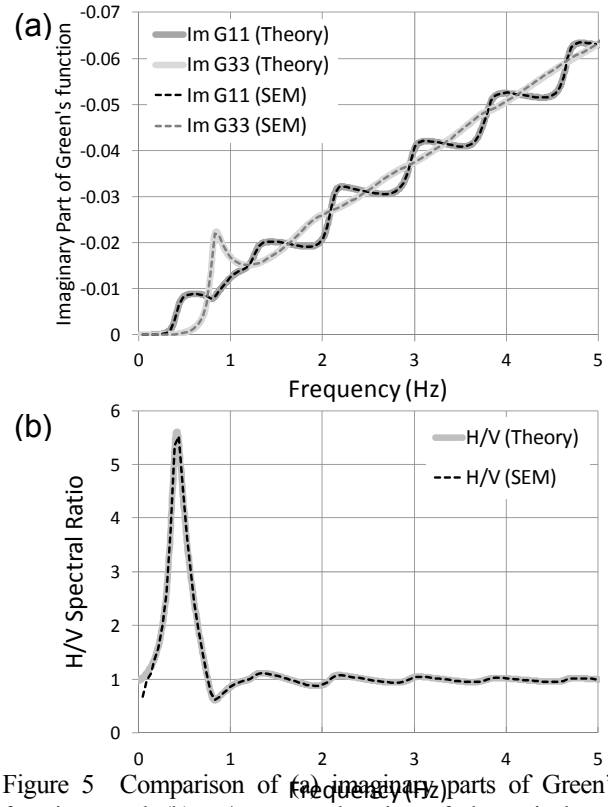

Figure 5 Comparison of (a) imaginary parts of Green's functions and (b) H/V spectral ratios of theoretical and numerical results for one layer one-dimensional velocity model in Table 3. The two calculations show very good match

by the SEM calculation is shown in Figure 4b. To honor the interface between the layer and the bedrock (especially at the basin edge), we use a mesh composed by unstructured hexahedra. As for the flat layered model, the mesh is also designed to be accurate with seven GLL nodes per wavelength at 5 Hz. For this model, we first calculate the H/V spectral ratio at a position of site C which is about 920m away from the basin edge and corresponds to the black arrows in Figure 3b. The H/V spectral ratio for this case is shown in Figure 6. The spectral ratios for NS/UD (black dotted line) and EW/UD (gray dotted line) show different characteristics with the amplitude larger for NS/UD ratio and peak frequency higher for EW/UD ratio. Although it is not as large as the observed, the difference between NS/UD and EW/UD ratios is well reproduced at least qualitatively. Another fact that we can point out is that the H/V spectral ratio is largely affected by the 2D basin structure and the amplitude of the spectral ratio for 2D basin model is much smaller than that of the 1D theory (solid black line). If we look at the wave propagation for unit loads on the surface of the model, we can clearly see the effect of the basin edge in the response at the same point as the load even in the direction parallel to the basin edge.

Next, we perform a second calculation for the target position at 260m from the basin edge, which is 660m to the east from site C, as shown by the gray arrows in Figure 3b. The depth of the bedrock at this point is about 270m. The H/V spectral ratios for this case are shown in Figure 7. We

can see that for this case the difference between NS/UD (black dotted line) and EW/UD (gray dotted line) ratios becomes larger and the peak amplitude of the spectral ratios become smaller compared to those at site C, although the amplitude of the H/V spectral ratio for a 1D theory (solid line) is similar to that at site C.

Table 3 One layer one-dimensional velocity model equivalent of site C for testing SEM calculation

	Thickness [m]	P wave velocity [m/s]	S wave velocity [m/s]	Density [kg/m^3]	$Q_{s,p}$

bedrock	-	5,083	2,348	2,600	9999

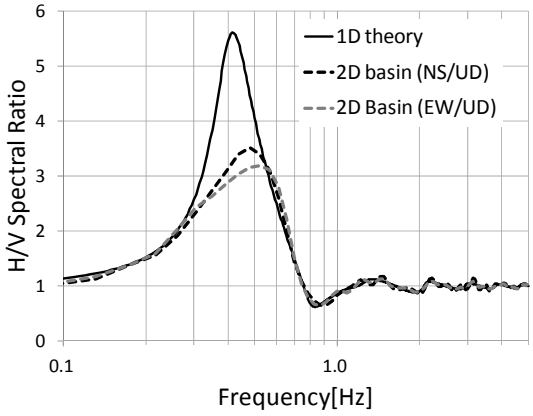

Figure 6 Spectral ratios of NS/UD and EW/UD (black and gray dotted line, respectively) at site C for the one layer two-dimensional basin model compared with the one layer one-dimensional theory (solid line)

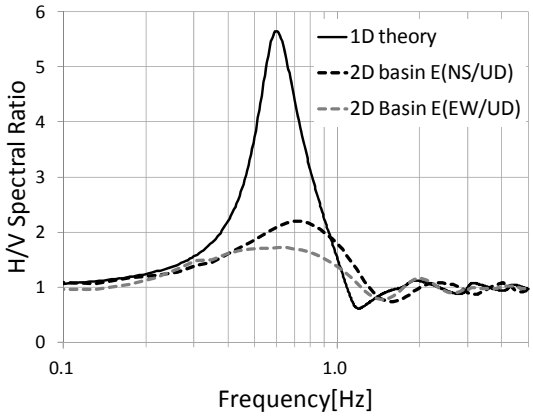

Figure 7 Spectral ratios of NS/UD and EW/UD (black and gray dotted line, respectively) at site 660m east of site C, 260m from the basin edge for the one layer two-dimensional basin model compared with the one layer one-dimensional theory (solid line)

5. CONCLUSIONS

In order to simulate the H/V spectral ratio for a site with lateral heterogeneity, we used a 3D SEM code to numerically calculate Green's functions to derive numerical H/V spectral ratios by the same procedure as the theoretical 1D H/V spectral ratios. From the comparison with theoretical and observational H/V spectral ratios, we confirmed the validity to use a SEM to calculate numerical H/V spectral ratios from the imaginary part of the Green's function for sites with lateral heterogeneity. We also confirmed that a SEM is adapted for solving such a difficult wave propagation problem that consists of modeling accurately the receiver located at the same location than a free surface point force. From the comparison of H/V spectral ratios for the 1D homogeneous model and the 2D basin model at two sites, we found that the 2D basin structure has significant effect on the H/V spectral ratios. They make the peak frequency slightly higher and the amplitude smaller and the frequency characteristics for NS/UD and EW/UD ratios are different. This indicates that when interpreting the H/V spectral ratio as an indicator for subsurface velocity structure, we need to first confirm that there is no strong influence from a lateral heterogeneity near the site, i.e. H/V spectral ratio for two orthogonal horizontal components are the same. If it is not the case, we need to take into account the fact that the H/V spectral ratio will be different from 1D theory.

Abstract: The new Indonesia Seismic Hazard Maps for revising the previous map in SNI 03-1726-2002 was published in July 2010. These maps developed by Team for Revision of Seismic Hazard Maps of Indonesia were based on probabilistic approach for 2% probability of exceedance (PE) in 50 years and deterministic approach by using three-dimensional seismic source models and by considering latest geological and seismological data and fragility curve of buildings. Seismic sources were represented by subduction, fault, and background zones. The new maps were developed based on PSHA method. A principal advantage of the probabilistic method is combining all the possible earthquakes affecting the site. This paper presents deaggregation of Indonesia Seismic Hazard Map 2010. Deaggregation for peak ground acceleration, 0.2-sec and 1.0-sec pseudo spectral acceleration (SA) is performed for 2% PE in 50 years (2475 years mean return period). The maps of mean and modal of magnitude and distance presented here are intended to provide information about the distribution of probabilistic seismic sources and to provide suggestions for seismic sources to use in developing artificial ground motion.

1. INTRODUCTION

Indonesia is located in a tectonically very active area at the point of convergence of three major plates and nine smaller plates creating a complex network of plate boundaries (Bird, 2003). The existence of interactions between these plates puts Indonesia in an earthquake prone region (Milson et al., 1992). Several great earthquake occurrences in Indonesia in the last six years inquire revision of seismic hazard parameters. Some of the great earthquakes are the 2004 Aceh Earthquake (Mw9.0-9.3) which was followed by tsunami, the 2005 Nias Earthquake (Mw 8.7), the 2009 Tasik Earthquake (Mw 7.3), and the latest 2009 Padang Earthquake (Mw 7.6). These earthquakes have caused thousands of casualties, destruction and damage to thousands of infrastructure and buildings, as well as billions of US dollars required for reconstruction and rehabilitation.

The Team for Revision of Seismic Hazard Maps of Indonesia has produced several new seismic hazard maps for Indonesia. The final model and maps were issued in 2010 as Summary of Study Team for Revision of Seismic Hazard Maps of Indonesia. The method and results given in this summary are the basis for BSN (National Standardization Agency) recommended seismic design provisions for the next edition of the Indonesian Earthquake Resistant Building Code SNI 03-1726 which will be issued in this year. This summary presented seismic hazard maps computed for sites on bed rock (Vs = 760 m/s2) at the 10% PE in 50 year and 2% PE in 50 year.

The seismic source models used in this study are subduction sources, fault sources, and background sources. Seismic hazard parameters for subduction considered recurrence relationship that includes truncated exponential model and pure characteristic model. For fault sources, truncated exponential model and characteristic model with aleatory uncertainty in the magnitude using a normal distribution sigma of ± 0.12 were used. For background source, only truncated exponential model were used in the development of hazard maps. Several attenuation functions including NGA and logic-tree were used. The detail information on seismic source models and seismic parameters for development seismic hazard maps appear in Asrurifak, 2010 and Fauzi, 2011.

This paper, in conjunction with Team for Revision of Seismic Hazard Maps of Indonesia, intends to convey information about the distribution of probabilistic seismic sources with explain typical values of earthquake magnitude and distance that are making the largest contributions to the seismic hazard maps. Identifying the predominant sources of hazard will lead to better choices for the design earthquake's characteristics. Performing deaggregations at more than one period will help to determine if one source dominates at all periods and clarify the need for one, or more than one, design earthquake (Halchuck and Adams, 2004).

2. PROBABILISTIC SEISMIC HAZARD ANALYSIS

PSHA was developed by McGuire (1976) is based on the probability concept developed by Cornell (1968). It is assumed that the earthquake magnitude M and distance R as a continuous independent random variables. In general, form of total probability theorem can be expressed in the

following formula

$$H(a) = \sum v_i \iint P[A > a | m, r] \, fMi(m) \, fRi|Mi(r,m) dr dm \quad (1)$$

where v_i is annual rate of earthquakes (with magnitude higher than some threshold value of M_{oi}) in source I, and $fMi(m)$ and $fRi|Mi(r,m)$ are probability density functions on magnitude and distance, respectively. $P[A > a | m, r]$ is the probability that an earthquake of magnitude m at distance r produces a peak acceleration A at the site that is greater than a.

The seismic hazard analysis was performed using this following procedure: 1) conducting literature review on geology, geophysics and seismology to identify activity of seismic sources in and around Indonesian region, 2) collecting and processing recorded earthquake data for entire Indonesian region, 3) modeling seismic source zones based on the advance models appropriate with USGS software, 4) determining seismic parameters which include a-b values, maximum magnitudes, and slip-rates, 5) calculating spectral acceleration based on the total probability theorem, 6) mapping spectral hazard includes peak ground acceleration (PGA) and short period (0.2 s) and 1.0 s period spectra values.

Software for PSHA used in this study obtained from the USGS. A site spacing of 0.1 degrees in latitude and longitude and area between 94°E to 142°E longitudes and 12°S to 8°N latitude were used in the analysis. The ground motion parameters obtained from this study computed for sites on bed rock (Vs = 760 m/s2). The verification seismic models and parameters in this research with Team for Revision of Seismic Hazard Maps of Indonesia are shown in Fauzi, 2011.

The method of deaggregation of hazard is separates the contributions into a limited number of bins of (annular) distance, magnitude, and ground-motion uncertainty (McGuire, 1995). For this research the distance annular width, ΔR, is 5 km and the magnitude bins is 0.5. For subduction sources, the maximum considered source to site distance is 1000 km. For fault and background sources, the maximum considered source to site distance is 200 km. Using PSHA result, the relative contribution of sources to the overall hazard results at the given site are deaggregated in different types of bins to determine and understand. The integration of the PSHA is carried out and the final results are presented often in terms of 3D M-R-ε bins or even geographical deaggregation (4D) (Harmsen and Frankel, 2001).

The mean distance and mean magnitude presented here are the weighted mean values of R and M, respectively, for all sources that contribute to hazard at each grid location. The modal distance and modal magnitude are the (R, M) pair having the largest contribution in the hazard deaggregation at each grid location. The maps develop using the grid increment of 0.1 degrees in both latitude and longitude and in area between 94°E to 142°E longitudes and 12°S to 8°N latitude so that deaggregations seismic hazard are performed for more than 96,600 sites. Software for Deaggregation PSHA used in this study obtained from the USGS.

4. SEISMOSECTONIC MODEL

Seismic parameters used in this study were derived from published journals, proceedings, previous researches conducted by team members, and latest information obtained during this study. This study has then compiled and integrated previous and current studies. Earthquake source parameters were determined based on earthquake catalog, geological, and seismological information of active faults. The earthquake catalog covered earthquake period between 1900 to 2009, relocated catalog by the year 2005, and area between 90oE to 145oE longitudes and 15oS to 15oN latitudes.

Seismic sources were divided into subduction, fault, and background zones by considering recurrence relationship that includes truncated exponential model, pure characteristic model, and both models. Geometry of fault and subduction were represented by three-dimensional (3D) models based on the result of tomography and slip-rates of faults were determined by considering the results of GPS measurement. Background source zones were modeled using gridded seismicity based on spatially smoothed earthquake rates. The earthquake catalog was used for developing gridded seismicity starting from 1900 to 2009 and the updated Engdahl catalog up to 2009 was used for control geometry of subduction. Several well-known attenuation functions were selected in accordance with the mechanism of seismic source including the Next Generation Attenuation (NGA). Logic tree was also applied to account for epistemic uncertainty including recurrence model, maximum magnitude, and several attenuation functions.

3. RESULTS AND DISCUSSION

One purpose of deaggregation analysis is to find plausible (R,M) pairs from which to choose accelerograms, A(t), for input to seismic design programs for structural response (Harmsen, et. Al 2003). The maps of mean and modal magnitude and distance for 10% probability of exceedance (PE) in 50 yr are shown in Figure 1 to Figure 4. Maps of mean and modal magnitude and distance for 2% probability of exceedance (PE) in 50 yr are shown in Figure 5 to Figure 8.

The analysis result showed that the maps of modal results are associated the highest contribution, for the areas near the fault, magnitude and distance of fault control. In areas far from the fault, the magnitude and distance from the subduction control and for areas far from faults and subduction, gridded seismicity model control. The mean magnitude and distance associated with the average of contribution from multimodal / multi scenario earthquake. The mean and modal maps showed different values of pair magnitude and distance so that most sites receive contributions from a broad distribution of source magnitudes and distances.

3. CONCLUSIONS

For most locations, the deaggregation reveal that more than one design earthquake will be required for engineering purposes. The maps of mean and modal of magnitude and distance presented here are intended to convey information about the distribution of probabilistic seismic sources and to provide prescriptions or suggestions for seismic sources to use in building design or retrofit projects. The information of deaggregation analysis can and perhaps should be considered in a complex seismic-resistant design decision-making environment.

ESTIMATION OF URBAN GROWTH USING TIME-SERIES LANDSAT SATELLITE IMAGES IN LIMA, PERU

Hiroyuki Miura[1)], Saburoh Midorikawa[2)], and Masashi Matsuoka[3)]

1) Associate Professor, Department of Architecture, Hiroshima University, Japan
2) Professor, Department of Built Environment, Tokyo Institute of Technology, Japan
3) Associate Professor, Department of Built Environment, Tokyo Institute of Technology, Japan
hmiura@hiroshima-u.ac.jp, smidorik@enveng.titech.ac.jp, matsuoka.m.ab@m.titech.ac.jp

Abstract: In order to develop building inventory data for building damage assessment in Lima, Peru, distribution of urban growth is estimated by time-series analysis of satellite Landsat images. Spectral indices calculated from the images are used to evaluate changed areas from vegetated and bare ground areas to built-up areas. Threshold analysis is performed to difference of the indices between the multi-temporal images to identify the spatial distribution of the expansion of the built-up areas. The result shows that the older built-up areas are widely distributed in the central part of Lima and the newer built-up areas are expanded to the northern, southern and eastern suburban areas.

1. INTRODUCTION

Due to the rapid urban growth in developing countries, built-up areas have been dramatically expanded to suburban areas with poor ground conditions such as steep slope areas. In order to discuss seismic vulnerability of such urban areas, it is important to identify spatial distribution and its temporal change of the built-up areas. The identification of the age of the built-up areas could be also useful to estimate construction age of the buildings and to evaluate seismic performance of the buildings.

In developing countries, however, detailed building inventory data that includes construction age information has been rarely developed. Remote sensing technology would be powerful tool to easily identify spatial distribution of the built-up areas. Peru is one of the developing countries located in a zone of high seismicity. Since Lima, the capital of Peru, is prone to be struck by a large earthquake in near future, disaster preparedness such as building damage assessment should be enhanced in the urban areas. In this study, to develop building inventory data for the damage assessment in Lima, spatial growth of the urbanized areas is evaluated by time-series analysis of satellite Landsat images.

2. DATA USED

Figure 1 shows the land use map in Lima with 1/25,000 scale developed in 2004. Orange and green blocks indicate built-up and vegetated areas, respectively. The land use map is digitized and geo-referenced in the geographical information system. Each pixel of the map image is classified into three categories; built-up area, vegetated area and other area (bare grounds and roads). Figure 2 shows the distribution of the land use with the resolution of 30 m. Pink, green and gray pixels indicate built-up, vegetated and other areas, respectively. The built-up areas in Fig. 2 represent the current distribution of the urbanized areas.

In this study, the time-series satellite Landsat-TM (Thematic Mapper) images are used for the estimation of urban growth because large number of images has been stored since 1970s. After searching the database of the Landsat images (USGS 2012), we found an oldest cloud free image in Lima observed in 1987. In order to capture the expansion of the built-up areas after decades, we also searched another images observed about ten and twenty years after the oldest image and found cloud free images observed in 1998 and 2006. These three Landsat images are used in this study. Figure 3 and Table 1 show the characteristics of the images. As shown in Fig. 3, the western coastal area in Lima is covered with cloud in the 2006 image. The Landsat image observed in 2002 is supplementary used in the cloud cover area. The Landsat-TM data consists of seven band images that cover visible, near infrared, mid infrared and thermal spectral range. The spatial resolution of the images is 30 m.

From the comparison between the time-series Landsat images in Fig. 3, many vegetated areas and bare ground areas in the older images are changed to built-up areas in the newer images. In this study, the age of the built-up areas are estimated by identifying the changed areas from the vegetated and bare ground areas to the built-up areas in the Landsat images.

3. SPECTRAL INDEX CALCULATION

3.1 Evaluation of Vegetated Areas

Spectral indices calculated from combination of multi-band images have been widely used to evaluate vegetated and bare ground areas in remote sensing technology. NDVI (normalized difference vegetation index), one of the powerful indices to evaluate vegetated areas in satellite images, is calculated from the following equation.

$$NDVI = \frac{B4 - B3}{B4 + B3} \quad (-1 \le NDVI \le 1) \qquad (1)$$

Here, *B3* and *B4* indicate the digital number (DN) of the band 3 (red) and band 4 (near infrared) images, respectively. Higher NDVI values represent greater density of greenness. Figure 4 shows the distribution of NDVI calculated from the images. Figure 5 illustrates the close-up of the 2004 land use map and the 2006 NDVI image. As shown by arrows in the figure, the green areas in the land use map show high NDVI in the image, indicating that NDVI is useful to evaluate vegetated areas in the image.

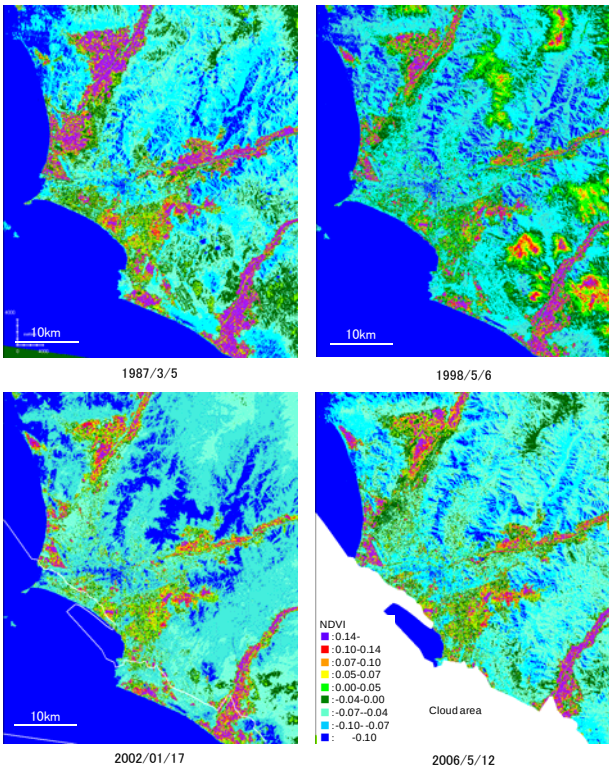

Fig. 4 NDVI images in 1987, 1998, 2002 and 2006

3.2 Evaluation of Bare Ground Areas

NDSI (normalized difference soil index) has been used as one of the spectral indices to evaluate bare ground areas from satellite images (Takeuchi and Yasuoka 2005). NDSI is also calculated from the combination of the multi-band images by the following equation.

$$NDSI = \frac{B5 - B4}{B5 + B4} \quad (-1 \le NDSI \le 1) \qquad (2)$$

Here, *B5* indicates the DN of the band 5 (mid infrared) image. Higher NDSI values would indicate greater possibility of bare ground in the image. Chen *et al.* (2010), however, pointed out that it is sometimes difficult to discriminate bare ground areas from built-up areas from only NDSI image because their spectral characteristics are similar each other in the near and mid infrared band images. In this study, other spectral indices are also calculated to evaluate bare ground areas.

$$NBI = \frac{B3 \times B5}{B4} \qquad (3)$$

$$NUI = \overline{B3} + \overline{B6} - \overline{B4} - \overline{B5} \qquad (4)$$

$$\overline{Bn} = \frac{Bn - Ave_{Bn}}{SD_{Bn}} \times 50 + 100 \quad (n = 3, 4, 5, 6)$$

NBI (new built-up index) proposed by Chen *et al.* (2010) is based on the characteristics that DNs of band 3 in bare ground areas are generally larger than those in built-up areas. Higher NBI values would indicate greater possibility of bare ground areas in the image. NUI (normalized urban index) proposed by Saito *et al.* (2002) is calculated based on the characteristics that DNs in built-up and bare ground area are higher in band 3 and 6 (thermal)

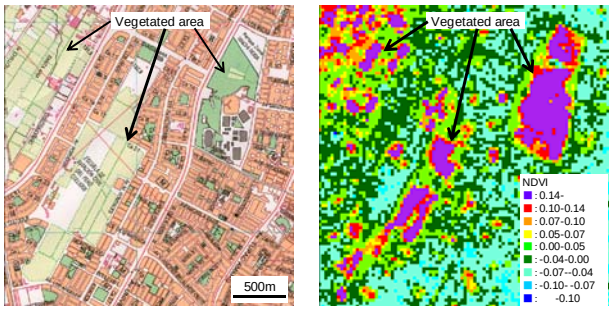

Fig. 5 Comparison of 2004 landuse map and 2006 NDVI image

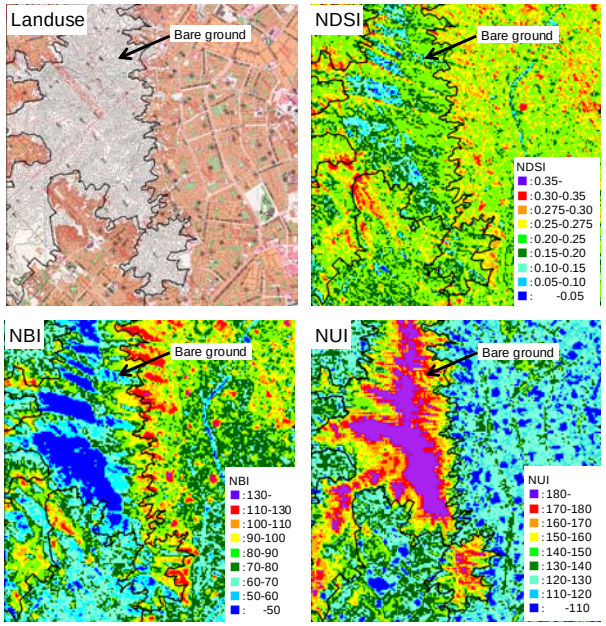

Fig. 6 Comparison of 2004 landuse map, NDSI, NBI and NUI images in 2006

than in band 4 and 5. NUI values in built-up and bare ground areas would be higher than in vegetated areas.

Figure 6 shows the distribution of the indices calculated from the 2006 Landsat image with the comparison of the 2004 land use map. Arrows in the figures indicate bare ground and mountain areas. The distribution of NDSI shows that NDSI in the bare ground areas is generally lower than that in the built- up areas. However, the boundary between the bare ground and the built-up areas could not be clearly identified in the NDSI image because many low NDSI pixels are distributed in the built-up areas. Also in the NBI image, it is difficult to identify the boundary between the bare ground and built-up areas because low NBI pixels are distributed not only in the bare ground areas but also in the built-up areas. On the contrary, in the NUI image, it is much easier to identify the boundary because NUI in the bare ground areas is much higher than that in the built-up areas. This may be because that the surface temperature in the bare ground is higher than that in the built-up areas and NUI is only the index based on the thermal band (band 6). In this study, the NUI image is used to evaluate bare ground areas. Figure 7 shows the distribution of NUI calculated from the Landsat images.

4. BUILT-UP AGE CLASSIFICATION

4.1 Methodology

The NDVI values are high in vegetated areas while they become lower in built-up areas changed from the vegetated areas. The NUI values are also high in bare ground areas while they become lower in newly developed built-up areas. Therefore, the differences of NDVI and NUI between the multi-temporal images are used to estimate the growth of the built-up areas.

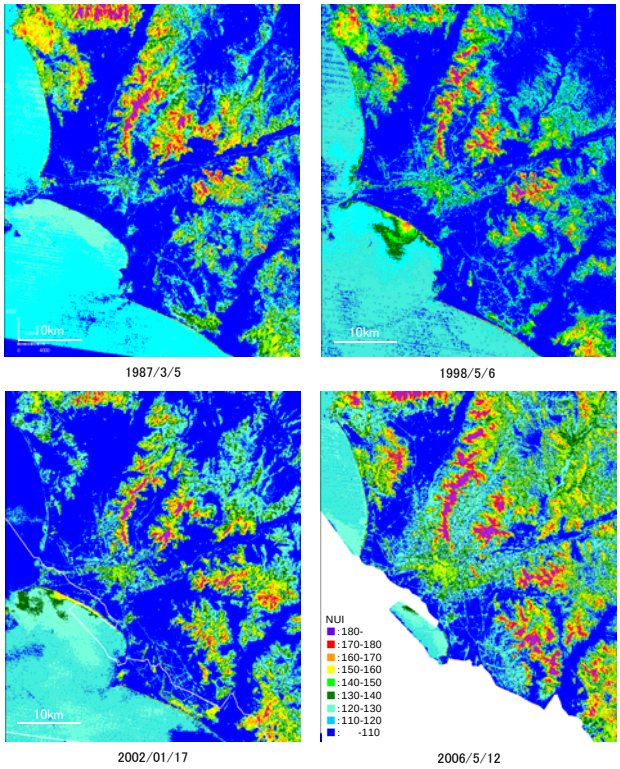

Fig. 7 NUI images in 1987, 1998, 2002 and 2006

In order to apply the method, validation data such as high-resolution images observed in the past and the present is necessary. Aerial photographs observed in 1984 are available in Lima. As shown solid line area in Fig. 8, the aerial photos are acquired in newly developed area located at the northern part of Lima. We assume that the 1984 aerial photos timely correspond to the 1987 Landsat image. The aerial photos are black-and-white images and the spatial resolution is approximately 20 cm. Recently, high-resolution satellite images are easily available. The satellite WorldView-2 (WV2) images observed in 2010 are used for the validation. The coverage of the 2010 WV2 images is shown in Fig. 8. We assume that the 2010 WV2 images timely correspond to the 2006 Landsat image. The spatial resolution is 50 cm.

Firstly, the built-up pixels are extracted from the 2004 land use map shown in Fig. 2 and only the built-up pixels are analyzed in the following procedure. The difference of NDVI and NUI between the 2006 and 1987 Landsat images is calculated for each pixel. Larger negative difference of the indices indicates greater possibility of the area where vegetation or bare ground is changed to built-up area.

Figure 9 shows the comparison of (a) the 1984 aerial photos, (b) the 2010 WV2 images and the distribution of the difference of (c) NDVI and (d) NUI. Purple and red color pixels in Fig. 9 (c) and (d) represent larger negative values of the difference of the indices. As shown in solid line polygons, training pixels are visually selected as changed areas. Green and orange line polygons represent the changed areas from the vegetated and bare ground areas to the built-up areas, respectively. Purple line polygons

represent the built-up areas in all the images, indicating the old built-up areas. The distribution of NDVI difference shows that many purple and red color pixels are concentrated in the green polygons. The distribution of NUI difference also shows that many purple and red pixels are concentrated in the orange polygons.

Histograms of the NDVI and NUI difference are illustrated in Fig. 10 (a) and (b) by extracting the training pixels of the polygons in Fig. 9. Red and blue lines in the histograms indicate the pixels of the changed areas from the vegetated and bare ground areas to the built-up areas, respectively. Black lines indicate the pixels of the old built-up areas in all the images.

From Fig. 10(a), the difference of NDVI in the old built-up areas shows almost larger than -0.1 while the difference of NDVI in the changed areas from the vegetated areas are widely distributed from -0.6 to 0.0. In this study, the threshold value for the difference of NDVI is selected at -0.1 to discriminate the changed areas from the unchanged areas.

From Fig. 10(b), the difference of NUI in the old built-up areas shows larger than 10 while the difference of NUI in the changed areas from the bare ground areas are distributed from -60 to 40. In this study, the threshold value for the difference of NUI is selected at 10 to discriminate the changed areas from the unchanged areas.

Table 2 shows the result of the classification accuracy based on the threshold analysis proposed above. The table shows the number of pixels in each land use, the percentages of correct classification and mis-classification. From the result of the thresholding using the difference of NDVI, about 75% of the changed pixels in the vegetated areas are correctly classified. Almost 100% of the bare ground and the old built-up areas are classified. From the result of the thresholding using the difference of NUI, about 80% of the changed pixels in the bare ground areas are correctly classified. Almost 100% of the vegetated and old built-up areas are classified.

4.2 Result of Built-up Age Classification

Based on the threshold values examined in the previous section, the built-up age classification is performed using the time-series Landsat images. Figure 11 shows the flowchart of the classification. First, the built-up pixels are extracted from the 2004 land use map. The difference of NDVI and NUI between the 2006 and 1998 Landsat images is calculated for the built-up pixels. The threshold analysis is performed based on the threshold values. The pixels whose difference values are lower than the thresholds are classified to the newer built-up areas developed after 1998. The pixels whose difference values are higher than the thresholds are classified to the older built-up areas and analyzed in the following steps. The difference of NDVI and NUI between the 1998 and 1987 Landsat images is calculated for the older built-up pixels.

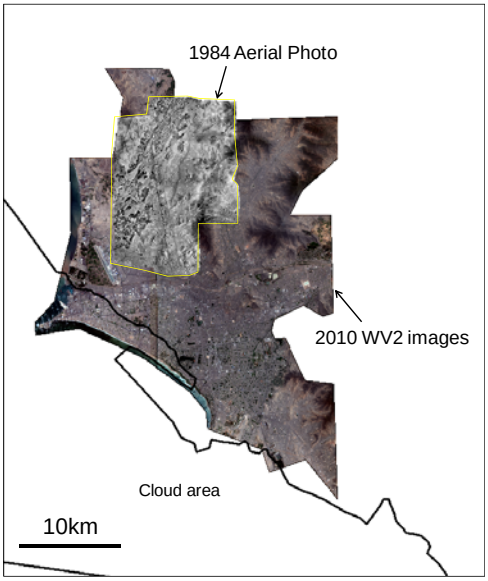

Fig. 8 Coverage of 1984 aerial photos and 2010 WV2 images

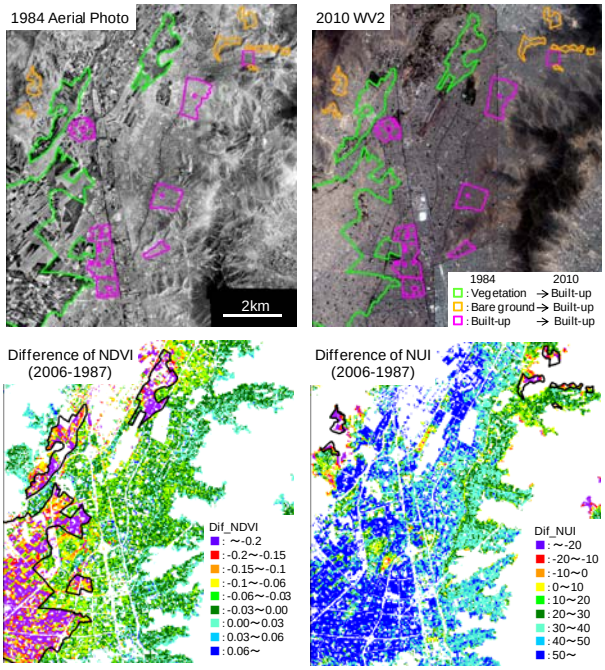

Fig. 9 Comparison of (a) 1984 aerial photo, (b) 2010 WV2 image, (c) difference of NDVI and (d) difference of NUI

The pixels whose difference values are lower than the thresholds are classified to the newer built-up areas developed between 1987 and 1998. The pixels whose difference values are higher than the thresholds are classified to the older built-up areas developed before 1987. In the cloud-cover areas of the 2006 image, same procedure is applied to the 2002 image instead of the 2006 image. Finally, the built-up age classification is estimated by combining the results.

Figure 12 shows the result of the built-up age classification. The pink, red and yellow pixels indicate the

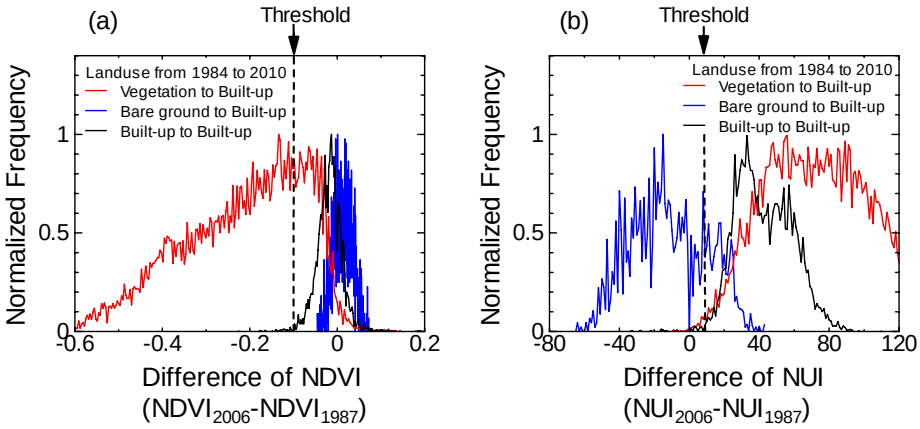

Fig. 10 Histograms of difference of NDVI and difference of NUI

Table 2 Classification accuracy of threshold by difference of NDVI and NUI

Landuse change from 1984 to 2010	Num. of Pixels	Threshold by Difference of NDVI			Threshold by Difference of NUI		
		Correctly classified (%)	Mis-classified (%)	Total (%)	Correctly classified (%)	Mis-classified (%)	Total (%)
Vegetation to Built-up	486,540	75.2	24.8	100.0	99.3	0.7	100.0
Bare ground to Built-up	30,105	100.0	0.0	100.0	80.5	19.5	100.0
Built-up to Built-up	149,859	99.5	0.5	100.0	99.3	0.7	100.0

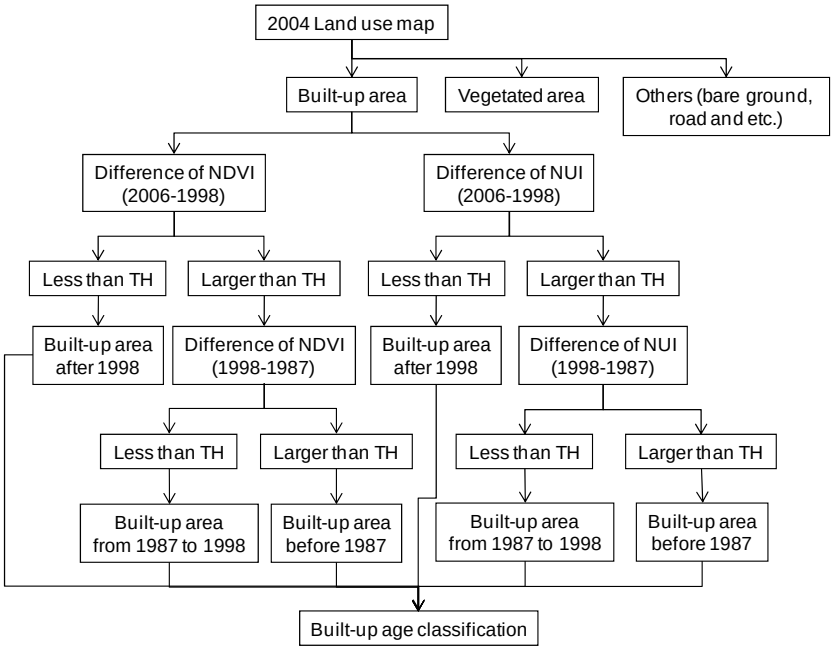

Fig. 11 Flowchart of built-up age classification using landuse map, NDVI and NUI images (TH: Threshold value)

built-up areas developed before 1987, between 1987 and 1998 and after 1998, respectively. Green and gray pixels represent vegetated areas and others, respectively. The result shows that most of the built-up areas in Lima had been developed before 1987. The newer built-up areas are expanded to the suburban areas in the northern, southern and eastern part of Lima.

Table 3 shows the number of pixels in each built-up area calculated from Fig. 12. The total area in each built-up area is also calculated from the mesh size of the Landsat images (30m x 30m). The total built-up area in Lima is about 1600 km2. About 70% of the total was developed before 1987. About 20% and 10% of the total were developed between 1987 and 1998, and after 1998, respectively.

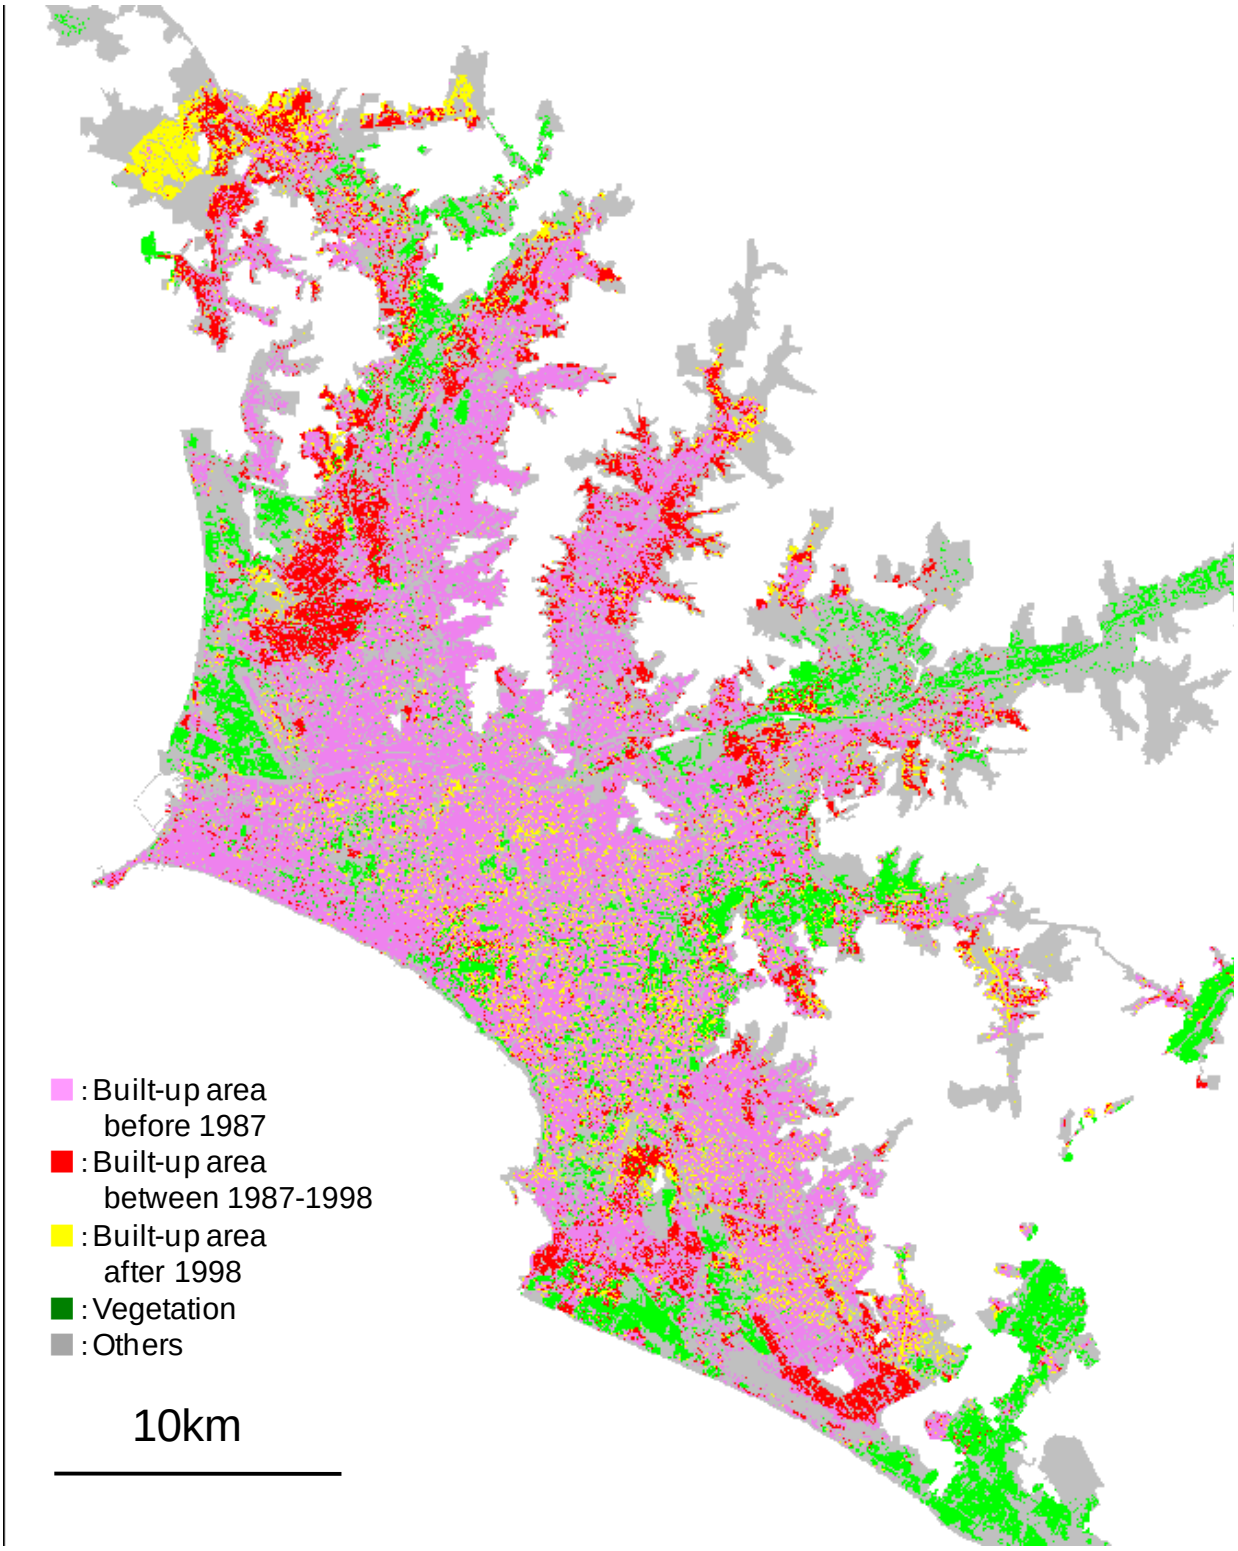

Fig. 12 Result of built-up age classification

Table 3 Number of pixels and area of each built-up area

Age	Num. of Pixels	Area (km^2)	Percent (%)
Built-up before 1987	1,192,567	1,073	68.1
Built-up between 1987-1998	314,830	283	18.0
Built-up after 1998	243,192	219	13.9
Total	1,750,589	1,576	100.0

5. CONCLUDING REMARKS

In order to develop the building inventory data in Lima, Peru, the distribution of the age of the built- up areas is estimated using the existing land use map and the time-series Landsat images. The changed areas from the vegetated and bare ground areas to the built-up areas are evaluated based on the spectral indices calculated from the images. The difference values of NDVI and NUI between the multi-temporal images are used to extract the changed areas. The threshold analysis is performed to estimate the spatial distribution of the built-up ages. The result shows that the older built-up areas before 1987 are widely distributed in Lima and the newer built–up areas are expanded to the suburban areas.

Abstract: QuiQuake (**Qui**ck estimation system for earth**Quake** maps triggered by observation records) is a seismic event triggered quick estimation system for the generation of earthquake maps using earthquake observation records. It is a system which provides extensive and detailed strong ground motion maps such as PGA, PGV, and seismic intensity right after a seismic event in and around Japan. QuiQuake also uses the combinations of amplification capability map and observed seismic records. The amplification capability is estimated from geomorphologic conditions, based on the Japan Engineering Geomorphologic Classification Map, with spatial resolution of 7.5 arc-second and 11.25 arc-second in latitude and longitude, respectively. The automatic calculation of spatial interpolation, including consideration of the attenuation characteristic from the seismic source, is started by harvesting the seismic data recorded at strong ground motion observation stations. The strong motion maps are published online using an Open Geospatial Consortium (OGC) standard web service interface..

1. INTRODUCTION

The GEO Grid (Global Earth Observation Grid) system (Sekiguchi et al., 2008) of the National Institute of Advanced Industrial Science and Technology, Japan (AIST) has developed a web service system for earthquake disaster response throughout Japan. The GEO Grid aims at providing integrated service using a wide array of geoscientific information such as geologic maps and other digital geographically referenced data, and assembles them into easy-to-use formats for potential stakeholders from several fields such as environmental conservation, resource exploration, hazard evaluation, and risk management. To provide these services, AIST set up web-based systems using Grid and Web service technologies in accordance with international standards. In order to take effective countermeasures against seismic disasters and implement business continuity plans (BCPs) for municipalities and private companies, the quick estimation of strong ground motions is very essential at the early stages of disaster response activities (e.g. Yamazaki et al., 1998; Ariki et al., 2004). QuiQuake (**Qui**ck estimation system for earth**Quake** maps triggered by observation records) is a seismic event triggered quick estimation system for the generation of earthquake maps using earthquake observation records. It is one of the geological hazard related applications on GEO Grid and the first system which estimates and illustrates the extensive and detailed ground motion maps such as peak ground acceleration (PGA), peak ground velocity (PGV), and JMA (Japan Meteorological Agency)-scale instrumental seismic intensity (I_{JMA}), right after an earthquake occurs. In this system, an amplification capability of ground motion and Vs30 average shear-wave velocity map, which is estimated from a 250-m grid cell map of the Japan Engineering Geomorphologic Classification Map (JEGM) (Wakamatsu and Matsuoka, 2011), are also used for the spatial interpolation calculation to generate strong motion maps. The interpolation also takes into account the characteristics of soil conditions. The strong ground motion maps are automatically calculated and published through an Open Geospatial Consortium (OGC) standard web service interface, right after the seismic observation data are released by the National Research Institute for Earth Science and Disaster Prevention (NIED). In this paper, we present the outline of QuiQuake, the data and algorithms used to generate strong ground motion maps.

2. QUIQUAKE OUTLINE AND CALCULATION PROCEDURE

Data flow and spatial interpolation procedure are shown in Fig. 1. The QuiQuake generates two kinds of strong ground motion maps with 250-m spatial resolution. The first one is QuakeMap which is calculated using the published seismic observation records at the portal site of the NIED. The second map is the QuickMap which is an output of

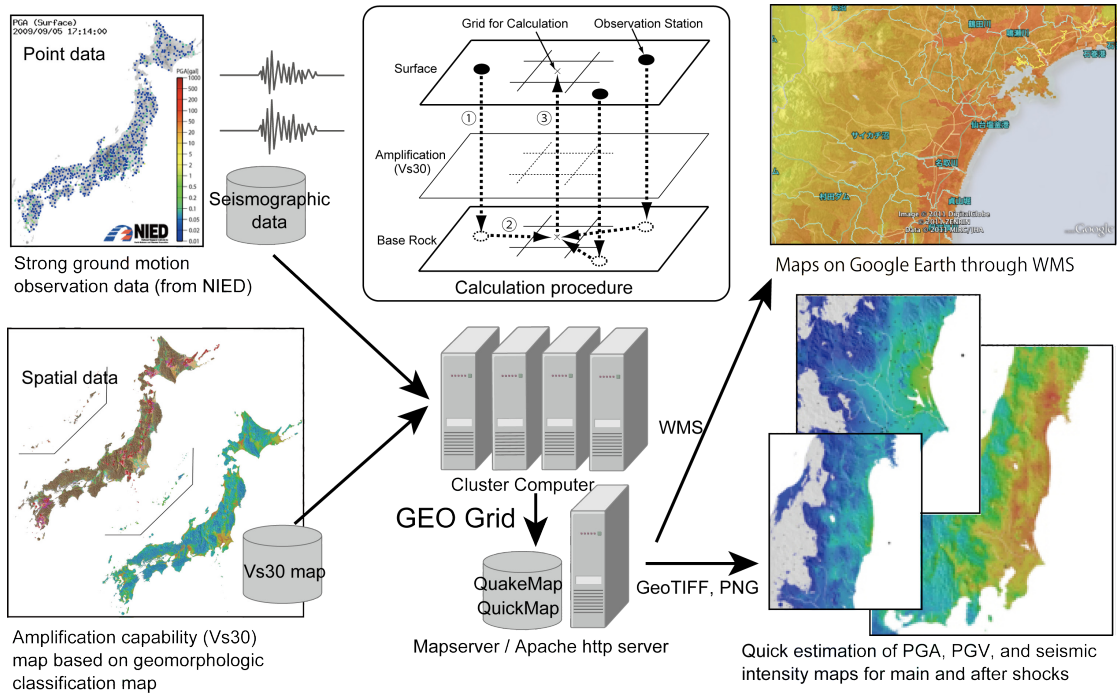

Figure 1 System overview and calculation procedure

quick estimation system. It is calculated using the near real-time information of strong ground motion parameters delivered by NIED right after an earthquake. Both maps are generated and published automatically using parallel computing techniques implemented by AIST's GEO Grid computer clusters.

The first phase of the generation of the ground motion maps is the processing of the near real-time observation data from K-NET (Kyoshin network). The ground motion parameters at the recording stations were assigned to the amplification capabilities estimated from the average shear-wave velocity of the ground in the upper 30 m (Vs30). The data are then converted to a base-rock level (Vs30 = 600 m/s) by using amplification factors. Since the earthquake motion on the ground surface is affected by the amplification characteristics of surface layers, the spatial interpolation by IDW (Inverse Distance Weighted) is carried out at the base-rock (outcrop) level. Finally, the spatial distributions of the ground motion parameters such as PGA, PGV, and I_{JMA} on the ground surface are obtained by multiplying the corresponding amplification factor for each grid cell. Following the aforementioned procedure, QuickMap could be generated.

When seismic waveform records at seismic stations from the K-NET and KiK-net (Kiban Kyoshin network) are published at the portal site, QuakeMap generation starts. The data are downloaded automatically and ground motion parameters, PGA, PGV, and I_{JMA} at the stations are calculated. Using the application factor, the parameters recorded on the surface are converted to values at the base rock level. For QuakeMap, one of the stochastic interpolation methods, called "Simple Kriging" with a prior trend component, is used to estimate the spatial distributions of ground motion parameters at the base rock level. The trend component is assigned for the attenuation relation obtained at the ground base level for each seismic event based on the location of the epicentre. PGA, PGV, and I_{JMA} maps on the ground surface are finally calculated by multiplying the amplification factors.

3. GROUND CONDITION AND AMPLIFICATION CAPABILITY MAPS

Local geologic and ground conditions play important roles in characterizing and estimating the site amplification capability of strong ground motion and geotechnical hazards. Accurate evaluation of site amplification characteristics requires detailed soil profile information such as the data on shear-wave velocity structures. However, high-density boring or PS-logging data throughout Japan are not available. It has been determined that approximate estimation of site amplification is possible using the average shear-wave velocity of ground in the upper 30 meters, also known as Vs30 (Borcherdt and Gibss, 1976; Joyner and Fumal, 1984; Midorikawa et al., 1994). Estimating Vs30s covering wider area could be done using surface geology and/or geomorphologic conditions, and digital elevation model. A product of Earthquake Hazard Program, SkakeMap, developed by the U.S. Geological Survey (USGS) uses Vs30 map for the key parameter to estimate site amplification characteristics (Wald et al., 2005). The QuiQuake also uses Vs30 as an amplification parameter and

Table 1 Description of geomorphologic map units in the 7.5-arc-second JEGM (Wakamatsu and Matsuoka, 2011)

Geomorphologic map unit	Definition and general characteristics	Subsurface soil condition	General depth of groundwater*
Mountain	Steeply to very steeply sloping topography with highest elevation and relative relief within a grid cell of more than approximately 200 m. Moderately to severely dissected.	Pre-Quaternary hard to soft rock.	Deep
Mountain footslope	Gently sloping topography adjoining mountains and composed of material sourced from the mountains such as colluvium, talus, landslide, and debris flow deposits.	Loose debris and soils consisting of colluvium, talus, landslide, and debris flow deposits.	Deep
Hill	Steeply to moderately sloping topography with higher elevation and relative relief within a grid cell of approximately 200 m or less. Moderately dissected.	Pre- Quaternary and Quaternary hard to soft rock.	Deep
Volcano	Steeply to moderately sloping topography with higher elevation and larger relative relief, composed of Quaternary volcanic rocks and deposits.	Quaternary hard to soft volcanic rock and/or deposits.	Deep
Volcanic footslope	Gently sloping topography located around skirt of volcano including pyroclastic-, mud- and lava-flow fields, and volcanic fan produced by dissection of volcanic body. Slightly dissected.	Quaternary loose to dense volcanic deposits consisting of ash, scoria, pumice, pyroclastic flow, lava, debris avalanche, etc.	Deep
Volcanic hill	Moderately sloping topography composed of pyroclastic flow deposits. Moderately to severely dissected.	Loose to moderately loose pyroclastic flow deposits such as ash, scoria, and pumice.	Deep
Rocky strath terrace	Fluvial or marine terrace with flat surface and step-like form, including limestone terrace of emerged coral reef. Thickness of subsurface soil deposits is less than 5 m.	Hard to soft rock.	Deep
Gravelly terrace	Fluvial or marine terrace with flat surface and step-like form. Covered with subsurface deposits (gravel or sandy soils) more than 5 m thick.	Dense gravelly soil.	Deep
Terrace covered with volcanic ash soil	Fluvial or marine terrace with flat surface and step-like form. Covered with cohesive volcanic ash soil to more than 5 m thick.	Stiff volcanic ash (cohesive soil).	Deep
Valley bottom lowland	Long and narrow lowland formed by river or stream between steep to extremely steep slopes of mountain, hill, volcano, and terrace.	Moderately dense to dense gravel or boulders in mountain, but loose sandy soil to very soft cohesive soil in plain.	Shallow
Alluvial fan	Semi-cone-like form composed of coarse materials, which is formed at the boundary between mountains and lowland. Slope gradient is more than 1/1000.	Dense gravel with boulders to moderately dense sandy gravel.	Deep in the central part of fan but shallow in the distal part of fan
Natural levee	Slightly elevated area formed along the riverbank caused by fluvial deposition during floods.	Loose sandy soil.	Shallow
Back marsh	Swampy lowland formed behind natural levees and lowlands surrounded by mountains, hills, and terraces.	Very soft cohesive soil containing peat or humus.	Very shallow
Abandoned river channels	Swampy shallow depression along former river course with elongated shape.	Very loose sandy soil occasionally covered with soft	Very shallow

		cohesive soil.	
Delta and coastal lowland	Delta: flat lowland formed at the river mouth by fluvial accumulation. Coastal lowland: flat lowland formed along shoreline by emergence of shallow submarine deposits, including discontinuous lowlands along sea- or lake- shore.	Loose fluvial sandy soil over-lying very soft cohesive soil.	Shallow
Marine sand and gravel bars	Slightly elevated topography formed along shoreline, composed of sand and gravel, which was washed ashore by ocean wave and/or current action.	Moderately dense to dense marine sand or gravel occasionally with boulder.	Shallow
Sand dune	Wavy topography usually formed along shoreline or river, comprised of fine to moderately aeolian sand; generally overlies sandy lowland.	Very loose to loose fine to medium sand.	Deep at crest of dune but shallow near base of dune
Lowland between coastal dunes and/or bars	Swampy lowland formed behind dunes or bars	Very soft cohesive soil containing peat or humus.	Very shallow
Reclaimed land	Former bottom flat of sea, lake, lagoon, or river that has been reclaimed as land by drainage.	Loose sand overlying very soft cohesive soil, sometimes covered with loose sandy fill.	Very shallow
Filled land	Former water body such as sea, lake, lagoon, or river reclaimed as land by filling.	Very loose to loose sandy fill, overlying very soft cohesive soil or loose sandy soils.	Very shallow to shallow
Rock shore, Rock reef	Irregular topography of rock or coral around beach zone.	Pre- Quaternary and Quaternary hard to soft rock	Near sea level
Dry riverbed	Nearly flat, irregular topography without water in normal time.	Loose sandy to gravelly alluvial soil, occasionally with boulders.	Very shallow
River bed	Nearly flat, irregular topography with varying water cover and having erosion and accumulation parts.	Loose sandy to gravelly alluvial soil, occasionally with boulders	
Lake	Inland water body.		
Nearshore waters	Nearshore water body.		

* Deep: deeper than 3 m below the ground surface, Shallow: within 3 m of the ground surface, Very shallow: within 1 m of the ground surface

Japan Engineering Geomorphologic Classification Map (JEGM) for the source of ground condition data.

3.1 7.5-arc-second JEGM

The map contains an attribute of geomorphologic land classification in grid cells that are 7.5 arc-seconds latitude × 11.25 arc-seconds longitude in size (approximately 250 × 250 m^2). A description of geomorphologic map units is presented in Table 1, together with the corresponding general ground conditions and general depth of groundwater. These criteria were based on the purpose of the mapping project, the identification and classification of subsurface ground conditions using standard geomorphologic classification. The geomorphologic factors presented in Table 1 are known to be correlated with subsurface ground and hydrologic conditions (e.g. Zuidam, 1986). Figure 2(a) shows a sample image of the 7.5-arc-second JEGM overlaid on the shade map created from the digital elevation model covering the entire country of Japan. The total number of cells of the map is approximately 6 million.

3.2 Average Shear-wave Velocity (Vs30) and Amplification Capabilities

The Vs30 values covering approximately 2,000 sites all over Japan were calculated from a previous study (Matsuoka et al., 2006). Geomorphologic units for all PS-logging data sites were interpreted. Then the correlation between geomorphologic units and geographical information derived from the JEGM and the Vs30 values were examined. It was found that the Vs30s showed some dependency on altitudes, slopes, and distances from mountains or hills formed during older periods (Pre-Tertiary or Tertiary). Based from this observation, a multiple linear regression formula for each geomorphologic unit was developed to estimate the Vs30 using elevation (*Ev*), slope (*Sp*), and distance (*Dm*) from a mountain or a hill as explanatory variables. The basic regression formula is

$$\log Vs30 = a + b\log Ev + c\log Sp + d\log Dm \pm \sigma \qquad (1)$$

where *a*, *b*, *c*, and *d* are regression coefficients, and σ as the standard deviation. The units of *Ev*, *Sp*, and *Dm* are meters, 1000 times tangent values, and kilometers, respectively. When the value of the explanatory variable is less than 1, we fixed the value as 1. Table 2 shows the regression coefficients and standard deviation of each geomorphologic unit obtained by regression analysis. The regression coefficients show that the higher is the elevation, the steeper is the slope. On the other hand, the shorter the distance from the mountain or hill the higher is the Vs30.

The Vs30 distribution with 250 m spatial resolution was computed using Eq.(1) and the attributes of the geomorphologic classification in the 7.5-arc-second JEGM, together with the geologic age, elevation, and slope values. Figure 2(b) shows the Vs30 map covering Japan. The Vs30 values are approximately 150 m/s on delta and coastal lowland, reclaimed land and back marsh. The areas covering valley bottom lowland also show a rather small Vs30

ranging from 180 to 200 m/s. To draw amplification capability maps, Vs30 was converted into the amplification factors for PGA, PGV, and I_{JMA} with respect to stiff soil, which corresponds to grounds with Vs30 of 600 m/s, using the empirical relationships (Fujimoto and Midorikawa 2006; Midorikawa et al., 2008).

4. PUBLICATIONS AND VERIFICATION

4.1 Portal Site and OGC Standards Publishing

The QuickMap results are generally available within 5 minutes after the occurrence of a 7.0 magnitude earthquake on QuiQuake homepage (http://qq.ghz.geogrid.org/QuickMap/index.en.html). Figure 3 shows the QuickMap portal site.

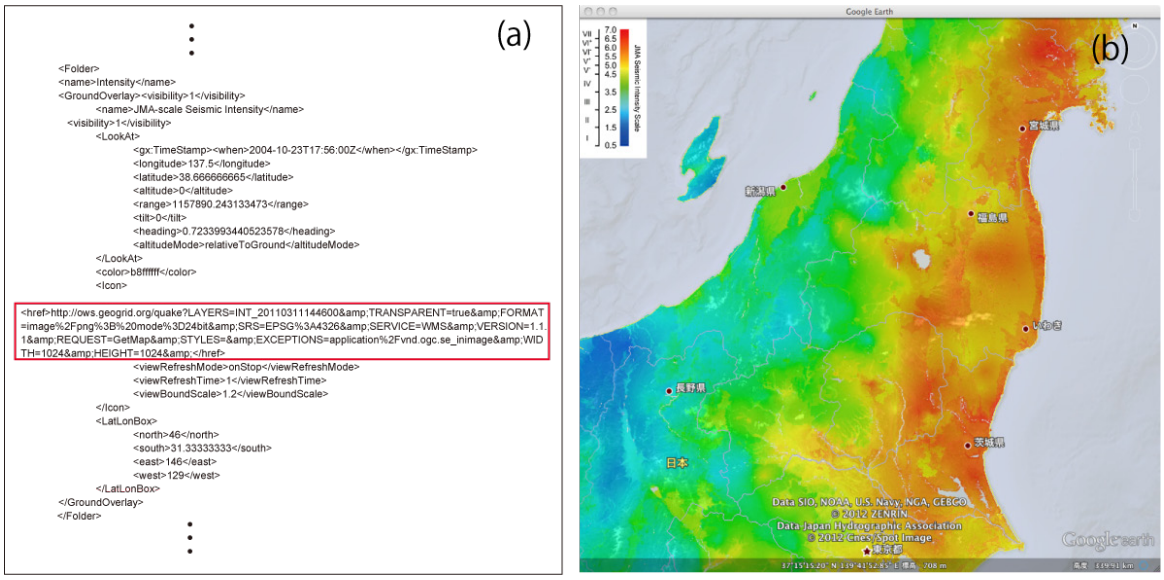

Figure 5 (a) Example of KML document containing the WMS URI of QuakeMap imagery. Red rectangle highlights the inserted WMS URI. (b) Spatial distribution of I_{JMA} of the 2011 Tohoku earthquake overlaid on Google Earth platform.

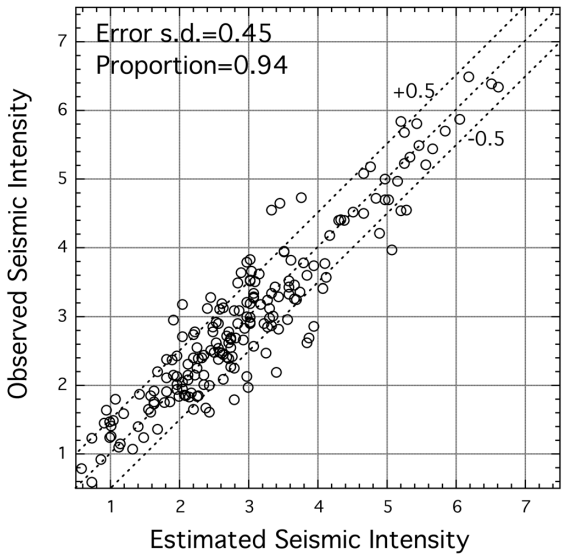

Figure 6 Comparison of the observed ground motion recorded by other organizations' seismic network stations and the estimated values at the stations estimated by Kriging using K-NET and KiK-net sites, and the amplification capability from Vs30 map for the 2004 Niigata-ken Chuetsu earthquake (Matsuoka et al., 2011)

The 8-bit unsigned integer GeoTiff file, which can be converted to the physical value of ground motion parameters, is downloadable from the site. Since calculation area is automatically determined to include the observation points where shaking occurred, the computation time is dependent on the magnitude of an earthquake. The automatic delivery of a message on Twitter (@QuiQuake) by "BOT" notifies that QuickMap is already available (see in Fig. 4). The QuakeMap, which take longer computation time than QuickMap, are also released on the homepage (http://qq.ghz.geogrid.org/QuakeMap/index.en.html). Furthermore, QuakeMap results for more than 8,600 major earthquakes after June 1996 have been computed and archived such that they chronologically represent the seismic motions over the last 16 years.

Earth observation data, such as strong motion observation records, shake maps, geological conditions, and remote sensing imagery are GIS based data that can be fully utilized through synergy with other GIS data available on the Internet. The most widely accepted standards are OGC (Open Geospatial Consortium) specifications such as the Web Map Service (WMS), Web Feature Service (WFS), and the Web Coverage Service (WCS). Since the QuickMap and QuakeMap contain information on each location-based grid-cell, it was decided to disseminate the maps using WMS/WCS. The example of KML document with WMS URI of QuakeMap imagery of the I_{JMA} distribution covering the 2011 Tohoku, Japan earthquake affected area is displayed on Google Earth as shown in Fig. 5.

4.2 Verification of QuakeMap Results

The accuracies of the estimated I_{JMA} in QuakeMap using strong motion observation records from other organizations' networks during the recent nine earthquakes; the 2000 Tottori-ken-seibu, the 2003 Miyagi-ken-oki, the 2003 Miyagi-ken-hokubu, the 2003 Tokachi-oki, the 2004 Niigata-ken Chuetsu, the 2005 Fukuoka-ken-seiho, the 2007 Noto-hanto-oki, the 2007 Niigata-ken Chuetsu-oki, and the 2008 Iwate-Miyagi-nairiku earthquakes were determined (Matsuoka et al., 2011). As in described in Section 2, ground motion values were estimated based on Simple Kriging of the K-NET and KiK-net data and the amplification capability estimated from the Vs30. The estimated I_{JMA} values were compared with observed I_{JMA} values recorded at

seismic stations owned by other organizations, such as the JMA, the Port and Airport Research Institute, the Central Research Institute of Electric Power Industry, the East Japan Railway Company, the NEXCO East, and the Committee of Earthquake Observation and Research in the Kansai Area. The standard deviation of estimation error (residual of the estimated and actual values) from the nine earthquakes is approximately 0.5 in I_{JMA}. Figure 6 shows the comparison for the 2004 Niigata-ken Chuetsu earthquakes. A relatively good agreement between the observed values and the estimated ones in QuakeMap is observed.

5. CONCLUSIONS

This paper outlines the components of the QuiQuake, which provides a 250-m resolution strong ground motion maps covering wide area, for quick disaster response right after an earthquake occurrence throughout Japan, is presented. In this system, an amplification capability map of ground motion (Vs30 map) based on Japan Engineering Geomorphologic Classification Map (JEGM) and seismic observation records from K-NET and KiK-net released by the National Research Institute for Earth Science and Disaster Prevention (NIED) are processed on a GEO Grid cluster computer of AIST. The use of the GEO Grid system in producing strong ground motion maps offers the following advantages: a) fully automatic, quick, and multi-task computing for mainshock and continued aftershocks, b) publication of the maps through Open Geospatial Consortium (OGC) compliant Web GIS server, and c) possibility to expand more stabilized and redundant operations by Virtual Machine in external servers and Cloud system.

Acknowledgements:

The QuiQuake system is supported by the National Research Institute for Earth Science and Disaster Prevention (NIED), the Japan Nuclear Energy Safety Organization (JNES), and ITOCHU Techno-Solutions Corporation (CTC). The system uses the data records of strong motion network (K-NET and KiK-net) administrated by NIED and the published program of Prof. Y. Hisada, Kogakuin University, to calculate instrumental seismic intensity. "RApid Shake Map simulator with Observed records (RASMO)" which was developed by Dr. I. Suetomi, Eight-Japan Engineering Consultants Inc. and Mr. M. Hashimoto, Kozo Keikaku Engineering Inc. and published by Kawasaki Laboratory, NIED is used for interpolation calculation. We optimized the software for fast calculation in the GEO Grid system. For validation of the system, we used the data from the JMA, the Port and Airport Research Institute, the Central Research Institute of Electric Power Industry, the East Japan Railway Company, the NEXCO East, and the Committee of Earthquake Observation and Research in the Kansai Area. To all of the aforementioned scientists and organizations, we would like to express our gratitude.

Abstract: To predict ground motions of local earthquakes in real time, we proposed a new method to directly estimate amplitudes of S-waves on the surface using amplitudes of P-waves obtained by KiK-net in the Kanto region. After analyzing many seismic records observed on the surface and in the deep borehole, we concluded that it is effective for an EEW system to rapidly estimate S-waves on the surface by the empirical relationship between peak amplitudes of P-waves in the deep borehole and S-waves on the surface. Also, we confirmed that the estimation accuracy of S-waves on the surface are improved using the empirical relationship between peak amplitudes of S-waves in the deep borehole and on the surface.

1. INTRODUCTION

In the railway field of Japan, to ensure the safety of trains running in a certain area which strong shakings will attack during earthquakes, the earthquake early warning (EEW) system using estimated earthquake information about the hypocentral distance and the magnitude has been installed practically since 1990's (Nakamura, 1996 and Ashiya et al., 2007).

Since many railway business operators bring in the EEW system to safely stop trains during earthquakes, the rapidness and the reliability for the EEW system have been essential. Recently, to improve the EEW system and issue the EEW as soon as possible, investigations of lead times and amplitudes of seismic records obtained in the deep borehole are performed (Iwakiri et al., 2012).

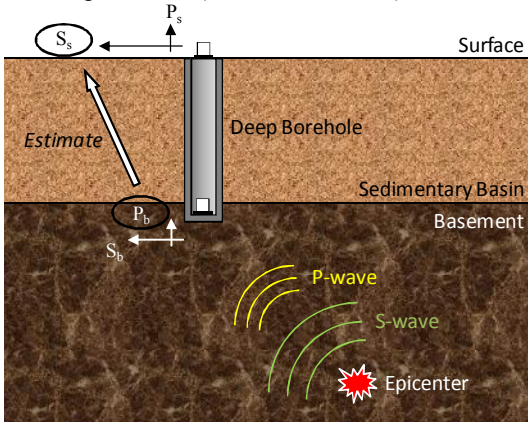

Fig.1 A Pattern Diagram of the New Method to Directly Predict Amplitudes of S-waves on the Surface (S_s) by Amplitudes of P-waves Observed in the Deep Borehole (P_b).

In the case of local earthquakes, the present system using P-waves on the surface may not work efficiently due to the shortness of P-S time delay. Therefore, we proposed the new method to directly predict amplitudes of S-waves on the surface by amplitudes of P-waves observed in the deep borehole, as shown in Fig.1. This method could make the lead time longer for propagation of seismic-waves through thick sedimentary basins. To apply this method to local earthquakes occurred beneath the Kanto region, at first, we performed a basic investigation for statistical relationships of P-waves/S-waves observed in the deep borehole and on the surface, using KiK-net data in the Tokyo Metropolitan Area and its vicinity.

2. SEISMIC STATIONS AND EARTHQUAKE DATA USED IN THIS STUDY

In this study, we used earthquake accelerograms recorded in the boreholes deeper than 2000m and on the surface at 6 seismic stations of KiK-net by NIED. Fig.2 shows locations of these seismic stations. Details of these seismic stations are described in Table 1. We selected local earthquakes whose epicenters are located from 34.5N to 37.0N and from 138.5E to 141.0E for the Kanto region, Japan.

We picked the on-set of P-waves and S-waves using a vertical (UD) component and horizontal (NS or EW) components, respectively. Data in which arrivals of P-waves and S-waves are not clear were excluded. PGAs of P-waves and S-waves were obtained using the UD component and the vector sum of NS and EW components, respectively. We processed accelerations and velocities by the band-pass filter using third-order Butterworth type with

the cutoff frequency of 0.1 and 20Hz.

Fig.2 Locations of Seismic Stations Used in this Study.

Table 1 Details of Seismic Stations Used in this Study.

No.	Code	Name	Latitude (N, °)	Longitude (E, °)	Depth of Borehole (m)	Remark

5	KNGH10	YOKOHAMA	35.4991	139.5195	2000	Not on the basement (Suzuki 2002)
6	TKYH02	FUCHU	35.6539	139.4704	2753	

The number of events and periods of earthquake data for each seismic station used in this study are shown in Table 2. The periods of earthquake data are largely different for each station. Distribution of epicenters and focal depths of earthquakes used in this study are shown in Fig.3. SITH01 (Iwatsuki) and CHBH04 (Shimohsa) tend to record earthquakes occurred beneath the northeast of the Kanto area. On the other hand, SITH04 (Tokorozawa), KNGH10 (Yokohama) and TKYH02 (Fuchu) tend to record earthquakes occurred beneath the southwest of the Kanto area. Locations of epicenters for TKYH11 (Koto) have more variety than those for other stations, because TKYH11 is located at the central Kanto area. Furthermore, at SITH01, earthquakes whose epicenters are located in the north of Ibaraki Pref. and Hama-dori of Fukushima Pref. are recorded, due to aplenty of many aftershocks of the 2011 Off the Pacific Coast of Tohoku Earthquake. Earthquakes which are occurred in the northwest of Chiba Pref. and the south of Ibaraki Pref. with focal depths of 40 to 80 kilometers are often recorded in all the stations. Frequency histograms of JMA magnitudes (Mj) of earthquakes for each station are shown in Fig.4. The dataset mainly consists of Mj 3.5 to 5.5 and the majority of the dataset is Mj 4.0 to 4.5 for all the stations.

3. LEAD TIME UNTIL ARRIVALS OF S-WAVES ON THE SURFACE BY ARRIVALS OF P-WAVES IN THE DEEP BOREHOLE

An example of accelerations observed in the deep borehole and on the surface at TKYH02 is shown in Fig.5, respectively. The earthquake whose magnitude and depth of hypocenter are 5.0 and 50km is used. In this case, a time difference between the arrival of P-wave in the deep borehole and the arrival of S-wave on the surface is 10.7s. We count up time differences between arrivals of P-waves in the deep borehole and arrivals of S-waves on the surface for each station using all earthquake data. The result is shown in Fig.6. The lead time of 5s is ensured at least and the average of lead times is about 10s for all the stations. The time differenece depends on the hypocentral distance.

4. EXAMINATION ON PEAK AMPLITUDES OF P-WAVES AND S-WAVES IN THE DEEP BOREHOLE AND ON THE SURFACE

Here, we examine about relationships between S-waves in the deep borehole (S_b) and S-waves on the surface (S_s), P-waves in the deep borehole (P_b) and S-waves in the deep borehole (S_b), using the peak amplitudes of accelerations and velocities.

4.4 Discussion

Correlation coefficients between peak amplitudes, which are R in Fig.7-Fig.12 are shown in Fig.13. The correlation coefficients between peak amplitudes of S_b and S_s are the highest values in the range from 0.8 to 0.9. Those correlation coefficients between peak amplitudes of S_b and S_s may be affected mainly by the S-wave velocity structures beneath the seismic stations. On the other hand, correlation coefficients between peak amplitudes of P_b and S_b are relatively low values in the range from 0.7 to 0.8. Those correlation coefficients between peak amplitudes of P_b and S_b may be affected by radiation patterns of individual earthquakes. Therefore, correlation coefficients between peak amplitudes of P_b and S_s may be affected by both S-wave velocity structures beneath the seismic stations and radiation patterns of earthquakes. For data at 6 stations used in this study, correlation coefficients between PGV of S_b and S_s are higher than those between PGA of S_b and S_s.

(a) PGA

(b) PGV

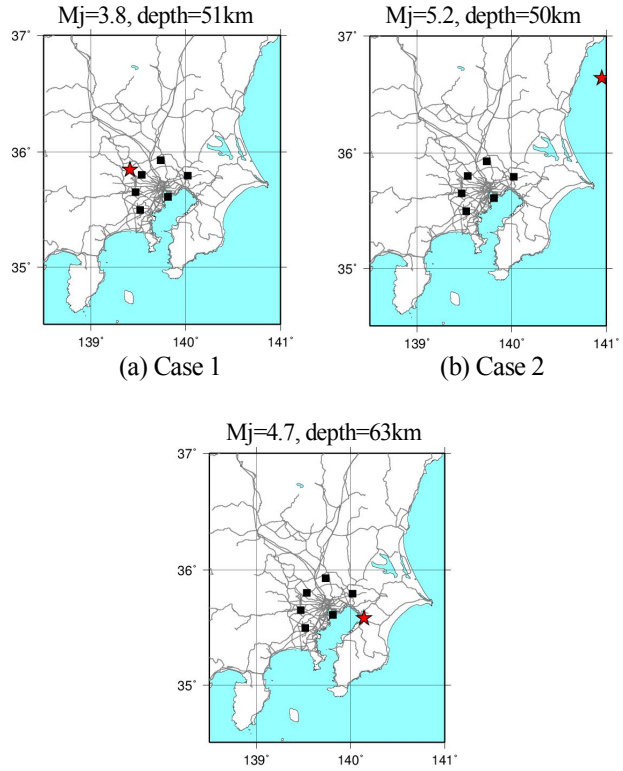
5. RAPID PREDICTIONS OF PEAK AMPLITUDES OF S-WAVES ON THE SURFACE USING THOSE OF P-WAVES OBSERVED IN THE DEEP BOREHOLE

For several earthquakes, we tried to estimate amplitudes of S-waves on the surface using the regression line calculated above. The regression equation is expressed as

$$\log y = a \log x + b \qquad (1)$$

where a and b are parameters determined by least-square method and described in Table 3. Two types of estimations for amplitudes of S_s, which are the two step method by S_b-S_s



and P_b-S_b regression lines and the direct method by P_b-S_s regression line, are considered. Information of earthquakes used in this estimation is shown in Fig.14.

The estimation results of PGA and PGV on the surface are shown in Fig.15 and Fig.16, respectively. Estimation results by both methods are almost same. The misfits between the estimated values and the observed values correspond to the variations between the regression equation and observations (see Fig.7-Fig.12).

6. CONCLUSIONS

To predict the local earthquakes occurred beneath the Kanto region, we performed a basic investigation for the lead time and the accuracy of prediction of ground motions on the surface, using earthquakes recorded in the deep borehole. As a result, we obtain the following knowledges.

1) Time differences between arrivals of P-waves in the deep borehole and arrivals of S-wave on the surface ensure 5s at least and the average of lead time is about 10s.

2) It is effective to estimate S-waves on the surface using the empirical relationship between the peak amplitudes of P-waves in the deep borehole and those of S-waves on the surface.

3) The estimation accuracy of S-waves on the surface are improved using the empirical relationships between peak amplitudes of S-waves in the deep borehole and on the surface.

In the future, we investigate the relationships between the empirical relations obtained in this study and velocity structures / radiation patterns to improve the accuracy of this method.

Abstract: Huge amount of digital data of the Great East Japan Earthquake is provided by the highly-developed digital data delivery system and storage technology. But as of now, the method and/or technique for analysis is not yet satisfactory. This paper proposes a running spectrum technique of text data for the purpose of analyzing changes or trend along the disaster management cycle. For verification of this technique, news reported by the newspaper Fukushima Minpo has been used. The result shows the characteristics of data change in the time domain.

1. INTRODUCTION

Huge amount of digital information related to the Great East Japan Earthquake has been released or published by newspapers, wire agencies and TV stations. The volume of information, by far, exceeds that of past disasters because tools to send out information have dramatically changed: websites, Twitter, Facebook and other Internet-based platforms are now widely used as popular sources for news updates. The contents covered include many different kinds of events and problems that were caused simultaneously by the earthquake. Reports on regional damage induced by the earthquake and tsunami, economical problems in the Tokyo metropolitan area, the Fukushima nuclear power plant accident and much other information spread out at the same time.

By using the cloud computing technology, more and more digital contents can be produced and stored in the digital world. This new innovative environment, incorporating powerful delivery data system and storage capacity, enables us to use information more easily for different purposes. Yet, the quality of data analysis technique in the disaster management field is far from enough. We need efficient means to distinguish important events out of the vast amount of information, to get the grasp of movements within a certain time frame, to know the changes occurring in the disaster management phase and so on.

Some algorithms in document/ literature evaluation method suggest using association rules such as TF-IDF, Z-score and MMI. The association rules and TF-IDF are based on term co-occurrence frequencies, while Z-Score and Mutual Information Measure (MIM) are based on term co-occurrence probabilities [1]. The characteristics of disaster-related-information change or shift in accordance with each disaster management cycle phase, which are namely damage mitigation, preparedness, prediction and early warning, damage assessment, emergency disaster response, recovery, and reconstruction/restoration.

When handling this kind of information with characteristics that depend on time-changing/shifting, it is necessary to make analysis within a certain time span. Therefore, we propose a dynamic analysis technique of document/literature/text with considerations on time series to offer proper and appropriate responses. This paper shows the overview of proposed techniques. News from the newspaper Fukushima Minpo has been used for its verification. The proposed technique is a powerful tool to effectively analyze the huge amount of digital data, thereby responding to the upcoming society with growing volume of information.

2. RUNNING SPECTRUM ANALYSIS OF TEXT DATA

2.1 Running spectrum analysis

Running spectrum analysis is a method widely used in the seismic ground motion analysis for understanding the wave characteristics in time and frequency domain. It is an approach that shifts a time interval as the analysis point to conduct analysis within a certain time frame. In our research, the target is further expanded to the document/ literature/ text field. Moving-average method is used for dynamic analysis (see Figure 1).

2.2 Flow of text data running spectrum analysis

Figure 2 shows the flow of running spectrum analysis text data proposed in this research.

Firstly, Japanese Kanji letters, Katakana letters,

numbers and alphabets are extracted from the documents separately as keywords. For this purpose, we have developed an "extract-keyword-program (EKP)". The EKP can extract each keyword individually and accurately. For example, “hinan” (“evacuation” in English) and “hinansya” (“evacuee” in English) are identified as different keywords within the same document. The EKP can also count the frequency of appearance within one certain day or all the days during the specified period. Users can freely reset the period depending on purposes.

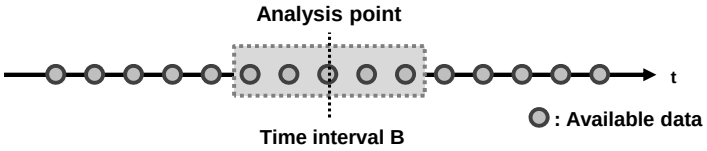

Figure 1 Time interval B of moving average method

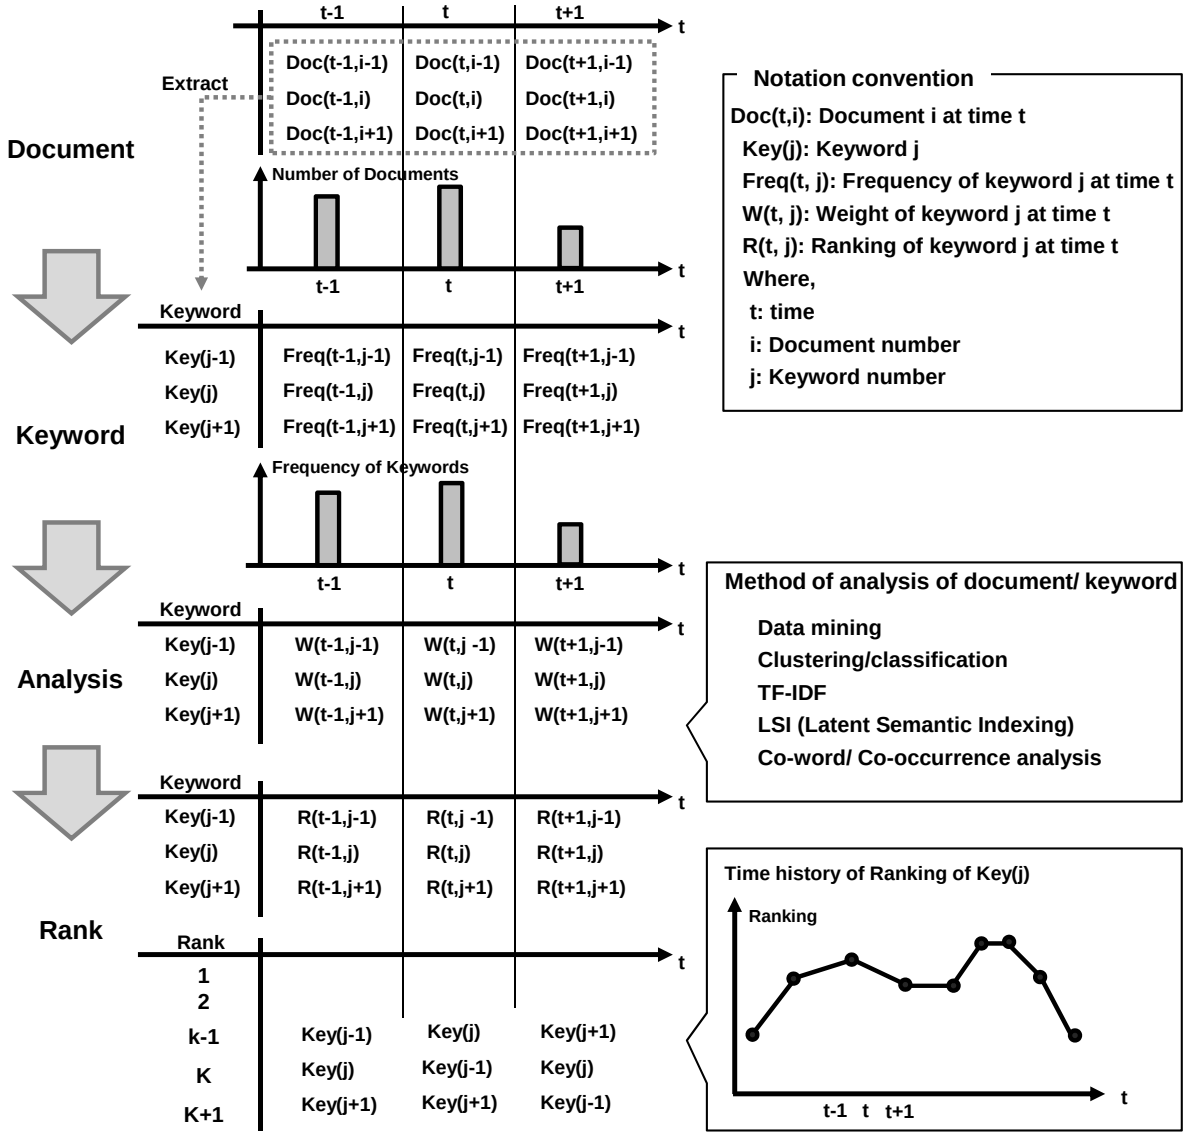

Figure 2 Flow of running spectrum technique

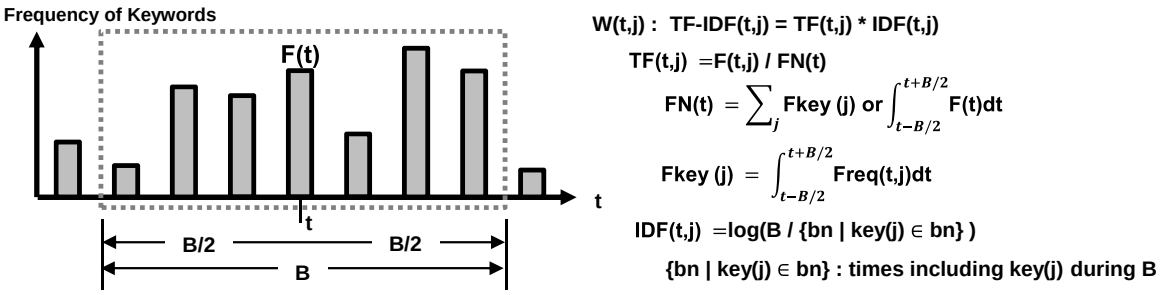

Figure 3 TF-IDF of running spectrum technique

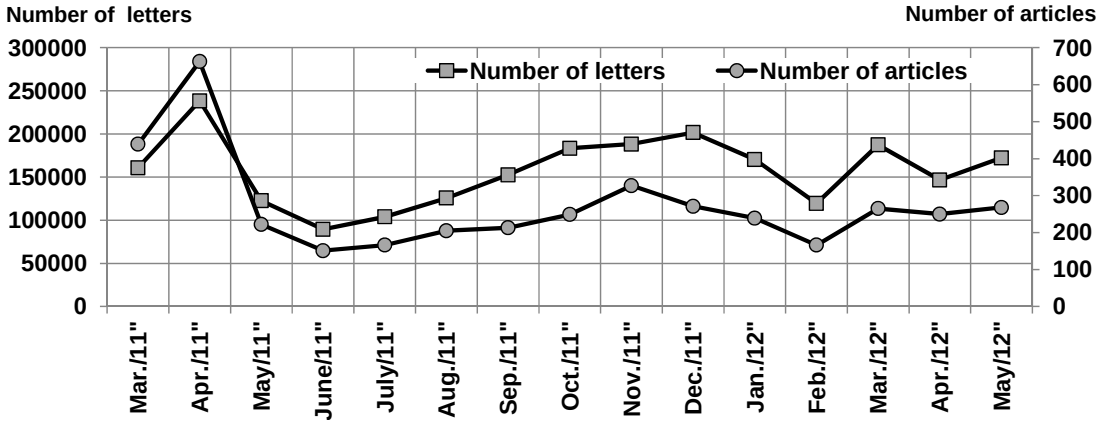

Figure 4 Archives of Fukushima Minpo newspaper

Secondly, keywords are reviewed and analyzed. The weights of all extracted keywords are calculated, respectively. Suggested algorithms for keyword analysis are: Clustering, TF-IDF, LSI, and Co-occurrence. Our proposed system can choose the most suitable weighing approach according to the purposes and requirements of each user. In this paper, we have used TF-IDF (Term Frequency-Inverse Term Frequency) in the time span B for verification as shown in Figure 3. TF-IDF is a statistical measurement method to evaluate the degree of importance of a specified keyword in a document among a collection of numerous documents. The importance level is determined by the frequency and distribution within the collection of all documents [1].

Thirdly, after the evaluation of the importance of each keyword in certain time span B, all keywords are ranked according to its weights.

3. CASE STUDY OF FUKUSHIMA MINPO NEWSPAPER

3.1 Newspaper data

Fukushima Minpo is a local newspaper, with circulation of 250 thousand copies per day, the largest in Fukushima Prefecture [2]. This paper repeatedly reports on nuclear power plant accidents as the company office is located near the site. Figure 4 shows news report archives from March 2011 to May 2012, analyzing articles by the running spectrum approach described above.

3.2 Extracting keywords

Figure 5 shows the number of keyword items and its frequency. A total of 67,881 different keywords have been extracted. Frequency is shown as “1” in 44,022 items (64.85% of the total), indicating that the keyword appears only one time. Most newspaper articles report the name, gender and age of those dead or injured, therefore the number of keywords with only one-time appearance equals the number of items.

Figure 6 represents keywords with high frequency. “Refuge” is listed as the most frequently used keyword with 1,696 appearances, followed by “residents” with 1,614 times over the period from March 2011 to May 2012. Keywords related to nuclear power accidents such as “decontamination”, “nuclear power plant accident”, “influence”, “radioactive material”, “children”, “dose of radiation” etc. are ranked high. In this case study, one-letter words have been omitted because the keyword alone often has no meaning by itself and therefore should be interpreted within idioms, phrases and contexts.

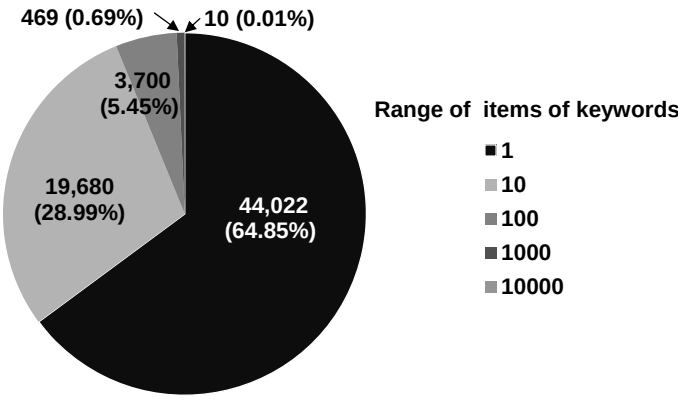

Figure 5 The number of keyword items and its appearance within a certain range

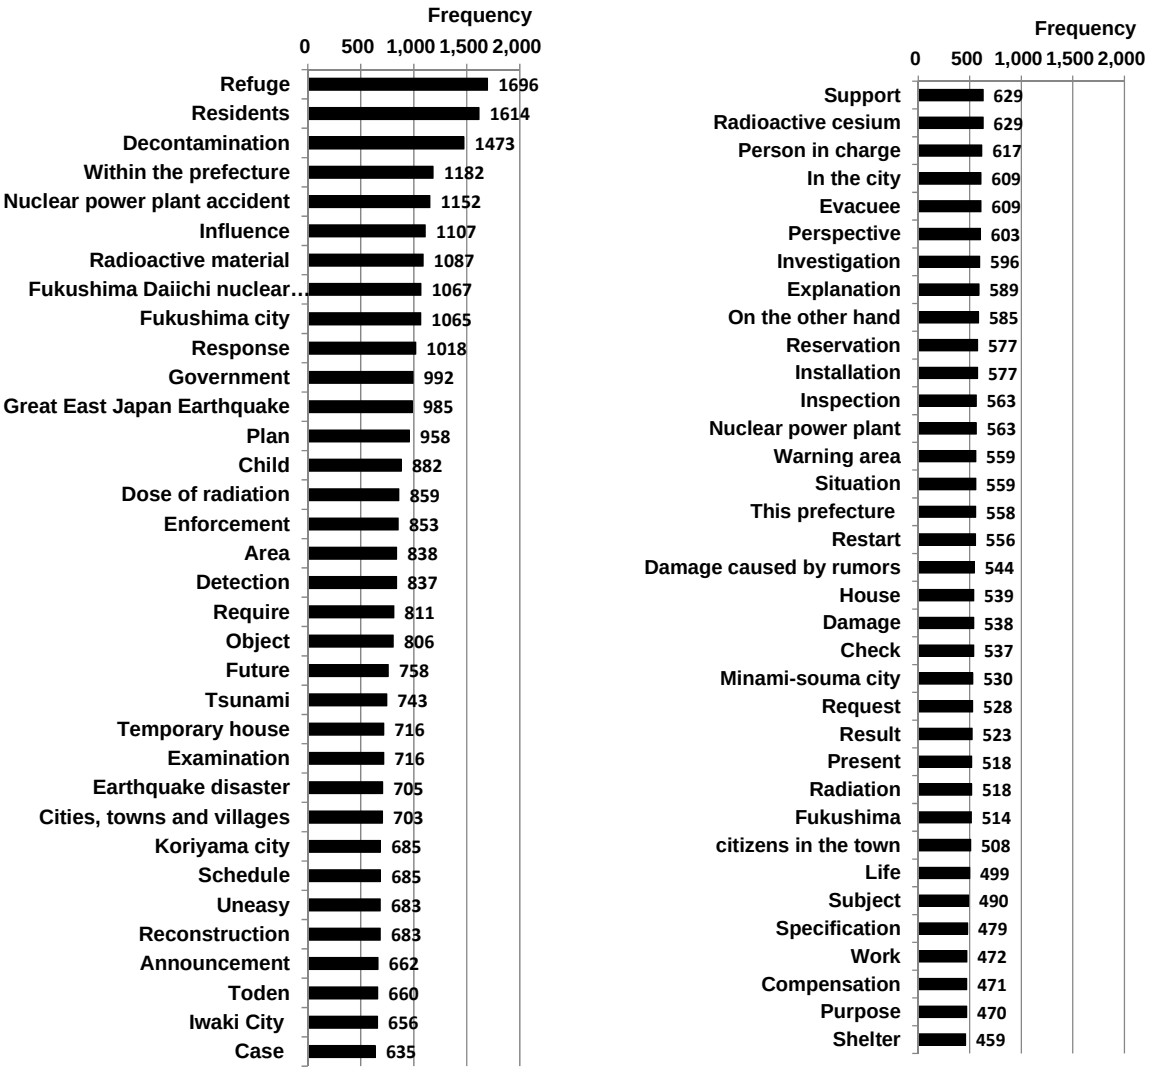

Figure 6 List of Keywords and its appearance frequency (high frequency part)

3.3 Results of running spectrum analysis

By using the proposed analysis technique, all keywords have been ranked respectively according to the results of a weighting algorithm on daily or monthly level, and have been listed in order of the ranks. We get to understand which keywords received attention at the time, also tracing down the hottest keywords changing with the circumstances of the moment.

1. *Time-chart of the top ranked keywords*: Table 1 shows the time chart of the top three ranked keywords in March 2011 as a sample period for B =3, 7 and 31 days respectively due to space limit of paper.

Table 1 Time chart of ranking of keywords: The number of each keyword shows the ranking in a day

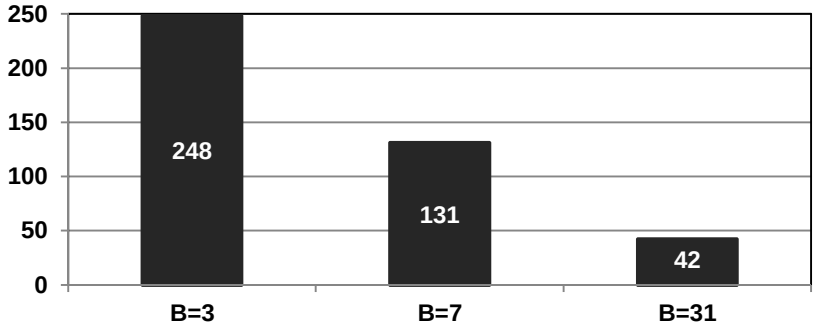

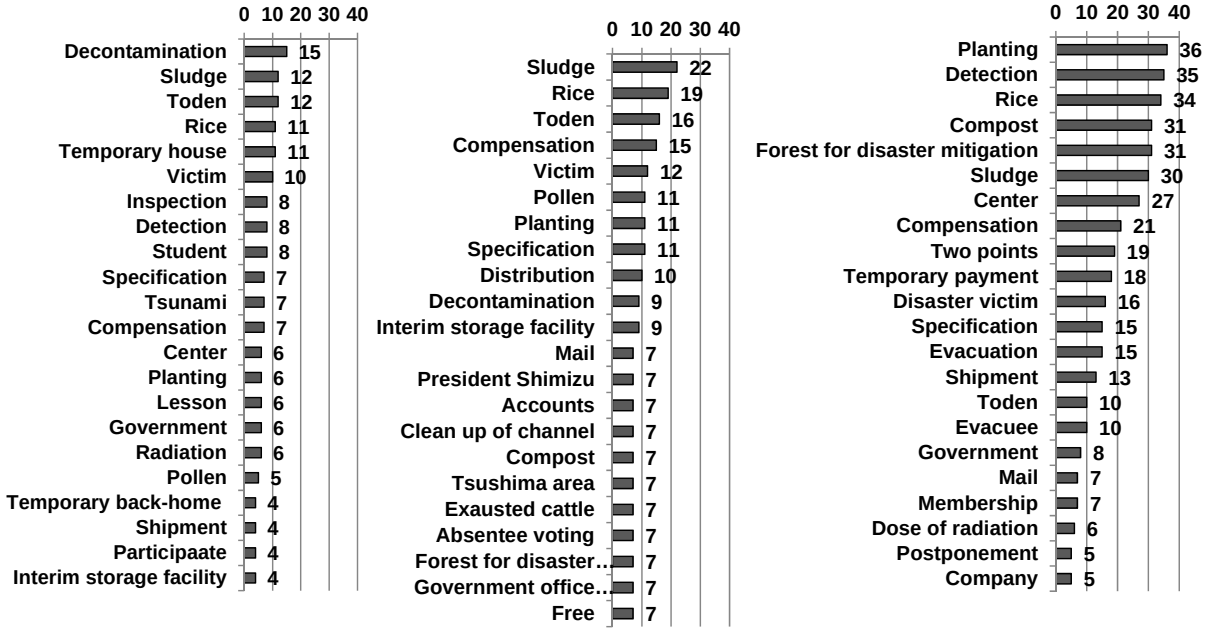

Figure 7 Comparison of items of keywords ranked No.1.

(a) B=3 (b) B=7 (c) B=31

Figure 8 Keywords ranked as No.1 and its frequency

Taking a look at the B=3 cases, frequently used keywords in this emergency period immediately after the quake include “tsunami”, “evacuation”, “disaster victim” and “debris”. “Blanket” was another important word since the earthquake occurred during the winter season and blankets were strongly required by the evacuees. On March 19th, due to worries about the spread of radiation from the nuclear power plant accident, the word “pregnant” was seen for the first time, On March 30th, “temporary home return” was ranked top. This was when the evacuees who had to leave their hometown for fear of radiation were allowed to pay a brief visit home just to bring their valuables.

The B=7 case, which is similar to the B=3 case, covers the time when the earthquake hit. Keywords described as emergency terms such as “tsunami”, “evacuation” and “debris” are seen. On March 16th and 17th, “pregnant” was ranked top indicating the serious concerns of radiation by pregnant women as in the B=7 case. As for B=31, “evacuation” and “refuge” were the most used keywords for some days during emergency period. From March 22nd, “election” was ranked high because the nationwide local elections in April were also another issue of attention.

2. *Effect of different time interval B*: Comparing the short and long time intervals in terms of “B” , we see that top ranked keywords change day by day in B=3 (in which the target time interval days are shorter). On the other hand, some specific keywords, such as “evacuation”, “refugee”, “acceptance” and “election”, tend to be ranked higher in the longer time intervals.

Table 2 Time-history of keywords that ranked as No.1 with its frequency

		B=3		B=7		B=31	
Year	Month	Keyword	Number of No.1	Keyword	Number of No.1	Keyword	Number of No.1

		Personnel	3	Pollen	4	Exausted cattle	5
	5	Cherry blossom	3	Sludge	7	Detection	23
		Sludge	3	Yanagisawa	7	Sludge	8
		Subsidy	3	Buying credit	4	–	–

Therefore, as the time interval B becomes longer, the analysis data is used from wide range period along with the smoothing effect.

The characteristics of the duration effect of time interval B can be explained by how many kinds of keywords were ranked No.1 at least once as shown in Figure 7. When observing different time intervals B = 3, 7 and 31 days, fewer keywords have been ranked in the longer time intervals of B. For example, the B=31 case shows only 42 kinds of keywords ranked No.1 while the B=3 case shows as many as 248.

3. *Keywords ranked No.1*: Figure 8 shows the keywords which were ranked No.1, and how many times the keyword has reached the No.1 position. The most frequently ranked as No.1 include: “decontamination” with 15 times for B=3 days, “sludge” with 22 times for B=7 days and “planting” with 36 times for B=31 days. From this result, we see that specific keywords were constantly listed high for the longer B due to the effect of soothing.

Table 2 shows the time-history of keywords that remained No.1 for a month. By reviewing this table, we can observe the timeline of events. Unfortunately, only the top three are shown in this table due to the limitation of paper space even though many keywords remained in the No.1 position for a month. Let us focus on the B=31 case as we look at the top keywords of the months in chronological order. “Evacuation” was the most important keyword in

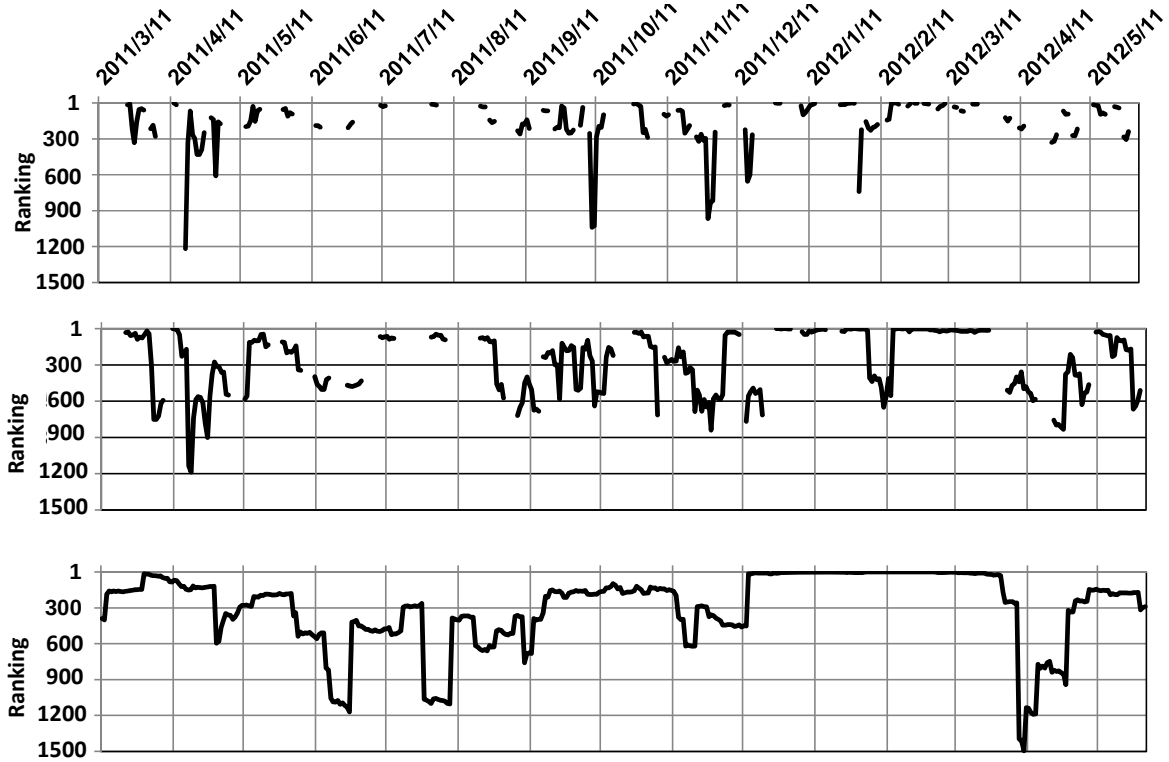

Figure 9 Time history of ranking of "Planting" (Top: B=3, Middle: B=7, Bottom: B=31)

March 2011, followed by "disaster victim" (April), "temporary payment" (May), "sludge" (June), "specification" (July), "compensation" (August), "two points" (September), "forest for disaster mitigation" (October), " compost" (November), "rice" (December). Moving onto 2012, "rice" (January), "planting" (February), "center" (March) and "detection" (April and May). By following the top keywords, we can see the outline and the stream of this complex disaster despite the intertwined problems and difficulties.

4. *Trend of each keyword*: This system also helps us see the trend of specific keywords that a system user might take interest in. Figure 9 shows the time history of the word "planting." The case B=3 shows high discontinuity, while continuity is clearly shown in B=31 due to the soothing effects. From around October 2011, the problems related to "planting" constantly emerge as shown in the B=31 case.

4. KEYWORD TIME CHART DATABASE

All results analyzed by this technique are collected into the database. A keyword, with its time history of weight value, can be easily and quickly searched by category and immediately visualized. The six categories: time, place, actor, society, space and event are prepared by the following WBS (Work Breakdown Structure) methodology. If you are interested in the trend of keywords related to society, the database can show the time history of the related keywords. "Planting" in Figure 9, belonging to the "society" category, suggests that a serious problem lies ahead in growing new rice and other farm products due to the nuclear power plant accident. The transition of ranking positions can also be visualized in graphs and charts.

5. CONCLUSIONS

We have proposed the running spectrum system for analyzing text data in the advanced society that has digital data delivery and storage environment. The news reported by Fukushima Minpo newspaper is used for the verification of the technique. The result shows the dynamic characteristics of the data that change in the time domain. As time goes on, more digital data/information on natural disasters will become available. Then, the proposed technique serves efficient and effective to analyze huge amount of digital information, thus providing appropriate understanding of the events and occurrences in chronological order.

Abstract: A comprehensive study was conducted to identify the impact of the 2011 Tohoku tsunami disaster and to understand the lessons towards the reconstruction of Tohoku to build tsunami-resilient community. Through an integrated investigation by field measurement, remote sensing and numerical modeling approaches with on spatial information sciences, the results lead to an implication for land use management and relocation planning to reconstruct tsunami-resilient coastal communities.

1. INTRODUCTION

On 11 March 2011, a devastating tsunami accompanied with M9.0 earthquake attacked the northern Pacific coast of Japan (Tohoku), and the coastal communities especially in Iwate, Miyagi, and Fukushima Prefectures were totally devastated. The total affected area by the tsunami was reported as 561 km2 along the Pacific coast of Japan (GSI, 2011), and the maximum tsunami run-up height reached up to 40 m in Iwate Prefecture (Mori et al., 2012). As of 27 June, 2012, National Police Agency reported 15,866 dead (4,671 in Iwate, 9,523 in Miyagi, and 1,606 in Fukushima) and 2,946 missing, 130,441 buildings/houses were collapsed or washed-away (National Police Agency, 2012). The economic impacts were estimated as 16 to 25 trillion yen (Cabinet Office, 2011), while FY2011 national budget of Japan was 92 trillion yen (Ministry of Finance Japan, 2011).

Having passed almost two years since the event occurred, the devastated areas have started moving forward to reconstruct their communities. Though the recovery process is still underway, local governments completed the draft of reconstruction plan including infrastructure design, transportation, land use management, urban design, relocation, and economic and industrial outlooks. This paper aims to summarize the impact of the 2011 Tohoku tsunami disaster with particular regard to structural damage, to understand the lessons towards reconstruction of Tohoku region. To identify the tsunami impact, we conducted an integrated studies of field measurement and aerial photo inspection with the approach of spatial information sciences. The findings lead to understandings structural vulnerability against the 2011 tsunami and to provide an implication for land use management and relocation planning to reconstruct resilient coastal communities.

2. MAPPING STRUCTURAL DAMAGE AND VULNERABILITY

2.1 Visual inspection of aerial photos

We conducted an effort of mapping structural damage through visual interpretation of aerial photos to identify the structural vulnerability against the 2011 tsunami. For visual inspection, we used the aerial photo archives of Geospatial Information Authority of Japan acquired in the devastated area (GSI, 2011b). The ortho photos of 80 cm/pixel resolution were composited with mosaic image processing. Combined with the ZENRIN building data (building shape files), the inspection was conducted for each building, by comparing pre- and post-tsunami aerial photos focusing on the existence of houses' roofs to add an attribution of classification "washed-away" or "surviving" as the damage status.

Figure 1 shows an example of the classification in Yuriage, Natori city. The result of mapping of structural damage in Miyagi Prefecture is summarized in Table 1 and the mapping results are on our web site (www.tsunami.civil.tohoku.ac.jp) to be used for field survey, land use management to understand vulnerable areas and reconstruction planning. Combined wit the results of mapping inundation zone, structural damage classification results enable to determine the number of exposed structures, then calculate P_D, as the proportion of the number of structure classified as "washed-away" and the number of exposed structure. Table 1 implies that almost 30 % of the structures in the tsunami inundation zone in Miyagi Prefecture were devastated and high proportion of devastated buildings are concentrated in the northern part of Miyagi Prefecture (Sanriku region). Sanriku coastline is particularly vulnerable to tsunamis, because it has many v-shaped bays that cause tsunami energy to converge and

amplify. In addition, the death ratio, which was obtained as a proportion of the number of death and exposed population, shows the correlation of with P_D.

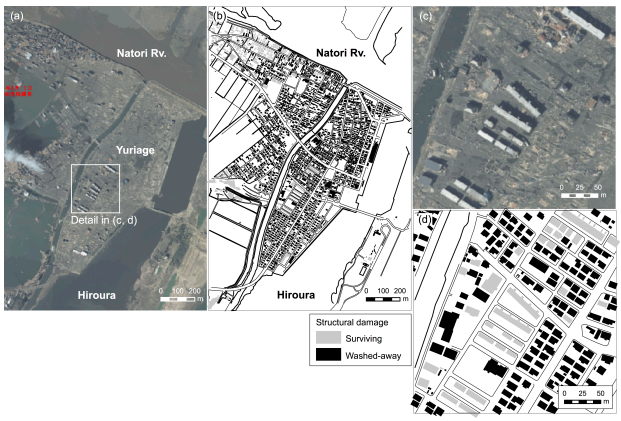

Figure 1 Example of mapping structural damage in Yuriage, Natori city, by inspection of post-event aerial photos.

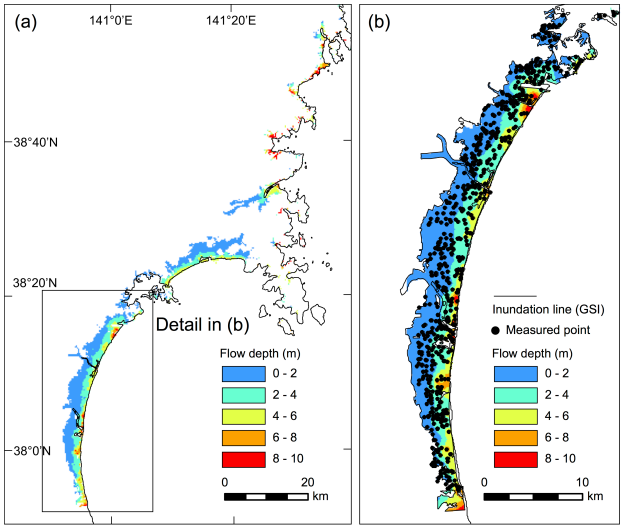

Figure 2 Mapping the tsunami flow depth measured by Miyagi Prefectural government and our survey team (Abe et al, 2011). Black dots indicate the measured points.

2.2 Structural vulnerability and tsunami fragility curves

Integrating structural damage mapping with field survey data, such as flow depths, lead to a new measure of identifying structural vulnerability against tsunami, as a form of tsunami fragility curve or tsunami fragility function. Tsunami fragility curve is defined as the structural damage probability or fatality ratio with particular regard to the hydrodynamic features of tsunami inundation flow, such as flow depth, current velocity and hydrodynamic force (Koshimura et al., 2009a).

Figure 2 shows the spatial distribution of flow depths measured in tsunami inundation zone. Spatial interpolation of measurement data (point data) to obtain raster data is combined with the structural damage mapping (Figure 1). The procedure of developing tsunami fragility curves is as follows.

1. Damage data acquisition: obtaining damage data from aerial photo interpretation.
2. Tsunami hazard estimation: estimating the hydrodynamic features of tsunami by field measurement.
3. Data integration between the damage data and tsunami hazard information: correlating the damage data and the hydrodynamic features of tsunami through the GIS analysis.
4. Calculating damage probability: determining the damage probabilities by counting the number of damaged or survived structures, for each range of flow depths.
5. Regression analysis: developing the fragility curves by regression analysis of discrete sets of damage probability and hydrodynamic features of tsunami.

Taking above procedure, the tsunami fragility curve is preliminary obtained as shown in Figure 3. The fragility curve shown in the figure indicates the damage probabilities of structural destruction equivalent to the flow depth. Structures in Miyagi Prefecture were especially vulnerable when the local flow depth exceeded 2 m, and 6 m flow depth would totally cause total devastation. This fact leads to a lesson to determine the land use plan which considers the effect of coastal protection.

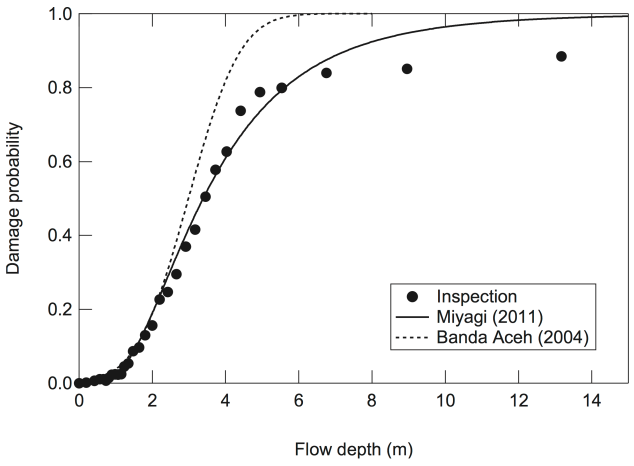

Figure 3 Tsunami fragility curve for structural destruction (washed-away). The solid line is obtained from Miyagi Prefecture (2011 event) and the dashed one is from Banda Aceh, Indonesia (2004 Indian Ocean tsunami).

3. EVALUATION OF RECONSTRUCTION PLAN

In April 2011, one month after the event occurred, the central government established the reconstruction policy council to develop a national recovery and reconstruction outlook for tsunami-resilient community. Besides, the central government decided the policy of coastal protection such as seawalls and break waters, which would be designed to ensure their performance to potential tsunami level of approximately 150 year recurrence interval. In this sense, the government policy of designing coastal protection is for

150-year tsunami level (this is called "Prevention Level") which ensures to protect lives and properties. And for the tsunami level more than 150-year recurrence interval, so-called extreme event, the government calls "Preparedness/Mitigation Level" to reduce the losses and damage by all of the efforts of coastal protection, urban planning, evacuation, and public education.

When the proposed reconstruction plan should be verified, numerical model becomes a powerful tool. Figure 4 shows the result of numerical modeling of the 2011 tsunami inundation in Sendai city (Maximum flow depth) based on the non-linear shallow water theories (Koshimura et al., 2009b). After the event occurred, the authors attempted to understand how the tsunami inundated to the Sendai coast by the tsunami inundation modeling using a 10 m topography grid, with a tsunami source model proposed by the authors. As shown in the figure, the tsunami penetrated more than 5 km inland to have caused devastation on the coast and to be consistent with the observed tsunami inundation extent. After several aspects of validations (Koshimura et al., 2009b) the tsunami numerical models can be used for evaluation of reconstruction plans from the view point of tsunami disaster mitigation.

Under the limitations and uncertain conditions of funding, prefectural and local governments have developed their own recovery and reconstruction plans, which assume 10 years to be completed. These plans consist of the combination of structural prevention/mitigation, urban planning, preparedness, and suggest their land use management, relocation, housing reconstruction and tsunami disaster mitigation plans. The key role of academia, in engineering point of view, is to verify and evaluate if these plans really work for future disaster reduction. For instance, based on the findings regarding the structural vulnerability (see Figure 3), Sendai city determined a reconstruction plan (Sendai city, 2011) to reduce the tsunami flow depth less than 2 m in the populated area with a conceptual image of multiple coastal protection (Figure 5). A significant feature of the Sendai city's reconstruction plan is integrating several coastal protection facilities such as seawalls, coastal forests, park (artificial hill) and elevated roads to minimize the potential losses. Figure 6 indicates the plan view of the multiple protection of Sendai city with a 7.2 m seawall and river dike and 6 m elevated prefectural road.

The authors conducted a tsunami numerical modeling under the 2001 tsunami source scenario, by incorporating the reconstruction plan, to evaluate how these protections will work in terms of tsunami reduction. Figure 7 shows one example from preliminary results. As indicated in the figure, we found that the multiple protection will contribute on substantial reduction of the tsunami inundation zone, and flow depth on Sendai plain especially at the western side of 6 m elevated prefectural road. Using this result, Sendai city determined the land used plan and the area of housing reconstruction and relocation. However, note that the tsunami (the 2011 scenario) will overtop even 7.2 m seawall and the 6 m elevated road. Here, the model assumes no destruction of structures. In this sense, the model cannot reproduce all the aspects of tsunami inland penetration. Coastal infrastructure such as breakwaters and seawalls cannot always protect life and property. Seawalls or coastal structures should be designed with the assumption of overtopping and resiliency, and communities should not rely on coastal infrastructures alone for protection.

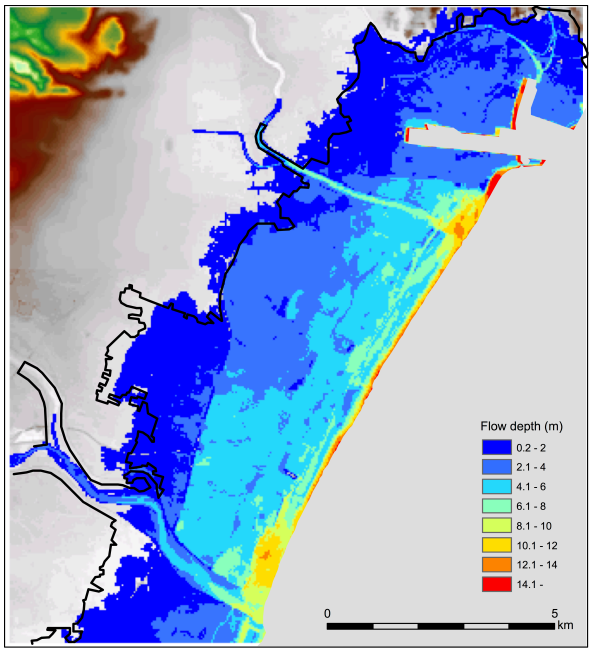

Figure 4 The result of numerical modeling of the 2011 tsunami inundation in Sendai city (Maximum flow depth). Black solid line is the tsunami inundation extent obtained by GSI (GSI, 2011b).

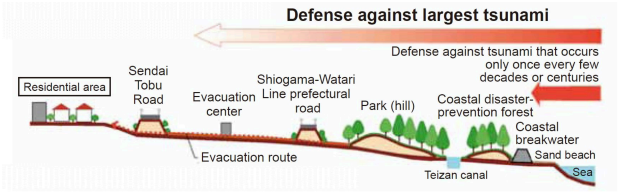

Figure 5 Conceptual image of tsunami-prevention facilities in Sendai city (Sendai city, 2011).

4. SUMMARY

Throughout the comprehensive studies based on the remote sensing, numerical models and spatial information sciences, the authors summarized the impact of the 2011 Tohoku earthquake tsunami disaster and discussed the lessons towards the reconstruction of Tohoku region. The 2011 event offers valuable lessons that should be applied, in order to build safer and more resilient coastal communities.

As observed in the devastated areas in Miyagi Prefecture, the tsunami flow depth over 2 m has potential to severely damage houses, and more than 6 m flow depth will cause total devastation. This finding can inform land use planning (zoning) or one goal of comprehensive tsunami disaster mitigation, so that residential areas will not be inundated more than 2m.

Since the 1896 Meiji Sanriku earthquake tsunami that killed 22,000 people, the 1933 Showa earthquake tsunami and since the more recent 1960 Chilean earthquake tsunami, Tohoku region has developed the coastal protection infrastructure of seawalls and breakwaters that have never been devastated throughout the history since 1934. Again, we need to note that coastal infrastructure cannot always protect life and property: even great seawalls may fail. Seawalls should be designed with the assumption of overtopping and resiliency, and communities should not rely on coastal infrastructures alone for protection.

3) Division Head, National Center for Research on Earthquake Engineering, Taiwan
4) Post-Doc, Department of Earth Science, National Central University, Taiwan

Abstract: Detailed shallow velocity structure was very important for site effect study. One of the most accurate but expansive ways was P-S logging measurement from boreholes which could give us not only Vs30 to classify site class but also detailed velocity structure including P and S wave (Kuo et al. 2012). However, this technique was usually hard to widely obtain due to economy consideration for construct large amount of high cost boreholes. Otherwise, free field strong motion stations were much more densely than boreholes in Taiwan that give some chance to calculate transfer functions in many ways. From mid-later of 20th century, transfer function from spectral ratio method between rock and soil site started to consider site effect. Microtremor (Nakamura 1989) and earthquake H/V spectral ratio (Lermo and Chávez-García 1993) as a transfer function than became popular on late 20th century. Wen and Huang (2012) constructed a dense microtremor survey in whole Taiwan except mountain region which possible could apply to this objective. In this study, the characteristic comparison of above three methods was made to discuss the spectrum difference in many cases in Taipei basin.

1. INTRODUCTION

Taipei basin is one of the most important regions in Taiwan, over two million people lives in Taipei city which was the capital of Taiwan. Strongly site effect occurred in here due to deeply sedimentary basin environment which could induce highly seismic risk during large earthquake. For instance 1999 Chi-Chi, Taiwan and 2002 March 31 earthquake caused some disasters in Taipei basin which hypocenter distance was about 100 km far. Ground motion was enlarged and peak motion was higher than closer hypocenter distance region such as Taoyuan County from site amplification effect. Directly underneath earthquake below Taipei basin also been taken seriously recent year since Sanchiao fault was redefined as a secondary activity fault (Lin et al. 2007).

Traditionally attenuation equation was widely used to predict peak ground motion including acceleration (PGA), velocity (PGV), Fourier amplitude spectrum (FAS), acceleration response spectra (SA), velocity response spectra (SV) and displacement response spectra (SD) etc. for engineering purposes. Seismologists tried hard to provide fully time history from simulation technique that attenuation equation can't afford it. But peak motion was usually in high frequency band (>1 Hz) that need detailed shallow velocity structure to obtain.

One convenient wide frequency simulation tool call stochastic method (Beresnev and Atkinson 1998, Motazedian and Atkinson 2005, Boore 2009) can provide acceptable high frequency (up to 10 Hz) behavior for rock sites. Precisely frequency spectrum could be obtained if the accurate transfer function was considered.

One of the most accurate but expansive ways to derive shallow velocity structure was from P-S logging measurement from boreholes which could give us not only Vs30 to classify site class but also detailed velocity structure including P and S wave (Kuo et al. 2012). There were totally 68 strong motion stations been measured with about 5-10 km interval in Taipei basin (Figure 1).

Taiwan Strong Motion Instrumentation Program (TSMIP) had operated 119 strong motion stations since 1991 and collected several hundred earthquakes in Taipei region. The plentiful earthquake database could help to understand site effect in the basin. In mid-later of 20th century, spectral ratio between horizontal spectrum in soil site and reference rock site (hereafter denoted as H/H ratio) started to estimate site response (Borcherdt 1970). However, good reference rock site was not easy to find in many regions. Microtremor H/V (Nakamura 1989) and earthquake H/V spectral ratio method (Lermo and Chávez-García 1993) than become popular. Dense microtremor survey was completed with 589 measure points and 0.5 km interval in whole Taipei basin (Wen and Huang 2012) which provide detailed site information for whole basin.

In this study, spectrum difference between H/H, H/V, microtremor H/V and from Stochastic Method Simulation (SMSIM) was identified in order to apply these transfer functions to wide frequency simulation technique. Precisely shake map prediction and frequency behavior even full time history could be provided in the future.

2. METHODS AND DATA PROCESSING

2.1 Database

Seismic data used in this study were recorded at strong motion stations in Taipei basin of TSMIP from January, 1991 to December, 2009. Magnitude collect here was less than Mw 6.0 (3.65-5.98, total number of earthquakes: 333) to deal with simple source condition. Hypocenter distance from 14 to 309 km. Earthquake hypocenter most located eastern Taiwan and some 1999 Chi-Chi aftershock in central Taiwan (Figure 2).

2.2 H/H Spectral Ratio Method

Earthquake response could divided into source, path and site effect. The equation could express as follows:

$$\mathrm{R(f)} = S_0(f) \times P(f) \times S_i(f) \tag{1}$$

which R(f) was frequency spectrum of strong motion record, S_0(f) means source, P(f) means path and S_i(f) means site effect. When there were two closer stations with different site condition (i.e. rock and soil) and which were far from the hypocenter during earthquake. Source and path effect were almost the same and could eliminate to understand site effect:

$$\frac{R_s(f)}{R_r(f)} \approx \frac{S_{is}(f)}{S_{ir}(f)} \tag{2}$$

Rs means frequency spectrum of soil site and Rr means reference rock site.

Finely reference rock site was hard to obtain due to outcrop surface station usually accompany with thin regolith layer which could induce some amplification in different frequency band. Another problem was even large amount earthquake occurred but rock site usually hard to trigger than induce lack of data to analyze.

2.3 H/V Spectral Ratio Method

Spectral ratio from single station was developed through microtremor measurement in down-hole seismometer (Nakamura 1989). Vertical amplification motion A_s(f) was treated as a part of source effect and needed to eliminate from site consideration.

$$A_S(f) = \frac{S_V(f)}{B_V(f)} \tag{3}$$

where S_v was vertical spectrum of surface soil site and B_v was borehole rock site. Traditional H/H ratio S_E(f) could describe as:

$$S_E(f) = \frac{S_H(f)}{B_H(f)} \tag{4}$$

where S_H showed horizontal spectrum of surface soil site and B_H showed reference rock site. Divided Eq. (3) to (4):

$$S_M(f) = \frac{S_E(f)}{A_S(f)} = \frac{\frac{S_H(f)}{B_H(f)}}{\frac{S_V(f)}{B_V(f)}} = \frac{\frac{S_H(f)}{S_V(f)}}{\frac{B_H(f)}{B_V(f)}} \tag{5}$$

Nakarura (1989) found $\frac{B_H(f)}{B_V(f)}$ will within unity and simplify Eq. (5):

$$S_M(f) \approx \frac{S_H(f)}{S_V(f)} \tag{6}$$

which means site effect could find from microtremor data of single surface station.

Lermo and Chávez-García (1993) stretched H/V technique to shear wave part of seismogram in Mexico and prove the spectrum was consistent with H/H ratio.

2.4 Transfer Function From Stochastic Method Simulation (SMSIM)

Stochastic modeling technique first assumed the average spectrum of each part of seismogram will follow ω^2 model (Boore 1983). For acceleration spectrum A(ω) of rock site (didn't consider site effect):

$$A(\omega) = 2\omega^2 S(\omega) P(\omega) e^{-\omega R/2QB} \tag{7}$$

where ω: angular frequency, S: source spectrum which followed Brune (1970), P: path attenuation spectrum, R: hypocenter distance, Q: quality factor.

Stochastic modeling technique was developed including two different source type (point source and finite-fault) to deal with simple and complex source problem. In this study, point source approach was used to consider site effect in Taipei basin using small earthquake (Mw<6.0).

2.5 Data Processing

Strong motion records in Taipei basin were firstly eliminated higher peak ground acceleration (PGA) that only keeps PGA less equal to 60 gal in our database to avoid possible non-linear site response (Wen et al. 2006) in transfer function calculation. Magnitudes of earthquakes were set an upper bound Mw6.0 for transfer function calculated from SMSIM.

Shear wave part of acceleration records of each site was cut through a window function which window length set on 10.24 sec. for H/H, H/V and SMSIM transfer function in this study. Five percent cosine taper was obtained in front and

final portion for window function to avoid frequency leakage from truncation of time history. Afterward, cut window of S wave portion was transformed to frequency domain and applied five times smoothing for whole frequency content. North-south and East-west component were root-mean-squared (RMS) to obtain horizontal spectrum. Finally, horizontal spectrum from soil site divided to spectrum from rock give us H/H ratio and horizontal divided to vertical spectrum obtain H/V ratio (see flow-chart in Figure 3). Station TAP071 was selected to be reference rock site for H/H ratio due to the average H/V ratio was flat (Figure 4), site class was B (velocity of top 30 meter, VS30 was 831 m/s) and located on the edge of basin which could represent outcrop of Taipei basin.

Figure 5 was flow chart of constructed transfer function of SMSIM and parameter show in table 1. Average motion of 11 rock site (site class B) for SMSIM were calculated first (black bold dash line in Figure 6) and treated it as reference rock site for calculating basin response. Afterward, transfer function from each single strong motion (soil site) was computed, general transfer function for each site class could find from averaging all the transfer function from stations with same site classification (Figure 6). Detailed of constructed transfer function of SMSIM and the application could find from Wen et al. (2013).

Microtremor H/V ratio was collected from Wen and Huang (2012), measure points which was close to strong motion stations was selected to be comparison in this study.

3. RESULTS AND DISCUSSIONS

3.1 Comparison of Four Kinds of Transfer Functions

Four kinds of transfer functions were compared for totally 65 strong motion stations in Taipei basin. Figure 7 showed the examples for different site condition. The frequency with highest ratio was selected as dominant frequency for each spectrum (circles in Figure 7). Degree of Spectrum Difference (DSPD) was assumed to quantitatively describe difference between each spectral ratios, the equation was as followed:

$$DSPD = \sum_{0.2}^{10} \left(\left| \log_{10} \left(\frac{SP_1}{SP_2} \right) \right| * df \right) \qquad (8)$$

where SP_1 and SP_2 means two spectrum whom been compared (Denoted on Figure 7, four pairs of DSPD were calculated including earthquake H/V vs. microtremor H/V; earthquake H/H vs. H/V; earthquake H/H vs. microtremor H/V and H/H vs. SMSIM). df was sampling frequency. DSPD value could explain area between two spectral ratios on the figure. For these example stations, dominant frequencies and whole trend were similar from four kinds of method but amplification ratio had some difference especially compared to H/H ratio. The amplitude of H/H ratio usually small then the others seems due to spectrum of reference rick site TAP071 were not flat enough and values not close to 1 (Figure 4). But good reference rock site was hard to obtain confined with geology distribution in Taipei basin. Maybe H/H ratio was not easy to obtain in this region. Otherwise, Earthquake H/V had a good agreement with microtremor H/V in this study (with average 1.81 DSPD for all stations, Table 2), which means microtremor H/V mad good ability to explain site response and could applied in some location didn't have strong motion stations or didn't have enough seismic records. Simultaneously, due to the processing of transfer function of SMSIM was similar with H/H ratio, their value of DSPD were rather small (with average 1.74 DSPD for all stations, Table 2).

3.2 Space Difference of DSPD in Taipei Basin

Spectrum difference was larger between H/H, H/V and H/H, Micro H/V especially in site class B and C (Table 2). Distribution of spectrum difference in space was considered in this section (Figure 8). Large value of DSPD of H/H vs. H/V spread on the edge of basin, usually occurred in site class B and C. This might due to H/V ratio could still response some thin layer which amplified spectrum but these layer had similar response in two rock site induced small amplification show in H/H ratio (Figure 8 (a)). Meanwhile, there's seems no space difference between H/H, microtremor H/V (Figure 8 (b)) and between H/V, microtremor H/V (Figure 8 (d)). Otherwise, obvious space difference between H/H and SMSIM and appear a south-east north-west direction related to reference rock site TAP071 (Figure 8 (c)). Since average response in B class was used as denominator for transfer function of SMSIM which should assume no difference in space. This might suggest distance between soil site and reference rock site in north-west Taipei basin should be corrected in the future to makes the H/H ratio more consistence in whole region.

3.3 Average Transfer Function for Different Site Class in Taipei Basin

Site response in Taipei basin showed different phenomenon in stiff sediment (B and C class) and soft sediment (D and E class) stations between these four kinds of transfer function (Figure 7). H/H ratio had obvious difference with H/V and microtremor H/V in whole frequency band of stiff site and difference mainly occur in low frequency band for soft soil site. In order to classified these difference more precisely, unity DSPD was considered to check spectrum difference in high and low frequency band, equation described as followed:

$$\overline{DSPD} = DSPD / f_band \qquad (9)$$

where f_band means frequency band of summation in DSPD calculations. 3 Hz was used here to divide high and low frequency band for averaging spectrum for different site class (Figure 9). For stiff site, spectrum difference was close in low and high frequency band for each transfer functions. Unity DSPD showed decrease trend from low to high frequency for C and D class.

Finally, H/H, H/V and microtremor H/V showed some

difference between each other and different with transfer function from SMSIM. It suggests no matter which kind of transfer function was applied to simulation technique the systematic difference should be considered to get accurately frequency behavior.

4. CONCLUSIONS

Four kinds of transfer function was discussed in Taipei basin in this study included H/H, H/V, microtremor H/V and from SMSIM. All these transfer function showed some difference in amplitude with H/H ratio which might due to reference rock site was not easy to obtain in this region. Meanwhile, microtremor H/V showed a good agreement with H/V ratio in different site class with average DSPD 1.81 (Table 2, Figure 7, 9). It could be widely applied to different location which didn't have strong motion station or enough seismic record.

Otherwise, spectrum difference was not clear for microtremor H/V and H/H, H/V ratio in space distribution. But H/V ratio showed some variance in edge of the basin might relate to some thin layers amplified frequency domain. Finally, when simulation technique tried to apply site correction from these transfer functions the systematic difference should be considered first. The precisely high frequency simulation might be more easier obtain in the future.

Abstract: Fragility analyses constitute the essential ingredients in performance-based seismic design of structures. To construct accurate seismic fragilities, a large number of ground-acceleration records capable to describe site seismicity is required. Since the number of site records is rather small, this number is augmented by, e.g. scaling real or artificial records. This approach provides limited information on structural performance since scaling does not change frequency content. Probabilistic models for the seismic ground acceleration process are usually calibrated to regional data so that they cannot provide detailed information on site seismicity.

It is proposed to combine the information provided by a seismological model with the site records within a Bayesian framework. The resulting model allows the simulation of an arbitrary number of ground motions that are consistent with all available information on seismic hazard at a site. The posterior model delivers spectral densities for seismic ground-acceleration processes at arbitrary sites as a function of earthquake magnitude and source-to-site distance. For illustration, a posterior model for the seismic hazard is constructed based on site ground-motion records.

1. INTRODUCTION

Earthquake hazards may have a catastrophic impact on human lives, environment and economy. Performance-based seismic design provides a balance between safety, functionality and life-time costs of structural systems. Seismic fragilities are response-based analyses which represent the probabilities of reaching a critical state under given characteristics of the ground motion. A large number of ground motions is required for their computation. Generally, the number of ground-motion records is insufficient to characterize the seismicity at a site which is vital for assessing seismic performance of structures. In practice, scaled versions of site records are used to calculate fragility curves as a function of selected intensity measures. Resulting fragilities provide limited information on structural performance, since scaling only affects the amplitude of the motion, but not its frequency content (Grigoriu 2011; Kafali and Grigoriu 2007; Baker and Cornell 2005; Baker and Cornell 2006).

Three types of models are currently used to characterize seismic hazard: models which use only real records selected by heuristic arguments (Douglas 2006) or by matching response spectral accelerations (Baker 2011; Ozer and Akkar 2012; Jayaram et al. 2011; Fengxin et al. 2006), models calibrated to recorded data which are used to generate artificial ground motions (Zentner and Poirion 2012) and models which combine real with artificial ground motions (Seyedi et al. 2009).

The Bayesian framework is employed in this study to construct a novel model which accounts for all available information on site seismicity. The proposed model is based on site ground-acceleration records and the specific barrier model (SBM). The SBM is a seismological model which delivers spectral densities of the ground motion as a function of moment magnitude m, source-to-site distance r and other parameters (Papageorgiou and Aki 1983b; Papageorgiou and Aki 1983a; Halldorsson and Papageorgiou 2005). The implementation of the Bayesian analysis requires to represent the ground-acceleration spectral density $g(\nu; m, r)$, given by the SBM, by a parametric model $\tilde{g}(\nu; \Theta, m, r)$, which depends on a vector Θ of uncertain parameters. The prior density for Θ is postulated such that the expectation of $\tilde{g}(\nu; \Theta, m, r)$ with respect to the prior distribution of Θ is equal to $g(\nu; m, r)$. The proposed methodology produces posterior versions of the specific barrier model, that is, updated versions of spectral densities for seismic ground-acceleration processes at arbitrary sites as a function of earthquake magnitude and source-to-site distance, under a well-defined probability law.

The paper also addresses another current problem. Models can only provide approximations for the physical phenomena and concerns are raised when dealing with extraordinary events which cannot be estimated by models in use. Events like the Tohoku Earthquake in Japan on March 11, 2011 and the 5.8-magnitude Virginia Earthquake in the USA on August 23, 2011 must be treated accordingly. The proposed hazard model can be updated sequentially

when new records become available. Updating hazard models to new data was considered before, in (Atkinson and Boore 2011) and (Wang and Takada 2009), in which the parameters of ground-motion prediction models are updated to new data available. The latter also employs Bayesian statistical methods for the update.

The model and the methodology proposed are tested and then used for various simulated seismic hazard scenarios. The posterior model for the spectral density is derived from simulated ground-motion accelerations. As the number of records increases, the output spectral densities converge to the SBM spectral densities and confidence intervals become narrower and concentrated around the SBM densities. When the sensitivity of the model is tested using data generated from other postulated spectral densities, the output of our model deviates from the SBM. The posterior data on the spectral densities stays within the range postulated by the prior information, but it departs from the prior mean depending on the type of data and on the number of records used in the analysis. Similar findings are reported for a simulated hazard scenario in Los Angeles.

2. SEISMIC HAZARD MODEL

The seismic model in this paper has two components: a seismological model calibrated to regional data and a site-specific model for the earthquake probabilities.

2.1 Model Description

We model the seismic ground motions as stochastic processes using a seismological frequency model, that is, the specific barrier model (SBM). This model produces spectral densities $g(\nu; m, r)$ for seismic ground motions as a function of m and r, considering also site effects and rupture mechanisms (Papageorgiou and Aki 1983b; Papageorgiou and Aki 1983a). The physical model of the source fault used in the SBM is a rectangular plane containing circular cracks with fixed diameters. A local stress drop $\Delta\sigma_L$ occurs in each crack and they spread radially outwards at sequential times until they reach their barriers. The most important output of the model is the amplitude spectrum shown in Eq. (1).

$$a(\nu; m, r) = cS(\nu; m, \Delta\sigma_L)F(\nu)Q(\nu; r)G(\nu) \qquad (1)$$

in which c is a scaling factor, S and F are the source and the frequency spectra, respectively, Q is a ground motion prediction model and G is a function which accounts for the soil effects. The key parameter in this model, $\Delta\sigma_L$, is fitted to global data (Halldorsson and Papageorgiou 2005; Foster et al. 2012) and it is assumed to be universally valid. Moreover, the SBM is calibrated to global data and it does not capture the variability in the seismic spectral densities at a site. Thus, we can refer to the output of the SBM as prior information means for the spectral densities depending on (m, r).

Seismic ground accelerations are complex processes which are caused by travelling seismic waves. Of these waves, surface waves are most relevant for civil engineers due to their damaging effects. These waves generate the so-called strong ground-motion part of the earthquake, which may be considered stationary (Li and Chen 2009). The time history model for simulating the strong ground-motion part is assumed to be a zero-mean, stationary Gaussian process $X(t)$ with the probability law described fully by the one-sided spectral density

$$g(\nu; m, r) = \left(2\pi t_f\right)^{-1} |a(\nu; m, r)|^2 \qquad (2)$$

Under the Gaussian model, the power spectral density in Eq. (2), depending only on the two parameters $(m,\ r)$, defines completely the probability law of the seismic hazard at a site. In practice, the stationarity assumption is relaxed by multiplying the stationary process with a modulation function (Rezaeian and Kiureghian 2010; Li and Chen 2009).

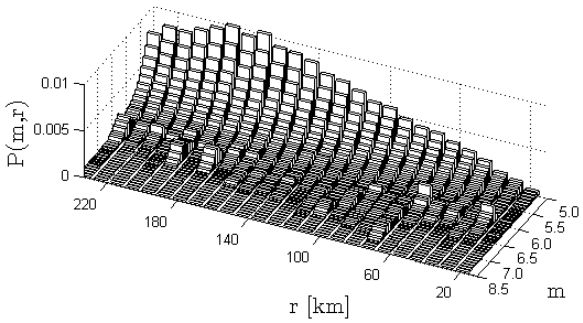

Figure 1 Seismic activity matrix for Los Angeles, CA

The second part of the hazard model is given by the seismic activity matrix, that is, a two-dimensional matrix defined in the (m, r) space, which provides the probability of occurrence of an earthquake of magnitude m and with an epicentral distance r. These matrices are calculated using the mean annual rates for earthquakes with coordinates (m, r), provided by the United States Geological Survey (USGS) for each zip code in the United States. The dimensions of the (m, r) space are flexible and they can be set up within the USGS database. Figure 1 illustrates the seismic activity matrix for Los Angeles, CA with ranges of the parameters $m \in [5; 8]$ and $r \in [5; 225] km$ and with a total number of cells $N = 875$. The two components of the seismic hazard for a specific site, that is, the spectral density $g(\nu; m, r)$ from the SBM and the seismic activity matrix, define completely the ground-acceleration process.

2.2 Model Approximation

The goal of this paper is to update the earthquake spectral density model using site records. The form of the spectral density, given by the SBM in Eqs. (1) and (2), is complicated and impractical since it is only available in an algorithmic form. To simplify calculations, a linear approximate model is sought. The singular value decomposition procedure (Chatterjee 2000) is used to construct a parametric model for $g(\nu; m, r)$.

Suppose the frequency band of $g(\nu; m, r)$ is discretized in n equal intervals $\Delta\nu$. Then, the spectral densities for a seismic activity matrix with N cells can be written in the form of a matrix A with n lines and N columns. The singular value decomposition of A is:

$$A = USV^T \tag{3}$$

where U and V are $n \times n$ and $N \times N$ orthogonal matrices, respectively and S is a $n \times N$ matrix with all off-diagonal elements equal to zero. The non-zero diagonal elements are arranged in ascending order $s_k = S_{kk}$, $k = 1, \dots, d$, where $d = \min(n, N)$. The values s_k are called singular values of A. We approximate A by

$$\tilde{A} = \sum_{k=1}^{\tilde{d}} s_k Q_k \tag{4}$$

where $\tilde{d} \leq d$ and $Q_k = u_k v_k^T$ is the modal matrix corresponding to the singular value s_k, and is the product between the $k-th$ column of U and the transposed $k-th$ column of V. The approximate representation of A in Eq. (4) improves as the number of modes $\tilde{d}$ increases.

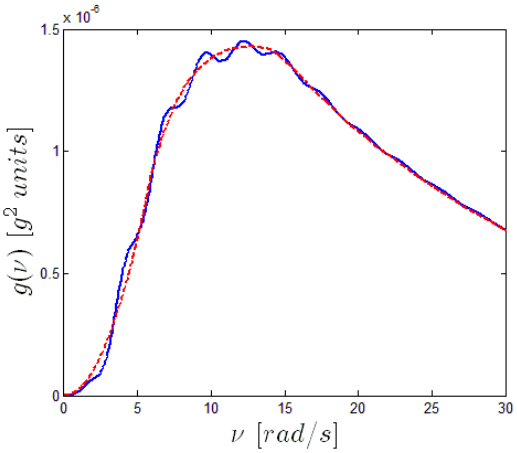

Figure 2 Power spectral density for cell $(m = 5.95, r = 85km)_{j=234}$

Each column j of A represents the power spectral density $g(\nu; (m, r)_j)$ for cell $(m, r)_j$ of the seismic activity matrix. Each column j of Q_k represents the $k-th$ mode of $g(\nu; (m, r)_j)$ and it is denoted by $\varphi_k(\nu; (m, r)_j)$. Figures 2 and 3 show the SBM and its singular value decomposition approximate representation with solid and dashed lines, respectively, for two cells, $(m = 5.95, r = 85km)_{j=234}$ and $(m = 8.05, r = 205km)_{j=771}$, using only the first $\tilde{d} = 6$ modes.

2.3 Bayesian Updating Framework

The Bayes' theorem is used to update the vector of unknown parameters Θ given the observed data X. According to the theorem, the posterior density $f(\Theta|X)$ of Θ is

$$f(\Theta|X) \propto f(\Theta) l(X|\Theta) \tag{5}$$

where $f(\Theta)$ is called the *prior* and the function $l(X|\Theta)$ is called the *likelihood* function. The likelihood accounts for the significance of the observed data X in the distribution of the unknown parameters Θ (Grigoriu 2012).

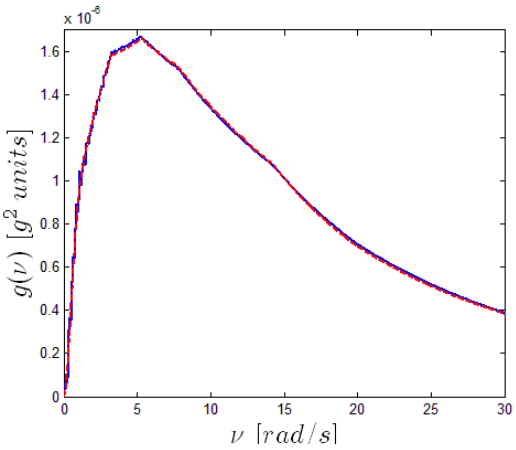

Figure 3 Power spectral density for cell $(m = 8.05, r = 205km)_{j=771}$

In this Bayesian framework, the singular values s_k are viewed as random variables θ_k with $E[\theta_k] = s_k$, with $k = 1, \dots, d$, where d is the number of singular values. They must also satisfy the existence condition of the spectral density, i.e. $g(\nu; \Theta, (m, r)_j) \geq 0$, for all $j = 1, \dots, N$, where N is the number of cells in the seismic activity matrix. Therefore, the uncertain model used in the Bayesian analysis is obtained from the discrete approximation for the spectral density and has the form

$$\tilde{g}(\nu; \Theta, (m, r)_j) = \sum_{k=1}^{d} \theta_k \varphi_k (\nu; \Theta, (m, r)_j) \tag{6}$$

where $\varphi_k(\nu; \Theta, (m, r)_j)$ is the $k-th$ mode in the $j-th$ cell of the seismic activity matrix. The spectral densities and the modes depend on $(m, r)_j$, but the unknown parameters $\theta_k, k = 1, \dots, d$, are global, i.e. they are unique for all cells of the seismic activity matrix. The notation $(m, r)_j$ is dropped and replaced by the index $j = 1, \dots, N$, denoting the $j-th$ cell in the seismic activity matrix.

Figure 4 illustrates the first seven singular values for the spectral densities matrix A for Los Angeles. The first couple of modes carry most of the weight in the approximation of A. Thus, to simplify the calculations, the representation in Eq. (6) is replaced by Eq. (7)

$$g_j(\nu; \Theta) = \theta_1 \varphi_{1,j}(\nu) + \theta_2 \varphi_{2,j}(\nu) + \theta^* \varphi_j{}^*(\nu) \tag{7}$$

where $\varphi_1(\nu), \varphi_2(\nu)$ are the first two modes of the decomposition and

$$\varphi_j{}^*(\nu) = \sum_{k=3}^{d} \theta_k \varphi_{k,j}(\nu) \tag{8}$$

is a cumulative mode, composed of all the other $d-2$ modes in the approximation of A.

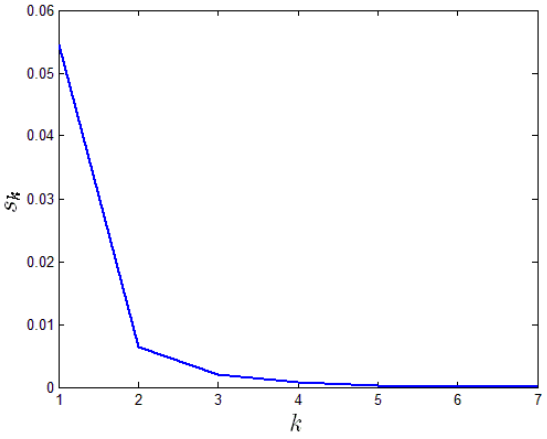

Figure 4 First seven singular values of $\boldsymbol{A}$

For calculations, the unknown parameters are normalized to have mean 1, by scaling modes $\varphi_{k,j}(\nu)$ by the corresponding s_k. The vector of unknown parameters is now $\Theta = (\theta_1, \theta_2, \theta^*)$, with a joint prior distribution $f(\Theta)$. In Figure 5 the three modes for cell $(m = 8.05,\ r = 205km)_{j=771}$ are shown.

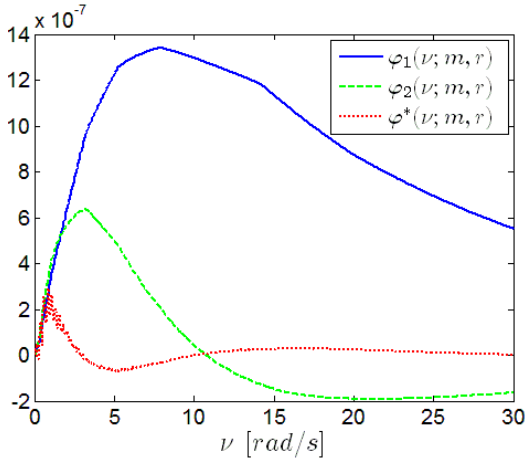

Figure 5 Modes for cell $j = 771$

The prior distribution $f(\Theta)$ of Θ must be postulated such that the two imposed conditions on Θ be satisfied. The joint prior probability density function proposed in the current analysis is

$$f(\theta_1, \theta_2, \theta^*) = f(\theta_1|\theta_2, \theta^*) f(\theta_2) f(\theta^*) \qquad (9)$$

in which θ_2, θ^* are independent, uniformly distributed and $f(\theta_1|\theta_2, \theta^*)$ is a $Gamma(\alpha, \beta)$ conditional prior probability density function centered around the mean $E[\theta_1]$=1, that is,

$$f(\theta_1|\theta_2, \theta^*) \propto (\theta_1 - E[\theta_1])^{\alpha-1} e^{-(\theta_1 - E[\theta_1])/\beta} \qquad (10)$$

where $\alpha > 0$ and $\beta > 0$ are the shape and the scale parameters, respectively.

The likelihood function $l(X|\Theta)$ depends on the recorded ground motions X and the unknown parameters Θ. As established before, X is only the strong-motion part of the ground-acceleration record, which is assumed to be a zero-mean, stationary, Gaussian process with spectral density $\tilde{g}_j(\nu; \Theta)$. Thus, we can write the likelihood function given the data time history X_i recorded in cell j as follows in Eq. (11)

$$l_j(X_i|\Theta) \propto \left|\Sigma_j(\Theta)\right|^{-\frac{1}{2}} \exp\left\{-\frac{1}{2} X_i^T \Sigma_j(\Theta)^{-1} X_i\right\} \qquad (11)$$

where $\left|\Sigma_j(\Theta)\right|$ is the determinant of the covariance matrix $\Sigma_j(\Theta)$, with components $\gamma_{u,v}^j$, calculated at all discrete times $u, v = 1, \dots, n_i$ with n_i being the number of discrete points in record X_i. The components of the covariance matrix are

$$\gamma_{u,v}^j(\Theta) = \sum_{k=1}^{q} \tilde{g}_j(\nu_k; \Theta) \cos(\nu_k (u - v))\, \Delta\nu \qquad (12)$$

where q is the number of discrete frequency points. Following standard practice, numerical calculations are based on the log-likelihood function given by

$$\log\left(l_j(X_i|\Theta)\right) \propto \log\left(|\Sigma_j(\Theta)|\right) + X_i^T \Sigma_j(\Theta)^{-1} X_i \qquad (13)$$

The posterior probability density of the unknown parameters is calculated from

$$f(\Theta|X_i) = \rho f(\Theta) l_j(X_i|\Theta) \qquad (14)$$

where ρ is a normalization constant, which assures that the posterior density function integrates to unity. The Bayesian updated model just illustrated is for a single record. For a larger set of ground-acceleration time histories $X_1, \dots, X_i, \dots, X_s$ recorded in cells $j(X_1), \dots, j(X_i), \dots, j(X_s)$ the same procedure should be used in a *cascade analysis*. This type of analysis is sequential and the posterior $f(\Theta|X_i)$ becomes the prior for the update with the following record X_{i+1}. The log-likelihood is then calculated as shown in Eq. (13). We can write the following recurrent upgrading relation:

$$f(\Theta|X_{i+1}) = \rho f(\Theta|X_i) l_{j(X_i)}(X_{i+1}|\Theta) \qquad (15)$$

for $i = 1, \dots, s-1$. Markov Chain Monte Carlo methods may be used for sampling Θ from the posterior density.

3. MODEL VALIDATION

The model proposed in the previous section is an updating model for the seismic spectral densities using the site records. Two important attributes of this model should be checked to validate it. The model should converge to the original values given by the SBM, when simulated data from the SBM are used in the analysis and yet be sensitive to exceptional ground-motion records. We show these properties by upgrading the spectral density model for a

single cell of the seismic activity matrix for Los Angeles, $(m = 8.05,\ r = 205km)_{j=771}$, rather than for the entire matrix.

3.1 Convergence

The parametric model $\tilde{g}(v;\Theta,(m,r)_j)$ is updated with samples generated from $g(v;\Theta,(m,r)_j)$ for a fixed, but arbitrary cell. Convergence means that the posterior spectral densities approach the SBM spectral densities as the number of samples increases indefinitely. Numerical results are shown for cell $j = 771$. The samples are generated as zero-mean, stationary normal processes using the spectral representation method (Grigoriu 1993; Kafali and Grigoriu 2007). Using the updating methodology presented in Eq. (15), the posterior density for the unknown parameters is obtained. As the number of data used in the analysis increases, the calculated means for all the uncertain parameters $\theta_1, \theta_2, \theta^*$ from the resulting posterior distributions converge to 1, the value corresponding to the SBM. Validating results are presented in Table 1.

Table 1 Convergence of the posterior means

Analysis	SBM	100 samples	1,000 samples	10,000 samples
$E[\theta_1]$	1	1.0236	1.0042	1.0001
$E[\theta_2]$	1	1.1109	1.0029	1.0017
$E[\theta_3]$	1	1.0011	1.0000	1.0000

Figures 6-9 show the marginal prior densities postulated in Eq. (10) and the marginal densities calculated for parameters $(\theta_1, \theta_2, \theta^*)$ for 100 and 1,000 samples, respectively. The spread of the posterior marginal density for parameter θ_1 narrows down more rapidly than for the other two parameters because both its weight in the model is higher and its prior $Gamma$ density postulated is much stronger than the non-informative uniform density used for the other two parameters.

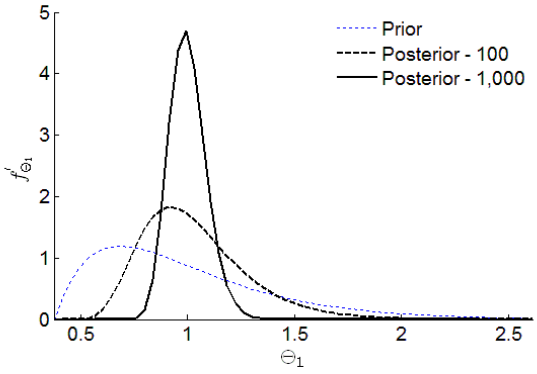

Figure 6 Posterior densities for $\boldsymbol{\theta_1}$

Each set of values $(\theta_1, \theta_2, \theta^*)$ corresponds to a spectral density function and has a probability mass given by the joint posterior density. Thus, we also have the probability law of the spectral densities at the specified site and in the cell or cells where the update was performed. Figures 9 and 10 illustrate the range of the spectral densities, the mean spectral density from the SBM and the 5-th and the 95-th percentiles, calculated for 100 and 1,000 samples, respectively. Since all the data in the analysis was generated using the SBM spectral density, the confidence intervals are concentrated around the SBM density. These intervals narrow down as the number of samples increases and they approach the mean spectral density.

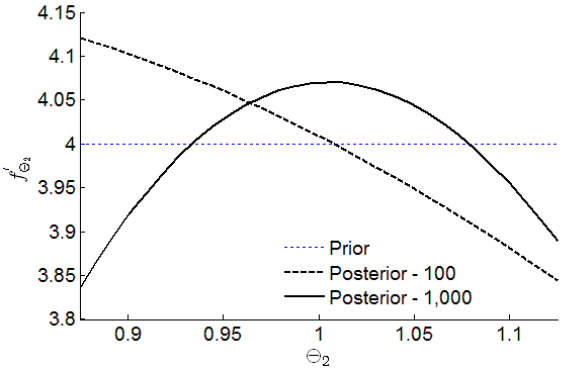

Figure 7 Posterior densities for $\boldsymbol{\theta_2}$

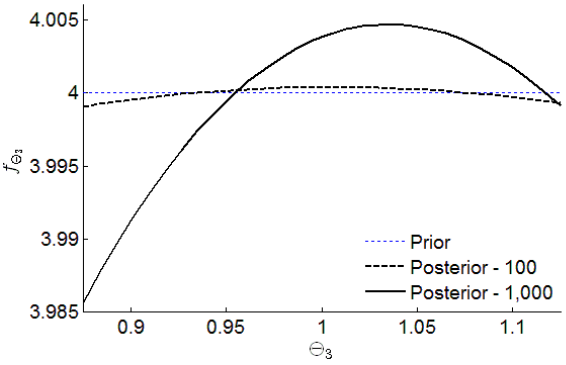

Figure 8 Posterior densities for $\boldsymbol{\theta_3}$

3.2 Sensitivity Analysis

Model sensitivity means that posterior spectral densities differ on average significantly from the SBM output if updated with records unlikely to be produced by $g(v;\Theta,(m,r)_j)$. The sensitivity of the model to uncommon earthquakes is important for updating the model with ground-motions records like the Tohoku earthquake in Japan.

In order to check this, we update the densities for the same cell $j = 771$, but using ground motion samples simulated by using the SBM spectral density for cell $(m = 5.95,\ r = 85km)_{j=234}$. The two cells used in the analysis have different frequency contents, as shown in Figures 2 and 3. Since the modes are cell dependent, we expect to see that the means of the unknown parameters diverge from the value 1 corresponding to the SBM spectral density.

The analysis is performed similarly to that in the previous section, using the sequential update methodology for 100 and 1,000 samples, respectively. In Figures 11 – 13, the marginal prior densities, and the two sets of marginal

posteriors are plotted for each of the three unknown parameters.

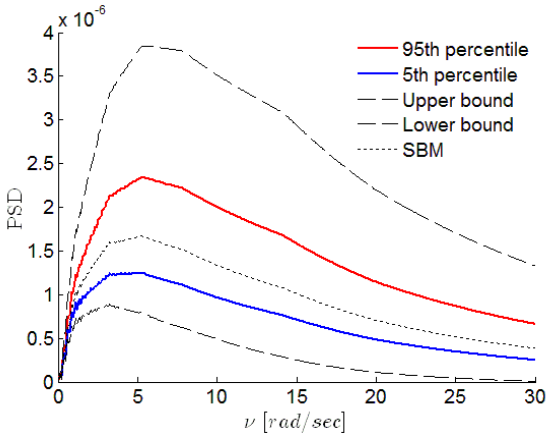

Figure 9 Statistics for the analysis with 100 samples

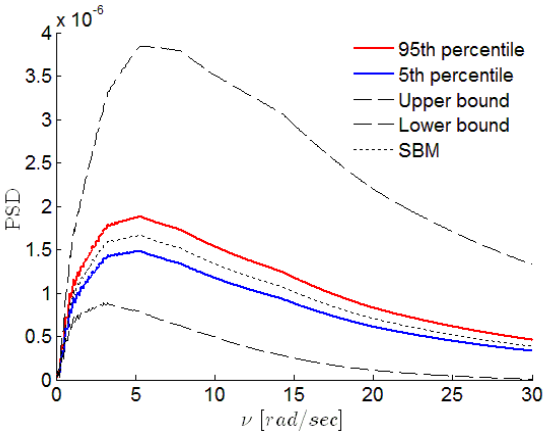

Figure 10 Statistics for the analysis with 1,000 samples

Using the same priors postulated before, just a slight deviation is noticed after the analysis with the first 100 samples, but after using all 1,000 samples, a conclusive deviation of the posterior mean from the mean 1 corresponding to the spectral density given by the SBM for cell $j = 771$ is noticed. Thus, we can state that the model is sensitive to unusual data. The information is processed through the Bayesian analysis, reflected in the posterior of the unknown parameters and implicitly in the posterior probability law of the spectral densities characteristic for that particular cell of the seismic activity matrix.

4. UPDATED SPECTRAL DENSITY FOR A SEISMIC SITE

The model responded as expected to the validation tests imposed in the previous section and it can be used for realistic applications. A posterior model for the spectral densities at a given site is developed by using the proposed methodology. For this purpose, we simulate a hazard scenario for Los Angeles. The updated posterior probability law for the spectral densities characteristic for this site is constructed in the Bayesian framework.

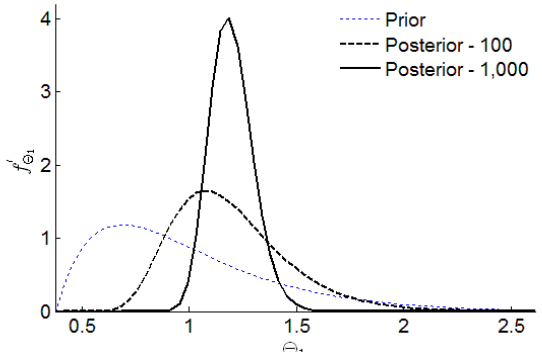

Figure 11 Sensitivity analysis for $\boldsymbol{\theta_1}$

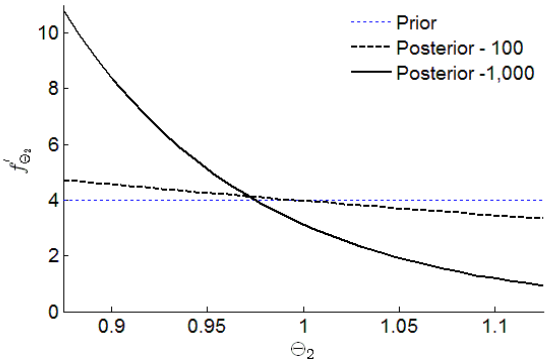

Figure 12 Sensitivity analysis for $\boldsymbol{\theta_2}$

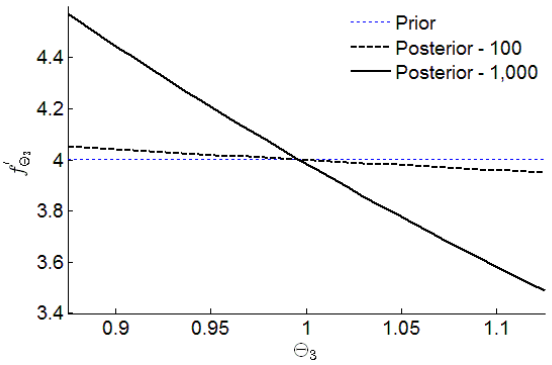

Figure 13 Sensitivity analysis for $\boldsymbol{\theta_3}$

4.1 Hazard Scenario

The hazard scenario is based on the seismic activity matrix shown in Figure 1 and the prior information on the spectral densities provided by the SBM. Unlike in the previous section, a global updated model is developed. The construction of the model in Eq. (6) allows for a global update since the uncertain parameters are global and match the SBM spectral densities for the entire seismic activity matrix.

The spectral density model for the entire seismic activity matrix can be updated for all cells in a single analysis. In practice, it is preferred to refer to seismic ground motions in relation to their corresponding seismic sources, which are characterized by location from the site and type of

earthquake magnitude produced. For the sake of this example, the seismic activity matrix is divided in four sub-matrices, each representing an imaginary source. We will refer to them as SAM1 corresponding to the seismic sources located at a distance $r < 100km$ from the site and which produce earthquakes of magnitudes $m < 6$, SAM2 for which $r < 100km, m \geq 6$, SAM3 for which $r \geq 100, m < 6$ and SAM4 with $r \geq 100km, m >= 6$.

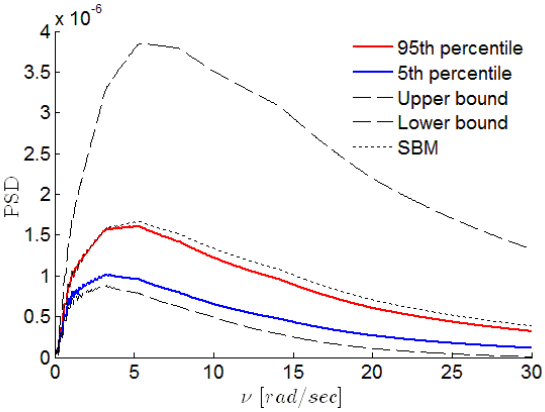

Figure 14 Statistics for densities in cell $\boldsymbol{j = 771}$ updated in SAM4

The priors for each sub-matrix are similar to the one described in Eq. (9), but their ranges are different to ensure the existence of the power spectral density for all combinations $(\theta_1, \theta_2, \theta^*)$ in all cells, for each individual sub-matrix. The likelihood function is calculated separately, for each ground motion record available, using the modes corresponding to the cell in which the record was registered.

Only 100 records are used in the analysis and they are simulated using the spectral densities provided by the SBM. The strong-motion ground acceleration time histories are generated in various cells chosen from the multinomial distribution described by the seismic activity matrix. As shown in Figure 1, the highest probability mass is concentrated in SAM4 and there is a lower probability mass concentrated in SAM1 and SAM3. According to the outcome of a 100-sample trial of this multinomial density, no ground motions are simulated in SAM3, 1 sample in SAM 1, 20 time histories are generated in SAM2 and the rest 79 motions are simulated in cells contained in SAM4.

4.2 Analysis

The update will be performed for each sub-matrix individually and using the ground motions corresponding to the cells belonging to each of them. Different posterior distributions are obtained for each sub-matrix because the ranges for the unknown parameters are different and number of available data used for each update is variable. Moreover, in SAM3 there is no update, since no data is available for the analysis. This suggests that the prior density is very important in the analysis. Thus, a non-informative uniform prior might be preferred to the $Gamma$ prior postulated. This assigns different probabilities to spectral density functions which cannot be corrected due to the lack of data.

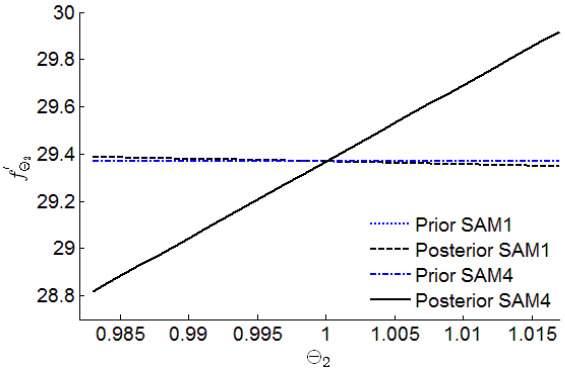

Figure 16 Posteriors for $\boldsymbol{\theta_2}$ in SAM1 and SAM4

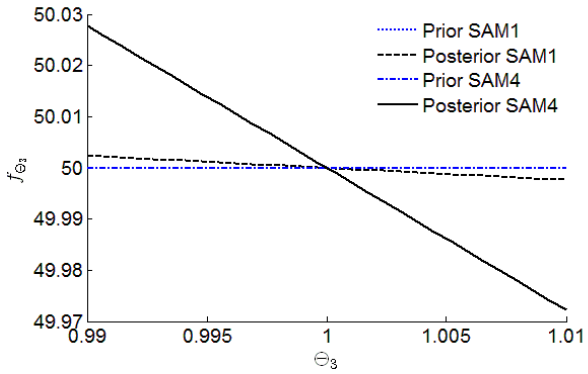

Figure 17 Posteriors for $\boldsymbol{\theta_3}$ in SAM1 and SAM4

For comparison with the results in the previous section, posterior statistics for cell j=771 are calculated again. Cell $(m = 8.05,\ r = 205km)_{j=771}$ belongs to SAM4 and only 2 samples from the 79 available for this sub-matrix belong to this cell. However, the update for the unknown parameters is performed using all 79 time histories available. Figure 14 shows the SBM density, the range and the 5-th and the 95-th percentiles, respectively. Unlike the results shown in Figures 9 and 10, where the update was done only using samples from the actual cell, the SBM spectral density is outside the confidence interval. This shows the importance in the variability of the ground motion and the necessity of using a site-specific model. The data suggests that the SBM

model overestimates the frequency content of the ground motions in this particular cell. It is also important to note that the confidence intervals stay within the limits of the prior range postulated.

The two cells used in our analyses, $j = 234$ and $j = 771$ correspond to SAM1 and SAM4, respectively. Figures 15-17 present the marginal priors and posterior densities of the unknown parameters of SAM 1 and SAM 4. For the two cells we keep the ranges for the parameters θ_2 and θ^* fixed, which leads to very different ranges for θ_1 for the two sub-matrices. Since only one sample is available for the analysis in SAM1, a very slight perturbation of the prior is noticed from the postulated prior, which emphasizes again the importance of the prior distributions. Since the number of samples of ground motion accelerations used in the analysis is very small, no convergence to the mean value 1 is observed in the posterior marginal distribution of the unknown parameters.

5. CONCLUSIONS

A novel model has been proposed for characterizing site seismicity. The model is based on the specific barrier model (SBM), a seismological model, which produces seismic power spectral densities as a function of moment magnitude and epicentral distance, and site records. A parametric representation of the SBM, depending on a vector of unknown parameters Θ, has been used to update the spectral densities provided by the original model, within a Bayesian framework using site records.

It was found that the proposed model converges to the SBM if it is updated with ground-acceleration records generated by the model as the sample size increases infinitely. If the ground-acceleration records are inconsistent with the SBM, the posterior version of the proposed model may differ significantly from the SBM. This is the most useful feature, which allows modifying the SBM to account for recent large seismic events.

Abstract: Kaohsiung city is the most important harbor and second large city in Taiwan. This study estimates the S-wave velocity structures by six microtremor arrays. We then conducted a research to study the site effects, which includes analyze three installed borehole seismometer arrays, and perform very dense microtremor measurements in the area. After carefully selection, we pick 705 records and use the H/V ratio method to get information of soil amplification. In this study, we select several frequencies to plot out the contour map for understanding the frequency responses in this area. For the 0.6 ~ 1.5 Hz, the contours show that main amplification effects occurred at the southern part of Kaohsiung area and most Pingtung plain. With the frequency increasing to 2.0 Hz, the main amplification area move from the plain area to the hill area. At the plain area, the dominant frequency is about 0.6 ~ 2.0 Hz, and the hill area is great than 2.0 Hz. We found that the basement structure can explain the contour very well. Yet, the H/V dominated frequency distribution map reveals more detail features. The Vs30 can't exactly respond the site effects in the plain area stations.

1. INTRODUCTION

Taiwan is located on the Circum-Pacific seismic belt. The seismicity in Taiwan area is very high (Hsu, 1961). Therefore, defense lives and possessions from disaster earthquakes are a major concern of the people in this region.

Amplification of strong ground motion by alluvial deposits during an earthquake has been documented on a lot of occasions and caused damage in recent large earthquakes, for example, 1985 Michoacan earthquake, 1989 Loma Prieta earthquake, 1994 Northridge earthquake, 1995 Kobe earthquake, and 1999 Chi-Chi, Taiwan earthquake. Many studies shown that the top alluvium layer will play an important role for site amplification effects (Boore et al., 1993; Boore et al.,1994; Anderson et al., 1996). Therefore, site effects study is very important for mitigating damage during an earthquake. Many methods have been used to characterize the site amplification. The Central Geological Survey had spent four years to bore more than 50 wells. And now, it is very clear to know the basement depth is changing from 120 to 40 meters for the western and eastern part of the Kaohsiung city. The harbor and commercial area locate at the western part of this area, and the eastern part is small hill area. In this study, we used the H/V ratio to analyze the site effect. The H/V ratio contours at some specific frequencies are selected to compare with the geological structures under the Kaohsiung area.

2. TSMIP NETWORK AND BOREHOLE ARRAYS

2.1 TSMIP Network

TSMIP is executed by the Seismological Observation Center of the Central Weather Bureau, Taiwan, ROC (Shin, 1993). The main purpose of this program is to study the characteristics of the ground motion in different geological conditions and the response of different types of man-made structures. All results can be used to improve the design spectrum and building codes of current use. The program installed up to 600 digital free field strong motion instruments and 400*3 digital channels of strong motion monitoring systems in nine metropolitan areas. The distribution of stations within the Kaohsiung and Pingtung area is shown in Figure 1 in triangle symbol.

2.2 Borehole Arrays

There had been installed three borehole seismometer arrays by the Central Geological Survey in the Kaohsiung area. Each array was installed three seismometers at different depth (surface, 50 m, 150 m). The location of the borehole arrays is shown in Figure 2 (KS001, KS002, KS003).

3. SHALLOW S-WAVE VELOCITY STRUCTURE

We had done microtremor array measurements at six different sites. Figure 2 also shows the distribution of the microtremor array in the study area in rhombus symbol. We set up 13 seismometers in several triangles at each microtremor array measurement, and receive microtremor at

the same time. The seismometer which we use to do microtremor measurements is made by the Tokyo Sokushin. The mode of the recorder is the SAMTAC-801B and the sensor is the VSE-311C. The sampling rate is 200 pps. There is a time shift between the pulse at each station. We use the F-K analysis to get a dispersion curve. Then we get the S wave velocity structure by using the Genetic Algorithm Search. Figure 3 shows the best 20 solutions at each microtremor array.

At the three borehole seismometer arrays, we had done the P-S velocity logging before the seismometer had installed in the deepest borehole (150 m). Comparing with the two methods, the shallow S-wave velocity structure can match well (Figure 4). After all the borehole seismometer arrays had been set up, we have received some earthquakes. We can use the earthquake records to calculate the transfer function between two different depths. We use the S wave velocity from the result of the P-S velocity logging and 1-D Haskell method to calculate the theoretical transfer function between two different depths and compare with the observed transfer function. Figure 5 shows the result of the Ks001 borehole seismometer array. We can find that the two results match very well, and it also reveals that the preciseness of the P-S velocity logging.

4. SITE EFFECT ANALYSIS

We perform a very dense microtremor survey in the study area. Most microtremor measurements were done during the midnight to reduce artificial effects in the urban area. The measurements are denser in the urban area than countryside. We measure about 18 minutes at each site. The sampling rate is 200 pps. After carefully selection, we pick 705 records and use the H/V ration method to study the soil amplification in the Kaohsiung and Pingtung area. Figure 6 shows the H/V ratio in different frequency. For the lower frequencies, the contours show that main amplification effects occurred at sedimentary area. For the higher frequencies, the main amplification area move from the harbor and coast area to the hill area. We pick the dominant frequency of each record and plot out the contour map (Figure 7). At the harbor and city area, the dominant frequency is about 0.5 ~ 0.9 Hz, and the hill part is about 3.0 ~ 5.0 Hz.

Then we use a very simple equation, that is V = 4 f x H, to transfer the dominant frequency to the thickness of the sediment. We get the S wave velocity of the top sediment which is about 250 m/s by using the P-S velocity logging. Then we can easily get the thickness of the sediment (Figure 8). Comparing with the true basement structure made by the drilling, the two results match very well. Yet, the H/V dominated frequency distribution map reveals more detail features.

Vs30 is a very important parameter in the Engineering. There are 41 TSMIP stations witch have been bored a well around 30 meters depth. The P-S velocity logging has been done at these stations. We use the S wave velocity from the result of the P-S velocity logging to calculate the theoretical transfer function and compare with the H/V ratio near the stations. At the hill area, the site classification is B type and the transfer function appears like a constant (Figure 9). At the edge of the plain, Vs30 can respond the geological condition and the transfer function can match the H/V ratio (Figure 10). But at the most plain stations, Vs30 can't respond the depth of the sediments which dominate the site effect. Figure 11 shows a quite different result at the plain stations.

5. CONCLUSION

We combine several methods to study the ground motion characteristics in this urban area. In the Kaohsiung area, with the frequency increasing, the main amplification area move from the harbor and the southern part of Kaohsiung area to the hill area, which locates at the eastern part of Kaohsiung area. For the higher frequency (3.0 Hz), there are no obvious high contour areas. In the Pingtung plain, the main amplification area moves around the Kaoping River at the frequency from 0.5 to 2 Hz. From the contour of the dominant frequency, We can find that the southwestern part of Kaohsiung city is about 0.5 ~ 0.9 Hz, and the northeastern part is about 1.3 ~ 1.7 Hz, and the basement structure can explain the site amplification result very well.

By comparing the 1-D Haskell method and H/V ratio, Vs30 is applied in the Engineering but sometimes can't respond the geological condition especially in the plain area.

APPLICATION OF WAVEFORM INVERSION TO ACTUAL SEISMIC REFRACTION DATA FOR RETRIEVING SHALLOW 2D S-WAVE VELOCITY PROFILE

Amrouche Mohamed[1], Hiroaki Yamanaka [2]

1) Doctoral Student, Dept. of Environmental Science and Technology, Tokyo Institute of Technology, Japan

amrouche.m.aa@m.titech.ac.jp,yamanaka @depe.titech.ac.jp

Abstract: We are attempting to develop a cheap and accessible seismic approach based on the inversion of the P-SV refraction data to retrieve the lateral variations of shallow soils. This method is based on the full wave field modeling based on a 2.5D Finite difference staggered formulation, source indepedent deconvolution is applied to boh observed and calculated waveforms to allow an inversion without requiring the knowledge of the source signature. The algorithm used for the inversion is the hybrid heuristic search method proposed by Yamanaka (2007). The current study aims to assess the applicability of the wave form inversion for 2D shallow soil profiling to actual refraction data. We conducted field survey in our university campus and tried to retrieve the lateral variations of the soil. Two soil profiles were inverted using shots at both ends of the survey line. The 2D soil profiles obtained by the inversion shows agreement with existing borehole data underling comparable soil structure. The inversion also allowed the detection of a lateral velocity gradient within the second layer of the soil.

1. INTRODUCTION

The near surface structural irregularities of soils may generate complex waves that interfere to disturb the expected response of buildings. Retrieving the two dimensional profile of shallow soils can have an important role to mitigate earthquake damage upon manmade structures. Many geophysical tools are available to profile the shallow soils such as the conventional seismic refraction method, or the multi-channel surface wave analysis (MASW) and each technique have its advantages and pitfalls.

We are proposing a new technique based on the wave form inversion of P-SV time series obtained from conventional seismic refraction, and the full wave field numerical modeling. The current study aims to verify the applicability of our method to actual refraction data and try to retrieve the two dimensional soil profiles.

2. METHODOLOGY

To simulate the behavior of waves inside a soil model, we used the Finite Difference P-SV staggered grid proposed by J.Virieux (1984), the classical 2D equations of motion implemented in the FD scheme to approximate velocity within the model are upgraded to 2.5D in order to include the three dimensional spreading in a 2D plan. To materialize our soil structure numerically, we use the combination of the tomographic cell and homogeneous layered model used by Takekoshi and Yamanaka (2009). This method allows dividing soil layers into several blocks with irregular interfaces. The inversion process consists then to attribute suitable values for depth and velocities at each block simultaneously in order to determine the adequate interface and the shear wave velocity.

The inversion algorithm used in this study is the hybrid heuristic search method proposed by Yamanaka (2007), this algorithm have shown excellent results on inverting phase velocity of Rayleigh waves in 1D soil profiles (Zaineh et al. 2011).

Since we are not supposed to know source frequency of the plank hammering during the data acquisition, it is important to get rid of the source effect from the signal. A source independent deconvolution was applied to the observed and calculated waveforms to delete source effect from our signal.

3. DATA ACQUISITION

We conducted a field survey in our university campus, Tokyo Institute of Technology Suzukakedai Campus in Yokohama city. We selected newly constructed parking lot as an investigation area because of the availability of a borehole data carried out previously for some geotechnical purposes. The availability of the borehole data allows correlating our 2D inverted soil model with existing one dimensional S wave velocity profile. It is very important to report that the parking area was modified after the drill of the borehole, the top surface layer was improved and a pavement layer with a thickness of around 20cm was constructed.

A conventional seismic refraction survey can be used to acquire waves generated by sledge hammering at the free surface. A line of receivers recorded the vertical component

of velocity. The survey line was spreaded nearby the borehole location. Fig.1 shows the location of the borehole as well as the survey line location. For polarity distinction, we will use the term upstream for the off shot near the borehole side, and downstream for the opposite side of the survey line.

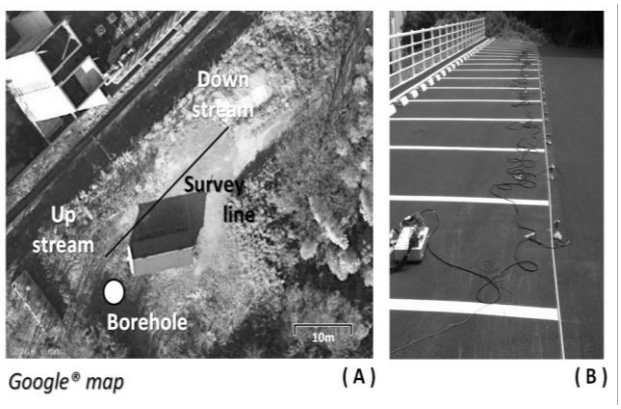

Figure 1 Location of the field data acquisition:
(A) Map of the investigated area before parking construction.
(B) Picture taken during survey after parking construction.

4. DATA PROCESSING AND INVERSION

The interception of the waves is carried out using 4.5Hz vertical geophones with a spacing of 2m covering the distance of 30m of the investigation area. Since we were performing the survey over a pavement, the geophones were fixed to the ground using artificial clay to ensure a correct transmission of the energy and reduce the coupling effect between the geophones and ground. Two vertical shots using a 5kg hammer excite the surface at both ends of the survey line; a wooden plate doubled with a sponge cushion is used to generate impacts without damaging the newly constructed pavement.

An auto-triggering system allows acquisition after the detection of the first motion at the nearest station from the shot; this station is considered as a triggering station and will not be included in the inversion. The geophones are connected to an amplificatory allowing tuning the appropriate amplification for analog recording along the survey line. The acquisition is performed using a 16 channels data logger with an acquisition window of 0.2s and a sampling rate of $5x10^{-5}$s.

We inverted the data from two shots at the upstream and downstream ends of the survey line independently. In data processing before the inversion, we applied a source deconvolution by dividing the whole signal by a reference station in the frequency domain; in our experiment we use the closest station to the source as a reference station. The division in frequency generates unwanted high frequencies, a band pass filter allows to keep the frequencies of interest and the frequency range used in the inversion is 20Hz-70Hz. Fig.2 shows the raw signal obtained from the upstream and the downstream shots and the processed waveforms.

A Finite Difference numerical grid of 400 x 200 grids is generated using a meshing of 0.1m to invert the two dimensional soil. A priori depth information obtained from the borehole data allows one to know the number of layers to be inverted and fixes the search limits for our inversion as in Table 3. Our target is to invert the two first layers of the soil, we divide each layer to 30 blocks, which brings it to a total of 120 unknown parameters. We set iteration number to 250 for 20 models at each generation. The P wave velocities obtained from the borehole data are utilized for the inversion.

Since many random numbers are used in the hybrid heuristic search inversion, the variation of the misfit function and the inverted parameters are more or less dependent on the random numbers used at each execution. In order to avoid any effect related to the initial models randomly generated, we conducted five inversions with different initial values of the random number generator for each inversion and average the models obtained to a single synthesis model.

Table1: inversion parameters of the real data.

	S-wave velocity (m/s)	P-wave velocity (m/s)	Depth(m)
Layer 01	100 – 450	480	0.2 – 4.0
Layer 02	100 – 450	725	4.5 – 7.0
Layer 03	Fixed (500)	1100	Half Space

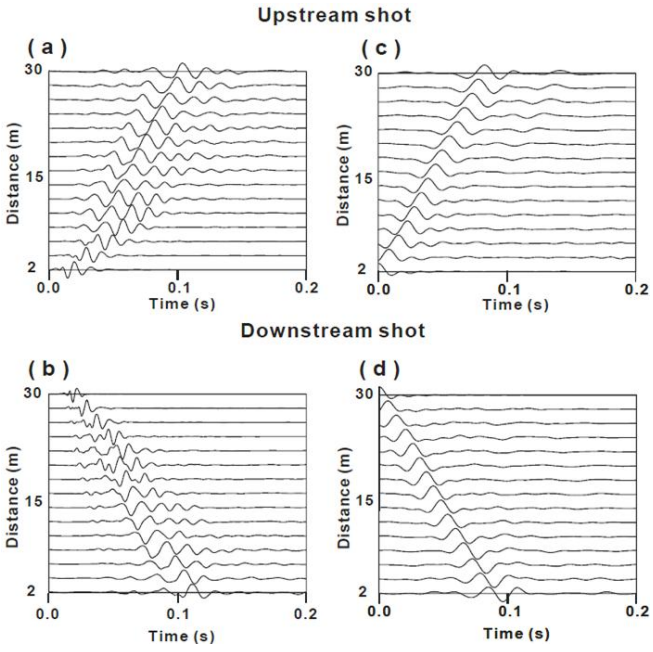

Figure 2 (a,b) Raw acquired data. (c,d) Deconvoluted and filtered waveforms.

The two dimensional averaged model from 5 inversions retrieved from each shot are displayed in Fig.3: The inverted waveforms of both shots show an acceptable fitting between the target waveform and the inverted ones, the main phase

arrivals at each station were well reproduced, except for some inaccuracies on the polarity of the initial breaks at the upstream shot.

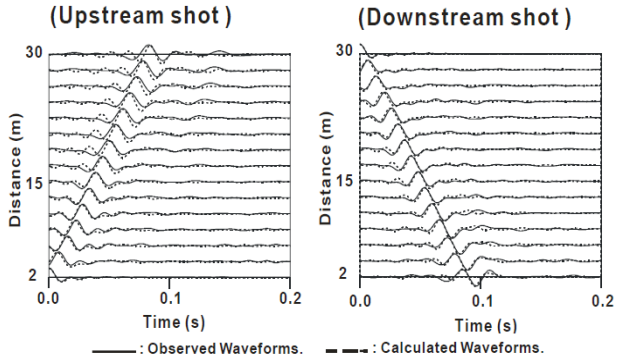

Figure 3 Comparison of the observed and final inverted waveforms.

5. INVERTED 2D PROFILES

The Figure 4 shows the 2D averaged inverted soil model from 5 inversions obtained from each shot. The source location is materialized by a black star and the black dashed lines in the profiles represents the area covered by receivers, zones outside the dashed lines do not enter the scope of observation and are out of our discussion.

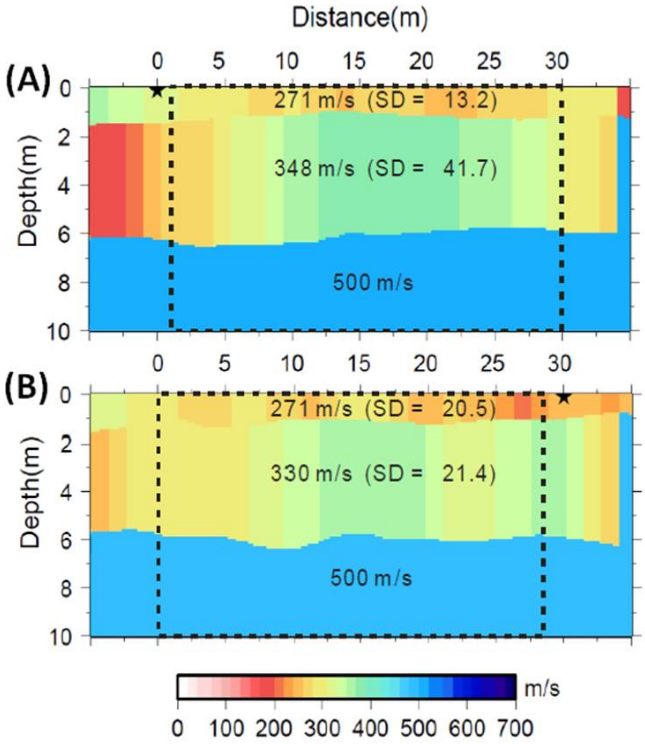

Figure 4 Two dimensional inverted soil models:
(A): Obtained from upstream shot.
(B): Obtained from downstream shot.

Comparing the 2D soil models inverted from each side of the survey line, we can clearly identify the layer boundaries around 1m and 6m depths respectively. The top layer was attributed a similar shear wave velocity of 271m/s. The second layer underlines a notable velocity variation, both profiles clearly underline a tendency of a velocity increasing between 12m and 22m, this lateral velocity is slightly pronounced in the upstream profile with velocities higher than the downstream profile, in fact the averaged velocities of the second layer are respectively 348m/s and 330m/s for both upstream and downstream profiles. This lateral velocity gradient may be explained by a local soil compaction carried out for construction purposes. We also calculated the standard deviation (SD) for block velocities at each layer, the values of the SD are displayed for each model in the Figure.

The detection of this lateral gradient among the second layer illustrates the utility of our approach; this kind of variation can never be detected if we just rely on a borehole data.

In order to validate our inverted models, we compared the inverted results with a borehole data located near the survey area (see Figure 01). To correlate the 2D inverted profiles with the borehole data, we sampled one dimensional profile from both upstream and downstream inverted models at 5m distance. Since our inversion targets are the two first layers of the profile, layers deeper than 6m are out of discussion. The comparison between the shear wave velocity of the borehole and the inverted velocities at 5m distance obtained from both upstream and downstream inversions are illustrated in Figure 5, the standard deviation from 5 inversions at 5m are also calculated and plotted in the figure.

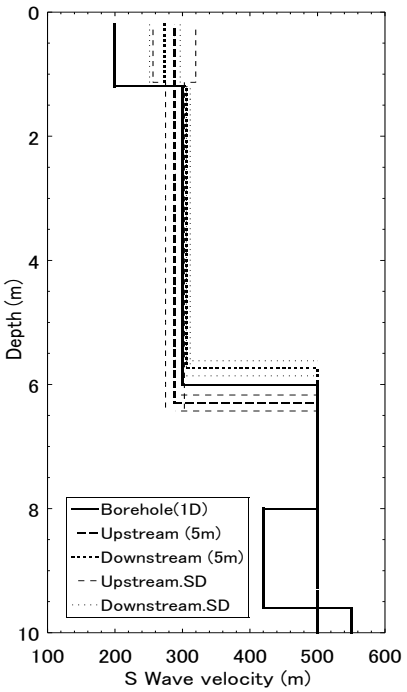

Figure 5 Comparison of the one dimensional Vs profile with standard deviation (SD) from 5 inversions for each shot.

The surface layer was attributed a velocity approximating 280m/s on the upstream profile, and 274m/s on the downstream profile while the borehole gives the surface layer a velocity of 200m/s. This over estimation can be explained by the improvements of the surface layer carried out before the construction. The Figure 6 displays a picture taken during the construction of the parking lot indicating a clear distinction between the original surface and the modified ground upon which the asphalt layer was constructed. The large standard deviation of the velocities from 5 inversions also underlines the difficulty of the algorithm to properly determine the velocity of the surface layer because of its complexity.

The second layer seems to be better estimated than the first layer and both profiles gives relatively close velocities to the borehole velocity.

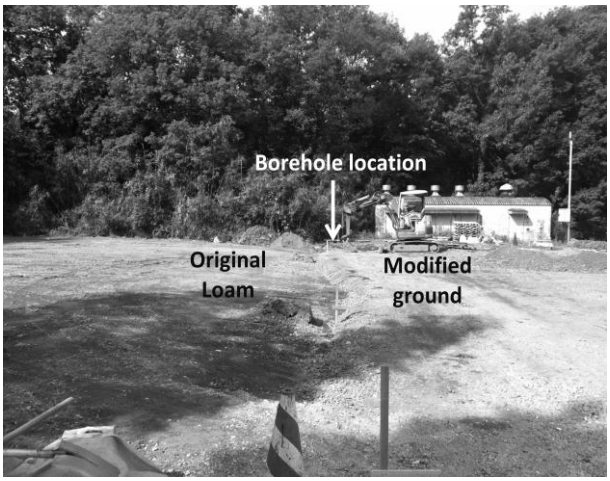

Figure 6 Picture taken during pavement construction.

6. CONCLUSIONS

We succeeded to deduce the two dimensional shallow soil using the full wave form inversion of actual refraction data. Two shots at the upstream and the downstream of the survey line gave models showing similar layer boundaries and approximated velocities, a lateral velocity gradient was revealed by both profiles in the second layer of the soil. Correlation of these profiles with an existing borehole profile showed acceptable agreements of the inverted soil structure except for shallow layer where improvements were carried out for construction purposes.

This method is still under development and the experiment discussed in this paper is just preliminary result. Further developments can be implemented by inverting several shots simultaneously in order to increase inversion precision.

Abstract: Since cross correlation of microtremor with seismic interferometry is known to give the Green's function between two stations, dispersion measurements with cross correlation functions of microtremors is expanding. However, the reason is still not clear why a cross correlation functions allow us a reliable dispersion measurements, and thus the constraint for the measurements is also not clear. In this work, we establish the reliability of dispersion measurements with cross correlation of microtremors observed in the Kanto region, Japan comparing with theoretical dispersion from estimated S-wave velocity structure. Since previous works shows the success in dispersion measurements only in the range of small wavelength, we compare the result of the measurements with wavelength.

1. INTRODUCTION

Seismic interferometry is known to reconstruct Green's function, and thereby it is extensively used for the dispersion measurements (e.g. Shapiro and Campillo, 2004). It is well known that seismic interferometry depends on the presence of sources in the zone of constructive interference, or stationary phase region by using a stationary phase approximation (Snider, 2004). Only the sources near the line connecting two stations will contribute to the signals observed in the cross correlation function (CCF). Sources at opposite side of the line will contribute to the signal at positive and negative lags in the CCF respectively, and many previous studies have showed that the amplitude of the CCFs become larger from the coastline to the continent (e.g. Gerstoft et al., 2006, Stehly et al., 2006). Therefore, the dispersion measurements with seismic interferometry are often constrained by the interstation distance larger than two or three wavelengths due to the source dependence (e.g. Bensen et al., 2008; Lin et al., 2008). The accuracy of dispersion measurements is also considered theoretically, suggesting the errors may be significant for relatively long-period waves and small station spacing (Tsai, 2009, Lin et al., 2008).

Here, we demonstrate that the reliability of the dispersion measurements with seismic interferometry by using observed microtremors in the Kanto, Japan, acquired with the temporal seismic networks constructed by the authours (Yamanaka et al., 2010). It is found that the errors are significant for long-period waves and small station spacing. Furthermore, we found that the errors become large even in the short-period range.

2. DATA AND DATA PRCESSING

2.1 Data

The authors have deployed the seismometers in the southern Kanto, Japan (Figure 1) for the long-term microtremor observation (Yamanaka et al., 2010). Microtremors were collected more than 1 year. We here use the data observed from August 2009 to July 2010. Unfortunately, the time series at some stations are less than yearlong due to the instrumental troubles.

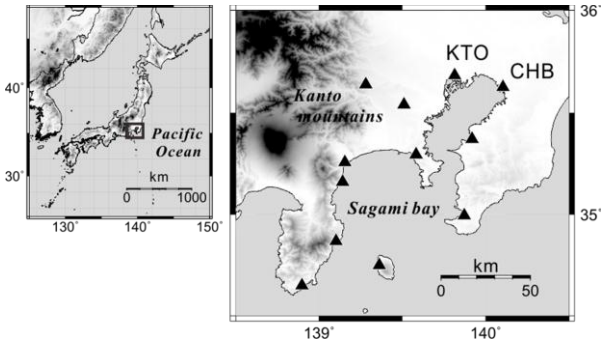

Figure 1. Locations of the long-term microtremor observations.

2.2 Data prcessing

We followed the data processing described in Prieto et al. (2011). The data processing applies no temporal normalization such as 1 bit normalization, which is commonly used in seismic interferometry (Bensen et al., 2007). Moreover, we did not apply filtering in the frequency domain for the microtremors, because it restricts the frequency range for the dispersion measurements. The

coherencies represented by equation 1 are calculated for the divided long-term microtremors with 1 hour segment. The coherencies for each segment are finally averaged and then Fourier inverse transform is performed to obtain the CCF.

$$\gamma_{xy}(\omega) = \left\langle \frac{u_x(\omega)u_y^*(\omega)}{\{|u_x(\omega)|\}\{|u_y(\omega)|\}} \right\rangle \Leftrightarrow C_{xy}(\tau) \quad (1)$$

where the brackets represent an ensemble average, the curly brackets { - } stand for a spectral average or spectral smoothing, the $\Leftrightarrow$ represents Fourier transform. $u_x(\omega)$ and $u_y(\omega)$ are the Fourier transformed ground motion at stations x and y, and C_{xy} represents the crosscorrelation function.

Figure 2 shows the CCFs with various durations of cross correlation time series which are band-pass filtered between 1 – 10 s for the averaged coherency between stations CHB and KTO shown in Figure 1. The waveforms become clearer with increasing the duration, suggesting the long duration gives the better results by reducing the noise.

Figure 3 is all the cross correlation functions estimated with yearlong microtremors with vertical components between all the possible stations pairs shown in Figure 1. The waveforms are filtered between 2 – 6 s periods for the averaged coherency. It is found that the waves are propagating with increasing the interstation distances.

3. FREQUENCY-TIME ANALYSIS

Dispersion can be measured with the frequency-time analysis (FTAN, Dziewonski, 1969). FTAN applies a series of Gaussian filter for the CCF. Figure 4 shows the results of the FTAN for the CCFs with various durations of the cross correlation time series for the positive and negative lags between the stations CHB and KTO shown in Figure 2. The result for the CCFs with the long duration clearly shows the dispersive features. On the other hand, the CCFs with the short duration does not clearly show such features. It indicates that the long duration makes it easier to measure the dispersion. And also the period range for dispersion measurements is broaden with the long duration. The difference between the positive and negative lags may be expected from the waveforms of CCFs as shown in Figure 2. The negative CCFs have much signal than the positive CCFs in both waveforms and the result of the FTAN. This difference is known to coming from the sources (e.g. Gerstoft et al., 2006; Stehly et al., 2006). Although the amplitudes between negative and positive have much difference, the traveltimes which can be observed at the period of about 5 s shows the similarity. This indicates that the seismic interferometry is able to extract the phase of Green's function but is has difficulty in reconstructing its amplitude.

4. DISPERSION MEASUREMENT

The dispersion of Rayleigh wave group velocity is also measured form the FTAN. Figure 5 is the measured dispersion from the CCFs with negative lags between stations CHB and KTO for the duration of 6890 hour illustrated in the bottom of Figure 2. Contour shows the normalized amplitude estimated with the FTAN. Circles are the velocities estimated from the lags of the CCF of which

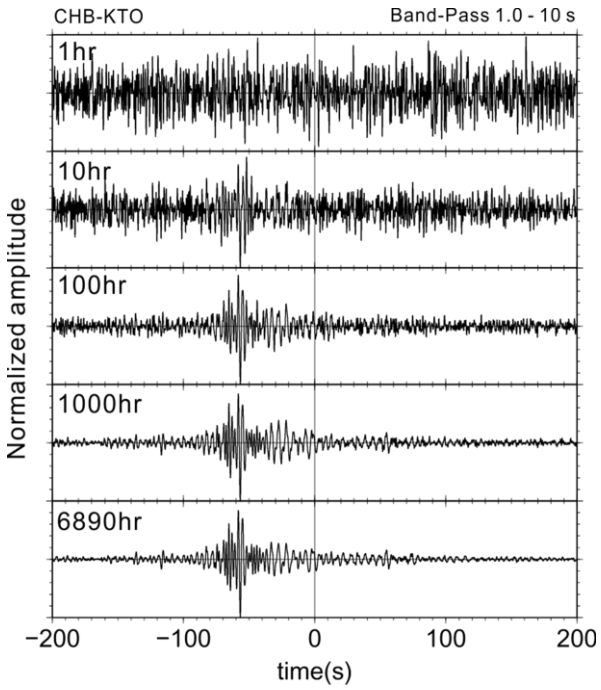

Figure 2. Cross correlation functions with various durations between stations CHB and KTO.

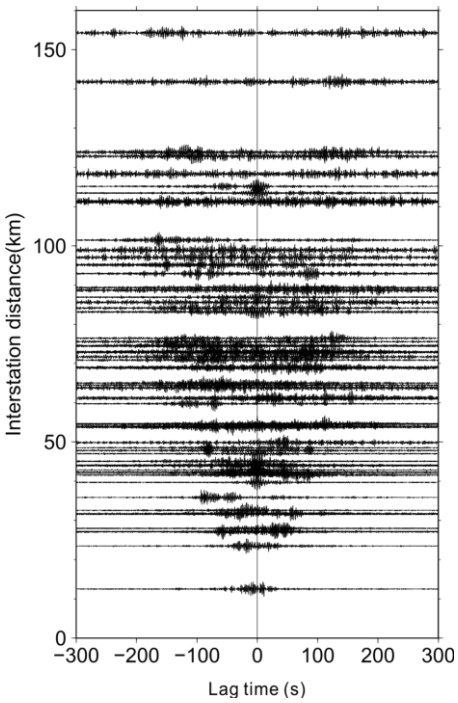

Figure 3. Cross correlation functions with vertical components estimated in the Kanto, Japan.

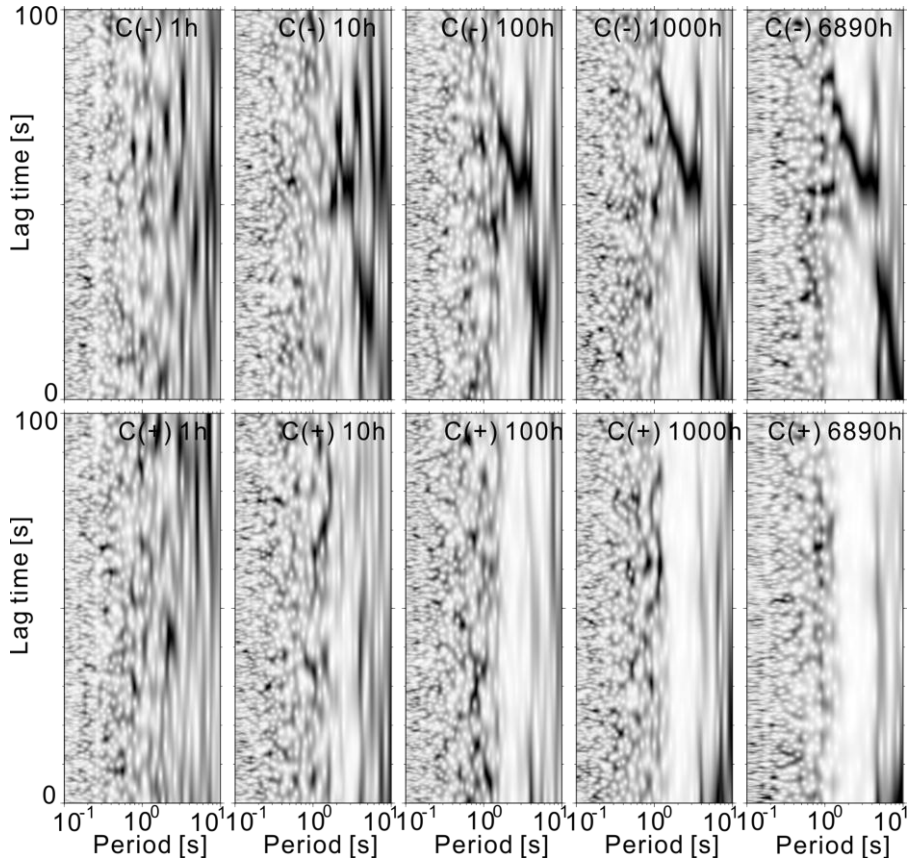

Figure 4. The results of the frequency-time analysis for the CCFs with various durations for the negative (top) and the positive (bottom) lags.

amplitudes attain the maximum value. For the comparison, we also plot the theoretical group velocities of fundamental mode of Rayleigh wave, which is calculated from the previous model of the region proposed by Yamanaka and Yamada (2006). The observed dispersion shows agreement with the theoretical dispersion in the period range from about 1 s to 7 s. However, observed group velocities at the periods above about 7 s are relatively large compared to the theoretical ones. At the period below about 1 s, group velocities are not well observed due to the fluctuation.

According to Aki and Richards (2002), the phase of Rayleigh wave is $i(kr+\pi/4)$, where i represents the imaginary, k and r are the wavenumber and the distance. It is also known that the phase of the cross correlation function is also described with kr (e.g. Snieder, 2004, Tsai, 2009). As mentioned above, the application of the dispersion measurements with seismic interferometry is often used the constraint criterion, minimum three wavelength interstation distance ($kr > 6\pi$). We here discuss about the observed dispersion of Rayleigh wave with kr. In Figure 5, we also illustrate the theoretical kr, which is calculated with the previous model in the region as described above. As we have observed, the errors of dispersion measurements is significant for long periods above about 7 s, which correspond to the kr of about 4π. It is well correspond to the theoretical consideration in Tsai (2009) Figure3, the error between the approximation and the exact velocity occurs

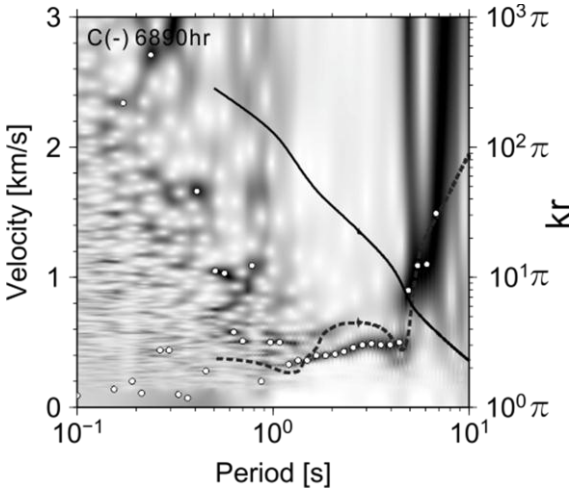

Figure 5. Contour shows the result of the dispersion measurement with the frequency-time analysis. Circles indicate the velocity which observed the maximum amplitude in the CCF. Broken and solid lines indicate the theoretical fundamental mode of Rayleigh wave group velocities and its kr.

about the *kr* below about 15. However, the error observed in the short period below about 1 s, which correspond to the *kr* of about 100π (Figure 5) is not clearly known.

5. RELIABILITY OF DISPERSION MEASURMENT

As we see in the last chapter, the reliability of the dispersion measurements depends on *kr*. In Figure 6, we plot the error of the estimation in the dispersion measurements between observed and theoretical dispersion given by equation 2.

$$Error = \left| \frac{V_{obs.} - V_{cal.}}{V_{cal.}} \right| \quad (2)$$

where $V_{obs.}$ is the observed group velocity and $V_{cal.}$ is the theoretical group velocity after Yamanaka and Yamada (2006). The $V_{obs.}$ is automatically measured as shown by circles in Figure 5 for only the signals can be observed in the dispersion measurements.

Figure 6 shows that the errors of the most of the CCFs are less than 100 percent in the *kr* range between about 5π and 100π. Even the errors of 100 percent are reasonable, because it is known that the Kanto region has three-dimensional high complexity, and the model accuracy is not clear especially around the Kanto basin (Yamanaka and Yamada, 2006). On the other hand, in the *kr* below about 5π and above about 100π, the errors are tremendously large, suggesting the measured dispersion is unreliable. The results shows the range for reliable dispersion measurements is between about 5π and 100π in the Kanto region.

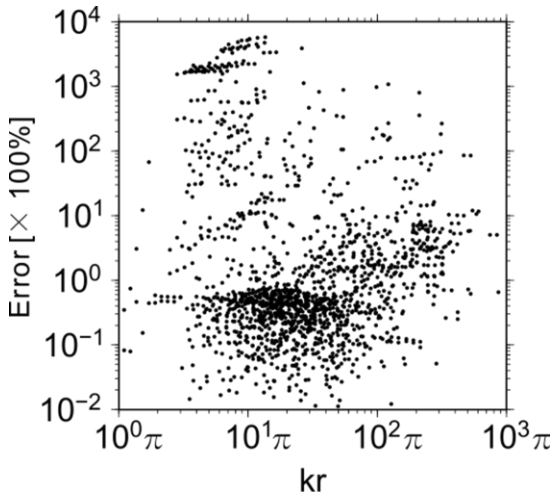

Figure 6. The errors between the observed and theoretical group velocities as a function of *kr*.

6. CONCLUSIONS

For the broad-band reliable dispersion measurements with seismic interferometry, we estimated the cross correlation functions by applying no filtering for the microtremors, acquired in the Kanto, Japan. The frequency-time analysis for the cross correlation functions with various durations of cross correlation time series showed the long duration makes it easier and broaden the period range for dispersion measurements. The comparison between the observed dispersion and theoretical dispersion showed the similarity in the *kr* range about 5π and 100π. However, the errors of measured dispersion out of the range become significant.

Abstract: Damage patterns in past earthquakes show that the local site conditions have a major effect on the level of ground shaking. Seismic microzonation, which is a methodology for mapping the seismic hazard at local scales to incorporate the effects of local site conditions, can provide input for urban planning and for assessment of the vulnerability of the building stock for different hazard levels. Site amplification factors were estimated following one dimensional shear wave propagation theory for vertical incident S-wave. We performed a multiple regression analyses with the averaged amplification factor as the criterion variable that defined by different topographic data in Damascus city. We found a good correlation between the site amplification and the elevation as well as the distance from Barada River. We simulated the strong ground motions using the source model of the 1759 Earthquake for a grid points system with 1.0 * 1.0 km in Damascus city. The microzonation maps with respect to peak ground velocity were estimated for the city. The highest values of *PGV* were concentrated at the central and eastern parts of the city. We also discussed the nonlinear amplification in the city following the equivalent linear approximation of nonlinear response of the 1-D soil strata. The non-linearity effects are more remarkable in the high frequency amplification for the central and eastern region of the city; this region suffered mainly from the foundation failure and slumping of the ground during the 1759 earthquake.

1. INTRODUCTION

1.1. Background

Damascus city is located about 30 km in the south-east of Serghaya Fault and might suffer a great damage in the case of big earthquakes along the fault. Serghaya Fault, as a branch of Dead Sea Fault System is considered as the main source of seismic risk potential for the city. Through the last 2000 years, many destructive earthquakes occurred in the region and caused much causality in the metropolitan of Damascus including the old city of Damascus (e.g. Poirier and Taher 1980; Guidoboni et al. 2004; Sbeinati et al. 2005). It is important to note that the seismic activity of DSFS during the last 100 years has been far lower than the historical one. Consequently, the public awareness on earthquake hazard as well as the government efforts toward urban risk mitigation is quite low in Syria.

In this study, site amplification factors were estimated and a multiple regression analysis was performed with the averaged amplification as the criterion variable and topographic data in Damascus city. Then, by using the source model of the November 1759 Earthquake (Zaineh et al. 2012b), the strong ground motions in Damascus city were simulated and the microzonation maps with respect to peak ground velocity were estimated and nonlinearity effects in the city were discussed.

1.2. Tectonic Settings

The Dead Sea Fault System forms the plate boundary that links the Arabian plate convergence in southern Turkey with the active seafloor spreading in the Red Sea. Figure 1(a) shows the plate tectonic settings of DSFS, (b) illustrates the tectonic settings of the northern Arabian plate, and (c) shows the active faults of the central part of the DSFS in Lebanon and southwest Syria. The recent relative motion between the Arabian and African plates is estimated to be 4-8 mm/yr, based on plate models (e.g. Joffe & Garfunkel 1987; Jestin et al. 1994) and recent GPS observations (e.g. McClusky et al. 2000, 2003). This is consistent with the geological estimates of Quaternary slip rates for the southern DSFS (e.g. Garfunkel et al. 1981; Klinger et al. 2000a).

The central part of the DSFS in Lebanon and southwest Syria is a ~ 200 km long northeast-southwest striking restraining-bend that strikes 25º-30º degrees from the main trend of the transform as illustrated in Fig. 1(b). At the southern end of this restraining-bend, the relatively simple trace of the southern DSFS branches into several distinct strike-slip faults (Walley 1988). Primary among these faults are (1) the Yammouneh Fault (YF), which is clearly observed beneath the Bekaa Valley (BV) between the Lebanon Mountains (LM) and the Anti-Lebanon Mountains (AL); (2) the Serghaya Fault (SF) in southwest Syria, which can be traced approximately 125 km through Anti Lebanon Mountains to the eastern edge of the Bekaa Valley; and (3) the Roum Fault (RouF) in southern Lebanon as shown in

Fig. 1(c).

The total length of Serghaya F. and the 2.0-2.5 m displacements, combined with the historical seismicity, suggest that the fault may be capable of generating large (M ~ 7) earthquakes. The results also suggest a slip rate of about 1.4 mm yr-1, with an average of approximately 2 m of slip per event at this location and a mean return period of about 1300 yr (Gomez et al. 2001 , 2003).

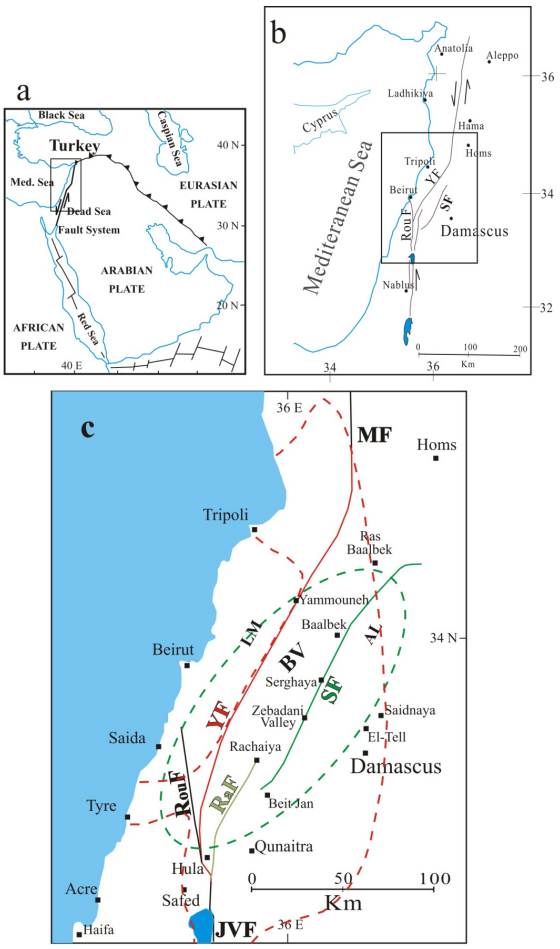

Figure 1(c) Plate tectonic context of DSFS. (b) Tectonic settings of the northern Arabian plate. (c) Active faults of the central part of the DSFS in Lebanon and southwest Syria.

1.3. Geology and Site Characterization of Damascus

Damascus city occupies the mostly part of Dimashq basin (Damascus basin), which is located to the south-western part of Syria. The north-western part of Damascus was formed after many tectonic evolutions that affected the region and started in Mesozoic period. As a result, many folding structures appear as Mt. Qasyoun and Mt. El-Qalamoun which bounded the basin at the north-west (Ponikarov, 1963). The south-eastern part of the area is quite different from the folded mountain system. It is a depression zone characterized typically by platform dislocations and intensive basaltic eruption (Ponikarov, 1963). The eruption of basalts in this area began in the middle Miocene and continued during the Pleistocene and as a result, some basalt flow reaches as far as about 20 km south of Damascus as Mt. El-Mane and Mt. El-Madani which bounded the basin at the south (Dubertret, 1929; 1940). Actually, the basin is filled by deposits of the surrounded heights and deposits carried by Barada River which flows through the basin and forms the lowland of the basin. Figure 2 shows the geological map of Damascus city, it is clear that the main part of the city lies on the sedimentary basin (Damascus Basin) and belong to the same geological category (Q_3). Single site Microtremor measurements were carried out for 300 sites in Damascus city. Horizontal to Vertical (H/V) spectral ratios were calculated and the results show big variations in H/V curves from area to area in Damascus city (Zaineh et al. 2010).

Zaineh et al. (2012a) estimated the shallow S-wave velocity structure at 30 sites in the city by using short-period microtremor explorations (sites locations are shown in Fig. 2). They estimated shear wave velocities and thicknesses of the layers down to the engineering bedrock (V_S ~750 m/s) by an inversion of Rayleigh wave phase-velocity data. Following a trial and error procedure, S-wave velocity of the deep soil layer (V_S ~1600 m/s) underline the engineering bedrock as well as the thickness of the engineering bedrock were assumed by fitting the theoretical ellipticities of Rayleigh wave with observed H/V of microtremors (Zaineh et al. 2012a). The deep soil layer was found to be uniform in the city. While the shallow structure (overlain the deep layer) is not uniform in Damascus city and there is a wide variation in the S-wave velocity and thickness of the shallow soil layers and the city can be divided into three different regions (***a, b***, and ***c***).

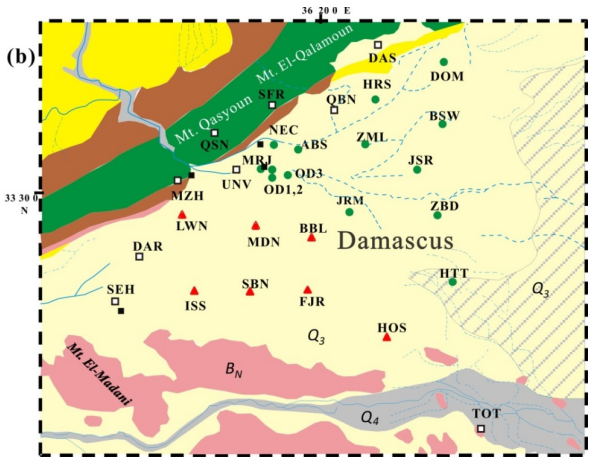

Figure 2 Geological Map of Damascus city (Ministry of Industry, 1963) with the locations of microtremor survey sites. Circles, squares, and triangles denote the sites of ***a, b***, and ***c*** regions respectively

2. SEISMIC MICROZONING OF SITE AMPLIFICATION

2.1 1-D site amplification factor

Site amplification factors were calculated by following

one-dimensional shear wave propagation theory for vertical incident S-wave using the resulted V_S structure (Zaineh et al. 2012a). We considered the uniform deep soil layer (V_S ~1600 m/s) as a half-space layer. Figure 3 shows the computed site amplification factors for the all sites of group ***a, b,*** and ***c***. The results show that region ***a*** has the highest site amplification among the regions due to the presence of a soft layer (V_S *~200 m/s*) near the surface which controls the site amplification in this region while the ***c*** region has the lowest site amplification.

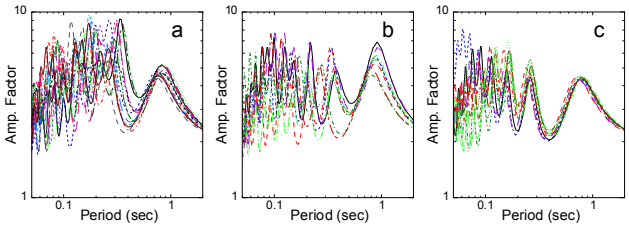

Figure 3 Computed site amplification factors for the all sites of group ***a, b,*** and ***c*** in Damascus city.

2.2. Amplification factor vs. topographic data

Since a topographic data are available for all areas with uniform sampling for the globe, while information about the surficial geology and shear wave velocity do not exist for many regions in the world. Intuitively, topographic data should be used as an indicator of the near-surface geomorphology and lithology to the first order, with steep mountains indicating the rock, nearly flat basins indicating the soil. Recently, many studies have confirmed a good correlations between the V_{S30} (V_{S30} internationally is well correlated with the site amplification) and the topographic conditions as well as the geomorphologic unit (Gallant J. C. et al. 2003; Matsuka M. et al. 2005; Chiou B. S. J. et al. 2006; David J.W. et al. 2007).

The averaged amplification factors (*AF*) for a period range (0.1s – 2.0s) for the 30 sites in Damascus city were estimated (Figure 3). The 30 sites have corresponding *AF* and elevation parameter (E_v) and we introduced the distance from the nearest river (D_r) as a possible geographic condition. For the elevation data, we used the SRTM data (3arcsec) to extract the elevation map of Damascus city. For the distance from river (D_r), it was calculated by considering the Barada River with its branches that shown in the blue lines in Fig. 2. We performed a multiple regression analyses with the average site amplification (*AF*) as the criterion variable that defined by E_v and D_r as independent parameters as shown in equation (1). In order that the numeric data are uniform (E_v and D_r), the data were standardized as shown in equation (2):

$$\log(AF) = 0.583 - 0.028 * \log(E_V') - 0.042 * \log(D_r') \quad (1)$$

$$X_i' = (X_i - \bar{X})/\sigma_x \quad (2)$$

Where, X_i is the original data, X_i' represents the standardized data, $\bar{X}$ is the mean value, σ_x is the standard deviation, and E_V' & D_r' are the standardized values of E_v and D_r. We found a good correlation between the site amplification and topographic conditions (E_v and D_r). This relationship can be used for seismic hazard assessment even though it needs to be improved. Figure 4 shows a comparison between the averaged amplification factors (*AF*) and the calculated ones (AF_{reg}) derived from the above equation (Eq. 1).

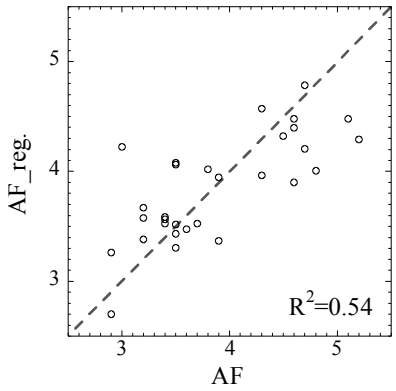

Figure 4 Comparison between the averaged amplification factors (*AF*) and the calculated ones derived from regression analysis (AF_{reg})

3. CHARACTERISTIC OF EARTHQUAKE GROUND MOTIONS IN DAMASCUS

Zaineh et al. (2012b) constructed a source model of the 1759 Earthquake and the appropriateness of their source Model was validated by comparing the calculated intensities with the observed ones by Ambraseys & Barazangi (1989). The strong ground motions in Damascus city were simulated and compared with the design requirements in the Syrian building code. Grid systems with 1.0 km * 1.0 km cells were adopted in Damascus city (Dashed lines in Fig. 6 and Fig. 7). We simulated the ground motions at the top layer of V_S = *1600 m/s* at each grid point using the source model of the 1759 Earthquake. Figure 5 shows the simulated velocity waveforms at the top layer of V_S = *1600 m/s* at some grid points in Damascus city. The horizontal peak ground velocity (PGV_{1600}) at each grid point was calculated from the root-mean-square combination of the two horizontal components. Figure 6 presents the distribution of PGV_{1600} at the top layer of V_S=*1600 m/s*. Generally, there is a decreasing in the values of PGV_{1600} from the north-western to the south-eastern sides of Damascus city. The largest values of PGV_{1600} (~45 cm/sec) were concentrated in the north-western sites that are the nearest to the central asperity in the proposed source model (Zaineh et al. 2012b). The smallest values (~15cm/sec) were concentrated in the south-eastern parts of Damascus city which are the farthest from the source.

Using the relationship between the averaged amplification factors (*AF*) with the elevation (E_v) and distance from river (D_r) (Eq. 1), we calculated the PGV_S at

the ground surface as follows:

$$PGV_S = PGV_{1600} * AF \qquad (3)$$

Figure 7 illustrates the distribution of PGV_S at the ground surface in the city of Damascus. Generally, the largest values of PGV_S were concentrated in the central and eastern parts of Damascus (region ***a***) due to the high site amplification in this area. And the smallest values were concentrated in the southern parts of the city (region ***b***).

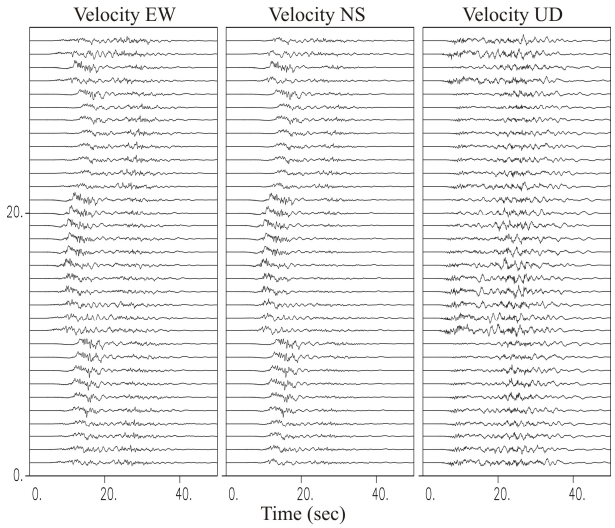

Figure 5 Simulated velocity waveforms at the top layer of V_S = *1600 m/s* at some grid points in Damascus city

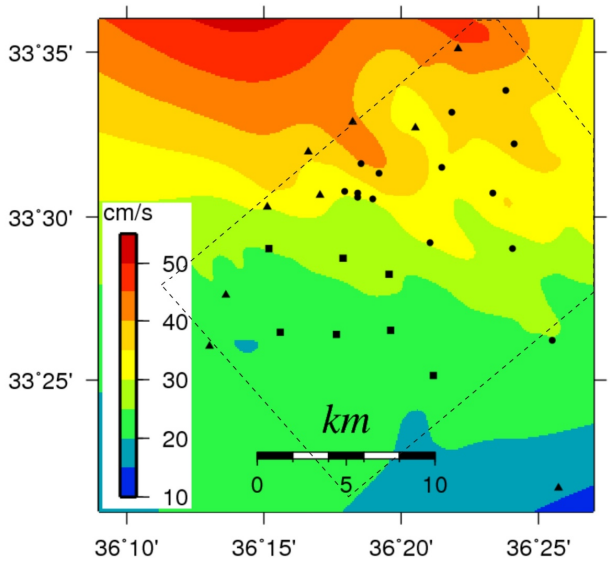

Figure 6 Distribution of PGV_{1600} at the top layer of V_S=*1600 m/s* in Damascus city, circles, squares and triangles represent the sites of groups ***a, b,*** and ***c*** respectively.

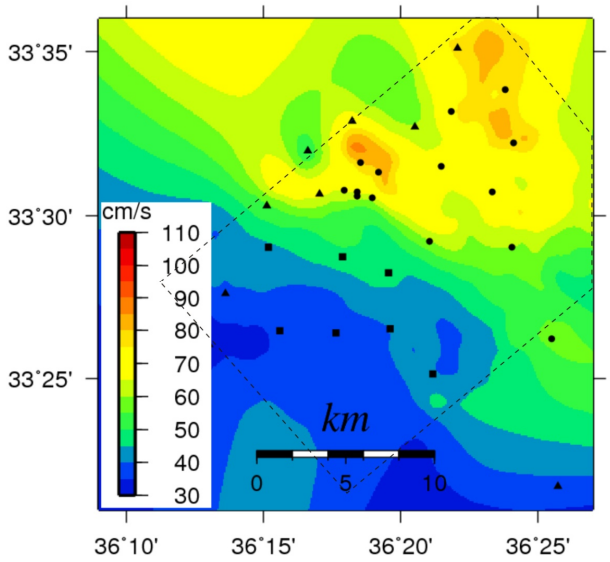

Figure 7 Distribution of peak ground velocities at the ground surface in Damascus city; circles, squares and triangles represent the sites of groups ***a,*** ***b,*** and ***c*** respectively.

4. NONLINEARITY EFFECTS IN DAMASCUS CITY

The simulated waveforms at the top layer of V_S=*1600 m/s* (Fig. 5) were used as input for 1-D site response analysis. Following the equivalent linear approximation of nonlinear response (Schnabel et al. 1972), we estimated the non-linear amplification factors. We used Koyamada's Model to express the nonlinear relations between the shear strain S_e with the shear modulus G, and the damping factor ***h*** (Miura et al. 2001). Figure 8 shows site amplification factors for some sites in Damascus city belong to different regions, the red doted lines represent the non-linear response and the solid lines represent the linear response of the soil strata at each site. The non-linearity effects are more remarkable in the high frequency amplifications of the sites of ***a*** region located in the central and eastern parts of the city than the sites of ***b*** and ***c*** regions due to the shallow soft layers in the ***a*** region sites. The non-linear transfer functions (amplification factors) of ***a*** region sites (DOM, ZBD, and HTT) were shifted toward lower frequencies as shown in Fig. 8. The non-linear effects are very small in the ***b*** and ***c*** regions where stiffer soil layers were observed.

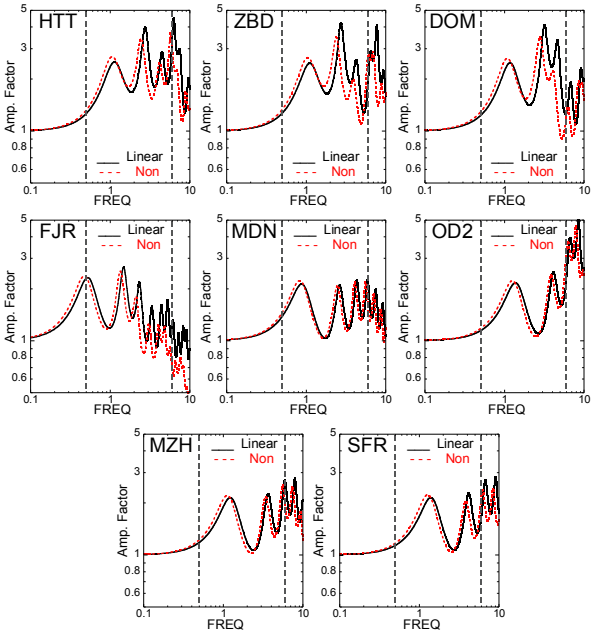

Figure 8 Site amplification factors for some sites in Damascus city belong to different regions, red doted lines represent the non-linear response and the solid lines represent the linear response of the soil strata at each site

5. CONCLUSIONS

Site amplification factors were calculated by one-dimensional shear wave propagation theory for vertically incident S-wave by using the resulted 1-D soil profiles (Zaineh et al. 2012a). The results show that region ***a*** has the highest site amplification among the regions due to the presence of a shallow soft layer (V_S *~200 m/s*) which controls the site amplification while the ***c*** region has the lowest site amplification.

We performed a multiple regression analyses with the average site amplification (*AF*) as the criterion variable that defined by different independent parameters in the case of Damascus city. We found a good correlation between the site amplification and topographic conditions (E_v, and D_r). The obtained relationship can be used for seismic hazard assessment even though it needs to be improved.

The microzonation maps with respect to peak ground velocity were estimated for Damascus city. The largest values of PGV_S were concentrated in the central and eastern parts of Damascus (region ***a***) due to the high site amplification in this area. And the smallest values were concentrated in the southern parts of the city (region ***b***).

We discussed the nonlinear amplification in the city following the equivalent linear approximation of nonlinear response of the 1-D soil strata. The non-linearity effects are more remarkable in the high frequency amplification for the central and eastern region of the city; this region was suffered mainly from the foundation failure and slumping of the ground during the 1759 earthquake.

Abstract: Making a model of ground structure is one of the most important topics in aspect of the earthquake ground motion prediction of a certain area. For the purpose, we are now developing a gravity and magnetic exploration system for moving careers. To discuss the sensitivity and practicability of the exploration system, air-borne survey had been carried out in Oct. 15th, 2012. We set the system on the autonomous-cruise-type uninhabited helicopter and navigate it over a concrete gravity dam with some magnetic body. Data analysis method have been applied to the observed data, and compare them with theoretical gravity effect which calculated by the terrain model. Finally, the improvement in these methods has been discussed.

1. INTRODUCTION

It is important for the regional earthquake disaster prevention to make an estimation model of ground structure and clarify the non-fairing nature of the ground in detail. For this purpose, gravity and magnetic surveys can be used to estimate the deep and vast velocity and density structures of the ground because of quick observations.

To observe over a very large area, it is desirable that observation sensors are installed on moving careers. However, these careers such as airplane or ships usually make very large vibration noise that might mask the signal we want. Conventional airborne or shipboard gravimeter has such a complicated and huge system to shutout the disturbance and to retain the sensor vertical by means of stabilized platform which controlled by the mechanical or fiberoptic gyroscope for accurate gravity observation. Also, very accurate measurement of position is required for the correction of the Eotvos effect.

Nowadays, since these implements such as gyroscopes, accelerometers, computers and GPS measurement system are dramatically improved, observation system becomes much smaller and higher-performance. We now aspire to make observation system simple, which sensors installed directly on the career, then correct the observed data by post processing from the accurate posture data. Furthermore, the new accelerometer sensor "D-servo", which has enough dynamic range for the carrier disturbance and resolution for detection of gravity anomaly had been developed as shown in Yokoi et al. (2012).

To discuss the sensitivity and practicability of the exploration system, air-bone survey has been carried out. We set the observation system on an autonomous-cruise-type uninhabited helicopter and navigate it over a huge concrete gravity dam, which makes big gradient in gravity, with some magnetic body as flood spillway. By means of GPS data of each cruise, theoretical gravity is calculated from terrain model made of 50m-mesh rectangular parallelepiped which height is altitude. Effects of stored water and dam itself are also considered. Some data analysis methods is applied to the observed data, and then compared with the result of the theoretical calculation to evaluate the system performance. Finally, the improvement of the proposed methods is discussed.

2. AIRBORNE OBSERVATION

2.1 Summarize of the Observation

The air-borne survey carried out on Oct. 15th, 2012, at a concrete gravity dam of Shizuoka pref., Japan. This dam is 155.5m height, 293.5m length, and 326,848,000m^{3}of impoundment (Figure 1). There is a flood spillway made of steel, which is magnetic body, on the top of the dam.

Schema of observation is shown in Figure 2. The helicopter navigates upper and lower stream of the dam body for 500m each in constant velocity 2m/sec. The height of these cruise are fixed to 50m or 70m from the base station at each

cruise. We set 3 cruise courses as shown in Figure 3. Except for the arrival and departure, helicopter is controlled automatically by the program, so that it is possible to keep the height, speed and course during the cruise. At first, the helicopter flew up to the start point of the course in upper stream, then start cruise in constant velocity and height to the lower stream. After it reached to the end point of the course, it flew back the same course in same speed without changing the heading direction. At the end of each cruise, the helicopter came back to the base station for data logging and oiling.

Figure 1 Observation Site

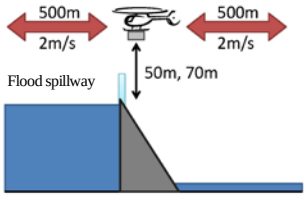

Figure 2 Schema of Survey

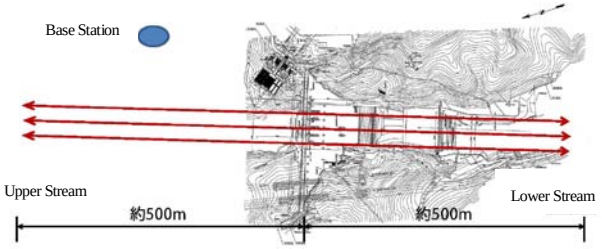

Figure 3 Cruise Course

2.2 Details of Exploration System

Sensors used for our exploration system are listed in Table 1. Since the helicopter cannot load heavy equipments, total weight of sensors and data loggers must be less than 10kg. We have 2 accelerometers for gravity detection; D-servo and VSE-156SG (both are made by Tokyo Sokushin; it is called VSE). These 2 sensors have enough resolution to detect gravity anomaly in mGal order, however VSE sensor has low dynamic range that cannot allow the large disturbance of the helicopter if the weather is too windy. In addition, there are 3-axis accelerometer, named hereafter Titan (Nanometrics) as inclinometers, Cesium magnetometer (Geometrics) for magnetic survey, and GPS & IMU unit (NovAtel, & Tamagawa Seiki) for the positioning detection system. These sensors and data loggers are set under the helicopter as shown in Figure 4. Cesium magnetometer is suspended under the helicopter since helicopter itself is also magnetized. Furthermore, GPS unit and Proton magnetometer had been set at the base station for reference. All data loggers are synchronized with GPS clock so that accurate time can be obtained in different sensors.

Table 1 Sensors of Exploration System

Sensor	Use	Range
D-servo (Tokyo Sokushin)	gravimeter	±992 [Gal]
VSE-156SG (Tokyo Sokushin)		±50 [Gal]
Titan (Nanometrics)	inclinometer	±4x980 [Gal]
Cesium Magnetometer (Geometrics)	magnetometer	-
GPS(NovAtel) & IMU (Tamagawa)	positioning	-

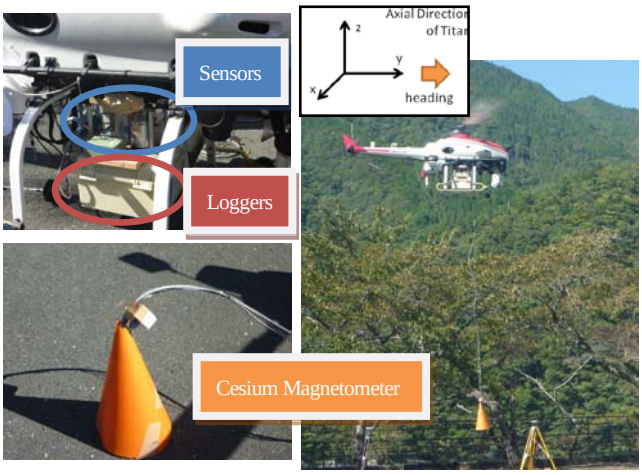

Figure 4 Exploration System

3. THEORETICAL CALCULATION

3.1 Gravity of Rectangular Prism

For calculation of the gravitational terrain effect, we assume geographical features as the set of rectangular prism whose height is an altitude. Exact solution of the gravitational attraction of a rectangular parallelepiped is obtained in Nagy (1966), and the formula simply deformed by Banajee and Das Gupta (1977). Let the coordinate of the measurement point(x_s, y_s, z_s), gravitational attraction caused by a rectangular prism whose base is rectangular with sides $x_{i+1} - x_i$ and $y_{j+1} - y_j$, height is h_{ij}, can be written as Eq.1 below:

$$g_{ij} = \frac{1}{2}G\rho\left[x\ ln\frac{R+y}{R-y} + y\ ln\frac{R+x}{R-x} - 2z\ tan^{-1}\frac{xy}{zR}\right]\Big|_{x_i - x_s}^{x_{i+1} - x_s}\Big|_{y_j - y_s}^{y_{j+1} - y_s}\Big|_{-z_s}^{h_{ij} - z_s},$$

where $R = \sqrt{x^2 + y^2 + z^2}$ and $[f(x,y)]\Big|_{x_1}^{x_2}\Big|_{y_1}^{y_2} = [f(x_2,y_2) - f(x_1,y_2)] - [f(x_2,y_1) - f(x_1,y_1)]$ (1)

Here, G is the gravitational constant and ρ is the density.

If we think that we can approximate the effect of the rectangular prism of horizontal cross-sectional area S with the effect of the center axis line of the prism which the density of the prism compressed into, that is, linear density approximation, we can rewrite Eq.1 into Eq.2 as follows:

$$g_{ij} = -G\rho S\left[\frac{1}{R}\right]\Big|_{h_{ij} - z_s}^{-z_s}$$
$$h_{ij} = \frac{z_{ij} + z_{(i+1)j} + z_{i(j+1)} + z_{(i+1)(j+1)}}{4} \quad (2)$$
$$R = \sqrt{\left(x_s - \frac{x_i + x_{i+1}}{2}\right)^2 + \left(y_s - \frac{y_j + y_{j+1}}{2}\right)^2 + {z_s}^2}$$

It is said that if the measurement point is too close to the prism, errors in Eq.2 cannot be neglected. At the observation in this study, since the measurement point is on the helicopter which parted from the ground surface, enough accuracy is satisfied in the calculation by means of Eq.2.

Either case using Eq.1 or Eq.2, since these gravity attractions are expressed in linear combination, total gravity of the whole model can be obtained as Eq.3:

$$g_{ALL} = \sum_i \sum_j g_{ij} \quad (3)$$

3.2 Terrain Model and Other Corrections

Flowchart of how to calculate theoretical gravity is shown in Fig.5. Terrain model is made from 50m-mesh altitude data provided by Geospatial Information Authority of Japan, as shown in Fig.6. Since x and y axis show numbers of meshes, size of the whole area we used at the calculation is 20 x 10km. However, the altitude data does not distinguish between ground and water surface, which difference of the density between these two elements must be considered for the calculation. Furthermore, gravitational effect caused by the dam body itself should be also considered. We make two layers, stored water layer and dam body layer above the field layer in the model. From Eq.3, we can calculate these 3 different layers apart and then sum up for the total gravity.

For the calculation, actual position of the helicopter is also required. GPS data are corrected and converted into latitude, longitude, height, velocity, and azimuth. Position data are converted into xyz coordinates to map on Fig.6, then gravitational terrain effects are obtained from Eq.2. Free air corrections and Eotvos corrections are also obtained here by using latitude, height, velocity and azimuth. Example of calculated reference gravity is shown in Fig.7. We can see that terrain gravitational effect is less than 10 mGal, and Eotvos effect is about 20 mGal during the flight.

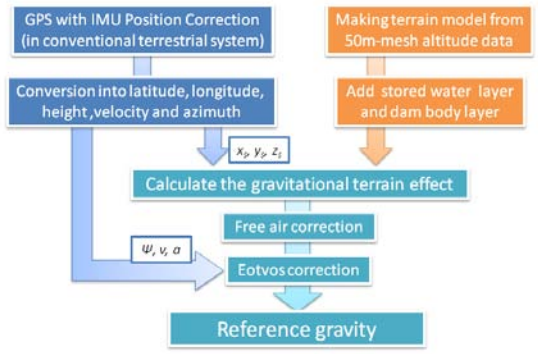

Figure 5 Flowchart of Theoretical Gravity Calculation

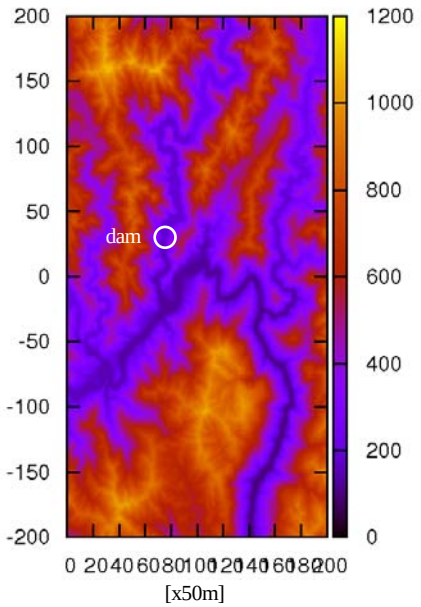

Figure 6 50m-mesh Field Data

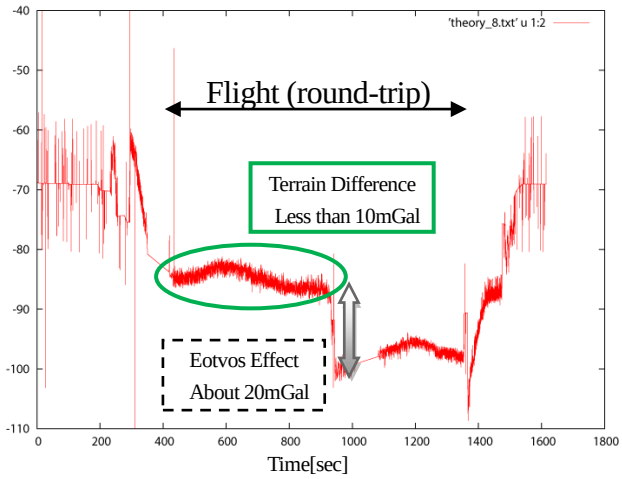

Figure7 Example of Obtained Reference Gravity

4. OBSERVED DATA

4.1 Magnetic Survey

Examples of observed magnetism are shown in Fig.8. These two figures show the magnetism of the same course, the center red line in Fig.3, which go through just over the magnetic body at the dam top, in different height, 50m and 70m from the level of the base station. Without any analysis, we can clearly see that sensors detect the magnetic body in stable. In addition, at different height, sensor only detect the magnetism intensity difference during the time pass through over the magnetic body, but almost same at other points. We can say that the sensor working very well to detect the effect of magnetic body.

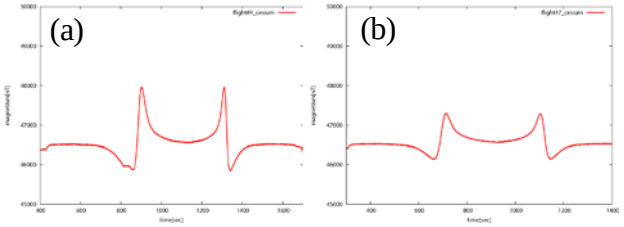

Figure 8 Magnetism in same course at different height (a)50m and (b)70m

4.2 Gravity Survey

Unlike magnetic data, effects of vibration or inclination of the career is much larger than gravity anomaly we want. Therefore, we can tell very few things from raw signals. To see details of gravity data, long-period low pass filter is required to ignore the short-term disturbance caused by careers. Fig.9 shows theoretical gravity obtained in Fig.7 and observed accelerometer data filtered by 5th Butterworth filter with cutoff 45 sec. Here, VSE and D-servo are gravimeters, and Titan is 3-axis accelerometer for detection of inclination, and positive direction of Z-axis is set downward so that gravitational effect is indicated in positive.

At a glance view of Fig.9, it seems that gravimeters describe main tendency of theoretical gravity in some extinct. However, their amplitude is quite different from calculated theoretical gravity. For example, we can note from Fig.7 that

amplitude of Eotvos effect is just about 20 mGal. On the other hand, difference we can see in the middle in gravimeters of Fig.9 is much larger, about 1Gal. It is clear that there are some other causes which make such a big difference in sensor outputs, that is, inclination of the career. Output of titan x and y, that are illustrated in Fig.9, also have a big difference at the same time. It suggests that there is long term inclination in cruise, during going and returning. Furthermore, fluctuation during going or returning cruise seems too large that we should correct before applying further analysis. Still more, large fluctuation before cruise or big change of inclination involves the trend when long-period filter is applied, that the effect might hide the gravitational terrain difference under a cover.

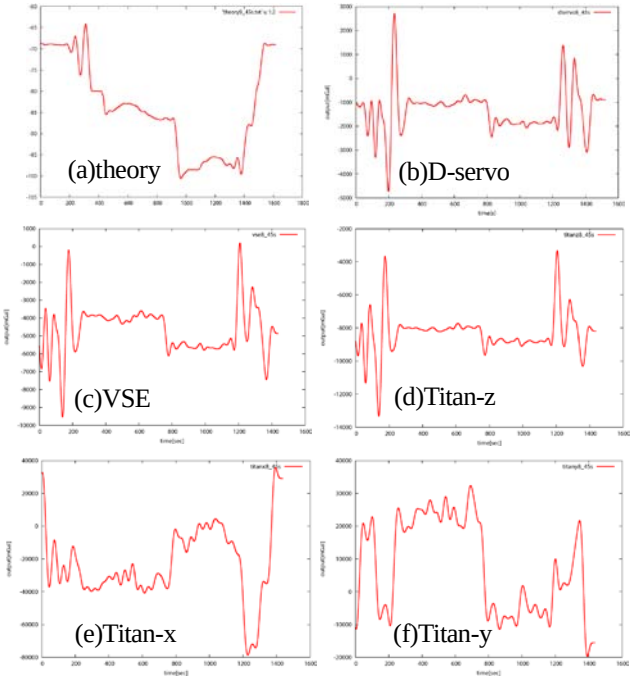

Figure 9 Theoretical Gravity and Data of Flight #8 (Filtered by Butterworth 45sec)

5. ANALYSIS OF GRAVITY DATA

5.1 Inclination Correction

Fig.10 shows a schematic figure of the inclination of the sensor. If we assume that inclined angle from horizontal plane to x or y axis as θ and output of Titan-x and y is 0 at horizontal plane, we can determine the angle θ from output of x or y and the gravity standard, $g = 980\mathrm{Gal}$, as follows:

$$\theta = sin^{-1}\frac{|x \text{ or } y|}{g} \qquad (4)$$

From Eq.4, we can calculate the inclination of the sensors. However, if we require more accuracy in this correction, accurate calibration of the whole sensors is quite important. In detail, 2 types of calibration of the sensor are required. At first, outputs of Titan-x and -y are adjusted to 0 at accurate horizontal plane so that assumption in Eq.4 is satisfied. Secondly, actual amount of change in output of all gravimeters and accelerometers must be measured just before the observation. Usually, outputs of sensors change with the angle as shown in Fig.11. It is clear from Fig.12, which is the raw signal of Titan-x, amplitude of going and returning cruise are different. This difference comes from Fig.11: if the fluctuation of the career is almost same during the whole cruise, difference in reference, that is, average angle in going or returning trip. This result also suggests that inclination correction is indispensable for the accurate gravity observation.

Inclination correction of gravity caused by x component which calculated by means of output of Titan-x and θ observed from Eq.4 are shown in Fig.13. Notice that we cannot calculate the amount of the correction from output of z-component because we usually adjust z with gravitational acceleration included, that is, output of z direction is not the absolute gravity. Even though the amplitude of the fluctuation in Fig.9 Titan-x has a little difference between going and returning cruise, difference in amount of correction in Fig.13 is much larger. This might suggest that Titan-x in this observation has some offset so that observed angle is slightly different from actual. We hardly detect these offset before or after the observation because environmental factor is dominant, such as temperature, air pressure, or how to load the system on different career. Since accuracy in angle is very sensitive to the output of gravity, we have to consider about suitable way for calibration during observation.

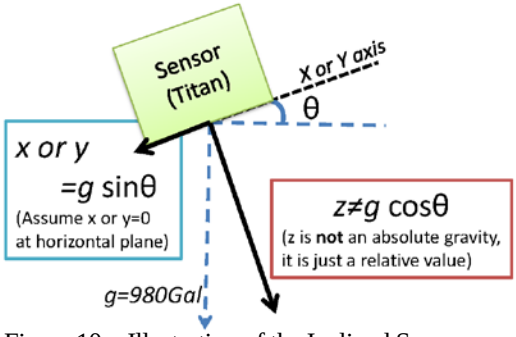

Figure 10 Illustration of the Inclined Sensor

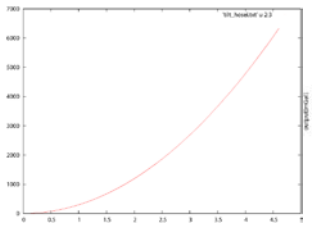

Figure 11 Output Difference with Angles[degree]

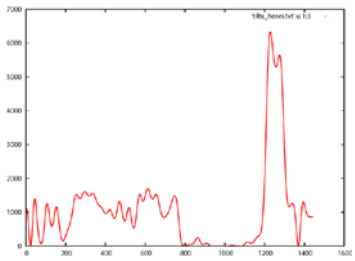

Figure 13 Inclination Correction (Titan-x)

5.2 Improvement of Gravity Analysis and Its Results

For detection of long-period components from the gravity data, Hilbert-Huang Transform (HHT) is used. Basic ideas of the method are described in Huang et al. (1998). HHT has an advantage in nonlinear and non-stationary data analysis, especially superior in long-term trend detection. On the other hand, this method is very susceptible for edge effect of the data. In addition, as we mentioned in section 4.2, long period filter tend to flatten the rapid change in the data, leaked effect sometimes cover up the signal we want. To ignore the short period disturbance for long-term inclination correction, we should pick out the data during the terrain difference should be detected from whole cruise data before apply filters. Moreover, to avoid the edge effect at HHT, we connected the same signal we picked out at head and tail of that data, namely we remade the picked out data as the same data repeated almost 3 times. Then, we tapered the data edge for 100 sec with linear declination. After the process, Butterworth filter is applied to remove the short-period disturbance and inclination correction is calculated. Finally, we divide the signal into some intrinsic mode functions (IMF) with different frequency by HHT, and look for the main term of the connected signal of objective frequency.

The procedure for analysis is summarized as follows:

1. Pick out the data during the term that we want to detect the gravity anomaly, then connect the picked out data at head and tail of the data itself. Apply the same procedure to all sensors.
2. Taper head and tail of the data for about 100sec each.
3. Apply a low-pass filter of Butterworth type with cutoff period of 30sec/45sec (hereafter, we call 30- or 45-sec filter) to remove the short-period disturbance.
4. By using filtered Titan-x and Titan-y data, calculate inclination correction of the z-components.
5. Apply HHT to divide the corrected output of the gravimeter into IMFs with different frequency. Then pick up the main term of the connected signal of objective frequency.

Results of the analysis of VSE and D-servo sensors during going cruise of flight #8 are shown in Figs.14 and 15, respectively. Fig.14 shows the sum of 10^{th} and 11^{th} IMF mode of the VSE signals and the analytical gravity of the corresponding term. In the same way, Fig. 15 shows the sum of 8^{th} and 9^{th} IMF mode of the D-servo signals. 30-sec and 45-sec filter is applied for the analysis. From both results, almost same signals have been detected, and they agree with the calculated analytical gravity very well in phase and period. Connecting the same data repeatedly make ease to pick up the IMF with constant frequency, such as the gravitational anomaly observed in constant career velocity. Furthermore, edge effect cannot reach to the main portion of the data by this process so that much clear trend in main portion can be separated by HHT. Same procedure for the analysis is also applied to Titan-z, yet the signal shown in Figs.14 or 15 cannot be detected. Titan accelerometer does not have enough resolution to detect the gravity anomaly, in other words, detected signals in Figs.14 and 15 seems to be the gravitaty anomaly.

Still, there are differences in amplitude. This might be the effect of inaccuracy in the inclination correction. For more detailed discussion, we should consider the calibration process, or devise some algorithm to determine the accurate inclined angle for the correction.

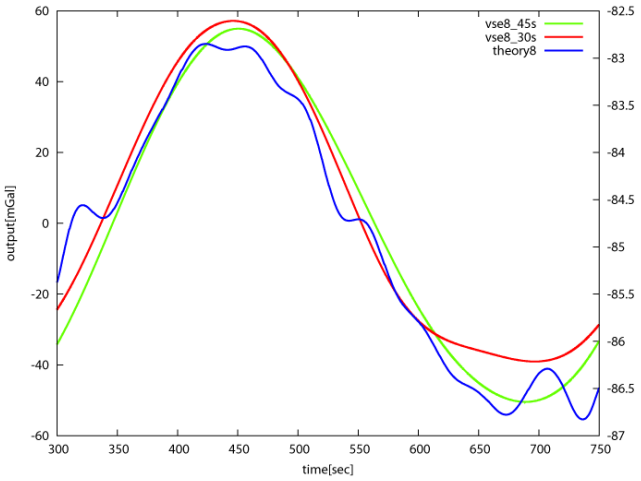

Figure 14 Result of Analysis (VSE)

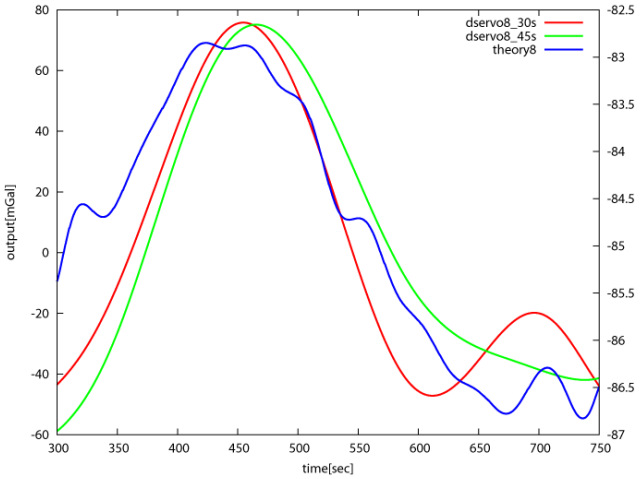

Figure 15 Result of Analysis (D-servo)

6. CONCLUSIONS AND FUTURE DEVELOPMENT

The exploration system had been tested at the airborne observation near a huge concrete dam. Theoretical gravity anomaly was calculated from terrain model. Sensitivity of the magnetic survey was quite well. On the other hand, inclination correction seems to be required in gravity survey. For the accurate correction, we should consider about suitable way of the calibration of sensors. Improved method for gravity analysis is proposed and the result has quite good agreement with theoretical gravity in phase and period of the signal, but there are still some disagreements in amplitude. Certain algorithm might be required to determine the accurate inclined angles for the correction. It will be also effective to apply the method to more stable career observation, such as shipboard observation.

Abstract: In March 2011, there were huge earthquake ground motions in Tohoku region. Furukawa, Japan, was one of a few places in Japan where had severe damages caused by earthquake ground motion. However, the interesting point is that size of this ciy is quite small but the damages were totally different from places to places, in area of 2km x 2km. Therefore, investigation of the ground structure is necessary. Firstly, very dense seismometers have been installed to observe the ground motions. Nevertheless, gravity survey method was conducted later to confirm that the ground structures are indeed different within this small area. Gravity survey was carried out at the intervals of hundreds meter because there was an estimation that soft soil sediment is not thick. The Bouguer anomaly, as a result from gravity survey, has some significant variations in some places, which correspond to the most severely damaged places. Furthermore, residual anomaly as extracted from regional anomaly also states the similar fashion to both Bouguer anomaly and severe damaged places. Final 3-D map showing the altitude of basement presents the variations of the depth in 2km x 2km with the maximum different up to 67 meters.

1. INTRODUCTION

The 2011 earthquake off the Pacific coast of Japan caused severe damage to many parts of Japan, particularly, in the Northeastern of the country. Most of those damages came from the attacked Tsunami or liquefaction just after the earthquake; however, there were a few places where the damages were the results of hit by earthquake ground motions. Furukawa in Osaki city, Figure 1, is one of those a few places.

Nevertheless, the interesting point, which motivated the observation in this area, is that the damages were not uniformly distributed, in the other word, the damages were greatly different in the distance of a few kilometers or area of 2km x 2km.

First step of observation was to collect the recorded seismogram installed in the area, after the inspection, we found that recorded response spectrum of two adjacent stations, JMA-Furukawa and K-NET-MYG006, which are a few kilometers apart having the response difference about two times, around 1.5-sec period as shown in Figure 2. Then we carried out the observation using dense sensors (Goto, 2011), 19 sensors by the end of 2011 for 2 km x 2 km area, to better understand the anomaly of the damage distribution. As a result, the anomaly of the ground motion is large

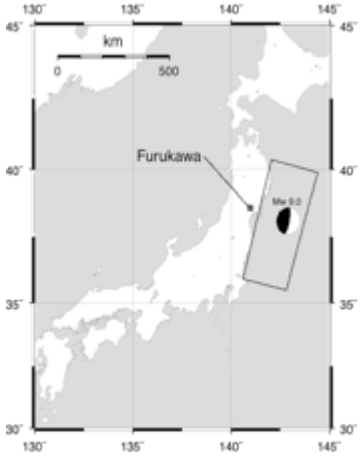

Figure 1 Location of the observation area, Furukawa, Osaki, Japan

beyond our consideration. The anomaly of ground motions should come from the anomaly of ground structure. Then we decided to carry out the gravity survey in this area. There is an estimated data suggesting that soft soil sediment is not so thick, or, depth to the engineering bedrock is less than 50 meters so very high resolution of gravity anomaly is required. Thus, we chose to do the gravity survey with the observing interval of a few hundred meters in the downtown area.

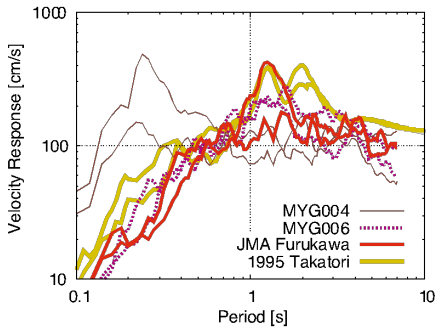

Figure 2 Velocity response spectrum of JMA-Furukawa and MYG006 stations, showing the recorded value different about 2 times, also comparing to 1995 Kobe earthquake (Goto, 2011).

2. PROCESSING OF GRAVITY SURVEY

2.1 Data Acquisition

Basically, gravity survey requires two kinds of data, which are gravitational value of the observed points and the exact location of those points i.e. latitude, longitude, and elevation. In this observation, we use the LaCoste and Romberg gravimeter (S/N:G911) to measure the gravity value, which can give the accuracy up to 3 microgals (approximation of gravitation field of the Earth is about 9.8 x 10^8 microgals). The gravitational acceleration of the Earth can be basically derived from the well-known Newton's equation: i.e.

$$F = Gm_1m_2/r^2 \qquad (1)$$

To position the exact location of the observed points, we measure by using Magellan GPS. In this study, we perform an observation 3 times i.e. September 2011, February 2012, and October 2012.

2.2 Data Processing

In order to analyze the gravity survey data, the absolute gravity value is necessary. Also, observation requires a loop survey, which we have to start and end at the same point, daily. So we designate absolute gravity value point, base point, in front of the JR Furukawa station by transferring the value from the closest known absolute gravity point in Tsukidate where is quite far from Furukawa and would consume a lot of time because gravity survey requires a loop survey daily, start and end at the same point. This known absolute gravity point, named as HRKB, has a value of 980098.8553 mgal with the latitude and longitude of 38.571339 and 140.967204, respectively, and the altitude is 59.483 meters.

The observed values must be corrected by many procedures because they contain several errors due to instruments, shape of the Earth, physical properties of surrounding area, and the location of observed points.

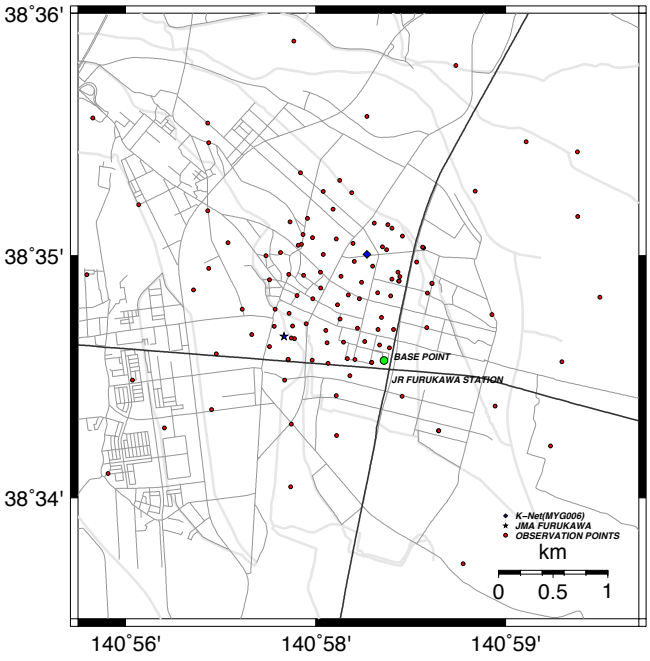

Figure 3 Map of the observed area with observed points (red dots) also JMA-Furukawa and K-NET-MYG006 stations. Bold-black lines show railway, thin-light lines show traffic way, and bold-light lines show stream way.

As the survey processes go on, of course, time passes by. Differences of time of reading the values from gravimeter have differences of gravitational value due to effect of attraction between moon and sun. This effect is called gravity tidal effect, which varies with time. There is another effect called drift, which comes from the gravimeter. Even the instrument is well controlled in every way; the spring and any connections inside the gravimeter are not perfectly stable and cause small error to the reading values. Latter effect is called drift. These tidal and drift effects must be corrected first before doing further analysis.

From the equation (1), gravity varies with elevation (distance from the center of the Earth), then any points those higher in elevation has lower gravitational acceleration comparing to those points with lower elevation. The gravity at a point on the surface of the Earth can be obtained by

$$g = GM / R^2 \qquad (2)$$

from this equation, if we take a derivative with the vertical direction, we will see that gravitational value varies with the elevation. In the other word, if the elevation correction of observed points were not made, a gravity map would be incorrect due to differences in elevation because we make a gravity map on a reference datum level. This effect is called free-air effect. The attraction of materials between a reference elevation and observed points also affects the reading values. This effect is called Bouguer effect and can be corrected by

$$g = 2\pi G\sigma h \qquad (3)$$

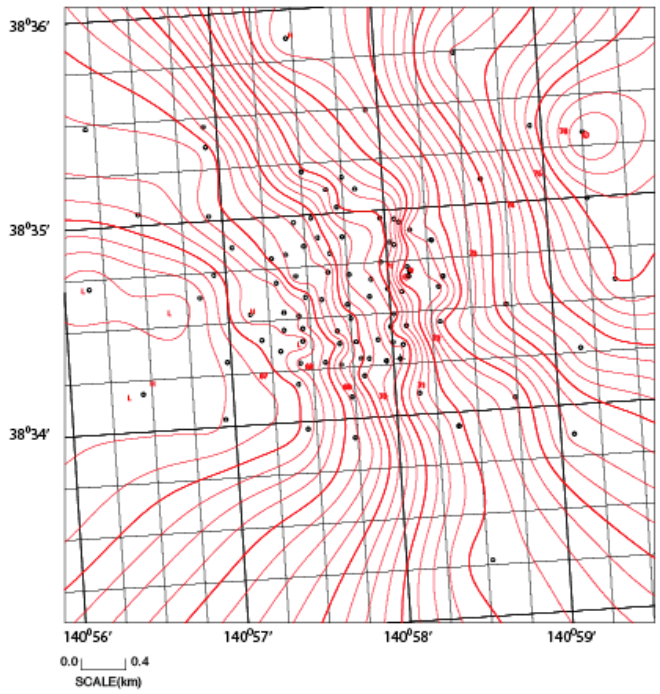

Figure 4 Bouguer anomaly map of the observed area, Furukawa, Osaki, Japan. Small black dots denote the observation points.

where σ is density of medium and h is thickness. In this study, we assume σ to be 1.90 g/cm^3.

Furthermore, owing to Earth is not a sphere, so gravitational values are not the same with difference of latitude. Gravitational acceleration is increased from equator to pole. This procedure is called latitude correction.

3. RESULTS FROM GRAVITY SURVEY IN FURUKAWA AREA

The primary goal of gravity survey method is to determine the ground structure beneath a survey area. By collecting and analyzing the observed gravitational values with corrections, we will yield a map called Bouguer anomaly map. In this study, we assume the density of engineering bedrock equal to 2.40 g/cm^3 together with the density of soft soil sediment equal to 1.90 g/cm^3 and the total numbers of observed points is 98. Obtained Bouguer anomaly map is shown in Figure 4.

From the above Bouguer anomaly map, it indicates that the gravitational value gradually decreased from the east to west. Figure 5 and Figure 6 show the regional gravity trend and residual gravity trend of observation area, respectively.

Regional gravity has the similar trend as the Bouguer anomaly map which is decreasing from east to west. This Regional anomaly trend gives the information on the regional geological structure, or, deep crustal features. While residual gravity map suggests that there are some small places where the gravitational value changes abruptly as indicated as loops due to the local gravity field, which is caused by local geological structures, or, shallow structure.

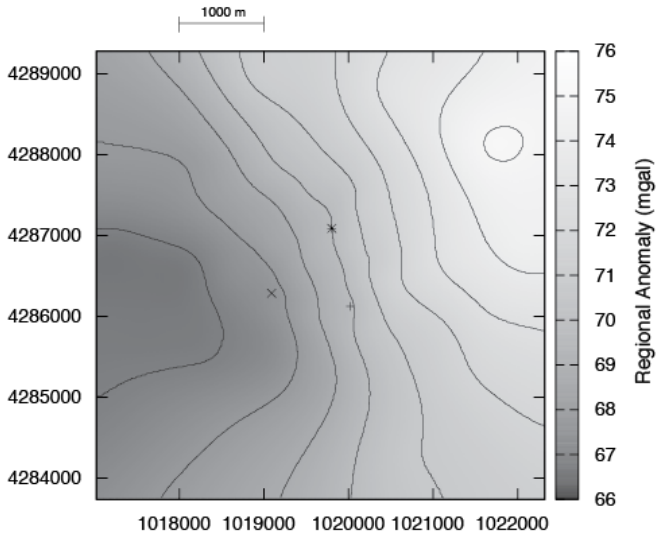

Figure 5 Regional gravity trend caused by regional geological structure shows that gravity value decreasing from east to west. The symbols +, ×, and * show the base point, JMA-Furukwa, and K-NET-MYG006 stations, respectively.

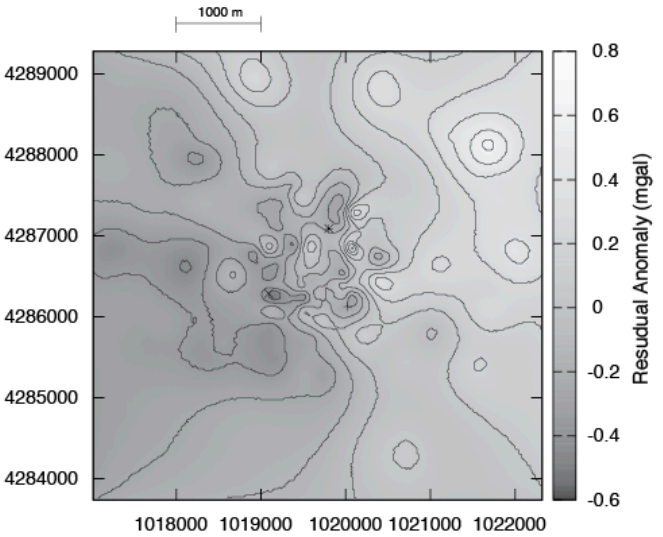

Figure 6 Residual gravity trend caused by local geological structure shows gravity variations due to local gravity field. Darker color suggests low gravity; which means soft soil sediment in shallow structure. The symbols +, ×, and * show the base point, JMA-Furukwa, and K-NET-MYG006 stations, respectively.

From those maps mentioned above, we estimate the basement map of the ground layer, Figure 7, showing the altitude of the boundary between surface sediments and engineering bedrock, which we set the values to be 1.90 g/cm^3 and 2.40 g/cm^3, respectively, together with the reference datum is set to be zero at the base point (HRKB). According to the simulated basement map, it can be seen that within the area approximately 5.0 km x 5.0 km, there are several places where the depth of soft soil sediment is quite deep relatively to surrounding area. The maximum different of depth to the bedrock is about 67 meters.

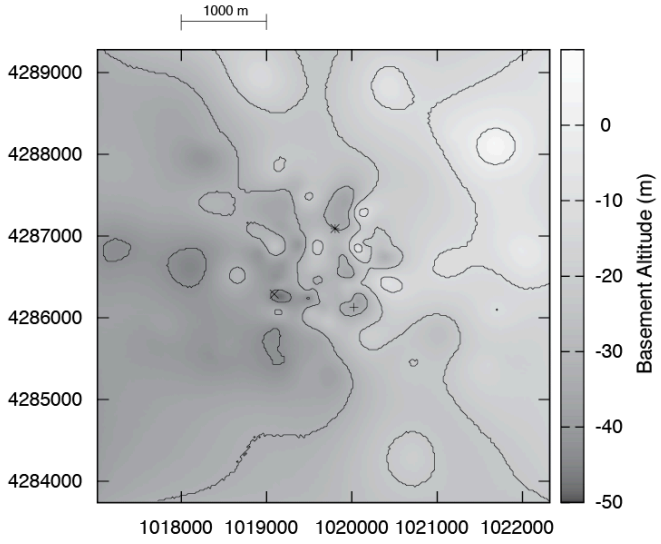

Figure 7 Basement map shows the thickness of soft soil sediment (1.90 g/cm^3) to the bedrock(2.40 g/cm^3). Engineering bedrock's altitude is deeper from east to west. The symbols +, ×, and * show the base point, JMA-Furukwa, and K-NET-MYG006 stations, respectively.

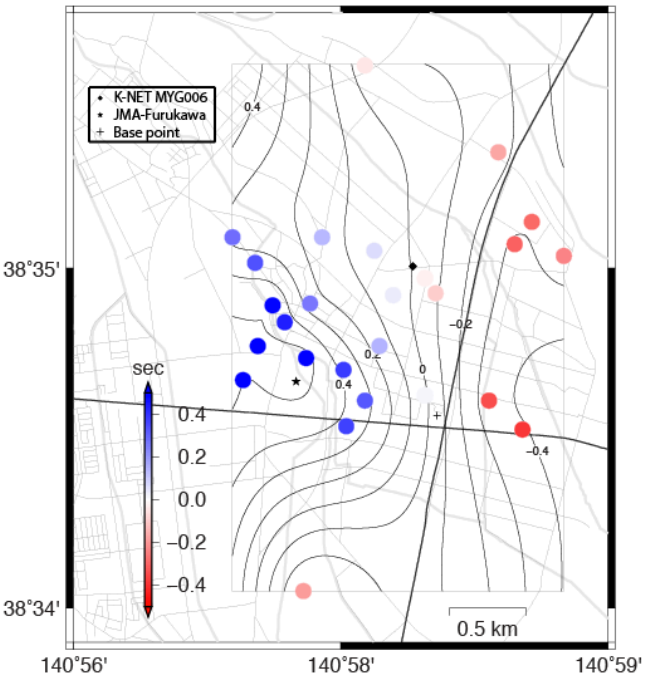

Figure 8 Arrival time at sensors installed in this area. Minus means prior arrive. Plus means later arrive, time delayed. Recorded waves came from east direction.

4. DISCUSSION

From the basement map, thickness of soft soil sediment, which we set to 1.90 g/cm3, is increasing from east of downtown to the western side, in other word; depth to the engineering bedrock is greater in the western side area. This information is corresponding to the real structural damaged data; which said that structures in the western side of Furukawa downtown were severely damaged; on the other hand, structures in the western side of downtown were little damaged or no damage. This result is not only matching with the structural damaged data, but also, corresponds to the pseudo-velocity response spectrum of the March 2011 aftershock event, which a record from JMA-Furukawa station that installed in the western side of downtown had a peak value about twice as a record from MYG006 K-NET installed in the north-eastern side of downtown.

Furthermore, on December 07, 2012, there was an earthquake event off the Pacific coast of Japan epicenter at 37.8N 144.2E with the magnitude of 7.3. Since we already installed seismometer densely (Goto, 2011) in this downtown area, so we have the information of the ground motion for this area. We did an analysis on the arrival time of surface wave, Rayleigh wave, because this surface wave travels in the surface layers, or, shallow layers, as we now have the information that ground structure beneath this area is not uniform, yet quite complicated. Analysis result of arrival time of Rayleigh wave is shown in Figure 8. This figure gives an information that if the ground structure was uniform in this small downtown, the arrival time at any sensors should be acted as a trend, parallel to each other, because the wave travels naturally as a straight-line so wave front must be parallel.

Cross line in the Figure 8 is the location of JR Furukawa station. Let us consider from the east side of figure vertically, the records at sensors from minus to zero have a trend of parallel, but when it passed 0-sec line, wave travelled with low velocity. Thus it suggests that those areas where wave travels with low speed comparing to adjacent areas should have soft soil layers because wave travels slower with low density of medium.

The results from Figure 7 and Figure 8 have similar trend for the shallow structure.

5. CONCLUSIONS

Shallow structures, or soft soil layers, underneath this downtown are not uniform and have some extremely soft soil basins distributed in the western side of downtown. This might be the reason that structures in this downtown suffered significantly level of damage even they are located near to each other within the range of few hundreds meters.

THE SIGNIFICANCE OF THE RATIO OF POWER SPECTRA BETWEEN TWO SITES IN THE WAVEFIELD OF MICROTREMOR

Xinrui ZHANG[1)] **and Hitoshi MORIKAWA**[1)]

1)Dept. Built Environment, Tokyo Institute of Technology

E-mail: zhang.x.aj@enveng.titech.ac.jp

ABSTRACT: In the SPAC method, the underground structure is assumed to be horizontal layers, which confines the accuracy of the estimation. On the other hand, the seismic interferometry theory makes it possible to identify the differnce of ground structure between each two sites by taking the ratio of power spectra respectively. Hence, we propose a method combining the conventional SPAC method and the concept of Green's function, which is known as the seismic interferometry. In order to show the availability of this combination, wavefield dominated by microtremors is simulated in which the SPAC method could be conducted effectively. Then the availability of seismic interferometry proposed previously is examined under the simulated wavefield and the need to take the ratio of the power spectra instead of using the power spectra itself directly is confirmed.

1. INTRODUCTION

Since Aki[1] proposed a new approach to estimate phase velocities of surface waves, spatial auto-correlation (SPAC) method has been a very useful tool to estimate ground structure because of its simple post-process. After that, many reseachers both in and out of Japan continued to publish papers on practical adaption of Aki's theory to microtremor exploration. However, in all those improved methods, the layers under surface can only be assumed to be horizontal through the SPAC method while in fact, the layers are likely to be inclined slightly with certain angle. Hence, it is expected to obtain more detailed information of ground structure such as inclination by making better use of the records.

In recent years, the seismic interferometry theory[2][3] has also been widely used to estimate ground structure. It is proved that in an elastic medium the Fourier transform of azimuthal average of the cross correlation of motion between two sites is proportional to the imaginary part of the exact Green's function between these sites[4]. Hence, it becomes possible to calculate the ratio of imaginary part of different Green's function by taking the ratio of corresponding cross correlation to analyze ground structure more particularly because Green's function indicates intrinsic property of the medium. Actually, seismic interferometry is conditionally consistent with the SPAC method[5] which offers the base of introducing seismic interferometry to SPAC method.

SPAC method requires the multiplification calculation of Fourier transformation of records at two sites of center of an array and a one site on the circular array. By taking the ratio of power spectral between two different sites, it is hoped to obtain the ratio of imaginary part of Green's function according to seismic interferometry theory correspondingly and analyze the difference of ground structure through the ratio. More information such as the inclination of layers could be obtained.

Since this new concept has been proposed[7][8], some problems has been pointed out and the availablity of the combination remains to be proved. Firstly, the ratio of power spectra is used to calculate the ratio of imaginary part of Green's function whicn means the wavefield is supposed to consist of mainly body wave[9] [10]. However, the SPAC method requires the wavefield to be dominated by microtremors. It seems to be paradox but it is believed that seismic interferometry theory itself satisfies wavefield of full wave[11]. It is hoped that by taking the ratio of power spectra between two sites, the surface wave content will be extinguished and the body wave content remains.

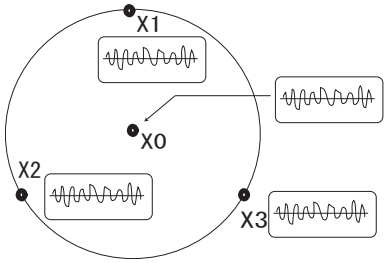

Figure 1. The equilateral-triangle array

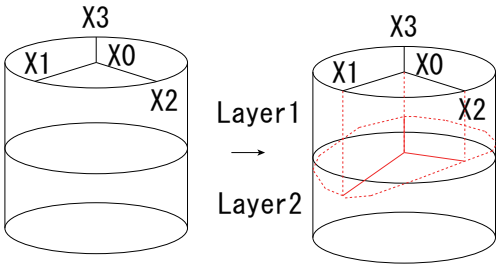

Figure 2. An example describing how the new method is expected to raise the accuracy of estimating ground structure.

Secondly, under the assumption of body wave being dominating, it is said that power spectra itself of each site could be used to analyze out the peak frequency of the ground structure (in simple case, the first layer) which tend to say that there is no need to take the ratio of them. Nevertheless, in wavefield dominated by microtremor and with the inclination of layers small enough, it is hard to extract useful information from each power spectra alone and to compare between them.

In this paper, the concept of SPAC method, interferometry and the combination of them are firstly proposed comprehensively. Then, in order to solve the two problems mentioned above, we use finite-difference method to simulate some 2-layered simple layered medium under the wavefield dominated by microtrmors. Next, SPAC method is applied to certain array of observation sites to examine if this wavefield is effective for SPAC method. Finally, the availability of seismic interferometry would be analyzed and the need to take the ratio of power spectra will be shown.

2. COMBINATION OF SPAC METHOD & SEISMIC INTERFEROMETRY

In this chapter, the basic knowledge of SPAC method and seismic interferometry will be introduced and the new concept of combining them will be proposed.

(1) SPAC method

Given an equilateral-triangle array as shown in Fig.1 and vertical time series records at four sites, the azimuthal-average of spatial auto-correlation coefficients $\rho(\omega,r)$ can be calculated as:

$$\rho(\omega,r)=\frac{1}{3}\sum_{j=1}^{3}\frac{S_{0j}(\omega)}{S_{00}(\omega)S_{jj}(\omega)}, \tag{1}$$

where ω and r are the angular frequency and radius of the circular array, respectively. $S_{jj}(\omega)$ and $S_{0j}(\omega)$ are the power spectra of vertical component of microtremors at site j ($j=0,1,2,3$) and the cross spectra of the vertical records between site j and 0. The site 0 is center of the array and sites 1, 2, and 3 are located on the circle.

Practically, $S_{jk}(\omega)$ is obtained by the product of Fourier transformation of records at two sites as

$$S_{jk}(\omega)=F(\omega,X_j)F^*(\omega,X_k), \tag{2}$$

where X_j is a location of site j and * stands for the complex conjugate.

Afterwards, a dispersion curve can be obtained and the property of under-surface layers are estimated using the curve.

(2) Green's function from correlation

It has been demonstrated[6][3] that in an elastic medium, the averaged cross correlation of motions at sites 1 and 2, whose locations are X_1 and X_2, can be written as:

$$\begin{aligned}&<F_\ell(\omega,X_1)F_m^*(\omega,X_2)>\\&\quad=-2\pi E_s k^{-3}\Im[G_{\ell m}(X_1,X_2,\omega)],\end{aligned} \tag{3}$$

where ℓ and m indicate one of three directions, (x,y,z). k and E_s are wave number of shear wave and the averaged energy density of shear wave, respectively. $<\cdot>$ stands for an expectation and $\Im[\cdot]$ for the imaginary part.

(3) Combination of SPAC method and Green's function

In the simpliest case using an equilateral-triangle array, ℓ and m are both set as vertical direction, which is z, and sites 1 and 2 as the same sites. Hence, it becomes

$$\begin{aligned}&<F_z(\omega,X_1)F_z^*(\omega,X_1)>\\&\quad=-2\pi E_s k^{-3}\Im[G_{zz}(X_1,X_1,\omega)]\end{aligned} \tag{4}$$

Therefore, let us take the ratio of the power spectra at center of the array and an azimuthal site so that the corresponding ratio of imaginary part of Green's function can be obtained as

$$\frac{S_{jj}(\omega)}{S_{00}(\omega)}=\frac{\Im[G_{zz}(X_j,X_j,\omega)]}{\Im[G_{zz}(X_0,X_0,\omega)]} \tag{5}$$

and it is expected to analyze the difference of ground structure between every two sites such as the inclination. The process is indicated simply in Fig.2.

In the simplist equilateral-triangle case, three ratios $\frac{S_{11}(\omega)}{S_{00}(\omega)}$, $\frac{S_{22}(\omega)}{S_{00}(\omega)}$, $\frac{S_{33}(\omega)}{S_{00}(\omega)}$ according to Eqn.5 can be obtained to analyze the difference between the corresponding two sites.

Table 1 Two-layered models of ground structure

Layer	P-wave velocity	S-wave velocity	Density	Thickness
	[m/s]	[m/s]	[t/m^3]	[m]
1	800	400	1.5	120
2	1800	1200	2.0	∞

Moreover, it is convenient and efficient to calculate this ratio because the power spectra is just the intermediate result in the process of SPAC method.

3. The VALIDITY OF SEISMIC INTERFEROMETRY IN THE WAVEFIELD DOMINATED BY MICROTREMORS

Since this new concept has been proposed, some preliminary research in order to confirm the availability of it has been done[7][8]. Through a smulation examination by finite difference method, the most compelling conclusion is drawn that Eqn.(5) is well satified in case of shallow ground structure[8]. However, until now, the SPAC method has not been taken consideration into the examination yet. Eqn.(5) is proved to be valid in diffused wavefield which is not necessarily an available one for SPAC method.

Besides, in terms of the assumption of SPAC method and Eqn.(5), the SPAC method requires the wavefield dominated by microtremor while the retrieval of Green's function from power spectra demands body wave's domination[10] [9]. The assumption seems to contradict with each other. Though, it is worth noticing that seismic interferometry itself is a full wave theory[11]. Though the power spectra should embody mainly surface wave, the ratio between them has the potential to contain information of body wave while the surface wave component diminishes through the division.

(1) A wavefield available for SPAC method

In order to show that SPAC method and seismic interferometry are both effective in the wavefield dominated by microtremor, firstly a wavefield available to apply SPAC method should be created. We still use Sakai's program[13] which is based on finite difference method as the tool to do simulation.

We assume the ground structure to be horizontally 2-layered medium, namely, no difference between each two sites. The inclined layered medium will be used afterward when adding the seismic interferometry theory. The property of each layer is shown in Table 1. To be ideal, we create the wavefield by exerting randomly distributed sources at random time surroundingly (as far away from the array as possible). Each source is on the surface or subsurface and with random force orientation. The source time function is a delta-like signal. The scope of simulation is $200 \times 200 \times 30$ with each mesh size of $20 \times 20 \times 20m$. The

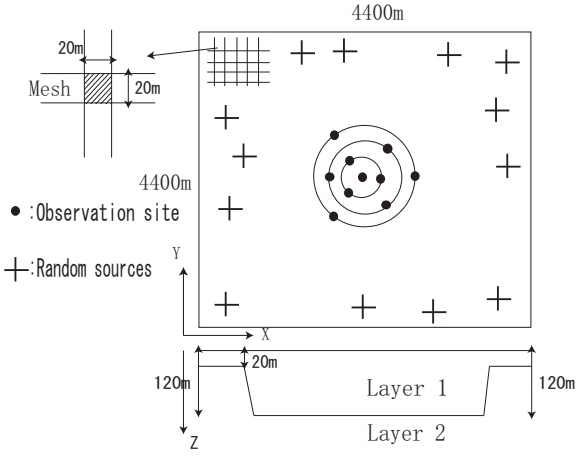

Figure 3. Plan and section plan of horizontally layered medium

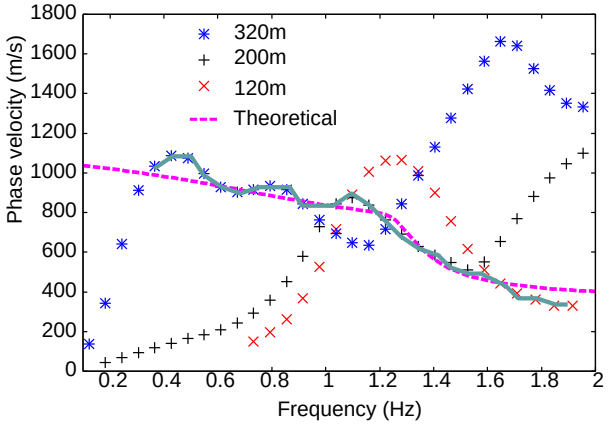

Figure 4. Dispersion curve

three observation arrays are set to be equilateral triangle with radius of 120*m*, 200*m*, 320*m* and 400*m* respectively. The plan and section plan are shown in Fig.3. The boderline of the first layer is set to be like a basin so as to help surface wave generate.

For simplicity, we use the vertical component of the record with duration of 64s and time step of 0.004s. Then the SPAC method metioned before is applied and the dispersion curve of 4 arrays is drawn as Fig.4 shows. The line is the theoretical phase velocity of rayleigh wave. The frequency range is limited because of the precision limit of Sakai's program[13] itself. We can see that the phase velocity disperses which means the wave field is

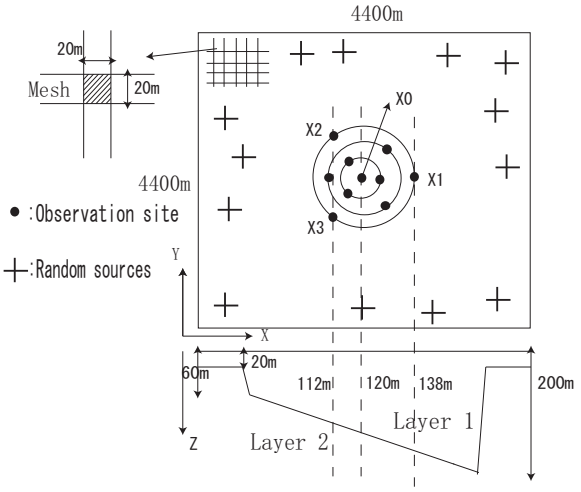

Figure 5. Plan and section plan of inclined layered medium

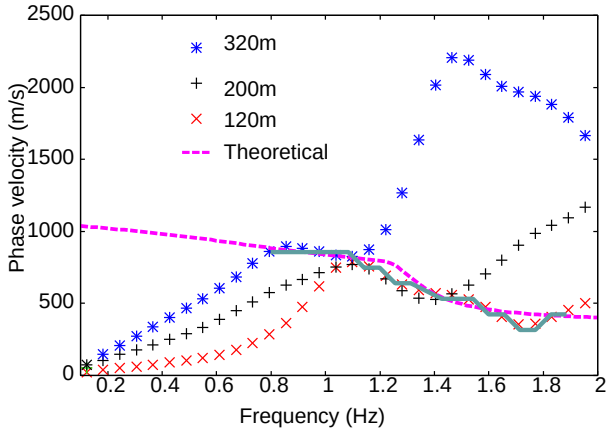

Figure 6. Dispersion curve

dominated by surface wave. Besides, the result from SPAC method coincides with theoretical one quite well which shows the wavefield is available to apply SPAC method.

(2) The availablity of seismic interferometry in the wavefield dominated by microtremor

As the way of creating wavefield available for SPAC method has been proved to be right, for the second simulation, the way to exert sources is the same while the model of ground structure is modified to be a inclined one. Because it is concluded the sensitivity and error will be large for deep structure[8], the first layer's thickness is set to be small value of around 120m. The plan and section plan of simulation are shown in Fig.5.

Then, in the same way, the SPAC method is applied using the records observed at the same 3 arrays of sites to see how it behaves when the layers are not horizontal but slightly inclined. The result is shown in Fig.6. It can be seen that the theoretical dispersion curve still matches with the result from simulation very well. Hence, even in slightly inclined layered medium, the SPAC method is still available.

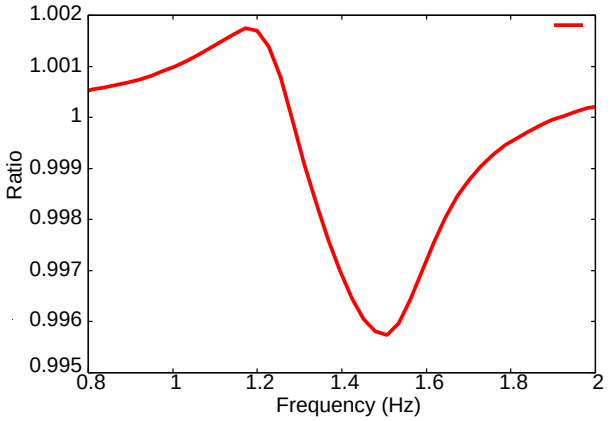

Figure 7. The theoretical ratio between site X1 and X2

Then, in order to examine if Eqn.(5) is satisfied, all the sites on the largest array are chosen as the examination sites as Fig.5 shows. For example, the site X1,X0 and X2(X3) corresponds to the depth of the first layer of 128m, 120m and 112m, respectively and the ratio is calculated between X1&X0, X1&X2, X1&X3, X0&X3 and X0&X2. The same thing is done for the other two arrays which means finally we obtain totally $5 \times 3 = 15$ ratios.

We use Hisada's program[14][15] to calculate the theoretical ratio of imaginary part of Green's function (the right hand side of Eqn.(5)) while the ratio of power spectra (the left hand side of Eqn.(5)) is easily calculated from the intermediate result (the power spectra of each site) just now. We use the frequency at which the ratio got the peak value (critical frequency) as the indicator to compare between them instead of comparing all over the whole range of frequency[8].

Because of the property of ground structure, even for the pair of sites (X1&X2) with the biggist difference in ground structure, the theoretical ratio of imaginary part of Green's function is quite small even at the critical frequency as shown in Fig.7. Besides, with the first layer's thickness varies in the small range, the shape of the ratio also changes quite slow. If we compare them one pair by another pair, the peak of simulation ratio will not be obvious for a part of pairs. In addition, the domination of microtremor and the system error of theoretical ratio[8] will exert bad influence on the result. Hence, we add all the ratios into one figure to see an comprehensive image. Accordingly, we choose 3 representative theoretical ratio in one figure to represent its rough moving scope. Finally, we compare them two as shown in Fig.8. We can see that for the theoretical ratio, there are two peaks which correspond to the two highest and densist peaks in simulatio ratio. They matches quite well which indicates that Eqn.(5) still works to certain degree in the wavefield dominated by microtremors.

(2) The neccessity of taking the ratio between

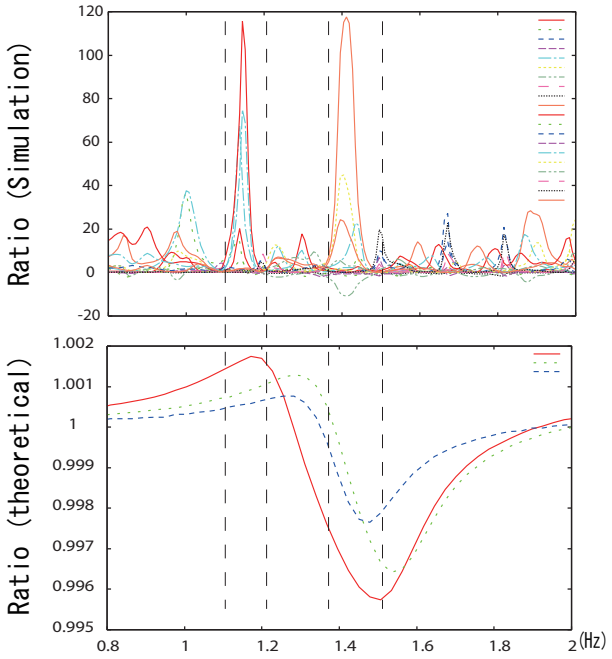

Figure 8. The comprehensive comparison between theoretical and simulation ratio

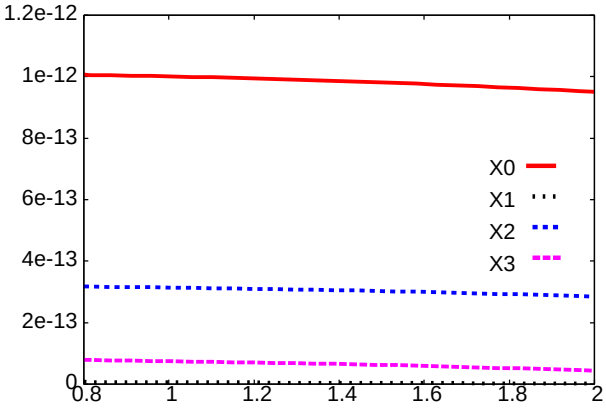

Figure 9. The power spectra of X0, X1, X2 and X3

two power spectra

This problem becomes easy to solve now. Fig.9 shows the power spectra of X1, X0, X2 and X3. It is obvious that there are almost no peak of power spectra over all the frequency range. In other words, it is hard to find the frequency at which the power spectra arrives at the peak. It is because that the microtremor takes on the main part of the power which makes it difficult to extract reflection response out.

However, by taking the ratio of X1 and X0, for example, the peak turns up and the peak coincides with the theoretical ratio of imaginary part of Green's function as Fig.10 shows. It indicates that the ratio contains the information of body waves. Therefore, taking the ratio of power spectra between two sites is necessary in order to get the critical frequency. This critical frequency denotes the differece between the reflection response of two sites.

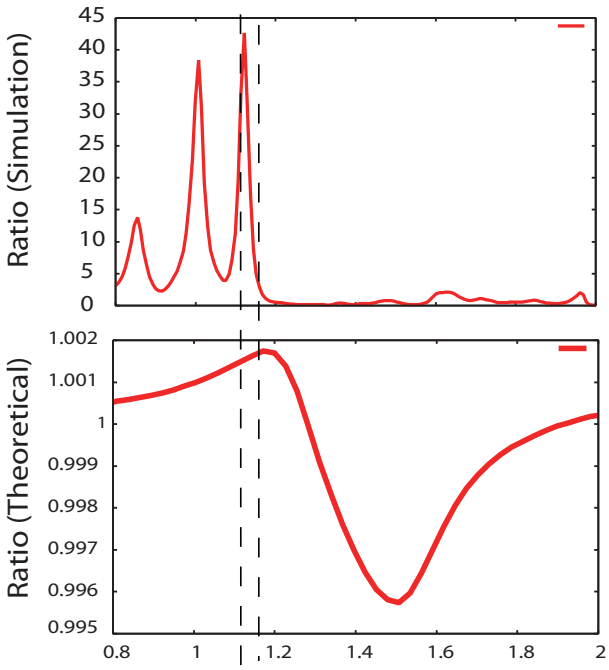

Figure 10. Comparison after taking the ratio of power spectra

4. CONCLUSIONS

We introduced the new method of combining SPAC method and seismic interferometry briefly and do the discussion mainly on the availability of seismic interferometry in wavefield dominated by microtremor. There are several conclusions.

(1) The SPAC method is available when the layers underground are slightly inclined in spite of the assumption of horizontally layered medium.
(2) Sesimic interferometry still works in the wavefield dominated by microtremor. In some case like the examination in this article, because of the property of ground structure, the peak value of theoretical ratio $\frac{\Im[G_{zz}(X_j,X_j,\omega)]}{\Im[G_{zz}(X_i,X_i,\omega)]}$ is quite small which causes the critical frequency hard to identify practically. Hence, we can make all the ratios in one figure to identify the most obvious peaks and do analysis. More work will be done on this in the future.
(3) It is necessary to take the ratio between power spectra of 2 sites because power spectra alone contains mainly microtremors and is hard to analyze.

Abstract: The stochastic finite fault method is applied to simulate records of 2010 Jiashian, Taiwan, earthquake. This study used the method which can divide the fault plane of large event into subfaults, and each subfault is treated as each point source and assigned an ω^2 spectrum.

The method consists of two steps. First, class B stations (NEHRP) of free field in southern Taiwan are used to calibrate model and found an excellent model with smaller average model bias. Model bias defined as the logarithm of the ratio of the FAS (Fourier amplitude spectrum) of observation to that of simulation. Second, use calibrated model to multiply transfer function to derive synthetic acceleration waveform of soil sites.

The transfer function in this study is H/V ratio (Nakamura, 1989; Lerom and Chávez-García, 1993) of seismic event that derived by 1991 to 2009 from CWB (Central Weather Bureau) database. Then, we use the spectrum result from the calibrated model and multiply by the transfer function to get the simulated waveform of horizontal component. The result also compare with the observed record.

1. INTRODUCTION

The Jiashian earthquake occurred at 08:18:53 A.M. on March 4, 2010 and it was a large earthquake with magnitude M_L = 6.4 and focal depth was 22.6 km (from Central Weather Bureau) in southern Taiwan. It caused many buildings damage, soil liquefaction, and two high speed rails derailed.

We want to know the error range of the PGA (peak ground acceleration) from the observation and simulation in southern Taiwan.

So we based on the Jiashian earthquake parameter by Lee (2012) and determined the unknown parameter in reasonable range. And then, using "class B" (HEHRP) of KAU series to calibrate model with model bias. Finally, we compare the error range of PGA from observation and calibrated model.

2. DATA

In this study, the data we used is recorded by the Taiwan Strong Motion Instrumentation Program (TSMIP). So we chose KAU station series (Figure 1) which received Jiashian earthquake record. The data using H/V method is based on CWB (Central Weather Bureau) database from 1991~2009 with PGA (Peak ground acceleration) less than 60 gal to calculate the mean spectral ratio value.

3. STOCHASTIC FINITE FAULT MODEL

3.1 Stochastic Finite-Fault Model

In this study, we use the fortran program EXSIM (Extend Finite-Fault Simulation ; Motazedian and Atkinson 2005), which is base on the new concept "dynamic corner frequency" and motified by FINSIM. In this method, a large fault plane divided into *N* subfaults and each subfault is considered as a small point source. The ground motion of subfaults are summed with a proper time delay in time domain to calculate acceleration time series, *a(t)*, from the entire fault plane,

$$a(t) = \sum_{i=1}^{nl} \sum_{j=1}^{nw} a_{ij}\left(t + \Delta t_{ij}\right), \qquad (1)$$

where n_l and n_w are the number of subfaults along the strike and dip of the main fault ($n_l \times n_w = N$), respectively, and Δt_{ij} is the relative delay time for the radiated wave from the ijth subfault to reach the observation point. According to Motazedian and Atkinson (2005), the dynamic corner frequency is depended on the arrival time of each subfault, and the rupture process controls the frequency content of simulated time series of each subfault. The acceleration spectrum of the ijth subfault, $A_{ij}(f)$, as follows:

$$A_{ij}(f) = C\, M_{0ij} H_{ij} (2\pi f)^2 / \left[1 + \left(f/f_{0ij}\right)^2\right], \quad (2)$$

where M_{0ij} and f_{0ij} are seismic moment and dynamic comer frequency of ijth subfault and H_{ij} is scaling factor, as follow :

$$M_{0ij} = \frac{M_0 S_{ij}}{\sum_{l=1}^{nl} \sum_{k=1}^{nw} S_{kl}}, \quad (3)$$

$$H_{ij} = \left(N \sum \{f^2/[1 + (f/f_0)^2]\} / \sum \left\{f^2 / \left[1 + \left(f/f_{0ij}\right)^2\right]\right\}^{1/2}\right), \quad (4)$$

where S_{ij} is the relative slip weight of the ijth subfault; The constant C in equation (2) is,

$$C = R^{\theta\varphi} F V / 4\pi\rho\beta^3, \quad (5)$$

Where $R^{\theta\varphi}$ is radiation pattern (average value of 0.55 for shear wave) , F is free surface amplification (2.0), V is partition onto two horizontal components (0.71), ρ is density, and β is shear-wave velocity.

3.2 H/V Method

Single station spectral ratio method propose by Nakamura (1989). The first step is painting the waveforms of seismic events from 1991~2009. A 10-sec S-wave portion was selected to calculate the Fourier amplitude spectrum. After 5% cosine taper, each ratio was smoothed by using the three-point average method for the weightings of 0.25, 0.5, and 0.25. The root-mean-square spectrum from the NS component and EW component was calculated as the horizontal spectrum. Finally, the H/V spectral ratio was derived horizontal spectrum by vertical spectrum.

4. DATA PROCESSING

The Jiashian earthquake records of 71 stations was used in this study, and the simulating time series data was from the finite-fault program EXSIM (Extend Finite-Fault Simulation ; Motazedian and Atkinson, 2005) using source and path parameters for 2010 Jiashian earthquake (Table 1).

We use the model bias (logarithm of Fourier Amplitude Spectrum of observation over simulation) to examine the model better or worse, and the waveform and FAS (Fourier amplitude spectral) of the 4 B-class stations of KAU series showed in Figure 2.

Now, the model bias (Figure 3) is logarithm of observation of B-class stations over simulation of A-class because there is no A-class station in Taiwan. The result showed the FAS of simulation that is larger than observation because observation record had more attenuation.

Originally, KAU003 is a B classification from Engineering Geological Database for TSMIP, but we found the PGA and frequency content of KAU003 (Figure 4) which are not as other B-class stations. Finally, we found the drilling of KAU003 which is not around seismic instrument, and we don't use KAU003 to calibrate in this study.

5. CONCLUSIONS

The simulating waveforms of 71 stations used fast Fourier transform to frequency domain, and multiply transfer function, and IFFT to time domain. In this study, the transfer function is single H/V method. The best result in 71 stations is KAU009 (Figure 5), the spectral amplitude of observation (black line) and simulation (red line) is similar, and PGA had no larger difference.

However, we compare the PGA from 71station of simulation and observation in Figure 6. Mostly, the observations were larger than simulations, and maybe this transfer function H/V method can not response total effects.

The PGA of observation and simulation versus distances from 71stations showed in Figure 7. The more near-fault stations existed more difference, and better result was at long distance.

Finally, we discuss the error range ($\ln Err_i$) from observation and simulation, used this formula, as following:

$$\ln Err_i = \ln PGA_i - \ln \overline{PGA_i}$$

here, PGA_i is the observed PGA of ith station and $\overline{PGA_i}$ is the prediction from EXSIM multiplying transfer function. The result of Figure 8 can compare with Figure 6, and the standard deviation of $\ln Err$ is 0.67. In further, this finite-fault method with attenuation relationship will become better.

Acknowledgements:
We used the Jiashian observed record from TSMIP and re-calculate the H/V spectral ratio of KAU stations. This study was supported by the National Science Council ubder grant numbers NSC 101-2116-M-008-021. Thanks Dariush Motazedian very much to provide the finite-fault program EXSIM. Abstract: Attenuation relationship (peak ground acceleration, PGA) is widely used by engineers in seismic hazard estimation studies. This study was conducted by combining stochastic point-source (Boore 2003) and equivalent-linear (Idriss and Sun 1992) methods to simulate ground motion, and compared the results to attenuation relationship. The stochastic method was performed to obtain simulated waveforms in rock site (TAP086 station) near of Wuku downhole and Wuku downhole. It showed decent results in rock site, while underestimated result in Wuku downhole. Simulated waveforms in rock sites were used as input motions for site correction. Site correction was performed in Wuku downhole using equivalent-linear method. Shear wave velocity profile (Wen et al. 1995 and Wang et al. 2004), geological soil profile (Liu 1999) of Wuku downhole and input motions are required for equivalent-linear method to obtain simulated waveforms in soil surface of Wuku downhole. Equivalent-linear method can assist to correct simulated PGAs and model bias at Wuku downhole using simulated waveform at rock site as outcropping input motion.

1. INTRODUCTION

Taipei city and several satellite cities are located in Taipei basin. Taipei city is the political, economic, and cultural center of Taiwan and demands serious attention to seismic risk mitigation. Many earthquakes of moderate to large magnitude ($5.3 \leq M_L \leq 7.3$) occurred near the Taipei metropolitan area since1659 from the limited historical records (Huang et al. 2008). Several downhole stations were installed in Taipei basin in order to study the basin effects and seismic wave propagation to anticipate future large and catastrophic earthquakes.

This study is conducted by combining stochastic point-source (Boore 2003) and equivalent-linear (Idriss and Sun 1992) methods to simulate ground motion at Taipei downhole basin and compared the results to attenuation relationship. Simulated waveforms in outcropping rock (TAP086 station) are obtained using stochastic point-source method. The simulated waveforms in outcropping rock are used as input motion at basement of Wuku downhole (679 m) to obtain simulated waveforms on surface using equivalent-linear method (Figure 2). Equivalent-linear method is performed for site correction in order to yield decent simulated waveforms.

2. METHOD

2.1 Data

Figure 1 shows earthquakes distribution and location of TAP086 station and Wuku downhole. Seven earthquakes with local magnitude M_L=5.6-6.6 were selected based on peak ground acceleration (PGA) in surface station of Wuku downhole which had PGA more than 10 gal. EQ2, EQ4, EQ5, EQ6 were located in northeastern Taiwan, while EQ1, EQ3, and EQ7 were located in offshore. EQ1, EQ2, EQ4 and EQ7 were shallow earthquake (less 35 km) while EQ3, EQ5 and EQ7 were deep earthquake (more than 35 km). TAP086 (V_{s30}=942.80 m/s) is one of the closest stations of class B to Wuku downhole about 18.57 km. Wuku downhole has stations at 0, 30, 60, 90, 141 and 352 m. EQ1, EQ2, and EQ3 were recorded at stations of 0, 30, 60, 90 and 141, while EQ4, EQ5, EQ6, EQ7 were recorded at stations 0, 30, 60, 141, and 352 m.

2.2 Stochastic Point-Source Method (SMSIM)

SMSIM is simple and powerful method for simulating high frequency ground motions is to combine parametric or functional descriptions of the ground motion amplitude spectrum with a random phase spectrum modified such that the motion is distributed over a duration related to the earthquake magnitude and to the distance from the source (Boore 2003). Table 1 shows parameters for stochastic

point-source method.

SMSIM was performed to obtain simulated waveforms at TAP086 station and Wuku downhole. Figure 5 shows that 15 seconds of selected S-window and this selected waveform was transformed into Fourier amplitude spectrum (FAS) for analysis of frequency range from 0.2-10 Hz.

2.3 Equivalent-Linear Method (SHAKE91)

SHAKE91 has been applied routinely in engineering community to evaluate one-dimensional soil site response and considers nonlinear site response. It showed decent simulated waveforms for small and large input motion (Lee et al. 2006).

Shear wave velocity of soil profile (Figure 3), geological soil profile (Liu 1999) and input motion (Figure 6) are required for SHAKE91 to produce waveforms in different layers or depths (Figure 7).

3. RESULT AND DISCUSSION

In order to verify reliability of model and methods, comparison of observed and simulated PGAs were performed as well as the model bias which is formulated as:

$$\text{Model bias}=\log\left(\frac{FAS_O}{FAS_S}\right) \quad (1)$$

FAS_O: Fourier amplitude spectrum of observed waveform
FAS_S: Fourier amplitude spectrum of simulated waveform

3.1 Verification on Artificial Layers of Wuku Downhole

Wuku downhole has depth 760 m. It was found that the basement of Wuku area about 679 m (Wang et al. 2004). This 679 m was divided into 50 artificial layers and each layer is assumed to have shear modulus reduction and damping factor of clay, sand or rock (Figure 4). To verify the reliability of these artificial layers, observed waveforms at 0 m were used as input motion for SHAKE91 to obtain simulated waveforms for different depths (Figure 8-12). Figure 8 to 12 show decent result of PGAs comparison and model bias for different depth.

3.2 Simulated Waveforms at Wuku Downhole Using Observed Waveforms at TAP086 as Input Motion for SHAKE91

Observed waveforms at TAP086 station were used as outcropping input motion to simulate waveform at Wuku downhole. Figure 13 shows decent comparison of PGA and model bias, the PGA comparison close to target line with average model bias 0.151 and 0.184 for east and north component respectively.

3.3 Simulated Waveforms at TAP086 Station Using SMSIM

SMSIM was performed to obtain simulated waveforms, and compared against observed waveforms for EQ4, EQ5, EQ6, and EQ7. Figure 14 shows that simulated and observed PGA close to target line which shows a decent result as well as model bias also shows a decent result by having average model bias 0.111.

3.4 Simulated Waveforms at Wuku Downhole Using SMSIM

SMSIM was performed to obtain simulated waveforms, and compared against EQ1 to EQ7. Figure 15 shows that simulated PGAs are generally underestimated to observed PGAs as well as model bias from frequency 0.2 to 4 Hz and the value of average model bias 0.290.

3.5 Simulated Waveforms at Wuku Downhole Using SMSIM and SHAKE91

Simulated waveforms at TAP086 station were used as input motion to simulate in surface station of Wuku downhole. Figure 16 shows that comparison of simulated and observed waveform close to target line as well as decent model bias with value of average model bias 0.217. If comparing to Figure 15, it showed that SHAKE91 can assist to correct the simulated PGAs and model bias.

4. CONCLUSIONS

The artificial layers of Wuku downhole and Wuku velocity structure are reliable which was showed by decent comparison of observed and simulated waveforms and model bias at different depths.

TAP086 records can be used as outcropping input motion to simulate waveform at Wuku downhole. Simulated waveforms using SMSIM at TAP086 station showed decent result.

Simulated waveforms using SMSIM at Wuku downhole were underestimated compared to observed waveforms.

SHAKE91 can assist to correct simulated PGAs and model bias at Wuku downhole using simulated waveform at TAP086 station as outcropping input motion.

Further study is required for other Taipei downhole basin arrays, and compared the result to attenuation relationship.

LONG-PERIOD GROUND MOTION SIMULATIONS IN THE KANTO BASIN USING DIVERSE VELOCITY MODELS FOR THE HYPOTHETICAL TOKAI EARTHQUAKE

Yadab Prasad Dhakal[1)] and Hiroaki Yamanaka[2)]

2) Professor, Department of Environmental Science and Technology, Tokyo Institute of Technology, Japan
dhakal.y.aa@m.titech.ac.jp, yamanaka@depe.titech.ac.jp

Abstract: In this study, we used the velocity models, proposed by Headquarters for Earthquake Research Promotion (HERP, 2012) and Yamada and Yamanaka (2012), of the Kanto basin for long-period (2~20s) ground motion simulations for the hypothetical Tokai earthquake (Mw~8). We used already available source model for the earthquake. Previous studies showed that the velocity models performed nearly similarly in the period range of 2 to 10 s at most sites in the Kanto basin for moderate magnitude (Mw<6.0) earthquakes which occurred beneath the basin. In this study, we compared the synthetics only for the large magnitude Tokai earthquake, and found that the models performed quite differently from each other at recognizable areas in the Kanto basin. This suggests a further evaluation and modification of the existing velocity models for reliable prediction of long-period ground motions from future large earthquakes.

1. INTRODUCTION

Many high-rise buildings and large oil-storage tanks, which are susceptible to long-period ground motions, are located today on the deep sedimentary basins. The 3-D velocity structure of a sedimentary basin greatly controls the amplitude and duration of long-period ground motions during large earthquakes. Many institutes are involved in constructing and updating the 3-D velocity structure model of the deep sedimentary basins for the seismic disaster mitigation planning in Japan (e.g., Koketsu *et al*., 2008). As a result, several 3-D velocity models have been proposed for the Kanto basin, which is the largest basin in Japan. Although the objective of constructing such models is to accurately predict the long-period ground motions, the models are different because they have been constructed using different data sets.

Recently, Headquarters for Earthquake Research Promotion (HERP, 2012) released a new version of its previous velocity model. Similarly, Yamada and Yamanaka (2012) (here after YY) made available an updated version of their previous deep velocity model of the Kanto basin. The HERP model has been reconstructed by compiling a diverse suite of data, geological, geophysical, deep borehole profiles, microtremor explorations, and so on (e.g, Tanaka et. al., 2005; Fujiwara et al., 2006; HERP 2012). On the other hand, the YY model has been reconstructed using the Rayleigh wave phase velocities at periods from 0.5 to 5 s deduced from microtremor array observations at more than 250 sites in the area. Considering stronger long-period shakings likely to occur in the Kanto basin than those observed during the 2011 Mw 9 Tohoku-oki earthquake (e.g.,Yoshimi et al., 2012), it is urgent to evaluate the existing deep velocity models of the Kanto basin for reliable prediction of long-period ground motions from future large earthquakes.

Previous studies by us (Dhakal and Yamanaka, 2012) showed that the models performed nearly similarly in the period range of 2-10 s for moderate magnitude earthquakes that occurred just beneath the basin. In this study, we compare the synthetics from YY model to those from HERP model for the hypothetical Tokai earthquake. In this case, we cannot evaluate which model performed better, but we hope to get some idea how the models perform for a future large earthquake. We perform waveform simulations using a finite difference method, and compare the waveforms at period from 2 to 20 s (0.05-0.5 Hz) at the K-NET and KiK-net sites in the Kanto basin and adjacent areas. Finally, we discuss the results with respect to our previous studies (Dhakal and Yamanaka, 2012), and recent observed records from large earthquakes.

2. VELOCITY MODEL PARAMETERS

In this study, we use two different velocity models, namely, HERP (2012) and Yamada and Yamanaka (2012) (YY) of the Kanto basin for long-period ground motion simulation. The HERP models were reconstructed using diverse suite of data: the geological maps, seismic reflection and refraction surveys, gravity surveys, H/V inversions of earthquake coda waves, deep borehole profiles, and layer

boundaries estimated by microtremor exploration method (e.g., Tanaka et. al., 2005; Fujiwara et al., 2006; HERP 2012). On the other hand, the YY model was reconstructed using the Rayleigh wave phase velocities at periods from 0.5 to 5 s deduced from microtremor array observations at more than 250 sites in the area. Thus, the models differ primarily on the basic data used for the model reconstructions. The two models mentioned above are the updated versions of their previous ones by the respective institutions.

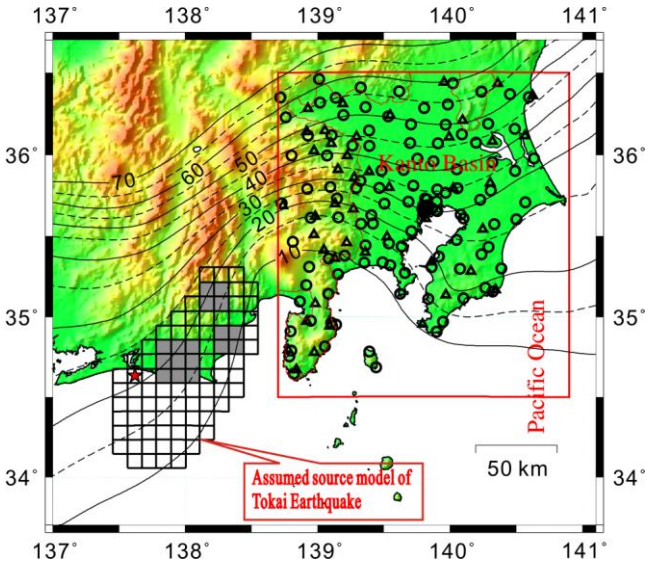

Figure 1. Index map showing the source model of Tokai earthquake (rectangular grids), and strong motion stations (circles: K-NET, and Triangles: KiK-net). A star denotes the hypocenter, and the shaded zones inside the fault plane indicate the location of asperities. The contours denote the depth to the upper surface of Philippine Sea plate. The red rectangle enclosing the stations indicates the model region for the Yamada and Yamanaka (YY) (2012) model. The thin red lines inside the YY model indicate the basin edge at the surface in the YY model.

The HERP model consists of twenty three layers in total (including the crustal and upper mantle layers). Among the twenty three layers, there are eleven layers above the seismic basement having Vs 3.2 km/s. However, we find that only three layers having Vs values of 0.5, 1.0, and 1.5 km/s above the seismic basement constitute the main sections of the Kanto basin in the HERP model. The YY model consists of only three layers above the seismic basement. The top layer comprises several sections of different Vs values (0.3 ~ 0.8 km/s), and the other two layers have Vs values of 1.0 and 1.5 km/s above the seismic basement. Outside the basin area, the velocity structures are adopted from the HERP model, so the velocity structures are same outside the basin for the both simulations using the HERP and YY models. All the layers overlying the Vs 2.9 km/s of the HERP model are removed in the Kanto basin area, and YY model is substituted. The depth of the layer having Vs 3.0 km/s of the YY model is set as a joining depth between the two models; the boundary depth of HERP model for the Vs 2.9 km/s layer is aligned with the depth of Vs 3.0 km/s of the YY model, and other layers in the HERP models are adjusted accordingly. The model regions are indicated in Fig. 1

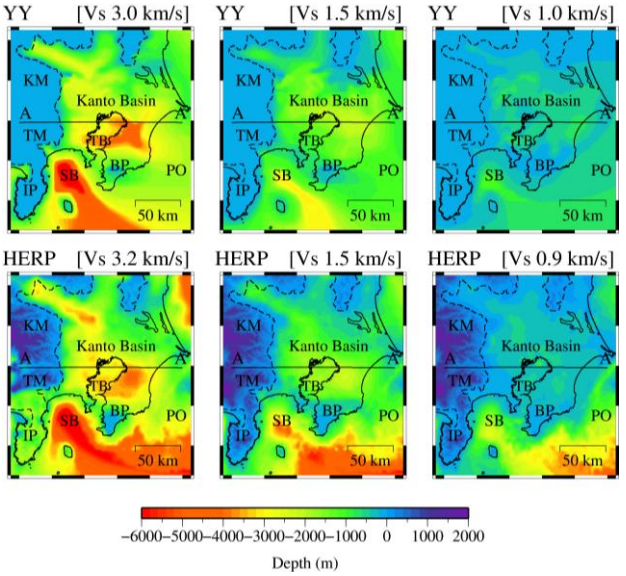

Figure 2. Maps showing depth to the top of three layers having similar S-wave velocities for the YY and HERP velocity structure models of the Kanto basin. The top panel depicts depth to the upper boundary of layers having S-wave velocity of 3.0, 1.5, and 0.9 km/s from left to right, respectively, for the YY model. Similarly, the lower panel depicts the depth to the upper boundary of layers having S-wave velocity of 3.2, 1.5, and 0.9 km/s from left to right, respectively, for the HERP model. A solid line AA' indicates a profile for the vertical section of the velocity structures, depicted in Fig. 3. A dashed line denotes the basin edge at the surface adopted in the YY model. The two letter codes TM, KM, IP, SB, TB, BP, and PO denote the Tanzawa Mountains, Kanto Mountains, Izu Peninsula, Sagami Bay, Tokyo Bay, Boso Peninsula, and Pacific Ocean, respectively.

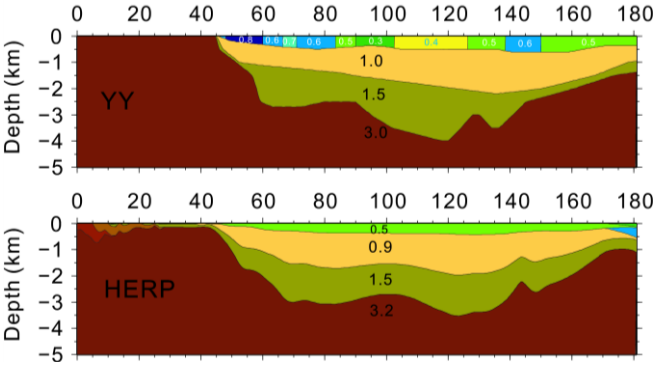

Figure 3. Vertical sections of the velocity structures along the profile A-A' depicted in Fig. 2 for the sedimentary layers in the Kanto basin in the YY (upper panel) and HERP (lower panel) models.

Figure 2 displays the depth to the upper boundary of three major layers having similar Vs values of about 1.0, 1.5, and 3.2 km/s in the two models. Vertical sections of the two

velocity structure models along an east-west profile are depicted in Fig. 3. It can be seen that the geometry of the interface between the seismic basement layer (Vs ~ 3.2 km/s; the lowest layer in the sections) and the overlying sedimentary layers is different between the two models. The location of the crests and troughs in the basement interface differ between the two models. The layer having Vs 1.5 km/s is almost missing at the western basin edge area in the YY model. Although the HERP model consists of some variations on the Vs values in the top layer, the vertical section illuminates that the top layer in the HERP model can be considered to be a single layer having a Vs value of 0.5 km/s. Since the models differ in the Vs values in the layers overlying the Vs 0.5 km/s layer in both the models, we adopt the top layer in the both models having Vs value of 0.5 km/s. The velocity model parameters are summarized in Tables 1 and 2 for the HERP and YY models, respectively.

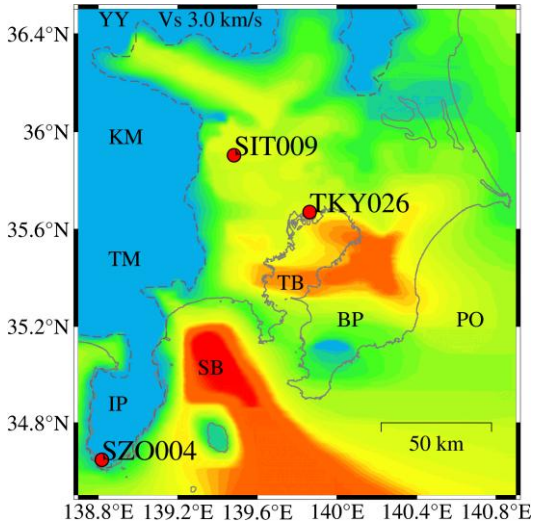

Figure 4. Location of strong motion sites where the synthetic ground motions are displayed in this paper. The background map indicates depth to the upper boundary of layer having S-wave velocity of 3 km/s in the YY model. For explanation on the two letter codes, see Fig. 2.

3. EARTHQUAKE SOURCE PARAMETERS

We used the characterized source model of the Tokai earthquake proposed by Headquarters for Earthquake Research Promotion (2009). The source fault area is depicted in Fig. 1. The asperities are shown by shaded rectangular areas, and, in total, three asperities are set. The fault is modeled with 91 point sources; 74 points as background point sources. In Fig. 1, the star denotes the rupture start point (hypocenter), and a uniform rupture propagation velocity of 2.7 km/s is used for the waveform simulation. We used triangle shaped moment rate functions for the waveform simulations. The rise time of the point sources are adopted from the source parameters table provided by HERP (2009). The orientation of the fault plane and seismic moments are also taken from HERP (2009).

4. WAVEFORM SIMULATION METHOD

We applied the staggered-grid finite difference method (Graves, 1996), with fourth-order accuracy in space and second-order accuracy in time, for the 3-D simulation. We used the method of discontinuous grids (Aoi and Fujiwara, 1999) to optimize computing time and memory. We divide the model region into two grid zones, namely the upper and lower grid zones, with different grid spacing. The upper and lower grid zones consist of grids with a uniform spacing of 0.15 and 0.45 km, respectively, in all three directions of the model region.

We consider a horizontal free-surface boundary condition for the top of the model space. The absorbing boundary condition of Clayton and Engquist (1977) and non-reflecting boundary condition of Cerjan et al. (1985) are implemented to eliminate artificially reflected waves from the other boundaries of the model space. We apply the method of Graves (1996) for the anelastic attenuation. According to Levander (1988), at least 5 grid points per wavelength are required for fourth order accuracy in the finite difference method. In our simulation more than six grid points per shear wavelength lie in the lowest velocity layer of 0.5 km/s at the maximum frequency of 0.5 Hz. Therefore, we limit our comparison between the synthetics from the two velocity models to the resolved frequency of 0.5 Hz in the simulations. We use a time increment of 0.008 s, which satisfies the stability criteria of the finite difference method for the entire grid used in our grid formulation (e.g., Aoi and Fujiwara, 1999).

Table 1. Material Parameters in the YY Model

No.	Vp (km/s)	Vs (km/s)	Density (g/cm^3)	Depth (km)	Qp, Qs
1	1.8-2.2	0.5-0.8	1.88-2.01	0.00	100
2	2.40	1.00	2.10	*variable*	100
3	3.20	1.50	2.25	*variable*	150
4	5.60	3.00	2.50	*variable*	300

5. RESULTS

In this section, we show the comparison of the velocity waveforms and their Fourier spectra in the frequency range of 0.05-0.5 Hz at selected sites (Fig. 4). We also show the comparison of the peak ground velocities at different frequency ranges between the two synthetics.

We show the comparison of the waveforms and Fourier spectra at the SZO004 site in Fig. 5. This site is located at the tip of the Izu Hanto peninsula. The ground motion at this site may be considered as an input motion to the Kanto basin. We can see that the waveforms are dominated by large amplitude phases of about 12-15s period, and the waveforms decay quickly after the body wave and surface waves propagated from the source. Since this site is located outside the basin, the synthetic waveforms for the both HERP and

YY models are similar as expected.

Table 1. Material Parameters in the HERP Model

No.	Vp (km/s)	Vs (km/s)	Density (g/cm^3)	Depth (km)	Qp, Qs
1	1.8	0.5	1.95	0.00	100
2	2	0.6	2	*variable*	120
3	2.1	0.7	2.05	*variable*	140
4	2.2	0.8	2.07	*variable*	160
5	2.3	0.9	2.1	*variable*	180
6	2.4	1	2.15	*variable*	200
7	2.7	1.3	2.2	*variable*	260
8	3	1.5	2.25	*variable*	300
9	3.2	1.7	2.3	*variable*	340
10	3.5	2	2.35	*variable*	400
11	4.2	2.4	2.45	*variable*	400
12	5	2.9	2.6	*variable*	400
13	5.5	3.2	2.65	*variable*	400

16	7.5	4.5	3.2	*variable*	500
17	5	2.9	2.4	*variable*	200
18	6.8	4	2.9	*variable*	300
19	8	4.7	3.2	*variable*	500
20	5.4	2.8	2.6	*variable*	200
21	6.5	3.5	2.8	*variable*	300
22	8.1	4.6	3.4	*variable*	500

We show the comparison of the waveforms and Fourier spectra at the TKY026 site in Fig. 6. We can see that the waveforms are dominated for a longer duration by the later phases, secondarily generated surface waves from the basin edges, and multiple reflections of the body waves from the sedimentary layers. It can be seen that the spectral amplitudes are larger for the HERP model in the periods from about 8s and over compared with those from the YY model. However, at periods smaller than about 8s, the spectral amplitudes are similar for both the models. The waveforms differ largely on the horizontal components. The vertical components are quite similar. A distinctive phase having a period of about 10s can be seen at time of about 130s using the HERP model.

We show the comparison of waveforms and Fourier spectra at the SIT009 site for the two models in Fig. 7. We can see that the waveforms obtained using the HERP model exceeds or tends to exceed the spectral amplitudes at periods over about 5s (>0.2 Hz), and the YY model exceeds or tends to exceed at frequencies smaller than 0.2 Hz. A similarity to this result is found at several other sites in the Kanto basin.

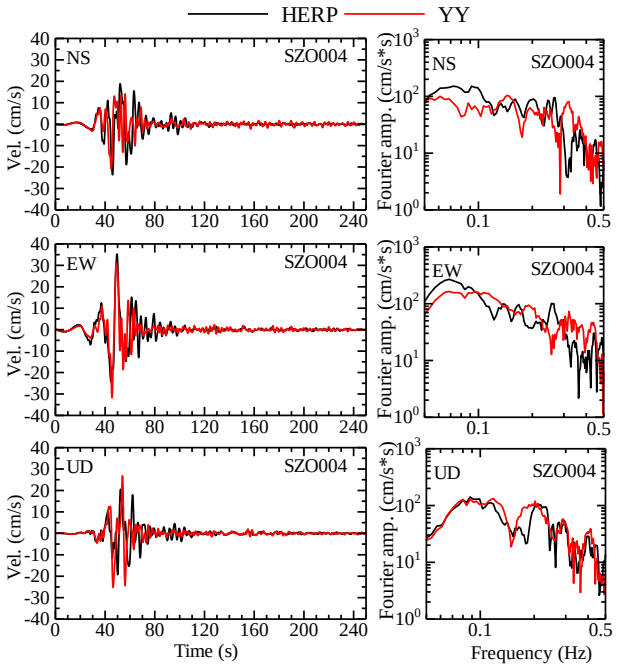

Figure 5. Synthetics at the SZO004 site. The waveforms were bandpass filtered at 0.05-0.5 Hz. The black and red traces are for the HERP and YY models, respectively.

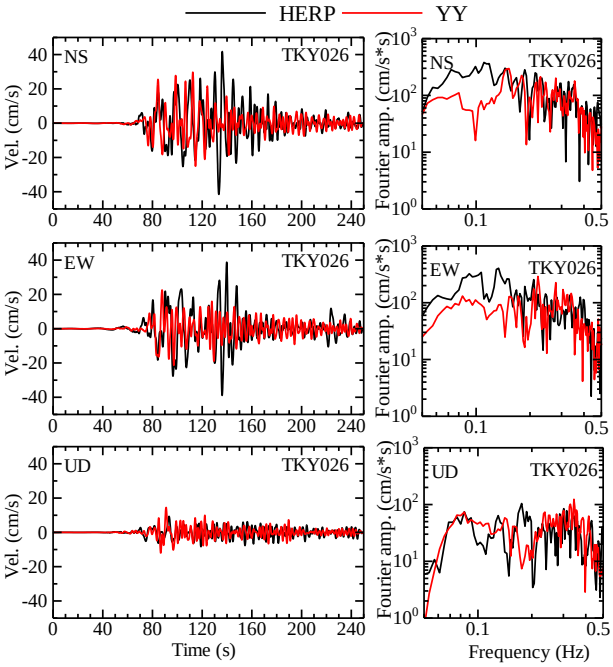

Figure 6. Synthetics at the TKY026 site. The waveforms were bandpass filtered at 0.05-0.5 Hz. The black and red traces are for the HERP and YY models, respectively.

We show a comparison of the peak ground velocities at four frequency bandwidths in Fig. 8. The frequency band-widths are 0.05-0.1 Hz, 0.05-0.2 Hz, 0.05-0.3 Hz, and

0.05-0.5 Hz from the top to the bottom of Fig. 8. The peak ground velocities were obtained at the K-NET and KiK-net sites depicted in Fig. 1.

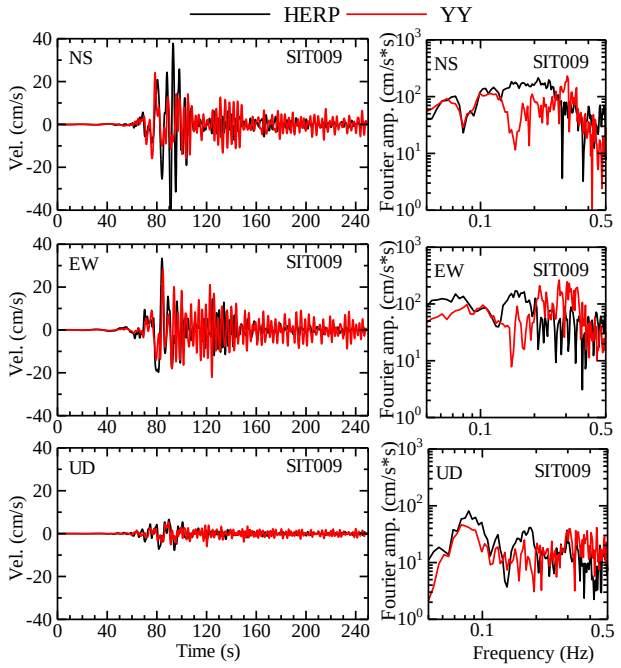

Figure 7. Synthetics at the SIT009 site. The waveforms were bandpass filtered at 0.05-0.5 Hz. The black and red traces are for the HERP and YY models, respectively.

In Fig. 8, it can be seen that the PGVs obtained using the HERP model are greater than those obtained using the YY model at frequencies 0.05 to 0.1 Hz at many stations. The PGVs between the two models scatter largely at frequencies 0.05 to 0.2 Hz, thus further indicating that the two models behave differently for the Tokai Earthquake. At increased frequency bandwidths, the scattering decreases, but the two models still differ noticeably.

6. DISCUSSIONS AND CONCLUSIONS

We performed 3-D FD simulations of long-period ground motions (2-20s) in the Kanto basin and adjacent areas using two different velocity models for the hypothetical Tokai earthquake. Since the models are reconstructed to predict long-period ground motions for future earthquake, we attempted to compare the ground motions in the Kanto basin using the HERP and YY models. The HERP model consists of velocity structure information not only of the sedimentary layers in the model region, but also the velocity structure information of the deeper crustal, and upper mantle structures. On the other hand, the YY model consists of velocity structure information of the sedimentary layers in the Kanto basin.

To simulate the ground motions using the YY model, we removed all the layers above Vs 2.9 km/s in the Kanto basin of the HERP model, and filled the basin with the layers from the YY model. The upper boundary of Vs value of 2.9 km/s in the HERP model is shifted up or down to match with the upper boundary of the Vs 3.0 km/s of the YY model. Outside the basin and beneath the layer having Vs value of 3.0 km/s, the HERP velocity structure is retained, and the ground motion simulations were performed. Some differences on the simulated ground motions might have resulted from using the above scheme, which causes modifications mainly just outside the basin, but within the YY model region, where the YY model is set to be a simplified structure of having Vs value of 3.0 km/s at the top.

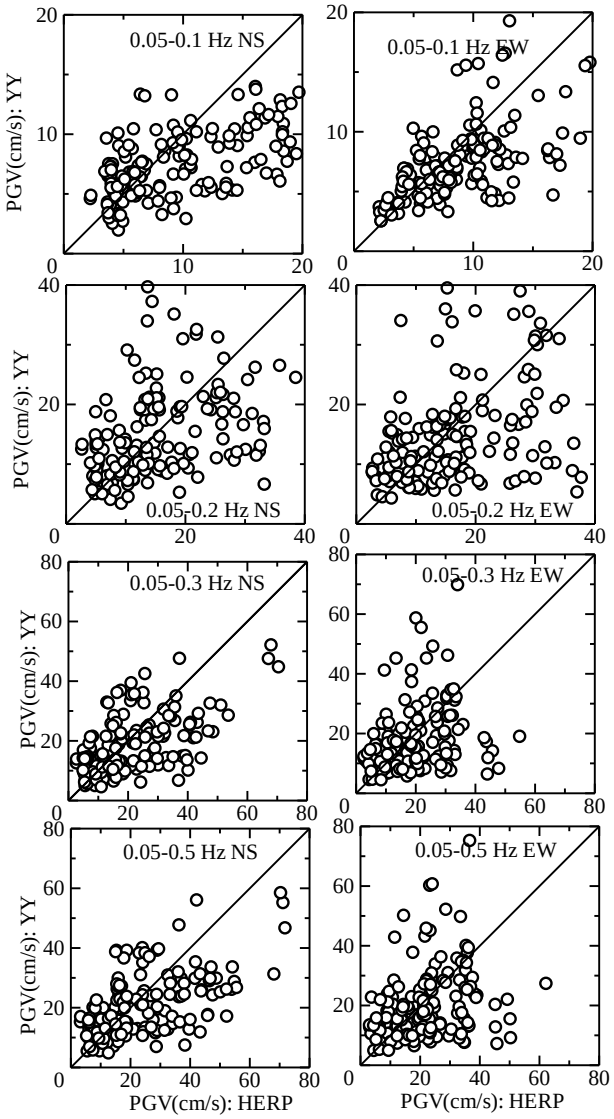

Figure 8. Comparison of PGVs at different frequency bandwidths obtained from using the HERP (along horizontal axis) and YY (along vertical axis) models. The frequency bandwidths and component names are indicated in each of subfigures.

Another source of difference between the two ground motions might be the removal of the layer having Vs value of 1.0 km/s in the HERP model inside the YY model region. Outside the YY model region, the layer extends as accretionary prism outside the YY model region. Further investigations on the velocity structures would make clear.

We show a comparison of the Fourier spectra at the

TKY026 site obtained for the records of Mw 9.0 off-Tohoku earthquake, the off-Ibaraki prefecture earthquake (Mw 7.8, the largest aftershock of the Tohoku earthquake), and the Tokai earthquake (Mw 8.0) in Fig. 9. Also shown are the Fourier spectra of the records obtained at the HKD129 site (Tomakomai) during the Mw 8.3, 2003 Tokachi-oki earthquake. It can be seen that the horizontal spectral amplitudes at the TKY026 site for the Tokai earthquake are much larger than those from the Mw 9.0 Tohoku earthquake at periods over about 7 s. For periods shorter than about 0.7 s, the spectral amplitudes for the Tokai earthquake match with those observed at the HKD129 site during the 2003 Tokachi-oki earthquake. Huge oil storage tanks were severely damaged at Tomakomai, which is located on thick sedimentary layers having total thickness over about 6 km. The spectral amplitudes from the off-Ibaraki prefecture earthquake are the lowest in the frequency range of analysis.

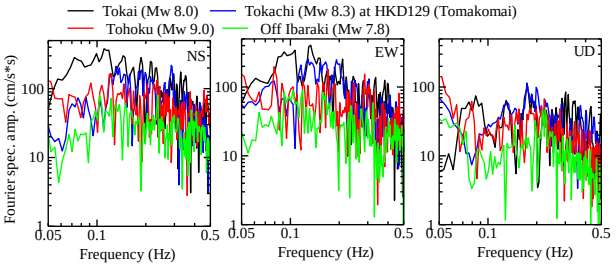

Figure 9. Comparison of velocity Fourier spectra at the TKY026 site between several earthquake records; black: hypothetical Tokai earthquake (Mw 8) (black), red: Off Tohoku earthquake (Mw 9), blue: Tokachi-oki earthquake record at HKD129 (Tomakomai site) (Mw 8.3), and green: Off Ibaraki prefecture earthquake (Mw 7.8).

In this study, we find that the two models generate ground motions differently for the Tokai earthquake at several sites, where the synthetic ground motions were more or less similarly reproduced during the smaller events that occurred just beneath the Kanto basin. This indicates that the two models differ primarily in the basin edge structure. Therefore, we conclude that further examination and tuning of the models are required for an improved prediction of long-period ground motions from future earthquakes.

Abstract: Estimation on earthquake ground motion and the associated damage is expected to be improved by estimating coseismic slip distribution accurately. Estimation of coseismic slip distribution can be improved by using large-scale analyses of the observed crustal deformation data based on detailed data of crustal structure. However, it has not been achieved because of the difficulty of generating high-fidelity models of crustal structure for numerical analyses. In this research, we developed a method for generating a high-fidelity three-dimensional finite element model for crustal structure whose degree-of-freedom of more than 100 million, and a method for crustal deformation analyses using the generated model. Crustal deformation analyses performed in Southwest Japan show that there may be a significant difference in estimation results of coseismic slip distribution, depending on whether the high-fidelity model is used or not.

1. Introduction

Enhancement of the estimation on earthquake ground motion and the associated damage could be made by estimating coseismic slip distribution accurately. Coseismic slip distribution is estimated by combining crustal deformation analysis in a large scale with the detailed data of the crust and the observation data of crustal deformation. Observation data with high accuracy have been accumulated owing to the development of observation technology. GEONET (operated by GSI: Geospatial Information Authority of Japan) is well known as a monitoring system of crustal deformation on the ground in the whole Japanese islands. Moreover, monitoring systems of crustal deformation on the seafloor such as DONET (operated by JAMSTEC: Japan Agency for Marine-Earth Science and Technology) have been launched recently. The errors of these monitoring systems are in cm-order at maximum. In addition, data of crustal structure themselves also have been accumulated. To be more specific, material data and geometry data in 1km grid of the crustal structure of the Japanese islands have been developed. However, there were difficulties in generating high-fidelity numerical models of crustal structure and computation using the model. As a result, in spite of the detailed crustal data, crustal deformation analyses have been performed by using a simplified crustal structure model such as homogeneous half-space.

Therefore in this research, by using accumulated data and the technique of high performance computing, we developed a method for generating a high-fidelity three-dimensional (3D) finite element (FE) model of crustal structure. A method for crustal deformation analyses with the generated model is also proposed. To show the advantage of our method, an application example of crustal deformation analyses in Southwest Japan will be shown.

2. Methodology

In this section, the analysis method and the numerical model generation method are briefly explained.

2.1 Formulation

We adopt a FE analysis as a numerical analysis method because it has an advantage in analyzing medium whose geometry is complex, such as crustal structure. We

investigate the crustal deformation resulting from the final coseismic slip distribution. Therefore, assuming crustal structure to be a linear elastic body, we perform a static analysis of crustal deformation due to fault dislocation. After taking boundary conditions into consideration, the target equation is as follows:

$$\mathbf{K}\,\mathbf{u} = \mathbf{f}$$

where **K**, **u**, **f** are the global stiffness matrix, displacement vector, and force vector, respectively. Fault slip is introduced by the split-node technique (Melosh and Rafesky 1981). The split-node technique can simply compute the effects of fault slip by virtually splitting the nodes on the fault plane. Infinite elements (Zienkiewicz *et. al.* 1983) are implemented on the side and bottom of the target domain to describe the infinite condition.

2.2 Model generation method

Conventionally, elasticity solution in a homogeneous half-space or numerical models with large approximation of the geometry has been used for estimating coseismic slip distribution. On the other hand, our method can automatically generate 3D FE model of crustal structure using background cell, which makes it possible to perform crustal deformation analyses taking complex geometry and heterogeneity of material of crust into consideration. The input data are layered crustal data (digital elevation model data and material data) with complex geometries of the ground surface and the layer interfaces (Figure 1 (left)). Tetrahedral elements are used near the surfaces to represent the geometries of the crust well, while voxel elements are used in the homogeneous areas, in order to achieve a good balance between reduction of the number of elements and reproduction of the geometry (Figure 1 (right)). This is an extension of the method proposed in Ichimura *et. al.* (2009). Its extension points improve the approximation of geometries, the control of multi-voxel generation, and the introduction of the infinite condition by an infinite element.

2.3 Computation method

Since the degree-of-freedom (DOF) of the generated models is large, the computation needs to be parallelized so that the computation is finished in a realistic time. We use shared memory parallelization (SMP) only, not using distributed memory parallelization. It is because using SMP only will have less communication overhead between each computer node when we compute many cases at once (as computation of Green's functions or Monte Carlo approach) with many computer nodes.

We need a memory-efficient method to solve the linear equation because the DOF of the target problem is large. The combination of Element-by-Element (EBE) method (Hughes *et. al.* 1983) and Conjugate Gradient (CG) method is used for that purpose. We don't need to store the entire **K** matrix on computer memory with this method, and the required memory space is largely reduced. As the preconditioning of CG method, Point Jacobi Method is used because it is memory-efficient, and relatively easy to be parallelized. Our code is verified by comparing the results with the elasticity solution in a homogeneous half-space (Okada 1985).

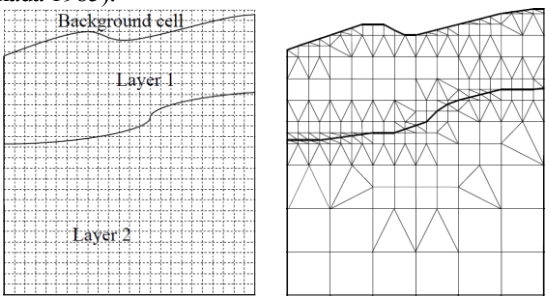

Figure 1 Schematic view of generating the 3D FE model: The target domain is covered by a uniform back ground cell (left); To generate a high-fidelity model of crustal structure, tetrahedral elements are used near the surfaces to represent the geometries of the crust well, while voxel elements are used in the homogeneous areas (right).

3. Application to crustal deformation analyses in Southwest Japan

As an application example, firstly 3D FE model of Southwest Japan is generated by the proposed method. Then, crustal deformation analyses in Southwest Japan are performed by inputting an estimated coseismic fault slip of Nankai Earthquake computed by an earthquake cycle simulation (Hyodo *et. al.* 2012) to the model. The target area for modeling is shown in Figure 2. The size of the area is 976km in *x* direction (east and west), 784km in *y* direction (north and south), and 400km in *z* direction (vertical). The crustal structure is modeled as a 4-layered structure, whose material properties are shown in Table 1. The generated model (we call it "our model") is shown in Figure 3. The DOF, the number of tetrahedral elements and voxel elements are 134,000,160, 44,713,627 and 36,405,531, respectively. To compare the result, we generate a model which considers neither of the surface geometry and the material heterogeneity (we call it "conventional model"). The solution obtained using this model is equivalent to the analytical elasticity solution in a homogeneous half-space. The average altitude of the ground surface in our model is used as the altitude of the ground surface in the conventional model. Its material property is the same as that of layer 1 in Table 1. The displacements on the ground computed by crustal deformation analyses using the 2 models are compared.

The computation was performed on one computer node with 12 computation cores (Intel(R) Xeon X5680×2) and 48GB computation memory. The computation time was 29650s (elapsed time). Figure 4 shows the distribution of surface displacement computed from the assumed fault slip shown in Figure 2. The relative difference of the surface displacement between our model and the conventional model is shown in Figure 5 and 6. The red points indicate the observation nodes of DONET. These figures show that

DONET observes crustal deformations in the area where the relative displacements are significantly large. The relative differences in the observation points located in those areas are shown in Table 2. In these points, the relative differences, which are up to 45%, are significantly large. From these analyses, we could find that the relative difference of the surface displacement is significantly large in the area where DONET monitors crustal deformation on the seafloor. It indicates that there is a significant difference in estimation results of coseismic slip distribution, if high-fidelity models as shown in this paper are not used.

4. Conclusion

In this research, aiming enhancement of the estimation on earthquake ground motion and damage it causes, we developed a method for generating a high-fidelity 3D FE model of crustal structure. Since the DOF of generated high fidelity model is large, fast computation method using memory-efficient solver and parallel computation is also developed. In the application example of crustal deformation analyses in Southwest Japan, significant differences are shown between the results of our model and the conventional model. Especially, larger differences could be seen near the observation area of DONET. These analyses indicate that there is a significant difference in estimation results of coseismic slip distribution, if high-fidelity models as shown in this paper are not used. We expect this method will contribute to setting more appropriate scenario fault rupture, and lead to enhancement of the estimation on earthquake ground motion.

As future work, we would like to apply our method to more appropriate estimation of coseismic slip distribution and stochastic approach to the ambiguity of crustal data. We also need to apply viscoelasticity to the model so that the model can be applicable to a longer time scale.

Acknowledgements:

I would like to thank Dr. Takuto Maeda for providing the crustal data of Southwest Japan and Dr. Yoshimitsu Okada for providing a subroutine for the verification. Part of the results is obtained by using the K computer at the RIKEN Advanced Institute for Computational Science (Proposal number hp120308).

Abstract: In the absence of instrumental recordings, the present study intended to generate synthetic ground motions for the Surat region, Gujarat (India) considering probable earthquake scenarios using stochastic finite fault simulation technique. The simulations have been composed of two stages. In the first stage, attempt has been made to simulate Bhuj (2001) earthquake of Mw 7.7 which was recognized as most devastating event occurred in the last century in India. In the second stage, the simulated results have been validated through actual recordings and data from literature. Using the calibrated regional parameters, ground motions of 2001 event for the Surat city has been simulated at 66 sites and spatial variation in PGA has been presented. In addition, the ground motions of the same event have been simulated for the important cities in the state which may be very useful for carrying out numerous seismic studies in the region. The developed ground motions inferred from these simulations are of immense value for the proposed seismic microzonation and site specific studies in the region.

1. INTRODUCTION

The January 26, 2001 earthquake occured near Bhuj in the Kutch region of Gujarat, India was the largest intra-continental event struck in the past century and caused considerable damages even to the far off city like Surat along with other cities/towns in the state of Gujarat. With the fast increasing density of population and large infrastructural establishments in recent times, the vulnerability of Surat city to the damaging earthquakes is increasing alarmingly day by day. Therefore it is of great need to have a reliable estimation of seismic hazard due to probable damaging earthquakes occurring in and around Surat region. The good regional coverage of strong motion observations play vital role in achieving this purpose However with best of our knowledge, no instrumental record has been found in Surat region till this date and even very few records of strong motions from earthquakes surrounding Surat are available due to lack of instrumentation.

The quantified dataset even for the Bhuj earthquake is very limited and sparse; hence, the researchers presently face a daunting problem in predicting ground motion level for future events in the region. The Strong Motion Accelerogram (SMA) records at various locations are the most commonly used data from the engineering point of view. However, for the Bhuj earthquake, the only available such instrumental record was from the basement of a ten-storey building, approximately 240 km away from the epicentre at Ahmedabad (23.04 0N, 72.61 0E). In addition to that the other instrumental data useful for the engineering purpose are on an array of spectral response recorders (SRR) at 13 different locations in the State of Gujarat are available for the same earthquake. In lack of a robust database of strong-motion records, seismological modeling is a vital alternative until sufficient instrumental records become available in Gujarat.

With this background the present study motivated by the need, envisaged to estimate the ground motions on firm rock conditions for Surat city for an earthquake of magnitude Mw 7.7 occurred in Kutch region of Gujarat. An improved version of the one dimensional stochastic simulation model of Boore (1983) to account for a finite fault as proposed by Motazedian and Atkinson (2005) is used for simulating ground motions. In this method, the characteristics of seismic source, path attenuation and local soil conditions are taken into account, while generating the ground motions. Database of the model parameters have been prepared from the extensive review of the literature. Further, numbers of synthetic time histories are generated assuming the probable earthquake scenarios for the Surat region by adopting suitable model parameters.

2. STOCHASTIC SIMULATION MODEL

The prediction of earthquake ground motion for large earthquakes is a crucial problem in earthquake engineering. Engineering analysis for seismic performance of structures requires seismological input that describes amplitude, frequency content and duration of the expected ground motions. Stochastic modeling of earthquake radiation is widely used in prediction of strong ground motions (Hanks and McGuire, 1981; Boore, 1983; Boore and Atkinson, 1987; Atkinson and Boore, 1997; Toro et al. 1997, Atkinson

and Silva, 2000). In this method, high frequency earthquake motions are represented as band limited Gaussian noise having ω^2 mean spectrum, where, ω = angular frequency (Aki, 1967; Brune, 1970, 1971; Boore, 1983). In most commonly employed approach, earthquakes are treated as point sources. Point source modeling of earthquake ground motion may not be appropriate for large earthquake, because the effects of a large fault plane, including fault geometry and directivity which influence the amplitudes, frequency content and duration of ground motion.

To consider these finite-fault effects in ground-motion modeling, Hartzell (1978) proposed a discrete finite fault model that captures the salient features of radiation from large earthquakes. A finite fault plane is subdivided into elements (sub-faults), and radiation from a large earthquake is obtained as the sum of contributions from all elements, such of which acts as a small independent sub-source. In the typical implementation, the rupture starts at a hypocentral point on the fault and propagates radially from it, triggering the sub-faults as it passes them. The field from all sub-events are geometrically delayed and added together at the observation point. This basic idea has been implemented in many studies (Irikura, 1983; Irikura, 1992; Kamae and Irikura, 1992; Irikura and Kamae, 1994; Bour and Cara, 1997). Beresnev and Atkinson (1998) used the same concept and proposed stochastic finite fault simulation code FINSIM. Motezedian and Atkinson (2005) made a major modification to FINSIM to introduce the concept of "dynamic corner frequency" in order to overcome difficulties associated with this code. The improved and more realistic stochastic finite-fault model, described above has been included in the EXSIM code has been used in the present study to estimate the synthetic ground motions for Surat region.

3. STOCHASTIC SIMULATION OF BHUJ (2001) EARTHQUAKE OF Mw 7.7

As mentioned earlier, the Bhuj (2001) earthquake is the most damaging event occurred in the state of Gujarat. Several studies are reported in the literature to simulate the ground motion of Bhuj (2001) earthquake using different approaches. Hough et al. (2002) and Singh et al. (2003) used a finite source stochastic simulation model (Beresnev and Atkinson, 1997, 1998) to estimate the near source ground motions. Iyengar and Raghukanth (2004) used seismological model of Boore (1983) based on point source modeling to derive ground motion attenuation relations for Peninsular India. Further, Iyengar and Raghukanth (2006) used an empirical Green's function and an analytical method to simulate the ground motion at Bhuj city and the peak ground acceleration values in the region respectively. Recently, Chopra et al. (2010a) used stochastic finite fault model (Motazedian and Atkinson, 2005) to simulate Bhuj (2001) event. The models adopted by Hough et al. (2002), Singh et al. (2003) and Iyengar and Raghukanth (2004) have got many limitations since it is based on olden concepts of stochastic modelling which have been revised subsequently as discussed in the section 2.0. Further, most of the above study attempted to simulate only high frequency PGA and hardly any effort has been made to simulate spectral accelerations in the frequency domains even in the latest model of Chopra et al. (2010a). Therefore, systematic efforts have been made to assess suitable model parameters for Bhuj (2001) earthquake from large dataset reported in the earlier studies and validating to the extent possible with the available instrumental as well data reported in the literature including simulations in the frequency domain. These parameters are used to generated ground motions of the same event at base rock level for Surat region which may useful further for estimation of site specific response or any seismic studies in the region.

3.1 Selection of Model Parameters

Ground motion at the particular site is influenced by three main elements i.e., source, path and local site conditions. The source parameters include size, depth, stress drop, rupture process and fault geometry. Travel path parameters include geometrical attenuation, dissipation of seismic energy due to inelastic properties of the earth and scattering of elastic waves. Local site factors include the properties of most rock/soil and the effect of the surface topography near the recording site. The source parameters of Bhuj (2001) earthquake has been studied by numerous authors (Rastogi et al. 2001; Negishi et al. 2001; Antolik and Dreger, 2003; Singh et al. 2003; Bodin and Horton, 2004). Mandal and Johnston (2006) estimated the source parameters for the aftershocks of 2001 main event. The most important source parameter for the simulation is the stress drop, which controls the spectral amplitudes at high frequencies. The intra plate earthquakes are generally characterized by large stress drop values in comparison to the plate boundary earthquakes (Kanamori and Anderson, 1975; Mandal and Johnston, 2006).

The various studies reported in the literature (Rastogi et al. 2001; Negishi et al. 2001; Bodin and Horton, 2004; Antolik and Dreger, 2003; Singh et al. 2003) revealed large static stress drop in the range of 125-246 bars for the Bhuj (2001) earthquake. Negishi et al. (2002) estimated stress drop in the range of 126-246 bars from the aftershock analysis. Antolik and Dreger (2003) estimated the stress drop value of 210 bar for the fault length of 45 km. Singh et al. (2003) have estimated the stress drop of 200 bars on the basis of stochastic finite fault modeling using FINSIM (Beresnev and Atkinson, 1998). Bodin and Horton (2004) have calculated stress drop of 150-200 bars on the basis of stochastic point source modeling. Mandal and Johnston (2006) estimated the stress drop in the range of 6.3 to 207 bars for the earthquakes in the Kutch region after analysing the 213 aftershocks of the same event. Recently Chopra et al. (2010a) proposed stress drop of 125 bars using stochastic finite fault simulation (Motazedian and Atkinson, 2005).

These large variations in observed stress drop values from the literature necessitate the systematic estimation of this parameter for the Bhuj (2001) event. Hence, simulations were carried out for stress drop values in the range from 80 - 260 bars with an increment of 10 bars. In the actual

earthquake ruptures, the slip may only be occurring on some part of the fault, whereas the other areas on the fault are passive. According to Motazedian (2006), only the active area contributes to the dynamic frequency at a given moment in time and therefore the cumulative number of pulsing sub-faults would increase with time at the beginning of the rupture and become constant at some fixed percentage of the total rupture area. This percentage is referred to as the '% pulsing area'. The percentage pulsing area is taken as 50 %, which means that at most 50 % of the fault plane is slipping at any moment in time. Same value has been adopted by Chopra et al. (2010a) for the simulations of the Bhuj (2001) earthquake. This parameter does not exert a large influence on the simulated amplitudes at most frequencies; however it exerts a moderate influence at lower frequencies (Motazedian and Atkinson, 2005). For simplicity, the random slip distribution has been assumed.

Aftershock studies of the 2001 Bhuj earthquake revealed an E-W trending strong cluster covering an area of 60 km x 40 km that dips to the south (Negishi et al. 2001; Bodin and Horton, 2004; Mandal et al. 2004a). Yagi and Kikuchi (2001) estimated the fault dimensions of 75 km x 35 km based on the teleseismic wave inversion. Mori (2001) used fault dimensions of 50 km x 40 km from the distribution of aftershocks for inversion of teleseismic data whereas; Antolik and Dreger (2003) used fault dimensions of 80 km x 35 km through the inversion of teleseismic broadband waves. In this study simulations were tried on all four fault dimensions.

In the implementation of the stochastic method, the attenuation effects of the propagation path are modelled through the empirical 'Q' and geometric attenuation model. It is observed that at high frequency (> 1 Hz) Q increases with frequency and can be represented in the form of $Q(f) = Q_o f^n$, generally Q_o is Q(f) a frequency of 1 Hz and n is the coefficient of frequency dependence (Chopra et al. 2010b), represents the level of tectonic activity of the region. The regions of high seismic activity are characterized by less Q(f) value compare to stable region where as higher 'n' value represents that the regions with high seismic activity and vise a versa (Roecker et al. 1982; Rodriguez et al. 1983; Van Eck 1988; Havskov et al. 1989; Mandal et al. 2001). Various researchers estimated the Q(f) values for Indian seismic regions (Gupta et al. 1995; Gupta, 1999; Paul et al. 2001; Singh et al. 1999, 2003, 2004; Bodin and Horton, 2004; Mandal et al. 2004c; Nath et al. 2008a; Chopra et al. 2010b). We have tried three available frequency dependent relations for the region i.e., $Q = 102 f^{0.98}$ (Mandal et al. 2004c) estimated from local coda waves, $Q = 508 f^{0.48}$ (Singh et al. 1999, 2003) obtained from regional Lg wave of Jabalpur (1997) earthquake data recorded at 10 broadband stations and $Q = 790 f^{0.22}$ (Bodin et al. 2004) from their study of ground motion prediction. For the geometric attenuation, the geometic spreading operator of 1/Rb, where b = 1 for $R \leq 40$ km, b = 0.5 for $40 < R \leq 100$ km and b = 0.55 for $R > 100$ km is assumed following the work of Bodin et al. (2004) with some modifications. It has been reported that the Ground motion of the Bhuj event is very close to the events of central or eastern North America (Bodin et al. 2004, Chopra et al. 2010a). Therefore the duration model developed for eastern North America (Atkinson and Boore, 1995) was used by keeping same hinges as in the attenuation model. This model gives duration (T) as 1/fc for $R < 10$ km, $1/f_c + 0.16R$ for $10 \leq R \leq 40$ km, $1/f_c - 0.03R$ for $40 < R \leq 100$ km and $1/f_c + 0.04R$ for $100 < R < 1000$ km, following Chopra et al. (2010a) with slight modifications. Another factor which affects the shape of the spectra is the near surface attenuation factor 'k'. Mandal et al. (2007) proposed a kappa 'k' value of 0.025 for the Kutch region. In the present study values of 'k' varying between 0.020 and 0.030 have been adopted.

The material properties like shear wave velocity and crustal density are taken a value of 3.6 km/sec and 2.8 g/cc as recommended by Singh et al. (2003) for Indian shield. Other parameters such as crustal amplification factor, location, hypocenter depth, depth of top of rupture etc are taken from Chopra et al. (2010a).

3.2 Calibration of Parameters and Model Validation

As mentioned earlier, no instrumental observations are available for Bhuj (2001) event in the near source region except few reading from spectral response recorder (SRR) and one recording of strong motion accelerogram installed at Ahmedabad (Cramer and Kumar, 2003; Iyengar and Raghukanth, 2004). The SRR gives the peak response of a simple harmonic oscillator with known damping coefficient (η) and natural period (T). There are 13 such SRR stations recording the spectral accelerations at $\eta = 0.05$, 0.1 and T = 0.40, 0.75 and 1.25 s operating within the radius of 300 km from the epicenter of Bhuj (2001) earthquake. The recorded spectral accelerations along with NEHRP class and geology of SRRs sites are presented in Table 1. These are the same stations where the various researchers (Singh et al. 2003; Iyengar and Raghukanth, 2006; Chopra et al. 2010a) have carried out simulations using different approaches. These simulations provide an opportunity to calibrate model parameters and validation of stochastic models in the absence of direct recorded PGA at different sites in the state of Gujarat.

Table 1 SRR Values at Three Different Time Periods with 5 % Damping with Site Conditions

S No.	Site	Distnace from Epicentre	Geology	NEHRP Class	Spectral Accelerations (Sa) at 5 % Damping		
					0.4 s	0.75 s	1.25 s
1	Anjar	44	Tertiary	C	1.616	0.705	0.423
2	Kandla	53	Tertiary	C	0.863	0.572	-
3	Niruna	97	Quaternary	D	0.811	0.650	0.300
4	Naliya	147	Tertiary	C	0.720	0.216	-
5	Khambhaliya	150	Basaltic Rock	A	0.192	0.102	0.06
6	Jamjodhpur	166	Basaltic Rock	A	0.176	0.094	0.056
7	Dwarka	188	Quaternary	D	0.211	-	0.058
8	Porbandar	206	Quaternary	D	0.191	0.248	0.054
9	Junagarh	216	Basaltic Rock	A	0.176	0.094	0.056
10	Amreli	225	Basaltic Rock	A	0.176	0.094	0.056
11	Ahmedabad	238	Quaternary	D	0.288	0.230	0.219
12	Cambay	266	Quaternary	D	0.488	0.041	-
13	Anand	288	Quaternary	D	0.144	0.061	0.045

Previously Kumar et al. (2001) estimated PGA values using SRR data. These values refer to the recorders on

different soil conditions and hence can not compare directly with the simulation results. To circumvent this difficulty, Cramer and Kumar (2003) corrected these data for firm rock (B/C boundary, NEHRP) condition using correction factors Joyner and Boore (2000). Singh et al. (2003) used finite fault stochastic model (Beresnev and Atkinson, 1997), whereas Iyengar and Raghukanth (2006) used analytical model in their studies and simulated PGA values for hard rock sites with shear wave velocity of 3.6 and 2.88 km/s respectively. Iyengar and Raghukanth (2004) estimated the PGA values from SRR data using empirical equations developed by multivariate regression of global database and these values has been modified to B/C site condition following the Cramer and Kumar (2003). Recently Chopra et al. (2010a) simulated Bhuj (2001) event using finite fault simulation for B/C boundary conditions and also for the hard rock conditions. In order to compare the results with earlier studies, the simulations were carried out at hard rock sites and for NEHRP B/C site conditions with shear wave velocity of 2.9 km/s and 760 m/s respectively at these 13 SRR locations adopting model parameters presented in section 3.1. The PGA values estimated in the present study using best fit model parameters along with those obtained in the previous studies are presented in Figs. 1 and 2.

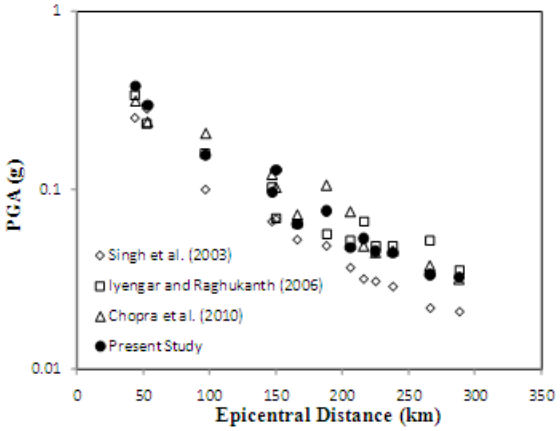

Figure 1 PGA Values Estimated in Present Study and Obtained in Literature for Hard Rock Site

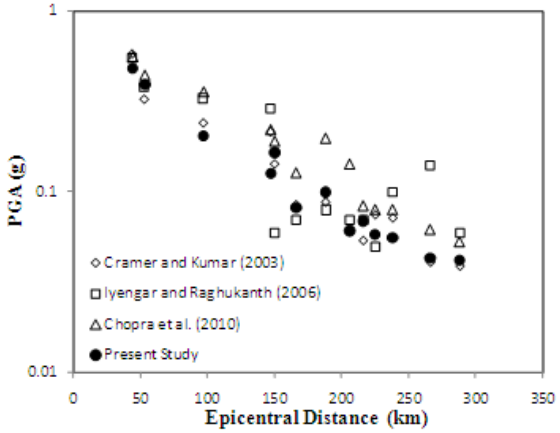

Figure 2 PGA Estimated in Present Study and Estimated from SRR Recordings for NEHRP B/C Site Condition (Vs = 760m/s)

It has been observed from Fig.1 that the PGA values obtained in the present study reconcile well with those obtained in the earlier studies for hard rock conditions except for Singh et al. (2003). The estimated PGAs in this study are higher in comparison to values predicted by Singh et al. (2003) for most sites, which is quite expected since the present PGA values are valid for NEHRP A conditions with Vs = 2.9 km/s whereas the results of Singh et al. (2003) are for rock outcrop with Vs = 3.6 km/s. The results presented in Fig. 2 reveal that, the PGA values obtained by Cramer and Kumar (2003) for the B/C site condition at SRR locations are in sound agreement with the simulated PGA in this study for majority of sites and provide slightly batter estimates than values predicted by Chopra et al. (2010a) whereas the values predicted by Iyengar and Raghukanth (2006) show comparatively scattered predictions.

The comparisons presented above are only in terms of PGA, and derived indirectly from seismological modeling or following empirical relations using SRR data. However, PGA alone does not provide complete representation of ground motion and question still arises as to the possibility of validating the simulated results by other means. Hence the spectral accelerations (Sa) at 5 % damping obtained from SRRs at three different natural periods such as 0.40, 0.75 and 1.25 s respectively corresponding to local site conditions as presented in Table 2 have been used simultaneously to calibrate model parameters in addition to PGA. First the simulations were tried for four hard rock (NEHRP A) sites. The comparisons of recorded and simulated spectral accelerations at hard rock sites are presented in Fig. 3 which indicates that the simulated values are in the favorable range with recorded values for most of the sites.

Table 2 Calibrated Model Parameters for the Simulations of Bhuj (2001) Earthquake

Parameter	Calibrated Parameters
Magnitude, Mw	7.7
Lat., Long.	23.36 0N, 70.34 0E
Hypocenter depth Strike, dip	22 km 780, 450
Fault Length and Width Rupture Depth	75 km x 35 km 10 km
Sub-fault size	5 km x 5 km
Stress drop, $\Delta\sigma$ Slip distribution	150 bar Random
Crustal Shear wave velocity, β Crustal Density, ρ	3.6 km/s 2.8 g/cc
Quality factor, Q(f)	Q = 508 f 0.48
Geometric Spreading Kappa 'k'	1/Rb b = 1 (R = 40 km) b = 0.5 (40 < R = 100 km) b = 0.55 (R > 100 km) 0.020
Duration (T) Pulsating %	1/fc (R < 10 km) 1/fc + 0.16R (10 = R = 40 km) 1/fc – 0.03R (40 < R = 100 km) 1/fc + 0.04R (>100 km) 50 %
Site Amplification	Boore and Joyner (1997) Atkinson and Boore (2006)

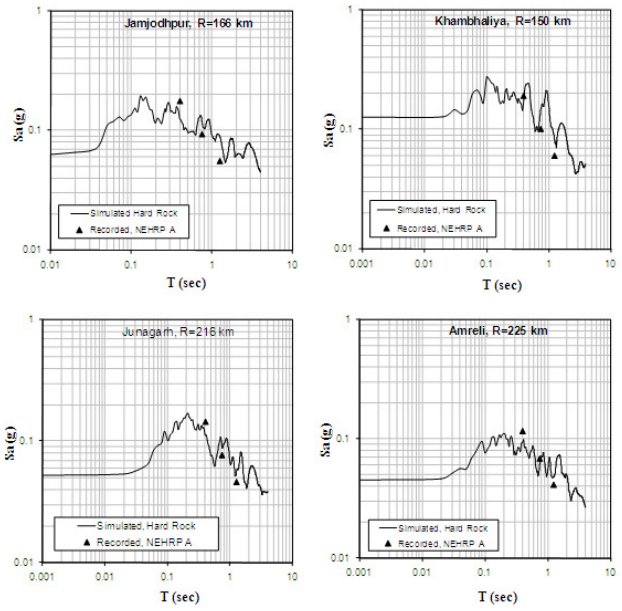

Figure 3 SRR Recordings and Simulated Response Spectra at 5% Damping for Hard Rock Sites

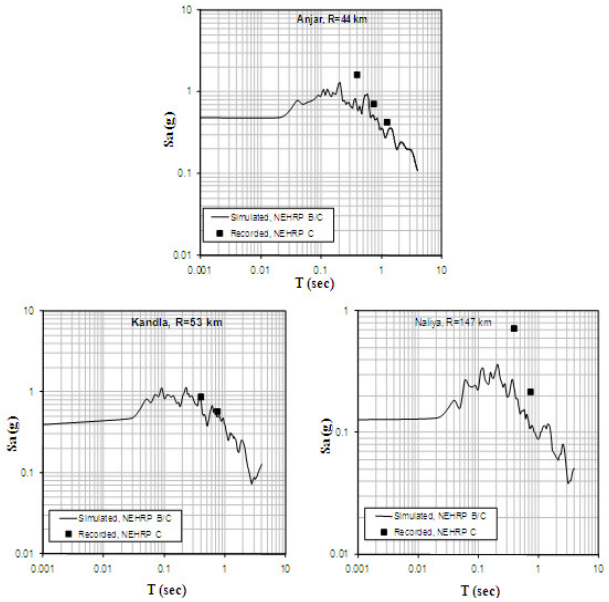

Figure 4 Simulated Response Spectra (5% Damping) at NEHRP B/C Site and SRR Recordings at NEHRP C Sites

Usually Class C and D sites are having relatively soft rock/Quaternary deposits over hard rock and large variations may be expected from site to site and hence the direct comparison might be difficult and more sound predictions may require extensive site specific analysis which is not in the scope of present study. Hence in lack knowing exact soil conditions, the SRR records on Tertiary sites (NEHRP C) and Quaternary sites (NEHRP D) compared qualitatively with simulated results of B/C sites as shown in Figs. 4 and 5. The comparisons indicate that the values predicted for class C and D sites are under predicted by model for most of the sites and it is also observed that the values predicted by the model showing much closer results for Class C in comparison to Class D sites. This is expected since model predicts the values for firm rock (B/C) site conditions. In and all, the model predicts the values reasonably well for most of site conditions. However, very limited recorded data, accuracy of this records and site conditions are also attributing to the variations and with more recorded data in future more accurate predictions can be made. The best fit calibrated model parameters are presented in Table 2.

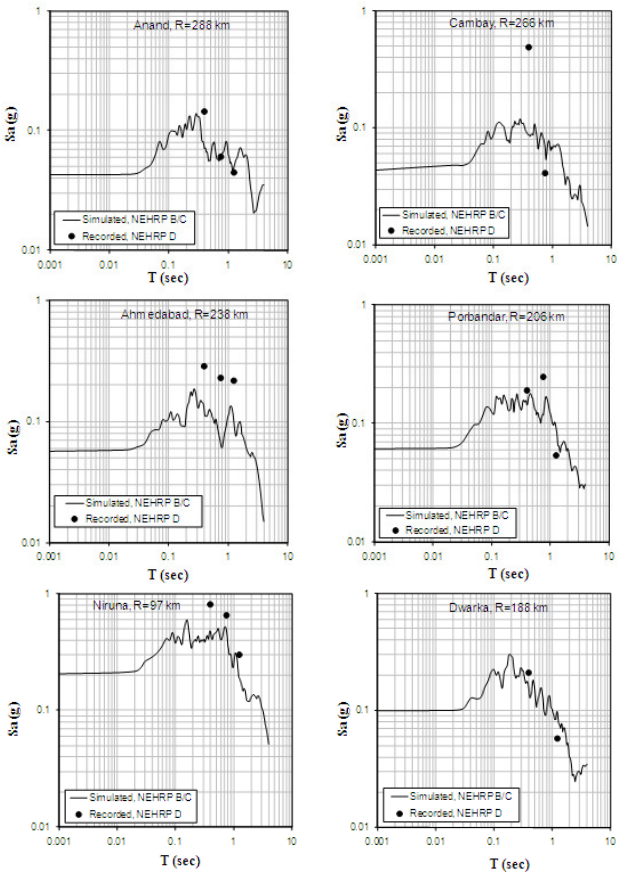

Figure 5 Simulated Response Spectra (5% Damping) at NEHRP B/C Site and SRR Recordings at NEHRP D Sites

Further, using the calibrated model parameters given in Table 2, simulations were carried out for 369 points in a grid of 0.4^0 x 0.4^0 spread all over Gujarat on B/C site condition, however slightly finer grid of 0.1^0 x 0.1^0 has been taken in near field region as decay rate is expected to be higher compare to other region. The spatial distribution of PGA values for the state of Gujarat is shown in the Fig. 6.

The PGA would have exceeded 0.60 g proximity to the epicenter of Bhuj (2001) event, reported by Iyengar and Raghukanth (2006) from the analytical results. According to Pervez et al. (2003), the design ground acceleration in epicenter zone reached up to 0.60 g and varies between 0.30 – 0.60 g and 0.08 – 0.15 g for the Kutch and Saurashtra regions respectively. Chopra et al. (2010a) estimated PGA variation from 0.20 to 0.62 g and 0.08g to 0.15 g for entire Kutch and Saurashtra region using similar approach. Present study yields PGA in the range of 0.20 g to 0.65 g for the Kutch and 0.05 g to 0.20 g for Saurashtra region. Iyengar and Raghukanth (2006) estimated PGA in the range of 0.31 - 0.37 g using empirical Green's functions to simulate ground

motion and 5 % damped response spectrum at Bhuj city. In the present analysis PGA varies from 0.30 to 0.35 g for the Bhuj. The above observations reveal that the results of present study are conciliate well with the earlier studies.

Now it would be interesting to see how well the PGA results correlate with field observation of damage after the earthquake. Several relations are available in literature (Trifunac and Brady, 1975; Wald et al. 1999) for estimating PGA from the intensity values. However it is recognized that the damage pattern and level depend on the vulnerability of the structures, which in turn varies from country to country (Raghukanth et al. 2008). Iyengar and Raghukanth (2006) addressed this issue and developed relation for Indian sub-continent using fourty three sampled data. Using this empirical relation given in Eqn. (1), the simulated PGA values have been converted into Modified Meracalli Intensity (MMI) values.

$$\ln(y) = 0.6782\,MMI - 0.8105;\ \text{where, } y = PGA\,(g) \qquad (1)$$

The simulated MMI values thus obtained have been contoured and compared with the reported intensity map following Chopra et al. (2010a) depicted in Fig. 7.

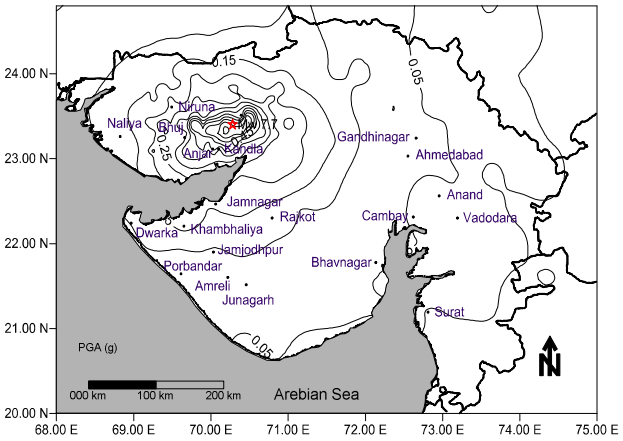

Figure 6 Predicted PGA (g) Model for Gujarat on NEHRP B/C Site Condition

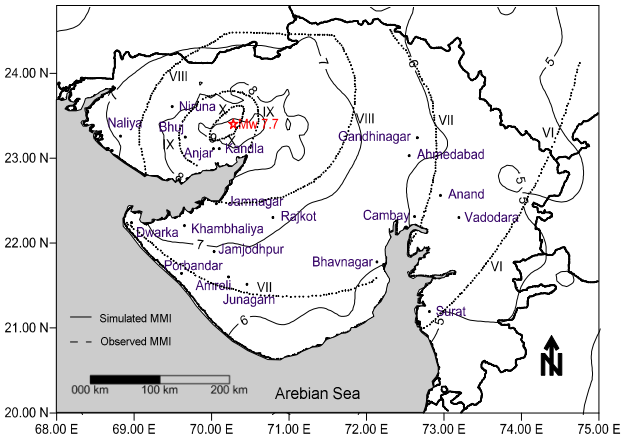

Figure 7 Simulated and Observed MMI Models

It has been observed from the Fig.7 that, the simulated MMIs ranges from 5 to 9 whereas the reported intensity values varied between VI and X. The reported intensity values are 1 unit greater than the simulated intensity values at most of the sites. This may be due to the fact that the simulated intensities were estimated from the PGA values computed at B/C site conditions whereas reported intensities are based on the many factors such as experience of the observant, damages and seismic hazards like, landslide, liquefaction, ground fissures etc (Richter, 1958).

As mentioned earlier, the only strong motion record of the 2001 event is available at Ahmedabad in the basement of the Passport Office; some 240km away from the epicenter. The recorded value of PGA at Ahmedabad is 0.10 g at site classified as NEHRP, D whereas simulated value at this site is 0.056 g for B/C boundary conditions (Fig. 2). This under prediction by the simulated model may be attributed to the local site effect. The same has been observed from Fig. 6.5 for Ahmedabad site therefore, the ground motion at surface has been computed adopting one dimensional ground response analysis. The ground response analysis has been carried out using DEEPSOIL program (Hashash et al. 2008).

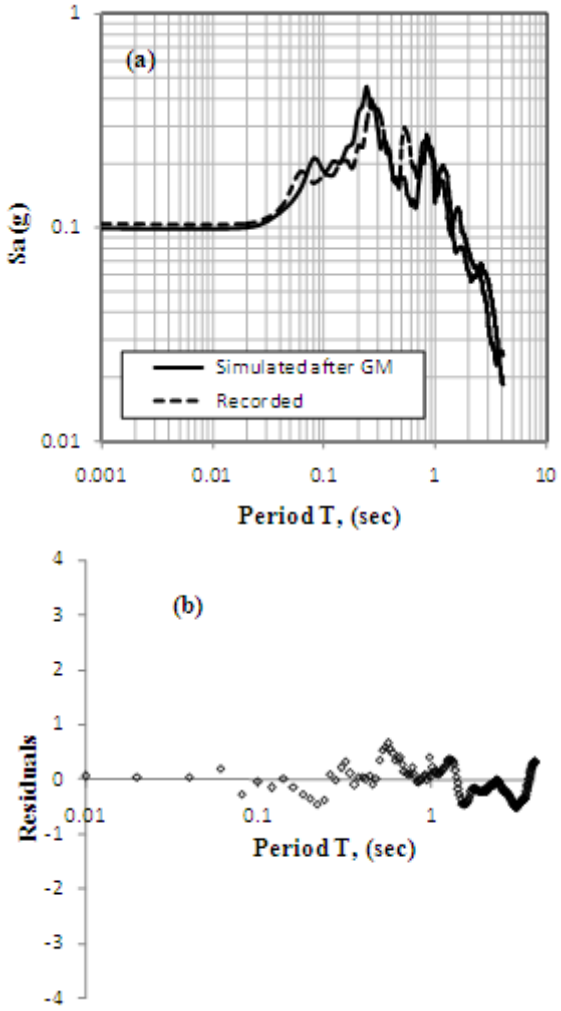

Figure 8 Recorded and Predicted Response Spectrum (b) Residual Plot at Ahmedabad

The detailed soil profile at the recording site including soil type, thickness of layer, shear wave velocity has been taken from the previous work (Trivedi et al. 2006; Trivedi, 2010).

A response spectrum of predicted ground motion at surface using ground response analysis has been compared with recorded one at the same site as shown in Fig. 8 (a). The Residual of the predicted and recorded spectral acceleration have been estimated for all the periods and presented in Fig. 8 (b). The comparison presented in the Fig. 8 indicates that the residuals are very close to the zero line and predicted spectral acceleration values reconcile considerably well with the recorded one for the most of the period ranges.

3.3 Generation of Ground Motion at Surat for Bhuj (2001) Event

The main purpose of the present study is to generate synthetic strong motion accelerogram records at Surat city in absence of actual recordings during 2001 event. It is observed that the stochastic model for the Bhuj (2001) earthquake has been reasonably validated using different approaches. Therefore calibrated finite fault model parameters given in Table 2 have been used to generate ground motion histories at important cities/towns in the state of Gujarat including Surat given Fig. 9.

In addition to that, the ground motions have been simulated at 66 sites in Surat region using the same model parameters. The results of these simulations indicate that the Bhuj (2001) earthquake may have generated PGA in the range of 0.026 g to 0.037 g for the Surat region. The spatial distribution of PGA for this region has been presented in Fig. 10. The ground motion generated here will be very useful for various seismic studies to be carried out in the region.

3. DISCUSSION AND CONCLUSIONS

In absence of recorded ground motion data, the seismological modeling seems to be a rational alternative in obtaining the ground motion during the significant event. The main aim of present investigations is to generate ground motions for the Surat region in absence of instrumental records which in turn useful for estimating future hazards in the region. First, the ground motions for Bhuj (2001) earthquake (Mw 7.7) were estimated using one dimensional stochastic finite fault modeling based on the dynamic corner frequency (Motazedian and Atkinson, 2005).

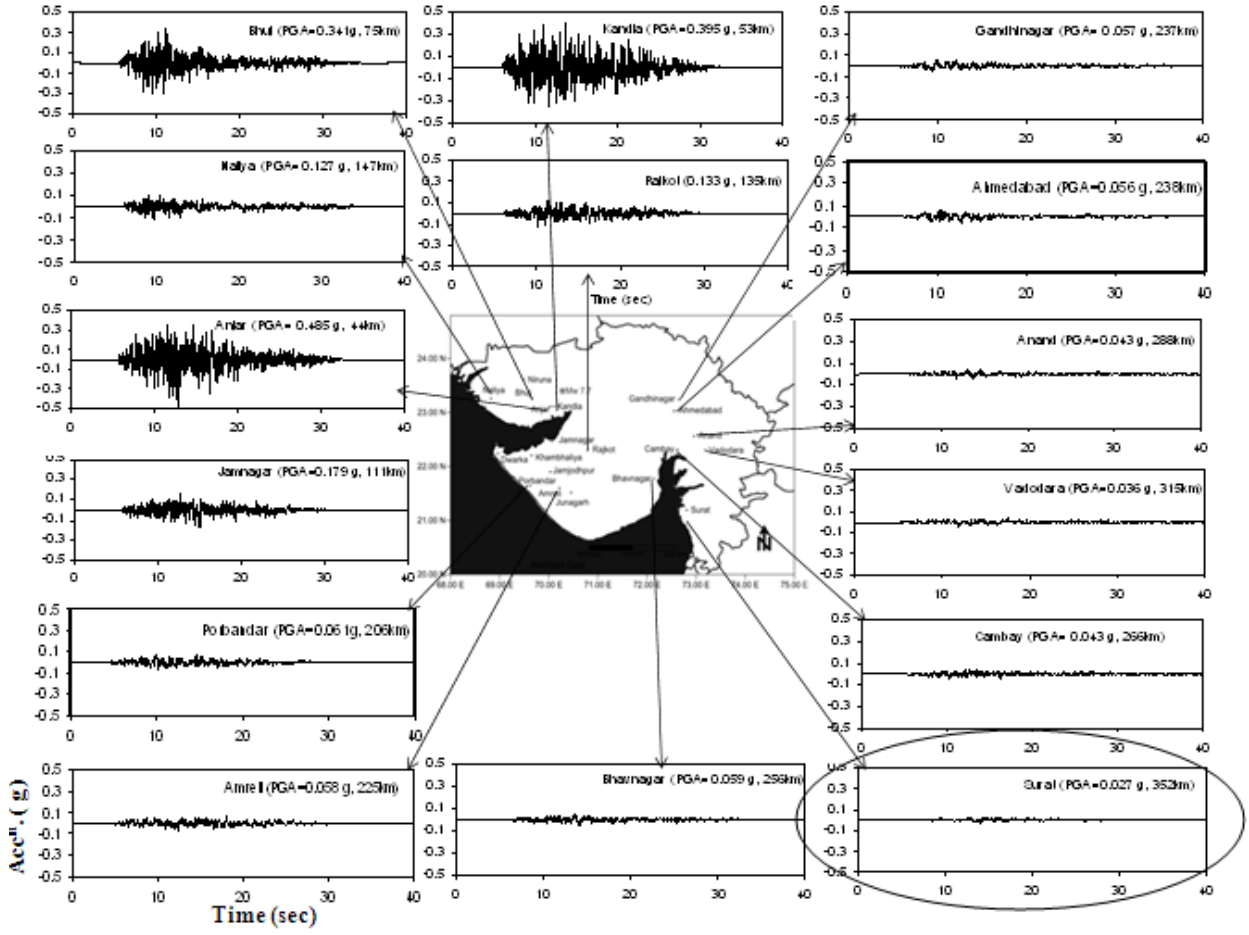

Figure 9 Simulated Ground Motions at Important Cities/ Towns in the State of Gujarat including Surat for B/C Site Condition

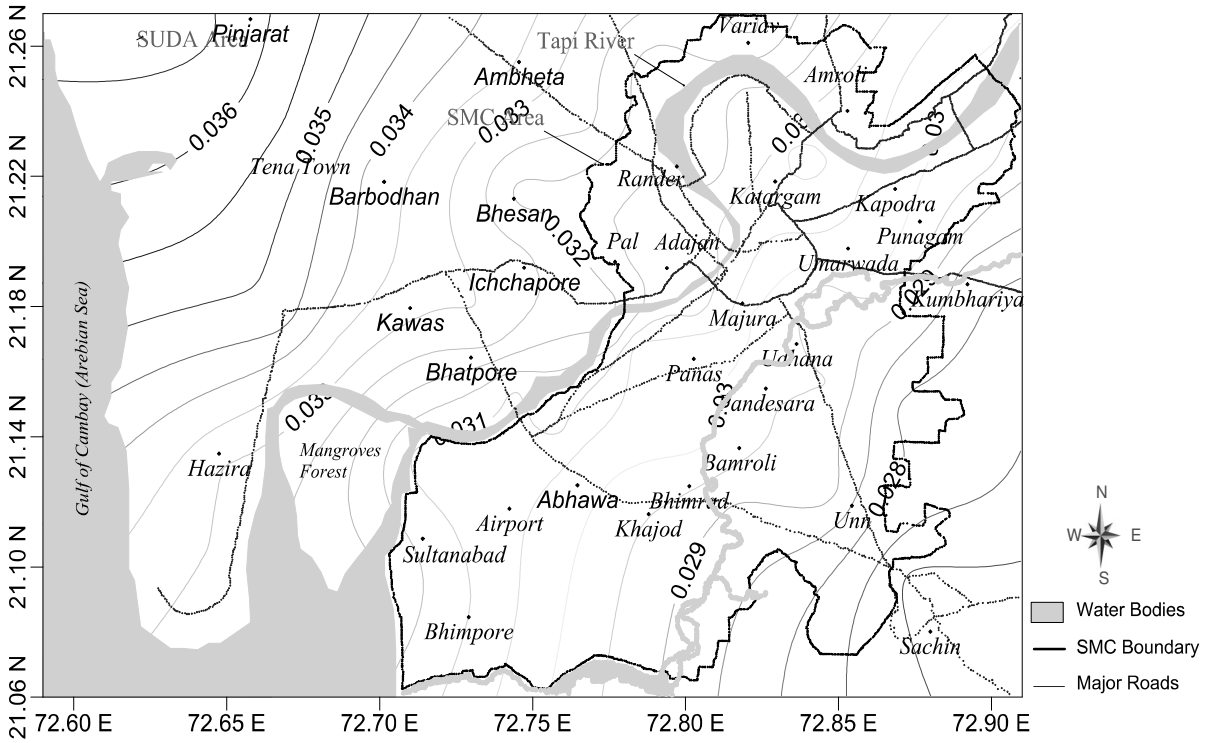

Figure 10 Simulated PGA of Bhuj (2001) Earthquake at Firm Rock (Vs = 760 m/s) sites for Surat Region

The results of simulations have been validated through different approaches. In the first approach, the ground motions were simulated at hard rock and NEHRP B/C boundary sites where SRR recordings are available.

The estimated PGA values at hard rock and B/C sites validated with those obtained in literature adopting different methodologies. The stress drop value of 150 bars estimated from above simulation which is in the range of the findings from earlier investigations carried out by Negishi et al. (2001) and Bodin and Horton (2004) for the same event whereas stress drop predicted by Antolik and Dreger (2003) and Singh et al. (2003) is quite high in comparison to the present study. On other hand, Chopra et al. (2010a) model underestimated the stress drop value in comparison to the present study. It is observed that the quality factor, $Q = 508f^{0.48}$ provides best fit estimations with available results. Hough et al. (2002) and Singh et al. (2003) adopted the same 'Q' value estimating near source ground motions of same event using a finite source stochastic modeling (Beresnev and Atkinson, 1997). Moreover, the same 'Q' has been used by Iyengar and Raghukanth (2004) for establishing the attenuation relations for western central region of India using extensive seismological modeling.

In the second approach, the predicted response spectrum has been compared with recorded spectral acceleration data from SRRs for different site conditions. The simulated spectra at hard rock site are in the close agreement with recorded accelerations for available period ranges. Whereas simulated spectra at B/C sites underestimates the recorded results of SRRs placed on NEHRP C and D sites on account local site effects. Further in third approach, the simulated PGA at B/C site conditions have been converted to MM Intensities using region specific empirical relation (Iyengar and Raghukanth, 2006) and validated with observed of Bhuj (2001) event in the state of Gujarat. The spatial distribution of PGA in Gujarat region brings out the western directivity effects on account of fault orientation and slip direction which is consistent with the observations of Chopra et al. (2010a). The PGA values are higher in the western side compare to east at comparable distances. The strong westward directivity has been observed towards the town Bhuj and Anjar, which are damaged extensively during the Bhuj (2001) earthquake. The estimated PGA values are also useful in understanding the ground motion attenuation with distance. It is observed that The PGA attenuating very fast up to the contour of 0.25 g, thereafter the rate of decay is reducing considerably on account of geometrical spreading function used in this study. Finally in the fourth approach, the influence of local site effects has been testified using site response analysis. The surface level ground motion has been obtained at Passport office, Ahmedabad using one dimensional ground response analysis validated with recorded time history at same sites.

The comparisons presented above highlights the importance of seismological modeling in the generation of ground motions. The simulated parameters have been used to predict ground motions of Bhuj (2001) event in the Surat region at 66 sites along with other important town/cities in the state of Gujarat. Generated synthetic ground motions will be very useful in assessing the performance of the structures in the state. The most probable earthquake scenarios have been selected considering the seismic hazard analysis and seismotectonic of the region.

Abstract: Liquefaction-induced deformations for geotechnical structures can be significantly affected by the effects of pore pressure diffusion and the associated void redistribution. Numerical simulations using a critical-state compatible constitutive model are shown to reproduce the pattern of void redistribution that was observed in a centrifuge model test. The capabilities and limitations in our current abilities to account for void redistribution in nonlinear deformation analyses are discussed.

1. INTRODUCTION

Design and evaluation of geotechnical structures affected by soil liquefaction requires engineering procedures that can account for liquefaction-induced strength loss and deformations. Laboratory tests on field samples have been used to estimate undrained shear strengths (e.g., Poulos et al. 1985), but the application of such results assumes that the void ratio of in-situ soils either stays constant or decreases during diffusion of earthquake-induced excess pore water pressures. Empirical correlations based on back-analyses of liquefaction flow slide case histories have instead been preferred for practice because they implicitly account for pore pressure diffusion (and associated void redistribution) and other in-situ mechanisms of strength loss that standard laboratory element testing cannot recreate. Nonlinear deformation analyses have provided insights on the mechanisms of strength loss associated with pore water pressure diffusion and void redistribution (e.g., Seid-Karbasi and Byrne 2007), but the ability of such analysis methods to confidently predict void redistribution effects has not been adequately demonstrated. For this reason, the application of nonlinear deformation analyses to practical problems still relies on case history experiences for estimating the in-situ residual shear strength of liquefied soils.

The mechanism of strength loss due to void redistribution is illustrated in Figure 1 for a liquefied soil layer within an infinite slope (Kulasingam et al. 2004). The liquefied layer is overlain and underlain by lower permeability soils, as shown in Figure 1a (after Whitman 1985). The shear stress ratio, stress-path, and void ratio response at the top and bottom of the sand layer (points A and C, respectively) are illustrated in Figures 1b, 1c, and 1d, respectively. Earthquake shaking generates excess pore water pressures, which result in an upward hydraulic gradient that causes pore water to flow up toward the interface with the overlying low-permeability layer. A thin zone at the top of the sand layer dilates in response to the net inflow of water and develops shear strains that are related to the imposed volumetric strains through the sand's dilation angle. The progressive loosening of this thin zone results in a shear strain concentration and can result in the sand eventually reaching critical state (point i). Any further inflow of water then results in the thin zone shedding shear stress and the slope becoming unstable.

This paper describes numerical simulations of a centrifuge model test involving silt interlayers in a saturated sand slope. The experimentally observed pattern of void redistribution is described, followed by the results of the numerical simulations. The capabilities and limitations in the numerical models and the challenges in numerically simulating the details of these mechanisms are discussed.

2. PHYSICAL MODEL STUDIES

Malvick et al. (2008) used back-analyses of time series data from a dense array of pore pressure transducers within a saturated sand slope with embedded silt layers to quantify several aspects of the pore pressure diffusion and void redistribution process. The test was performed on a 9-m-radius centrifuge at a centrifugal acceleration of 45 g; results are presented in equivalent prototype units unless otherwise stated. The arrangement of pore pressure

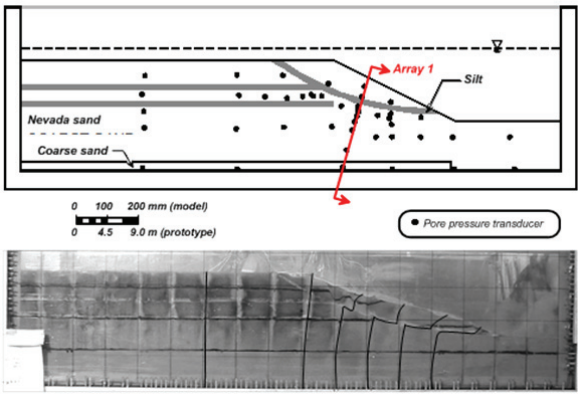

Figure 2. Localization along a lower permeability interlayer in a saturated sand slope tested in a 9-m-radius centrifuge (after Malvick et al. 2008)

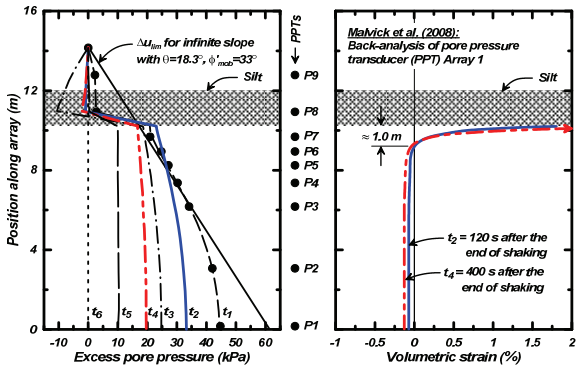

Figure 3. Results of back-analyses of data from the dense array of pore pressure transducers: Excess pore pressures and volumetric strains at different times (after Malvick et al. 2008)

transducers and a photograph of the post-testing deformed geometry of the model slope are shown in Figure 2. The pore pressures and volumetric strains calculated for Array 1 are shown in Figure 3. Hydraulic gradients were calculated by numerical differentiation of the measured pore pressure distribution with respect to position along the array. Flow rates were computed based on Darcy's Law and integrated with respect to time to obtain flow quantities, from which volumetric strains within specific intervals were computed. Their analysis results showed that a dilating (loosening) zone of about 1 m or greater thickness developed in the sand immediately beneath the embedded silt layer during diffusion of the excess pore pressures (Figure 3). They concluded that the dilating zone corresponded to regions where the mobilized friction angle exceeded the critical state friction angle, and that the dilating zone can be initially relatively thick before its size eventually diminishes to the thickness of a thin shear band.

Kamai and Boulanger (2010) obtained similar results from back-analyses for a dense array of pore pressure transducers within a dynamic centrifuge model test involving liquefaction-induced lateral spreading of a clay crust overlying a loose liquefying sand layer. Their results indicate that loosening occurred over an approximately 0.6-m-thick interval at the top of the sand layer, and that the greatest volumetric strains (a few percent) occurred immediately near the interface with the clay crust.

The results of these and other physical modeling studies have demonstrated that the effects of void redistribution depend on the initial D_R, slope geometry (e.g., low-permeability interlayers, sand layer thickness), shaking duration, shaking amplitude, and shaking history (e.g., Liu and Qiao 1984; Elgamal et al. 1989; Dobry and Liu 1992; Fiegel and Kutter 1994, Kokusho 1999, 2003, Kulasingam et al. 2004, Malvick et al. 2008, Kamai and Boulanger 2010).

3. SIMULATIONS

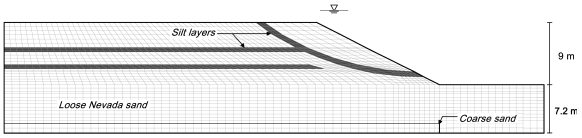
Simulations were performed for the centrifuge test by Malvick et al. (2008) shown previously in Figure 2. The simulations were performed using the finite different mesh shown in Figure 4, and included a sensitivity study covering a range of cyclic strengths, hydraulic conductivities, mesh size, and other parameters.

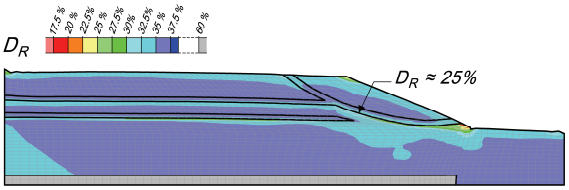
The constitutive model used in these analyses, PM4Sand, was developed by Boulanger (2010) and Boulanger and Ziotopoulou (2012). The model follows the basic framework of the stress-ratio controlled, critical state compatible, bounding-surface plasticity model for sand presented by Dafalias and Manzari (2004), with a number of modifications and additions as described in Boulanger and Ziotopoulou (2012). The model was implemented as a user-defined material for use with the commercial program FLAC (Itasca 2011). Details of the implementation for version 2 of the model, which was the version used for the simulations presented herein, are given in Boulanger and Ziotopoulou (2012).

The numerical simulations captured the trends and magnitudes of the recorded accelerations and pore pressures during shaking reasonably well. The simulations were in reasonable agreement with the final deformed geometry, but did not reproduce the delayed timing of the post-shaking slope deformations that were observed in the experiment. Details of the numerical modeling procedures are given in Kamai (2011); note that the simulation results in Kamai (2011) used version 1 of the PM4Sand model whereas the results shown here differ slightly because they were performed using version 2 (Boulanger and Ziotopoulou 2012).

The sand elements immediately below the silt arc in this mesh were generally about 200 mm thick, which is comparable to the expected dimensions of a potential shear band in this model. The median particle size for this sand is about 0.17 mm (model scale), such that a 10 to 20 grain diameter thick shear band would be 2 to 4 mm thick in model scale and thus 90 to 180 mm thick in the prototype scale used for the simulations. Analyses were also performed using a slightly more refined mesh, with the differences in results being consistent with those discussed previously. Considering the approximations involved in estimating the thickness of the localization zone, the values of the strains within the localized shear zone computed using the mesh in Figure 4 are expected to be reasonable for illustrating the mechanism of void redistribution.

Computed patterns of void redistribution for this model are illustrated by the results in Figure 5 for two different values of sand permeability. The sand permeability for the case shown in Figure 5a was set equal to the value obtained in laboratory element tests, whereas the sand permeability was increased by a factor of five for the case shown in Figure 5b. This variation of permeability was chosen in part because some studies have suggested permeability increases markedly when liquefaction is triggered (e.g., Haigh et al. 2012) and partly to examine the sensitivity of analysis





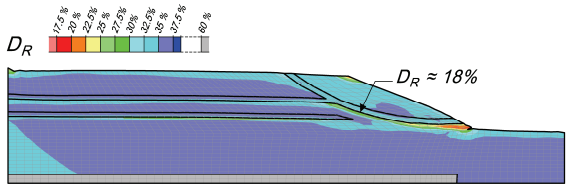


Figure 4. Model configuration and finite difference mesh for EJM02.

(a) sand permeability of 0.012 cm/s

(b) sand permeability of 0.06 cm/s

Figure 5. Deformed mesh and contours of D_R for two analysis cases that both start with an initial D_R = 35%:

results to the uncertainty in input parameters. These two numerical simulations produce patterns of void redistribution that are consistent with the patterns identified through back-analyses of the data from the dense array of pore pressure transducers (Figure 3). The simulation results are consistent in showing that there is an approximately 1.0 to 3.0 m thick zone (varies along the arc) of sand immediately beneath the silt arc that loosens as a consequence of a net inflow of pore water, and that the greatest degree of loosening occurs in a thin zone immediately beneath the silt arc. For the case shown in Figure 5a, the sand elements immediately beneath the silt arc near the middle of the slope loosen from D_R = 35% before shaking to $D_R \approx 29\%$ at the end of shaking and then to $D_R \approx$ 24.5% about 300 seconds after the end of shaking. For the case shown in Figure 5b, the same sand elements loosen more rapidly until they reach critical state at $D_R \approx 18\%$ just before the end of shaking; these elements do not experience significant changes in D_R after shaking for this case, since most of the excess pore pressure dissipates during shaking due to the higher permeability. Thus, the five-fold increase in permeability between the models in Figures 5a and 5b increased the volumetric strains from about 2.2% to 3.6% at this point in the slope, caused a greater proportion of the strains to occur during shaking versus after shaking, and also increased overall slope deformations by about 18%. These

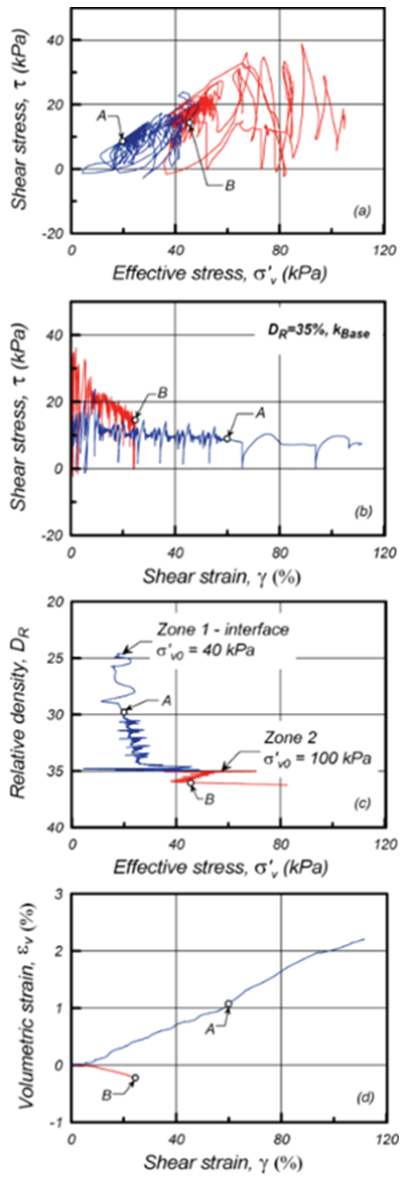

Figure 6. Stress and strain paths of two elements from one scenario simulation: Element 1 is in the sand just beneath the silt interlayer and Element 2 is about 6 m below Element 1. Points A and B represent the end of shaking for Elements1 and 2, respectively.

effects are consistent with the simpler analytical and dimensional analysis results obtained by Kulasingam (2004).

The stresses and strains that were computed for two elements in the mesh for the simulation with the lower sand permeability are shown in Figure 6. Element 1 is a sand element just beneath the silt arc near the middle of the slope, whereas Element 2 is a few meters below Element 1 (below the zone of dilation). Points A and B correspond to the end of shaking for Elements 1 and 2, respectively. The sand at Element 2 developed high excess pore pressures and shear strains of several percent during shaking, but then progressively contracted (densified) due to the net outflow of pore water from this zone both during and after shaking. The sand at Element 1 also develops high excess pore pressures during shaking, but it progressively loosens under the net inflow of pore water and accordingly develops very large shear strains under the combined effects of this pore water inflow and continued small levels of shaking. The simulation paths are very consistent with the expected patterns presented schematically in Figure 1 by Kulasingam et al. (2004).

4. CHALLENGES IN PRACTICE

There are a number of technical challenges that need to be addressed for improving the ability to numerically simulate the process of void redistribution and its effects on residual shear strengths and deformations. The length scale for any eventual localization needs to be consistently accounted for and better understood for conditions where geologic contacts are less distinct and/or have gradually varying soil properties (e.g., permeability in a fining-upward sequence). Constitutive models are also needed that can better simulate post-liquefaction reconsolidation strains because these volumetric strains directly affects the volume of water given off by consolidating zones. Existing elastic-plastic continuum models generally under-estimate post-liquefaction reconsolidation strains, which can be expected to cause an under-estimation of the magnitude of void redistribution and difficulties in simulating delayed slope deformations. In addition, there are numerical challenges in simulating localization processes using any continuum model, whether it is void redistribution or cracking of overlying crusts with associated graben formation during the sliding process. It follows that there remains an important need to evaluate the extent to which any numerical modeling procedure can differentiate between cases (e.g., physical model tests) where void redistribution has and has not led to significant concentrations of shear strains and contributed to the associated deformations.

Simulating void redistribution effects for field conditions involves even further challenges, including improving our ability to characterize geologic heterogeneities, geology contacts, in-situ soil properties, and ground motion characteristics. Geologic details can be expected to have a major influence on the thickness and/or continuity of any loosening zones and on the formation of ground cracks or soil boils that may reduce the progression of loosening in certain zones.

5. CONCLUSIONS

Physical model tests involving liquefiable sands with lower-permeability interlayers have demonstrated how various factors can influence the degree to which void redistribution can affect shear strength losses and slope deformations. The potential for void redistribution to cause

strain localizations and associated deformations in liquefied soil depends on the soil properties (initial relative density, cyclic resistance ratio, permeability), slope geometry (layer thicknesses, slope angle, continuity of interfaces), and ground motion characteristics (shaking intensity, shaking duration, shaking history).

Numerical simulations using the critical-state compatible constitutive model PM4Sand (Boulanger and Ziotopoulou 2012) with the commercial program FLAC (Itasca 2011) were shown to reasonably reproduce the patterns of void redistribution, but did not reproduce the delayed timing of the post-shaking scope deformations that were observed in the experiment. Numerical simulations provide additional insight on the mechanisms of void redistribution, although there remain several factors that currently limit our ability to simulate void redistribution effects in practice.

LIQUEFACTION POTENTIAL EVALUATION: ENERGY-BASED METHOD VERSUS STRESS-BASED METHOD

Takaji Kokusho[1)]

1) *Professor, Department of Civil & Environment Engineering, Chuo University, Japan*

Abstract: A data set of undrained cyclic triaxial test for liquefaction parametrically changing relative density and fines content is reviewed and interpreted in scope of energy. It is found that the strain amplitude or pore-pressure buildup during cyclic loading is uniquely correlated not only to energy dissipated in soil specimens but also to strain energy given from outside. An energy-based method (EBM) is developed in which liquefaction potential can be evaluated by comparing the strain energy for liquefaction in a sand layer with upcoming seismic energy with no regard to the differences in seismic motions. Comparative studies in soil models demonstrate that the effect of various input motions is intrinsically included in EBM, whereas it has to be considered by choosing a proper coefficient in a conventional stress-based method (SBM). Another significant difference is that liquefaction potential tends to be higher for a shallower depth in EBM, while it is vice versa in SBM in a uniform sand deposit.

1. INTRODUCTION

From the dawn of the liquefaction research, a stress-based method (SBM), comparing undrained cyclic strength with seismically induced shear stress, was employed (Seed and Idriss 1971) and standardized in engineering practice for liquefaction potential evaluations in many design codes.

On the other hand, an energy-based method (EBM) was proposed by Davis and Berrill (1982) and Berrill and Davis (1984), assuming that the pore-pressure buildup is directly related to the amount of seismic energy dissipated in the soil. In order to demonstrate the energy-dependency of liquefaction, laboratory soil test was conducted (e.g. Figueroa et al. 1994), which showed that the dissipated energy per unit volume during undrained cyclic loading is closely connected to pore-pressure build-up.

Despite a close link between dissipated energy and pore-pressure build-up, the application of EBM has been very limited so far in engineering practice. In this paper, a systematic research is undertaken, in which laboratory tests and seismic energy evaluations are combined to propose an approach of EBM. It is then applied to a hypothetical sand deposit to compare the result with that of SBM under the same seismic motions.

2. SOIL TEST RESULTS ON DISSIPATED ENERGY DURING CYCLIC LOADING

In order to examine correlations between dissipated energy and excess pore-pressure as well as soil strain, a series of undrained cyclic triaxial test data obtained in the previous research (Kokusho et al. 2012) have been reviewed here. The test was carried out using reconstituted specimens of Futtsu beach sand (along the Tokyo Bay), with the mean grain size D_{50}=0.19 mm and the uniformity coefficient U_c=1.9, which consists of non-weathered sub-round particles. The size of the specimen was 10 cm in diameter and 20 cm

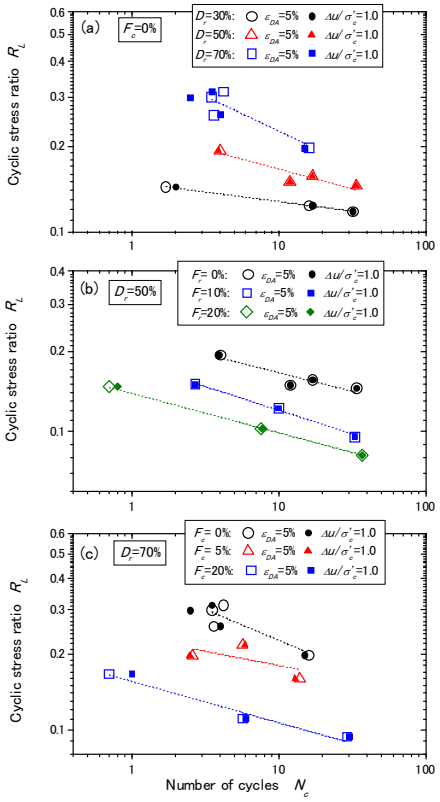

Figure 1 Cyclic stress ratio R_L versus number of cycles N_c

in height. The relative density was varied nominally in three steps; D_r≒30, 50 and 70%. In some cases, low-plasticity fines (the plasticity index I_p=6) was mixed to make sand samples with various fines content F_c.

The samples were isotropically consolidated to an effective stress of σ_c' =98 kPa, and cyclically loaded with frequency 0.1 Hz under a undrained condition with a constant axial cyclic stress amplitude σ_d . Number of cycles N_c to attain double-amplitude axial strains ε_{DA} =2, 5, 10% and the pore-pressure ratio $\Delta u/\sigma_c'$ =1.0 were measured under various cyclic stress ratios $R_L = \sigma_d / 2\sigma_c'$.

Fig. 1 shows cyclic stress ratios R_L versus number of load cycles N_c on the log-log chart for ε_{DA} =5% and $\Delta u/\sigma_c'$ =1.0 for a series of tests; (a) only clean sands (F_c=0%) with D_r ≒30, 50, 70%, (b) F_c=0~20% with D_r≒50% and (c) F_c=0~20% with D_r≒70%. The plots in the chart are approximated by an empirical formula with positive constants *a* and *b*;

$$R_L = aN_c^{-b} \qquad (1)$$

Despite data scatters, it may be said that the R_L-value for ε_{DA} =5% increases systematically with increasing D_r, and decreasing F_c.

Fig. 2 exemplifies a typical stress-strain relationship for D_r=51% and F_c=0%. The dissipated energy per unit volume in a test specimen is calculated in each stress cycle for

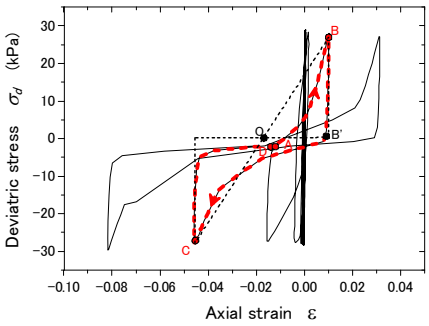

Figure. 2 Typical stress-strain relationship during undrained cyclic triaxial test.

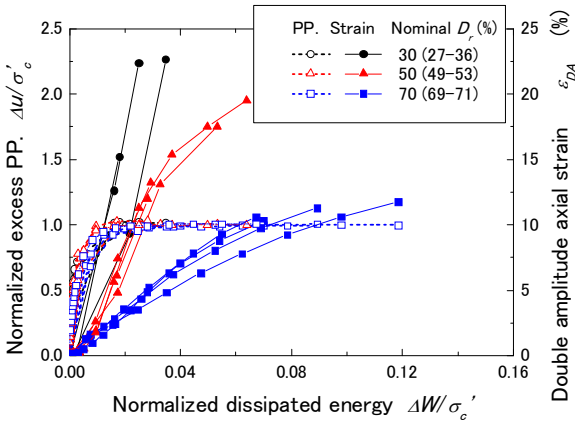

Figure 3 Relationships between normalized dissipated energy at each cycle and corresponding excess pore-pressure and double amplitude axial strain.

a hysteretic area ABCD shown in the figure with a thick dashed curve and summed up for all the cycles from the start to a particular cycle *k* as

$$\Delta W = \sum_k \left(\int_A^D \sigma_d d\varepsilon \right)_k \qquad (2)$$

In Fig. 3, the maximum values of ΔW are read off in individual loading cycles from time-histories for all the test data. The ΔW -values are plotted versus maximum values of pore-pressure Δu and double-amplitude axial strain ε_{DA} in the corresponding cycles with different symbols for sands of F_c=0 and nominal D_r-values 30, 50 and 70%. Here, the pore-pressure and the dissipated energy per unit volume is non-dimensionalized by the effective confining stress σ_c' . It is remarkable that the pore-pressure build-up occurs with increasing dissipated energy almost uniquely despite the difference in D_r, and approaches $\Delta u/\sigma_c'$ =1.0 at $\Delta W/\sigma_c'$ =0.02 or smaller.

In a good contrast, a dominant effect of D_r is visible on the strain amplitude versus energy relationship in Fig. 3. The induced strain ε_{DA} is almost in proportion to the normalized energy $\Delta W/\sigma_c'$ for each relative density D_r up to a certain strain around ε_{DA} = 10% even after the onset of liquefaction. Thus, the dissipated energy can be correlated consistently with strain amplitude depending on individual D_r-values up to the initial liquefaction (ε_{DA} =5%) and thereafter, and serve as an indicator for severity of liquefaction.

In Fig. 4, the normalized dissipated energies $\Delta W/\sigma_c'$ are plotted in the vertical axis versus the number of load cycles N_c in the horizontal axis on log-log charts to attain strain amplitudes, ε_{DA} =2, 5, 10%, and pressure build-up, $\Delta u/\sigma_c'$ =1.0. The plots in (a) are for clean sand (F_c=0) with parametrically varying nominal relative density D_r≒30, 50 and 70% and those in (b) are for sand containing parametrically changing fines content (F_c=5~20%) having relative densities, D_r≒50 and 70%. There are groups of 2 to 4 data-points with the same symbols for which the same prescribed strain ε_{DA} or pore-pressure $\Delta u/\sigma_c'$ were attained in different numbers of cycles N_c, because multiple tests for test specimens having the same F_c and nominal D_r were carried out with different cyclic stress amplitudes. The lines connecting them do not show consistent increasing or decreasing trend in $\Delta W/\sigma_c'$ -values with increasing N_c. They may be judged to be essentially flat in all the test cases, despite some lines for dense sands showing non-systematic up-down trends particularly for ε_{DA} =10%. The trends in Fig. 4 seem to indicate that the dissipated energy almost uniquely determines the strain amplitude or pore-pressure buildup during cyclic loading, no matter how many cycles N_c and how large the associated applied stress ratio R_L are required to attain a particular strain amplitude ε_{DA} or pressure buildup. This further indicates that a R_L-N_c line for particular strains or $\Delta u/\sigma_c'$ =1.0 drawn in Fig. 1, normally addressed as a basis for the stress-based approach of liquefaction potential evaluation, actually represents a line of equal-energy dissipation (Green and Terri 2005). This ob-

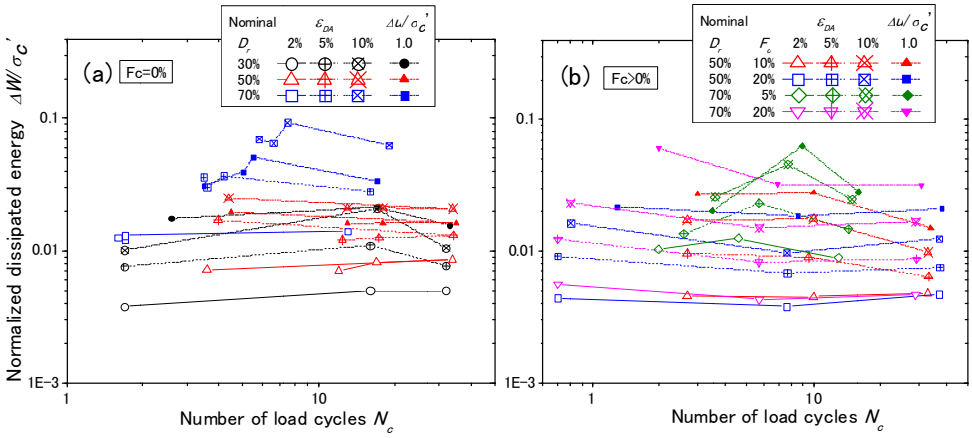

Figure 4 Normalized dissipated energy for ε_{DA}=2, 5, 10% and $\Delta u/\sigma'_c$=1.0 plotted versus number of load cycles.

servation paves a way to an energy-based method (EBM) using conventional soil data in the stress-based method (SBM).

Based on the test results in Figs. 1 and 4 for $D_r \fallingdotseq$30-70% and F_c=0-30%, a direct relationship between cyclic resistance ratio R_{L20} for N_c=20 and corresponding dissipated energy $\Delta W/\sigma'_c$ can be developed as shown in Fig. 5. Despite differences in relative density and fines content, the R_{L20}–values for the strain level ε_{DA}=5% (circles) may be uniquely correlated with $\Delta W/\sigma'_c$ and approximated by a parabolic function

$$\Delta W/\sigma'_c = 0.032 - 0.48R_{L20} + 2.40R_{L20}^2 \qquad (3)$$

for practically meaningful R_{L20}–values ($R_{L20} \geq 0.1$) with a regression coefficient RC=0.93. For ε_{DA}=2% and 10%, similar curves with the vertical coordinate 0.4 times and twice that of ε_{DA}=5%, respectively, are drawn in the chart. The curves seem to be compatible with the plots, because ε_{DA} is almost in proportion to the normalized energy $\Delta W/\sigma'_c$ up to around ε_{DA} = 10% as indicated in Fig. 3.

Because the relationship between R_{L20} and corresponding dissipated energy $\Delta W/\sigma'_c$ in Fig. 5 holds uniquely for sands with various densities and fines content, it may also be applicable to natural sands with different soil fabrics such as those reflecting long geological histories. This indicates that relationships between the cyclic resistance ratio R_{L20} and SPT N-value already established and practically used in SBM, may be transformed into a direct energy versus N-value correlation to be used in EBM.

Based on the research results combining undrained cyclic triaxial tests on intact samples recovered by in situ freezing technique and associated in situ SPT logging (Matsuo 1997), the following empirical formula giving R_L (ε_{DA}=5%) from normalized SPT blow counts N_1 was proposed for clean sand (F_c<10%) (Japan Road Association 2002).

$$R_L = \begin{cases} 0.0882\sqrt{N_1/1.7} & : N_1 < 14 \\ 0.0882\sqrt{N_1/1.7} + 1.6\times10^{-6}(N_1 - 14)^{4.5} & : 14 \leq N_1 \end{cases} \qquad (4)$$

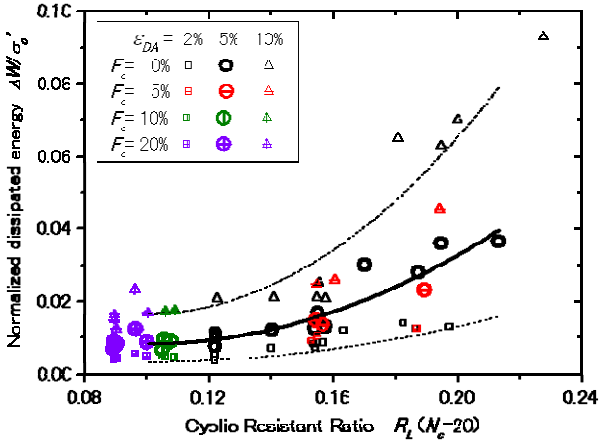

Figure 5 Normalized dissipated energy versus cyclic resistance ratio for ε_{DA}=2, 5, 10% for sand specimens with different fines content.

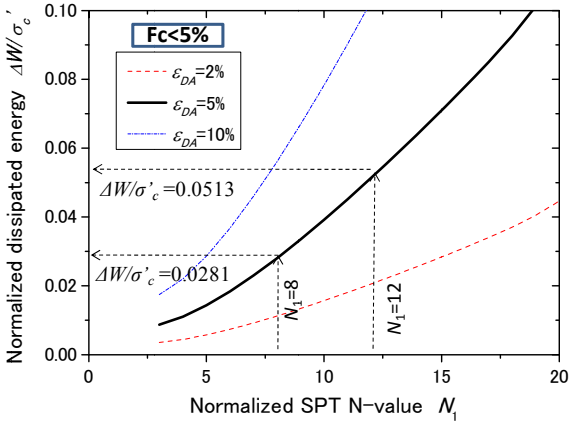

Figure 6 Direct relationship between normalized N-value (N_1) and Normalized dissipated energy $\Delta W/\sigma'_c$ for clean sand of F_c<5%.

Here, the value N_1 is calculated from SPT N-value and effective overburden stress σ'_v in the next equation (p_0=98 kPa).

$$N_1 = 1.7N/(\sigma'_v/p_0 + 0.7) \quad (5)$$

Fig. 6 shows a direct relationship between N_1 and $\Delta W/\sigma'_c$ thus developed using Eqs. (3) and (4). The curves are drawn not only for ε_{DA}=5% (normally considered as the onset of liquefaction) but also for ε_{DA}=2% and 10% by assuming the proportionality between ε_{DA} and $\Delta W/\sigma'_c$. Other relationships may readily be obtained if site-specific R_L versus N_1 curves other than that in Eq. (4) considering various effects (such as fines content, aging, and over-consolidation) is combined with the R_{L20} versus $\Delta W/\sigma'_c$ correlation in Fig. 5.

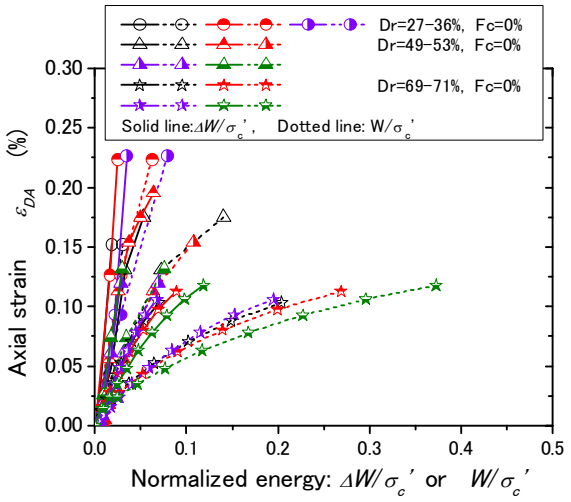

Figure 7 Relationships between normalized dissipated energy $\Delta W/\sigma'_c$ or normalized strain energy W/σ'_c versus axial strain obtained in the triaxial tests.

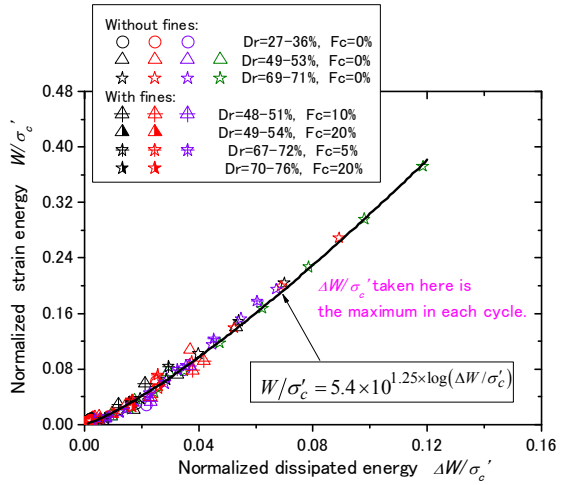

Figure. 8 Relationship between normalized dissipated energy $\Delta W/\sigma'_c$ versus normalized strain energy W/σ'_c for all triaxial test results.

In order to compare the dissipated energy with the wave energy in the field, it is necessary to know how much wave energy is needed for a certain amount of energy ΔW to be dissipated inside the soil for liquefaction. The wave energy may well be replaced by strain energy in laboratory tests. Hence, the strain energy W was evaluated together with the dissipated energy ΔW in the same triaxial test series already explained.

The strain energy per cycle in the triaxial test is defined as 4 times the area of a triangle OBB' illustrated in Fig.2, and the strain energy accumulated up to a certain cycle k is calculated as

$$W = \sum_k 4\left(\mathrm{OB'} \times \mathrm{BB'}/2\right)_k \quad (6)$$

In Fig. 7, strain energies defined in Eq.(6) and normalized by the effective confining stress as W/σ'_c is plotted versus axial strain and compared with corresponding normalized dissipated energy, $\Delta W/\sigma'_c$, of the same symbols for all the test results of clean sands (F_c=0%). Energies represented by symbols connected with dashed lines (W/σ'_c) are obviously larger than those by the same symbols connected with solid lines ($\Delta W/\sigma'_c$), and the ratio of the two energies seems to be almost constant despite large differences in the energy values.

In Fig. 8, the normalized strain energies W/σ'_c in the vertical axis directly compare with the normalized dissipated energies $\Delta W/\sigma'_c$ in the horizontal axis not only for clean sands but also for sands containing fines. Though the two energies are not proportional, it is remarkable that W/σ'_c and $\Delta W/\sigma'_c$ are uniquely correlated for sands with largely different relative densities and fines contents. This also indicates that the dissipated energy in sand in the liquefaction process is uniquely correlated to the energy given from outside regardless of the cyclic stress amplitude and the number of cycles. An empirical formula is obtained as

$$W/\sigma'_c = 5.4\times10^{1.25\times\log(\Delta W/\sigma'_c)} \quad (7)$$

and superposed on the plots in Fig. 8. This equation may presumably be applicable even to irregular cyclic stresses for in situ liquefaction evaluation to determine threshold seismic wave energy per unit volume for liquefaction.

3. UPWARD SEISMIC WAVE ENERGY EVALUATION

In order to evaluate a liquefaction potential based on the energy-based method, it is necessary to compare the threshold energy for liquefaction given by Eq. (7) with seismic wave energy coming upward at a site during design earthquakes. There may be two methods, (a) and (b), to determine the upward seismic energy.

In the first method (a), seismic energy can be estimated by a simple formula assuming spherical energy radiation of body waves from a source (a causative fault) as

$$E_{IP} = E_{Total} \Big/ \left(4\pi R^2\right) \tag{8}$$

where, E_{IP} is incident energy at a site per unit area (kJ/m^2), R is a distance (m) from a center of energy release. A total energy E_{Total} (kJ) in Eq. (8) to radiate from the center is calculated from an earthquake magnitude M (Gutenberg 1956) as;

$$\log E_{Total} = 1.5M + 1.8 \tag{9}$$

In the energy-based evaluation method proposed by Davis & Berrill (1982), the dissipated energy in liquefiable sand was directly correlated with seismic energy arriving at a site calculated by essentially the same formulas as Eqs. (8) and (9). In their method, however, it was not addressed at which depth the incident energy is given by the equations, or how it transmits upward from deep bedrock to liquefiable sand layer. Instead, the seismic energy thus evaluated was directly compared with liquefaction case histories to empirically draw a boundary separating plots of liquefied and non-liquefied sites on a SPT N-value versus energy charts (Berrill and Davis 1985).

Using vertical array records, Kokusho and Suzuki (2011, 2012) has demonstrated that the upward wave energy E_u starting from a base layer tends to decrease drastically with decreasing ground depth in most sites and the decreasing trend is almost in proportion to the power of 0.70 of the seismic impedance ratio between corresponding soil layers such as;

$$\beta = \alpha^{0.7}: \quad \alpha < 1, \quad \beta = 1.0: \quad \alpha \geq 1 \tag{10}$$

Here, values $\alpha = \left(\rho V_s\right)_i \Big/ \left(\rho V_s\right)_j$ and $\beta = E_{u_i} \Big/ E_{u_j}$ stand for impedance ratio (ρV_s = impedance) and upward energy ratio, respectively, between an upper layer i and a lower layer j at arbitrary levels. Thus the upward energy E_u at a layer shallower than the base layer may be determined from incident energy at the base E_{IP} and the impedance ratio α with respect to the base layer.

In the second method (b), if a site-specific design motion is available, the seismic energy can be evaluated from it based on the multiple reflection theory of SH wave. It is well known that upward and downward SH waves at arbitrary levels can be evaluated from a record at any level (e.g. Schnabel et al. 1972), provided that the soil profile is known and approximated to behave as linear or equivalent linear materials. The upward energy supplied to a liquefiable layer can be calculated from particle velocity of SH wave propagating upward $\dot{u}$ for a time interval, $t = 0 \sim t_1$ (Kokusho and Motoyama 2002) , as

$$E_u = \rho V_s \int_0^t \left(\dot{u}\right)^2 dt \tag{11}$$

In the present paper, the second method using the one-dimensional dynamic response analysis will be employed, assuming the soils behave as equivalent linear materials. In SBM, input earthquake motions are normally defined at a ground surface. In order to compare the results of EBM with the conventional SBM, the input motion is given at a ground surface in the equivalent linear analysis to calculate not only maximum shear stresses for SBM but also upward wave energies for EBM.

In the equivalent linear analysis, a strain-dependent damping ratio D iteratively decided is used in computing dynamic soil response. This indicates that the strain energy W to be evaluated in Eq. (7) can also be determined from ΔW by using the damping ratio D as

$$W/\sigma_c' = \left(\Delta W/\sigma_c'\right)/\left(\pi D\right) \tag{12}$$

This appears to be more consistent with the analysis. Unlike Eq. (7), however, Eq. (12), using hysteretic damping ratio D measured in normal cyclic loading tests for a small to medium strain range, may not properly reflect the energy dissipation on the process to liquefaction. Therefore, Eq. (7) is used in this paper for the strain energy evaluation in liquefying soils.

4. STUDY ON HYPOTHETICAL SAND DEPOSIT

A comparative study is undertaken here in which EBM is applied to a hypothetical site to compare with SBM. A level sand deposit 10 m thick underlain by a stiff base shown in Fig. 9 is considered. The sand is divided into 5 layers, 2 m thick each, numbered 1 to 5 from the top. The top 2 m (L1) is unsaturated with the density ρ_t =1.8 t/m^3 and the lower 8 m (L2 to L5) are saturated with ρ_{sat} =1.9 t/m^3. In Model-A, the sand is uniform with the normalized SPT N-value N_1=8. In Model-B, N_1=8 in the upper three layers (L1 to L3) and N_1=12 in the lower two layers (L4, L5). The corresponding S-wave velocity V_s (m/s) is determined from N-value, calculated from N_1 in Eq. (5), using the next equation (Japan Road Association 2002).

$$V_s = 80N^{1/3} \tag{13}$$

S-wave velocity of each layer is assigned at its middle depth to give V_s-distributions shown in Fig. 9 for the one-dimensional dynamic response analysis.

In order to make an equivalent linear analysis of the hypothetical ground, strain-dependency of shear modulus ratio G/G_0 and damping ratio D for the sand layer are given by the next equations.

$$G/G_0 = \frac{1}{1 + \left(\gamma/\gamma_r\right)^{\alpha}} \tag{14}$$

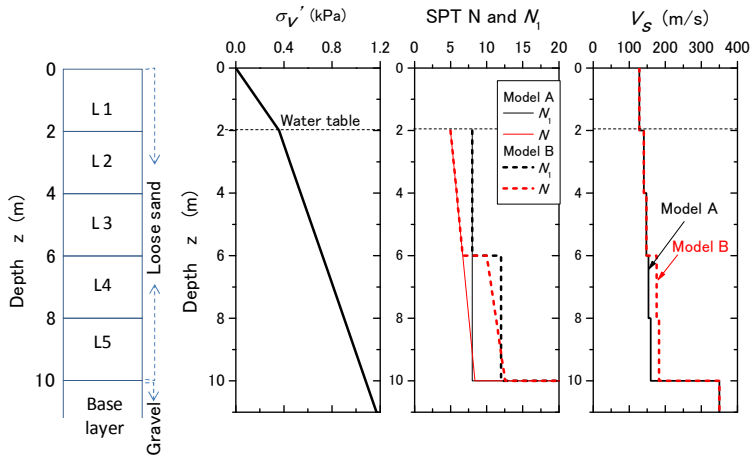

Figure 9 Hypothetical soil models A & B of 10 m thick loose sand underlain by a base layer

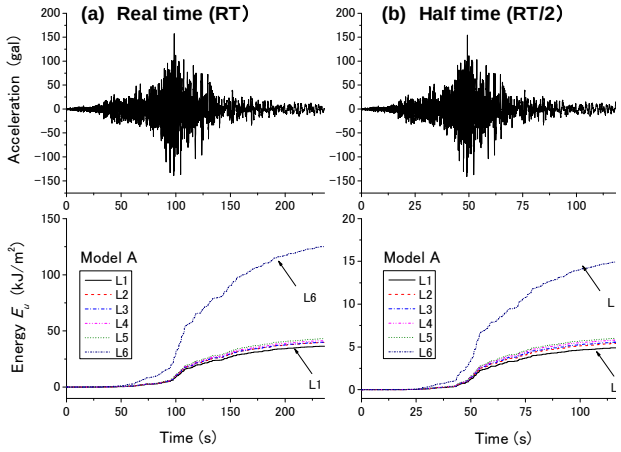

Figure 10 Input acceleration motions at ground surface at K-net Urayasu for the main shock during 2011 Tohoku earthquake (M=9.0) and corresponding upward energies for Real time (RT)(a) and Compressed half-time (RT/2) (b).

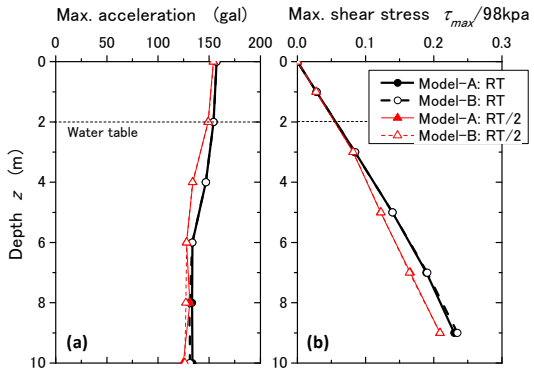

Figure 11 Maximum acceleration (a) and maximum shear stress (b) in the soil models A & B calculated along the depth.

$$\frac{D-D_0}{D_{\max}-D_0}=\left(1-\frac{G}{G_0}\right)^{\beta} \tag{15}$$

These equations are modified versions of the original formulas by Hardin-Drnevich (1972), by introducing power constants α, β as well as initial and maximum damping ratios, D_0 and $D_{\max}$, respectively, to have better fitting with measured data (Kokusho and Motoyama 1998). The reference strain γ_r in Eq. (14) corresponding to modulus degradation $G/G_0 = 0.5$ is proportional to the square root of the effective mean stress σ'_m (Hardin-Drnevich 1972).

A horizontal ground motion obtained during 2011 Tohoku earthquake (M_w=9.0) at a strong motion station, K-net Urayasu (EW direction), shown in the top of Figs. 10 (a) and (b) is given at a surface of the model ground to conduct a 1D equivalent linear analysis using SHAKE (Schnabel et al. 1972). The duration of the motion used in the analysis is 236 s, which covers from P-wave arrival to the end of major contribution of SH-wave. This motion is given either in the real time scale RT (a) with digitized time increment Δt =10 ms (duration 236 s) or in a compressed half time scale RT/2 (b) with Δt =5 ms (duration 118 s). Maximum accelerations and shear stresses along the depth obtained in the analyses for RT and RT/2 in Models-A and B are shown in Fig. 11 (a) and (b), respectively. Both the accelerations and stresses are almost identical in the two models, and slightly smaller for the compressed half time scale (RT/2) than for the real time scale (RT).

4.1 Stress-Based Method (SBM)

In a normal SBM, liquefaction is to occur if a factor F_L expressed in Eq. (16) is lower than unity.

$$F_L = R/L \tag{16}$$

Here in situ cyclic resistance ratio R is determined from R_L corresponding to isotropically consolidated triaxial test specimens as

$$R = R_L\left(1+2K_0\right)/3 \tag{17}$$

using in situ earth-pressure coefficient at rest K_0. Seismically induced cyclic stress ratio L at a certain depth is ob-

tained from the maximum seismic stress ratio $L_{\max} = \tau_{\max}/\sigma'_v$ as

$$L = r_n L_{\max} = r_n \tau_{\max}/\sigma'_v = \tau_0/\sigma'_v \tag{18}$$

The equivalent amplitude of cyclic stress τ_0 is determined by multiplying the maximum stress $\tau_{\max}$ by a constant r_n, where r_n is a reduction coefficient of stresses, $\tau_0 = r_n \tau_{\max}$, to replace a irregular motions with the maximum stress $\tau_{\max}$ to an equivalent sinusoidal motions with a given number of cycles of stress amplitude τ_0 (Seed and Idriss 1971). Here, the stress reduction coefficient r_n is given in the next empirical formula using an earthquake magnitude M proposed by Tokimatsu and Yoshimi (1983).

$$r_n = 0.1(M-1) \tag{19}$$

M=7.5 in Eq. (19) gives r_n =0.65 and if K_0=0.5 is assumed, then the factor F_L becomes as follows.

$$F_L = R/L = \frac{1+2K_0}{3r_n}\frac{R_L}{L_{\max}} \approx R_L/L_{\max} \tag{20}$$

However, if the earthquake magnitude of the 2011 Tohoku earthquake, M=9.0, is considered in lieu of M=7.5, r_n =0.80 in Eq. (19). If K_0=0.5 is used again, then

$$F_L = R/L \approx R_L/1.2L_{\max} \tag{21}$$

In Fig. 12, the R_L-values compare with L_{max} (r_u=0.65) or $1.2L_{max}$ (r_u=0.80) in (a) Model-A and (b) Model-B to evaluate liquefaction potential for RT and RT/2-motions. In Fig. 13, the F_L-value thus evaluated in Eq. (20) or Eq. (21) is illustrated along the depth for the two models.

In Model-A, the cyclic resistance ratio R_L is 0.191 constant in the uniform sand layer with N_1=8 from Eq. (4). For the RT-motion, if the R_L-value is compared in Eq. (20) with the maximum seismic stress ratios L_{max} for r_u=0.65 (M=7.5), F_L≈1.0 in L2 and F_L<1.0 in L3 to L5. If R_L is compared in Eq. (21) with 1.2 L_{max} for r_u=0.80 (M=9.0), F_L becomes still lower and F_L<1.0 in L2 to L5, hence all the saturated sand layers are to liquefy. For the RT/2-motion, though F_L-values become slightly higher, the results are not so much different from the RT-motion. It is noted that, in the uniform soil model (Model-A), the deeper the layer, the lower its F_L-value and the higher its liquefaction potential for both RT and RT/2-motions.

In Model-B, R_L is 0.191 and 0.234 in the upper and lower two layers with N_1=8 and 12, respectively, according to Fig. 8. For the RT-motion, if L_{max} for r_u=0.65 (M=7.5) is compared in Eq. (20) with the R_L-value, F_L<1.0 in L3 and F_L≈1.0 in other layers, indicating that only L3 is to liquefy obviously. If r_u=0.80 (M=9.0) is chosen, then F_L<1.0 in Eq. (21) for all the saturated sand (L2-L5) including the lower layers with higher N_1-values. If the RT/2-motion is considered, F_L≈1.0 for L3 and F_L >1.0 for other layers if r_u=0.65 (M=7.5) is chosen, whereas F_L<1.0 again for r_u=0.80 (M=9.0) similar to the RT-motion.

The above results in SBM may be summarized that the choice of r_u=0.65 or r_u=0.80 tends to have a great effect on the F_L-value, while the difference of input motions, RT or RT/2, seems to have a smaller effect, despite a considerable difference of energy in the two motions as will be mentioned later. It is also pointed out that liquefaction potential tends to be higher in deeper layers than shallower layers in a uniform sand deposit.

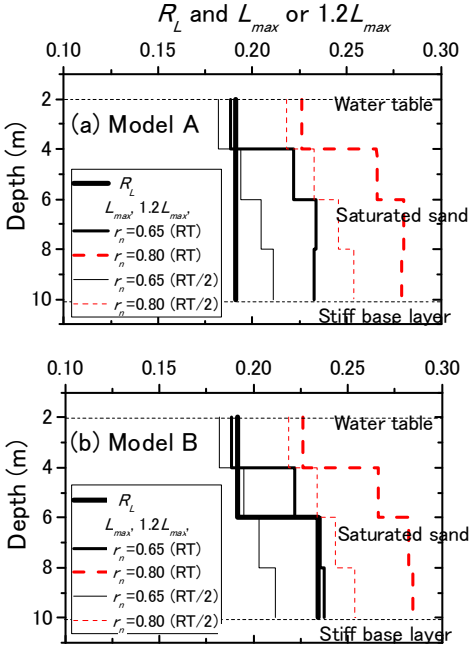

Figure 12 Depth-dependent R_L-profiles compared with L_{max}-profiles for RT & RT/2-motions: (a) Model-A & (b)Model-B

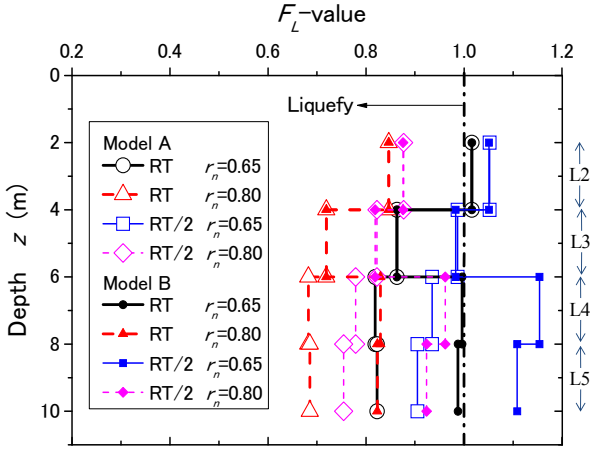

Figure 13 Depth-dependent F_L-profiles in Models-A & B for RT & RT/2-motions obtained by SBM.

4.2 Energy-Based Method (EBM)

Based on the same one-dimensional equivalent linear analyses using the same input motion, upward energies at the top of layers of 2 m thick each were calculated in Models-A and B using Eq. (11). At the bottom of Fig. 10, typical time-histories of upward energies E_u are shown together with the acceleration time histories at the top, for (a) the real time motion (RT), and (b) the compressed half time motion (RT/2), respectively. The energies E_u are not so much different in the sand layers (L1 to L5) after experiencing remarkable reduction at the boundary between the stiff base layer and the loose sand layer. Also note that the energy dramatically decreases if the time scale of the input acceleration is halved (RT/2), because, for the same absolute acceleration $\ddot{u}$, the particle velocity $\dot{u}$ and $(\dot{u})^2$ becomes 1/2 and 1/4 smaller, respectively, and the energy calculated by Eq. (11) for the time duration a half of RT becomes $(1/2)^3$=1/8 smaller. The final accumulated upward energy in each layer at the end of shaking denoted here as E_{uf} will be used in EBM.

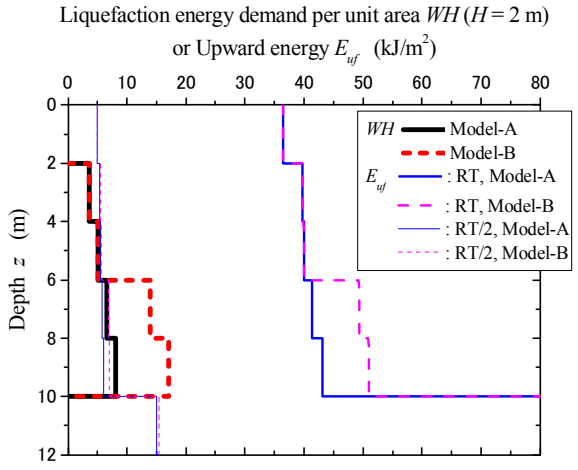

Figure14 Liquefaction energy demand WH compared with Upward energy E_{uf} along the depth in Models-A & B for RT & RT/2-motions

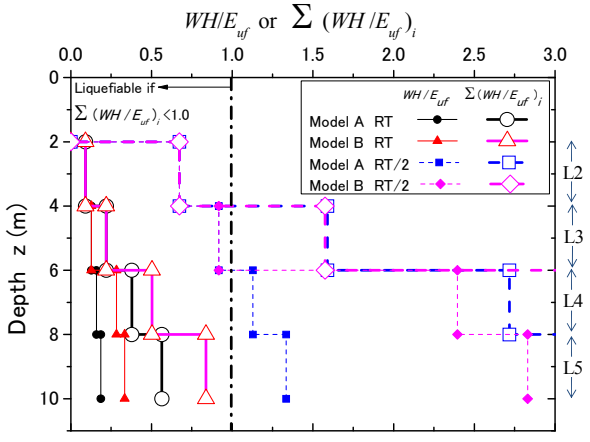

Figure15 Energy ratio WH/E_{uf} or accumulated energy ratio $\Sigma(WH/E_{uf})_i$ along the depth obtained by EBM in Models-A & B for RT & RT/2-motions.

The EBM procedure proposed in this paper to compare with SBM generally consists of following steps.

a) A soil model is divided into layers of a constant thickness H (H=2 m in this paper) in accordance with penetration test data of the same depth interval. The normalized dissipated energy $\Delta W/\sigma_c'$ for a soil of unit volume to liquefy is determined for each layer from penetration test results, using a relationship such as in Fig. 6. For the onset of liquefaction, $\Delta W/\sigma_c'$ corresponding to double amplitude axial strain ε_{DA}=5% in triaxial test data is chosen.

b) The normalized strain energy W/σ_c' given from outside corresponding to $\Delta W/\sigma_c'$ per unit volume of soil to liquefy is evaluated by Eq. (7).

c) Then the strain energy for a layer with a thickness H to liquefy WH (named here as liquefaction energy demand) is calculated. Here, the effective confining stress σ_c' is assumed to be equal to an average mean effective stress in the layer, $\sigma_m' = (1+2K_0)\sigma_v'/3$.

d) Upward energy E_u is calculated at each layer using an equivalent linear one-dimensional wave propagation analysis of a horizontally-layered soil model and the energy at the end of shaking E_{uf} is evaluated.

e) The liquefaction energy demand WH is directly compared with the upward energy E_{uf} in the corresponding layer by calculating an energy ratio WH/E_{uf}. It may well be interpreted that a layer with a smaller energy ratio WH/E_{uf} has higher liquefaction potential than others in a soil profile.

f) The energy ratios of individual layers are numbered sequentially starting from the lowest ratio (i=1) toward higher ones and summed up as $\Sigma\left(WH/E_{uf}\right)_i$.

g) Liquefaction occurs in that sequence and in those layers for which $\Sigma\left(WH/E_{uf}\right)_i$ <1.0, because the upward energy can liquefy individual sand layers in the above-mentioned sequence until it is totally consumed by the energy demands.

In Model-A, the normalized dissipated energy per unit volume to liquefy the uniform sand layer of N_1=8 can be read off from the curve in Fig. 6 corresponding to ε_{DA}=5% as $\Delta W/\sigma_c'$ =0.0281. Then, the corresponding normalized strain energy per unit volume is given as W/σ_c' = 0.0621 from Eq. (7). The liquefaction energy demand WH for H=2 m thick layer to liquefy is calculated using the corresponding average confining stress $\sigma_c' = \sigma_v'(1+2K_0)/3$, assuming the earth-pressure coefficient at rest K_0 is 0.5. In Fig. 14, the liquefaction energy demands WH (thick lines) are shown together with the upward energies E_{uf} along the depth for Models-A and B. As already mentioned, E_{uf} is quite different between the two input motions, RT (thin line) and RT/2 (very thin line).

In Fig. 15, the energy ratios WH/E_{uf} calculated in individual layers is shown along the depth with thin lines plus smaller symbols for Models-A and B. Because the energy ratio WH/E_{uf} is obviously smaller for layers with shallower depths both for RT and RT/2 motions even in the uniform sand deposit (Model-A), liquefaction tends to occur first in L2 and descend in sequence to the deeper layers. The thick

lines with larger symbols in the same figure are the accumulated energy ratio $\Sigma\left(WH/E_{uf}\right)_i$ calculated in the EBM procedure (f) explained above. For the RT-motion shown by thick solid lines, $\sum\left(WH/E_{uf}\right)_i$ <1.0 for the summation from L2 to L5, indicating that the upward energy is enough to liquefy all the saturated sand layers not only in Model-A but also in Model-B. In contrast, for the RT/2-motion shown by thick dashed lines, $\Sigma\left(WH/E_{uf}\right)_i$ <1.0 only for L2 (the shallowest saturated layer), indicating the upward energy is not enough to liquefy other than L2 in the two models. Thus, there exists a clear difference in liquefaction potential between the two input motions, reflecting the tremendous energy reduction in the RT/2-motion as mentioned before.

4.3 Comparison of EBM and SBM

If the results by EBM in Fig. 15 are compared with those by SBM in Fig. 16, the following observations may be made. First, the two results both in Model-A and B appear to be essentially consistent in that all the saturated sand layers are to liquefy by the RT-motion. This consistency gets better if the stress reduction coefficient in Eq. (19) is taken as r_n =0.80 considering the M=9.0 earthquake in SBM. If r_n=0.65 is used as in normal practice considering a smaller magnitude earthquake, the two results disagree partially, because L2 is hard to liquefy in SBM. In EBM, the effect of input motions due to different earthquake magnitude, which has to be considered by choosing the coefficient r_n properly in SBM, is intrinsically included.

The effect of the compressed half-time scale motion (RT/2) is far more evident in EBM because the upward energy E_u reduces to 1/8 of the RT-motion. The reduced upward energy is sufficient to liquefy only L2 both in Model-A and B in EBM. In contrast, the effect is minor in SBM with about 10% change in the seismic stress $\tau_{\max}$ and F_L as well, as indicated in Figs. 11 and 13, respectively. In Models-A and B, all the layers (L2 to L5) are to liquefy if r_n=0.80 is chosen, quite contradictory to the results of EBM. If r_n=0.65 is chosen considering that the RT/2-motion should represent an earthquake magnitude lower than 9.0 because of its shorter duration, only L2 are not to liquefy in Model-A and only L3 is on the verge of liquefaction in Model-B, which are contradictory more or less with EBM, again.

Another significant qualitative difference between the two methods is that liquefaction potential is higher in shallower layers than in deeper layers in a uniform sand deposit (Model-A) in EBM as shown in Fig. 15, whereas it is vice versa as indicated in Fig. 13 in SBM. In shake table liquefaction tests on uniform saturated sand, it is normally observed that liquefaction first starts near the ground surface and then moves down to deeper portion as shaking continues (e.g. Kokusho et al. 1980). This seems to indicate a higher liquefaction potential in shallower depth if sand is essentially uniform as obtained in the EBM evaluation, though more detailed study is needed considering the effects of various soil conditions and input motions.

Thus, a basic procedure of EBM has been developed and applied to soil models to compare with SBM. Further studies on its applicability to case histories with detailed soil investigations and seismic motions are certainly needed to show its reliability in actual site conditions.

5. CONCLUSIONS

In order to develop an energy-based method (EBM) for liquefaction potential evaluation, a series of undrained cyclic triaxial test data was examined from a viewpoint of energy, yielding following major findings;

1) Dissipated energy per unit volume accumulated to a given cycle, ΔW, is almost uniquely correlated with pore-pressure buildup $\Delta u/\sigma_c'$. The ΔW-value is almost proportional to axial strain for each relative density group up to a strain around $\varepsilon_{DA} \approx 10\%$.
2) The ΔW-value thus evaluated is quite insensitive to the number of load cycles N_c to induce a given strain under different cyclic stress ratio R_L, indicating that a R_L-N_c correlation addressed in the stress-based method (SBM) can be interpreted as an equal-energy line.
3) The ΔW-value may be uniquely correlated with a cyclic resistance ratio such as R_{L20} for N_c=20, irrespective of different fines content and soil fabrics. It paves a way to develop a direct relationship between ΔW and N_1 for EBM using a R_L -N_1 curve already available in SBM.
4) The ΔW-value is closely connected with associated strain energy W accumulated to a given cycle in the same soil test data. A correlation between ΔW and W is almost unique despite differences in relative density and fines content, and formulated as Eq. (7).
5) If a soil profile of a site is divided into layers of equal thickness H, the energy demand for each layer to liquefy is expressed as WH using the strain energy W corresponding to the onset of liquefaction. The WH-value thus obtained can be directly compared with upward seismic energy to evaluate liquefaction potential by EBM in the field.

Then, the liquefaction potential of sand deposit of 10 m thick (Model-A: uniform loose sand of N_1=8 and Model-B: loose sand of N_1=8 underlain by sand of N_1=12) was evaluated by EBM to compare with a conventional SBM. An input motion of a M=9.0 earthquake has been given at the ground surface in a real time scale (RT) or a compressed half-time scale (RT/2) to have following major findings.

6) The upward energy of RT-motion is enough to liquefy all the saturated sand layers not only in Model-A but also in Model-B. This evaluation by EBM is apparently consistent with that by SBM using the stress reduction coefficient r_n= 0.80 considering the M=9.0 earthquake. The effect of input motions of larger magnitudes is intrinsically included in the EBM, whereas it has to be considered by choosing proper coefficient r_n in SBM.
7) The effect of the compressed half-time scale motion (RT/2) is far more evident in EBM because the upward energy E_u reduces to 1/8 of the RT-motion. The re-

duced energy is not sufficient to liquefy more than L2 both in Model-A and B in EBM. In contrast, the effect is minor in SBM with only about 10% reduction in seismic shear stress, so that all the layers (L2 to L4) are still to liquefy if r_n=0.80 is chosen, and only L2 is unlikely to liquefy if r_n=0.65 is chosen in Model-A, more or less contradictory to EBM again.

8) A significant qualitative difference is recognized between the two methods that the liquefaction potential is higher in shallower layers than in deeper layers in a uniform sand deposit in EBM whereas it is vice versa in SBM. Observations in previous shake table tests on uniform soil models seem to be more compatible with the evaluation in EBM than SBM.

Thus, EBM seems to highlight some significant aspects of liquefaction potential evaluation from the viewpoint of energy demand versus energy supply, which may not be sufficiently taken into account by SBM. As already demonstrated, dissipated energy can be a good unique parameter to evaluate the pore-pressure buildup and induced strain. The key of the energy-based liquefaction evaluation is how to properly determine the upward energy to compare with the energy demand. In this paper, the upward seismic energy was calculated from one-dimensional dynamic soil response analyses, although it may also be determined in a more simple way from earthquake magnitude, a distance from earthquake energy source and site-specific seismic impedance ratios. More research on actual case histories is needed to improve the energy approach to be more reliable and applicable in actual engineering design.

Acknowledgments

Ex-graduate students Ryo Kato, Fumiki Ito and Yohta Nagao of Civil Engineering Department in Chuo University for past several years who conducted laboratory soil tests and data reduction in terms of energy for this research are appreciated. NIED, Tsukuba Japan, who disseminated valuable K-net data during the 2011 Tohoku earthquake Japan, is gratefully acknowledged. Scholars, Liam Finn, Peter Byrne, Ernest Naesgaard and Russell Green, with whom the present author discussed on how to compare the energies in EBM are also appreciated.

NUMBER OF EQUIVALENT CYCLIC SHEAR AND EFFECTIVE DURATION FOR SOIL LIQUEFACTION IN TOKYO BAY AREA DURING THE 2011 GREAT EAST JAPAN EARTHQUAKE

Hiroshi Arai[1)]

1) Senior Researcher, Building Dept., National Institute for Land and Infrastructure Management, MLIT, Japan
arai-h92ta@nilim.go.jp

Abstract: Number of equivalent cyclic shear N_{eq} and effective duration t_d for soil liquefaction at two sites in Tokyo bay area are estimated by using one-dimensional effective stress analyses for the 2011 Great East Japan earthquake (M_w = 9.0). Also estimated are those at liquefied and non-liquefied sites for the past earthquakes. On the basis of the estimated results and discussions on their relationships with earthquake magnitude M referring to the previous studies, the following conclusions are made: 1) The N_{eq} and t_d estimated in Tokyo bay area during the 2011 earthquake are about 20-60 and about 25 s, respectively, which might be about 2-6 times larger than those at the liquefied and non-liquefied sites during the past earthquakes. 2) The N_{eq} and t_d values could roughly be predicted for a huge earthquake with magnitude M > 8 by extrapolation of the existing M-N_{eq} and M-t_d relations for the past earthquakes with magnitude M < 8, respectively, those were empirically proposed in the previous studies.

1. INTRODUCTION

During the 2011 Great East Japan earthquake (M_w = 9.0), about 15000 residential houses were significantly settled and/or tilted with either no or slightly damage to their superstructures due to soil liquefaction in Tokyo bay area, where are located about 300-400 km away from the epicenter of the main shock (Ministry of Land, Infrastructure, Transport and Tourism, 2011). In the area, strong ground motions were recorded at a number of observatories during the main shock and aftershocks. The peak horizontal ground accelerations of the main shock were no more than 1.5-2.5 m/s^2 in the area, however, the whole durations of the ground motion records were over 2-3 minutes because of the huge earthquake magnitude.

Many reports have suggested that one of the causes for soil liquefaction in Tokyo bay area during the 2011 earthquake could mainly be due to the long durations of the ground motions during the main shock and subsequent aftershock (e.g., Architectural Institute of Japan, 2011; Tokimatsu *et al*., 2012). To verify that suggestion quantitatively, the number of equivalent cyclic shear N_{eq} and the effective duration t_d for soil liquefaction should properly be evaluated in the area during the main shock. The N_{eq} and t_d are the key parameters to control whether the liquefaction could occur or not in sandy soils at a site during earthquakes (e.g., Tokimatsu and Yoshimi, 1980; Seed *et al*., 1983).

The objectives of this article are to estimate the number of equivalent cyclic shear N_{eq} and the effective duration t_d for soil liquefaction in Tokyo bay area during the 2011 Great East Japan earthquake, and to examine their relationships with the earthquake magnitude M.

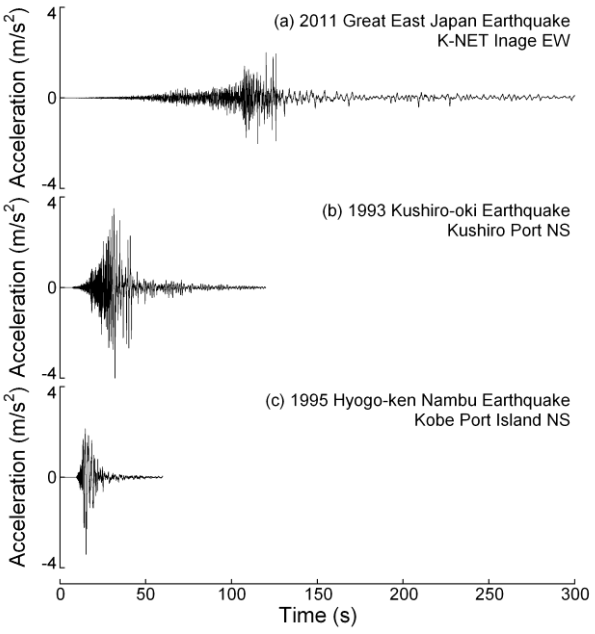

Figure 1 Typical strong ground motion records at liquefied sites in Japan

2. CHARACTERISTICS OF STRONG GROUND MOTIONS IN TOKYO BAY AREA DURING THE 2011 EARTHQUAKE

Figure 1(a) illustrates the acceleration time history of horizontal ground motions recorded at K-NET Inage station located in Tokyo bay area (National Research Institute for

Earth Science and Disaster Prevention, 2011), where sand boil and fountain were observed on ground surface during the main shock and subsequent aftershock. Also shown below the figure (as Figures 1(b) and 1(c)) are typical ones recorded at the liquefied zones in Kushiro and Kobe cities during the 1993 Kushiro-oki and the 1995 Hyogo-ken Nambu earthquakes, respectively (Iai *et al*., 1995; Architectural Institute of Japan, 1995). From the figures, it is revealed that the duration of strong ground motions in Tokyo bay area during the 2011 earthquake is much longer than those at the liquefied zones during the past earthquakes.

In Figure 1(a), the spiky acceleration waveforms are observed at a time of 120-130 s during the main shock. This might be caused due to cyclic mobility of sandy soils in K-NET Inage site. At that time, furthermore, the amplitude and predominant period of acceleration time history change drastically, suggesting that soil liquefaction could have been induced in sandy layers of the site.

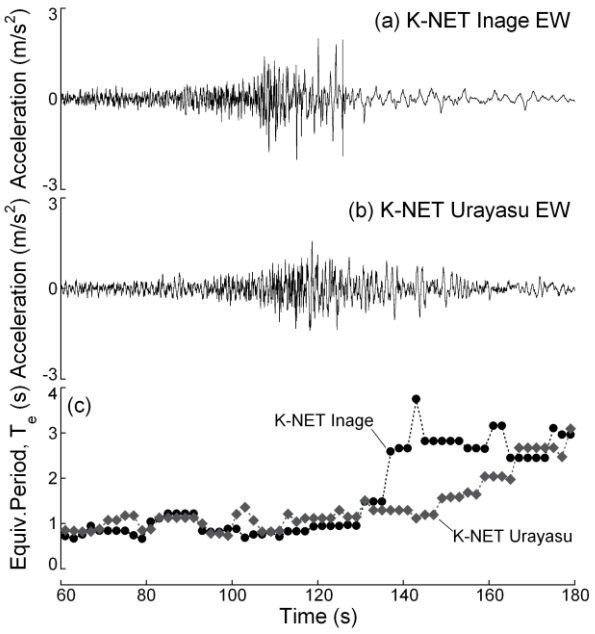

Figure 2 Time histories of acceleration and equivalent predominant period of horizontal ground motions at K-NET Inage and Urayasu stations during the 2011 earthquake

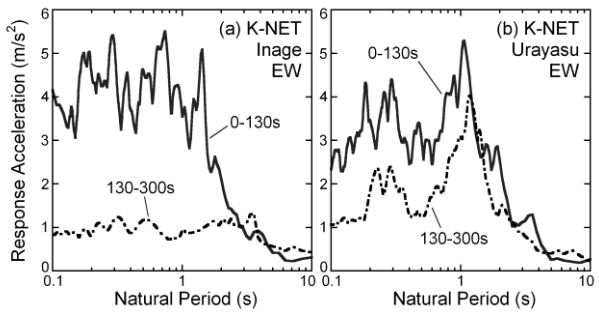

Figure 3 Acceleration response spectra with damping factor of 5 % for horizontal ground motions at K-NET Inage and Urayasu stations during the 2011 earthquake

Figures 2(a) and 2(b) indicate the acceleration time histories of horizontal ground motions recorded at K-NET Inage and Urayasu sites where were liquefied and not, respectively, in Tokyo bay area during the main shock and subsequent aftershock. From the figures, it is again suggested that the horizontal acceleration waveforms on ground could significantly change due to soil liquefaction. The equivalent predominant period at a time t, $T_e(t)$, of the horizontal ground motions recorded for the sites during the main shock are then computed through Eq. (1):

$$T_e(t) = 2\pi \frac{\max\left|v\left(\left|\tau - t\right| < T_w/2\right)\right|}{\max\left|a\left(\left|\tau - t\right| < T_w/2\right)\right|} \qquad (1)$$

in which T_w is the length of time window (= 5 s), $a(t)$ and $v(t)$ are the acceleration and velocity time histories of horizontal ground motions, respectively. In this study, $v(t)$ is determined from $a(t)$ by using the Fast Fourier Transformation (FFT) method.

The computed equivalent predominant period $T_e(t)$ at K-NET Inage and Urayasu sites during the main shock are shown in Figure 2(c). From the figure, $T_e(t)$ at the both sites vary from 1 to 3 s in a duration of 60-180 s, however, their variations with time are not similar. $T_e(t)$ for K-NET Inage site changes drastically at a time of 130-140 s, while that for Urayasu does gradually in the whole duration. Compared among Figures 2(a)-(c), this could be caused due to soil liquefaction occurred in K-NET Inage site (Architectural Institute of Japan, 2011; Tokimatsu *et al*., 2012).

The acceleration response spectra with damping factor of 5 % for horizontal ground motions in durations of 0-130 and 130-300 s are, furthermore, calculated at the both stations for the main shock, and are shown in Figure 3. In the figure, it is again confirmed that the strong ground motion characteristics could have changed drastically at a time of about 130 s in K-NET Inage site because of soil liquefaction.

3. NUMERICAL SIMULATIONS OF DOWNHOLE ARRAY RECORDINGS TO ESTIMATE SHEAR STRESS TIME HISTORIES IN TOKYO BAY AREA

To evaluate the number of equivalent cyclic shear and the effective duration for soil liquefaction at a site during an earthquake, the shear stress time histories of sandy soils at the site should properly be determined for the earthquake, for example, based on a nonlinear dynamic response analysis. In Tokyo bay area, the downhole array recordings during the main shock are available at two sites: Chiba port and Yumenoshima strong ground motion stations (Port and Airport Research Institute, 2011; Bureau of Port and Harbor, Tokyo Metropolitan Government, 2011). At the both sites, the PS velocity logging data and the results of in-situ laboratory tests on nonlinear dynamic properties including liquefaction for undisturbed soil samples are also disclosed (Chiba Port Office, Ministry of Transport, 1997; Ishihara *et al*., 1989). During the main shock and aftershocks, remarks of soil liquefaction, e.g., sand boil, fountain, ground lateral

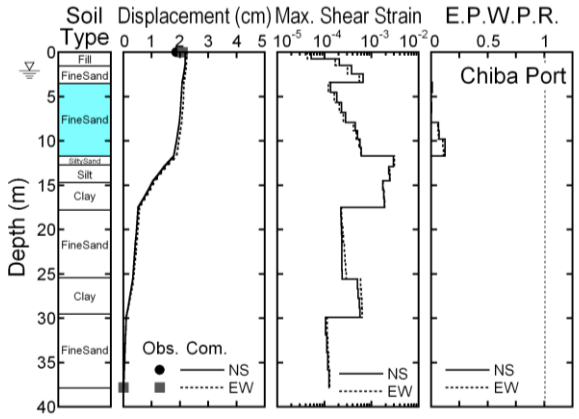
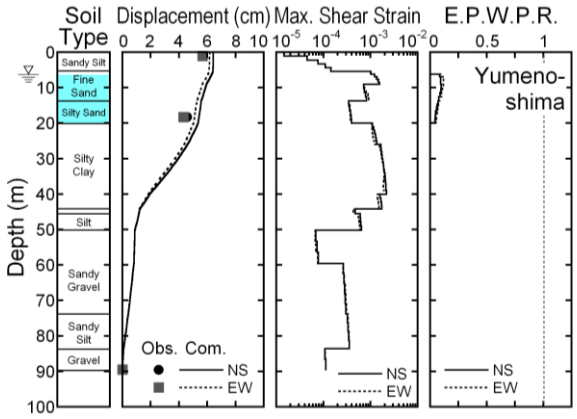
deformation and/or settlement, were not observed on ground surfaces at the both sites.



Thus, the one-dimensional (1-D) effective stress analyses are conducted for the soil profiles with the horizontal underground motions recorded at depths of 37.8 and 89.5 m in Chiba port and Yumenoshima sites, respectively, to estimate the shear stress time histories of liquefiable soils in Tokyo bay area during the main shock. The soil layer models and parameters employed in the analyses, which are set from the results of ground investigations stated previously, are listed as Tables 1 and 2 for Chiba port and Yumenoshima sites, respectively. In the analyses, the modified Ramberg-Osgood model is used for presenting the shear stress-strain relations of soils. The constitutive models to compute the excess pore water pressure induced by cyclic shear in sandy soils are those proposed by Shamoto *et al*. (1992, 1997) and Zhang *et al*. (1997), considering the effects of both cyclic mobility and post liquefaction. Further details of the effective stress analyses employed in this study can be found elsewhere (e.g., Shamoto *et al*., 1992).



Figures 4 and 5 indicate the acceleration time histories of horizontal ground motions resulted from the effective stress analyses at Chiba port and Yumenoshima sites, respectively, compared to those from the observed records. Also shown in the figures are the time histories of shear stress and excess pore water pressure ratio in the liquefiable sandy layers estimated from the analyses. The variations of maximum values for lateral displacement, shear strain, and excess pore water pressure ratio with depth at Chiba port and Yumenoshima sites are shown in Figures 6 and 7, respectively. In the figures, the estimated ground responses during the main shock are in good agreement with the observed ones at each site. The maximum values of excess pore water pressure ratios are less than about 0.1-0.2 at the both sites, which seem to be consistent with the fact that no liquefaction remarks were observed on ground surfaces at the sites during the main shock. These suggest that the estimated shear stress time histories at the sites could reliably be reasonable.

4. NUMBER OF EQUIVALENT CYCLIC SHEAR AND EFFECTIVE DURATION FOR SOIL LIQUEFACTION IN TOKYO BAY AREA

4.1 Number of Equivalent Cyclic Shear

Based on the textbook by Yoshimi (1991) and Figure 8, the number of equivalent cyclic shear for soil liquefaction N_{eq} can be computed by using Eq. (2):

$$N_{eq} = \frac{1}{2} N_e \sum_i N_i^{-1} = \frac{1}{2} \tau_e^{\frac{1}{C}} \sum_i \tau_i^{-\frac{1}{C}} \qquad (2)$$

in which τ_e is the effective shear stress (= 0.65× τ_{max}: τ_{max} is the maximum shear stress for a whole time history), τ_i is the peak shear stress at i th half cycle in the time history, and C is the inclination of liquefaction resistance line on a log-log scaled plot showing relationship between number of cyclic shear and shear stress ratio (see Figure 8).

Figures 9(a) and 9(b) illustrate the relationships between the number of equivalent cyclic shear for soil liquefaction N_{eq} and the effective shear stress ratio τ_e/σ'_{m0} computed by using Eq. (2) with the shear stress time histories derived from the effective stress analyses at Chiba

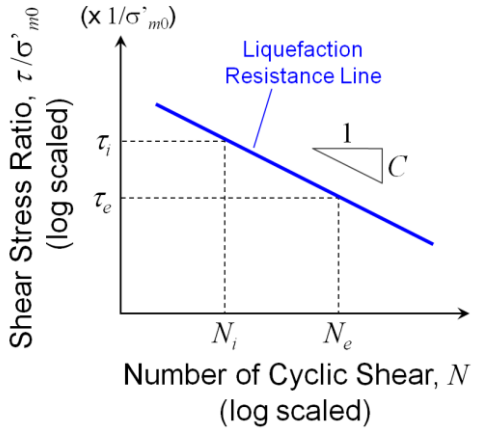

Figure 8 Schematic diagram showing relationship between number of cyclic shear and shear stress ratio on a log-log scaled plot to determine liquefaction resistance line of loose saturated sand under undrained condition

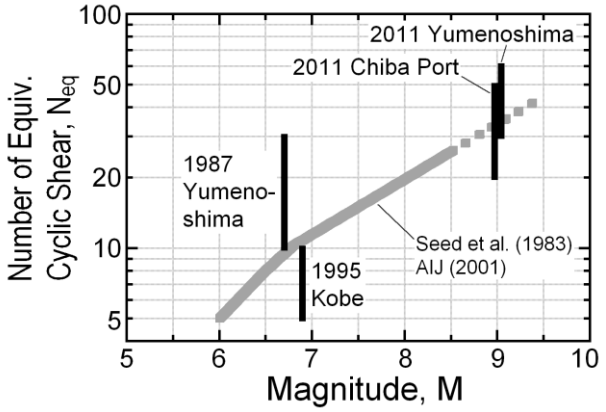

Figure 10 Relationship between earthquake magnitude M and number of equivalent cyclic shear for soil liquefaction N_{eq} resulted from this and previous studies

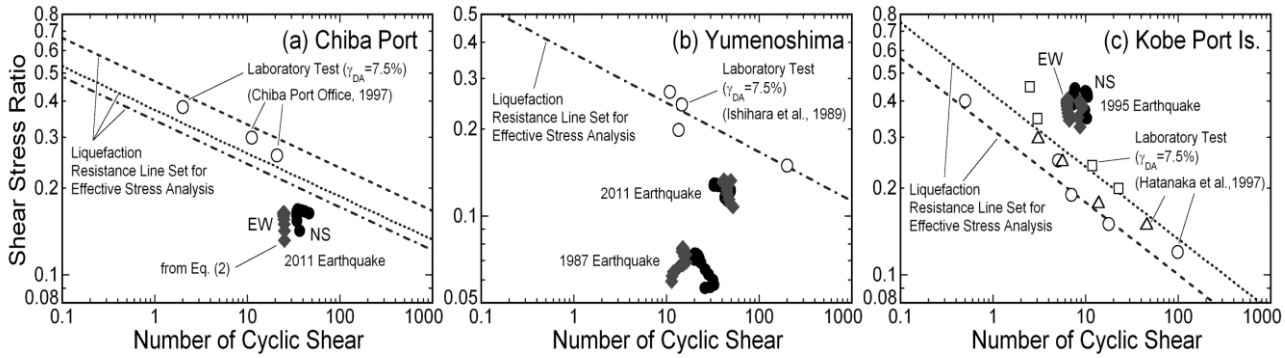

Figure 9 Relationships between number of equivalent cyclic shear for soil liquefaction N_{eq} and effective shear stress ratio τ_e/σ'_{m0} resulted from 1-D effective stress analyses compared to liquefaction resistance data from in-situ laboratory tests at (a) Chiba port, (b) Yumenoshima, and (c) Kobe port island sites

port and Yumenoshima sites, respectively. Also shown in Figures 9(b) and 9(c) are those computed similarly at Yumenoshima and Kobe port island sites for the 1987 Chiba-toho-oki and the 1995 Hyogo-ken Nambu earthquakes, respectively. Subsurface soils at Kobe port island site were heavily liquefied during the 1995 earthquake, while there were no liquefaction remarks on ground surface at Yumenoshima site during the 1987 earthquake (e.g., Architectural Institute of Japan, 1995; Ishihara *et al.*, 1989). Open circles, squares, and triangles shown in Figures 9(a)-(c) indicate the liquefaction resistance data from in-situ laboratory tests for undisturbed sandy soil samples at the sites (Chiba Port Office, 1997; Ishihara *et al.*, 1989; Hatanaka *et al.*, 1997). Comparison of these figures with the ground surface conditions observed during the earthquakes suggests the following:

i. The N_{eq}-τ_e/σ'_{m0} relations estimated from the effective stress analyses in this study are consistent with the facts whether subsurface soils were liquefied or not at the sites during the earthquakes.
ii. The N_{eq} in Tokyo bay area during the 2011 earthquake could be about 20-60, which might be about two times larger than that in the area during the 1987 earthquake.
iii. The N_{eq} in Kobe port island during the 1995 earthquake could be about 5-10, which might be about 1/4-1/6 times smaller than that in Tokyo bay area during the 2011 earthquake.

Figure 10 shows the relationship between the earthquake magnitude M and the number of equivalent cyclic shear for soil liquefaction N_{eq} estimated in this study as vertical black bars. The solid and broken gray lines in the figure indicate the existing M-N_{eq} relation for the past earthquakes with magnitude $M < 8$ (e.g., Seed *et al.*, 1983; Architectural Institute of Japan, 2001) and its extrapolation with a range of $M > 8$, respectively. The M-N_{eq} relation estimated in this study (the distribution of vertical black bars) seems to roughly be consistent with the both solid and broken gray lines. This indicates that the number of equivalent cyclic shear for soil liquefaction N_{eq} could roughly be predicted for a huge earthquake with magnitude $M > 8$ by extrapolation of the existing M-N_{eq} relation for the past earthquakes with magnitude $M < 8$, which was empirically proposed in the previous studies.

4.2 Effective Duration

To evaluate the effective duration for soil liquefaction t_d, Tokimatsu and Yoshimi (1980) have introduced the time history index $\beta(t)$ defined as Eq. (3):

$$\beta(t) = \frac{\text{Cumulative number of equiv. cycles at time } t}{N_{eq}} \qquad (3)$$

The t_d is then determined from the length of time for which the $\beta(t)$ value changes from 0 to 1.

Figure 11 indicates the $\beta(t)$ of the liquefiable sandy soils estimated from the effective stress analyses at Chiba port and Yumenoshima sites for the 2011 earthquake, compared to those evaluated at the liquefied sites for the past earthquakes with magnitude M < 8 (after Tokimatsu and Yoshimi, 1980). In the figure, the effective duration for soil liquefaction t_d in Tokyo bay area during the 2011 earthquake would be about 25 s, while those for the past earthquakes be less than about 10-15 s.

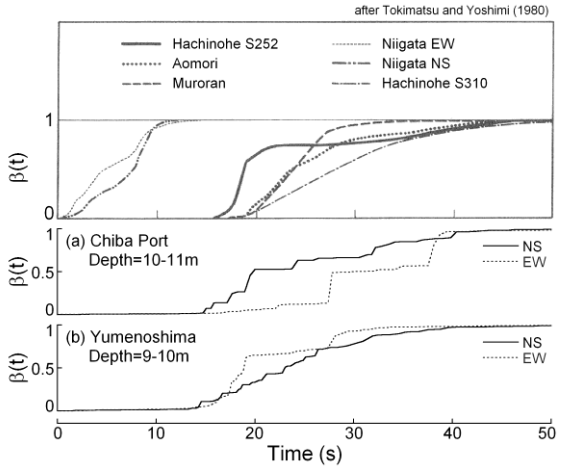

Figure 11 Time histories of cumulative index $\beta(t)$ defined as Eq. (3) to evaluate effective duration for soil liquefaction

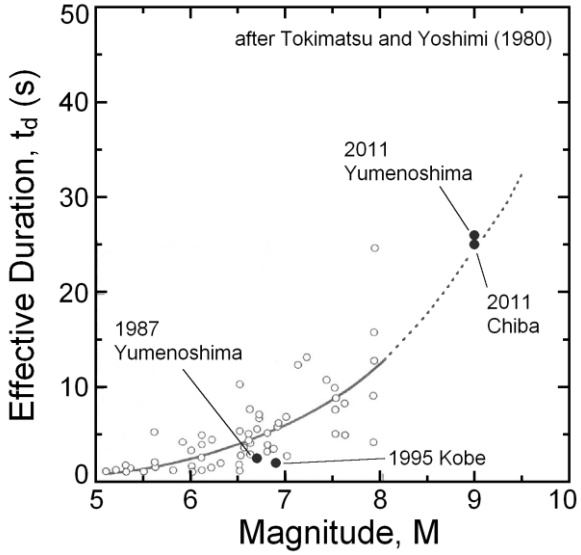

Figure 12 Relationship between earthquake magnitude M and effective duration for soil liquefaction t_d resulted from this and previous studies

Figure 12 shows the relationship between the earthquake magnitude M and the effective duration for soil liquefaction t_d estimated in this study as solid circles. Open circles and solid curve in the figure are the existing M-t_d relational data derived at the liquefied sites for the past earthquakes with magnitude M < 8 and their regression curve, respectively (after Tokimatsu and Yoshimi, 1980). The broken curve with a range of M > 8 is the extrapolation of the existing regression one in the figure. The M-t_d relation estimated in this study (the distribution of solid circles) seems to be consistent with the both solid and broken curves. This also suggests that the effective duration for soil liquefaction t_d might be forecasted for a huge earthquake with magnitude M > 8 by extrapolation of the existing M-t_d relation for the past earthquakes with magnitude M < 8, which was empirically proposed in the previous studies.

5. CONCLUSIONS

The number of equivalent cyclic shear N_{eq} and the effective duration t_d for soil liquefaction at Chiba port and Yumenoshima sites in Tokyo bay area are estimated by using the one-dimensional (1-D) effective stress analyses for the 2011 Great East Japan earthquake (M_w = 9.0). Also estimated are those at Yumenoshima and Kobe port island sites for the 1987 Chiba-toho-oki and the 1995 Hyogo-ken Nambu earthquakes, respectively. Based on the estimated results and discussions on their relationships with earthquake magnitude M referring to the previous studies, the following conclusions are made:

1. The N_{eq} and t_d estimated in Tokyo bay area during the 2011 earthquake are about 20-60 and about 25 s, respectively, which might be about 2-6 times larger than those at the liquefied and non-liquefied sites during the past earthquakes.
2. The N_{eq} and t_d values could roughly be predicted for a huge earthquake with magnitude M > 8 by extrapolation of the existing M-N_{eq} and M-t_d relations for the past earthquakes with magnitude M < 8, respectively, those were empirically proposed in the previous studies.

EFFECT OF GRAIN SIZE DISTRIBUTIONS ON LIQUEFACTION RESISTANCE FOR A LARGE NUMBER OF LOADING CYCLES

Jun IZAWA[1] and Yoshitaka MURONO[2]

1) Assistant Senior Researcher, Earthquake and Structural Engineering, Structures Technology Division, Railway Technical Research Institute, Japan

Abstract: This paper describes the results of the hollow cylindrical cyclic torsion shear tests on effects of grain size distributions on liquefaction resistance for a large number of loading cycles, which is considered to affect soil liquefaction due to a long duration earthquake with low acceleration, for example, observed in the Tokyo Bay area in the 2001 Great East Japan Earthquake. The test results clearly show that the tendency of decrease of liquefaction resistance for a large number of loading cycles is influenced by mean grain size, inclination of grain size distribution and so on. Finally, the effect of liquefaction resistance curve characteristics on assessment of liquefaction potential was examined using the cumulative damage theory.

1. INTRODUCTION

Liquefaction of saturated non-cohesion soils was observed in the past severe earthquakes in Japan, such as 1995 Hyogo-ken Nambu earthquake, 1964 Niigata earthquake and so on. Such liquefaction areas were located near the epicentre of the earthquakes, and are considered to have been heavily vibrated by strong earthquake motions. On the other hand, in the 2001 Great East Japan Earthquake, severe liquefaction was observed in the Tokyo Bay area, which is far from the epicenter, and acceleration observed there was less than 200 Gal. One of the possible reasons for such liquefaction due to low acceleration earthquake is considered to be very long shaking duration, which was longer than 300 seconds. Additionally, according to the report of Ino et al. (2011), silty soils with relatively small particle size and relatively gentle inclination of particle size distribution curve, which seem to have relatively large liquefaction resistance as compared with that of layers composed of uniform grain size soils, liquefied in the same area. In view of these aspects, it is considered that liquefaction observed in the Tokyo Bay area in t the 2001 Great East Japan Earthquake might have a relationship with both characteristics of the earthquake and grains size distributions of the layer.

Liquefaction potential is generally assessed with F_L method. F_L method determines factor of safety by comparing the shear stress ratio acting on the soil layer, L and the liquefaction resistance, R. In many case, R_{20} is used as the representative value of liquefaction resistance, which is the shear stress ratio for soils to liquefy by 20 loading cycles with the same stress amplitude in the soil test samples. Effect of characteristics of input earthquakes cannot be considered by the method, which uses R_{20}. Thus, design standard for Japan Highway Bridges (Japan Road Association 2012) uses the correction factor for irregularity of input earthquake, C_w, which is calculated by ccumulative damage degree method (D value) with liquefaction resistance curve of Toyoura sand (Azuma et al. 1997). By using C_w, the liquefaction resistance can be increased against near-field earthquakes, which may have large acceleration and short duration. On the contrary, $C_w = 1.0$ is used for ocean trench earthquakes. This means that R_{20} indicates almost the same resistance mobilized against ocean trench earthquakes, which have relatively low acceleration but long duration. Some researchers studied the value of C_w for ocean trench earthquqkes. Yashiro et al. (2003) suggested $C_w = 0.9$ from the results of the effective stress analyses and assessment of liquefaction potential with the cumulative damage degree. Yoshida et al. (2009) determined $C_w = 0.5$, which was also obtained from the comparative studies between effective stress analyses and assessment of liquefaction potential for 236 grounds. In the design standard for railway structures (Railway Technical Research Institute 2012), effect of characteristics of input earthquakes on soil liquefaction resistance is directly evaluated with cumulative damage degree method for liquefaction layers and the design earthquakes, which is described by Annaki & Lee (1976) for example. The authors verified the applicability of this method from the comparative studies on effective stress analysis and the cumulative damage degree method against some earthquakes (Izawa et al. 2012). Furthermore, it was found that the liquefaction potential against long duration earthquake with low acceleration greatly depends on the accuracy of the liquefaction resistance curve especially for a

large number of loading cycles. This means that not only R_{20} but also the shape of the liquefaction resistance curve should be considered in assessment of liquefaction potential in view of soil characteristics.

In this study, then, a series of hollow cylindrical cyclic torsion shear tests was conducted to investigate the effects of particle size distributions on liquefaction resistance for a large number of loading cycles, which is considered to affect soil liquefaction due to long duration earthquakes with low acceleration.

2. CYCLIC TORSION SHEAR TESTS

2.1 Outline of the tests

A series of hollow cylindrical cyclic torsion shear tests were conducted, especially focusing on the effects of grain size distribution on liquefaction resistance for a wide range of loading cycles, which ranged from about a few cycles to about 1000 cycles. The size of the test pieces was 200 mm in outer diameter, 120 mm in inner diameter and 300 mm in height. After the samples were consolidated with the constraint pressure of 98 kPa (back pressure was 200 kPa), 5 or 6 test data of the liquefaction resistance were obtained. The occurrence of liquefaction was defined as the moment when the shear strain reached 7.5%.

4 soil samples were chosen in this study, which were the samples A, B, C and DL Clay, whose properties are summarized in Table 1. The samples A, B and C were artificially prepared by mixing the Fujinomori Clay with Silica sand No. 6 and 7, to obtain the target particle size distributions. The grain size distributions of Sample A, B and C are plotted in Figure 1, in which the grain size distribution of Toyoura sand is also plotted for comparison. The target grain size distribution of the sample A was set so as to have the smallest mean grain size, D_{50}, and to be the most well-graded soil among the boiled sands taken by Ino et al. The sample B has almost the same shape of grain size distribution as that of the sample A, but its D_{50} is about 0.1 mm larger than that of the sample A. That is, if the grain size distribution of the sample A is moved so as to have larger grain size, the target grain size distribution of the sample B can be obtained. The sample C and Toyoura sand have almost the same D_{50} as that of the sample B, but they are poorly-graded in the order of the sample C and Toyoura sand as shown in Figure 1. Finally, DL Clay has the smallest grain size among all the samples, and poorly-graded equivalent to that of Toyoura sand. The target distributions were obtained in general, although there are some discrepancies between the idealized distribution and the obtained one as shown in Figure1.

Table 2 lists the test cases conducted in this study. Target relative densities, Drs, of the sample A and DL clay, which are as dense as possible by the air pluviation method, are about 90 % and 80 % respectively,. Unit weight of the sample B was set so as to be the same as that of the sample A, resulting in the fact that Dr was 60%. The sample B with relative density of 84% was also made to investigate effect of unit weight. Relative density of the sample C was set at 80%, to obtain almost the same dry density as that of the

sample B(Dr=84%). The test pieces of DL Clay were prepared so as to be as dense as possible. The test results for Toyoura sand conducted by Aono et al. (1986) were used in this study.

2.2 Results and Discussions

Figure 2 shows the relationships between the liquefaction resistance and the number of loading cycles of the samples A, B (Dr=60%) and DL clay, whose dry unit weight are almost the same. Regarding the samples B and C whose average particle sizes, D_{50}, are almost the same, their liquefaction strength curves are shown in Figure 3. Results of Aono et. al. were plotted in the figure for comparisons. It should be noted that the liquefaction resistances of the Toyoura sand were increased by 1.2 times so as to be able to be compared with the results obtained from the torsion shear tests referring to the past study(Tanaka et al. 1999), as these data were obtained from cyclic triaxial tests.

The solid lines in the figures are approximated by the following equation (1) with a liquefaction strength at 20 cycles, R_{20}, and a coefficient α, which are summarized in Table 3.

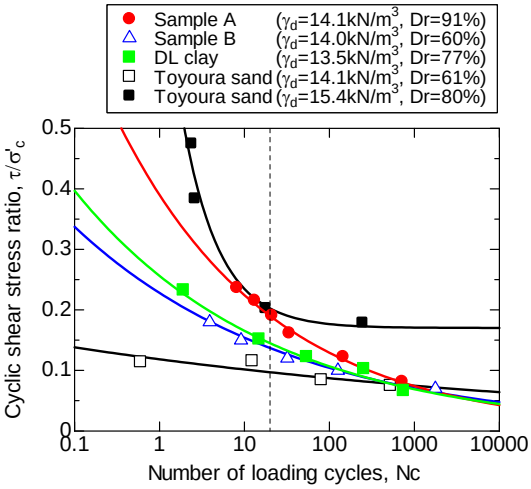

Figure 2 Cyclic shear stress ratio versus number of loading cycles reaching to shear strain of 7.5% for samples with almost the same unit weight.

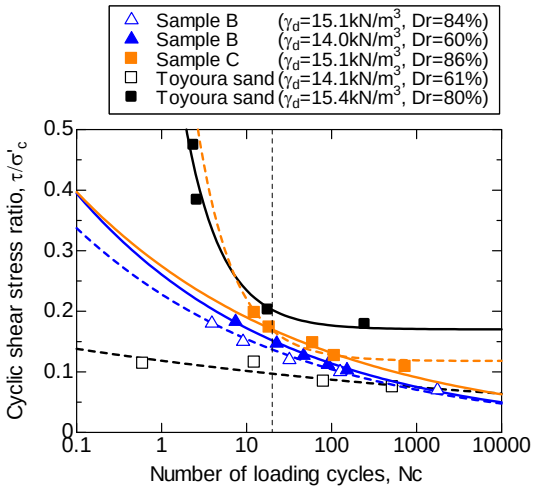

Figure 3 Cyclic shear stress ratio versus number of loading cycles reaching to shear strain of 7.5% for samples with almost the same mean grain size.

Table 3 Summary of the liquefaction tests

	Dr(%)	R_{20}	R_{1000}	α
Sample A	91.2	0.190	0.074	0.24
Sampe B	60.0	0.137	0.070	0.17
	84.0	0.152	0.074	0.18
Sample C	85.8	0.170	0.095*	0.16*
DL clay	77.0	0.145	0.070	0.19
Toyoura sand[4)]	80.0	0.200	0.17	-
	61.0	0.134	0.109	0.05

*The coefficient for approximation with the Equation (1)

$$R_i = R_{20}\left(\frac{N_c}{20}\right)^{-\alpha} \quad (1)$$

As shown in Figure 2, the sample A, which has smaller grain size and the well-graded distribution, shows the largest R_{20} among all the samples, but the liquefaction resistance decreases to almost the same resistance as those of the sample B and DL clay with an increase of loading cycles. On the other hand, Toyoura sand with relative density of 80%, whose R_{20} is almost the same as that of the sample A, did not show decrease after the cyclic number of about 100. Since the liquefaction resistance curve of Toyoura sand with Dr=80% is very different from those of the other samples and could not be fitted with the equation (1), the curve was approximated with a hyperbolic curve, as indicated by the equation (2).

$$R_i = \frac{0.643}{Nc} + 0.171 \quad (2)$$

DL clay, which has very small grain sizes, shows relatively large decrease for a large number of cycles, although it is very poorly-graded soil similar to Toyoura sand. Similarly, the results of the sample B shows relatively large decrease for a large number of cycles as shown in Figure 3, and then the liquefaction resistance curve can be fitted with the equation (1). The results of the sample C, whose properties are in between that of the sample B and Toyoura sand, did not show large decrease, and the liquefaction resistance curve can be fitted with the equation (3) as indicated with broken line in Figure 3.

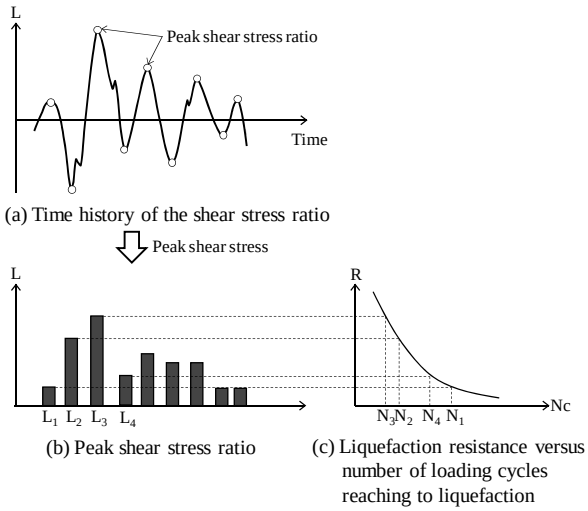

Figure 4 Procedure for determining the *D* value used in the assessment of liquefaction potential.

$$R_i = \frac{1.02}{Nc} + 0.118 \quad (3)$$

There is large discrepancy of liquefaction resistance curves between Toyoura sand with Dr = 80 % and 60%. On the other hand, such large discrepancy cannot be observed between the case of the sample B with Dr = 84% and that with Dr = 60%. It is considered that effect of the relative density on the liquefaction resistance is influenced if the soil is poorly-graded.

3. EFFECT OF LIQUEFACTION POTENTIAL

It is found that the shape of liquefaction resistance curve may be influenced by the grain size distribution of soils. Effect of such difference of the shape of liquefaction resistance curves on liquefaction potential was evaluated by the cumulative damage degree method as it is used in the design of Japanese Railway structures. Procedure of the method is simply explained as follows.

Firstly, the liquefaction resistance for cyclic number of 20, R_{20} is determined from the laboratory tests or estimated with N value indicated in the Japanese railway standard.

Then, the liquefaction resistance curve, which shows the relationship between liquefaction resistance, R_i and number of cycles, N_c can be estimated by the following equations (4) and (5), where relative density, Dr is also estimated from N value.

i) $N_c \leqq 20$

$$R_{(i)} = R_{20}\left(\frac{Nc}{20}\right)^{-1.35\exp(-3.64+0.037\,Dr)} \quad (4)$$

ii) $N_c > 20$

$$R_{(i)} = R_{20}\left(\frac{Nc}{20}\right)^{-0.23} \quad (5)$$

Secondly, peak accelerations at the ground surface are picked up with zero crossing method and peak values of shear stress acting on soil layers are calculated by the following equation.

$$L = (1.0 - 0.015z)\frac{a}{g}\frac{\sigma'_v}{\sigma_v} \quad (6)$$

where L: peak shear stress ratio, z: depth of ground(m), a: surface peak acceleration(Gal), g: garavity(Gal), σ_v:total vertical stress(kN/m^2), σ'_v: effective vertical stress(kN/m^2). The largest peak shear stress ratio, L_{max} is used as the representative shear stress ratio in the assessment. The required cyclic number for the soil to liquefy with each peak shear stress can be obtained based on the liquefaction strength curve as shown in Figure 4. Then, the cumulative damage degree, D is calculated by the equation (7).

$$D = \sum \frac{1}{2Nc} \quad (7)$$

When the cumulative damage degree, D reaches 1.0, it can be considered that the soil layer liquefied. Then, the peak shear stress ratio is repeatedly corrected until D becomes just 1.0. When D is equal to 1.0, the largest peak shear stress ratio, $L'_{\max}$ is set to be R_D, which is the liquefaction resistance corrected with the cumulative damage degree. Finally, the liquefaction resistance, R_L which is corrected in consideration of stress anisotropy in natural ground, is determined by the equation (8).

$$R_L = \frac{1+2K_0}{3} R_D \quad (8)$$

Liquefaction potential can be assessed with the following equation.

$$F_L = \frac{R_L}{L_{\max}} \quad (9)$$

If the $F_L < 1.0$, the ground is assessed as liquefaction ground. Degree of liquefaction of the ground can be evaluated with P_L value obtained by the following equation.

$$P_L = \int_0^H (1 - F_L)(10 - 0.5z)dz \quad (10)$$

where H: length of liquefaction layer (m), z: depth(m), and z is less than 20m. If $P_L \geqq 5$, the ground is assessed as liquefaction ground. If $P_L \geqq 20$, severe liquefaction may occur.

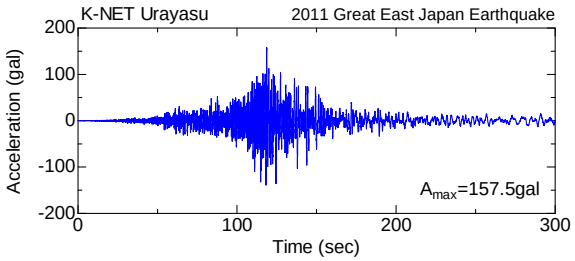

Figure 5 The input wave used for the assessment of liquefaction potential.

Table 4 Results of assessment of liquefaction potential

	Dr	R_{20}	L	R_D	R_L	F_L	P_L
Sample A	—	0.190	0.330	0.290	0.193	0.587	31.0
Sample B	84.0%	0.152	0.310	0.229	0.153	0.494	38.0
	60.0%	0.137	0.323	0.205	0.138	0.426	43.1
Sample C	85.8%	0.170	0.310	0.252	0.168	0.542	34.3
DL clay	77.0%	0.145	0.330	0.220	0.146	0.444	41.7
Toyoura sand	80%	0.200	0.321	0.345	0.230	0.716	21.3

R_D: Liquefaction resistance corrected with the cumulative damage degree.
R_L : Liquefaction resistance corrected in consideration both of stress anisotropy in natural ground and properties of input wave.

In the sensitivity analysis of the liquefaction resistance curve, a layer with depth of 10m composed of sample A or B or Toyoura sand respectively is used. K-NET Urayasu wave shown in Figure 5 is used, which is a typical long duration earthquake with low acceleration observed in the 2001 Great East Japan Earthquake. Table 4 shows the results of the assessment of liquefaction potential. The layer composed of the sample A shows about 20% smaller F_L value than that of Toyoura sand, whose R_{20} is almost the same as that of the sample A. Consequently, about 1.5 times larger P_L value is calculated. Figure 6 shows the liquefaction resistance curve obtained in this study and the time history of peak shear stresses used in determining D value in the assessment. The greater part of the shear stress ratio is under 0.20, which corresponds to about R_{20} of Toyoura sand and Sample A. Therefore, characteristics of the liquefaction resistance for a large number of loading cycles greatly affected to the assessment of liquefaction potential against a long duration earthquake with low acceleration. This result clearly shows that the shape of the liquefaction resistance at a number of cycles may influence liquefaction potential.

4. Summary

This paper describes the effect of grain size distribution on the liquefaction resistance for a large number of loading cycles, which may influence liquefaction potential against a long duration earthquake with low acceleration based on the results of liquefaction resistance tests together with the torsion shear tests. As a result, the following trend can be obtained.

1) Well-graded soils may show large decrease of liquefaction resistances for a large number of loading cycles, even although they can have a large liquefaction

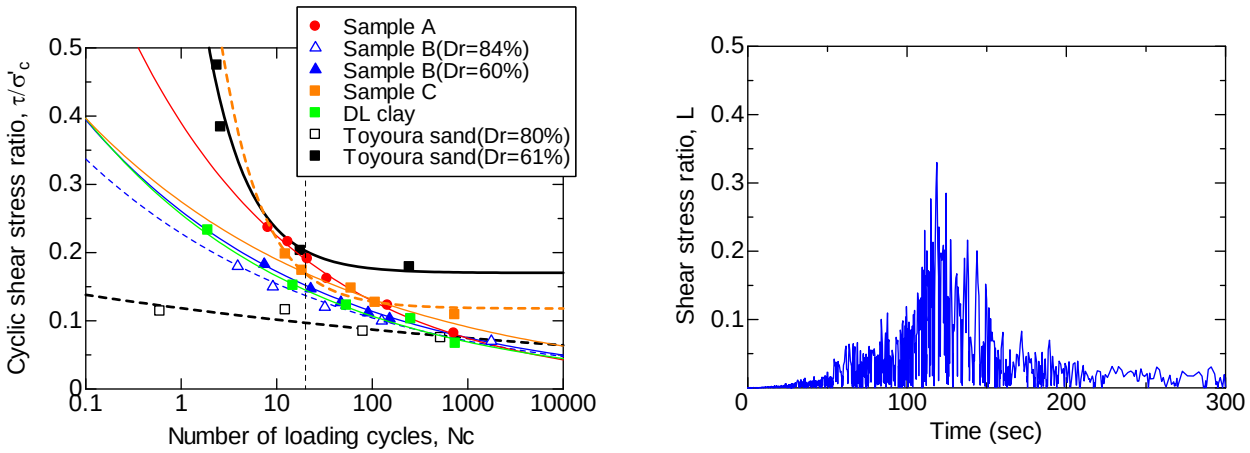

Figure 6 Cyclic shear stress ratio versus number of loading cycles reaching to shear strain of 7.5% and shear stress ratio used for assessment of liquefaction potential.

resistance at 20 loading cycles, R_{20}. Additionally, effect of relative density on the liquefaction resistance curve is small if the soil is well-graded.

2) Poorly-graded soils with relatively large particle size didn't show large decrease of liquefaction resistances for a large number of loading cycles. On the other hand, poorly-graded soils with small particle size may show decrease of liquefaction resistances for a large number of loading cycles.
3) Difference of the liquefaction resistance curve for a large number of loading cycles may affect results of assessment of liquefaction potential by the cumulative damage degree method.

Abstract: Liquefaction potentials estimated by some methods based on boring logs were compared with damage distribution of sand boiling in Mihama ward of Chiba city. Horizontal surface displacements estimated by simplified method are in roughly good agreement with damage distribution of sand boiling. Despite the fact that horizontal surface displacements estimated by integrating shear stress calculated by equivalent linear analysis are totally small, those seem to correlate with damage distribution of sand boiling.

1. INTRODUCTION

The 2011 Tohoku earthquake (MW 9.0) that struck the east area of Japan on March 11 caused Tsunami and extensive damage. In Mihama ward of Chiba city that is located in the east of Tokyo, more than 300 km away from the epicenter and consists entirely of reclaimed ground along Tokyo Bay, a huge number of liquefaction damage, such as sand boiling, ground deformation and floor incline of buildings including 23 fully destroyed houses, occurred, and strong motions at the grounds with peak ground accelerations (PGA) of more than 3 m/s^2 were recorded.

Although small sand boiling was found on the main road, narrower streets inside a block were almost completely covered with sand boiling as thick as 45 cm. One of the interesting phenomena, however, is that there are some no-damage blocks right next to heavily damaged blocks.

The objective of this study is to compare the damage distribution and estimated liquefaction potential based on boring logs in Mihama ward of Chiba city.

2. LIQUEFACTION DAMAGE DISTRIBUTION

The liquefaction damage distribution was surveyed on public roads in Mihama ward immediately after the earthquake from March 12 to 20 (Sekiguchi and Nakai, 2012). The target area of the investigation is all the public roads and parks which could be entered in the ward. The damage of sand boiling is classified into 3 levels ; heavy, minor and none.

Figure 1 shows distribution of sand boiling using 50 m square grids. Heavy sand boiling is densely distributed in coastal area when compared to inland area. On the other hand, there are some districts where little sand boiling was found in coastal area.

3. ESTIMATED LIQUEFACTION POTENTIAL

3.1 Simplified Method

Horizontal surface displacements due to liquefaction (D_{cy}) were estimated for 540 boring logs in the ward based on simplified method (AIJ, 2001). The peak ground acceleration was set with 2.5 m/s^2 based on strong motion record in the ward. The magnitude of earthquake was set with 9.0. Because almost all boring logs have no data of

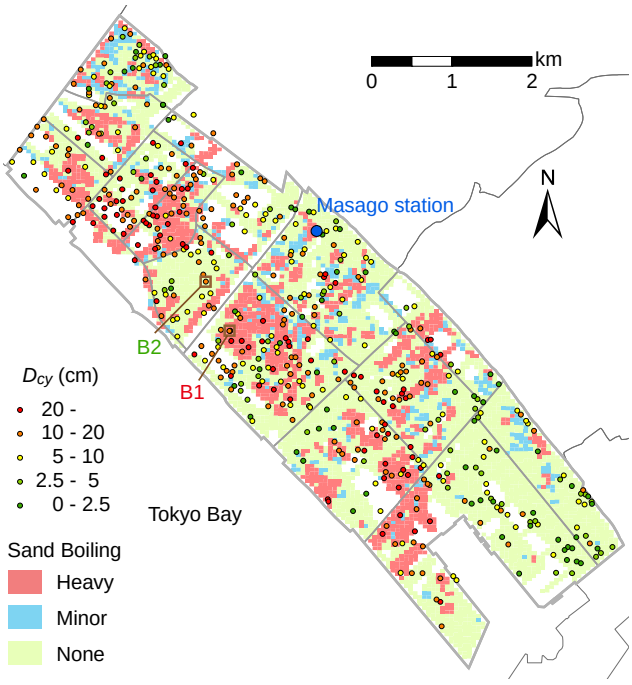

Figure 1 Distribution of Sand Boiling and Estimated Horizontal Surface Displacements due to Soil Liquefaction

soil test, fine fraction contents (F_c) of each layer were set depending on the soil type based on reference (Yamanaka et. al,2010). Minimum F_c of sand is supposed to be 10 % corresponding to fine sand.

In figure 1, estimated horizontal surface displacements for boring logs are also plotted by circle. The displacements in heavy damage area tend to be relatively large.

Figure 2 shows frequency distribution of estimated horizontal surface displacement classified into three liquefaction damage level of the surrounding area. At area with heavy damage of sand boiling, about 80 % of estimated displacements are more than 10 cm. On the other hand, about 60 % of estimated displacements are less than 10 cm at area with none damage.

3.2 Method with Equivalent Linear Analysis

The shear wave velocity structure models of surface soils were made using boring logs in Mihama ward. The one-dimensional shear wave velocity profiles to a depth of engineering bedrock were estimated based on 314 boring logs. The shear wave velocities were estimated from the soil types and *N*-values by empirical equations in Chiba prefecture (Nagata et al. 2008).

One-dimensional equivalent linear dynamic response analyses with frequency dependent damping (Schnabel at al., 1972, Sugito et al., 1993) were conducted using the estimated soil profiles from boring logs. The nonlinear dynamic soil properties used for the analysis are based on the study by Imazu and Fukutake (1986). The acceleration record of the EW component at Masago station shown in Figure 1 during the Tohoku earthquake was used as the input ground surface motion to compute the outcrop bedrock motion at the engineering bedrock layer.

Calculated shear stresses of sand layers were used as $(\tau_{max})_d$ for simplified method estimating horizontal displacement. Figure 3 shows distribution of estimated horizontal surface displacements using shear stress calculated by equivalent linear analysis. A tendency same as figure 1 is seen.

Figure 4 shows frequency distribution of estimated horizontal surface displacement using shear stress calculated by equivalent linear analysis. The tendency seems to be same as figure 2.

Figure 5 shows boring logs, estimated shear wave velocity profiles, depth distribution of shear stress ratios, factor of safety for liquefaction (F_L), and shear strain calculated from equivalent linear analysis at B1 with heavy damage and B2 with no damage in figure 1. At B1 with heavy damage, there are soft sand layers to the depth of 6 m, and factor of safety for liquefactions are low around a depth of 5m. The estimated horizontal surface displacement is, therefore, relatively large. At B2 with no damage, although there is no soft sand layer to a depth of 8m, estimated displacement is not so small. The reason is that shear strains at a depth from 8 to 18 m might affect the surface displacement. Liquefaction at such a large depth, however, might not affect damage at ground surface such as sand boiling.

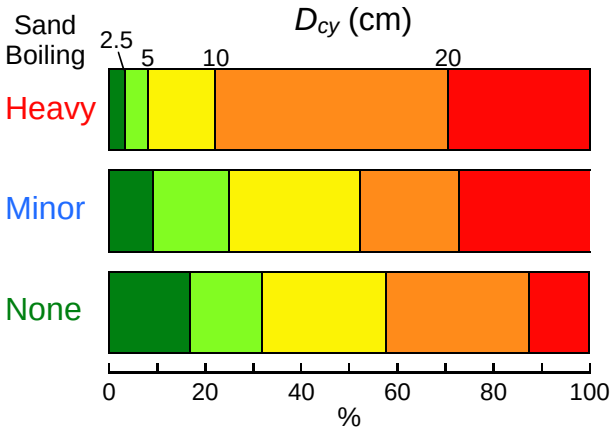

Figure 2 Frequency Distribution of Estimated Horizontal Surface Displacements due to Soil Liquefaction

Figure 3 Distribution of Estimated Horizontal Surface Displacements using Shear Stress Calculated by Equivalent Linear Analysis

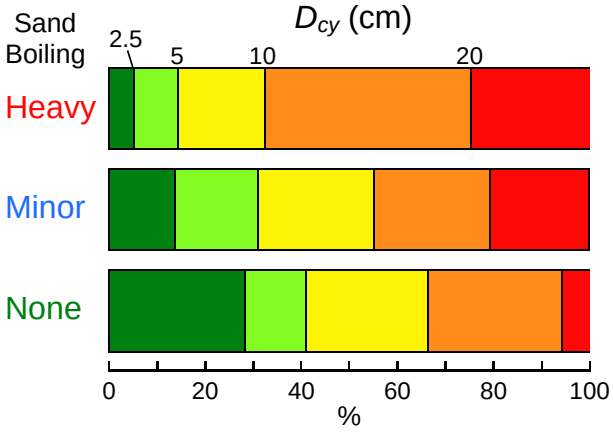

Figure 4 Frequency Distribution of Estimated Horizontal Surface Displacements using Shear Stress Calculated by Equivalent Linear Analysis

Figure 6 Distribution of Estimated Horizontal Surface Displacements by Integrating Shear Strain of Sand Layers

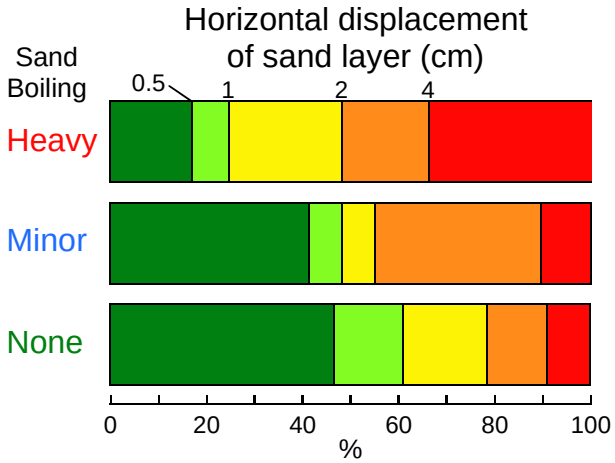

Figure 7 Frequency Distribution of Estimated Horizontal Surface Displacements by Integrating Shear Strain of Sand Layers

3.3 Integration of Shear Strain from Equivalent Linear Analysis

In terms of shear strain in figure 5, those at sand layers around a depth of 5 m at B1 are relatively large, and those at sand layers at B2 are small. Horizontal surface displacements were estimated by integrating the shear strain of sand layers calculated by equivalent linear analysis.

Figure 6 shows distribution of estimated horizontal surface displacements by integrating the shear strain of sand layers. Figure 7 shows frequency distribution of estimated horizontal surface displacement by integrating the shear strain of sand layers. At points with large displacement estimated by simplified method in spite of no damage such as B2, displacements become relatively small. Despite the fact that estimated displacements are totally small, those seem to correlate with damage distribution of sand boiling.

4. CONCLUSIONS

Liquefaction potentials estimated by some methods based on boring logs were compared with damage distribution of sand boiling in Mihama ward of Chiba city. The following conclusions can be made through this study:

1. Horizontal surface displacements estimated by simplified method are in roughly good agreement with damage distribution of sand boiling.
2. Despite the fact that horizontal surface displacements estimated by integrating shear stress calculated by equivalent linear analysis are totally small, those seem to correlate with damage distribution of sand boiling.

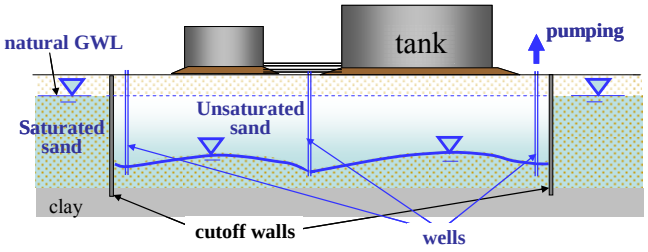
Abstract: A series of centrifuge model test has been conducted to investigate the dynamic behavior of the desaturated sand with a super structure under relatively long period shaking. In the centrifuge tests, two desaturation methods were employed, one is lowering and raising ground water table, which can make wider desaturation area, and the other air injection with a limited desaturation area under the structure. A shaking table test of the model was conducted to discuss the effects of shaking time and method of desaturation.

1. INTRODUCTION

Liquefaction is a phenomenon commonly observed in saturated sandy soils at almost every past moderate to large earthquakes. Since liquefaction has caused serious damage to many structures, a large number of researches have been conducted, particularly for the development of its countermeasures, for example, sand compaction piles as a densification method, deep cement mixing as a solidification method, and gravel drains as a method for excess pore pressure dissipation. However, these countermeasures are often costly and difficult to apply due to surrounding environment especially for the long or large scale structures, such as coastal dykes and housings in residential area. Considering these limitations, soil desaturation has been considered as an inexpensive liquefaction countermeasure without large disturbance in the environment in its execution.

The degree of saturation, S_r, has a significant effect on liquefaction resistance (Yoshimi et al, 1989; Okamura et al., 2006; Okamura and Soga, 2006; Ueno et al., 2008). Entrapped air in the soil is considered to be utilized for an economical countermeasure against liquefaction in suppressing the buildup of excess pore water presure, if the air bubbles in the pore of the soil introduced by the desaturation process can be sustained below ground water table.



Okamura and Soga (2006) found a unique relationship between the liquefaction resistance ratio (R_u/R_s, where R_u and R_s are liquefaction resistance of unsaturated and saturated soils respectively) and the potential volumetric strain, ε_v^* as given in the following equations:

$$R_u/R_s=\log(6500\varepsilon_v^*+10) \qquad (1)$$

$$\varepsilon_v^* = \frac{\sigma_c'}{p_0+\sigma_c'}(1-S_r)\frac{e}{1+e} \qquad (2)$$

where σ_c', p_0, e denote effective confining pressure, absolute pressure of the pore fluid and void ratio of soil respectively.

Centrifuge modeling has been used as a useful approach in the study of soil liquefaction, especially for verification of countermeasures against liquefaction (e.g., Kimura et al, 1995). In particular, considering eq.(2), the dependence of effective confining pressure on the stress level implies that the effect of the degree of saturation cannot be represented

well in small scale models under laboratory floor conditions.

From a series of centrifuge model tests, Takemura et al. (2009, 2010, 2012) confirmed that soil desaturation is effective as a liquefaction countermeasures. The methods of soil desaturation considered by Takemura are air injection and groundwater lowering and raising respectively as illustrated **Figures 1**. However, the shakings applied in these models were relatively short about 15sec in a prototype scale under 50g. The dynamic behavior of desaturated sand subjected to a long seismic motion, like the one observed in the 2011 Earthquake off the Pacific Coast of Tohoku has not been well studied.

In this study, an attempt was made to prepare partially saturated model sand by the two methods, i.e., lowering and raising ground water table and air injection. The former method can make wider desaturation area with over-consolidation history, while the latter one makes the desaturation area limited under the structure. A shaking test was then conducted for the desaturated sand with a gravity type footing by applying relatively long sinusoidal shaking motion of 1 minute in a prototype scale. From the test results, discussed are dynamic behavior of the desaturated sand during the long shaking motion and the applicability of soil desaturation as a liquefaction countermeasure.

2. CENTRIFUGE MODEL TESTS

2.1 Soils used in the tests

Silica sand No.8 was used to make the model ground and Silica No.3 was for the drainage layer beneath the model ground. Properties of the sands are given in **Table 1**. Water was used for pore fluid in the model. Silica sand No.8 is fine sand with relatively small permeability. Although the permeability in a prototype scale under 50g is 50 times larger when water is used, it is still small enough to create liquefaction phenomena in the model. As seen in **Figure 2**, this fine sand has high residual degree of saturation and can hold air bubbles in the pore to make a relatively small degree of saturation in submerged condition especially under large buoyancy force in high centrifugal accelerations.

Figures 3 show liquefaction curves of Silica sand No.8 obtained from cyclic triaxial tests. The effect of decreasing S_r from 100% to 90 is similar to that of increasing D_r from 60 to 80% (Figures 3(a) and (b)). Overconsolidation also has the effect of increasing liquefaction strength (Figure 3(c)). It should be noted that the changes of relative density by the

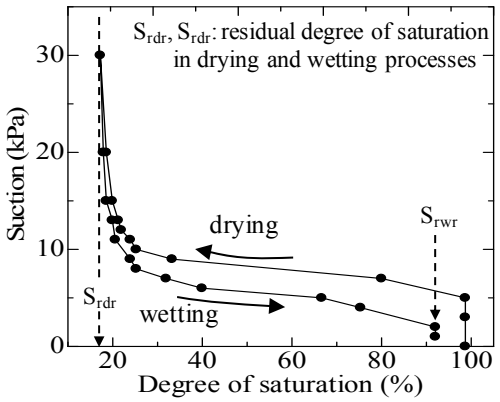

Figure 2 Capillary pressure and degree of saturation curve : Silica sand No.8.

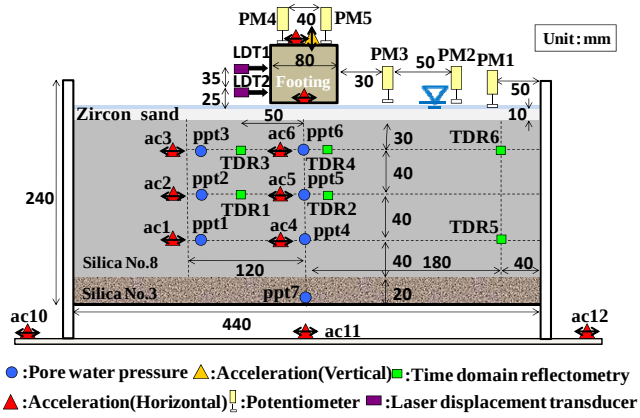

Figure 4 (a) Test setup and implementations of centrifuge model test.: Ground water lowing (GWL) case.

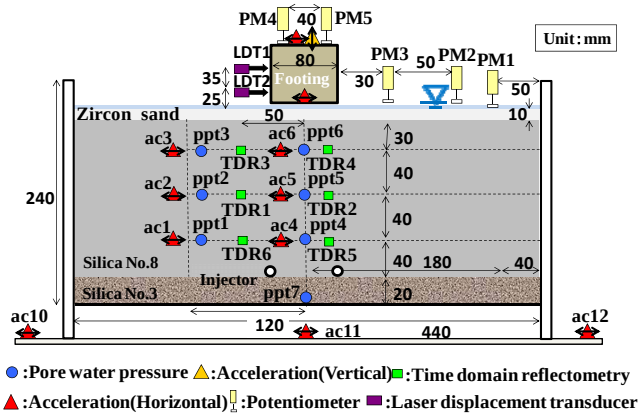

Figure 4 (b) Test setup and implementations of centrifuge model test.: Air Injection (AI) case.

desaturation and the preconsolidation with relatively large pressure are both very minute and the increases of the strength should be exclusively introduced by the effect of air in the pore and the overconsolidation respectively.

2.2 Model preparation

A laminar type shear box made of aluminum with inner sizes of 440mm in width, 150mm in length and 240mm in depth (Kimura et al, 1995) was used in the tests. Test setups employed are shown in **Figures 4**. In the model preparation Silica sand No.3 was first placed as the bottom drainage layer by compaction with a wooden rod. Then, layer of dry Silica sand No.8 was made by air pluviation in a loose condition (Dr=64%). 10mm thick Zircon sand was laid on the top surface of the model ground to give the surcharge pressure of 10kPa in 50g. A model footing made of solid aluminum with the dimensions of 80mm in width, 80mm in height and 150mm in breadth was then placed on the center of the ground surface carefully. Mass of the footing is 2.5kg, giving the base contact pressure, p_f=100kPa in 50g. The model ground was fixed on a mechanical type shaker (Kimura et al, 1988) and then put into a vacuum tank with the shaker to saturate the sand by introducing deaired water from the bottom of the box. After saturating the sand, the shaker was then mounted on Tokyo Tech Mark III Centrifuge and displacement sensors were placed at locations shown in **Figures 4(a) and (b)**. Having completed the test setup, the centrifugal acceleration was gradually increased up to 50g.

2.3 Test cases and shaking tests

a) Saturated model

As a reference of the desaturated model, shaking test was conducted for saturated model sand without desaturation process.

After confirming the equilibrium condition of the model sand in 50g, a shaking test was conducted by applying a sinusoidal motion using the shaker in about 1.0 second with the frequency of 40Hz (**Figure 5**). The prototype duration and frequency of the input motion are 50sens and 0.8 Hz respectively. During the shaking test, accelerations, excess

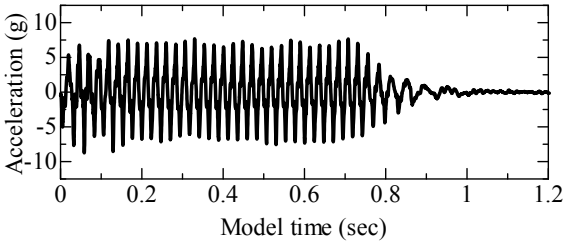

Figure 5 Input base acceleration of the centrifuge test.

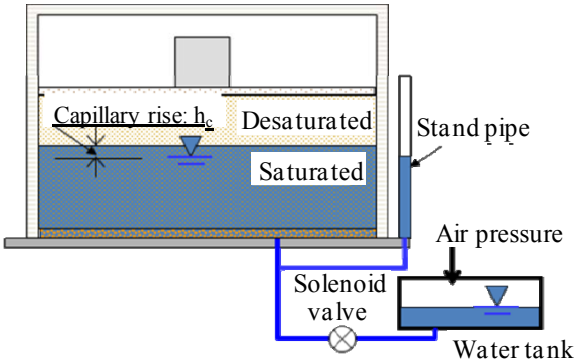

Figure 6(a) Desaturation process by ground water lowing and rising: GWL.

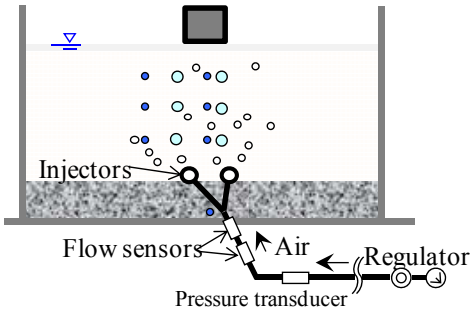

Figure 6(b) Desaturation process by air injection: AI .

pore water pressures and settlements were measured by the sensors shown in **Figure 4(a)**.

b) Desaturation by lowering and raising ground water (GWL)

In 50g, the water was drained from the bottom to the water tank by opening the solenoid valve (**Figure 6(a)**). The valve was closed when the groundwater level (GWL) in the standpipe lowered to the bottom of the Silica sand No.8 layer. Achieving a stationary reading in the Time Domain Reflectometry (TDR) sensor, the water was recharged from the bottom by applying air pressure to the water tank and opening the valve.

Confirming no change in the reading of TDR sensors and PPTs after the water table recovered to the original level, a shaking test was conducted by applying the same input motion as the saturated case.

c) Desaturation by air injection (AI)

In 50g field, the air was injected through the injector by increasing air pressure gradually. This injector is made by porous ceramics, which produces very minute air bubbles. Air pressure transducer and flow sensors were positioned along pressure line as shown in **Figure 6(b)**.

Air pressure transducer provided continuous measurements of the air pressure at the bottom of test box prior to the onset of injection. Flow sensors measured the rate of injected air. The air injection was stopped when TDR sensors reached a stationary state.

Confirming no reading change in TDR sensors and PPTs after stopping air injection, the shaking was conducted as described earlier.

Conditions of test cases are summarized in **Table 2**.

Table 2 Test cases and conditions

Test code	Saturated	GWL	AI
Relative density: Dr	64%	64%	64%
Desaturated area	Non	whole	Below footing
Degree of saturation	100 %	89-95 %	95-98 %
Input accel. amplitude	8g	8g	8g

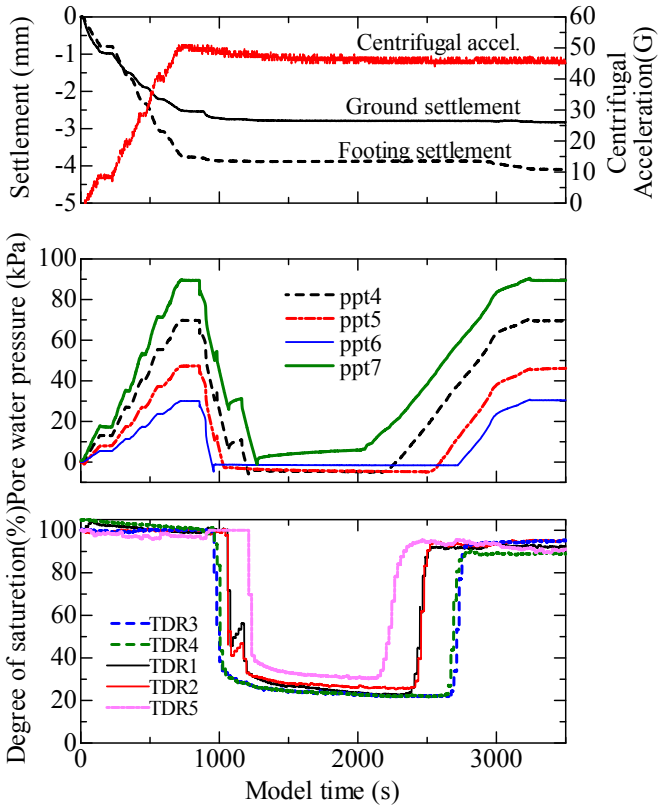

Figure 7 Variation of settlement, pore water pressure and degree of saturation in G-increase and desaturation process: GWL.

3. TEST RESULTS AND DISCUSSIONS

In the following discussion, test results are given in prototype scales except for **Figures. 7, 8 and 9.**

3.1 Desaturation process

1) Lowering and raising groundwater (GWL)

Figures 7 show observed settlements, pore water pressures and degrees of saturation observed during the desaturation process of GWL. Depth profiles of the minimum S_r and the S_{r_res}, which were observed during and after desaturation process, are depicted in **Figure 9**. The degrees of saturation in the desaturation process were calculated from the water volumetric content measured by TDRs assuming full saturation before lowering the water table. For the case of GWL, S_{r_res} was observed to increase with depth. By lowering the GWL, S_r decreased to about 20% and plateaued to 87% to 92% after the GWT returned to its original position.

R_u/R_s estimated by equations (1) and (2) with σ_c', p_0 and e, together with those for different S_{r_res}s range from 1.8 to 2.2. The liquefaction resistance increased with a decrease in the degree of saturation. For the same S_{r_res}, R_u/R_s increases with depth due to the effects of effective confined pressure. But this effect could be cancelled by the increase of S_{r_res} with depth for the GWL case, giving the less variation of R_u/R_s with depth. On top of that, it should be noted that the sand was overconsolidated by the increase of effective unit weight in GWL process and suction induced by the desaturation to the relatively small S_r (see **Figure 2**). Considering the high suction with smaller S_{r_min} and smaller vertical stress σ_c', it is expected that the overconsolidation ratio was larger at the shallow depth than the deep depth.

2) Air injection (AI)

Figures 8 shows the variation of injection pressure and air flow rate with time in the AI case. Observed variations of S_r are also shown in the figure.

Observed S_{r_min} and S_{r_res} of AI case are shown in **Figure 9**. The minimum degrees of saturation of AI case were much higher compared to those of GWL case. As a

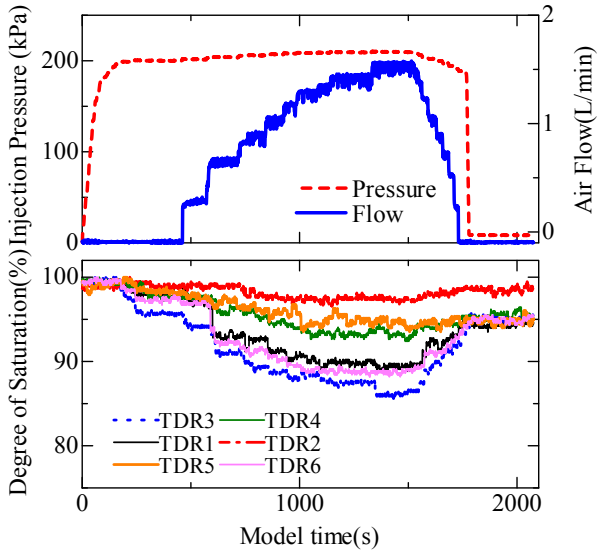

Figure 8 Variation of air flow rate, injection pressure and degree of saturation during air injection: AI

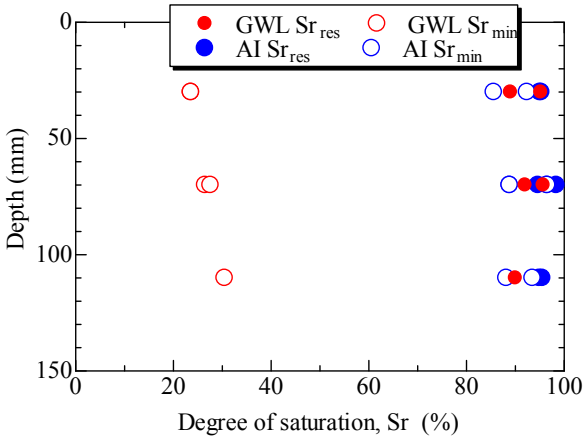

Figure 9 Minimum and residual degrees of saturation obtained in GWL and AI tests.

result, the residual degrees of saturation of AI were higher than those of GWL case. As for the area to which the air bubbles reached, it could not be confirmed by the TDR sensor, as all sensors responded similarly except of the TDR 2, middle depth below footing. However, from the pore water pressure behavior during the shaking, it could be inferred that the air could horizontally reached between the locations of TDR1 and ppt2 at the middle depth and the location of ppt3 at the shallow depth.

3.2 Shaking test

1) Acceleration response

Horizontal accelerations which were observed by the accelerometers at the upper free ground are compared for 3 cases in **Figure 10.** Clear attenuation was observed in the saturated case and the air injection case but not in the groundwater lowering and raising case. **Figure 11** shows variations of the accelerations measured at the top and bottom of the footing. For AI case, large noise in data was

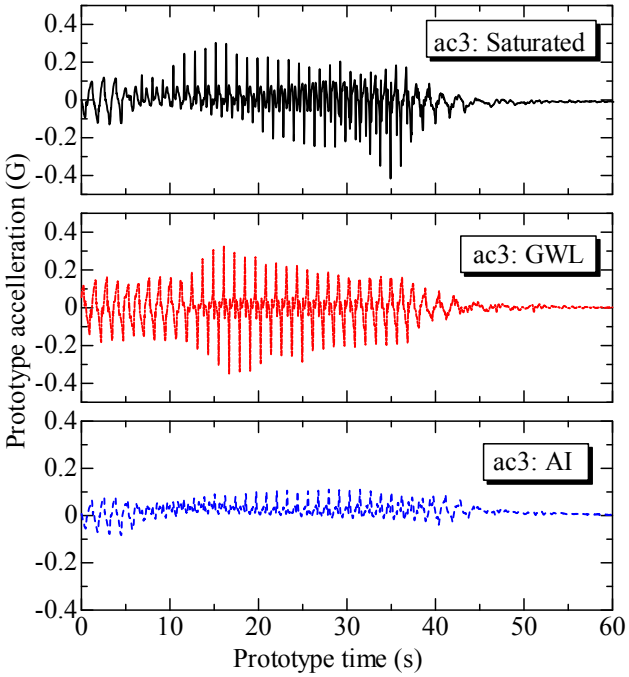

Figure 10 Observed acceleration at the shallow depth in level ground (ac3).

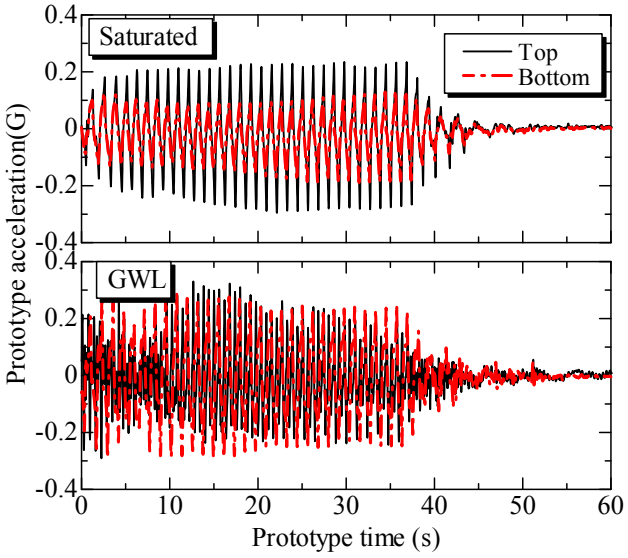

Figure 11 Observed accelerations at top and bottom of the footing.

observed, thus was not included in the presentation of results. In Saturated case, the amplitude at the top was larger than that at the bottom, showing a clear rocking motion. While in GWL case, the similar accelerations were observed at the bottom and top, but they are amplified larger than the input acceleration.

2) Pore water pressure behavior

Figure 12 compares the generated excess pore water pressure (Δu) during shaking, as measured by different pore pressure transducers (ppt) for all the cases. In this figure, effective vertical stress (σ'_{v0}) and effective vertical stress due to footing pressure (σ'_{vf}) are also shown. Generally the

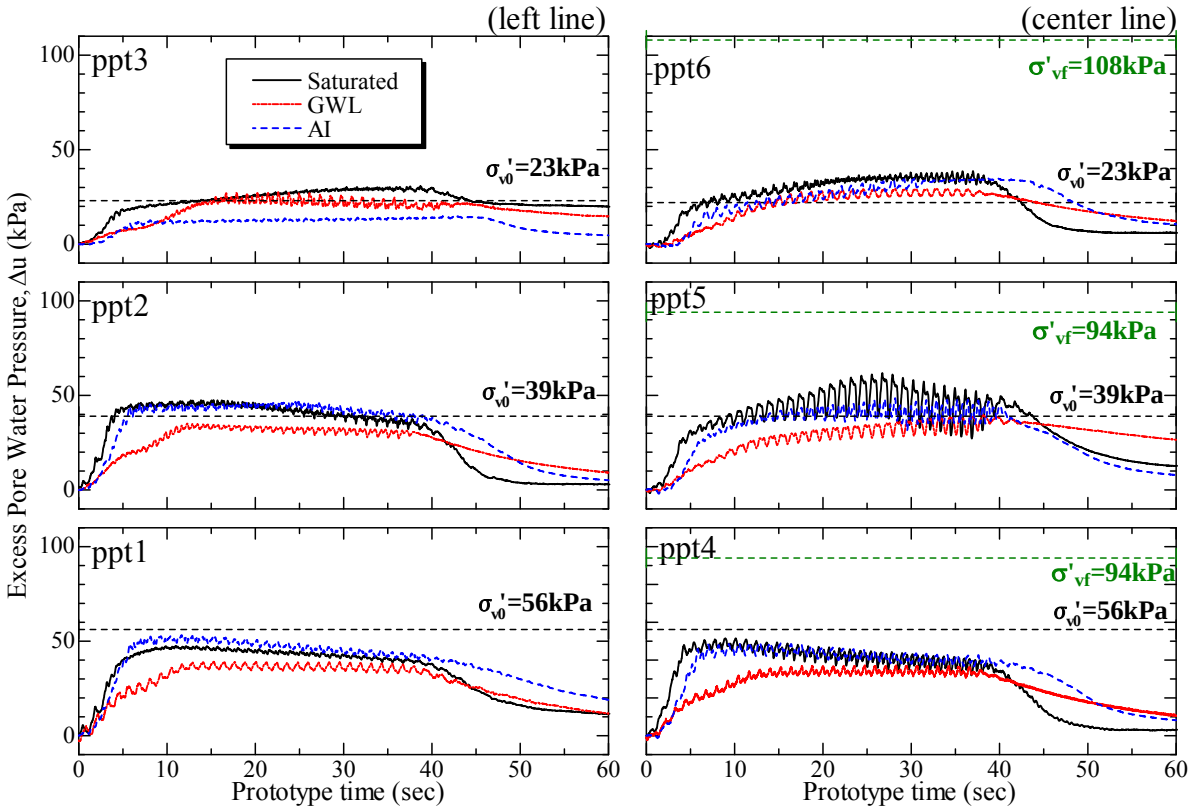

Figure 12 Excess pore water pressures observed during shaking . σ'_{v0} is the effective vertical stress in free field ; σ'_{vf} the effective vertical stress underneath the footing.

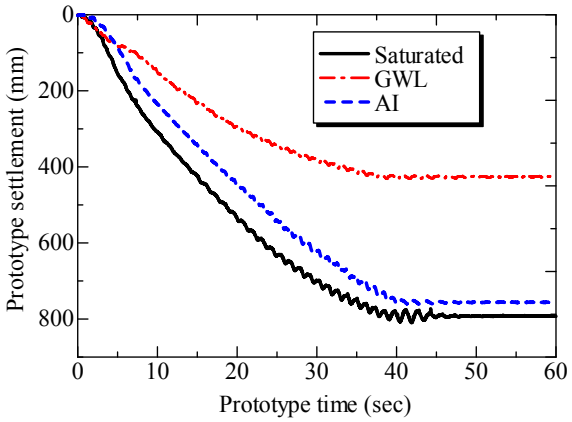

Figure 13 (a) Footing settlements observed during the shaking.

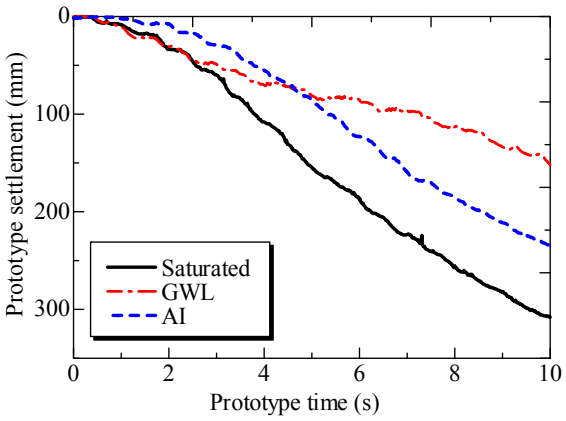

Figure 13 (b) Footing settlements observed in the early stage of shaking.

excess pore water pressures were smaller for the desaturated cases than for the saturated case. However Δus observed at ppt1 and ppt2 are almost the same, which indicates the extent to which air propagated and inhibited the generation of pore water pressure. Thus, the effectiveness of AI could be limited in the region enclosed by ppt3 to ppt6.

The excess pore water pressures generated in GWL case are smaller compared to Saturated and AI, except of AI case in the early stage of shaking before 4-5 secs. This difference in the efficiency of preventing Δu generation could be attributed to the higher S_r of AI case than GWL case and overconsolidation effect introduced in GWL case. Both desaturated cases show less amplitudes of excess pore water pressure change in the cyclic behavior, indicating the effect of air compression in the soil pore. Furthermore the dissipation of Δu after the shaking was slower for the desaturated case than the saturated case especially for GWL case, which also implies the effects of high compressibility on the coefficient of consolidation.

It should be note that even in GWL case Δu gradually increased with time and got close to the values of the other cases in the later stage of shaking.

3) Settlement behavior

Observed settlements of the footing during shaking tests are shown in **Figure 13(a).** Marked efficiencies of desaturation in preventing the footing settlement can be confirmed especially for GWL case. The footing settlement of GWL is about 390 mm (50%) smaller than that of saturated case. Such clear improvement effect in reducing the settlement cannot be confirmed for AI case. However, from the settlement behavior in the early stage of shaking (**Figure 13(b)**), the settlement of AI case is found delayed and smaller than that of Saturated case.

In **Figure 14**, settlement rates of the footing during shaking are shown together with the excess pore water pressure ratio obtained at ppt5. Some correlation between the rate and Δu can be confirmed in the period of rapid increase of Δu. But the rate gradually decreases after the rapid increase of Δu. Due to the delay of the Δu increase the time at the peak of the rate of GWL was also delayed. The rate of AI case became larger than that of Saturated case in the later stage of the shaking.

Total footing settlements of three models are compared by bar chart in **Figure 15**. The settlements in different time period are shown in the figure with the ratio of the settlement in each period to that of Saturated case. From the figure it can be reconfirmed the effect of desaturation in the different loading periods. The desaturation in the limited area underneath the structure by air injection could have limited efficiency for reducing the settlement in the beginning of the shaking and the settlement in the subsequent shaking is almost the same or even larger than the saturated case. On the hand the desaturation by GML has efficiency for long time.

The above mentioned effect of desaturation in wide area can be more clearly confirmed in preventing the inclination of the footing (**Figure 16**). Very small inclination took place by the shaking for GWL case, but the very large inclinations were observed in Saturated and AI cases. Although, the accumulated inclinations are comparable for the two cases, the amplitude of AI case was larger than that of Saturated case. This observation implies that the larger amplification of the footing took placed in AI case than Saturated case, could be a reason why the settlement rate of AI case became larger than that of Saturated case in the later stage of shaking (**Figure 14**). Although the stiffness of the sand under the footing was deteriorated but the reduction of stiffness is expected smaller than that of Saturated case. This is attributed to the difference in the dynamic response between Saturated and AI cases.

4. CONCLUSIONS

From the centrifuge done in this study, the following conclusions can be drawn about the dynamic behavior of the desaturated sand with a super structure during relatively long shaking motion.

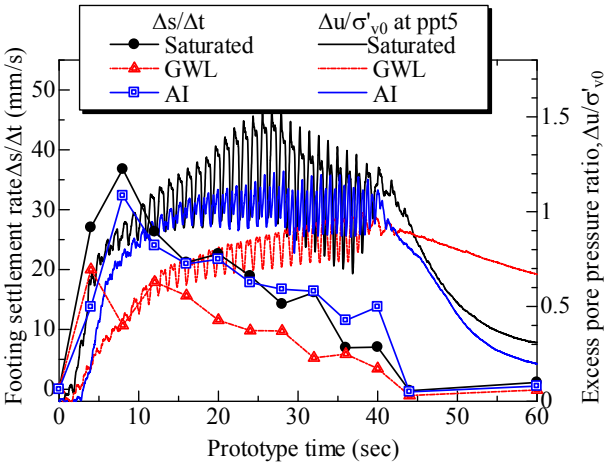

Figure 14 Variation of settlement rate of the footing and excess pore water ratio $\Delta u/\sigma'_{vo}$. of ppt5.

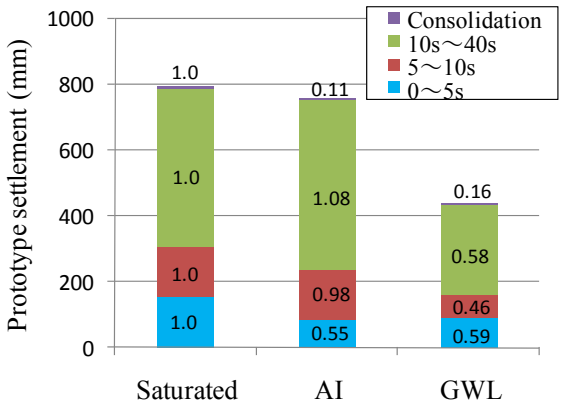

Figure 15 Comparison of settlement at various shaking period..

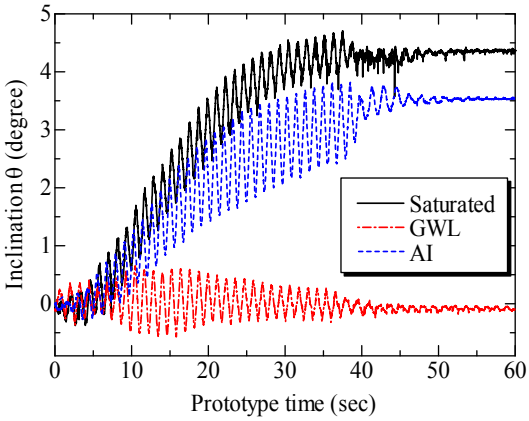

Figure 16 Inclination of the footing during the shaking.

1) Air injection (AI) and ground water lowering and raising (GWL) processes were able to inhibit the generation of excess pore water pressures especially for the latter process.
2) GWL process can securely provide the desaturation in a wider area of the ground and introduce overconsolidation. Because of these combined effects the GWL process can have a wide-ranging effect in terms of prohibiting the occurrence of liquefaction. However, even for the GWL process, the excess pore water pressures gradually increase with time and reach to those for the saturated case. The prevention of pore water pressure generation by GWL process can contribute to the reduction of the settlement of the structure, especially to the reduction of the differential settlement.
3) Air injection can make desaturation in the area of interest below the structure. If the injected area is small, the effect of AI process is very limited for very short period of shaking. After the level of pore water pressure at the mid-depth reached to that of the saturated case, settlement rate became the same of that of the saturated case and even larger.

Abstract: Underground structures are typical infrastructural components in mega cities around the world and range from tunnels, underground parking facilities, storage units, industrial/service structures to shopping centers as well as entertainment and sports facilities. In seismic active areas those underground systems are particularly vulnerable to earthquake damage. In order to better understand the behavior of underground structures and the soil - structure interaction when subjected to various levels of earthquake shaking, a large scale shake table experiment was conducted at E-Defense in Miki, Japan in February of 2012. With the aim of gaining insight in the interactive behavior between underground structures and surrounding soil, a set of innovative load cell based pressure sensors was developed and installed along a vertical shaft of 6.5m depth. Measurements of seismic soil pressures for various levels of shaking (50% & 80% Kobe 1995) were recorded and evaluated to be compared with traditional theories and current design methods. Consistent with classical observations, the pressure distribution was found to increase linearly with depth. A strong dependency of pressures on the level of acceleration was noticed. While classical methods significantly under-predicted measured pressures at small accelerations (<0.2g), pressures at accelerations larger than 0.4g tended to be smaller than theoretical methods suggest.

1. INTRODUCTION

Underground structures are typical infrastructural components in mega cities around the world and range from tunnels, underground parking facilities, storage units, industrial/service structures to shopping centers as well as entertainment and sports facilities. In seismic active areas, underground systems are particularly vulnerable to earthquake damage with consequences extending from minor structural damages (e.g., repairable crackings) and temporary closure (economical loss) to superstructure collapse and loss of lives. Typical lateral design of foundation systems and retaining structures often relies on classical (static) earth pressure theories and frequently tends to neglect seismic effects due to the lack of understanding thereof and the shortcoming of experimental data. While this assumption can be accurate for foundation systems exposed to small levels of seismic shaking, stronger accelerations due to larger magnitude earthquakes as observed during the past three years (Chile 2010, New Zealand 2010, Haiti 2010, Japan 2011) can cause significant damage to the foundations and the superstructures.

Retaining structure failures due to large lateral pressures (resulting from wall damage, post liquefaction lateral spreading or a combination of excessive lateral impact loads and soil displacement) are often observed during reconnaissance efforts, in particular, in port regions and urban areas with condensed underground construction. With the aim of gaining insights in the interaction between underground structures and the surrounding soil, as well as the soil pressures developed against the retaining structure, a set of newly developed load cell based pressure sensors was exported to Japan to be installed in an experiment that investigated the behavior of underground structures during a variety of seismic events. The project was conducted the Hyogo Earthquake Engineering Research Center (E-Defense) in Miki, Japan (Lead Principle Investigator) in collaboration with the Network for Earthquake Engineering Simulation (NEES).

2. LITERATURE REVIEW

2.1 Classical Approaches

In 1776, Charles Coulomb was the first scientist to study the static lateral earth pressures on retaining structures (Kramer, 1996). Using the concept of an imaginary planar surface inside the backfill where the weight of the soil above this surface created the lateral earth pressure acting on the structure, Coulomb determined the magnitude of the soil thrust acting on the retaining structure for both minimum active and maximum passive earth pressures using the principle of force equilibrium. Rankine (1875) simplified Coulombs approach by making assumptions about the stress conditions and strength envelope of the backfill soil as well as by neglecting the wall soil interface friction angle to obtain minimum and maximum lateral pressures on the wall. Extending Coulombs theory further, Okabe (1926) along with Mononobe and Matsuo (1929) developed a method of estimating seismic soil pressures following the 1923 Great Kanto Earthquake in Japan. Known as the M-O method, the

Mononobe-Okabe approach is currently the most widely used method in practice for estimating seismic soil pressures. The total active dynamic thrust per M-O can be expressed as

$$P_{AE} = \frac{1}{2} K_{AE} \gamma H^2 (1 - k_v) \quad (1)$$

where P_{AE} is the seismic active earth pressure, K_{AE} is the dynamic active earth pressure coefficient, γ is the unit weight of the soil, H is the height of the backfill material and k_v is the vertical acceleration in the soil mass in g. The point of application of the M-O active resultant force is assumed to be at a height of *H/3* above the base of the wall. The total pressure on the retaining system can be determined by adding the static (P_A) and dynamic (P_{AE}) active thrust as

$$P_A + P_{AE} = P_{TOT} \quad (2)$$

Seed and Whitman (1970) adapted the M-O method in predicting the seismic earth pressures, but suggested that the point of application of the dynamic increment thrust should be between 1/2 to 2/3 the wall height above its base. In particular, Seed and Whitman recommended that the dynamic component acts at approximately 0.6H from the base. This introduced a concept of inverted triangle where the base of the triangle is inverted to be on the top. Seed and Whitman expressed the seismic active earth pressure as:

$$P_{AE} = \frac{1}{2} \gamma H^2 \left(k_A + \frac{3}{4} k_h \right) \quad (2)$$

where k_A is the active static earth pressure coefficient per Coulomb and k_h is the horizontal seismic acceleration.

2.2 Recent Numerical & Experimental Studies

Gazetas *et al.* (2004) presented a numerical study of dynamic stresses imposed on a variety of retaining systems under short-duration and impulsive base excitation. Rigid and flexible systems were modeled using FEM analysis and subjected to ground motions such as the 1999 Athens earthquake. In general results showed that total shear force and overturning moment acting at the base of the wall were smaller than those computed with the M-O theory for the same acceleration.

Psarropoulos *et al.* (2005) developed a general finite-element method that specifically focused on the distribution of dynamic earth pressures on rigid and flexible walls. The analytical model investigated the effects of wall rigidity and the rocking base compliance, combined with both: homogeneous and inhomogeneous backfill, as well as backfills with a multi-layer soil system. By trial analyses of numerical modeling, this study observed that the magnitude of the wall pressures was proportional to the wall height. Results from this experiment also confirmed the general agreement between M–O and elasticity-based solutions for structurally or rotationally flexible walls.

Madabhushi and Zeng (2007) conducted centrifuge tests accompanied by numerical simulations to investigate the seismic response of cantilever retaining walls under earthquake loading backfilled with dry and saturated soil material. Earthquake effects were more severe on the retaining system with saturated backfill than that with dry backfill due to the combined effects of increased inertial force, hydrodynamic pressures, and excess pore pressure in the backfill material.

Al-Atik and Sitar (2010) conducted a combined analytical (FEM) and experimental (centrifuge) research program to evaluate the magnitude and distribution of seismically induced lateral earth pressures on cantilever retaining structures with dry medium dense sand backfill. Two centrifuge tests with a flexible and a stiff retaining wall placed in a soil container filled with a two-layer sand model with varying stiffness were performed under various ground motions. The observed pressure distribution can be reasonably approximated as triangular with the resultant force located approximately 1/3 above the base of the wall, as suggested by Mononobe-Okabe. The measured dynamic pressure magnitudes were generally inconsistent with the M-O assumptions and maximum values did not occur in phase with inertial forces. The measured dynamic pressures on both stiff and flexible walls were about 65% of what was estimated by Mononobe-Okabe. The experiment also observed that dynamic effects at the maximum dynamic wall moments were not significant when the peak ground acceleration did not exceed 0.4g, that is, for peak ground accelerations less than 0.4g, the maximum dynamic wall moment was mainly due to the inertia of the wall itself and seismic soil pressures are generally negligible.

Sitar et al. (2012) expanded the centrifuge testing program to braced and un-braced, U-shaped, underground structures interacting with a free standing cantilever wall placed in a flexible shear beam container. Results showed that the seismic earth pressure increments increased with depth, which is consistent with the static earth pressure distribution. Pressures predicted using the M-O approach formed the upper limit for the results. The inverted triangle of dynamic earth pressure increment, computed using the Seed and Whitman (1970) solution, was not observed during the experiment. However; results showed that the Seed and Whitman (1970) approximation represented a reasonable upper limit for the value of the seismic earth pressure increment for both fixed base cantilever structures (U-shaped walls) and cross-braced, basement-type walls. For the case of the free standing cantilever walls, small amounts of rotation and translation significantly decreased the forces acting in the retaining structure. This data was consistent with the suggestion by Seed and Whitman (1970), that well designed retaining structures should be capable of withstanding ground motions with PGA of 0.3g without the need for specific seismic design provisions.

3. Experimental Setup

3.1 Test Specimen

The test specimen consisted of a 40-ring laminar container with dimensions of 6.5 m in height and 8.0 m in

diameter, as shown in Figure 1. The soil container was mounted on the shake table as empty container and then furnished with underground test structures and filled with soil material. The underground system consisted of two shield tunnels in horizontal direction at the bottom of the soil container, two vertical shafts and a cut-and-cover tunnel connecting the vertical shafts via a rigid and a flexible joint (see Figure 2). All structures were aluminum constructions scaled at a ratio of 1/20 to approximate the stiffness/flexibility of the prototype model.

Figure 1: Laminar Soil Box mounted on E-Defense's Shake Table (Photo: Y. Kawamata)

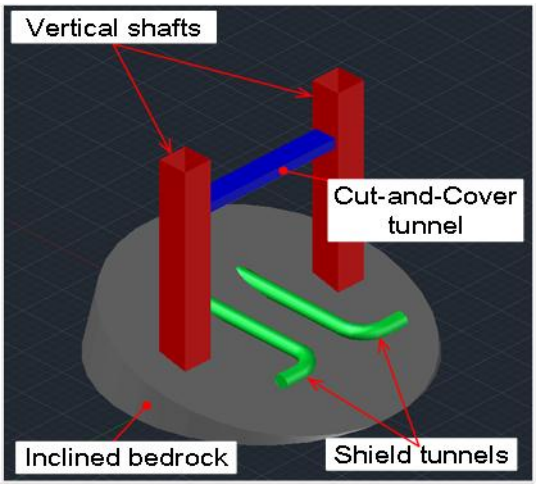

Figure 2: Model of Underground Structures placed inside the Laminar Soil Box (Source: Kawamata et al., 2012)

The two independent shield tunnels embedded in soil material at a lower elevation in the container (green) represent typical underground transportation systems. Both tunnels were placed partly in stiffer (cemented) soil and partly in softer soil as indicated in Figure 2. The tunnels had a diameter of 0.4 m and were located at approximately 1.1 m from the bottom of the container. The two vertical shafts represent vertical infractructure components such as elevators, station buildings, emergency exits, maintainance facilities etc. The vertical shafts were built as 0.8 m square hollow sections and were fixed to the bottom of the contained via bolts, as well as embedded in the stiff cemented soil that was placed underneath the sand fill. The upper horizontal cut-and-cover tunnel system is used to model underground structures such as shopping centers, transit stations, possibly office or maintainance/storage facilities. The horizontal tunnel was connected to the vertical shafts via flexible and rigid joints and were 0.6 m wide and 0.3 m high. The tunnel was located at an elevation of 5.3 m from the bottom of the container and was covered by a 0.4 m thick layer of soil fill (soil surface elevation).

3.2 Instrumentation

The test specimen was instrumented with sensors consisting of strain gauges, LVDTs, accelerometers, soil-pressure sensors and optical devices to monitor the specimen behavior during test conduction. US funding through the Natioanl Science Foundation (NSF) was provided to develop and install load cell based soil pressure sensors on one of the vertical shafts. The selected shaft was the vertical shaft with the rigid cut and cover tunnel connection and is shown as the shaft on the left side in Figure 6. Pressure sensors were developed by AFB Engineered Test Systems and modified for this particular application. The sensors (shown in Figure 3) have a surface area of 78.54 cm^2 (Diameter of 10 cm) and a capacity of 144kPa (3ksf) and 288 kPa (6ksf) respectively. Higher capacity sensors were installed at lower shaft elevations. The sensors were manufactured with aluminum cases to comply with the shaft material and attached using special ring adapters from the inside of the shaft. In this manner the sensor surface and the vertical shaft surface were one continous flush area and localization effects around the sensors were avoided. As shown in Figure 4, a total of 20 pressure sensors were installed by US collaborators distributed over 3 shaft sides. Readings of the pressure sensors were recorded at a frequency of 200 Hz.

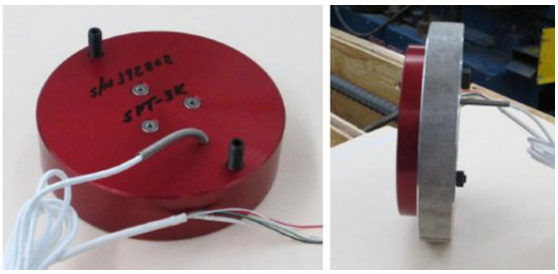

Figure 3: Soil Pressure Sensor installed along the vertical shaft

3.3 Soil Material

The soil consisted of fine sand (#48 Albany Silica Sand) and was placed in multiple layers in the laminar container. Approximately 1000 tons of material were used and compacted to about 35% relative compaction using vibratory equipment as well as via mechanically dropping of weights. Soil properties were investigated via laboratory testing in Japan (Kawamata *et al.*, 2012, and personal communication) and revealed a unit weight γ of 1.616 g/cm^3, an average relative density D_R of 55%, and a water content w

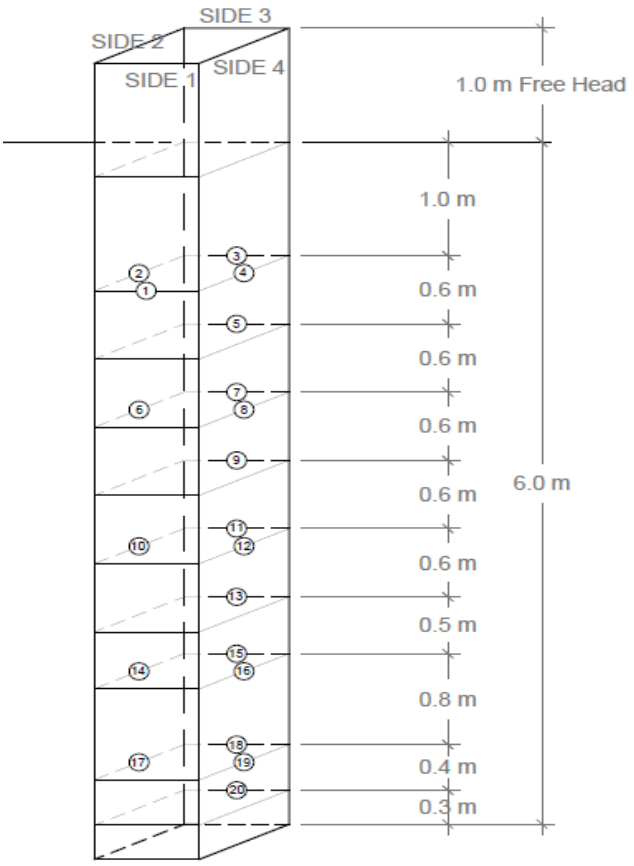

Figure 4: Installation location of pressure sensors

of about 5.1%. Triaxial shear tests (CU) for soils at D_R of 40% revealed a friction angle ϕ of 31.7° and a cohesion *c* of 31.8 kPA. A second soil sample tested at D_R of 60% showed a friction angle of 35.5° and a cohesion of 18 kPA.

The soil material at the bottom of the soil container was mixed with cement to create a stiff layer at the container bottom that could simluate a bedrock layer in the prototype model. Figure 5 shows the soil material in storage at the E-Defense facility and Figures 6 and 7 show the test specimen in plan and section view and indicate the "bedrock" layer and its geometry in the soil container.

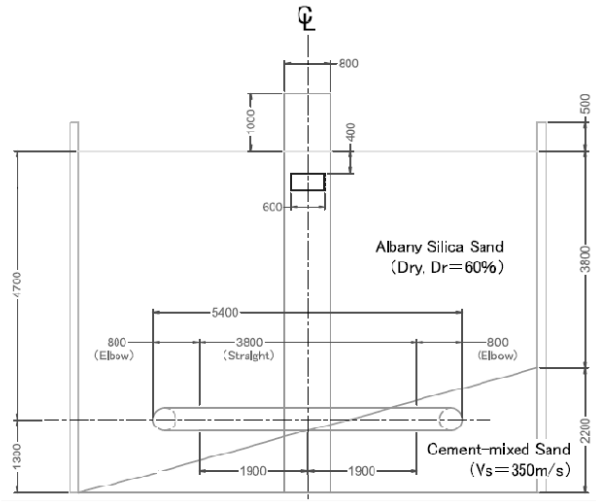

Figure 7: Section View (B' – B') of Soil Container (Drawing: Y. Kawamata)

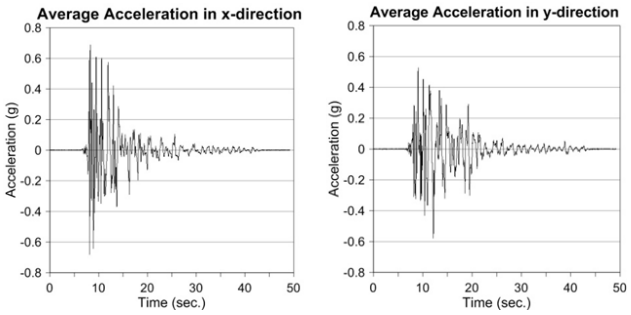
3.4 Input Motions

The experiment was performed using input ground motions of the 1995 Kobe earthquake scaled to 50% and 80% of the accelerations measured at the JR Takatori station in Kobe, Japan. Table motions were observed to vary slightly from the target input due to noise in the hydraulic system, the interaction between the table and the test specimen and the nonlinar behavior of the test specimen itself (Kawamata *et al.*, 2012). Table accelerations were measured at four location on the shake table and are presented in Figure 8 for the 80% scaled Takatori record. The input motions were two- dimensional (x & y only), however a vertical (z) acceleration was recorded in the accelerometers that can be addressed to table rocking during the experiment conduction. Vertical accelerations showed a magnitude of only 4-6 % of the horizontal acceleration and are therefore negligible. The NS component of the Jakatori

earthquake was input in the specimen's y-axis and the EW component was applied to the specimen's x-axis.



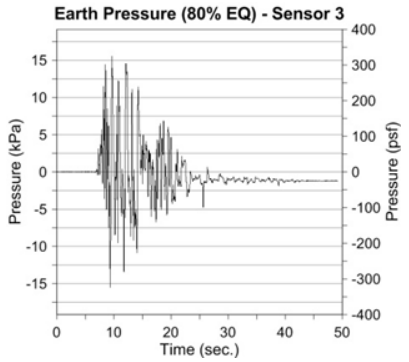


Figure 8: Table Records of Input Motion: 80% Takatori Station, 1995 Kobe Earthquake

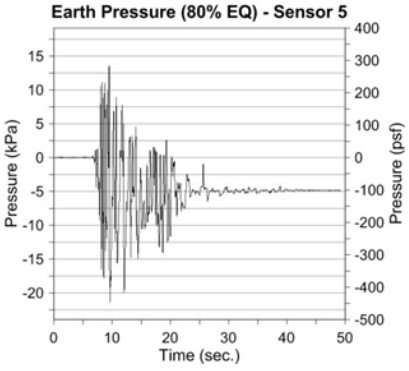
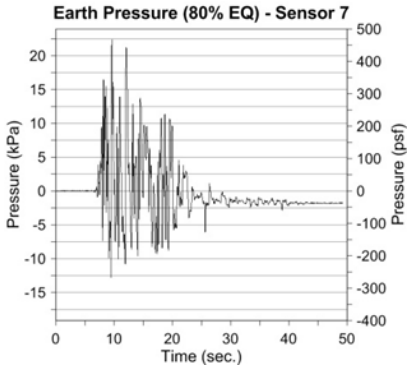
A series of step sine motions gradually increasing from 1-20 Hz was conducted on every test day prior to the actual shake table experiment to better quantify the obtained test results. Sine sweep results are not shown for briefty of this paper.



4. PRELIMINARY RESULTS

4.1 Soil Pressure Time Histories



Figures 9a-i show exemplarily the seismic increments of the pressure-time histories along side 3 of the vertical shaft during the 80% Takatori input motion. Side 3 has the densest instrumentation and faces the laminar soil box in (-)x direction in Figure 6. It can be observed that the soil pressures increase with depth up to the embedment of the vertical shaft in the cemented soil (sensors 18 & 20). Pressures reduce significantly as the shaft and the cemented soil move together (likely as "*rigid*" body) at the bottom of the container. To reiterate, the graphs shown in Figure 9 (a-i) only present the seismic pressure increment since all instrumentation installed in the test specimen was "zeroed" before test begin.

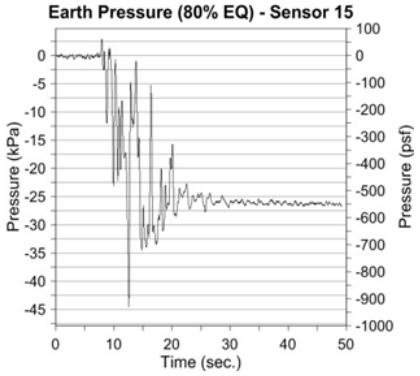
@ - 2.2m



@ - 2.8m

@ -3.4m

@ -4.0m

@ -4.5m

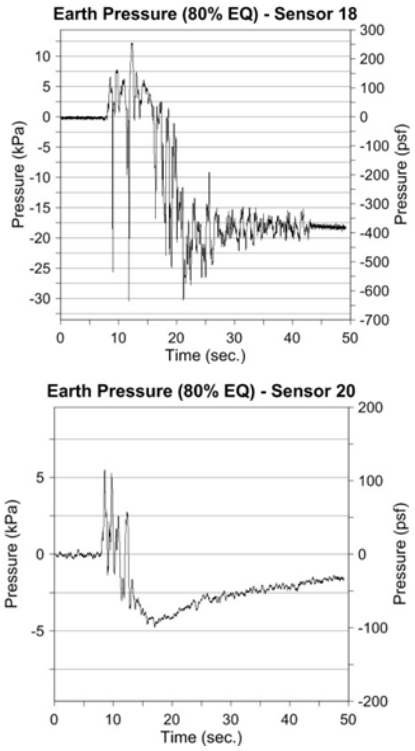


Figure 9a-i: Soil Pressure Time Histories at Various Locations along the Vertical Shaft

The time histories indicate a permanent shift of the measured seismic pressures with residual values up to 24 kPa (500 psf). Residual pressures increase with depth up to the point of fixity of the shaft into the cemented material. The same trend was observed during the 50% shaking with only slightly smaller residual pressures. Settlement of the soil material occurred during both tests (50% and 80%), with a stronger settlement noticed during Test 1 (50%), in particular underneath the cut and cover tunnel. This observation was expected given the relative low percentage of relative compaction of the soil material (RC ~ 35%) and led to significant densification of the soil towards the bottom of the laminar container.

4.2 Earth Pressure Distribution

The vertical earth pressure distribution along side 2, 3 and 4 for the vertical shaft with the rigid joint is shown for selected accelerations in Figures 10, 11 and 12. Data measurements are currently still being processed and more results will be available for publication in the near future to provide a detailed insight into both, ground motion tests and sine sweeps.

The pressure versus depth distribution is relatively similar in magnitude and shape for all continuously instrumented sides. Side one had only one sensor installed at the top and therefore does not provide any meaningful data. The soil pressures increase approximately linearly with depth up to a depth ratio of *z/H* of 0.7, where *z* is the depth of the sensor inside the soil taken from the top surface, and *H* is the total depth of the soil inside the laminar box. Beyond depths of 4.5 m from the surface, the soil pressures reduce significantly as the shaft is fixed into the cemented material and moved along with the cemented material similar to a rigid body motion. The "*fixity*" at the bottom leads to a parabolic shape of the total pressure distribution as indicated in Figures 10-12. The total active seismic pressure resultant occurs at a height of 0.4 – 0.44 H from the bottom of the shaft.

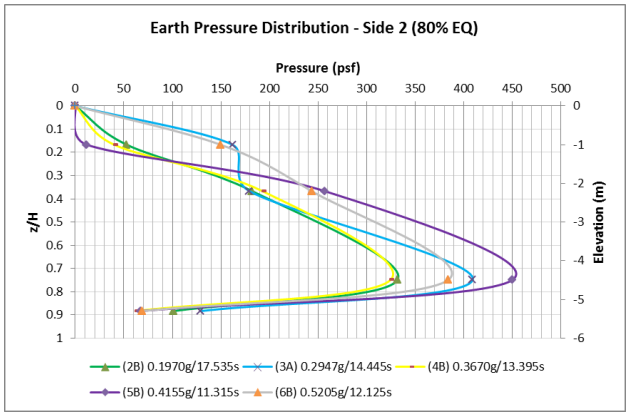

Figure 10: Pressure distribution vs. depth along side 2 of the US- instrumented vertical shaft

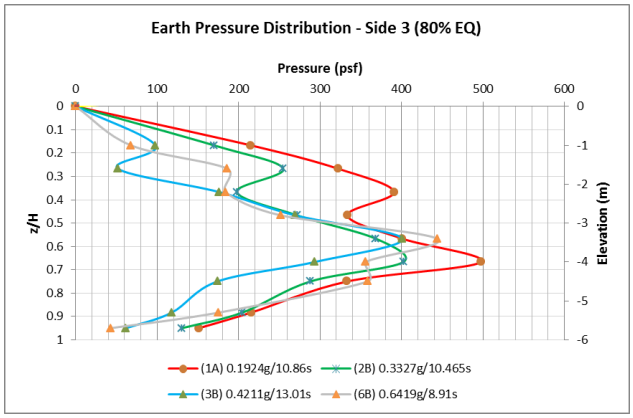

Figure 11: Pressure distribution vs. depth along side 3 of the US- instrumented vertical shaft

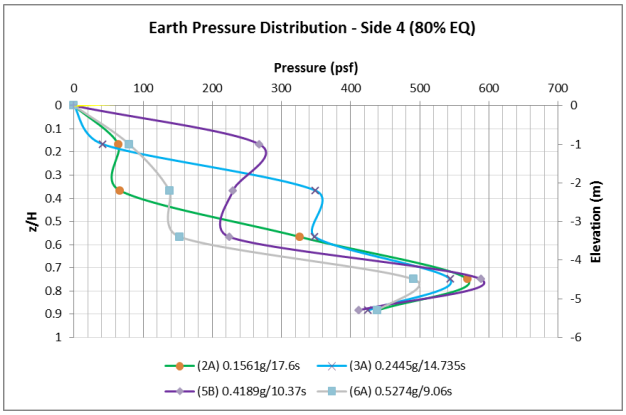

Figure 12: Seismic pressure distribution vs. depth along side 4 of the US- instrumented vertical shaft

The soil pressure at the bottom of the shaft does not return to

zero pressure but recorded small pressures between 2 – 7 kPA (50 – 150 psf) due to slight movement of the vertical shaft. Post test excavations revealed that part of the fixed connection at the bottom of the container was loosened (during Test 1 at 50% ground motion) allowing for small rotations of the shaft starting at the bottom of the container (personal communication with Dr. Kawamata). This rotation (pounding against the cemented materials) may be reflected in the non-zero pressures at the depths greater than z/H > 0.75. Straing gauge data are currently being processed by our Japanese colleagues to account and correct for this effect.

4.3 Comparison of Measured and Calculated Earth Pressures

The seismic increment of the vertical earth pressure distribution is compared to the M-O and Seed & Whitman methods for a range of accelerations using equations (1) and (3). The vertical acceleration was taken as constant value using the measured vertical records of the table motions (as explained in section 3.4). Accelerometer readings from sensors placed inside the soil mass are not publicly available at this moment per E-Defense data sharing regulations and will not allow further processing until 2 years following test completion (i.e. February 2014). The presented pressure distributions are collected from both tests (50% and 80%) to present a better range of accelerations and pressures measured therein. All pressure distributions are presented for side 3. The comparisons of interest in Figures 13 - 18 are the red line labeled Dynamic 1 which represents the seismic pressure calculated using the M-O method and the green line labeled Dynamic 3 which represents the Seed and Whitman method. In both methods the seismic soil pressure was determined by calculating the total pressure and subtracting the static portion using the Coulomb theory.

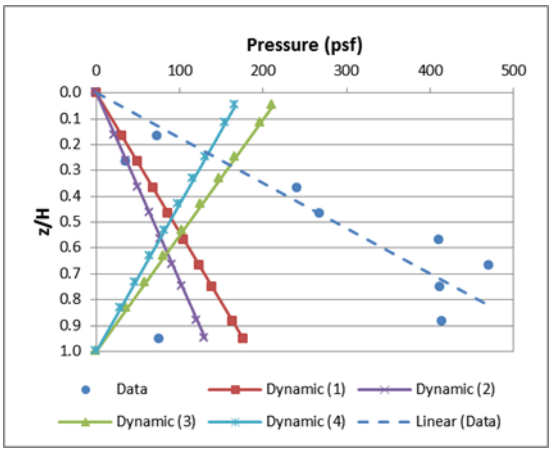

Figure 13: Comparison of measured pressures with the M-O (Dynamic 1) and S & W (Dynamic 3) methods at an acceleration of 0.1495 g

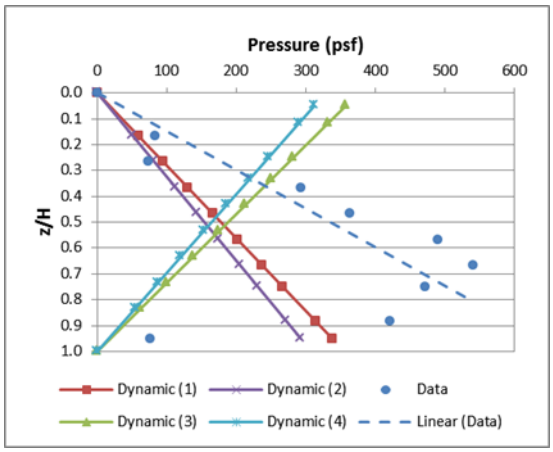

Figure 14: Comparison of measured pressures with the M-O (Dynamic 1) and S & W (Dynamic 3) methods at an acceleration of 0.2523 g

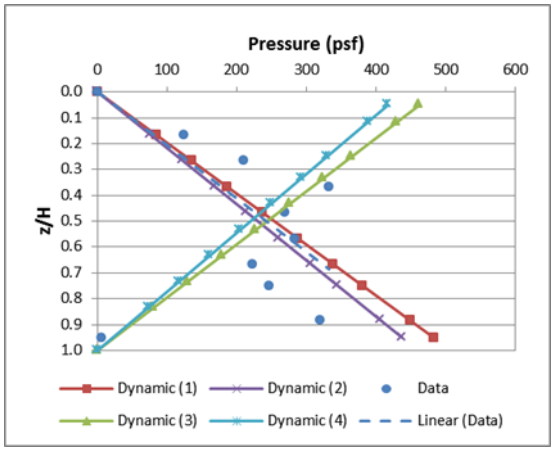

Figure 15: Comparison of measured pressures with the M-O (Dynamic 1) and S & W (Dynamic 3) methods at an acceleration of 0.3627 g

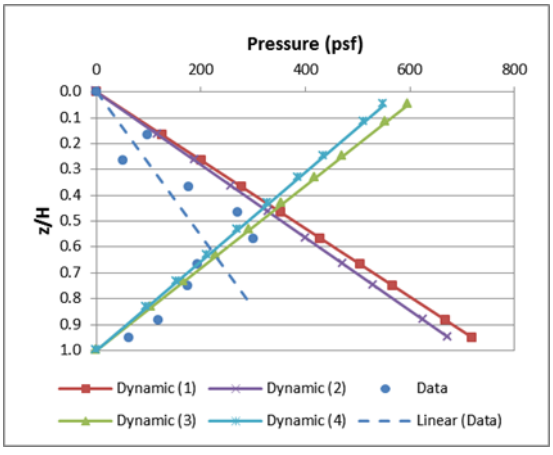

Figure 16: Comparison of measured pressures with the M-O (Dynamic 1) and S & W (Dynamic 3) methods at an acceleration of 0.4211 g

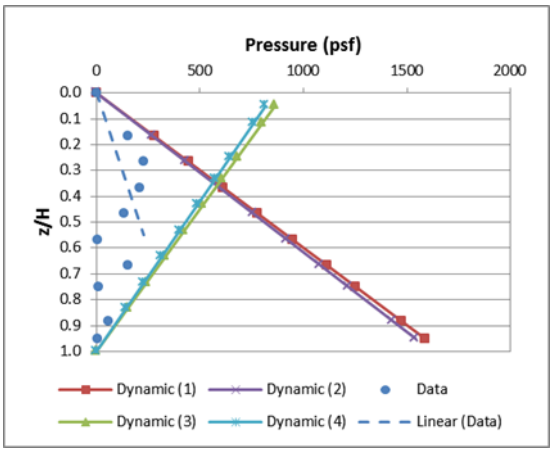

Figure 17: Comparison of measured pressures with the M-O (Dynamic 1) and S & W (Dynamic 3) methods at an acceleration of 0.6093 g

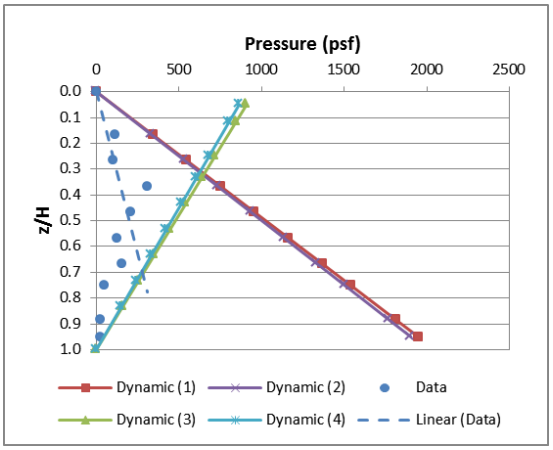

Figure 18: Comparison of measured pressures with the M-O (Dynamic 1) and S & W (Dynamic 3) methods at an acceleration of 0.6423 g

Figures 13- 18 present the variation of the seismic pressure increments along the shaft for table accelerations ranging between ~ 0.15g – 0.64g. For accelerations below 0.3g the measured results showed much larger earth pressures (2-3 times) than estimated using the M-O method (Figure 13 & 14). An approximate linear fit was added to the measured data; however, earth pressures at small accelerations did not show a consistent trend in shape. Measured results and analytical approximations matched comparably well for accelerations around 0.3g – 0.4g (Figure 15). This was observed for both shake table tests and is consistent with findings of other researchers (Seed and Whitman, 1970, Sitar *et al*, 2012). At accelerations beyond 0.4g, measured pressures were only slightly lower than the analytical solutions. Large differences in pressures were observed for accelerations beyond 0.45 g, as shown in Figures 17 and 18 for accelerations > 0.6g. M-O overestimated pressures with magnitudes of almost 10 times compared to test observations, S & W's maximum pressure overestimated the measured values by a factor of 3- 4.

It is important to mention that the observations presented in this manuscript can not be easily generalized since the test structure shows a somewhat different structural behavior than a typical reinforced concrete retaining structure subjected to similar ground motions. In particular, the observed larger pressures at smaller accelerations may be attributed to the flexibility of the vertical aluminum shafts and the relatively loose soil material. This effect is likely not to occur for a stiff retaining wall. While the pressure measurements at small accelerations contradict with previous experimental research findings (e.g. Al-Atik & Sitar, 2010); results observed at larger accelerations agree well with studies found in literature (Seed & Whitman 1970, Sitar *et al*. 2012) and general observations in practice.

Since the test structure is subjected to a much stronger 3-dimensional effect than the implemented analytical methods consider, the authors anticipate to continue and expand this study upon release of further data (e.g. accelerometer readings in the soil mass over the depth of the laminar soil box, strain gauge data along the vertical shaft). Test data should be compared with analytical solutions that consider the effects of wave propagation inside the soil mass, dynamic properties of the soil (e.g. shear wave velocity), the frequency content of the input motion and the acceleration distribution along the vertical height of the test specimen as studied by researchers like Wood (1973), Veletsos et al., (1994) and Ostadan (2005).

3. CONCLUSIONS

A large scale shake table experiment was conducted at the E-Defense facility in Miki Japan to investigate the behavior and interaction of underground structures subjected to scaled ground motions from the Kobe 1995 earthquake. The system of underground structures consisted of 2 vertical shafts connected by a cut and cover tunnel, and 2 horizontal shafts at a lower elevation. The bottom of the container was furnished with cemented soil material at a slope of 2:1 and filled thereafter with Albany Silica sand to a total height of 6.0m. The test structures were heavily instrumented. Measurements from soil pressure sensors installed at one of the vertical shafts are presented in this paper and compared to classical analytical methods such as Monobe-Okabe (M-O) and Seed & Whitman (S & W). Pressures were observed to increase linearly with depth up to the "*point of fixity*" (i.e. the point where the shaft is embedded in the cemented material). Pressures exceeded estimates of the M-O method for accelerations less than 0.3g possibly due to the flexibility of the shaft structure and the properties of the soil material. More work is needed at this point to fully quantify the observed experimental behavior. Measured data and analytical predictions matched reasonably well for accelerations between 0.3g and 0.4g. Seismic pressures at high accelerations (e.g. 0.6g) were significantly lower than analytical methods suggest. The point of application of the dynamic earth pressure resultant was calculated to be between 0.4 – 0.44H from the bottom of the vertical structure. Further studies integrating the dynamic soil

properties and the acceleration distribution / wave length propagation in the soil mass are suggested at this time to fully understand the specimen behavior under a wider range of ground motions.

Acknowledgements:

The authors would like to thank the National Science Foundation (NSF) for providing partial support for the conducted research under award # CMMI 1201213. We highly appreciate the assistance and collaboration of our Japanese colleagues Dr. Kawamata and Dr. Nakayama at E-Defense in Miki, Japan for providing and sharing their facilities and test instruments for the collection of data. Their willingness to accommodate our requests and provide additional data and figures (photographs and graphics shown in this paper) is gratefully recognized. We would like to thank Steve Keowen from AFB Engineered Test Systems and Dr. Alberto Salamanca from NEES@UCLA for their assistance with the sensor manufacturing and calibration. Dr. Akio Abe of Tokyo SOIL is acknowledged for installing the sensors at the test specimen in Japan.

Abstract: Dynamic centrifuge model tests are conducted to investigate the influence of embedded footing on the seismic behavior of a pile-supported building with semi-rigid pile head connections in liquefiable soil. The test results show the followings. (1) The earth pressure acting on an embedded footing with semi-rigid pile head connections works as a reaction force to the inertia force, whereas that with rigid pile head connections acts as an external force during liquefaction. (2) The maximum acceleration of a superstructure with semi-rigid pile head connections becomes smaller than that with rigid pile head connections during liquefaction. (3) The pile damage reducing effect of the semi-rigid pile head connection method is enhanced in liquefiable ground as compared with that in non-liquefiable ground, because the lateral force on pile heads with semi-rigid pile head connections is considerably reduced because of conclusion (1) and (2).

1. INTRODUCTION

In these days, various semi-rigid pile head connection methods have been developed that permit the rotation of pile heads as more effective pile design methods (Umeno 2005, Kitagawa 2007). The static structural properties of these pile heads have been verified through structural tests such as bending tests and shear tests, confirming that the new methods offer good deformation capacity (e.g., Yasuda et al. 2006 , Aoshima et al. 2006). And the dynamic interaction between a building with semi-rigid pile head connection methods and soil has previously been investigated by numerical analysis, in which the rotational characteristic at the pile heads is modeled using a rotational spring element (e.g., Muramatsu et al. 2002, Funahara et al. 2003). But there have been few experimental studies using a whole building and soil. Especially in liquefied soil, the influence of the dynamic interaction on pile damage reduction and superstructure response has yet to be elucidated. Shaking table tests of a pile-supported building model with a semi-rigid pile head connection method in dry sand were conducted by the authors to examine the dynamic interaction (Ishizaki et al. 2006). Further, Ishizaki et al. (2011) conducted centrifuge model tests to investigate the seismic behavior of buildings with semi-rigid pile head connections in liquefiable soil. The test results showed the followings. (1) The semi-rigid pile head connections effectively reduced the bending moment of piles both before and during liquefaction. (2) The acceleration of a superstructure with semi-rigid pile head connections decreased during liquefaction. But in these studies, the influence of embedded footing was not considered. In this study, dynamic centrifuge model tests are conducted to investigate the influence of embedded footing on the seismic behavior of a pile-supported building with semi-rigid pile head connections in liquefiable soil.

2. TEST OUTLINE

Dynamic centrifuge model tests were performed at 50g centrifugal acceleration using a geotechnical centrifuge at the Technology Center of Taisei Corporation. Two soil-pile-structure models were used: a building model with either rigid pile head connections (Model RB) or semi-rigid pile head connections (Model SB). The models were prepared in a laminar shear box measuring 560×210×400mm (L×W×D).

2.1 Physical Models

Figure 1 shows the soil-pile-structure models used in the tests. The soil profile consists of three layers: two saturated sand layers and a top dry sand layer. The saturated layers were created using Toyoura sand with a target relative density of 90% in the lowest layer and 60% in the middle layer. These two layers were saturated with silicone oil 50 times more viscous than water. And, the dry silica sand No.3 was further pluviated to form non-liquefiable layer around the footing.

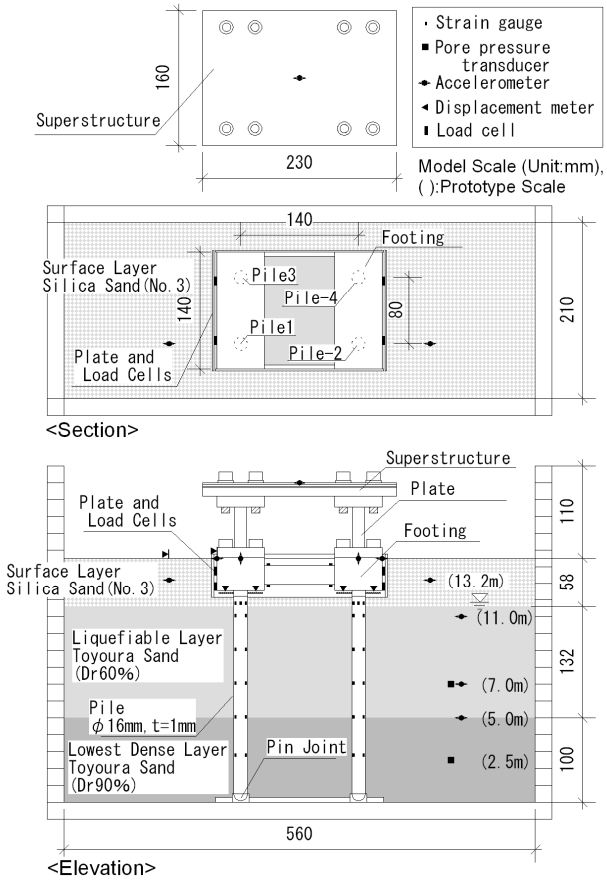

Figure 1 Model Layout

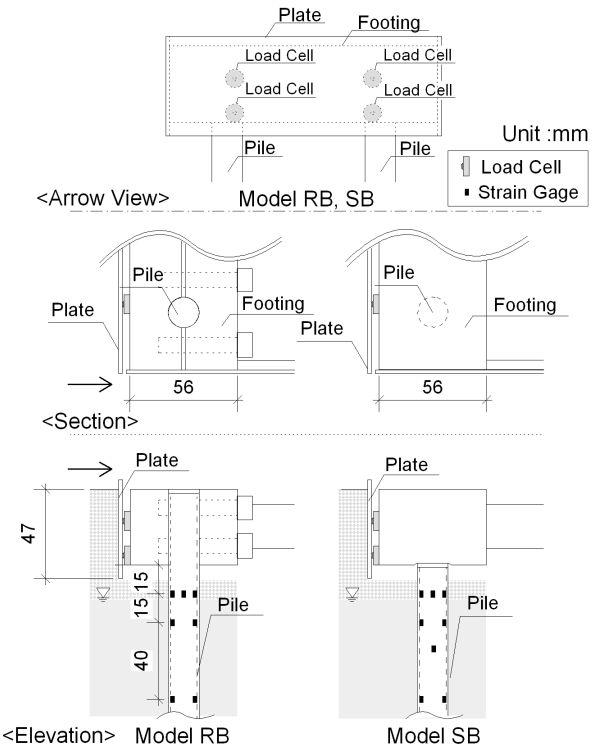

Figure 2 Models of Pile Heads and Footings

The mass of the superstructure was 5.2 kg and that of the foundation was 3.0 kg. The natural period of the superstructure at small excitation was 0.003 s (0.15 s in the prototype scale). The pile groups consisted of 2×2 stainless steel pipes, each of 16 mm diameter and 1mm wall thickness. The elastic coefficient of the pipe was 1.97×10^8 kN/m^2. The pile tips were connected to the base of the laminar box with pin joints.

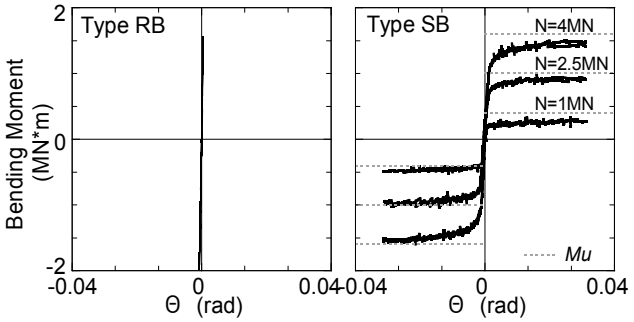

Figure 3 Rotational Characteristics of Pile Heads

The pile head models are shown in Figure 2. The pile heads were connected to the footing either rigidly or semi-rigidly according to the model type. In Type RB, the pile heads were sandwiched between individual sections of the footing and fastened by bolts, while in Type SB, the footing simply rested on the pile heads. The rotational characteristics at the pile head connections were identified by preliminary static bending tests. Figure 3 shows the relations between the bending moment and rotation angle at pile heads for both types of connections. In Type SB, the initial rigidity was small, and the rotation angle increased drastically as the bending moment increased. The relation curve was almost the same either in loading or unloading (non-linear elastic behavior). In Type SB, the relations vary according to the axial force. The maximum resistance of moment M_u is given by:

$$M_u = N/2D \qquad (1)$$

where, D is pile diameter and N is axial force. M_u at each axial force is also shown in Figure 3.The bending moment at the semi-rigid pile head connections are close to M_u for the respective axial forces. The rotational characteristic of the actual semi-rigid pile head connection (Aoshima et al. 2006) is mostly reproduced in the model.

The model of the embedded footing is also shown in Figure 2. Plates supported by four load cells each were set up on the right and left sides of the footing to evaluate the earth pressure acting on it. Teflon sheets were pasted on the sidewalls of footing, parallel to the shaking direction, to reduce sidewall friction. There was a clearance between the base of the footing and the underlying soil. Hence the sidewall friction and base friction were negligible.

2.2 Measurement

The measurement parameters are also shown in Figure 1. The horizontal accelerations of the soil and structure, vertical accelerations of the footing, strains in the piles, pore water pressures in the soil, and the earth pressures acting on both sides of footing were measured. The displacements of

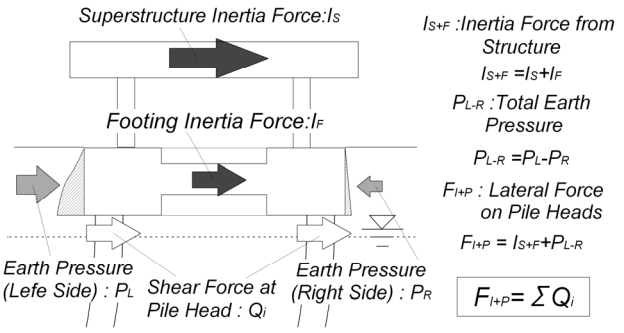

Figure 4 Forces acting on Structure and Pile Heads

the structure and soil were calculated by double integration of the accelerations with respect to time.

Figure 4 is a schematic figure showing the forces acting on the pile heads, the embedded footing, and the superstructure.

The inertia forces imposed by the superstructure and footing were evaluated from their respective masses and the measured accelerations. The total of the inertia force from the structure (I_{S+F}) was then calculated by summing these individual inertia forces from the superstructure (I_S) and the footing (I_F). The total earth pressure acting on the footing (P_{L-R}) is calculated by the difference between earth pressure on the left side (P_L) and that on the right side (P_R), because the side wall friction and base friction were almost negligible. And then, in Type B, the total force acting on the pile head (F_{I+P}) calculated by the summation of I_{S+F} and P_{L-R} is equal to ΣQi.

3. TEST RESULTS

This section consists of analysis and discussion of the results of main excitations for Model SB and RB. All data presented in this sections are of prototype scale.

3.1 Response of Soil

The time histories of accelerations of the soil and shaking table, soil displacements, and excess pore water pressures in the soil, in Model SB and RB, are shown in Figure 5. The excess pore water pressures at heights of 7.0 m above the base of the laminar box reach the initial effective vertical stresses, and the middle layers then liquefy in both models.

3.2 Response of Structure

Figure 6 shows the time histories of superstructure accelerations, footing displacements, bending moments and rotational angles at the pile heads.

Prior to 14s, at which time instant the excess pore water pressures in the liquefiable layers are rising, the superstructure acceleration in Model SB is similar to that in Model RB. After 25s, by which time the soil in the liquefiable layer has almost liquefied, the accelerations in both models show similar oscillation in periods when the superstructure acceleration in Model RB is relatively small, such as 64.5 to 67 s and 99 to 107 s. But in periods when the superstructure acceleration in Model RB is large, such as 50 to 55 s, 77 to 83 s, and 93 to 98 s, the superstructure acceleration in Model SB tends to be smaller and somewhat delayed as compared with that in Model RB. Furthermore, the maximum acceleration of the superstructure in Model SB is about 60% of that in Model RB. The further effect of semi-rigid pile head connections on reducing superstructure acceleration is identified not only in the model with non-embedded footing (Ishizaki et al. 2011) but also in the this model with embedded footing.

The footing displacements in both models increase during liquefaction. It is confirmed that the footing displacements correspond to the respective surface soil displacements which are not illustrated in this paper.

3.3 Lateral Force on Pile Heads

The time histories of I_{S+F}, P_{L-R}, and F_{I+P} are shown in Figure 7. P_{L-R} in Model SB is a little larger but shows similar oscillation to that in Model RB prior to 13.5 s (Fig. 7(b)). But during liquefaction (after 25 s), P_{L-R} in Model SB tends to be smaller and delayed as compared with that in Model RB. In the periods from 50 to 55 s and from 77 to 83 s, in

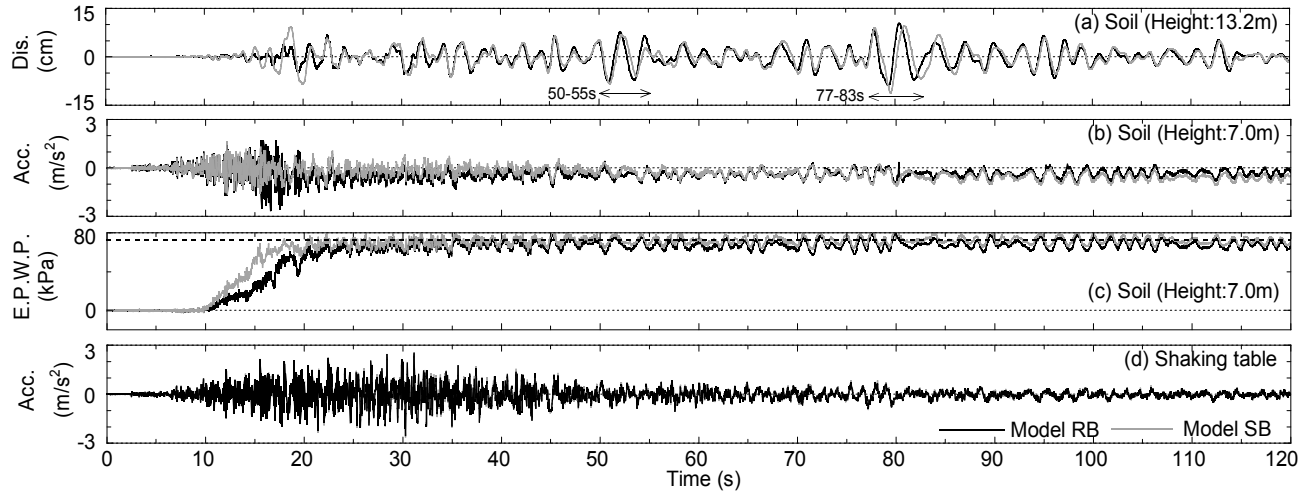

Figure 5 Time Histories of Accelerations of Soil and Shaking Table, Displacements of Soil, and Excess Pore Water Pressures of Soil

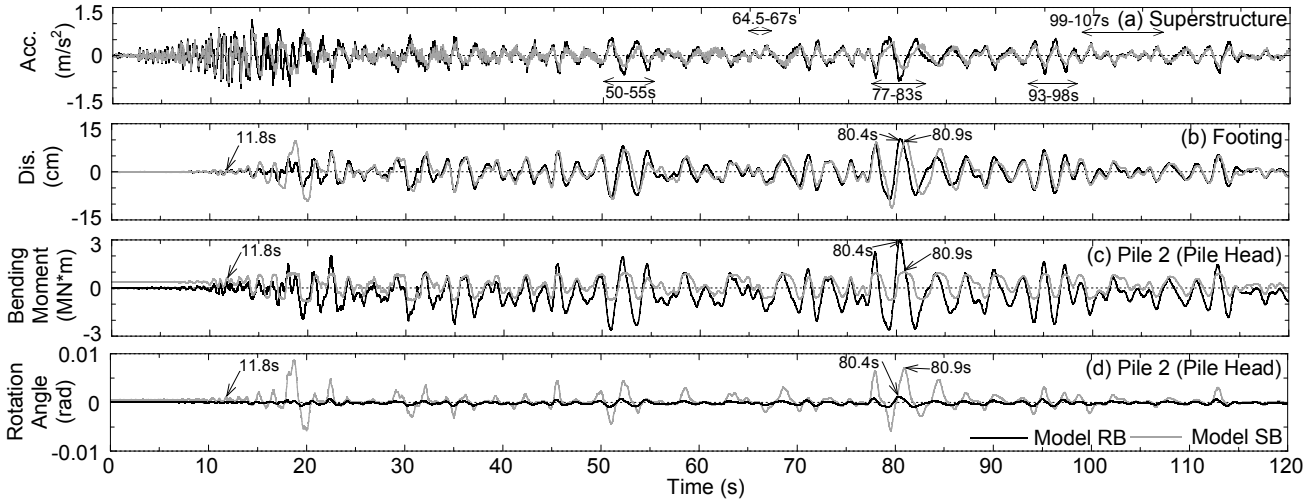

Figure 6 Time Histories of Accelerations of Structures, Displacements of Footings, and Bending Moments and Rotation Angles at Pile Heads

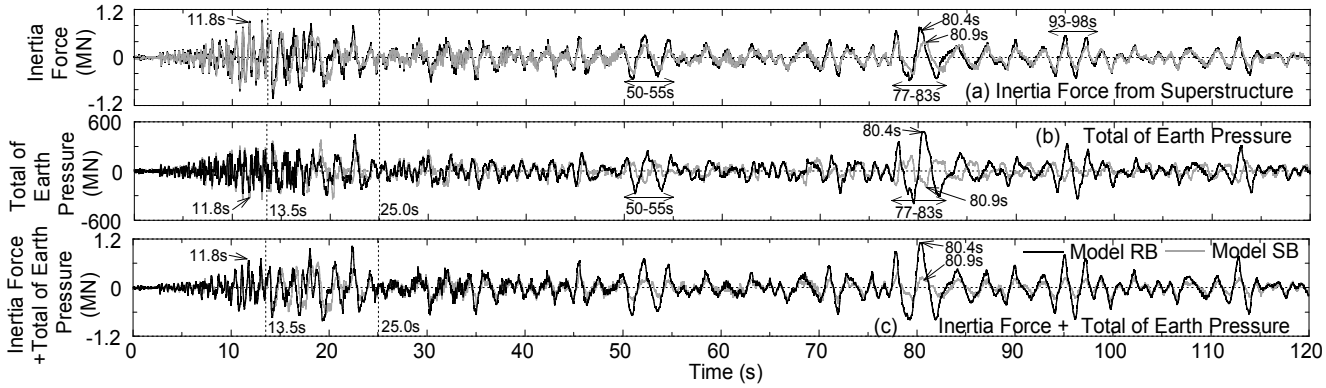

Figure 7 Time Histories of Inertia Forces from Structures, Total Earth Pressures Acting on Footing, and Total Lateral Force on Pile Heads

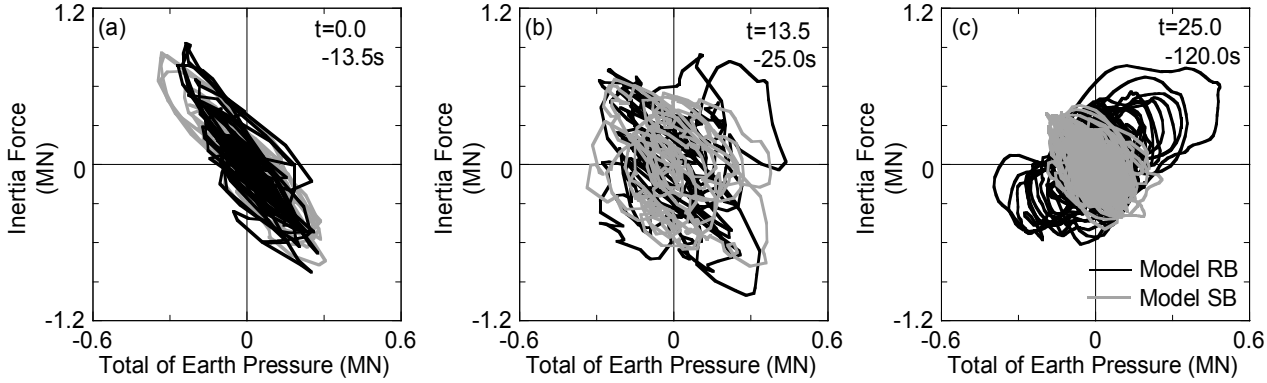

Figure 8 Relations Between Inertia Force from Structure and Total Earth pressure Acting on Footing

particular, the sign of $P_{L\text{-}R}$ in Model SB tends to be opposite to that in Model RB.

During liquefaction, the maximum value of I_{S+F} in Model SB is smaller than that in Model RB because the maximum superstructure acceleration in Model SB is smaller than that in Model RB (Fig. 7(a), 6(a)).

Figure 8 shows the relations between I_{S+F} and $P_{L\text{-}R}$ in the period from 0.0 to 13.5 s (the early process of liquefaction), in the period from 13.5 to 25.0 s (later process of liquefaction), and after 25.0 s (during liquefaction).

In the early process of liquefaction, $P_{L\text{-}R}$ in each model is negatively correlated with I_{S+F}; i.e., the total earth pressure acting on the embedded footing works as a reaction force against the inertia force imposed by the structure. Therefore, the total lateral force on the pile heads (F_{I+P}) decreases due to the embedment effect, a mechanism that is recognized in the seismic design of pile foundation in non-liquefiable ground (AIJ 2001).

In the later process of liquefaction, the differences in phases between I_{S+F} and $P_{L\text{-}R}$ in both models become

distinctive as the excess pore water pressure rises.

During liquefaction, $P_{L\text{-}R}$ in Model RB is positively correlated with I_{S+F}; that is, $P_{L\text{-}R}$ acts as the external force and F_{I+P} increases due to the influence of the embedded footing (Fig. 8(c), 7(c)). In contrast, in Model SB, $P_{L\text{-}R}$ is negatively correlated with I_{S+F}; that is, $P_{L\text{-}R}$ acts as a reaction force to I_{S+F}. Therefore, in Model SB, the embedment effect which reduces the total lateral force on the pile heads is observable not only before liquefaction but also during liquefaction (Fig. 7(a), (c)).

In Model SB, F_{I+P} is a little smaller than that in Model RB before 13.5 s (Fig. 7(c)). It tends to decrease with increasing excess pore water pressure and is considerably smaller than that in Model RB during liquefaction.

3.4 Effect on Pile Damage Reduction

Figure 9 shows distributions of bending moments along the piles at 11.8 s (the time instant during the early process of liquefaction when F_{I+P}s are almost the same in the both models), 18.7/22.4 s (when the bending moments at the pile heads take a peak during the later process of liquefaction), and 80.4/80.9 s (when the bending moments at the pile heads take a peak during liquefaction). In the early and later process of liquefaction (Figs. 9(a), (b)), the maximum bending moment along the pile in Model SB, which occurs within the soil, is greater than the peak bending moment in the soil in Model RB. And the maximum bending moments in Model SB are about 60 to 75% of those that occur at the pile heads in Model RB. In contrast, during liquefaction, the peak value of bending moment of the pile in the soil in Model SB is smaller than that in Model RB. And the maximum bending moments along the piles in Model SB occur at the pile heads and are about 20 to 35% of the maximum bending moments in Model RB. Therefore, the effect on pile damage reducing of semi-rigid pile head connection method is enhanced during liquefaction.

The reasons for the considerably smaller maximum bending moments along the piles during liquefaction in Model SB are considered as follows. The natural own periods of the superstructures are shorter than those of the liquefied soil. Therefore, the soil deformation tends to acts the same direction as the inertia force from the structure (Tamura et al. 2002). In Model RB, the deformation performance of the pile foundation is inferior because the pile heads are connected rigidly to the footing. Hence, the soil deformation is larger than that of the pile foundation. And the relative displacement between the pile/footing and the liquefied soil increases, leading to the increase in both earth pressure acting on the embedded footing and subgrade reaction acting on the piles (Fig. 7(b)). Moreover, during liquefaction, the earth pressure acting on the footing in Model RB acts as an external force which increases the lateral force on pile heads (Fig. 8(c), 7(c)). Consequently, the maximum bending moments along the piles in Model RB become particularly high during liquefaction, especially when the soil displacement especially increases (Figs. 9(a) to (c)). On the other hand, in Model SB where rotation of the pile heads is allowed, the deformation performance of the pile foundation is superior from the beginning and the pile foundation follows the deformation of soil during liquefaction. The earth pressure acting on the embedded footing and the subgrade reaction for the piles does not increase because there is no increase in relative displacement. Furthermore, the earth pressure works as a reaction force to the inertia force at the moment when the inertia force increases, whereas that in Model RB acts as an external force (Fig. 7(b), 8(c)). In addition, the acceleration of the superstructure with semi-rigid pile head connections tends to be smaller than that with rigid pile head connections; that is, the inertia force imposed by the structure with semi-rigid pile head connections is smaller than the inertia force that with rigid pile head connections (Fig. 7(a)). Consequently, the lateral force on piles with semi-rigid pile head connections is considerably smaller than

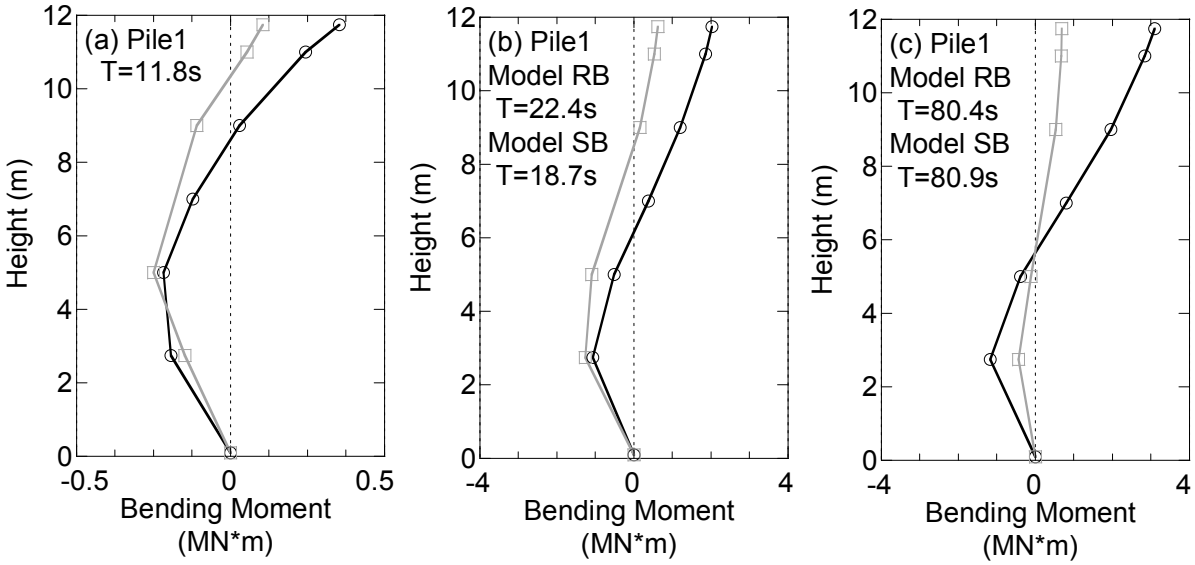

Figure 9 Distributions of Bending Moment along Piles at About 11.8s (Before Liquefaction), 18.7 or 22.4s (Later Process to Liquefaction), and 80.4 or 80.9s (during Liquefaction)

that with rigid pile connections (Fig. 7(c)) because of the above mentioned three reasons: no increase in the total earth pressure and the subgrade reaction, the total earth pressure working as a reaction force against the inertia force, and the decreasing inertia force. Therefore, the pile damage reduction effect of semi-rigid pile head connection method is enhanced in liquefiable ground as compared with that in non-liquefiable ground (Fig. 9(a) to (c)).

4. CONCLUSIONS

Dynamic centrifuge model tests were conducted to investigate the influence of embedded footing on the seismic behavior of a pile-supported building with semi-rigid pile head connections in liquefiable soil. Based on the test results and analysis, the following effects of adopting the semi-rigid pile head connection method in liquefiable soil have been demonstrated.

1. The earth pressure acting on an embedded footing with semi-rigid pile head connections is smaller than that with rigid pile head connections when the soil is liquefied. Furthermore, the earth pressure works as a reaction force to the inertia force, whereas that with rigid pile head connections acts as an external force during liquefaction.
2. The maximum acceleration of a superstructure with semi-rigid pile head connections becomes smaller than that with rigid pile head connections during liquefaction. To paraphrase this finding, the inertia force imposed by the structure on the pile heads is reduced.
3. The main reason for conclusions 1) and 2) is that the pile foundation with semi-rigid pile head connections has superior deformation performance compared to that with rigid pile head connections and this characteristic becomes more evident during liquefaction.
4. The semi-rigid pile head connections effectively reduce the maximum bending moment along piles both before and during liquefaction. Furthermore, the pile damage reducing effect of the semi-rigid pile head connection method is enhanced in liquefiable ground as compared with that in non-liquefiable ground, because the lateral force on pile heads with semi-rigid pile head connections is considerably reduced because of conclusion 1) and 2).

In order to fully verify these effects in liquefiable ground, it is important to accumulate more experimental data for various conditions of soil-profile, superstructure, rotational characteristic of pile head, input motion, and so forth. Furthermore, an analytical approach able to simulate the dynamic interactions between a building with semi-rigid pile head connections and liquefied soil is also awaited.

Abstract: In this paper, the pre-shaking technique is presented for both measuring the V_s profile of soil deposit and determining the fundamental frequencies of both the soil deposit and the soil-structure system in a centrifuge model tested at an acceleration of 80 g. The pre-shaking is a non-destructive test, use of the shaker as a wave source and a vertical array of accelerometers embedded in the sand bed and the accelerometers attached on the pile as receivers. Accordingly the method of pre-shaking can be easily used for both the in-flight subsurface exploration (measurements of V_s profile) and the in-flight SI on the soil-structure systems. A soil-pile centrifuge model is used to demonstrate the application of pre-shaking in a routine centrifuge shaking table test. The testing setup, testing procedures, and the related system identification techniques and signal processing for the soil-pile system are discussed. The natural frequencies measured from the pre-shaking tests are consistent with those derived from the theoretical basis.

1. INTRODUCTION

The damage caused by earthquakes is strongly dependent upon the local site condition, and thereby site characterization has become an important role in earthquake-resistant design and must be taken account of. Several system identification (SI) techniques have been developed for estimation of in situ soil properties and local site parameters (i.e., shear wave velocity profile of soil, fundamental frequencies of soil and structure), using recorded earthquake data (Oskay and Zeghal, 2011).

An alternative approach to geotechnical earthquake engineering small-scale dynamic centrifuge modeling has been used to provide insights into the behavior of soil-structure interaction during shaking. Thus an inexpensive and non-destructive technique for model soil bed characterization as those used in situ, that is capable of performing both the in-flight subsurface exploration and the in-flight SI on a model soil bed and/or on a model structure any time, is urgently required.

In geotechnical earthquake engineering the shear wave velocity of soil, V_s, can be used to evaluate in-flight dynamic soil properties in centrifuge models as well as in situ dynamic soil properties. Centrifuge modelers have developed several methods for in-flight V_s measurements. Brandenberg et al. (2006), Gohl and Finn (1991), and Lei et al. (2004) used a pair of bender elements to generate (transmit) and detect (receive) shear waves in geotechnical centrifuges. Arulnathan et al. (2000) used a miniature air hammer to generate shear waves, and the propagating shear waves were recorded using a vertical array of four accelerometers positioned at different depths. More recently, Rammah et al. (2006) and Kim & Kim (2010) developed bender element tomography systems to investigate in-flight shear wave velocity distributions in centrifuge models.

2. TECHNIQUES OF PRE-SHAKING

Several SI techniques have been performed on the measured output (response) and input (excitation) in order to gain insight into the system properties of soil stratum and structure. Transfer functions, or ratios of amplitude spectra of input and out acceleration pairs, have employed to estimate fundamental frequencies of geotechnical systems and associated shear wave velocities of deposit in geotechnical earthquake engineering practice. Adopting these SI techniques in the centrifuge test, however, the saturated loose sand bed even subjected to the smaller but the longer duration vibration may generate considerable amount of excess pore water pressure and consequently results in disturbing the sand fabric of and in reducing the stiffness of sand bed.

In this paper, the pre-shaking technique is presented for both measuring the V_s profile of soil deposit and determining the fundamental frequencies, f, of both the soil deposit and the soil-structure system in a centrifuge model. The pre-shaking is a non-destructive test, use of the shaker as a wave source and a vertical array of accelerometers as

receivers. Accordingly the method of pre-shaking can be easily used for both the in-flight subsurface exploration (measurements of V_s profile) and the in-flight SI on the soil-structure systems. A soil-pile centrifuge model is used to demonstrate the application of pre-shaking in a routine centrifuge shaking table test. The testing setup, testing procedures, and the related system identification techniques for the soil-pile system are discussed as follows.

3. GEOTECHNICAL CENTRIFUGE MODELING

This experimental work was undertaken in the Centrifuge at the National Central University (NCU), Taiwan. The NCU Geotechnical Centrifuge has a nominal radius of 3 m and equips a 1-D servo-hydraulically controlled shaker integrated into a swing basket. The shaker has maximum nominal shaking force 53.4 kN with maximum table displacement of ±6.4 mm and operates at up to 80 *g* centrifugal acceleration. The nominal operating frequency range is 0 - 250 Hz. A laminar container with inside dimensions of 711 mm x 356 mm x 353 mm (L×W×H) is constructed from 38 light-weight aluminum alloy rings arranged in a stack. The laminar container is designed for dry or saturated soil models. The boundary effects of the laminar container used in the study is minimal; hence the container permits development of stresses and strains associated with one dimensional shear wave propagation (Lee et al., 2012). Fig. 1 shows the laminar container resting on the NCU Geotechnical Centrifuge Shaker.

Three instrumented model bending piles (L-Pile, B-Pile, and S-Pile) were fabricated with the same aluminum-alloy tubes of 9.6 mm outer diameter and 8 mm internal diameter. The embedment depth of model pile was 330 mm. Strain gauges were placed externally at eight positions to measure the distribution of bending moment along the pile depths. Resin was coated on the surface of model pile for waterproofing. The model piles after coating were designed to replicate 0.96 m diameter circular pile with an embedment depth of 26.4 m if tested at an acceleration of 80 g and they have flexural stiffness (*EI*) of 725848 kN-m^2 in prototype scale. Here *E* and *I* are the Young's modulus and the moment of inertia of the pile. The instrumented bending piles with pin joints at each pile tip were calibrated for establishing the relation of the output voltage and the bending moment prior to the model tests. A tip mass was attached on each pile head to simulate the dead weight of superstructure. Three different tip masses were attached on the pile heads for simulating seismic response of the piles with different weights of superstructures as shown in Fig. 2. Table 1 lists the basic characteristic of tip masses attached on the L-Pile, the B-Pile, and the S-Pile.

A fine quartz sand was used to prepare the uniform sand deposit. The characteristics of the quartz sand are summarized in Table 2. The instrumented bending piles attached with different tip masses on the pile head were first connected to the container base with pin joints and then the quartz sand was pluviated with a regular path into the container from a hopper at a constant falling height and at a constant flow rate for preparing fairly uniform sand deposits having the relative density of about 60%. After finishing the preparation of saturated sand bed the centrifuge was then accelerated at a 10 *g* per step until it reached the centrifugal acceleration of 80 *g*.

Quartz sand	2.65	0.193	0.147	1.66	1.44

Fig. 3 presents a typical setup to show the dimensions of tested sand bed, the position of piles, and the types and the positions of instrumentations used in the model tests. Each model contained two piles those which were attached with different tip mass on the pile heads as listed in Table 1. The model dimensions are in centimeters, and the prototype dimensions in parentheses are in meters. The thickness of model sand bed is 33.9 cm in model scale, simulating a 27.2-m thick and 56.8-m long sand deposit if tested in an acceleration of 80 *g*. The sand bed was instrumented with

eight vertical spaced accelerometers (A#) to record the shear wave propagating from the base to the ground surface as shown in Fig.3. At the same elevations close to the accelerometers eight pore water pressure transducers (P#) were instrumented as well in the saturated sand deposit. No pore water pressure transducer was instrumented in the dry sand model. One LVDT (Linear variable differential transformer) was installed at the top of ground surface to measure the time histories of surface settlement. All the measuring points are far from the boundary of laminar container to prevent from the boundary effects (Lee et al., 2012).

Two LVDTs and two accelerometers were also instrumented on the tip mass for each pile to measure the horizontal displacements and the horizontal accelerations at two different levels. Consequently the time histories of the angular acceleration and the angular displacement for the tip masses can be calculated. The bottom of tip mass was clear of the surface of sand. Thus the model piles had translation fixity but rotational free at the pile tips and free to rotation and sway at the pile heads as shown in Fig. 3.

Three LVDTs were attached on the side wall of laminar container to measure the free field soil lateral deformations along the depths during shaking and after shaking. Eight strain gauges on each pile were used to measure the profiles of bending moment along the pile depths. This comprehensive instrumentation and detailed measurements are necessary to understand the seismic behavior of pile embedded in a liquefiable sand deposit. All the measurements are presented in prototype units unless specially noted otherwise.

A series of centrifuge shaking table tests at the acceleration of 80 g was conducted; the test conditions for each model are listed in Table 3. Totally seven models were conducted in the study. Test P-D-1, P-D-2, and P-D-3 were the dry sand models, whereas Test P-W-1, P-W-2, P-W-3, and P-W-4 were all the sand models having relative densities of about 60%. The elevation of the water table in the saturated sand models was at the ground surface. Two instrumented piles with various tip mass were embedded for each sand model. Each model was first subjected to one cycle of smaller sinusoidal vibration (pre-shaking) with different frequencies (1 *Hz*, 2 *Hz*, and 3 *Hz*) for the in-flight subsurface exploration and the in-flight SI to determine the shear wave velocity profile along depths and the nature frequencies of both the sand deposit and the piles. Subsequently each model was subjected to multiple earthquake events for evaluating the seismic response of the pile embedded in the sand deposit. In this paper only the test results of pre-shaking are reported and discussed.

4. TEST RESULTS AND INTERPRETATIONS

Most centrifuge models are instrumented with vertical arrays of accelerometers for monitoring the dynamic response of the soil bed and thereby the accelerometers are the requisite transducers. In the study the model sand bed was subjected to pre-shaking driven by the shaker as listed in Table 3 to measure the profile of the shear wave velocity and to identify the fundamental frequencies in terms of the vertical accelerometer array. The shaker fired one cycle of smaller controlled amplitude sinusoidal wave (around 0.01 *g* in amplitude and 1, 2, and 3 *Hz* in frequency, both in the prototype scale) that provided a source of vibrations. A higher sampling rate of 30k samples/sec was used to acquire the acceleration time histories of the vertical accelerometer array. The instrumented accelerometers registered identifiable signals with a higher sampling frequency so that the sampling interval was sufficiently small relative to the travel times to avoid low-resolution V_s estimates.

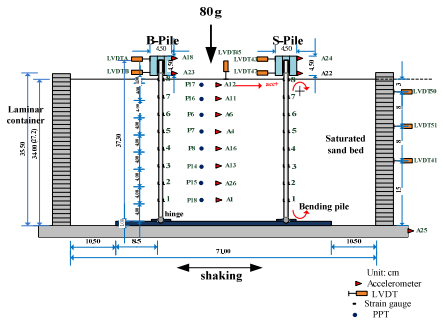

Figure 3 Typical testing setup and instrumentations.

Table 3 Test conditions in the study

Test No.	Relative density, D_r (%)	Pre-shaking Event	Tested pile	Remark
P-D-1	63	S1-1Hz S1-2Hz S1-3Hz	L-Pile and B-Pile	Dry sand bed
P-D-2	66	S1-1Hz S1-2Hz S1-3Hz	L-Pile and B-Pile	Dry sand bed
P-D-3	60	S1-1Hz S1-2Hz S1-3Hz	B-Pile and S-Pile	Dry sand bed
P-W-4	63	S1-1Hz S1-2Hz S1-3Hz	L-Pile and B-Pile	Saturated sand bed
P-W-9	62	S1-1Hz S1-2Hz S1-3Hz	B-Pile and S-Pile	Saturated sand bed

The shear waves were picked up by the array of embedded accelerometers. Each pair of adjacent accelerometers registered the arrival time of the first wave, the time difference between two accelerometers allowed the average shear wave velocity in the sand layer to be calculated. Figure 4 shows the signals acquired on the accelerometer array, with band pass filtering (0.1-10 *Hz*), for Test P-W-9 after the shaker fired a one-cycle smaller amplitude sinusoidal wave (around 0.01 *g* in amplitude and 2 *Hz* in frequency). The first peak on each time history of acceleration could be selected. The measured first peak amplitudes of the acceleration varied from 0.015 *g* (0.15 m/s^2) at the bottom of the sand bed to 0.03 *g* (0.3 m/s^2) at the top of sand bed. Each signal exhibited a pronounced first peak, as shown in Fig. 4. The traveling time was determined

by the first peak to the first peak criterion on the accelerometer pairs (A1 and A16; A16 and A11; and A4 and A11). Accordingly, the average shear wave velocity, V_s , of the soil stratum between the accelerometer pairs could be calculated as follows:

$$V_s = \Delta S/\Delta t \quad (1)$$

where ΔS and Δt are the distance between adjacent accelerometers and the registered time difference between the first peaks of accelerometer pairs, respectively. Fig. 5(a), 5(b), and 5(c) display the profiles of measured shear wave velocity for the tests as listed in Table 3. Although the dry sand beds (P-D-1, P-D-2, and P-D-3) and the saturated sand Beds (P-W-4, and P-W-9) have the similar relative density ($D_r \fallingdotseq 60\%$), the measured V_s values from the dry sand beds are higher than those from the saturated sand beds as shown in Fig. 5(a) and 5(b) because of the higher effective overburden pressure developing in the dry sand bed. The measured average shear wave velocities for the tested sand beds are summarized in Table 4.

Consider a uniform layer of isotropic, liner elastic soil deposit overlying rigid rock, which is subjected to a 1-D vertically propagating shear wave from the bedrock. The nature frequency of deposit, f_n, which depends only on the thickness and shear wave velocity of the deposit, provides a useful indication of the frequency of vibration at which the most significant amplification can be expected. The nature frequency is given by

$$f_n = \frac{V_s}{4H} \quad (2)$$

where H = thickness of uniform sand deposit. Substituting the measured average shear wave velocity of the tested sand deposit into Eq. (2), the nature frequency is calculated and listed in Table 4.

As described previously the nature frequency of vibration system is the frequency at which a system naturally vibrates once it has been set into motion. Figures 6(a) and 6(b) display the typical time histories of acceleration measured at the depths of 10.4 m and 12.6 m for Test P-W-9 during pre-shaking which was excited with 2 *Hz*. The start time of the free vibration are also pointed at in the figures. Fig. 7 displays the Fourier amplitude spectra for Test P-W-9, those which were computed from the time histories of acceleration (A16 and A7) measured at the sand deposit in the period of free vibration as shown in Fig. 6(a) and 6(b).

The maximum peak amplitude measured with the accelerometers of A1, A16, A4, and A11 all appears at the same frequency of 1.5 *Hz*. This frequency is defined as the calculated nature frequency of sand deposit. Moreover, the same value of calculated nature frequency is obtained no matter which exciting frequency used in the pre-shaking. The measured nature frequencies of the sand deposit are also listed in Table 4. The nature frequencies measured from the Fourier amplitude spectra are lower than those calculated with Eq. 2 in terms of the measured shear wave velocities. Both the measured and the calculated nature frequencies of dry sand deposit have the higher than those obtained from the saturated sand deposits. These consistent results of the nature frequency may illustrate that the use of pre-shaking is a convenient tool for the SI on the tested sand bed.

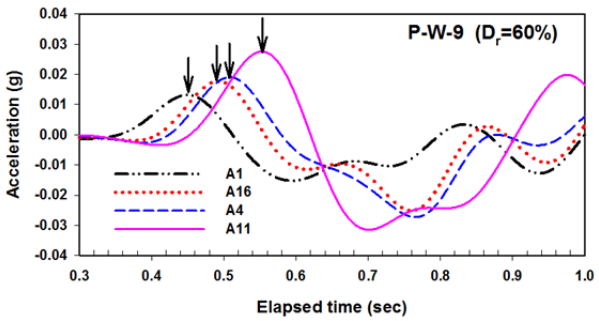

Figure 4 Time histories of acceleration measured during pre-shaking (exciting frequency of 2 *Hz*)

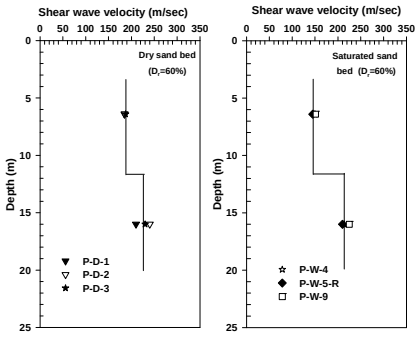

Figure 5 The profiles of measured shear wave velocity: (a) dry sand bed ($D_r \fallingdotseq 60\%$); (b) saturated sand bed ($D_r \fallingdotseq 60\%$)

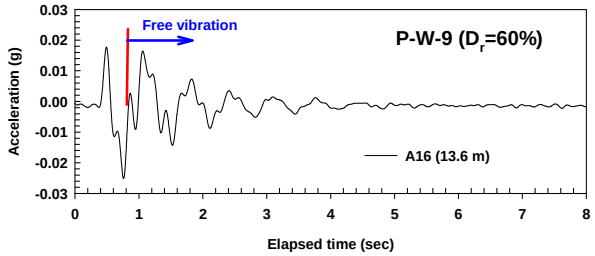

Table 4 Summary of average shear wave velocities, calculated and measured nature frequencies of sand beds

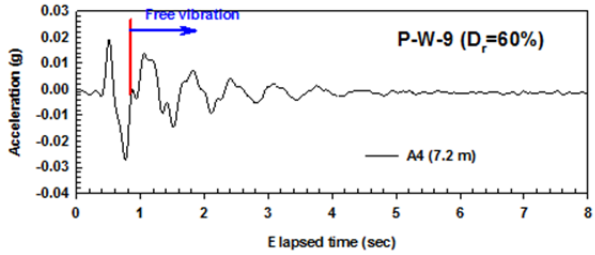
Test No.	Average V_s (m/sec)	Calculated f_n (Hz)	Measured f_n (Hz)
P-D-1	210	1.9	1.6
P-D-2	210	1.9	1.7
P-D-3	210	1.9	1.7
P-W-4	170	1.6	1.5
P-W-9	170	1.6	1.54



The accelerometers attached on the top and the bottom of tip mass of the pile can measure the time histories of acceleration during pre-shaking. Figures 8(a) and 8(b) display the typical time histories of acceleration measured at the top and bottom of tip mass attached on the B-Pile and S-Pile during pre-shaking which was excited with 2 *Hz* for Test P-D-3. The start time of the free vibration are also pointed at in the figures.

Fig. 9 displays the Fourier amplitude spectra for Test P-D-3, those which were computed from the time histories of acceleration (A18 and A24, A22 and A23). The same results are obtained from the other model tests in the study. The Fourier amplitude spectrum of each pile has two maximum peak amplitudes. One is the nature frequency of sand deposit the pile is embedded, the other is the nature frequency of pile. Table 5 gives the summary of the nature

frequencies of piles. The pile with the largest tip mass (L-Pile) has the lowest nature frequency (≒0.82 *Hz*), the pile with the second large tip mass (B-Pile) has the second low nature frequency (≒1 *Hz*), the pile with the lowest tip mass (S-Pile) has the highest nature frequency (≒3.2 *Hz*).

P-W-4		1.5	1.5		1.0	3.2
P-W-9		1.5			0.96	3.2

5. CONCLUSIONS

The pre-shaking technique is capable of measuring the V_s profile of soil deposit and determining the nature frequencies of both the soil deposit and the soil-structure system in a centrifuge model tested at an acceleration of 80 g. The pre-shaking is a non-destructive test, use of the shaker as a wave source and a vertical array of accelerometers embedded in the sand bed and the accelerometers attached on the pile as receivers. Accordingly the method of pre-shaking can be easily used for both the in-flight subsurface exploration (measurements of V_s profile) and the in-flight SI on the soil-structure systems. The natural frequencies measured from the pre-shaking tests are consistent with those derived from the theoretical basis. This technique can be conducted at any time before and after major earthquake events are fired.

A CASE STUDY ON MULTIPLE MECHANISM MODEL IN THREE DIMENSIONAL SOIL-STRUCTURE INTERACTION ANALYSES

Ryo Ueda[1] and Ariyoshi Yamada[2]

1) Kobori Research Complex .inc, Japan
2) Kajima Corporation, Japan
uedar@kobori-takken.co.jp

Abstract: Directional nonlinear interaction in non-linearity of soil is an essential issue especially in three dimensional soil-structure interaction analyses. The multiple mechanism model is a rigorous method which is able to represent it, but it is seldom studied in details for practical adaptation so far. This study describes the effects of directional nonlinear interaction on dynamic response behavior of soil and structure, using three dimensional finite element analyses with multiple mechanism model. The results show that structural response subjected to two-directional input is analytically consistent with response to one directional synthesized input.

1. INTRODUCTION

Recently, some structures are constructed on relatively soft soil site, and their shape of foundation become complicated according to requirement of building design. Accurate computation is desired in such intricate cases. Multiple mechanism model is a rigorous method used for representing a soil non-linearity. In the method, polyhedron model is often introduced for the non-linear behavior, where the three dimensional stress and strain on virtual plains interact to each other.

The strain space multiple-mechanism model is originally proposed by Iai (Iai et al., 1993). The stress and stiffness is given by combining all the partial stress contributions from the virtual plain strain shear mechanisms over the entire directions of the axes.

Authors (Ueda et al., 2012) studied validity and accuracy of multiple mechanism model based on several case studies with a simple layered soil model, in which two directional responses were tested. It is shown that the response of soil subjected to two directional input is consistent with response to one directional synthesized input, and 8 plains model is comparable to 20 plains model in their accuracy. This implied that 8 plains model is expected to be applicable to execute three dimensional analyses under limited computational resources. However the effect of directional interaction in three dimensional model is not yet known in details so far.

2. COORDINATE TRANSFORMATION THEORY

Iai represents the theory of coordinate transformation for three dimensional analysis with reference to Cook,1981. With some mathematical and engineering background, coordinate transformation between original coordinate and transformed one is conducted a series of manipulations of matrix. In the three dimensional space the stress and strain vectors are written by

$$\{\varepsilon\}^T = \{\varepsilon_x \varepsilon_y \varepsilon_z \gamma_{xy} \gamma_{yz} \gamma_{zx}\} \tag{1}$$

The stress and strain vectors on transformed coordinates on virtual plain will given as

$$\{\tilde{\varepsilon}\}^T = [T_\varepsilon]\{\varepsilon\} \tag{2}$$

in which

$$[T_\varepsilon] = \begin{bmatrix} a_1^2 & b_1^2 & c_1^2 & a_1b_1 & b_1c_1 & c_1a_1 \\ a_2^2 & b_2^2 & c_2^2 & a_2b_2 & b_2c_2 & c_2a_2 \\ a_3^2 & b_3^2 & c_3^2 & a_3b_3 & b_3c_3 & c_3a_3 \\ 2a_1a_2 & 2b_1b_2 & 2c_1c_2 & (a_1b_2+a_2b_1) & (b_1c_2+b_2c_1) & (c_1a_2+c_2a_1) \\ 2a_2a_3 & 2b_2b_3 & 2c_2c_3 & (a_2b_3+a_3b_2) & (b_2c_3+b_3c_2) & (c_2a_3+c_3a_2) \\ 2a_3a_1 & 2b_3b_1 & 2c_3c_1 & (a_3b_1+a_1b_3) & (b_3c_1+b_1c_3) & (c_3a_1+c_1a_3) \end{bmatrix} \tag{3}$$

On the equation (3), components a_i ,b_i ,c_i (i=1,2,3) are direction cosines between original coordinate and transformed coordinate. Now let us define the directions of the axes with the angles ψ and ζ of a spherical coordinate shown in Figure1. The components are given by

$$\begin{bmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{bmatrix} = \begin{bmatrix} \cos\psi\cos\zeta & \sin\psi\cos\zeta & -\sin\zeta \\ -\sin\psi & \cos\psi & 0 \\ \cos\psi\sin\zeta & \sin\psi\sin\zeta & \cos\zeta \end{bmatrix} \tag{4}$$

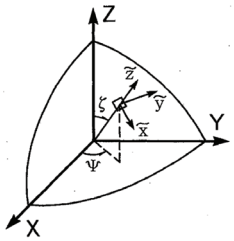

Figure 1 Spherical Polar Coordinate (Iai et al.1993)

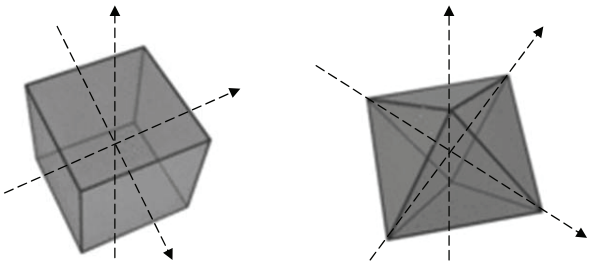

Transformed strains on each virtual plain are moreover transformed and decomposed into an assembly of simple shear strains on multi-spring model. Constitutive equation of relationship between strain and stress is adopted on each spring on all virtual plains.

The shape of virtual plain is theoretically arbitrary in general. Once the shape of virtual plain is decided the angles of spherical polar coordinates can be determined.

3. DIRECTIONAL NONLINEAR INTERATION

Directional nonlinear interaction, or simply "directional interaction," is explained as below. When a shear strain γ_{zx} is considered, the shear stiffness μ_{zx} should decrease due to non-linear effect. Then it should also affect other component μ_{yz}. The shear strain γ_{yz} affects γ_{zx}, vice versa. In order to consider this effect, multiple mechanism model combines all the partial stress contributions from the virtual plain strain shear mechanisms

As written in beginning in introduction, virtual plains for coordinate transformation are often defined as polyhedron, which has mathematical symmetry. Shapes of polyhedron are shown in Figure 2. The first is 6-plains model, what is called "cube". Cube has, needless to say, plains parallel to absolute coordinate. It is simple and easy to understand but it cannot follow the directional interaction behavior of x and y direction because virtual plains on any direction are independent to each other. The second is 8-plains model, "Octahedron". It can follow the directional interaction obviously.

6 Plains (Cube) 8 Plains (Octahedron)

Figure 2 Polyhedrons

4. ANALYSIS MODEL

A three dimensional soil-structure interaction model for case study is shown in Figure 3. It consists of 8-node solid elements of soil, rigid foundation, and shear spring model of structure. Analytical dimension is 200m in width and 80m in depth. The structure is 35-storied typical high-rise building with embedded raft foundation. Side and bottom boundary surfaces are supported with viscous boundary, and interaction correction force is considered adequately.

For more details, see also Figure 4. This is an enlarged view of octagonal foundation. In this case study, the shape of foundation must be axial-symmetric along the axis of input wave, because its soil impedance has to be equal in each direction of input wave.

Characteristic of soil is shown in Figure 5. Soil is composed of three layers. The foundation is built on second layer of 300m/s in S-wave velocity, and engineering bedrock at the bottom is 500m/s.

Input wave is shown in Figure 6. It is one of the waves defined by seismic design code in Japan. Its amplitude is normalized to 0.1G. One directional input case with $\sqrt{2}$ times amplitude as a benchmark, and 6 and 8 plains model for two directional input were computed.

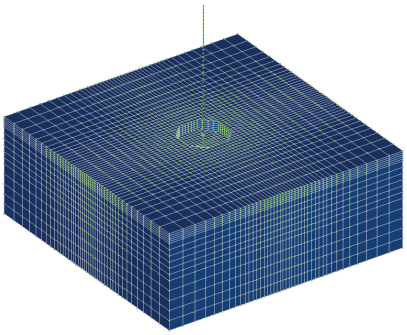

Figure 3 Model for Case Study

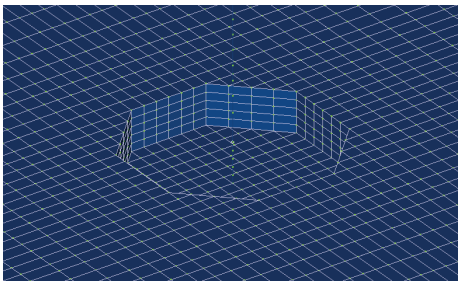

Figure 4 Model (Enlarged View of Foundation)

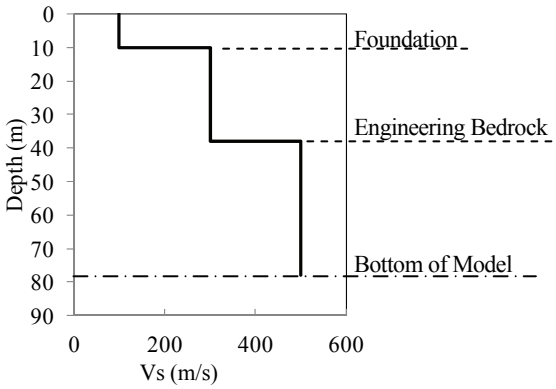

Figure 5 Characteristic of Soil

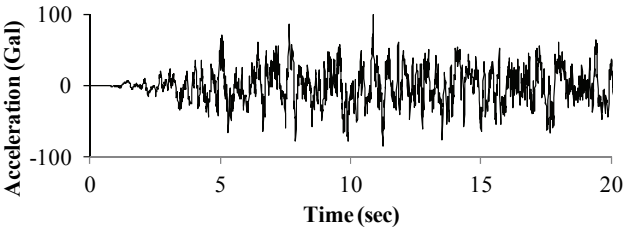

Figure 6 Acceleration of Input Wave

4. RESULTS

For grasping the result, figure 7 shows deformation and strain contour of three dimensional model. The building and surface of soil are deformed, while the boundary keeps semi-infinite condition. This implies that analysis is executed with sufficient numerical accuracy.

4.1 Validation of 8 Plains Model

Figure 8 shows response accelerations at 35th floor, foundation, and ground surface. Here the acceleration of benchmark model of one directional input is normalized in its amplitude with divided by $\sqrt{2}$. 8-plains model is almost consistent to the benchmark. To the contrary, 6-plains model is different in the wave form and its maximum acceleration. The case of 6-plains model overestimates the acceleration. The difference is larger in the ground surface and less in the top of structure.

The difference can be seen clearer in the acceleration spectrum shown in Figure 9. The predominant period of structure is about 2.0 sec. The difference is relatively small at period domain longer than 1.0 sec. It implies that directional interaction effect becomes larger on low-rise building.

Distribution of displacement on the ground surface and foundation at the time of 15sec is shown in Figure 10. The outline of foundation is represented by a dotted line. The figure of 8-plains model with two directional input is almost consistent to the benchmark if it is rotated by 45 degrees, while the figure of 6-plains model shows smaller values than benchmark obviously.

These results show that the 8-plains model is successful to compute the directional nonlinear interaction.

4.2 More Improvement of Accuracy

Let us examine the case of another direction of input. Figure 11 shows displacement orbits of ground surface, in which the waves are input in the direction of 45 degrees and 22.5 degrees, also axial symmetric, toward the x-axis. Theoretically displacement orbit should draw a straight line independently to direction of input. It is confirmed in the case of 45 degrees. Nevertheless it is found that the orbit of 22.5 degrees input is irregularly fluctuating in the 6-plains model case. Comparing 8-plains model, its fluctuation is lessened, even though not perfect. Now an additional case of 20-plains model, shown in Figure 12, is introduced here. Its fluctuation is even slighter than other former cases.

These results show that the accuracy could be improved by increasing the number of plain.

5. CONCLUSIONS

This paper represents a case study on three dimensional soil-structure interaction analyses using multiple mechanism model. The directional nonlinear interaction is computed successfully and applicability of multiple mechanism model to three dimensional analysis is demonstrated.

Meanwhile, the accuracy of calculation could be improved by increasing the number of plain, which is approximating to the ideal sphere. 8 plains model gives practically sufficient accuracy in consideration with engineering purpose and computational cost. However, when more detailed examine is required for such as highly complicated structure, liquefiable soil, severe earthquake, and so on, it would be better to refer to results obtained by using more than 8 plains model.

LONG-TERM SETTLEMENT OF HOLOCENE CLAY GROUND AFTER THE 2011 GREAT EAST JAPAN EARTHQUAKE

Naohiro Nigorikawa[1] and Yoshiharu Asaka[2]

1) Researcher, Institute of Technology, Shimizu Corporation, Japan
2) Senior Research Engineer, Institute of Technology, Shimizu Corporation, Japan
n.nigorikawa@shimz.co.jp, yoshiharu.asaka@shimz.co.jp

Abstract: The aim of the study reported in this paper is to reveal the long-term settlement of Holocene clay ground after the 2011 Great East Japan Earthquake. The authors have taken level readings five times across Urayasu City, Chiba prefecture, during the period from April 2011 to April 2012. The result is a chronological record of changes in settlement of first-order benchmarks and survey points showing that long-term ground settlement is taking place due to the earthquake. The settlement rate is shown to be 7 mm/year, more than 2.5 times the rate of settlement before the earthquake. However, no such subsidence is observed where reclaimed land has been improved using the sand drain and fill preloading methods. Further, the alluvial lowland has also not settled since the earthquake.

1. INTRODUCTION

Until now, on the types of ground-related disaster receiving most attention tends to have been those caused by liquefaction of sandy ground and liquefaction-induced deformation. Liquefaction was observed in the 2011 Great East Japan Earthquake (termed the 3.11 Earthquake in this paper), with coastal reclaimed areas of Tokyo Bay, including Urayasu City in Chiba Prefecture, suffering extensive damage over a wide area. Many studies and experiments related to liquefaction were carried out in the wake of the 1964 Niigata Earthquake, with the result that the public is now well aware of the liquefaction problem.

On the other hand, cohesive ground behaves rather differently in an earthquake; there is no instantaneous deformation, as occurs with sandy grounds, so no seismic capacity problem has been noted. As a result, design and construction methods related to architectural and civil engineering structures do not allow for any consideration of the co-seismic and post-seismic behavior of cohesive ground. Yet detailed observations of disaster areas as well as centrifuge model tests (Hotta et al., 1998) carried out in recent years have shown that land subsidence might occur over a long period of time following an earthquake, particularly in soft cohesive ground. Thus an essential consideration in the design of foundations not directly supported by stiff ground layers or embankments is the evaluation of post-seismic residual ground deformation. But with a scarcity of accumulated measurements of cohesive ground settlement, there has been little effort to investigate or analyze this phenomenon (ex. Koishi et al., 2012).

In this paper, data on the long-term ground settlement of Holocene clay in Urayasu City following the 3.11 Earthquake is obtained by taking levels and trends in settlement based on the measurements are reported.

2. GEOLOGICAL CONDITIONS IN URAYASU CITY

2.1 STRATAL ORGANIZATION

Figure 1 shows the location of Urayasu City in the west of Chiba Prefecture. The southern part of Urayasu was formed from reclaimed land along the shores of Tokyo Bay, and three-quarters of the city stands on reclaimed land. The reclamation was carried out mainly with sand excavated from the seabed off Urayasu. Reclamation began in 1964 and was completed in 1980, with the work taking place in phases: the first phase ran from 1964 through 1971, with the rest of the reclamation taking place in the second phase from 1975 through 1980. The upper layer at the surface consists of sandy fill in most areas, underlain by Holocene sand with an N-value between 2 and 20, below that is Holocene clay

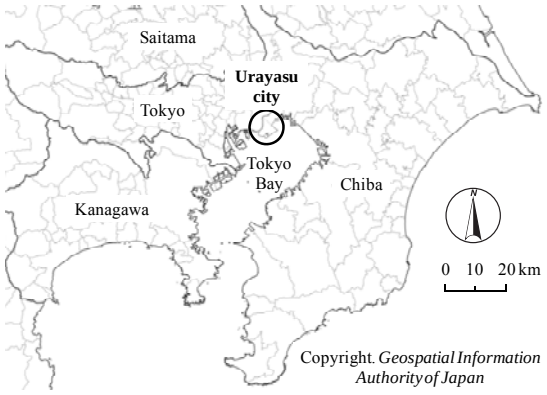

Figure 1 Location of Urayasu city

with an N-value between 0 and 5. Pleistocene sand with an N-value of 50 or greater is deposited below these Holocene layers. In addition, there is humus soil underlain by Pleistocene sand in some places.

Figure 2 shows the history of this land reclamation as well as two geological sections through Urayasu. The data in this figure was obtained on the basis of borehole investigations. Buried valleys and buried terraces are present below Urayasu, causing complex variations in the thickness of the Holocene clay. Along line A-A' the clay is 30 to 40 meters thick, while along B-B' it is 10 meters thick near the old coastline to the northern end and 40 meters thick at the seaward end, with a marked thickening toward the sea (in the southeast direction).

As this makes clear, there are thick layers of Holocene clay under Urayasu. In fact, there were concerns about consolidation of Holocene clay layer from the beginning of the reclamation work. According to a contemporary report on foundation improvement work, the eastern side of the area reclaimed in the second phase was improved using the sand drain and/or fill preloading methods as a solution the problem. The improved area is indicated in Fig. 2.

2.2 LEVEL FLUCTUATION OF FIRST-ORDER BENCHMARKS MEASURED BY THE PREFECTURAL GOVERNMENT

The Chiba prefectural government takes levels every year in order to observe ground level fluctuation in the prefecture. Figure 3 shows recent level changes of first-order benchmarks near the cross sections in Fig. 2, illustrating ground displacement in this part of Chiba Prefecture before the 3.11 Earthquake. Vertical ground displacement has been close to zero overall at benchmarks U1 and U14. On the other hand, benchmarks U3A and U16 have settled. These points are located in areas reclaimed in the first phase. This means that post-reclamation consolidation has been continued until the present. Figure 4 shows linear approximate equations fitted to the settlement measurements for benchmarks U3A and U16 before the 3.11 Earthquake. The settlement is linear at a rate of 0.004-0.008 mm/day (or approximately 1.4-3.0 mm/year).

3. OUTLINE OF LEVEL SURVEYS BY THE AUTHORS

3.1 SURVEY LINES AND SURVEY POINTS

The authors began by establishing two survey lines across Urayasu. Figure 5 shows the locations of the survey lines, survey points, and first-order benchmarks (as managed by Chiba prefecture). Line-A connects Maihama with Chidori. It has a total length of about 3 kilometers. Line-B, taking Urayasu Station (on the Tozai subway line) as its starting point, links Kitasakae and Nekozane with Hinode and Akemi. It has a total length of about 5 kilometers. These lines were chosen to cross the alluvial lowland and reclaimed land from northwest to southeast in order to look squarely at the relation between long-term settlement after the 3.11 Earthquake and the reclamation history.

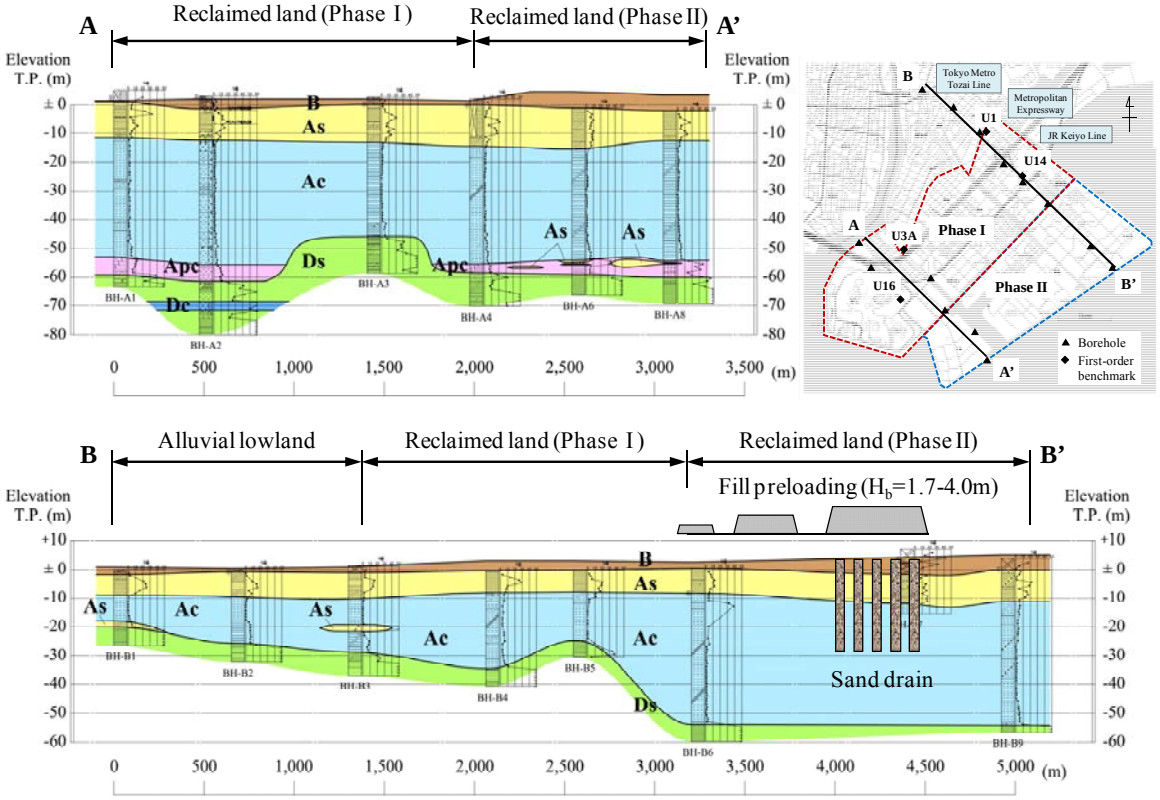

Figure 2 History of the land reclamation and geological sections through Urayasu

Neighborhoods toward the southern ends of these lines lie on comparatively new ground.

Eight survey points were selected on Line-A and twelve on Line-B. The interval between these points ranges from 150 to 800 meters. The points were selected as having a small chance of being redeveloped, demolished, removed,

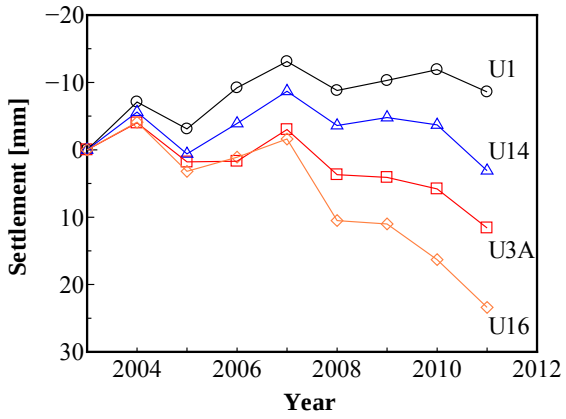

Figure 3 Level changes for first-order benchmarks before the 3.11 earthquake

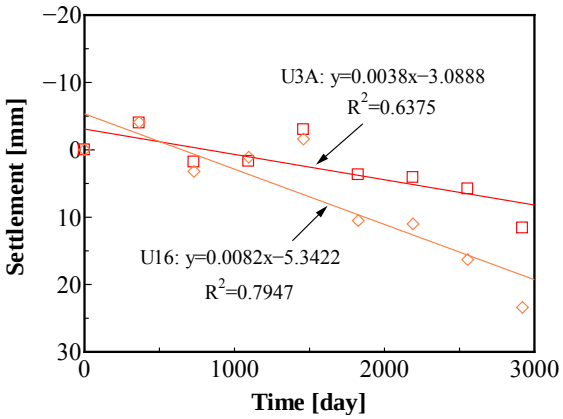

Figure 4 Linear approximate equations fitted to the settlement measurements for benchmarks U3A and U16 before the 3.11 Earthquake

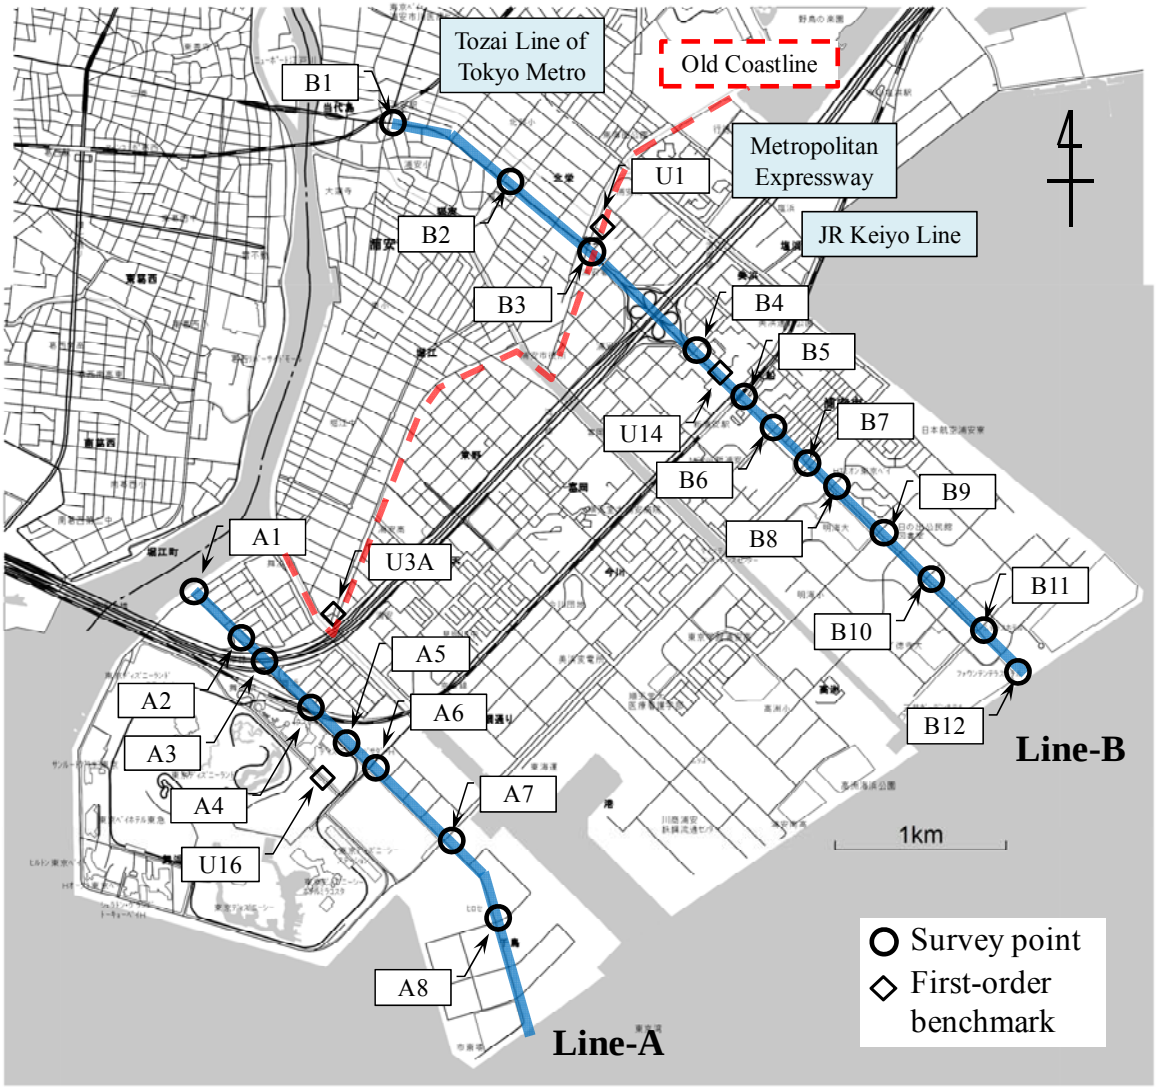

Figure 5 Location of survey lines, survey points, and first-order benchmarks

and suffering local subsidence since the intention is to obtain accurate level data over a long period. The same points were surveyed in each set of level readings. As examples of the survey points chosen, Photo 1 shows point A2, the foundation of a street lamp, and Photo 2 shows point B4, a metal marker.

All reference marks, which would not be affected by ground level fluctuation, were set up on structures supported by bearing piles or on elevated bridge piers. The type of foundation was identified by company or public records of construction.

3.2 LEVEL READINGS

The authors used the following procedure to obtain the level readings:

(1) Measure level of the reference mark (Photo 3);

(2) Relay the reference level to a location close to the survey point (Photo 4). Relay points are at intervals of 30-40 meters;

(3) Measure the relative elevation of the survey point as seen from the reference mark (Photo 5).

To control the accuracy of the observations, measurements were made out and back between three or four survey points. The difference at closure is less than 2 millimeters.

Measurements began in April 2011 and survey point levels have been taken five times as of April 2012 (including measurement of the initial levels). In addition, the first-order

benchmarks (U1, U14, and U16) were measured each time.

4. RESULT OF LEVEL SURVEYS BY THE AUTHORS

4.1 SETTLEMENT OF FIRST-ORDER BENCHMARKS

Figure 6 shows the measured settlement of the first-order benchmarks with respect to the initial April 2011 elevations recorded after the 3.11 Earthquake. Benchmark U1, sited above the alluvial lowland of the old coastline, has fallen and risen and there is no overall trend in the subsidence. On the other hand, benchmarks U14 and U16 located centrally in the phase I reclaimed land show a monotonic downward settlement. For the purpose of investigating the long-term settlement trend following the earthquake, fitted lines obtained by calculation are shown in Fig. 7. The two lines have almost the same gradient and the settlement rate is 0.02 mm/day (or 7 mm/year).

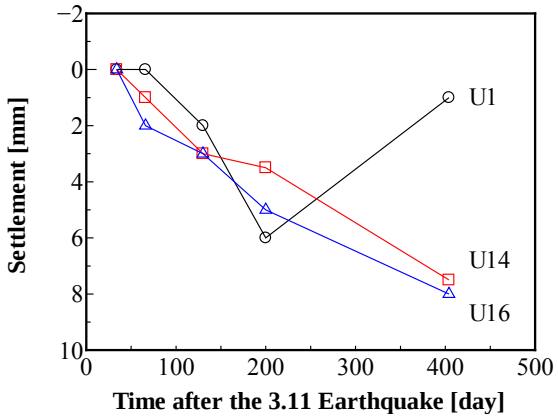

Figure 6 Level changes of the first-order benchmarks measured by the authors after the 3.11 Earthquake

Table 1 compares the settlement rate before and after the 3.11 Earthquake. The vertical strain rate, defined as the amount of settlement divided by the total thickness of the Holocene clay layer, is taken as an index of settlement in this paper because it is well known that settlement is closely linked to the Holocene clay thickness. In the case of benchmark U14, consolidation settlement by reclamation had been convergent before the earthquake. However, subsidence has re-occurred since the earthquake. As for benchmark U16, the post-earthquake vertical strain rate is 2.5 times its value before the earthquake.

Figure 8 shows the overall time history of the settlement of benchmark U16. This shows the displacement of the horizontal ground surface, which includes the following components: consolidation settlement following reclamation before the earthquake; immediate post-earthquake settlement caused by liquefaction; and long-term settlement of the Holocene clay following the earthquake. The amount of liquefaction settlement is based on an investigation of liquefaction damage (Fukutake et al., 2011) carried out seven days after the earthquake. The slope

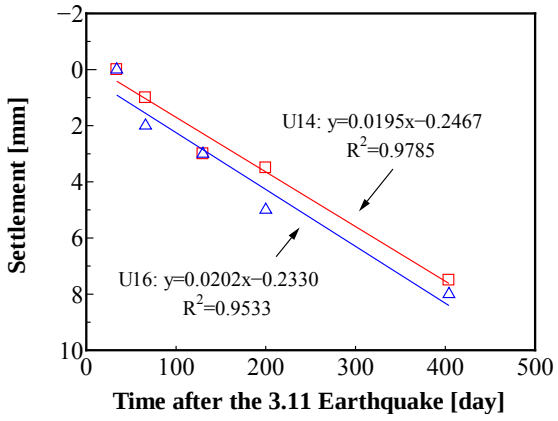

Figure 7 Linear approximate equations fitted to the settlement measurements for the first-order benchmark after the 3.11 Earthquake

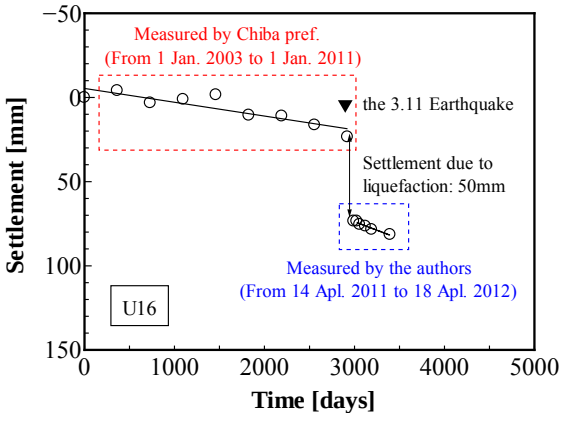

Figure 8 Overall time history of the settlement of the first-order benchmark U16

Table 1 Settlement rates before and after the 3.11 Earthquake

Bench-mark	Before the 3.11 Earthquake			After the 3.11 Earthquake			Ratio of vertical strain rates (After/Before)
	Settlement rate		Vertical strain rate	Settlement rate		Vertical strain rate	
	[mm/day]	[mm/year]	[/year]	[mm/day]	[mm/year]	[/year]	
U14	0.000	0	—	0.02	7	1.6E-04	—
U16	0.008	3	8.8E-05	0.02	7	2.2E-04	2.5

of the settlement line is clearly steeper after the earthquake; as noted above, the ratio of pre- and post-earthquake settlement strain rates is 2.5 times.

4.2 SETTLEMENT OF SURVEY POINTS

This section discusses the settlement of the survey points, which exhibit a characteristic behavior.

Figure 9 shows the vertical displacement of survey points B1 to B3 following the 3.11 Earthquake. None of these points have settled significantly. As seen in Fig. 5 previously, these three survey points are located to the south of Line-B and lie above the alluvial lowland ground which has been deposited for over ten thousand years and therefore compacted more than reclaimed ground. From this it is considered that the post-earthquake settlement rate at these points is not greater than before the earthquake.

Figure 10 shows the settlement of survey points B8 to B11 after the 3.11 Earthquake. These points are all located on the phase II reclaimed land. Nevertheless, the ground settlement behavior of each point is different. Survey points B8 and B9 have settled, while the other two have not. As already noted in section **2.1**, eastern areas of the phase II reclaimed ground were improved using both the sand drain and fill preloading methods. It is assumed that survey points B10 and B11 lie within this improved area, so they have not exhibited any settlement yet. On the other hand, survey point B8 and B9 are located in improved areas using only fill preloading, so they have seen significant settlement.

These results demonstrate that the long-term settlement behavior of the Holocene ground since the earthquake differs according to whether the area was reclaimed or reclaimed and then improved.

Figures 11 and 12 shows the chronological changes in settlement along the two survey lines. It is clear in this figure that subsidence occurs predominantly above thick Holocene clay layers.

5. CONCLUSIONS

The authors have carried out level surveys with the aim of observing the long-term settlement of Holocene clay in

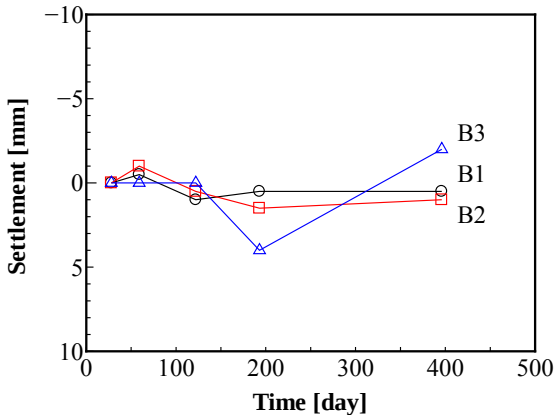

Figure 9 Settlement of survey points B1 to B3 following the 3.11 Earthquake

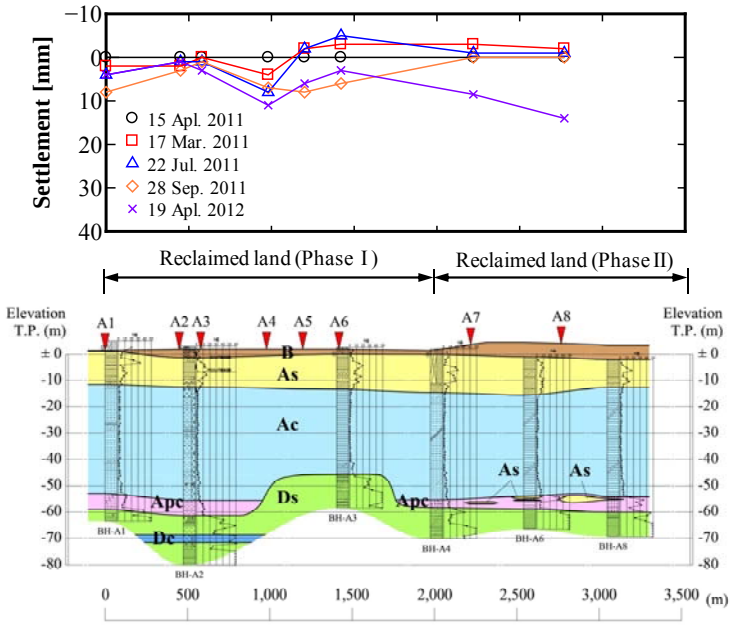

Figure 11 Chronological changes in settlement along the survey line: Line-A

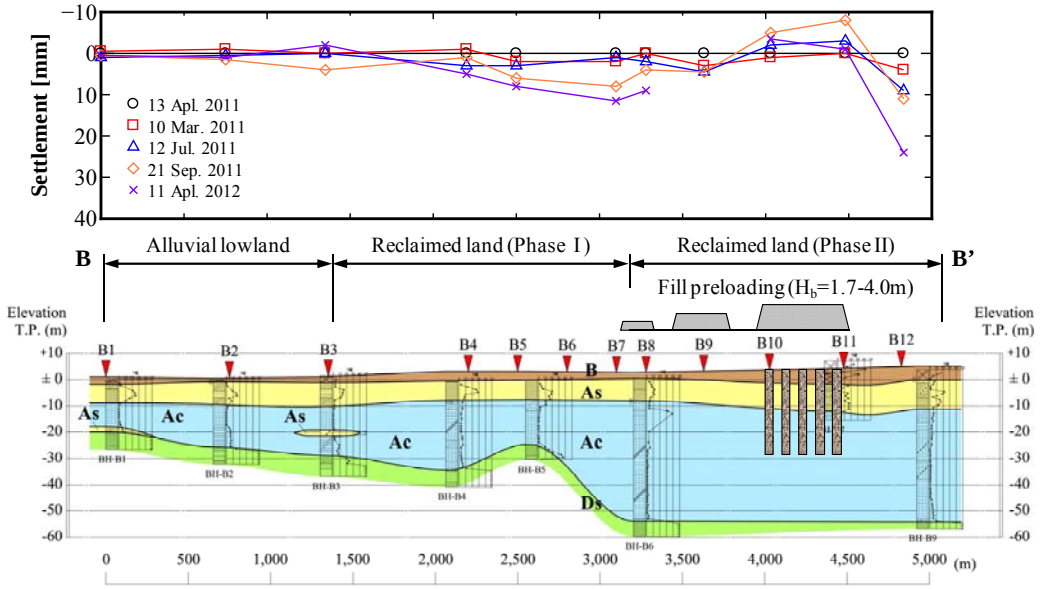

Figure 12 Chronological changes in settlement along the survey line: Line-B

Urayasu, Chiba Prefecture, following the 3.11 Earthquake. The results of the investigations can be summarized as follows:

(1) Long-term settlement of Holocene clay following the 3.11 Earthquake was observed at the first-order benchmarks and the survey points on reclaimed ground;

(2) The settlement rate observed at phase I reclaimed land after the earthquake was 7 mm/year. This is 2.5 times the settlement rate observed before the earthquake. That is, the earthquake has accelerated the subsidence of Holocene clay ground;

(3) The long-term post-earthquake settlement behavior is different according to whether the reclaimed land has been improved or not. Post-earthquake subsidence was not observed in the case of reclaimed land that had been improved using both the sand drain and preloading methods. The alluvial lowland ground also has not settled since the earthquake.

The results reported in this paper are based on ground displacement data collected by the authors in the year following the earthquake. However, there is concern that settlement of the Holocene clay may continue, so the authors plan to continue level surveys on a regular basis.

Acknowledgements:

The authors are grateful to Dr. Kiyoshi Fukutake of Shimizu Corporation for the information about the 3.11 earthquake damage in Urayasu. Also the insightful advice of Dr. Yasuhiro Shamoto and Mr. Tadashi Sakamoto of Shimizu Corporation on establishing survey points is highly appreciated. Additional data for this study was quoted from boring logs and level fluctuations of first-order benchmarks published by Chiba prefecture.

Abstract: In order to estimate the effects of alternately cyclic loading on bearing capacity and pull-out resistance of piles, monotonic and cyclic vertical loading tests were conducted on a pile with or without a wing plate near the pile tip under a centrifugal force field of 30 G. In the test model, a pile model penetrated a dry sand deposit prepared in a rigid box. Both the pull-out shaft friction and wing resistance decrease with increasing amplitude and number of cyclic loadings. In contrast, the pushing shaft friction also decreases but the pushing wing and tip resistances increase with increasing amplitude and number of cyclic loadings.

1. INTRODUCTION

Piles supporting a structure suffer cyclic vertical loading due to overturning moment from the structure. In cases of tower-like structures and/or tall buildings, the vertical load induced by the overturning moment is considered to be large. The cyclic vertical loading lowers frictional resistance of piles, which might have affected the bearing capacity and pull-out resistance of piles. In the field survey made after the 2011 Tohoku Pacific Ocean Earthquake, it was found that the damaged piles were pulled out with toppled structures in the coastal areas that tsunami attacked. It is possible, when soil liquefaction and/or cyclic loading had lowered the frictional resistance of piles, horizontal and buoyant forces of the tsunami were applied to the building, pulling the piles out of the ground (Architectural Institute of Japan, 2011). It is hence important to investigate the frictional resistance in such a case, where soil liquefaction and/or cyclic loading occur.

To investigate the bearing capacity and pull-out resistance of piles, in-situ alternately cyclic loading tests have been conducted on full-scale pile models. Yajima et al. (1992) have suggested that the maximum shaft friction of a pile is larger in the pushing direction than in the pulling direction. Nonomura et al. (2004) have suggested that the maximum shaft friction is smaller in alternately cyclic loading than in cyclic axial compressive loading. In cases of a pile with a wing plate near the pile tip, the wing resistance could act against vertical load (Kokuda et al., 2006). Komatsu et al. (2003) have confirmed that, in the pulling direction, the wing resistance acts against vertical load instead of the shaft friction after the shaft friction is lowered. However, in-situ tests need large-scale apparatus, and therefore many in-situ tests were not conducted.

To estimate the bearing capacity and pull-out resistance of piles, centrifugal model tests were conducted. In the tests, for a pile with or without a wing plate, alternately vertical cyclic loading, monotonic compressive loading and monotonic tensile loading were conducted. In this study, the effects of alternately cyclic loading on shaft friction, wing resistance and tip resistance are investigated based on the centrifugal model tests.

2. CENTRIFUGAL MODEL TESTS ON PILES WITH OR WITHOUT A WING PLATE

To investigate the effects of alternately cyclic loading on bearing capacity and pull-out resistance of piles, centrifugal model tests were conducted on piles with or without a wing plate. Fig. 1 shows a test model. In the test, a pile model was set in a dry sand deposit constructed in a cylindrical rigid box with an inner diameter of 500 mm and a height of 500 mm. To

carry out loading, a hydraulic actuator was jointed with the pile model. Fig. 2 shows pile models with or without a wing plate. The pile models were made of stainless steel pipes having a diameter of 21.7 mm and a thickness of 3 mm. In the case of a pile with a wing plate, a wing plate with a diameter of 33.6 mm and a thickness of 3 mm was welded to the pipe near the tip. Both the piles had strain gauges on the inner surface and a load cell at the tip, as shown in Figure 2. The gauges were placed at seven depths, which were named SG1 to SG7. To increase the shaft friction on the pile surface, dry sand was applied on the pile surface. To prepare a dry sand deposit in a cylindrical box, Toyoura sand (e_{max} = 0.982, e_{min} = 0.604) was used. The sand layer had a relative density of 90 % and a height of 400 mm. The sand was air-pluviated to form a uniform layer. When the height of the sand layer reached the designated height (160 mm), the pile model was set with a penetration of 10 mm into the sand layer.

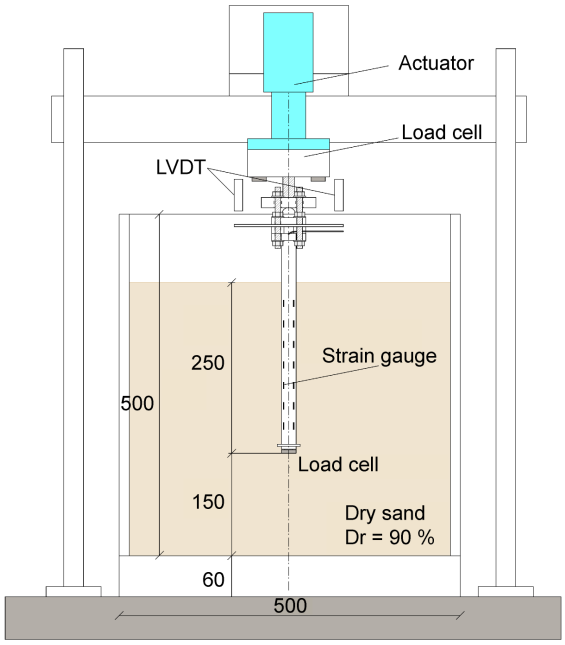

Figure 1 Test model

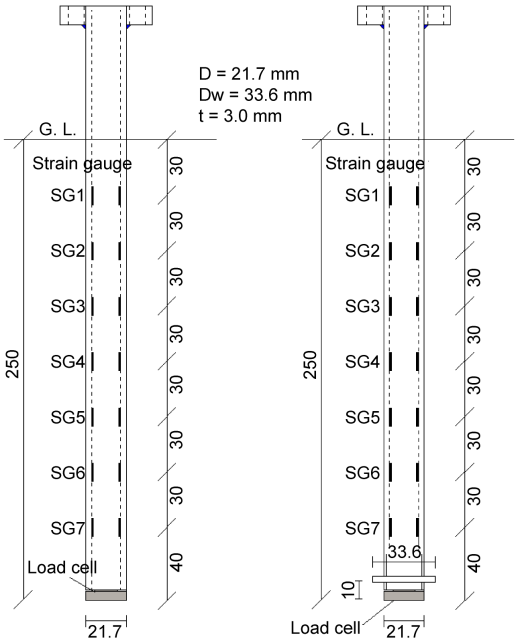

Figure 2 Pile models

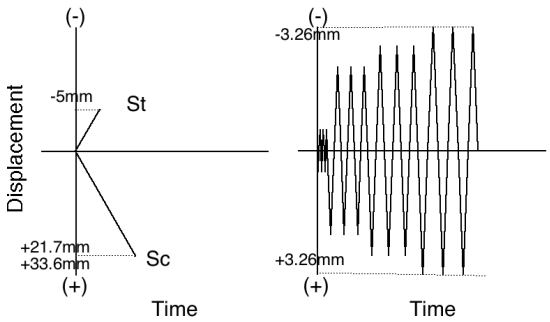
All tests were performed under a centrifugal acceleration of 30G. Table 1 and Figure 3 show test series conducted in this study. Alternately cyclic loading and monotonic loading for piles with or without a wing plate were conducted under displacement control with a loading rate of about 1.0 mm/min. In Table 1, a subscript of "d" stands for percentage (%) of pile displacement with respect to a pile diameter. The maximum loading displacement was equal to a pile diameter (21.7 mm) or a wing plate diameter (33.6 mm) in the monotonic compressive loading tests and was equal to 25 % of a pile diameter (5.0 mm) in the monotonic tensile loading test. In the alternately cyclic loading tests, the loading amplitude was gradually increased in four steps (1, 5, 10 and 15 % of a pile diameter). In each step, the loading was repeated three times, as shown in Figure 3(b). In the tests, vertical load and vertical displacement at the pile head, tip resistance and axial strains at seven depths of piles were observed. Henceforth, a pile without a wing plate is called Pile-S and that with a wing plate is called Pile-W, respectively.



To estimate the bearing capacity and pull-out resistance of piles, P, forces acting on the piles are defined by the following equations:

$$\text{Pile-S} \quad \text{<pushing>} \quad P = R_p + R_f \tag{1}$$

$$\text{<pulling>} \quad P = R_f \tag{2}$$

$$\text{Pile-W} \quad \text{<pushing>} \quad P = R_p + R_f + R_w \tag{3}$$

$$\text{<pulling>} \quad P = R_f + R_w \tag{4}$$

Figure 3 Loading displacement

Table 1 Test cases

	Pile model	Loading	Loading displacement (mm)
S_Sc	Pile-S	Compressive loading	+21.7
W_Sc	Pile-W		+33.6
W_St	Pile-W	Tensile loading	-5.0
S_C1	Pile-S	Alternately cyclic loading	±0.217(d_1), ±1.09(d_5), ±2.17(d_{10}), ±3.26(d_{15})
W_C1	Pile-W		

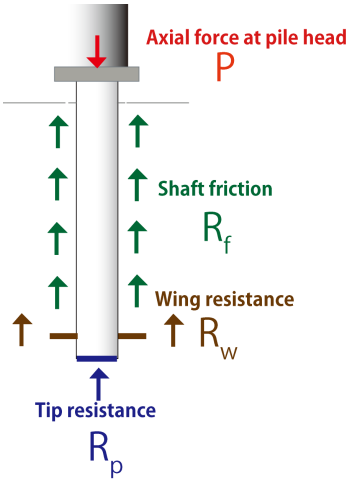

Figure 4 Forces acting on pile

in which R_p, R_f and R_w stand for tip resistance, entire shaft friction and resistance of wing plate (wing resistance), respectively. In this study, P and R_p correspond to the vertical load observed at the pile head and at the pile tip. R_f is estimated from the difference between the vertical load at the pile head and the axial force observed at strain gauge SG6. R_w is estimated from the difference between the tip resistance and the axial force observed at strain gauge SG6. The reason why strain gauge SG7 is not used is because SG7 was located closely to a device for setting a load cell and its observed values might have been inaccurate (Figure 2). In this study, positive values stand for compressive force or displacement in the pushing direction, while negative values stand for tensile force or displacement in the pulling direction. The values shown in the following part correspond to the observed values in the model scale and not in the prototype scale.

3. EFFECTS OF ALTERNATELY CYCLIC LOADING ON BEARING CAPACITY AND PULL-OUT RESISTANCE OF PILES

3.1 Bearing capacity and pull-out resistance of piles in monotonic loading

Figure 5 shows the relations of pile displacement with axial force at the pile head, tip resistance, shaft friction and wing resistance for monotonic loading tests. In the figures, the relations for Pile-S are presented in black lines and those for Pile-W are presented in gray lines. The shaft friction is significantly smaller than other forces because the pile length is relatively short (7.5 m in the prototype scale). The tip resistance does not reach the ultimate value under a large loading displacement (Figure 5(b)). In contrast, the shaft friction reaches the ultimate value with a displacement of 1-2 mm, and then it gradually decreases with increasing displacement (Figure 5(c)). The wing resistance does not reach the ultimate value in the pushing direction but reaches the ultimate value in the pulling direction (Figure 5(d)).

The yield displacement of the shaft friction (1-2 mm) corresponds to 30-60 mm in the prototype scale. This is larger than the yield displacement presented in the AIJ Recommendation (Architectural Institute of Japan, 2001), in which the yield displacement is 5-20 mm. The previous study has shown that the yield displacement is larger in cases of gravel than in cases of fine sand (Isemoto et al., 2000). The difference in the yield displacement between reduced scale and prototype scale might have been induced by the scale effect.

3.2 Bearing capacity and pull-out resistance of piles in alternately cyclic loading

To estimate the effects of alternately cyclic loading on bearing capacity and pull-out resistance of piles, Figure 6 shows the relations between pile displacement and axial force at the pile heads in black lines. In the figures, grey lines indicate the relations for monotonic loading tests. In the pushing direction, the axial force at the pile head increases with increasing amplitude and number of cyclic loading. In contrast, in the pulling direction, the axial force at the pile head decreases. This suggests that alternately cyclic loading might have increased bearing capacity but decreased the pull-out resistance. The pull-out resistance becomes close to zero with amplitude of 2.17 mm (d_{10}) in the case of Pile-S and of 3.26 mm (d_{15}) in the case of Pile-W.

To estimate the decrease in pull-out resistance, normalized load in the cyclic loading tests is determined.

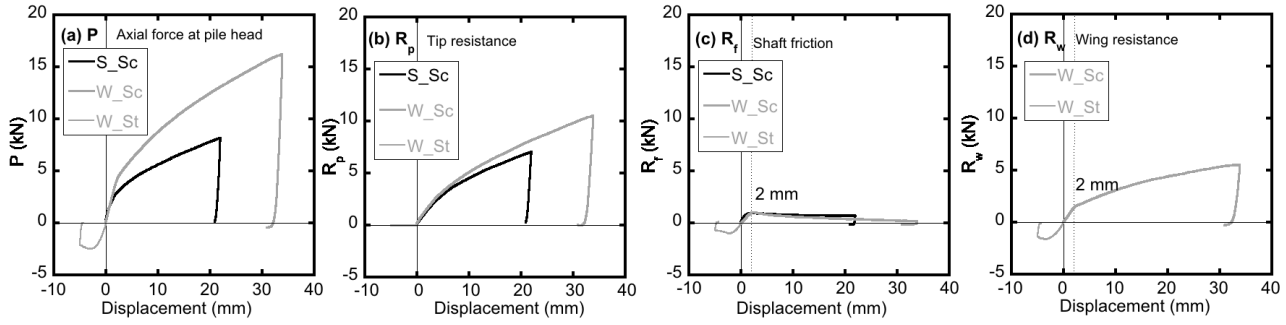

Figure 5 Relation of resistance with vertical pile displacement in monotonic loading tests

The normalized load is given as a ratio of the value in cyclic loading tests with respect to that in monotonic loading test with the same loading displacement. A monotonic tensile loading test on Pile-S was not conducted. Further, in the case of Pile-S, the shaft friction is assumed to be the same between the pushing and pulling directions as the shaft friction of Pile-W is almost the same between the pushing and pulling directions. Namely, the pull-out resistance of Pile-S is equal to the observed shaft friction in the pushing direction, as shown in Eq. (2). Henceforth, the subscripts "mono" and "cyc" indicate the values in the monotonic loading tests and in the cyclic loading tests respectively.

Figure 7 shows the normalized pull-out resistance of the first and third cycle in each step. The normalized pull-out resistance decreases with the cyclic loading when the loading amplitude is greater than 1.09 mm (d_5). A comparison in the normalized resistance in the third step with amplitude of 1.09 mm (d_5) between Pile-S and Pile-W shows that a ratio with respect to the monotonic loading is 30 % in Pile-S and 50 % in Pile-W. Further, with amplitude of 3.26 mm (d_{15}), the pull-out resistance becomes as low as 20 % of that in the monotonic loading tests.

To estimate the increase in bearing capacity in the pushing direction, Figure 8 shows the relations of tip resistance with pile displacement. The tip resistance increases with increasing amplitude and number of cyclic loading in both the cases of Pile-S and Pile-W. These trends are related to those in the axial force at the pile head (Figure 6), indicating that the increase in the axial force at the pile head is induced by the increase in the tip resistance. To notice a displacement, at which the tip resistance develops in pushing, the displacement is shifted from 0 mm at the initial stage to the negative side after cyclic loading. In the final loading step, the tip resistance develops with a displacement of -2.0 mm (Figure 8(b)). These findings indicate that the sand might have moved beneath the pile tip in pulling and might have been densified by the pile tip in pushing, as shown in Figure 9.

To estimate the effects of alternately cyclic loading on the shaft friction, Figure 10 shows the relations of shaft friction with pile displacement. With increasing amplitude and number of cyclic loading, the shaft friction becomes smaller than that in the monotonic loading in both the cases of Pile-S and Pile-W. The normalized shaft friction is computed as a ratio of the shaft friction with respect to that with the same loading displacement in monotonic loading tests. Figures 11 and 12 show the normalized shaft friction for the first and third cycles in each loading step. The normalized shaft friction significantly decreases when loading amplitude is greater than 1.09 mm (d_5). The ratio of shaft friction in cyclic loading with respect to that in monotonic loading is 50 % in the pushing direction and 20 % in the pulling direction.

Figure 13 shows the distributions of axial force for the first and third cycles with loading amplitude of 1.09 mm (d_5). It is to be noted that the axial force decreases at around 180 mm depth in Pile-W; this is because the wing resistance acts against the axial force. The difference between the first and third cycles is more significant in the pulling direction than in the pushing

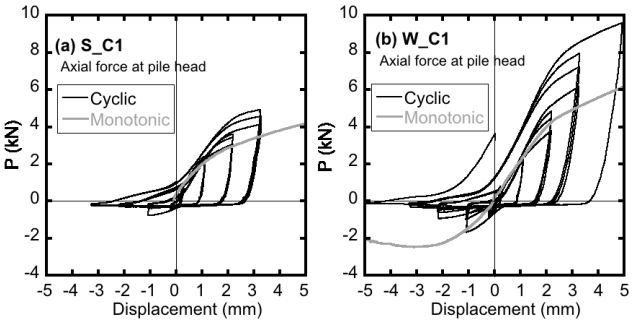

Figure 6 Relation of axial force with pile displacement

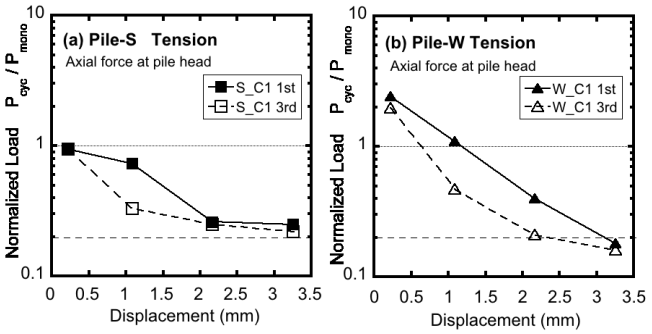

Figure 7 Relation of normalized axial force with loading amplitude in pulling

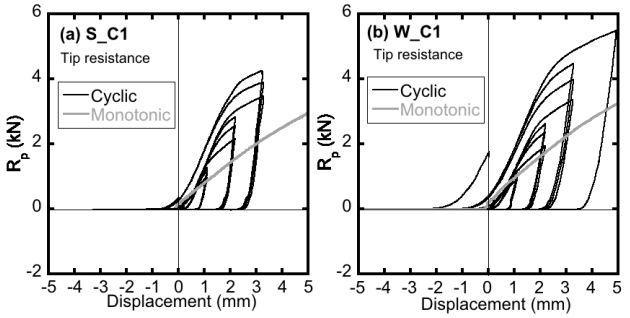

Figure 8 Relation of tip resistance with pile displacement

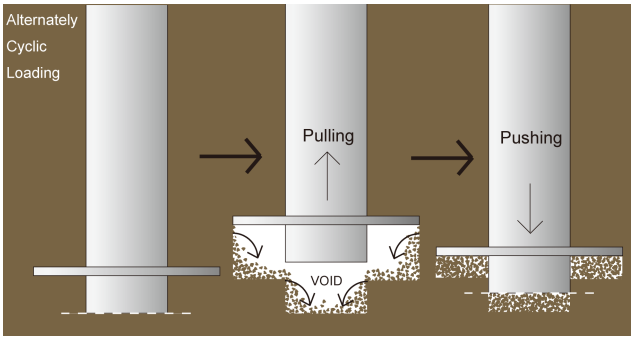

Figure 9 Increase in sand density beneath pile tip due to alternatively cyclic loading

direction, confirming that the decrease in shaft friction is more significant in the pulling direction than in the pushing direction. This is probably because the shaft friction depends on the overburden load. The shear deformation caused by pushing a pile acts to increase the overburden load in the soil around the pile. In contrast, the shear force caused by pulling a pile acts to decrease the overburden load in the soil around the pile.

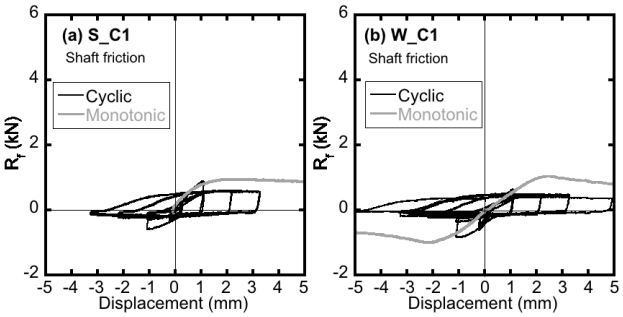

Figure 10 Relation of shaft friction with pile displacement

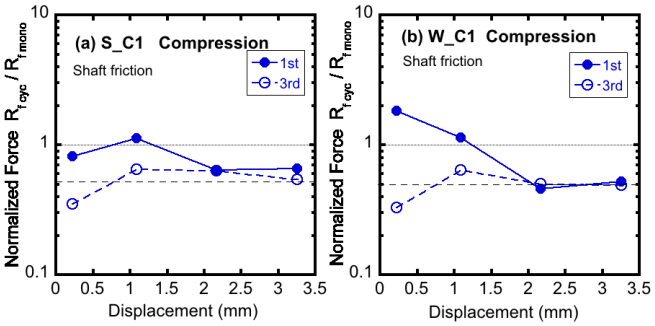

Figure 11 Relation of normalized shaft friction with loading amplitude in pushing direction

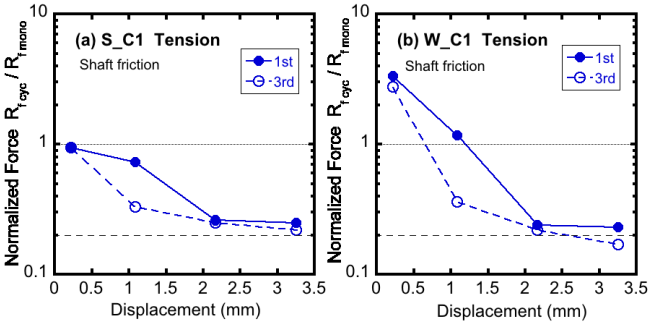

Figure 12 Relation of normalized shaft friction with loading amplitude in pulling direction

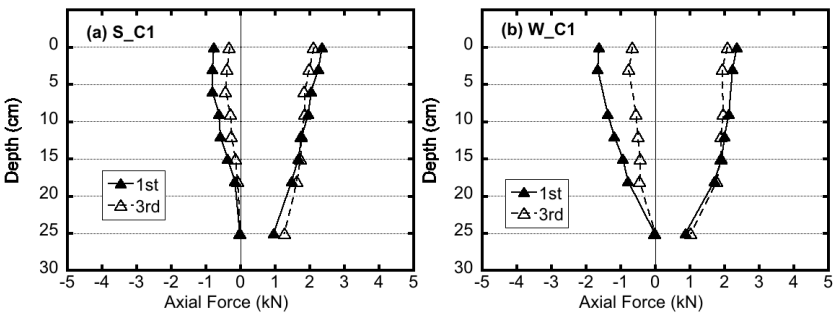

Figure 13 Distribution of axial force with depth under loading amplitude of 1.09 mm

To estimate the effects of a wing plate, Figure 14 shows the relations of wing resistance with pile displacement. The wing resistance in the pushing direction increases with increasing amplitude and number of cyclic loading, the trend of which is similar to that in the tip resistance shown in Figure 8. A displacement, at which the wing resistance develops in the pushing direction, is shifted from zero to the negative side. Namely, the wing plate tends to move and increase the density of the soil beneath the wing plate, similarly to the pile tip. In contrast, in the pulling direction, the wing resistance decreases with increasing amplitude and number of cyclic loading.

Figure 15 shows the normalized wing resistance for the first and third cycles in each loading step in the pulling direction. It is given as a ratio of the wing resistance in cyclic loading with respect to that in monotonic loading. The wing resistance decreases after the loading amplitude exceeds 1.09 mm (d_5), and finally it becomes as low as 20 % of that in monotonic loading. This is probably induced by a disturbance and a decrease of density of the soil above the wing plate. A comparison of the trends between the shaft friction and the wing resistance in pulling shows that the decrease is more significant in the shaft friction than in the wing resistance. As a result, the wing resistance dominates over the shaft friction in resisting pull-out loading.

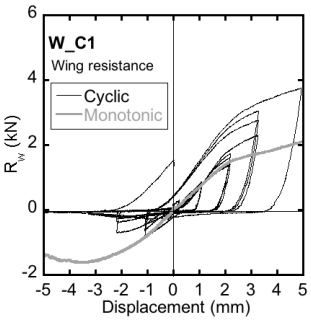

Figure 14 Relation of wing resistance with pile displacement

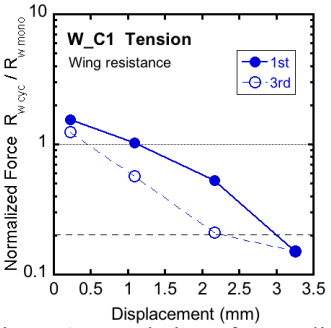

Figure 15 Relation of normalized wing resistance with loading displacement

4. CONCLUSIONS

To estimate the bearing capacity and pull-out resistance of a pile with or without a wing plate, monotonic loading tests and alternately loading tests were conducted under centrifugal acceleration of 30 G. The test results and discussions have led to the following conclusions:

1) When the cyclic loading amplitude exceeds 5-10 % of pile diameter, the bearing capacity increases but the pull-out resistance decreases. This is because the pushing and pulling shaft friction and the pulling wing resistance decreases but the pushing tip and wing resistances increase with increasing amplitude and number of loading displacement.

2) The increase in the tip resistance might have been induced by a phenomenon in which the pile tip tends to move and to densify the soil beneath the pile tip.

3) The shaft friction decreases when the cyclic loading amplitude becomes greater than 1.0 mm. The shaft resistance in the pullout direction decreases to as low as 1/5 of the peak value in the monotonic loading, whereas that in the pulling direction decreases to 1/2. This is because the shear deformation of the soil around a pile induced by loading increases overburden load in pushing but decreases overburden load in pulling.

4) The pushing wing resistance increases with increasing amplitude and number of cyclic loading, the trend of which is similar to that of the tip resistance. In contrast, the pull-out wing resistance decreases with cyclic loading. The decrease in the pulling direction is more significant in the shaft friction than in the wing resistance. As a result, in the case of a pile with a wing plate, the wing resistance dominates over the shaft friction in resisting pull-out loading.

APPLICABILITY OF EQUIVALENT LINEAR SEISMIC RESPONSE ANALYSIS UNDER LARGE EARTHQUAKES

Nozomu Yoshida[1)]

1) Professor, Department of Civil and Environmental Engineering, Tohoku Gakuin University, Japan

Abstract: Equivalent linear analysis and truly nonlinear analysis are compared at 268 sites under 11 earthquake motions in order to grasp general feature of the applicability of the equivalent linear method. SHAKE and YUSAYUSA are used for equivalent linear and truly nonlinear methods, respectively. The stress-strain relationships are modeled into the hyperbolic model whose elastic modulus and shear strength are evaluated based on the soil profiles and the SPT-*N* value. SHAKE shows larger peak acceleration and smaller peak displacement than YUSAYUSA, but other indices such as instrumental seismic intensity, peak velocity, and spectral intensity are nearly same to each other. In conclusion, equivalent linear analysis is applicable when truly nonlinear analysis is applicable except the case that peak acceleration and/or peak displacement are important. Even in this case, however, since peak acceleration is overestimated, it is a conservative side evaluation for the design of structures.

1. INTRODUCTION

Seismic response analysis of ground is one of the frequently used tools for the design of various structures. Various methods and computer programs have been proposed. One of the frequently used computer programs is SHAKE (Schnabel et al., 1972), which uses equivalent linear techniques. The name SHAKE is now used as if it is a common noun, and it is also used as common noun in this paper. Unlike the name "equivalent", however, it is an approximate method. Therefore, it is believed that it cannot be applied at large strains. For example, Ishihara (1982) suggests constitutive models and methods of the seismic response analysis related to different shear strain ranges and soil properties as shown in Figure 1.

On the other hand, input earthquake motion has increased significantly in Japan, especially after the 1995 Kobe earthquake and more after 2007 Niigataken-chuetsu-oki earthquake. Magnitude of the design earthquake motion, for example, exceeds 1 G in the design of a nuclear power plant. Design input earthquake motion with maximum acceleration more than 0.5 m/s^2 is not an extraordinary case, but frequently appears in the practical design of civil and building structures. In these situations, maximum shear strain frequently reaches a few percent or more. Regardless of the applicable range in Figure 1, however, SHAKE is still used in many engineering practice partly because of the easy handling and stable numerical integration.

There are not a few researches comparing the SHAKE and truly nonlinear analysis, and some of them pointed that they agree to each other well and some are not. This difference comes from various reasons. At first, there are shortages in SHAKE because it is an approximated method, which is discussed in detail by the authors (Yoshida et al.,

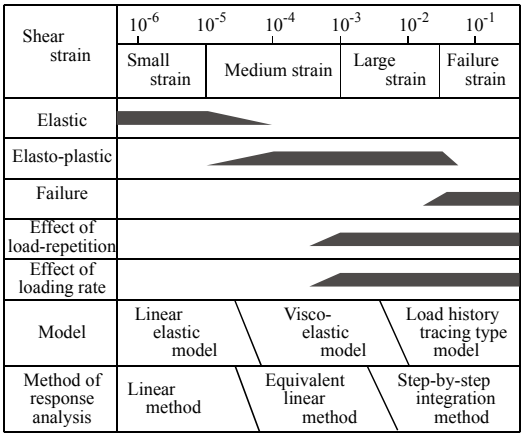

Figure 1 Change in soil properties with shear strain and corresponding modelling principle and method of response analysis (Ishihara, 1982)

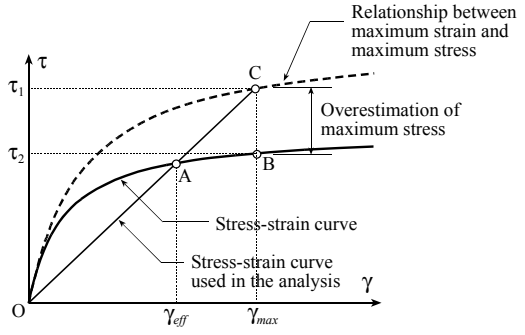

Figure 2 Mechanism of overestimation of maximum shear stress (Yoshida et al., 2002)

2002). There are two shortages in addition to the fact that it cannot express the accurate stress-strain behavior because it is produced by the complex moduli.

The first shortage is overestimation of the maximum acceleration. The mechanism is shown in Figure 2. Since stress-strain relationships is a linear line passing the point A (γ_{eff}, $\tau=G\gamma_{eff}$), maximum stress at $\gamma=\gamma_{max}$ (τ_1 at point C) is larger than actual stress (τ_2 at point B), which overestimation of maximum shear stress result in overestimation of maximum stress.

The second shortage is typically seen in Figure 3. Amplification is significantly underestimated at high frequency. Maximum acceleration is underestimated by this mechanism.

These two factors work in the opposite way. The first mechanism overestimates maximum acceleration and the second mechanism underestimates maximum acceleration. Degree of effects depends on the degree of nonlinearity. This

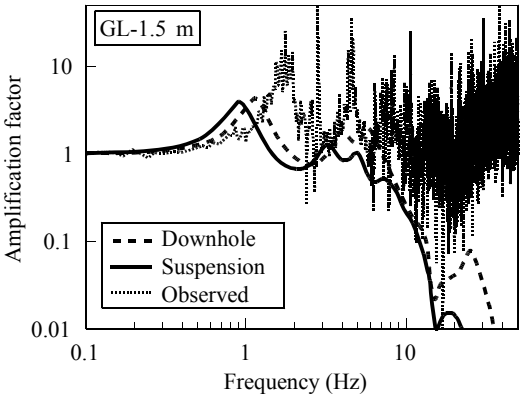

Figure 3 Underestimation of amplification at high frequencies (Yoshida et al., 2002)

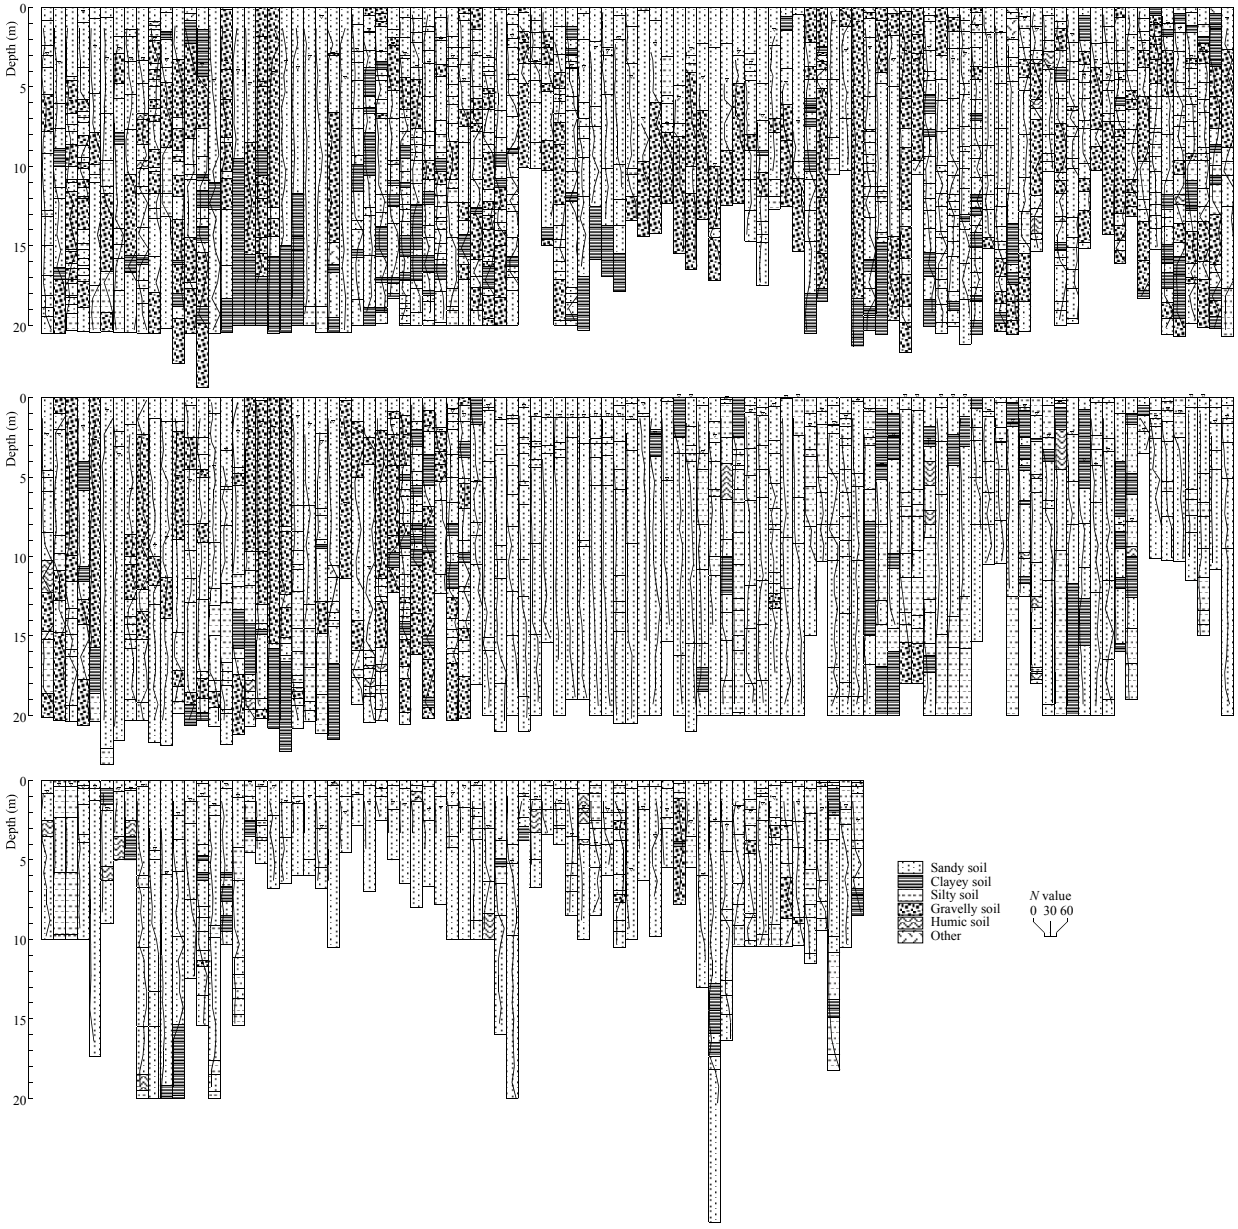

Figure 4 Soil profiles

may be one of the reasons why evaluations of SHAKE scatter.

Another reason of scatter of the evaluation is the method how to evaluate the applicability or the accuracy of the seismic response analysis. Agreement of the maximum acceleration was sometimes used and sometimes frequency characteristics were used, and sometimes others. It means that indices convenient for the purpose have been used.

There are many indices that express intensity of the earthquake motion, which also makes the evaluation of applicability difficult. In addition, only a small number of ground model and./or small number of earthquake motion were used in the past researches. In addition, difference may appear depending on earthquake motions.

In this paper, accuracy of SHAKE is evaluated by comparing the truly nonlinear method for more than 200 sites and under various types of input earthquake motions.

2. GROUND AND MODELING

Figure 4 shows soil profiles and SPT-*N* value of the ground used in this paper; in total, 268 sites are used. These sites were the sites used to evaluate applicability of the conventional method to evaluate onset of identification during the 1995 Kobe earthquake (Public Work Research Institute, 1996). Among them, 137 sites are related to the Kobe earthquake and the rest to other earthquakes.

Soils are classified into 6 categories, i.e., sand, silt, clay, gravel, humus, and others. Here, others include concrete and cobble, etc. In the modeling, humus soil are treated same as clay, and others are set same as soil below. The SPT-*N* values are averaged in the same soil layer. If there is no *N* value data in a layer, it is set same with the below layer. These modeling may not be good if actual behavior of the ground is investigated, but are not because the purpose of this paper is to investigate different ground model.

Unit weight of each layer was included in the original data. The shear wave velocity V_s is evaluated based on the specifications for highway bridges (JRA, 2012), i.e.,

$$V_s = 100N^{1/3} \quad \text{(clayey soil)} \tag{1}$$

$$V_s = 80N^{1/3} \quad \text{(soil other than clay)} \tag{2}$$

Shear strength of the clayey soil is evaluated as an average value suggested by JGS (2004)

$$\tau_f = 19N \quad \text{(kPa)} \tag{3}$$

On the other hand, the internal friction angle ϕ is evaluated based on Hatanaka and Uchida (1996) as

$$\phi = 20 + \sqrt{20N_1} \quad \text{(degree)} \tag{4}$$

where N_1 is corrected *N* value considering the effective over burden stress, and is evaluated as (JRA, 2012)

$$N_1 = \frac{170N}{\sigma'_v + 100} \quad (\sigma'_v \text{ in kPa}) \tag{5}$$

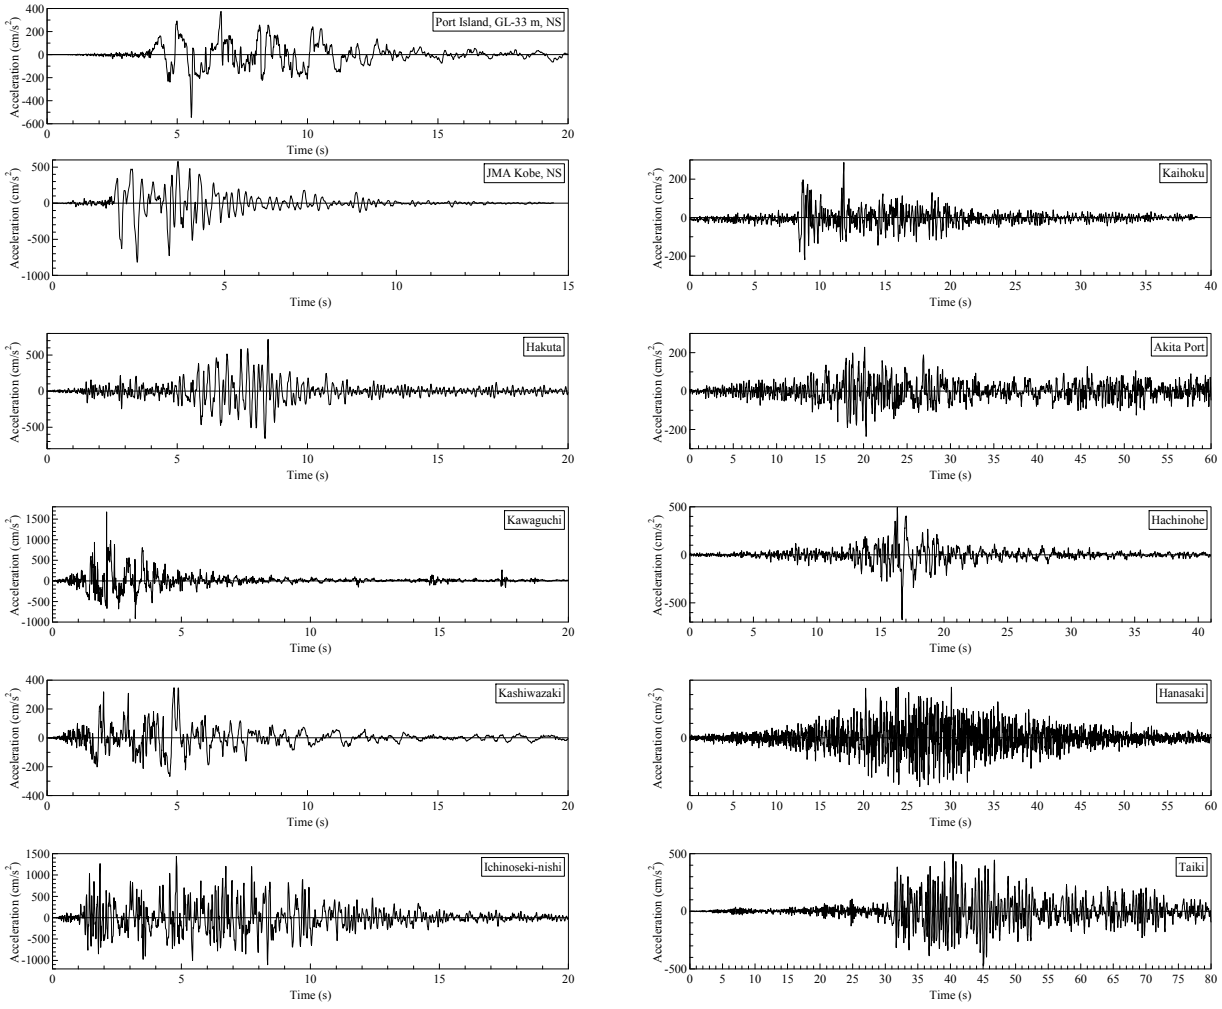
The hyperbolic model

$$\tau = \frac{G_0\gamma}{1 + \tau_f\gamma / G_0} \tag{6}$$

is used for shear stress τ- shear strain γrelationships, and the Masing's rule is used to obtain hysteresis curve.

3. EARTHQUAKE MOTION

Input earthquake motion must have various and typical nature in order to obtain the general feature of the response. Eleven recorded earthquake motions which have different characteristics are employed so as to confirm this requirement. They are as follows.



1) Inland earthquake
   Port Island GL-33 m, NS, 1995 Kobe eq.
   JMA Kobe, NS, 1995 Kobe eq.
   Hakuta, NS, 1999 Tottoriken-seibu eq.
   JMA Kawaguchi, EW, 2004 Niigataken-chuetsu eq.
   TEPCO Kashiwa-Kariwa Service hole SG1, NS, 2007 Niigataken-chuetsu-oki eq.
   Ichinoseki-nishi, EW, 2008 Iwate-Miyagi-nairiku eq.
2) Ocean trench earthquake
   Kaihoku bridge EW, 1978 Miyagiken-oki eq.
   Akita port, 1983 Nihonkai-chubu eq.
   Hachinohe office, EW, 1994 Sanriku-haruka eq.
   Hanasaki, EW, 1994 Hokkaido-toho-oki eq.
   Taiki, EW, 2003 Tokachi-oki eq.

These waves are applied as the earthquake motion of the outcropped base. Layers with V_s=300 m/s is added at the bottom of the ground in Figure 4 in the SHAKE analysis. The shear wave velocity of the base layer is confirmed not to affect the behavior in the subsoil (Usami et al., 2009)

Waveforms of the input motion are shown in Figure 5. Generally speaking, duration of the earthquake is shorter in the inland earthquakes. Figure 6 shows response spectra of the input motions under 5% damping.

4. METHOD OF ANALYSIS

Two different methods, equivalent linear method and truly nonlinear method, are used to evaluate applicability of SHAKE. A computer program DYNEQ (Yoshida, 1995) is used for the equivalent linear analysis. DYNEQ is an open source program that has various functions based on complex moduli method, among which technique same with SHAKE is used in the calculation, and is referred as SHAKE. A computer program YUSAYUSA-2 (Yoshida and Towhata, 1991), which is also an open source program, is used for the

(a) Inland earthquakes (b) Ocean trench earthquakes

Figure 5 Input earthquake motions

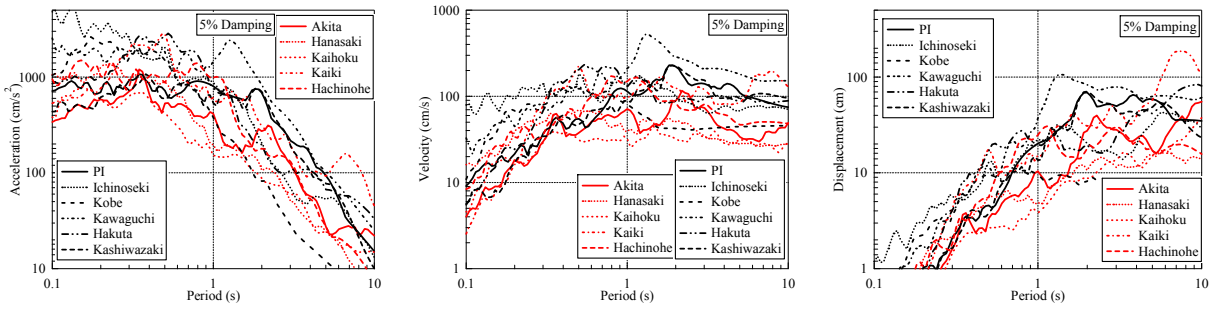


Figure 6 Response spectra of input motion

truly nonlinear analysis. It will be referred as YUSAYUSA.

These two programs are examined under the same condition, i.e., the same ground model and the same stress-strain relationships. The only difference is that velocity proportional damping is considered in YUSAYUSA for the stability of numerical integration. Since the Rayleigh damping is employed, viscous coefficient matric [c] is calculated from the mass matrix [m] and stiffness matrix [k] as

$$[c] = \alpha[m] + \beta[k] \tag{7}$$

where α and β are constants and are set 0.090, 0.00091 so that average damping ratio between 0.5 Hz and 6 Hz becomes 1.43 % (Q=35).

5. COMPARISON AND DISCUSSION

5.1 Earthquake motion index

Many earthquake motion indices have been proposed, which indicates difficulty to express the intensity of the ground motion in one index. In this paper, several frequently used indices are used.

1) Peak acceleration

Peak acceleration is the most frequently used index because it directly related to inertia force of the structure. However, it is sometimes too sensitive.

2) Peak velocity

Applicability of the peak acceleration as an earthquake motion index becomes less for longer period structure. Instead of it, peak velocity becomes a good index. Here, this velocity is absolute velocity, but not relative velocity from the base although relative velocity is frequently used as output because it is directly obtained by solving the equation of motion.

3) Peak displacement

Displacement is a very important index for the design of the underground structures. Comparison of relative displacement with recorded one is very difficult to evaluate them from the earthquake record because vertical array records are necessary and because it depends on the method of integration as will be seen in in Figure 11. However, it can be done between analyses.

4) Instrumental seismic intensity

Seismic intensity has been used to express the degree of damage or ground shaking. Because of its nature, it takes time to evaluate the seismic intensity. After the 1995 Kobe earthquake, Japan Meteorological Agency made an seismic intensity which can be calculated from the acceleration time history and which is consistent with traditional JMA seismic intensity (Muramatsu, 1996). Evaluation of seismic intensity can be done very quickly. Instrumental seismic intensity I_{JMA} is evaluated as

$$I_{JMA} = 2\log a_0 + 0.94 \tag{8}$$

where a_0 is the acceleration in cm/s^2 that sum of duration in which acceleration exceeds a_0 is 0.3 s in the filtered acceleration-time history. It is defined by using three directional component, but only one-directional component is used in this paper.

5) Spectral Intensity

Spectral intensity SI is first proposed by Housner (1965) by integrating the response spectrum from 0.1 s to 2.5 s. It is modified to divide 2.4 s in order to make the dimension of the seismic intensity to be same with velocity. Then it is calculated as

$$SI = \frac{1}{2.4}\int_{0.1}^{2.5} S_{v,0.2}\,dt \tag{9}$$

where $S_{v,0.2}$ is a velocity response spectrum under 20 % damping. Equation (9) indicates that SI is an average of velocity spectrum between 0.1 and 2.5 s. Pseudo velocity spectrum is sometimes used instead of velocity spectrum, but velocity spectrum is used in this paper.

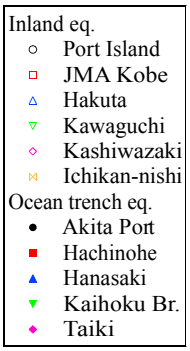

Figure 7 Legend to distinguish input earthquake

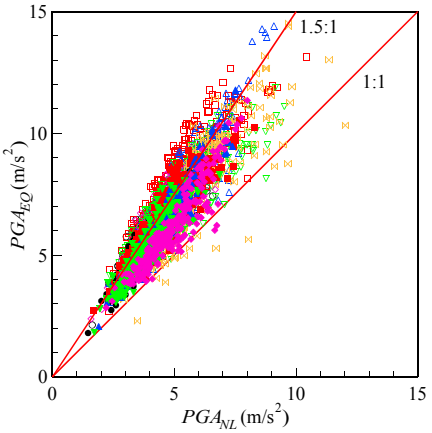

Figure 8 Comparison of peak ground accelerations

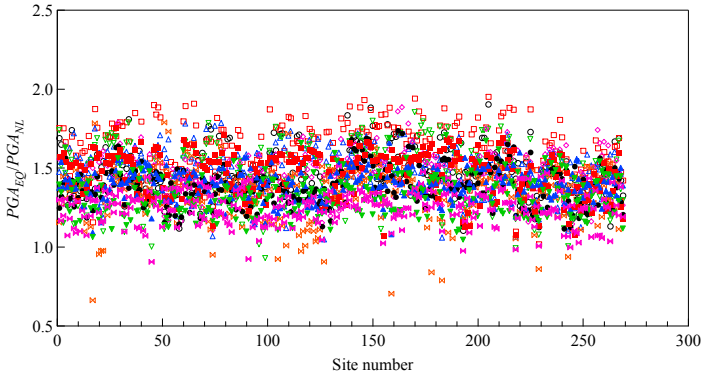

Figure 9 Acceleration ratios (SHAKE/YUSAYUSA)

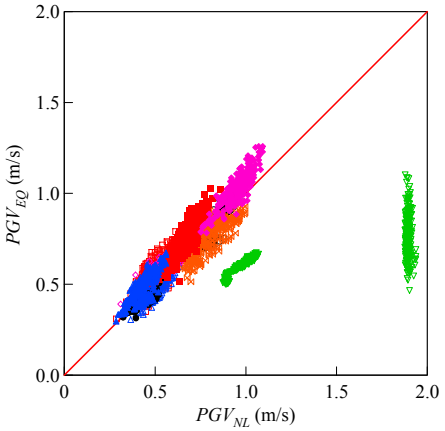

Figure 10 Comparison of peak ground (absolute) velocity

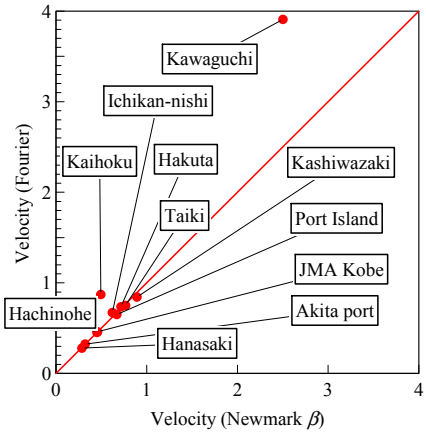

Figure 11 Maximum velocity of input earthquake motions

5.2 Comparison of indices

Result under 11 earthquake motions are shown in one figure in the followings. Result of each earthquake motion is distinguished by the symbols in Figure 7.

Figure 8 compares PGAs by all analyses, where subscript *EQ* indicates equivalent linear method (SHAKE) and *NL* indicates nonlinear method (YUSAYUSA). Two lines are drawn in the figure whose gradients are 1:1 and 1.5:1. PGA by SHAKE is always larger than that by YUSAYUSA except only several cases. PGA is overestimated more than 1.5 times in SHAKE in many cases. The mechanism of this overestimation is already pointed out by Yoshida et al. (2002).

Figure 9 shows ratio of PGA in each soil profile. The same symbols seem to lie nearly horizontally although PGA scatters widely as seen in Figure 8.

Peak ground velocity, PGA, is compared in Figure 10. Both PGV's are nearly the same although that by the equivalent linear method seems to be a little larger than that by the nonlinear analysis. There are, however, two exceptions. PGV by nonlinear method shows much larger value than that of equivalent linear method under Kawaguchi (△) and Kaihoku (▼). This is not caused from the difference of the analytical methods but other reason.

Input earthquake motions are integrated to obtain absolute velocity by Fourier transform in SHAKE and Newmark's β method (β=0.25) in YUSAYUSA, respectively. Zero-th order or constant term is neglected in SHAKE, but is also integrated in YUSAYUSA. Figure 11 compares maximum velocity integrated by the Fourier transform and by the Newmark's β method. Almost all earthquake motion shows the same maximum velocity in two methods, but maximum velocity by the Newmark's β method is much larger than that by Fourier transform for Kaihoku and JMA Kawaguchi, which is the reason why PGV's by YUSAYUSA are much larger than those by SHAKE in Figure 10.

Considering these it can be concluded that PGV's are nearly the same for both SHAKE and YUSAYUSA although those by SHAKE is a little larger than those by YUSAYUSA.

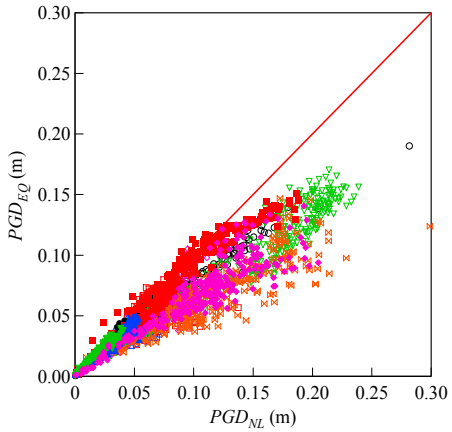

Figure 12 Comparison of PGD

Figure 12 compares displacements at the ground surface relative to base, PGD. PGD by SHAKE is in general smaller than that by YUSAYUSA. This behavior can be explained by the mechanism in Figure 2. Since stiffness is estimated large in SHAKE, resulting stress becomes small. It is also seen that degree of difference depends on the earthquakes as the same symbol shows similar tendency. Both analyses, for example, show similar PDG under Kaihoku. PDG's under Hachinohe also seem similar although PGD by SHAKE becomes smaller when PDG becomes larger than 0.1 m. In addition, agreement is better under the ocean type earthquake than under the inland earthquake, except under Taiki.

Figures 13 and 14 compare JMA seismic intensity I_{JMA} and spectral intensity *SI*, respectively. Same with PGV, both indices are nearly the same although those by SHAKE are a little larger than that by YUSAYUSA. It is also pointed out that data under the same earthquake motion show similar characteristics

Figure 15 shows comparison of maximum stresses by both methods. Here, the largest strain in each ground is used as the maximum strain. Therefore, it may not be the same layer. If the mechanism shown in Figure 2 works, the shear

strain by SHAKE is smaller than that by YUSAYUSA. Validity of this mechanism was confirmed through Figure 2 and Figure 12 in general. However, there are many data that strains by SHAKE are larger than those by YUSAYUSA. It may indicate that vibration mode are different under each analysis.

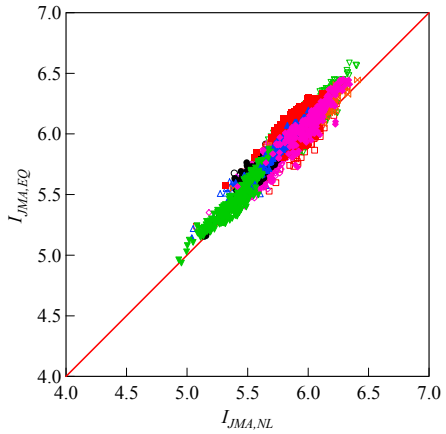

Figure 13 Comparison of JMA seismic intensity

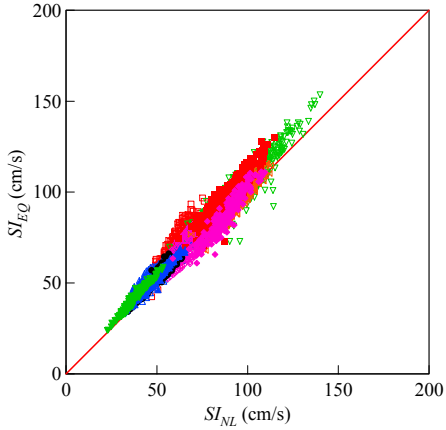

Figure 14 Comparison of SI value

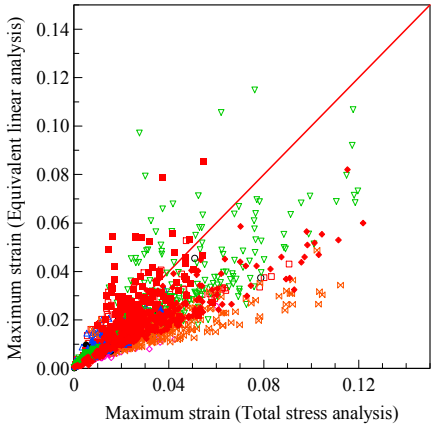

Figure 15 Comparison of maximum strains

6. CONCLUDING REMARKS

Applicability of the equivalent linear analysis (SHAKE) under large earthquakes is examined by using more than 200 sites and 11 earthquakes. The following conclusions are obtained.

1) PGA is overestimated by the equivalent linear method. Sometimes, it is more than 1.5 times larger than that by the truly nonlinear method.

2) PGD is underestimated by the equivalent linear method. It is frequently less than a half compared with that by the truly nonlinear method.

3) Other indices such as PGV, seismic intensity, and spectral intensity are nearly the same between the equivalent linear method and truly nonlinear method although evaluation by the equivalent linear method is a little larger than that by the truly nonlinear method.

4) Vibration modes may be different between the equivalent linear method and the truly nonlinear method.

5) Amplification characteristics are affected by the input earthquake motion.

Considering these, equivalent linear method is applicable in many fields because it shows a little conservative result, except the case that maximum displacement and maximum acceleration are interested at.

Abstract: The 2011 off the Pacific Coast of Tohoku Earthquake caused large deformation of river levees in Miyagi, Fukushima and Ibaraki Prefectures in eastern Japan. The river levees along Naruse River in Miyagi Prefecture settled largely about 30 km far from the river mouth. Liquefaction of the bottom part of river levee underneath ground water caused the deformation of levees on soft clayey ground. On the other hand the river levees along Naruse River close to the river mouth did not deform largely although the levees settled over 30cm in 1978 off Miyagi-ken earthquake and had large cracks on the top in 2003 Miyagi-ken inland earthquake. It was possible that liquefaction of sandy foundation ground caused the damages in 1978 and 2003 earthquakes. The river levees showed different performance dependent on earthquake motions. This study discusses the effect of input motion characteristics on seismic deformation of the river levee on liquefiable ground using two practical effective stress analyses.

1. INTRODUCTION

River levees on soft ground have often suffered from severe damages in past earthquakes. The 2011 off the Pacific Coast of Tohoku Earthquake caused large deformation of many river levees in Miyagi, Fukushima and Ibaraki Prefecture in eastern Japan (Sasaki et al. 2013, Oka et al. 2013). The river levees along Naruse River in Miyagi Prefecture settled largely about 30 km far from the river mouth. Liquefaction of the bottom saturated part of river levee caused the deformation of levees on soft clayey ground. On the other hand the river levees along Naruse River close to the river mouth did not deform largely although the levees settled over 30cm in the 1978 off Miyagi-ken earthquake (JSCE 1980) and had large cracks on the top in the 2003 Miyagi-ken inland earthquake (JGS 2003). It was possible that liquefaction of sandy base ground caused the damages in the 1978 and 2003 earthquakes (JSCE 1980). The river levees showed different performance dependent on earthquake motions. This study discusses the effect of input motion characteristics on seismic deformation of the river levee on liquefiable ground using two practical effective stress analyses.

Two numerical codes of 2-D soil-water coupled dynamic analysis code "LIQCA" (Oka et al. 1999) and "FLIP" (Iai et al. 1992) are used in this study to avoid the effect on the results of differences in the numerical codes. Both of numerical methods have been validated through numerical simulation of model tests and damage cases and have been used for practical prediction of seismic deformation of river levees for over ten years. The analyses use two observed motions of 2003 and 2011 earthquakes. The 2011 earthquake motion has the long duration and the large number of cycles, and the amplitude of acceleration is middle range. In comparison with the 2011 earthquake, the 2003 earthquake motion has the shorter duration and the smaller number of cycles, and the amplitude of acceleration is larger. The material parameters of soil layers are empirically determined based on the sounding tests.

2. DAMAGED LEVEE

2.1 Earthquake and Damage

The damaged "Hamaichi" levee is located on the left bank at the distance of 1.55 km from the mouth of the Naruse River in Figure 1. Table 1 shows damage overview after three major earthquakes around Hamaichi levee. This embankment was severely damaged during the 1978 off Miyagi-ken earthquake on 12 June 1978. The Japan Meteorological Association (JMA) assigned M_{JMA} of 7.4 to this earthquake. The epicenter and the focal depth were estimated about 60 km off Miyagi coast and about 40 km deep respectively. We call the earthquake "1978 Eq." hereafter. The embankment top settled about 30 – 50 cm, and a number of longitudinal cracks were observed on the top in Figure 2. Revetments on the surface of embankment and sheet pile were installed as the restoration after the earthquake.

The second earthquake occurred at an inland north area of Miyagi Prefecture at 7:13, local time, on 26 July, 2003.

Figure 1 Location of damaged levee

Table 1 Damage overview after three earthquakes at Hamaichi levee

Eq.	Location	Damage	Restoration
1978	0.2k+33m -1.4k+185m	Severe Settlement of top: 30-50cm	Revetment, Sheet pile
2003	0.3k - 0.7k	Moderate Longitudinal crack: max. 20 cm width	
2011	1.1k - 1.4k	No major cracks on the top Erosion at landside by overtopped tsunami	

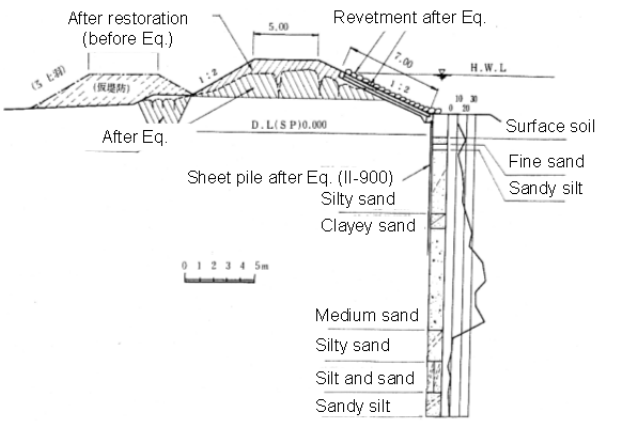

Figure 2 Damage, restoration and soil profile at Hamaichi levee after 1978 Eq. (JSCE 1980)

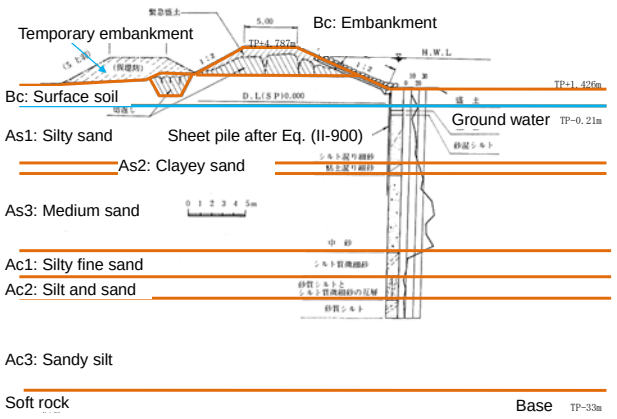
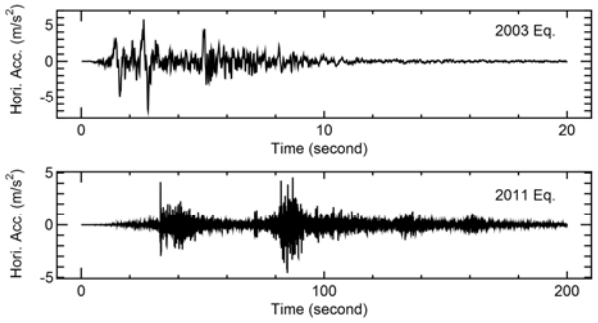
Photo 1 No major damage on the top at Hamaichi levee after 2011 Eq. (23 Nov. 2011)

We call the earthquake "2003 Eq." hereafter. The National Research Institute for Earth Science and Disaster Prevention





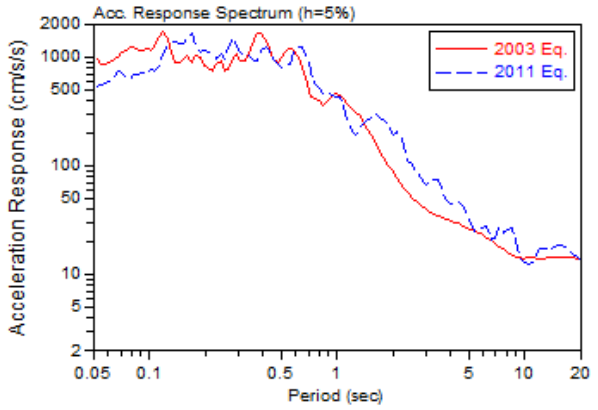


Figure 3 Soil profile at the damaged site

(a) Acceleration time histories

(b) Acceleration response spectra

Figure 4 Input acceleration histories and acceleration response spectra in 2003 Eq. and 2011 Eq.

(NIED) assigned M_w of 6.1 to this earthquake, with about 12.9-km focal depth. After the earthquake longitudinal cracks with the width of about 20 cm were observed on the top of embankment at 0.3 km – 0.7 km from the river mouth. The damage degree was not severe as in 1978 Eq.

The third earthquake is the 2011 off the Pacific Coast of Tohoku Earthquake at 14:46, local time, on 11 March, 2011. JMA assigned M_w of 9.0 to this earthquake, with about 24 km focal depth. We call the earthquake "2011 Eq." hereafter. No major cracks on the top of embankment was observed after 2011 Eq. The overtopped tsunami water eroded the toe of embankment slope at landside in Photo 1. Detailed

damage investigation was difficult due to tsunami disaster.

2.2 Ground Condition

Figure 3 shows the soil profile under the levee. The shallow layers (As1) with the depth of about 5 m consist of fine sand and silt with the SPT N-value of 10 – 20. The shallow layers were inferred to be liquefied during 1978 Eq. The deep layers (As2, As3) with the depth of 5 – 11 m consist of medium sad with the SPT N-value of over 30. The deeper layers (Ac1, Ac2, and Ac3) consist of silt mainly. The base layer of soft rock is located at GL – 34 m.

2.3 Earthquake Motion

During 2003 Eq. and 2011 Eq., vertical array records were observed at at Nakashimo strong motion station in Fig. 1. The Nakashimo site is about 900 meters apart from the Hamaichi levee. Figure 4 shows the deconvoluted acceleration histories and acceleration response spectra at the soft rock base layer. The duration of 2011 Eq. is much longer than 2003 Eq., and the predominant period of 2011 Eq. is slightly longer than 2003 Eq. The deconvoluted acceleration at soft rock base layer were calculated waves from the observed waves at GL -13 m by using elastic wave propagation analysis. In 1978 the strong motions site was not established; therefore we performed seismic analyses with acceleration histories during 2003 Eq. and 2011 Eq.

3. NUMERICAL DATA

The two-dimensional finite element model in Fig. 5 was made based on the cross section in Fig. 2 and 3. The soil was modeled by plain strain elements and the sheet pile (II-900) was modeled by beam elements. The soil at the bottom boundary was viscous boundary where the horizontal accelerations in Fig. 4 were input. The lateral boundaries in LIQCA were periodical boundaries which were tied to reproduce the same displacement at the same depth. The lateral boundary in FLIP was viscous boundary with free field motion. The bottom and lateral boundaries were impermeable. The ground water level was located on TP -0.21 m. Pore water migration in FLIP was not considered. The numerical results of self-weight analysis were considered in the dynamic analysis as the initial effective stress and pore water pressure. The coefficients in Newmark implicit time integration were 0.6 and 0.3025 in LIQCA. The time increments were 0.001 and 0.005 seconds in LIQCA and FLIP respectively.

The As1 layer only was assumed to be liquefiable soil layer because there is no detailed soil investigation at this site. Most material parameters in Table 2 were empirically determined from SPT N-value in Fig. 2. Figure 6 shows the liquefaction strength curves of As1 soil in LIQCA and FLIP.

4. NUMERICAL RESULTS

Figure 7 shows the deformed configurations and distributions of excess pore water pressure ratio after 2003 Eq. The excess pore water pressure ratio is defined the

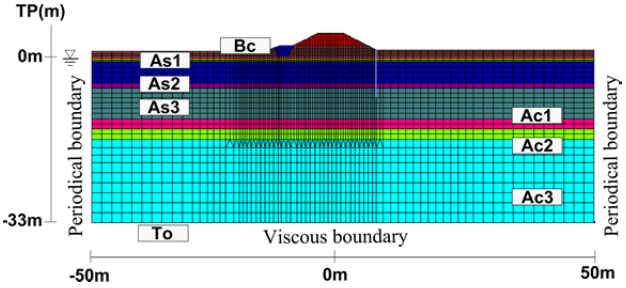

Figure 5 FE model at the damaged site

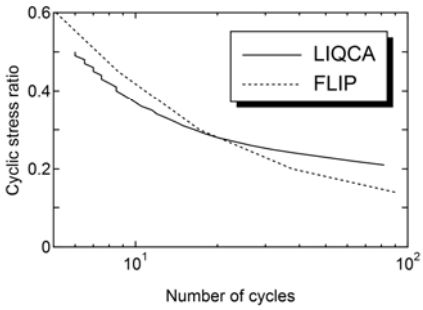

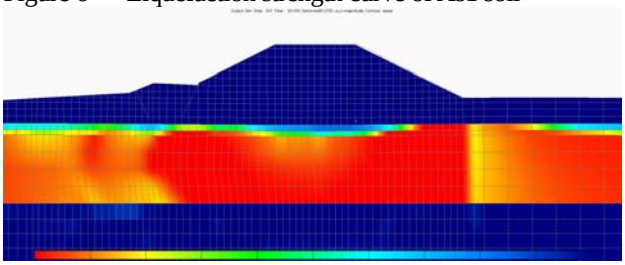

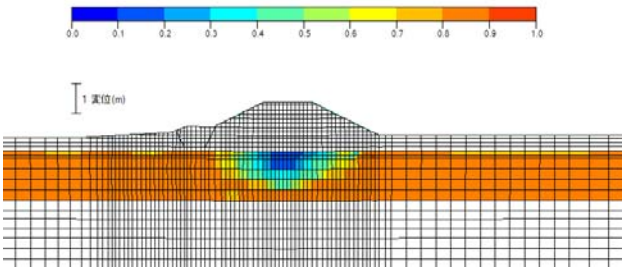

Figure 6 Liquefaction strength curve of As1 soil

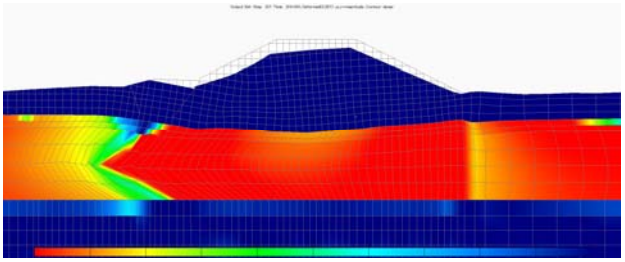
(a) LIQCA

(b) FLIP

Figure 7 Deformed configurations and distributions of excess pore water pressure ration after 2003 Eq.

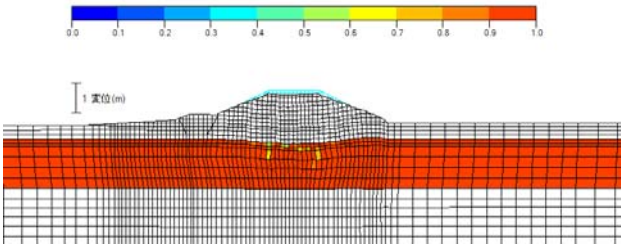
excess pore water pressure divided by initial effective overburden pressure. Both of numerical methods showed partial liquefaction in As1 layer, and the settlement at the top of embankment after the earthquake was less than 10 cm. The results by LIQCA showed slightly larger excess pore water pressure ratio, and the settlement was also larger than FLIP. These results reproduced the actual minor damage in Table 1.

Figure 8 shows the deformed configurations and the distributions of excess pore water pressure ratio after 2011 Eq. Both of numerical methods showed complete liquefaction in As1 layer, and the settlement at the top of embankment after the earthquake was about one order larger than 2003 Eq. The different results between two earthquakes



are due to the input motions. The number of cycles of input motion in 2011 Eq. was much larger than 2003 Eq. although the maximum acceleration responses were almost same in Fig. 4. The results by LIQCA showed larger deformation in As1 layer at the left side (land side) than FLIP. However no major cracks on the top of embankment was observed after 2011 Eq. although the overtopped tsunami water eroded the toe of embankment slope at landside in Photo 1. It is possible that large number of cycles of the input motion does not always cause large deformation of river levee. We need further investigation with detailed soil properties.

5. CONCLUSIONS



The Hamaichi levee near the mouth of the Naruse River showed different performance after three major earthquakes in 1978, 2003 and 2011. This study discussed the effect of input motion characteristics on seismic deformation of the river levee on liquefiable ground using two practical effective stress analyses. Both of numerical methods reproduced the different damage of river levee with different earthquake motions. The numerical results suggested that large number of cycles of the input motion does not always cause large deformation of river levee.

Abstract: An eccentric mass shaker mounted to the crest of a model levee resting on very soft peat soil was used to measure dynamic base shear-displacement and base moment-rotation relations. The model levee rotated and translated visibly during testing, exhibiting a response that deviates significantly from the one-dimensional wave propagation assumption often used to analyze the seismic response of levees. We evaluate complex-valued stiffness and damping of the levee-foundation soil interaction for translational and rotational modes of vibration. The damping is strongly dependent on frequency, indicating that it is controlled by radiation of energy away from the vibrating levee. These radiation damping effects are dominant even at low frequencies that are well within the range of engineering interest for ground failure evaluations. Interestingly, the levels of radiation damping are roughly comparable, when expressed as percentage of critical, to predictions from classical models for impedance functions of rigid rectangular foundations on an elastic half-space. More research is needed to generalize these observations for application to seismic analysis of levees resting on peat.

1. INTRODUCTION

The seismic response of levees is a crucial issue for flood control and water distribution systems. Levees are often founded atop soft soils that have the potential to perform poorly during earthquakes. Peat is the softest and most compressible type of soil on which levees are founded, but very little is known about its seismic performance. Levees resting atop peat have been observed to fail during past earthquakes (e.g., Sasaki 2009), but it is often difficult to separate the contribution of the peat from the contribution of other problematic soils such as liquefiable sands.

Seismic stability of levees is a particularly important issue in the Sacramento / San Joaquin Delta, which is the hub of California's water distribution system. Unlike typical flood control levees that are intermittently loaded, the Delta levees constantly convey water and protect land that is below sea level due to subsidence of peaty organic soil. A recent seismic risk analysis predicts that a moderate earthquake in the region would simultaneously breach many levees, thereby flooding multiple islands and drawing saline water from the bay (DRMS 2009). This event is projected to halt water delivery for a period of years, causing tens of billions of dollars in direct losses. A significant limitation for this type of loss estimation analysis is lack of knowledge regarding the seismic response of peaty organic soils.

This paper presents results from a large-scale field test of a model levee resting atop very soft and compressible peat. An eccentric mass shaker imposed earthquake-level motions on the levee, and the response was recorded using dense sensor arrays. This paper focuses on the seismic interaction between the soft peat and the comparatively stiff levee fills using soil-structure interaction concepts.

2. MODEL CONFIGURATION

A photo of the model levee and eccentric mass shaker is shown in Fig. 1. The model levee was composed of compacted clay reinforced with geogrids. The levee was

Figure 1. Model levee with MK-15 eccentric mass shaker mounted on crest.

1.8m tall, 12m long at the base (from left-to-right in Fig. 1), and 3.7m wide. The clay was compacted in six 0.3m thick lifts that were wrapped with geogrid to form vertical side walls, thereby modeling a slice of levee. A sturdy timber frame was embedded in the upper three lifts, and the nees@UCLA MK-15 eccentric mass shaker was attached to the frame.

The model levee was constructed on the interior of Sherman Island, near Antioch, CA. Deposition of the peat began about 11,000 years ago at the end of the last ice age. Following reclamation of Delta lands beginning in 1850, the peat has subsided at a rate as high as 10 cm/year, and many islands now lie more than 5m below sea level. The soil profile beneath the model levee consisted of 2m of unsaturated desiccated peat overlying 9m of soft fibrous peat overlying a deposit of Pleistocene dune sand (Fig. 2). The saturated fibrous peat exhibited water contents as high as 500%, and shear wave velocities near 25 m/s. At a depth of 2m, the peat is nearly entirely organic, with very little visible evidence of inorganic minerals, with increasing content of inorganic clay minerals deeper in the deposit. Details of the laboratory testing program that accompanies the test can be found in Shafiee et al. (2013).

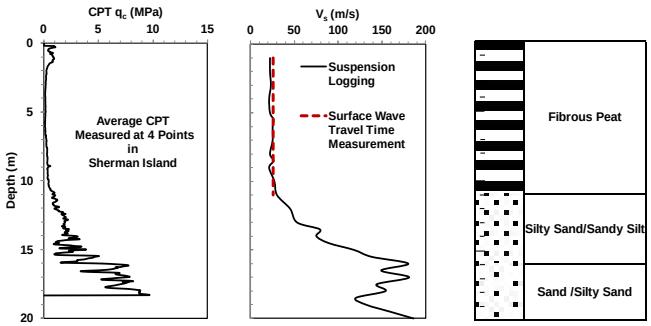

Figure 2. Cone tip resistance and shear wave velocity profiles for free-field Sherman Island site (Shafiee et al. 2013). Suspension log conducted by GeoVision (2000) at a similar site near the test site.

3. DATA PROCESSING AND ANALYSIS

This section explains the procedures used to calculate the base shear, base moment, average base displacement, and average base rotation of the model test levee for the purpose of defining the stiffness and damping of levee-foundation soil interaction. A schematic of the levee and the accelerometers used to calculate these values can be seen in Fig. 3. Eight EpiSensor triaxial accelerometers were placed on each side of the embankment: four along the base, two at mid-height, and two on the crest. Sixteen total accelerometers were mounted on the levee (eight on each side) and additional accelerometers were placed on the ground surface away from the levee, and subsurface accelerometers and piezometers were placed in the peat beneath the levee, though these sensors are beyond the scope of the paper. The embankment was then divided into sixteen tributary wedges, and the centroid, volume, and weight of each wedge was calculated. The test data used to calculate desired quantities consisted of the x and z components of acceleration of the accelerometers on the embankment and the shaker force F_{shk} [see Reinert et al. (2012) for details on F_{shk} calculation].

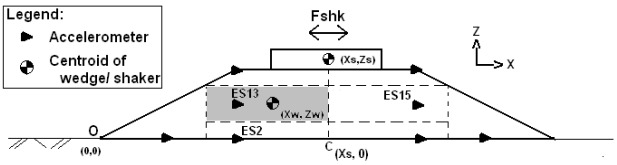

Figure 3. Schematic of model levee including shaker and instrumentation.

The first step was interpolating acceleration at the centroid of each wedge from the measured accelerations. For example, consider the shaded wedge in Fig. 3. The z-component of acceleration at the centroid was interpolated between ES13 and ES15 since vertical acceleration is anticipated to vary horizontally due to rotation of the levee. The x-component of acceleration was taken as being equal to ES13 in this case since the elevation of the centroid is equal to the elevation of ES13. For some wedges, the elevation of the centroid is not identical to the elevation of any accelerometer, in which case the centroid acceleration is interpolated vertically between the nearest two sensors.

Once the representative accelerations for each wedge were computed, we then calculated the base shear and moment of the embankment by (*i*) computing inertia force for each wedge in the horizontal and vertical directions, (*ii*) summing horizontal inertia forces plus shaker force to obtain base shear, and (*iii*) summing horizontal inertia force multiplied by vertical moment arm, vertical inertia force multiplied by horizontal moment arm, and shaker force multiplied by the height to the centroid of the shaker. Moments were computed about the center of the base [i.e., at point (x_s,0) in Fig. 3]. Shear is positive from left-to-right, and moment is positive clockwise. Steps (ii) and (iii) are explicitly defined in Eqs. 1 and 2.

$$V_{base} = F_{shk} + \sum_{i=1}^{16} -m_i a_{x,i} \tag{1}$$

$$M_{base} = z_s \cdot F_{shk} + \sum_{i=1}^{16} -m_i a_{x,i} z_{w,i} + \sum_{i=1}^{16} m_i a_{z,i} (x_{w,i} - x_s) \tag{2}$$

The final step of calculations was to compute a representative base displacement and rotation, which are combined with the shear and moment to evaluate frequency-dependent stiffness. First, displacements were

computed by double-integrating the acceleration records in time. The Fourier transform of each record was computed, and the real and imaginary components were multiplied by a Butterworth filter with an order of 5 and a corner frequency of 0.2 Hz. Note that this filter is acausal (i.e., it does not alter the phase of the signals) since the real and imaginary components are both multiplied by the same scalar. The filter was required to remove low frequency noise that would otherwise cause erroneous drift in the displacement records. The representative base displacement was then computed as the average of the x-component of displacement from the eight accelerometers along the base of the levee. Very little variation in these motions was observed, and an equally-weighted average is therefore reasonable.

The representative rotation is complicated by flexibility of the model levee. Fig. 4 shows undeformed and deformed positions of the accelerometers during positive and negative loading cycles. The base of the levee is clearly nonlinear, which indicates that the rotation varies along the length of the levee. The representative rotation in this case was computed using a weighted least squares regression approach in which the weights for the two sensors nearest to the center of the levee were three times larger than the weights of the sensors nearest to the toes of the levee slopes. The motivation for using a weighted least squares procedure is that more mass lies near the center of the levee, therefore the rotation near the center should be more representative of the flexible levee response.

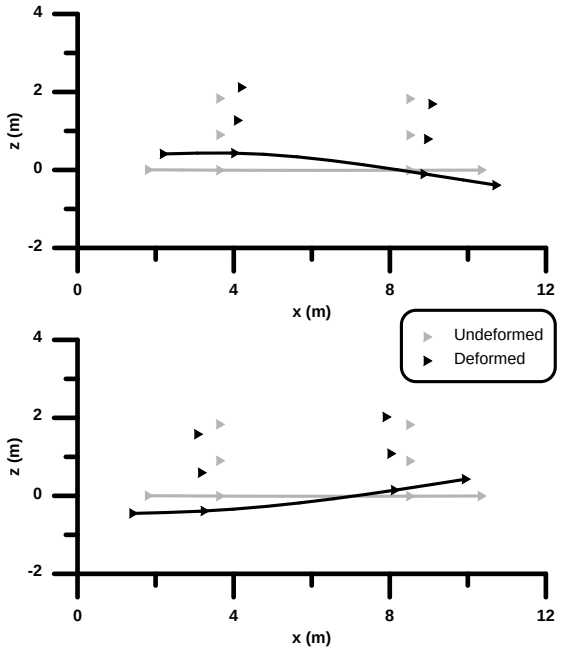

Figure 4. Deformed and undeformed displaced positions of sensors during a positive and negative loading cycle (displacements amplified × 100).

4. MEASURED SHEAR-DISPLACEMENT AND MOMENT-ROTATION RESPONSES

Measured levee-foundation soil responses are presented in Figs. 5 and 6 in terms of base shear versus horizontal translation and base moment versus representative rotation. The results in Fig. 5 apply for a medium intensity motion that resulted in a maximum horizontal crest acceleration of 0.04g. At 1Hz, the moment-rotation relation is essentially linear with no measurable damping, while the horizontal force-displacement relation exhibits a small amount of damping. Radiation damping and hysteretic damping are likely present in the measurement, though separating the relative contribution of each is not possible from the measured data. As the frequency increases, the damping increases as well, and the force-displacement curves are essentially circular at 3Hz. Damping also increases for moment-rotation, but not as significantly as for force-displacement. This trend was also observed by Tileylioglu et al. (2011) for a rigid concrete foundation on stiff soil.

Fig. 6 presents the measured responses for a high intensity motion that resulted in a maximum crest acceleration of 0.27g. The curves for f=3Hz are not presented because the shaker capacity was mobilized during this motion, and could not reach frequencies higher than 2.6Hz. For a given frequency, more damping is apparent in the responses for the high intensity motion compared with the medium motion. This trend is likely the result of higher shear strains mobilized in the soil by the high intensity motion, which would cause (i) increased hysteretic damping, and (ii) increased radiation damping due to the reduction in shear modulus (and reduction of equivalent shear wave velocity) of the peat and associated increase in dimensionless frequency, $a_o = \omega B/V_s$, where ω = angular frequency = $2\pi f$, and B = footing half-width. The non-harmonic features in the shear-translation and moment-rotation responses for the higher frequency motions were caused by pounding between the timber frame and the model levee.

The dramatic increase in damping with frequency is consistent with analytical solutions for rigid footings on an elastic halfspace. For example, consider B = 1.85m, V_s = 25m/s, and f = 3Hz. The dimensionless frequency is $a_o = 2\pi(3\text{Hz})(1.85\text{m})/(25\text{m/s}) = 1.4$. The radiation damping for a rigid rectangular footing with L/B = 12m/3.7m = 3.2 is 86% for translation and 108% for rotation using the solutions suggested by Pais and Kausel (1988). These very high radiation damping values at low frequencies are caused by the peat's extraordinarily low shear wave velocity.

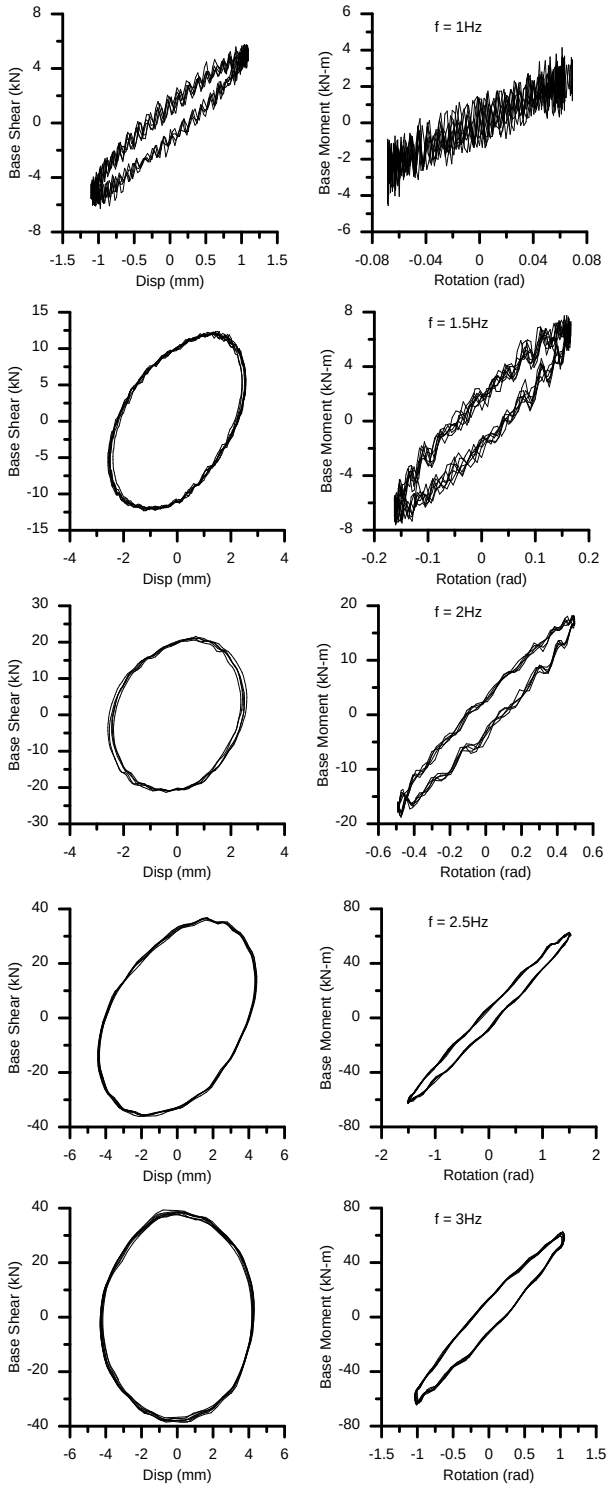

Figure 5. Impedance relations for a medium intensity motion that resulted in peak horizontal crest acceleration of 0.04g.

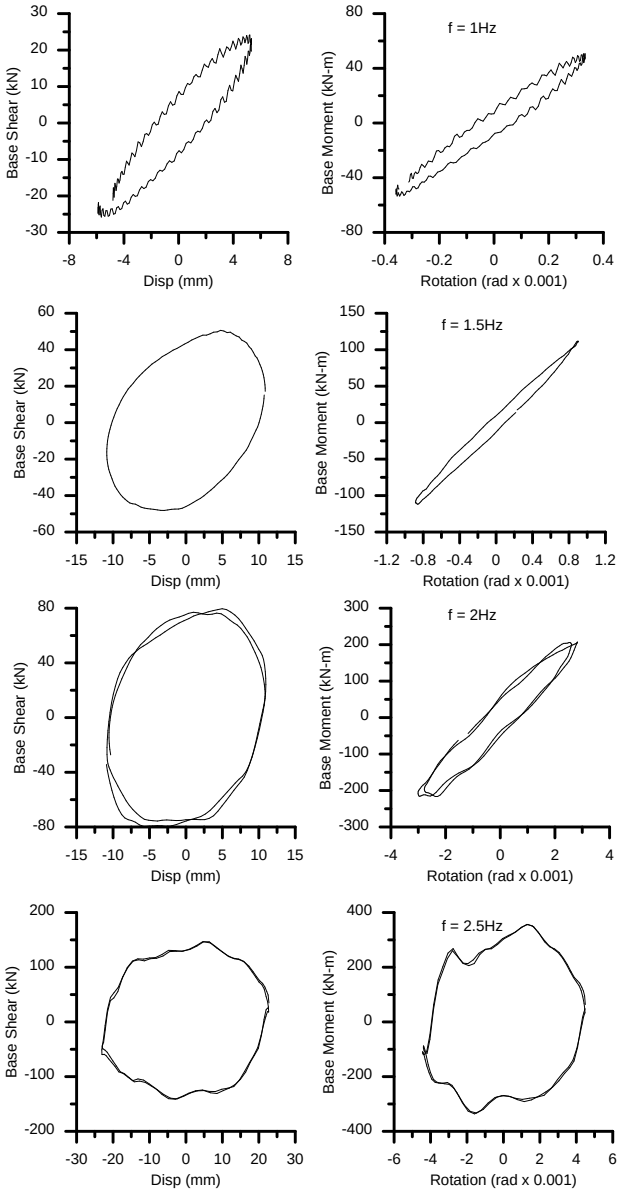

Figure 6. Impedance relations for a large intensity motion that resulted in peak horizontal crest acceleration of 0.27g.

4. CONCLUSIONS

A dynamic test of a model levee on very soft peat soil was interpreted herein using soil-structure interaction concepts. This approach is reasonable because the levee fill is significantly stiffer than the underlying peat, which had a shear wave velocity of only 25m/s. Measurements of V_s for the levee fill have not yet been processed, but we anticipate that V_s was at least 150 m/s based on visual/manual observations of the unsaturated clay fill. The model levee translated and rotated significantly during shaking. The response of the levee indicates that seismic analysis of levees using one-dimensional wave propagation theory may be inappropriate when the foundation conditions are very soft. For example, a one-dimensional site response analysis of a profile below the levee crest could not possibly capture the rotational response, and may result in erroneous prediction of crest acceleration. Furthermore, rotational deformation of the levee causes rotations of principal shear stresses, resulting in a stress path that is different from simple shear, particularly near the levee toes. Liquefaction of saturated cohesionless levee fill is a significant concern for many levees, including those in the Sacramento / San Joaquin Delta, and modifications to traditional liquefaction triggering procedures may be needed for levees on peat. More research is required to develop such modifications.

Relations for the complex shear-translation and moment-rotation responses were computed from a dynamic test of a model levee on very soft peat soil. The results indicate a significant amount of radiation damping at frequencies that are well within the bandwidth of typical earthquake ground motions and that are of interest for ground failure analysis. Whether this conclusion can be generalized to the earthquake behavior of levees resting on peat is currently unclear for a number of reasons. First, the model levee was shaken at the crest in a top-down configuration, which is different from the bottom-up propagation of seismic waves during an earthquake. Second, the model levee was smaller than typical levees, and a scale effect is possible due to the size of the levee relative to the thickness of the peat, and the higher consolidation pressures (and associated lower void ratios and higher stiffness) that would exist in the peat beneath a larger levee. Third, the model levee was a three-dimensional slice rather than a long two-dimensional earth structure that would be more consistent with a real levee. Nevertheless, the test data identified an important fundamental issue that requires further study.

CONFINING EFFECT OF BEARING PLATE AND HELIX ON SLIDING RESISTANCE OF REINFORCED SLOPE USING STEEL PIPE PILES

Akihiro Takahashi[1], and Yohei Nakamichi[2]

Abstract: To examine confining effect of bearing plate and helix on sliding resistance of reinforced slope using steel pipe piles, a series of centrifuge tests were conducted. Test results reveal that (1) installation of the inclined preventive piles increases the frictional resistance at the interface between the sliding and stable layers, (2) confinement provided by bearing plate at pile head or helix along the pile increases the sliding resistance of reinforced slope by 20~50% within the scope of tests, (3) the bearing plate makes the tensile resistance of the pile notably larger, and (4) marked effectiveness of pre-stressing is confirmed at the beginning of loading.

1. INTRODUCTION

Preventive pile against slope failure is a major reinforcement method. The reinforcement mechanism of the preventive pile is very complicated, because it is designed to prevent slope failure with its passive resistance induced by the interaction between the pile and the ground. Preventive piles had been usually constructed in vertical direction because of the limitation of construction methods. However recently, it is becoming available to construct the piles in any direction, i.e., non-vertical direction, and there is a possibility to design the preventive pile more effectively.

Takahashi and Morikawa (2012) demonstrated that the preventive pile inclined toward the downslope direction with respect to the sliding surface shows the larger resistance against sliding through a series of the centrifuge tests. In their tests, increase of the sliding resistance is attributed not only to the shearing and axial resistance of piles, but also to confining effect of piles, i.e., existence of piles increases the shearing resistance of soil.

When a slope is reinforced by ground anchors, bearing plates play an important role in providing pressure to increase sliding resistance. If such a bearing plate is fitted with the head of the preventive pile, we can expect increase of the sliding resistance. Probably use of helical piles as preventive piles may have similar effects to increase shearing resistance at the interface between the sliding and stable layers.

Objective of this study is to examine confining effect of bearing plate and helix on sliding resistance of reinforced slope using steel pipe piles through a series of centrifuge tests. Model slopes are similar to those tested by Takahashi and Morikawa (2012), but by considering capacity of the loading system; tests were conducted at 15g, which is half of that applied by Takahashi and Morikawa (2012).

2. OUTLINE OF CENTRIFUGE TESTS AND TEST CONDITINOS

A schematic view of the experiment system is illustrated in Fig.1. Experiment system that can impose the ground movement with the prescribed sliding surface is used. The model stable layer and mobile (or sliding) layer were made in a steel rigid box with the sliding layer size 630mm in width, 300mm in depth, and 250mm in thickness. All experiments were conducted under 15g of centrifugal acceleration. Thus, the thickness of the sliding soil mass

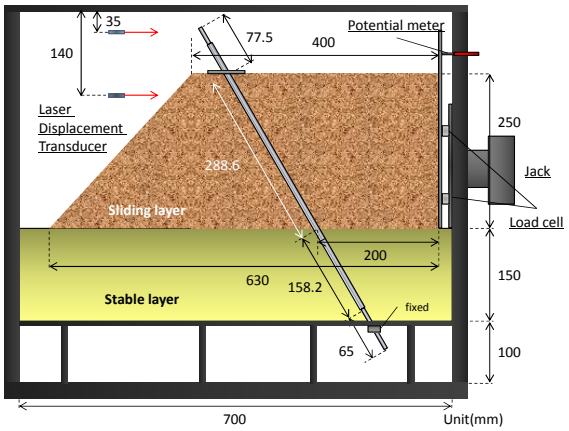

Figure 1 Experiment system (Dimensions are in model scale)

Table 1 Test cases

Case	Num. piles	Bearing plate	Helical piles
1	–	–	–
2	3	–	–
3		60mm-square	–
4		90mmm-square	–
5		60mm-square (Pre-stress = 0.175kN/pile)	–
6		–	Helix dia. = 18mm

corresponds to 3.75m in the prototype scale.

The stable layer was modelled as a relatively stiff layer having the SPT N-value of around 20. Stiffness of the stable layer was estimated by the empirical relationship between the Young's modulus and SPT N-value (NERI, 2010). The stable layer was made of urethane rubber whose Young's modulus was about 20MPa. The stable layer have holes that model pile could be installed, and the pile tip can be fixed at the bottom of the stable layer, i.e., the tip of the piles could be regarded as the fixed end. Three model piles were arranged in a row with equally spaced for all the cases (Distance between the piles = 1.5m (≈ 11 *D*) in the prototype scale). In the tests, the stable layer was covered with Teflon sheet so that friction between the stable and sliding layers could be minimized.

The sliding layer made of Edosaki sand (Takahashi & Izumi, 2010) was constructed on the stable layer by compacting the soil with a water content of 15% to achieve a degree of compaction of 90%. The displacement was given only to the sliding layer by the jack through the loading plate. Slip of the sliding surface occurred at the interface between the sliding and stable layers in all the cases.

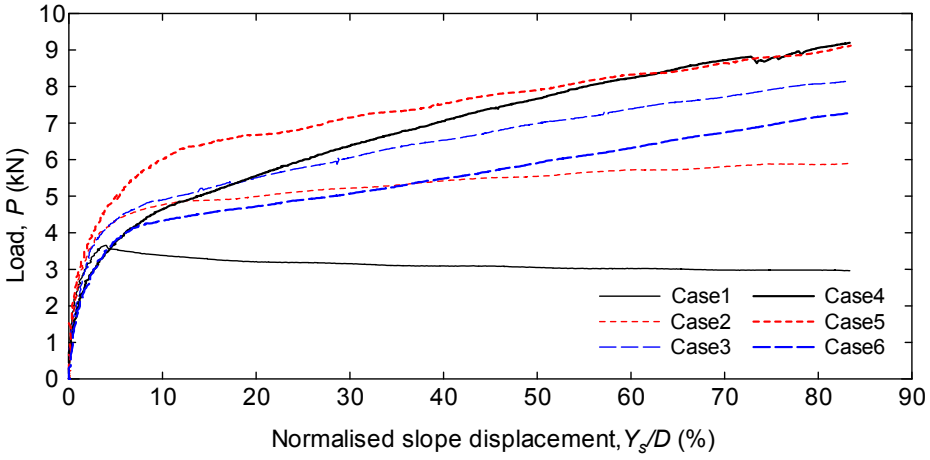
Model pile is a hollow steel pipe made of ferritic stainless steel. The outer diameter is 9mm and the thickness is 0.5mm. The corresponding pile in the prototype scale was 135mm in outer diameter. The model pile had 28 strain measurements inside the steel pipe for monitoring axial strain or bending strain along the pile. Six test cases were conducted as shown in Table.1. In the case with pre-stressing (Case 5), prescribed tension of the pile was given by means of spring attached on the bearing plate before spinning the centrifuge. In case 6, spacing of the helix on the pile was 18mm and the thickness of the helix was 1mm.

3. TEST RESULTS

Figure 2 shows relationships between the load measured with the load cells and normalised horizontal displacement of the slope nearby the pile. From the figure, definite reinforcement effects of piles against sliding are confirmed by comparing the cases with piles to that without piles (Case 1). In Case 1 (without preventive piles), the load reaches steady state with 3kN when the horizontal displacement is around 2mm (≈ 20% *D*). This corresponds to the frictional resistance arise from the interface between the sliding and stable layers.

In Cases 2 (with straight piles) and 3 (with straight piles capped by small bearing plate), there is no large difference compared to Case 1 at the beginning of loading (before yielding), while the load continuously increases even after Case 1 had reached the steady state. This increase of the load is regard as a reinforcement effect of the piles on the slope. Unexpectedly, Cases 4 (with straight piles capped by large bearing plate) and 6 (with helical piles) show softer response at the beginning of loading, compared to Cases 1~3. This may be attributed to disturbance of the ground near the piles when the piles were installed.

By comparing Case 2 to Case 3, Case 3 shows the larger load than that for Case 2. Case 2 shows plateau in the load-displacement curve after reaching the displacement of 60% *D*, while the load continuously increases in Case 3 because of the confining effect of the bearing plate. As expected, the case with the larger bearing plate (Case 4) exhibits larger resistance when the larger displacement is imposed compared to the case with the smaller plate (Case 3). The pre-stressing has marked confining effect at the



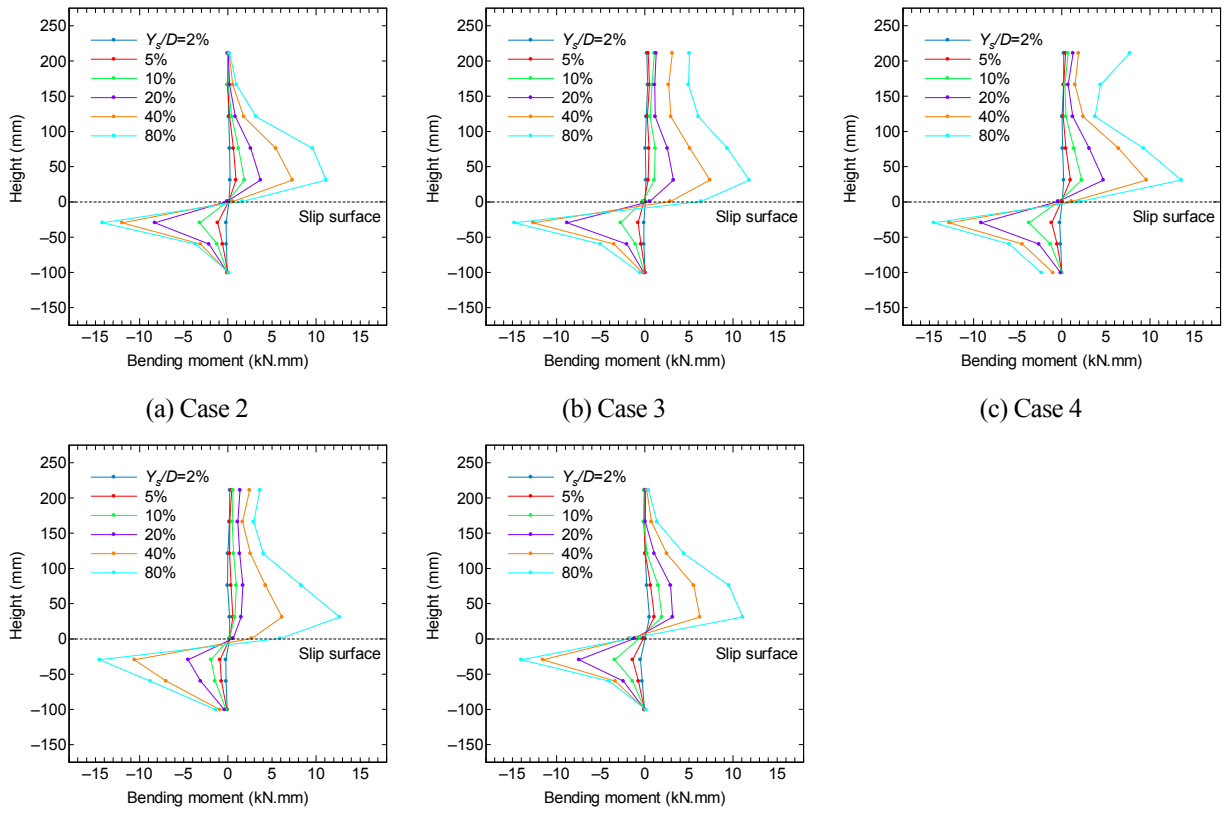


Figure 2 Load-displacement curves for all cases

(a) Case 2 (b) Case 3 (c) Case 4

(d) Case 5 (e) Case 6

Figure 3 Bending moment profiles

beginning of the loading (see Cases 5 and 3). The confining effect in the case with the helical piles (Case 6) is somewhat weak, but the marked difference can be seen in contrast to Case 2. The confining provided either by bearing plate or by helix had an effect on enhancement of sliding resistance of reinforced slope and it increased the resistance by 20~50% by compared to the case with the straight piles (Case 2).

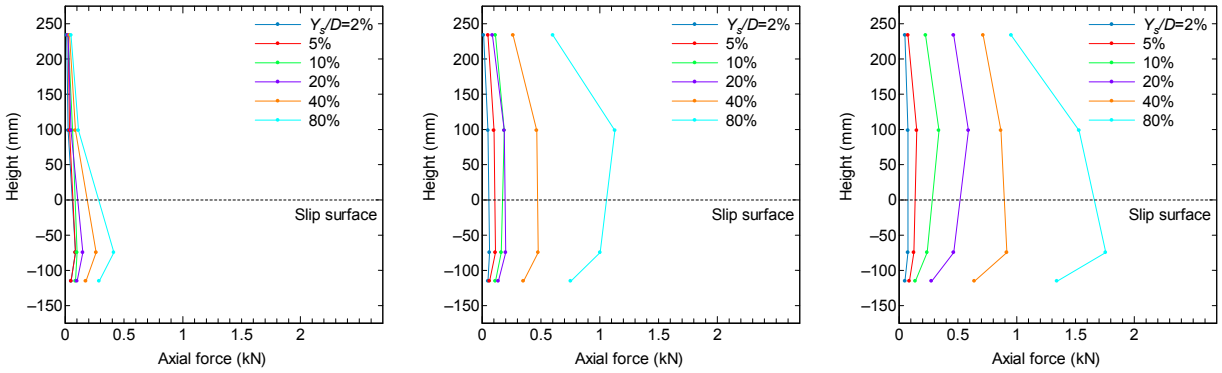

Figure 3 shows distributions of bending moment of the pile in all the cases. Large positive bending moment is observed just above the interface between the sliding and stable layers, while the large negative bending moment appears in the stable layer. Magnitude of the minimum bending moment in the stable layer is larger than that of the maximum bending moment in the sliding layer for all the cases. In the cases where the bearing plate is attached to the pile head (Cases 3~5), a certain amount of bending moment appeared around the pile head, since rotational movement of the pile head was restrained by the bearing plate.

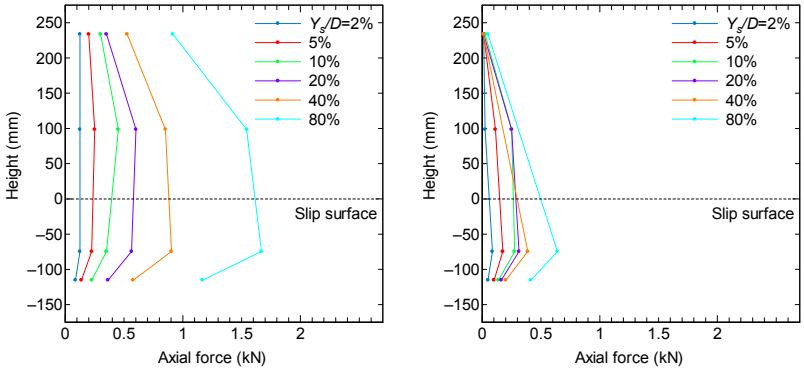
Figure 4 shows distributions of axial force of the pile in all the cases. In the cases where the bearing plate is attached to the pile head (Cases 3~5), very large axial force is observed. Among them, in Case 5 where pre-stressing was given before loading, due to the better contact of the bearing plate with the ground surface from the beginning, magnitude of the axial force was large from the beginning of the loading. Case 6 (with helical piles) shows relatively large axial force by comparison with Case 2, but not that much compared to the cases where the bearing plate is attached to the pile head (Cases 3~5).



Considering equilibrium of forces in the experiment system, the load can be expressed by the sum of the resistance of piles and the friction at the interface. The sum of the horizontal components of shear and axial forces at the sliding surface is the horizontal resistance induced by piles. Figure 5 shows the share of the horizontal resistances for Cases 2, 4 and 5. The line of filled circle in the figure is the measured load–displacement curve, while the lines with open triangle and open square are horizontal component of shear force and axial force, respectively. Consider the equilibrium of force mentioned above, the resistance induced by the ground friction can be calculated. Difference between the calculated frictional component and Case 1 (see Fig. 2) should correspond to the increase of the frictional resistance at the interface between the sliding and stable layers as a result of the sliding layer – pile interaction. From this figure, it can be said that (1) installation of the inclined preventive piles increases the frictional resistance at the interface, (2) the bearing plate makes the tensile resistance of the pile notably larger, and (3) marked effectiveness of pre-stressing is confirmed at the beginning of loading.

Abstract:

This paper presents the results between centrifuge modeling test and numerical simulations of propagation of an active dip-slip fault rupture through a dense, uniform sand soil layer which is covering the rigid bedrock. A series of centrifuge modeling (dip angle=60°) in the conditions of acceleration of 1g, 40g and 80g were performed to investigate the ground surface deformation trough due to reverse faulting. Sets of test datum were obtained during the period of increasing gravity and uplifting the fault throws, The datum of increasing gravity of centrifuge modeling test were used to calibrate the parameters of PFC^{2D} (Particle Flow Code) modeling, and the calibration parameters were used in the PFC^{2D} main program to simulated the ground surface deformation, After comparison of the results between centrifuge modeling test and PFC^{2D} numerical simulations, It shows that, the ground surface deformation of centrifuge modeling test and PFC^{2D} numerical simulation were quite agreement. A sigmoid(Probability Density Function ,PDF) curve equation was used to fit the ground surface deformation of centrifuge test data, and extend study for underground rupture path propagation were simulated by PFC^{2D}, the growth of rupture path can be seen and the primary influence zone can be obtained.

1. INTRODUCTION

Ground movement due to the dip-slip faulting has been considered as a significant affecting to the man-made structure, in year of 1999, three majors earthquake were occurred in Turkey (Kocaeli and Duzce) [Ulusay et al., 2001] and Taiwan (Chi-Chi). Several man-made structures were destroyed due to foundation displacement in which fault rupture occurs on the ground surface [Dong et al., 2000]. Eurcode EC8 (1994) banned the structure adjacent to the active fault and may request some set-back distance from fault trace. After 1999 Chi-Chi earthquake, the evidence shows that the set-back distance of seismic code is not so conservative, and the issue of ground surface deformation become important, some field observations [Chen et al., 2000], small scale tests [Lin et al., 2006], centrifuge experiments of normal/reverse fault [Bransby et al., 2008] and numerical analysis [Anastasopoulos et al., 2007; Dimitrios et al., 2009]results were published, and they are showing the very good results for understanding the ground surface deformation.

In order to observe deformation zone of the ground surface which was induced by reverse faulting, the centrifuge modeling tests of reverse fault were performed, the ground surface deformation datum were recorded and interpreted. A PFC2D simulation was used to conduct the numerical results of underground deformation and rupture path propagation in this study.

2. Centrifuge modeling test

The capacity of NCU centrifuge is 100 g-ton , the nominal radius is 3 meters, the dimensions of centrifuge platform are 100 cm×55 cm×72 cm (length × width ×height) and the maximum payload of platform is 400 kg [Lee et al., 2012]. The centrifuge was accelerated at an acceleration of 10 g per step until it reached the target acceleration or the acceleration of 80 g. In each step the surface profile scanner was trigged to scan the surface of soil bed for measuring the changes in the surface elevations. Once the target acceleration was achieved, normal faulting or reverse faulting was carried out. The fault throw was increased with a constant velocity of 2 mm/min by the motor for both normal faulting and reverse faulting. The surface profile scanner was driven once to scan the surface elevations per 2.5 mm increment throw. The fault displacement was increased until a final throw of 5 cm (corresponding to 4 m at prototype scale) was actuated. The testing program is detailed in Table 2-I, and the test results of 80g were shown on figure 2-I (a) and (b).

Table 2-I Reverse fault testing program

test number	height of specimen (mm)	relative density (%)	acceleration (*g*)	fault throws (mm)
R_200_70_1*g*	200	70	1	50
R_200_70_40*g*	200	70	40	50
R_200_70_80*g*	200	70	80	50

3.PFC^{2D} modeling

PFC^{2D} (Particle Flow Code-2 dimension) models the movement and interaction of circular particles by the distinct element method [Cundall et al., 1979]. The particle model was used to understand uniform element behavior, and used to solve real problems that involve complicated deformation patterns.

In PFC^{2D}, the relative parameters are density (ρ, kg/m^3), normal stiffness (K_n, N/m^2), Shear stiffness (K_s, N/m^2), friction coefficient (tanφ), wall property and the radius of the particle. For the test sand, the radius of quartz particle (D_{50}=0.193 mm) are too small, for the modeling of 200mm x 1000mm (Figure 3-I) may need about 680,000 particles. In general, the standard computer can't afford such a heavy duty or may need a long time to deal with a simple question; it seems not so realistic and economy to use real particle size in the PFC^{2D} modeling. In this study, the same particle distribution curve but shift to 20 time of real particle size was used as a fundamental size, by means of random and pluviation method to create element particles and to stack the sand soil layer. In Figure 3-I, wall 2 and wall 3 were considered as a fixed wall, wall 1,wall 4 and wall 5 can be moving uplift, and its moving vector is along the direction of fault plane angle, all the wall were considered as a rigid and frictionless element. X_0 denotes the width from fault tip to point of maximum ground surface inclination and X_{tot} denotes the width of the overall ground surface distortion zone (influence zone) in Figure 3-I.

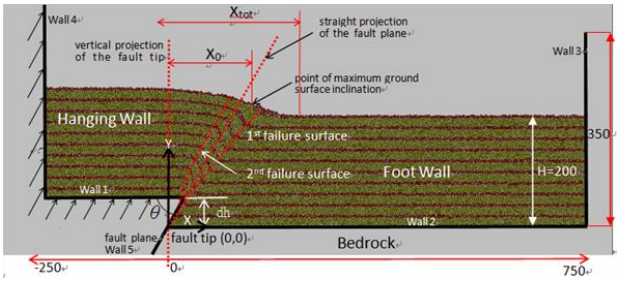

Figure 3-I PFC modeling

4. Comparing with centrifuge test and PFC^{2D}results

Kn=0.5e7N/m^2, Kn/Ks=3, tanØ = 36°, m=0.4 were used as parameters of PFC^{2D} simulations, comparison of PFC^{2D} simulation and centrifuge 1g, 40g, 80g test results were shown on the Figure 4-I(a)~(c), where the dot line is PFC^{2D} simulation results, continuous line is centrifuge modeling test results. In 1g simulation Figure 4-I (a), shows the trends of ground surface deformation is similar, Figure 4-I (b)~(c) show the 40g , 80g fitting condition, they show the good agreement of PFC^{2D} simulation results and centrifuge test data. Figure 4-I (a),(b),(c) show the results of ground surface deformation in the condition of 1g,40g and 80g which the throws are 1cm, 2cm, 3cm, 4cm and 5cm, that means the ratio of dh/H are 5%,10%,15%,20% and 25% respectively. By means of regression, the probability density function (PDF) curve can be used to fit the shape of ground surface deformation, the equation of PDF curve and differential equation of PDF curve were shown on the equation (1) and equation (2).

$$f = y_0 + \frac{a}{1+e^{-\left(\frac{x-x_0}{b}\right)}} \quad (1)$$

$$f' = \frac{ae^{-\left(\frac{x-x_0}{b}\right)}}{b}\left(1+e^{-\left(\frac{x-x_0}{b}\right)}\right)^{-2} \quad (2)$$

f : height of probability density function (PDF) curve
f' : slope of PDF curve
y_0 : average elevation of original ground surface
X : horizontal distance from fault tip
X_0 : the expected value
b : parameter of the shape of the curve, minus sign

represents the curve is from left hand side down to right hand side, and the smaller the b value, the deeper the shape of the curve.

a : distance from original ground surface elevation to the ground surface elevation of hanging wall.

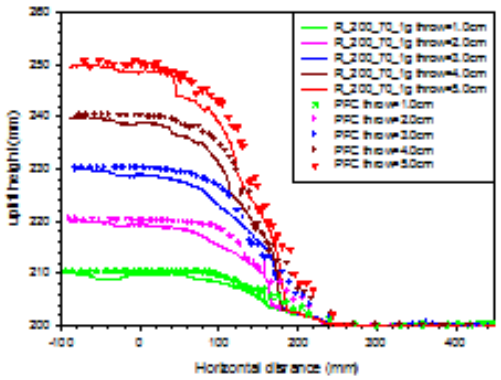

Figure 4-I(a) comparison of PFC^{2D} simulation and centrifuge test_ 1g,

5 PFC^{2D} simulation for rupture path propagation and influence zone

Figure 5-I(a) ~ (b) show the original dh/H=0% (throws=0m) mesh and dh/H=25% (throws=4m) mesh deformation during the reverse faulting, figure 5-I (b) shows that, the larger mesh deformation concentrates on the fault rupture path. When the fault rupture dislocated, the particle that around the rupture path will rotate in terms of counter clockwise or clockwise, in the lager distortion area the particles may cause more rotation. According to the particle rotation, PFC^{2D} simulation shows the growth of rupture path in the condition of 80*g*. Figure 5-II (a) ~ (h) shows the growth of rupture path in the different dh/H ratio from 1.25% to 25%. When the dh/H ratio is less or equal to 1.25%, the 1strupture path is beginning to form from the bedrock (fault tip) in the vertical direction, the height of rupture is about 30% of the soil disposal height. While dh/H ratio is equal to 2.5%, 2nd rupture were formed on the right hand side of the 1st rupture, the rupture path direction is same as fault plane angle (dip angle), in the same time, the 1st rupture height extended to about 50% of the soil disposal height. In the condition of dh/H ratio is equal to 3.75%, the 2nd rupture extended to the ground surface. The 1st rupture extended to the ground surface, while the dh/H ratio is equal to 5%, in the same time, the shear zone were developed on the left hand side of the 2nd rupture path. During the dh/H ratio is from 6.25% to 25% the distortion zone were enlarged both side of the rupture. since the rupture force direction is 60 degree from the down-left side to the up-right side, the soil layer in the hanging wall will squeeze the 2nd rupture path, and forced 2nd rupture to the right hand side, so the slope of the top rupture is smoothing than the rupture in the bottom side. during the range of dh/H is 15%~20%, the 2nd rupture is gradually stopping extend to the right hand side, in the mean time, the rupture force still acting on the footwall, the rupture squeeze by the hanging wall, the distortion zone were suffered more disturbs, and main distortion zone are concentrate on the area of 2nd rupture and maximum inclination point. From Figure 4-II (h), in the condition of the ratio of dh/H is equal to 25%, the primary influence zone was measured, and it shows the length of the primary influence zone about 1.25H under the condition of particle rotation is larger than 15 degree.

6. Conclusions

1. A probability density function (PDF) curve can simulate the different ground surface deformation profile for the various thickness of soil formation after the reverse faulting, and the influence zone can be predicted by using the technique of regression.
2. According to the PFC^{2D} simulation, the rupture path were formed in the stage of dh/H is less or equal to 1.25%, and 2 rupture paths extended to the ground surface in the dh/H ratio is 3.75%~5%. In the dh/H=25%, the primary length of influence zone is about 1.1 times of soil disposal (H).
3. In this paper, the sand deposit of relative density Dr=70%, dh/H=1.25%~25% and dip angle is 60 degree were used to perform the physical model test only, different dip angle centrifuge test or PFC^{2D} simulation results can be analyzed by means of the regression of the probability density function curve, and ground surface deformation and influence zone can be predicted.

METHODOLOGY FOR COMBINING MICROTREMOR MESUREMENTS AND SIMPLIFIED GROUND RESPONSE ANALYSIS

Atsushi Mikami[1)]

1) Associate Professor, Dept. of Civil and Environmental Engineering, The University of Tokushima, Japan

Abstract: For the evaluation of seismic performance of line structures such as tunnels, levees, etc, it is necessary to evaluate seismic ground response as well as to conduct soil investigation over a wide area. This study proposes a method of combining simple soil investigation and three dimensional ground response analysis. Assuming to conduct microtremor measurement on a ground surface as the soil investigation, a best-simplified ground model that is in congruity with the simplicity and accuracy of the simple soil investigation is derived. Eigenvalue analysis of a soil deposit on undulating bedrock showed that similar results were obtained from the proposed method and three dimensional finite element method with detailed soil data provided.

1. INTRODUCTION

Line structures such as tunnels and levees are different from other structures such as buildings and dams in a sense that they extend over a very long distance. In order to give input motions to such structures, it is of necessity to evaluate surface level ground motions taking into account three-dimensional topographical and geological conditions. It would be ideal if we could use some numerically sophisticated methods such as the three dimensional finite element method together with densely investigated PS soil logging data that provides all the three-dimensional mesh properties for the analysis. However, this is usually cost-prohibitive.

This paper proposes a method that combines three component microtremor measurements conducted on a ground surface and a three dimensional ground model used for ground response analysis. The major emphasis of this study is placed on derivation of a best-simplified ground model that is in congruity with the simplicity and accuracy of simple soil investigation. The method of microtremor measurement used in this study is both a work and cost saving investigation as is described in the following. Two horizontal and one vertical components are observed on a ground surface for approximately ten minutes, and the ratio of these orthogonal components are taken to calculate the H/V spectral ratio. As mentioned above, this method has an advantage that it is quite simple, hence, it can be applicable for a wide area soil investigation without the need for the heavy and costly work.

2. MICROTREMOR MESUREMENTS

2.1 Method of Soil Investigation

As a simple soil investigation that can be applicable to a wide area, microtremor measurement is assumed to be employed. Three component microtremor measurements are carried on the ground surface, and horizontal to vertical spectral ratio (H/V spectrum, known as Nakamura's method, 1989) is calculated. This is quite a simple and cost-effective investigation without the need for heavy work, thus, it has the potential to be applicable to a wide area.

2.2 Estimation of Predominant Frequency at a Site

Microtremor observations were conducted at sites where PS-logging information is available (such as K-NET and KiK-net sites). Three component servo type velocity meters (Tokyo Sokushin VSE-15D) with a portable vibration observing system (SPC-35) were used. At each site, microtremors were observed for approximately ten minutes with a sampling frequency of 100 Hz.

Observed three component microtremor time histories were Fourier transformed, then, power spectra was calculated. Smoothing with Parzen window that has bandwidth of 0.4(Hz) was applied. By taking the ratio of smoothed horizontal and vertical spectrum of microtremors, H/V spectral ratio is calculated. H/V spectral ratios calculated by using NS and EW components were eventually averaged to obtain the H/V spectral ratio.

Figure 1 shows an example of H/V spectral ratio. Five different segments (approximately 20 seconds data for each) are extracted from the horizontal and vertical components of microtremor time histories to calculate each H/V spectral ratio. Then, they are averaged to obtain the final result (red curve). It seems that consensus has been formed on the point that the peak frequency of H/V spectral ratio indicates predominant frequency at the site.

Figure 2 shows the relationship between predominant frequency of S wave calculated based on the

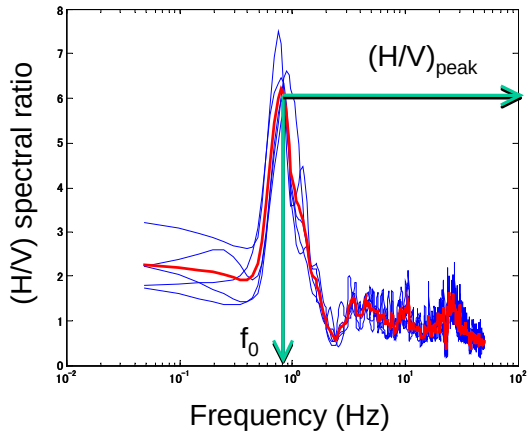

Figure 1 An Example of H/V Spectral Ratio (KiK-net Sendai)

quarter-wavelength rule and peak frequency of H/V spectral ratio, respectively. They show significant agreement with each other. This result indicates that fundamental frequency at a site can be evaluated from microtremor measurement on a ground surface. Similar results can be seen in previous research such as Ohmachi et al. (1994).

In addition, similarity of frequency characteristics of H/V spectral ratios calculated from microtremor and seismic records was confirmed by Okuma et al. (2002). Hence, if there are some seismometers near the construction site, the observed records can also be utilized for the purpose of ground modeling. Figure 3 shows a comparison of H/V spectral ratio calculated from microtremor and seismic records at KiK-net Tokushima site where contrast in soil stiffness between surface soil and bedrock is high. Similar H/V spectral ratios were also calculated at this site.

However, we can not identify each of the Vs and H only from the H/V spectral ratio because there is a trade-off between Vs and H (i.e. fundamental frequency can be expressed by the ratio of Vs and H). Hence, we assume here that depths of the base rock can be ascertained from soil boring (such as the standard penetration test) information which recently has been becoming available nationwide to the public (such as KuniJiban (Public Works Research Institute, 2008)). Averaged Vs of the surface soil deposit can then be estimated from microtremor measurement. In the following section, a multi-layered surface soil is replaced with a homogeneous soil overlying bedrock, and amplification characteristics are estimated.

3. EVALUATION OF 1D SITE RESPONSE BY AN EQUIVALENT GROUND MODEL

3.1 Replacement of multi-layer ground with an equivalent homogeneous ground

Knowing the predominant frequency of a multi-layered ground from microtremor measurement, the multi-layered ground is replaced with an equivalent homogeneous soil

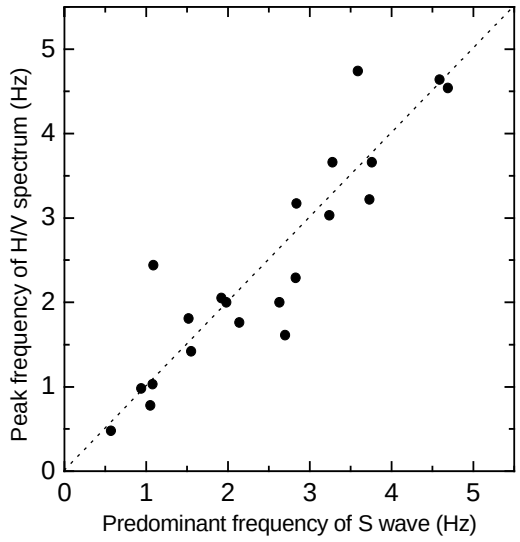

Figure 2 Predominant Frequency

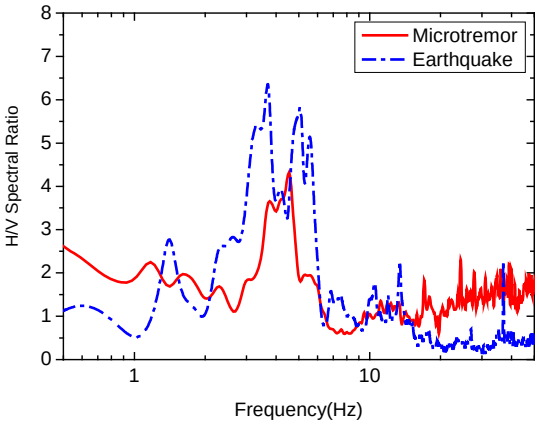

Figure 3 H/V spectral ratio calculated from microtremor and seismic records

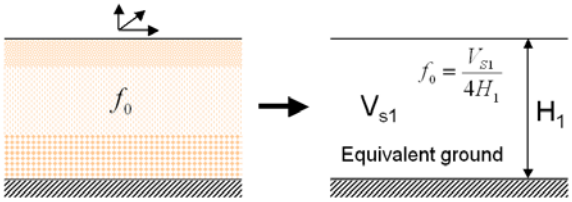

Figure 4 Replacement of Multi-layer Ground with an Equivalent Homogeneous Ground

overlying bedrock as shown in Figure 4. “Equivalent” indicates that the replaced homogeneous soil model has an identical predominant frequency as that of multi-layered ground.

3.2 Site Amplification Characteristics

In order to investigate site amplification characteristics

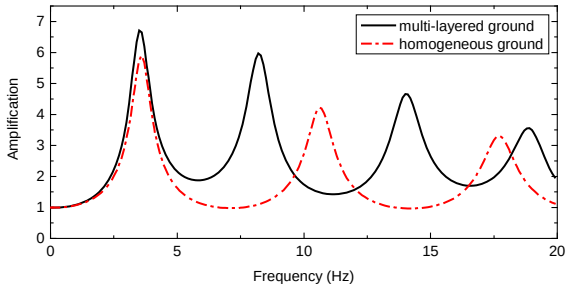

Figure 5 Site Response Functions (model ground)

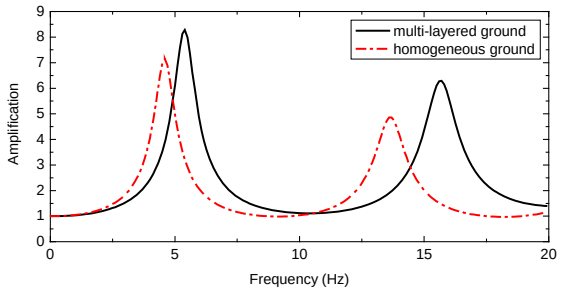
Table 1 Properties of Sample Ground

Layer	Depth (m)	Soil	Thickness (m)	Density (kg/m^3)	Shear Modulus (N/m^2)
1	0-3.8	Clay	3.8	1500	1.18×10^7
2	3.8-7	Sandy Clay	3.2	1670	2.84×10^7
3	7-10.9	Sand	3.9	1850	5.59×10^7
4	10.9-	Soft Rock	-	1950	4.90×10^8

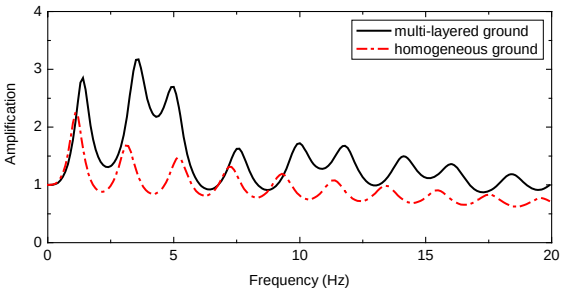
of the replaced ground, Figure 5 compares one dimensional site response functions of a sample ground shown in Table 1 (Osaki, 1994). Complex shear modulus G^* and damping constant h, which are expressed as below, are incorporated in both multi-layered ground and homogeneous ground model.

$$G^* = G(1+2ih) \tag{1}$$



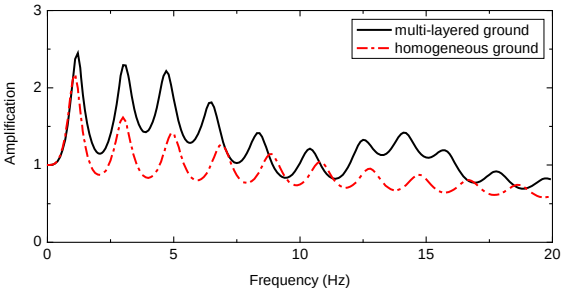
$$h = \frac{\alpha}{\omega} + \beta \tag{2}$$

where α and β are damping coefficients of the ground. They are assumed to be 2 and 0.02, respectively, for all the soil layers.



The thick line shows site response function of multi-layered soil and the dotted line indicates that of equivalent homogeneous ground. The response function calculated with homogeneous soil shows a good fit with the multi-layered soil in a relatively low frequency range. This result implies a reasonable approximation and further simplification that the soil model uses only the first mode along the depth of homogeneous soil.

3.3 Site Amplification Characteristics at Several Sites



Site responses are calculated for several actual sites where microtremor measurements were conducted in the past by the author as shown in Figure 6. The same damping model and damping coefficients are assumed in the analysis. Figure 6(a) shows site response function from KiK-net

(a) KiK-net Tokushima

(b) Tokushima University

(c) A Certain Place in Koto-Ward, Tokyo

Figure 6 Site Response Functions

Tokushima which is located in the edge of Tokushima plain. Thickness of the surface soil deposit is approximately 15(m) underlain by bedrock. Slight difference can be seen in the peak frequency of the first mode.

Site response functions are also compared for Tokushima University sites (located in the middle of Tokushima plain) and for a certain place in Koto-Ward, Tokyo as shown in Figure 6 (b) and (c). They are consistent with each other near the first mode frequency, however, difference becomes larger for the higher mode responses.

4. FURTHER SIMPLIFIED MODEL

4.1 Derivation of further Simplified Ground Model

At the end of the previous section, a simplified soil model that considers only the first mode along the depth of equivalent homogeneous soil was suggested as being further simplified but efficient modeling, taking into account the site

amplification characteristics of the equivalent homogeneous ground derived as reasonable model to utilize microtremor measurements. Referring to previous work by Nogami et al.(2001), further simplified model is derived in the followings starting from the three dimensional governing equation.

The governing equation for three dimensional soil is given as shown below.

$$\rho\frac{\partial^2 u}{\partial t^2}=\frac{\partial\sigma_{xx}}{\partial x}+\frac{\partial\sigma_{xy}}{\partial y}+\frac{\partial\sigma_{xz}}{\partial z} \tag{3}$$

$$\rho\frac{\partial^2 v}{\partial t^2}=\frac{\partial\sigma_{yx}}{\partial x}+\frac{\partial\sigma_{yy}}{\partial y}+\frac{\partial\sigma_{yz}}{\partial z} \tag{4}$$

$$\rho\frac{\partial^2 w}{\partial t^2}=\frac{\partial\sigma_{zx}}{\partial x}+\frac{\partial\sigma_{zy}}{\partial y}+\frac{\partial\sigma_{zz}}{\partial z} \tag{5}$$

where σ_{ij} = stress components, ρ = soil density, u, v, w = displacements in the x, y, z direction.

Converting the equilibrium equations to the equation with respect to displacement, and ignoring vertical motion,

$$\rho\frac{\partial^2 u}{\partial t^2}=\frac{\partial}{\partial x}\left[\lambda\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right)+2\mu\frac{\partial u}{\partial x}\right]+\frac{\partial}{\partial y}\left[\mu\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)\right]+\frac{\partial}{\partial z}\left[\mu\frac{\partial u}{\partial z}\right]$$
$$\rho\frac{\partial^2 v}{\partial t^2}=\frac{\partial}{\partial y}\left[\lambda\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right)+2\mu\frac{\partial v}{\partial y}\right]+\frac{\partial}{\partial x}\left[\mu\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)\right]+\frac{\partial}{\partial z}\left[\mu\frac{\partial v}{\partial z}\right]$$

(6),(7)

Separation of variables as $u=U(x,y,t)\phi(z)$, $v=V(x,y,t)\phi(z)$ is applied.

$$\rho\frac{\partial^2 U}{\partial t^2}\phi=(\lambda+\mu)\phi\frac{\partial}{\partial x}\left(\frac{\partial U}{\partial x}+\frac{\partial V}{\partial y}\right)+\mu\phi\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)U+\mu U\frac{\partial^2\phi}{\partial z^2}+\frac{\partial\mu}{\partial z}\frac{\partial\phi}{\partial z}U$$
$$\rho\frac{\partial^2 V}{\partial t^2}\phi=(\lambda+\mu)\phi\frac{\partial}{\partial y}\left(\frac{\partial U}{\partial x}+\frac{\partial V}{\partial y}\right)+\mu\phi\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)V+\mu V\frac{\partial^2\phi}{\partial z^2}+\frac{\partial\mu}{\partial z}\frac{\partial\phi}{\partial z}V$$

(8),(9)

Galerkin's method is applied along the z direction as Nogami (2001),

$$\int_0^H\left(-\rho\frac{\partial^2 U}{\partial t^2}\phi+(\lambda+\mu)\phi\frac{\partial}{\partial x}\left(\frac{\partial U}{\partial x}+\frac{\partial V}{\partial y}\right)+\mu\phi\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)U+\mu U\frac{\partial^2\phi}{\partial z^2}+\frac{\partial\mu}{\partial z}\frac{\partial\phi}{\partial z}U\right)\phi dz=0$$
$$\int_0^H\left(-\rho\frac{\partial^2 V}{\partial t^2}\phi+(\lambda+\mu)\phi\frac{\partial}{\partial y}\left(\frac{\partial U}{\partial x}+\frac{\partial V}{\partial y}\right)+\mu\phi\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)V+\mu V\frac{\partial^2\phi}{\partial z^2}+\frac{\partial\mu}{\partial z}\frac{\partial\phi}{\partial z}V\right)\phi dz=0$$

(10),(11)

Applying integration by parts to the last two terms, the following equations are finally obtained.

$$\rho^*\frac{\partial^2 U}{\partial t^2}+k^*U=(\lambda+\mu)^*\frac{\partial}{\partial x}\left(\frac{\partial U}{\partial x}+\frac{\partial V}{\partial y}\right)+\mu^*\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)U$$
$$\rho^*\frac{\partial^2 V}{\partial t^2}+k^*V=(\lambda+\mu)^*\frac{\partial}{\partial y}\left(\frac{\partial U}{\partial x}+\frac{\partial V}{\partial y}\right)+\mu^*\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)V$$

(12),(13)

where $\rho^*, k^*, (\lambda+\mu)^*, \mu^*$ are expressed as follows.

$$\rho^*=\int_0^H\rho\phi^2 dz \tag{14}$$

$$k^*=\int_0^H\mu\left(\frac{\partial\phi}{\partial z}\right)^2 dz \tag{15}$$

$$(\lambda+\mu)^*=\int_0^H(\lambda+\mu)\phi^2 dz \tag{16}$$

$$\mu^*=\int_0^H\mu\phi^2 dz \tag{17}$$

These resulting model is basically the same as the Quasi-Three-Dimensional Ground Model (Q3DGM) developed by Tamura et al. (1991). Incidentally, the governing equation for a two dimensional case is given as can be seen below.

$$\rho\frac{\partial^2 u}{\partial t^2}=(\lambda+\mu)\frac{\partial}{\partial x}\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right)+\mu\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)u$$
$$\rho\frac{\partial^2 v}{\partial t^2}=(\lambda+\mu)\frac{\partial}{\partial y}\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right)+\mu\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)v$$

(18),(19)

Comparing these equations, the only difference is k^*U and k^*V terms which work as restoring force regarding relative horizontal displacement along z direction.

4.2 Finite Element Modeling

Governing equation for the Q3DGM is given as shown below.

$$\frac{\partial\sigma_{xx}}{\partial x}+\frac{\partial\sigma_{xy}}{\partial y}=\rho\frac{\partial^2 u}{\partial t^2}+ku$$
$$\frac{\partial\sigma_{yx}}{\partial x}+\frac{\partial\sigma_{yy}}{\partial y}=\rho\frac{\partial^2 v}{\partial t^2}+kv \tag{20},(21)$$

The governing equation is multiplied by weight functions w_x, w_y, and integrating over the area,

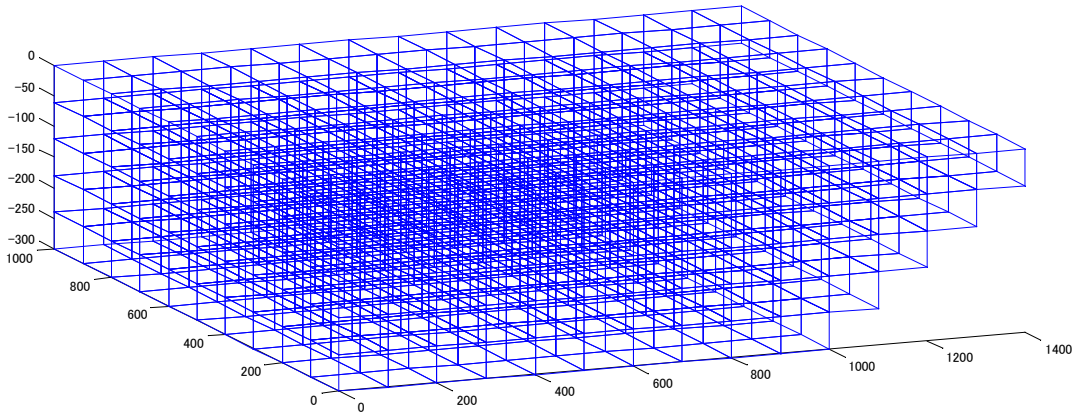


Figure 7 Soil Deposit on Undulating Bedrock

$$\int_S w_x \frac{\partial \sigma_{xx}}{\partial x} dS + \int_S w_x \frac{\partial \sigma_{xy}}{\partial y} dS = \int_S w_x \rho \frac{\partial^2 u}{\partial t^2} dS + \int_S w_x k u dS$$

$$\int_S w_y \frac{\partial \sigma_{yx}}{\partial x} dS + \int_S w_y \frac{\partial \sigma_{yy}}{\partial y} dS = \int_S w_y \rho \frac{\partial^2 v}{\partial t^2} dS + \int_S w_y k v dS$$

(22),(23)

Introducing Green-Gauss theorem,

$$\int_S w_x \sigma_{xx} n_x dS - \int_V \frac{\partial w_x}{\partial x} \sigma_{xx} dV + \int_S w_x \sigma_{xy} n_y dS - \int_V \frac{\partial w_x}{\partial y} \sigma_{xy} dV = \int_V w_x \rho \frac{\partial^2 u}{\partial t^2} dV + \int_V w_x k u dV$$

$$\int_S w_y \sigma_{yx} n_x dS - \int_V \frac{\partial w_y}{\partial x} \sigma_{yx} dV + \int_S w_y \sigma_{yy} n_y dS - \int_V \frac{\partial w_y}{\partial y} \sigma_{xy} dV = \int_V w_y \rho \frac{\partial^2 v}{\partial t^2} dV + \int_V w_y k v dV$$

(24),(25)

Then, rearranging the equations,

$$\int_V \left(\frac{\partial w_x}{\partial x} \sigma_{xx} + \frac{\partial w_x}{\partial y} \sigma_{xy} \right) dV = \int_S w_x t_x dS - \int_V w_x \rho \frac{\partial^2 u}{\partial t^2} dV - \int_V w_x k u dV$$

$$\int_V \left(\frac{\partial w_y}{\partial x} \sigma_{yx} + \frac{\partial w_y}{\partial y} \sigma_{yy} \right) dV = \int_S w_y t_y dS - \int_V w_y \rho \frac{\partial^2 v}{\partial t^2} dV - \int_V w_y k v dV$$

(26),(27)

Addition of these equations yields,

$$\int_V \{\nabla w\}^T \{\sigma\} dV = \int_S \{w\}^T \{t\} dS - \int_V \{w\}^T \{\rho \ddot{u}_i\} dV - \int_V \{w\}^T \{k u_i\} dV$$

(28)

Displacement vector is approximated by using a shape function $[N]$, and the weight function is expressed as well, by the following equation.

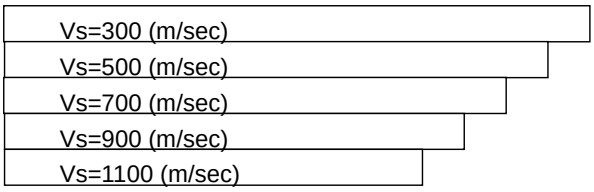

Figure 8 Soil Profile

$$\{u\} = [N]\{a\}$$
$$\{w\} = [N]\{c\}$$

(29),(30)

Finally, the following equation is obtained.

$$\int_V \rho [N]^T [N] dV \{\ddot{a}_i\} + \int_V [B]^T [D] [B] dV \{a\} + \int_V k [N]^T [N] dV \{a_i\} = \int_S [N]^T \{t\} dS$$

(31)

5. COMPUTATIONAL RESULTS

The proposed simplified ground model is verified in this section. Eigenvalue problem of multi-layered irregular shaped ground was solved by the three dimensional finite element method and by the proposed method. Fundamental vibration modes calculated by these methods are compared.

5.1 Soil Deposit on Undulating Bedrock Used for the Analysis

Irregular shaped ground model was prepared as shown in Figure 7. The boundary of the ground model varies three dimensionally; it consists of a flat and inclined bedrock section. The bottom and four sides are fixed boundaries. The surface soil deposit consists of horizontal layers of 60m

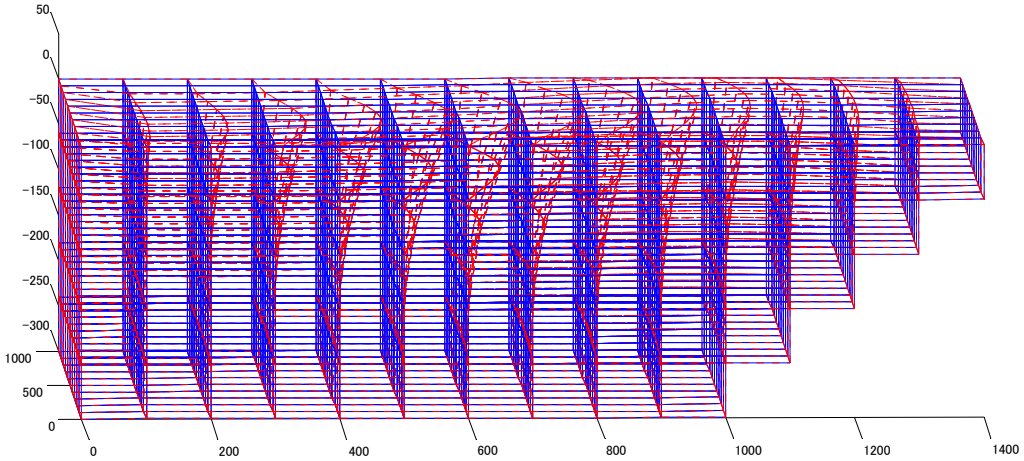

Figure 9 Vibration mode along depth by 3D FEM (unit in meters)

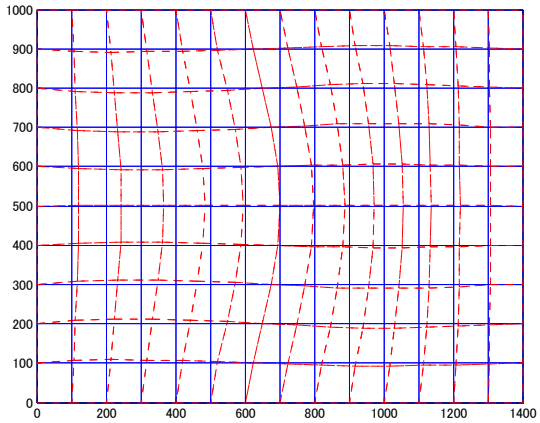

Figure 10 Top view of fundamental mode by 3D FEM (unit in meters)

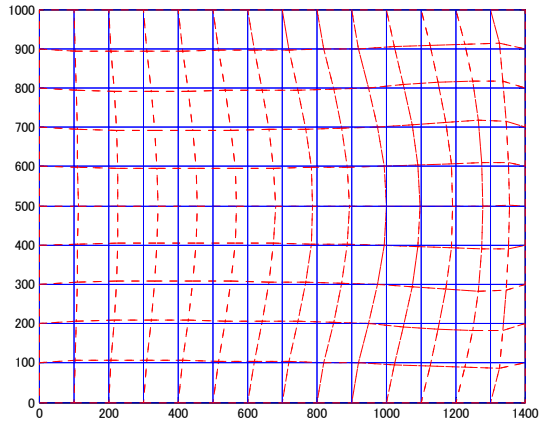

Figure 11 Top view of fundamental mode by Q3DGM (unit in meters)

thickness each with different soil properties as shown in Figure 8. Soil density and Poisson's ratio are assumed to be constant over the volume; they are 1800(kg/m^3) and 0.4, respectively.

5.2 Results by Three Dimensional Finite Element Method

The three dimensional finite element method with 8 nodes solid element is used. Fundamental vibration mode along the depth is shown in Figure 9. Fundamental frequency of the model became 0.7618(Hz). Vertical motion can also be found in this analysis. Figure 10 shows computational results at the surface (top view) for the first mode frequency. From these results, we can clearly recognize that ground vibration dominates in the flat bedrock section near the irregular bedrock section.

5.3 Results by the Simplified Ground Model Proposed in this Study

Each soil column which consists of horizontal layers is modeled with homogeneous soil column that has the identical fundamental frequency. Hence, the replaced surface soil is no longer three dimensional; it is a two dimensional model in which three dimensional topographical effects are reflected.

Similar result was obtained from the proposed method as shown in Figure 11, even though computation time is much shorter. The calculated fundamental frequency became 0.8608(Hz). No vertical motion exists in this case since vertical motion is neglected in this model. There was similar horizontal displacement mode in the short direction (perpendicular to the direction of sloping bedrock).

6. CONCLUSIONS

This study proposed a method of combining simple soil investigation with microtremor measurements and simple ground response analysis. Assuming to conduct microtremor measurements on a ground surface while assuming that the depths of bedrock are known, and utilizing H/V spectral ratio evaluated from microtremor measurements, multi-layered surface soil deposit is replaced with a homogeneous soil deposit overlying bedrock. A

best-simplified ground model that is in congruity with the simplicity and the accuracy of the microtremor measurement is derived in the following steps. Showing a result that the simple soil model is suitable to be used in a low frequency range, the model is attributed to a further simplified ground model, which is basically the same model as the Quasi-Three-Dimensional-Ground Model proposed by Tamura et al. Similar computational results were obtained by dynamic analysis of multi-layered, irregular-shaped ground model between the proposed method and the three dimensional finite element method with detailed soil data provided. Hence, the proposed approach may be rational and cost effective when ground response analysis is needed for a wide area.

Abstract: The elasto-plasticity based on the finite deformation theory is roughly classified two types which are the formulation by the additive decomposition of deformation rate using the hypo-elastic constitutive model and the formulation by the multiplicative decomposition of deformation gradient using hyper-elastic constitutive model. The latter formulation is becoming main stream recently, because the elastic energy dissipation does not occur and the objectivity is kept since it is not necessary to transform the rate form of constitutive model into incremental form. In this research, the implicit stress-update algorithm by using exponential return-mapping method for the extended sub-loading Cam-Clay model with the hardening/softening due to shear deformation is proposed in the framework of the finite deformation theory based on the multiplicative decomposition of deformation gradient. The accuracy of the proposed method is validated by comparing the stress updated by large deformation and small deformation.

1. INTRODUCTION

The relationship between the stress and the deformation of geo-material based on the finite deformation theory has both of the material nonlinearity and the geometric nonlinearity. Therefore a method that can implicitly integrate the stress-deformation relationship is needed. The stress update algorithm based on return mapping method have been developed to solve such a problem by Simo and Ortiz (1985), Simo and Taylor (1985), Ortiz and Simo (1986). The elasto-plasticity based on the finite deformation theory is roughly classified two types which are the formulation by the additive decomposition of deformation rate using the hypo-elastic constitutive model and the formulation by the multiplicative decomposition of deformation gradient using hyper-elastic constitutive model. The former one is widely used because the formulation is relatively easy although the constitutive model is complicated. The latter formulation is becoming main stream recently, because the elastic energy dissipation does not occur and the objectivity is kept since it is not necessary to transform the rate form of constitutive model into incremental form. Yamakawa et al. (2010) formulated extended sub-loading Cam-Clay model in the framework of the finite deformation theory based on the multiplicative decomposition of deformation gradient and developed the stress-update algorithm by using return mapping method. In this research, the implicit stress-update algorithm by using exponential return-mapping method for the extended sub-loading Cam-Clay model with the hardening/softening due to shear deformation (Hashiguchi et al. (1998)) is proposed in the framework of the finite deformation theory based on the multiplicative decomposition of deformation gradient. The accuracy of the proposed method is validated by comparing the stress updated by large deformation and small deformation.

2. ALGORITHM FOR STRESS UPDATE

2.1 multiplicative decomposition of deformation

Two material points $\mathbf{X}$ and $\mathbf{X}+d\mathbf{X}$ move to $\boldsymbol{x}=\phi(\mathbf{X})$ and $\boldsymbol{x}+d\boldsymbol{x}=\phi(\mathbf{X}+d\mathbf{X})$ in the current configuration respectively from the reference configuration to the current configuration due to motion of the continuum as shown in Fig. 1. By applying Taylor expansion to the motion $\phi(\mathbf{X}+d\mathbf{X})$, the infinitesimal vector $d\boldsymbol{x}$ is obtained as

$$d\boldsymbol{x}=\mathbf{F}\cdot d\mathbf{X} \tag{1}$$

where $\mathbf{F}$ is deformation gradient tensor which is defined as

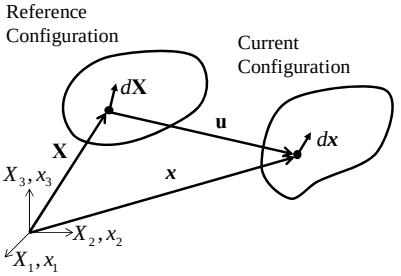

Fig. 1. Movement of infinitesimal vector $d\mathbf{X}$ near a material point $\mathbf{X}$

$$\mathbf{F} = \frac{\partial \boldsymbol{x}}{\partial \mathbf{X}}. \tag{2}$$

Equation (1) represents that the infinitesimal vector $d\mathbf{X}$ near the material point $\mathbf{X}$ is transformed to $d\boldsymbol{x}$ due to the motion of continuum. In order to formulate motion of continuum in the framework of hyper elasto-plasticity, the intermediate configuration is adopted. The intermediate configuration is imaginary configuration defined near an individual material point which is removed stress and elastic deformation from the current configuration. A schematic figure explained the multiplicative decomposition of deformation gradient is shown in Fig. 2. Plastic deformation gradient $\mathbf{F}^p$ describes deformation from the reference configuration to the intermediate configuration. Elastic deformation gradient $\mathbf{F}^e$ describes deformation from the intermediate configuration to the current configuration. In this research, the multiplicative decomposition of deformation gradient proposed by Lee (1969) is employed.

$$\mathbf{F} = \mathbf{F}^e \cdot \mathbf{F}^p \tag{3}$$

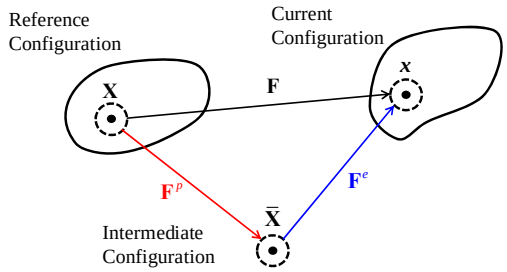

Fig. 2. Schematic figure explained the multiplicative decomposition of deformation gradient

2.2 Return mapping algorithm

Since the relationship between stress and deformation of geo-material generally has nonlinearity, a method to solve nonlinear equations implicitly is needed. The return mapping algorithm (Simo and Ortiz (1985); Ortiz and Simo (1986)) is employed to update the stress. This section summarizes the return mapping algorithm for finite deformation theory. A schematic figure explained the procedure of return mapping algorithm is shown in Fig. 3.

Considering a problem to obtain the stress at the time $t = t_{n+1}$ when an increment of displacement $\Delta\mathbf{u} = \boldsymbol{x}_{n+1} - \boldsymbol{x}_n$ from the time $t = t_n$ to the time $t = t_{n+1}$ is given, the deformation during the time step is described as

$$f_{[n,n+1]} = \frac{\partial \boldsymbol{x}_{n+1}}{\partial \boldsymbol{x}_n} = \frac{\partial\left(\boldsymbol{x}_n + \Delta\mathbf{u}\right)}{\partial \boldsymbol{x}_n} \tag{4}$$

where $f_{[n,n+1]}$ is the relative deformation gradient. The deformation gradient from the reference configuration to the current configuration at the time $t = t_{n+1}$ is described as

$$\mathbf{F}_{n+1} = f_{[n,n+1]} \cdot \mathbf{F}_n \tag{5}$$

The stress-update algorithm using the return mapping method is divided into two operations. One is "elastic predictor" and the other one is the "plastic corrector". In the "elastic predictor", we assume that the given deformation is totally caused by elastic deformation. The assumed elastic deformation gradient is called as the trial elastic deformation gradient and described as

$$\mathbf{F}^{e,trial}_{n+1} = \mathbf{F}_{n+1} \cdot \mathbf{F}_n^{p^{-1}} \tag{6}$$

By substituting the trial elastic deformation gradient to the hyper elastic constitutive equation, the stress can be updated on trial. By substituting the stress updated on trial to the yield function which the internal plastic variables are fixed at the time $t = t_n$, the elasto-plastic state can be judged. If yield function is negative, i.e. the stress is within the yield surface, the stress updated on trial is the stress at the time $t = t_{n+1}$ and we can proceed to the next step. On the other hand, if yield function is zero or positive, the elasto-plastic constitutive equations including plastic development rules is solved iteratively to update the stress by Newton-Raphson method in "plastic corrector" because the assumption that the given deformation is totally caused by elastic deformation is wrong. The detail procedure in the "plastic corrector is described in the next section.

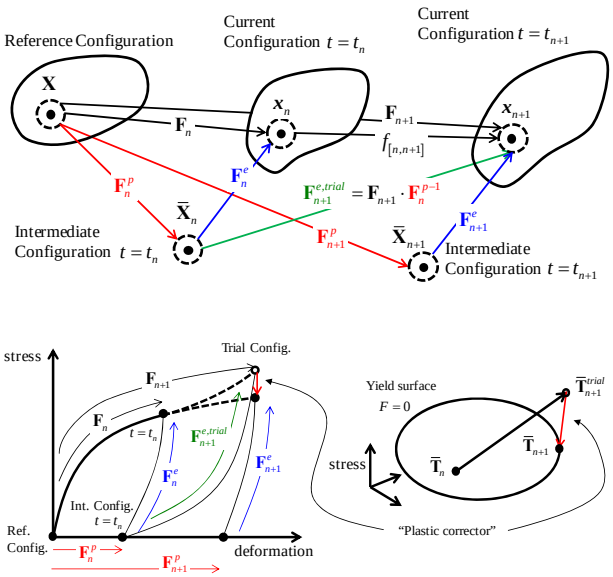

Fig. 3. Schematic figure explained the procedure of return mapping algorithm

2.3 Governing equations

The governing equations describing elasto-plastic behavior based on the fi

nite deformation theory are the multiplicative decomposition of deformation gradient (Eq.(3)), the hyper-elastic constitutive equation (Eq.(13)), the sub-loading function of the modified Cam-Clay type (Eq.(18)), the associated flow rule (Eq.(19)), the isotropic hardening rule (Eq.(20)), the development rule of hardening parameter

(Eq.(21)), the development rule of similarity ratio (Eq.(22)) and the development rule of similarity center (Eq.(23)). The hyper-elastic constitutive equation is

$$\bar{\mathbf{S}} = 2\frac{\partial \mathcal{W}^e}{\partial \bar{\mathbf{C}}^e}. \tag{7}$$

$\bar{\mathbf{S}}$ is second Piola-Kirchhoff stress referenced the intermediate configuration and is defined as

$$\bar{\mathbf{S}} = J\mathbf{F}^{e^{-1}} \cdot \boldsymbol{\sigma} \cdot \mathbf{F}^{e^{-T}} \tag{8}$$

where $J = \det \mathbf{F}$ is the volume change. $\boldsymbol{\sigma}$ is the Cauchy stress. $\mathcal{W}^e$ is hyper-elastic potential function. In elastic model of the modified Cam-Clay model, elastic bulk modulus and elastic shear modulus usually depend on the pressure so that the linear relationship of $\ln v - \ln p$ is represented. In this research, the hyper-elastic constitutive model depends on pressure proposed by Yamakawa et al. (2010) is employed. The hyper-elastic potential is defined as

$$\mathcal{W}^e(J^e, \hat{\bar{\mathbf{C}}}^e) = \bar{\mathcal{W}}^e(J^e) + \hat{\mathcal{W}}^e(J^e, \hat{\bar{\mathbf{C}}}^e), \tag{9}$$

$$\bar{\mathcal{W}}^e(J^e) = -\bar{P}_0 \tilde{\kappa}^* \left(\frac{J^e}{J_0^e} \right)^{-1/\tilde{\kappa}^*}, \tag{10}$$

$$\hat{\mathcal{W}}^e(J^e, \hat{\bar{\mathbf{C}}}^e) = \frac{1}{2}\mu^e \left(tr\hat{\bar{\mathbf{C}}}^e - 3 \right), \tag{11}$$

where J^e is an elastic volumetric change which is determinant of an elastic deformation gradient tensor $\mathbf{F}^e$. J_0^e and $\bar{P}_0$ are an elastic volumetric change and a pressure in the reference configuration respectively. $\hat{\bar{\mathbf{C}}}^e$ is a constant volume component of elastic right Cauchy-Green deformation tensor $\bar{\mathbf{C}}^e := \mathbf{F}^{e^T} \cdot \mathbf{F}^e$. $\tilde{\kappa}^*$ is elastic compression index. μ^e is a elastic shear modulus depend on pressure:

$$\mu^e = \mu_0^e + \frac{\alpha}{\tilde{\kappa}^*} \bar{\mathcal{W}}^e \left(J^e \right) \tag{12}$$

where μ_0^e is constant component of elastic shear modulus. α is a coefficient concerning with pressure dependency of elastic shear modulus. Second Piola-Kirchhoff stress referenced the intermediate configuration $\bar{\mathbf{S}}$ is derived by differentiating Eq.(9) with respect to $\bar{\mathbf{C}}^e/2$:

$$\bar{\mathbf{S}} = \bar{P}_0 \left(\frac{J^e}{J_0^e} \right)^{-1/\tilde{\kappa}^*} \left[1 + \frac{\alpha}{2\tilde{\kappa}^*} \left(tr\hat{\bar{\mathbf{C}}}^e - 3 \right) \right] \bar{\mathbf{C}}^{e^{-1}} + J^{e^{-2/3}} \mu^e \left(\mathbf{1} - \frac{1}{3} tr\hat{\bar{\mathbf{C}}}^e \bar{\mathbf{C}}^{e^{-1}} \right). \tag{13}$$

The normal yield function of the modified Cam-Clay model is employed.

$$F\left(\bar{\mathbf{T}}, \bar{P}_c\right) = \frac{\bar{Q}^2}{\mathrm{M}^2} + \bar{P}\left(\bar{P} - \bar{P}_c\right) = 0 \tag{14}$$

where $\bar{\mathbf{T}}$ is Mandel stress tensor referenced the intermediate configuration defined as

$$\bar{\mathbf{T}} = J\mathbf{F}^{e^{-1}} \cdot \boldsymbol{\sigma} \cdot \mathbf{F}^{e^{-T}} = \bar{\mathbf{C}}^e \cdot \bar{\mathbf{S}}. \tag{15}$$

Mandel stress is work-conjugate with plastic rate of deformation tensor $\bar{\mathbf{L}}^p$ defined as

$$\bar{\mathbf{L}}^p = \dot{\mathbf{F}}^p \cdot \mathbf{F}^{p^{-1}}. \tag{16}$$

$\bar{P}$ and $\bar{Q}$ are mean Mandel stress and deviatoric Mandel stress respectively. M is critical state parameter. The subscript c indicates the variable in pre-consolidated state. Hashiguchi et al. (1998) proposed the extended sub-loading surface which is always inside the normal yield surface in stress space. The sub-loading surface has similar figures and position to the normal yield surface. After Hashiguchi et al. (1998), modified Mandel stress defined by following equation is adopted.

$$\bar{\mathbf{T}}_{\mathrm{mod}} = \bar{\mathbf{T}} - (1 - R)\bar{\mathbf{A}} \tag{17}$$

where R is called similarity ratio expressed the ratio of size of the normal yield surface to the sub-loading surface. $\bar{\mathbf{A}}$ is called similarity center. The extended sub-loading function is described as

$$f\left(\bar{\mathbf{T}}, \bar{\mathbf{A}}, \bar{P}_c, R\right) = \frac{\bar{Q}_{\mathrm{mod}}{}^2}{\mathrm{M}^2} + \bar{P}_{\mathrm{mod}}\left(\bar{P}_{\mathrm{mod}} - R\bar{P}_c\right) = 0. \tag{18}$$

The associated flow rule is described as

$$\bar{\mathbf{L}}^p = \dot{\gamma}\bar{\mathbf{M}} \tag{19}$$

where $\dot{\gamma}$ is the plastic consistent parameter. $\bar{\mathbf{M}}$ is the first derivative of sub-laoding function with respect to Mandel stress. The isotropic hardening law is

$$\frac{\dot{\bar{P}}_c}{\bar{P}_c} = -\Theta\dot{\chi}. \tag{20}$$

Θ is defined as $1/\left(\tilde{\lambda}^* - \tilde{\kappa}^*\right)$. $\tilde{\lambda}^*$ is elasto-plastic compression index. χ is the hardening parameter. The development rules of hardening parameter, similarity ratio and similarity center are as follows.

$$\dot{\chi} = tr\bar{\mathbf{L}}^p + \sqrt{\frac{2}{3}}\mu \left\| \bar{\mathbf{L}}^{p(dev)} \right\| \left(\frac{\bar{Q}}{\bar{P}} + \mathrm{M}_d \right) \tag{21}$$

$$\dot{R} = -u_0 \ln R \left\| \bar{\mathbf{L}}^p \right\| \tag{22}$$

$$\dot{\bar{\mathbf{A}}} = c\left(\bar{\mathbf{T}} - \bar{\mathbf{A}}\right)\left\| \bar{\mathbf{L}}^P \right\| + \frac{\dot{\bar{P}}_c}{\bar{P}_c}\bar{\mathbf{A}} \tag{23}$$

where μ, M_d, u_0 and c are material parameters.

Assuming that plastic rate of deformation tensor $\bar{\mathbf{L}}^p$ is constant during a time step Δt and integrating Eq.(16) with respect to time from t_n to t_{n+1}, the following equation is derived:

$$\mathbf{F}^p_{n+1} = \exp\left(\Delta t \bar{\mathbf{L}}^p_{n+1}\right) \cdot \mathbf{F}^p . \tag{24}$$

Making dot product Eq.(24) and $\mathbf{F}^e_{n+1}$, $\mathbf{F}^{p^{-1}}_n$ and taking account that inverse tensor of $\exp\left(\Delta t \bar{\mathbf{L}}^p_{n+1}\right)$ is $\exp\left(-\Delta t \bar{\mathbf{L}}^p_{n+1}\right)$, Eq. (24) yields

$$\mathbf{F}^e_{n+1} = \mathbf{F}^{e,trial}_{n+1} \cdot \exp\left(-\Delta t \bar{\mathbf{L}}^p_{n+1}\right) \tag{25}$$

where $\mathbf{F}^{e,trial}_{n+1} := \mathbf{F}_{n+1} \cdot \mathbf{F}^{p^{-1}}_n$ is trial elastic deformation gradient tensor assumed plastic deformation is not occurred during a time step Δt. By backward Euler approximation, Eq.(19) takes the form:

$$\bar{\mathbf{L}}^p_{n+1} = \frac{\Delta\gamma_{n+1}}{\Delta t}\bar{\mathbf{M}}_{n+1} . \tag{26}$$

Substituting Eq.(26) to Eq.(25), the following equation is derived:

$$\mathbf{F}^e_{n+1} = \mathbf{F}^{e,trial}_{n+1} \cdot \exp\left(-\Delta\gamma_{n+1}\bar{\mathbf{M}}_{n+1}\right). \tag{27}$$

The stress is updated by substituting the elastic right Cauchy-Green deformation tensor at the time $t = t_{n+1}$: $\bar{\mathbf{C}}^e_{n+1}$ to the hyper-elastic constitutive equation (Eq.(13)), therefore it is more convenient transforming Eq.(27) to the folloing equation.

$$\bar{\mathbf{C}}^e_{n+1} = \bar{\mathbf{Q}}^{p\ T}_{n+1} \cdot \bar{\mathbf{C}}^{e,trial}_{n+1} \cdot \bar{\mathbf{Q}}^p_{n+1} \tag{28}$$

where $\bar{\mathbf{Q}}^p_{n+1} := \exp\left(-\Delta\gamma_{n+1}\bar{\mathbf{M}}_{n+1}\right)$. By backward Euler approximation and using Eq.(26), Eq.(22) and Eq.(23) take the forms:

$$R_{n+1} - R_n = -u_0 \Delta\gamma_{n+1} \ln R_{n+1} \left\| \bar{\mathbf{M}}_{n+1} \right\| \tag{29}$$

$$\bar{\mathbf{A}}_{n+1} - \bar{\mathbf{A}}_n = c\Delta\gamma_{n+1}\left(\bar{\mathbf{T}}_{n+1} - \bar{\mathbf{A}}_{n+1}\right)\left\| \bar{\mathbf{M}}_{n+1} \right\| + \frac{\bar{P}_{c.n+1} - \bar{P}_{c.n}}{\bar{P}_{c.n+1}}\bar{\mathbf{A}}_{n+1} \tag{30}$$

In the iterative process, the unknown variables $\bar{\mathbf{C}}^e_{n+1}$, $\Delta\gamma_{n+1}$, R_{n+1} and $\bar{\mathbf{A}}_{n+1}$ are calculated by solving simultaneously Eq.(28), Eq.(18), Eq.(29) and Eq.(30). The pre-consolidated stress $\bar{P}_{c.n+1}$ is obtained from the isotropic hardening law (Eq.(20)) and development rule of hardening parameter (Eq.(21)). By integrating Eq.(20) with respect to time, the following equation is derived:

$$\bar{P}_{c.n+1} = \bar{P}_{c.n} \exp\left(-\Theta\Delta\chi\right) \tag{31}$$

where

$$\Delta\chi = \Delta\gamma_{n+1} tr\bar{\mathbf{M}}_{n+1} + \Delta\gamma_{n+1}\sqrt{\frac{2}{3}}\mu\left\| \bar{\mathbf{M}}^{(dev)}_{n+1} \right\|\left(\frac{\bar{Q}_{n+1}}{\bar{P}_{n+1}} + \mathrm{M}_d \right) \tag{32}$$

The equations to solve by return mapping method are summarized as follows:

$$\mathbf{Y}_{\bar{\mathbf{C}}^e} = \bar{\mathbf{C}}^e_{n+1} - \bar{\mathbf{Q}}^{p\ T}_{n+1} \cdot \bar{\mathbf{C}}^{e,trial}_{n+1} \cdot \bar{\mathbf{Q}}^p_{n+1} = 0 \tag{33}$$

$$Y_f = f\left(\bar{\mathbf{T}}_{n+1}, \bar{\mathbf{A}}_{n+1}, \bar{P}_{c.n+1}, R_{n+1}\right) = 0 \tag{34}$$

$$Y_R = R_{n+1} - R_n + u_0\Delta\gamma_{n+1}\ln R_{n+1}\left\| \bar{\mathbf{M}}_{n+1} \right\| = 0 \tag{35}$$

$$\mathbf{Y}_{\bar{\mathbf{A}}} = \bar{\mathbf{A}}_{n+1} - \bar{\mathbf{A}}_n - c\Delta\gamma_{n+1}\left(\bar{\mathbf{T}}_{n+1} - \bar{\mathbf{A}}_{n+1}\right)\left\| \bar{\mathbf{M}}_{n+1} \right\| - \frac{\bar{P}_{c.n+1} - \bar{P}_{c.n}}{\bar{P}_{c.n+1}}\bar{\mathbf{A}}_{n+1} = 0 \tag{36}$$

By defining the unknown vector $\mathbf{X}$ and the residual vector $\mathbf{Y}(\mathbf{X})$ as

$$\mathbf{X} = \left(\bar{\mathbf{C}}^e_{n+1}, \Delta\gamma_{n+1}, R_{n+1}, \bar{\mathbf{A}}_{n+1}\right)^T \tag{37}$$

$$\mathbf{Y}(\mathbf{X}) = \left(\mathbf{Y}_{\bar{\mathbf{C}}^e}, Y_f, Y_R, \mathbf{Y}_{\bar{\mathbf{A}}}\right)^T , \tag{38}$$

The equations to solve yields

$$\mathbf{Y}(\mathbf{X}) = 0 . \tag{39}$$

By linearize Eq. (39) to solve iteratively by Newton-Raphson method, the following equation is deribed.

$$\mathbf{Y}\left(\mathbf{X}^{(k)}\right) + \frac{\partial\mathbf{Y}}{\partial\mathbf{X}}\left(\mathbf{X}^{(k)}\right)\cdot\delta\mathbf{X} = 0 \tag{40}$$

The blanketed superscript indicates the number of iteration. By solving Eq. (40), we can correct the unknown vector at the time t_{n+1} by

$$\mathbf{X}^{(k+1)} = \mathbf{X}^{(k)} + \delta\mathbf{X} . \tag{41}$$

In differentiate the residual vector by the unknown vector, the exponential tensor have to be differentiate, because exponential tensor is included in Eq. (33). The derivative of exponential tensor is derived by Neto (2001).

3. NUMERICAL EXAMPLES

In this chapter, the simulation of constant volume shear test and the cyclic loading test with constant strain amplitude are carried out to confirm the accuracy of the implicit stress-update method using return mapping algorithm based on finite deformation theory described in the previous chapter. The simulation of cyclic loading test with constant stress amplitude is also carried out to confirm the ability to express the cyclic behavior of the constitutive model.

3.1 Simulation of constant volume shear test

In order to confirm the accuracy of the stress-update method, the result of simulation which is input large deformation is compare with the result which is input small deformation. In the simulation, deformation gradient is given as

$$\mathbf{F} = \mathbf{F}^* \cdot \mathbf{F}_0, \quad \mathbf{F}^* = \begin{bmatrix} 1 & F_s & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{42}$$

where $\mathbf{F}_0$ is an initial deformation gradient. $\mathbf{F}^*$ is deformation from initial configuration. The shear component of deformation gradient F_s is set to be 0.2. The given deformation gradient is divided evenly into 1000 steps and 5 steps. The initial stress state is set following three cases. In case 1, the initial stress state is isotropic normally consolidated state and pre-consolidated stress in terms of Mandel stress is -100kPa. In case 2, the initial stress state is isotropic over-consolidated state and initial mean stress in terms of Cauchy stress is -100kPa. The pre-consolidated stress in terms of Mandel stress is -400kPa i.e. over consolidation ratio is 4.0. In case 3, the initial stress state is anisotropic over consolidated state and initial mean stress in terms of Cauchy stress is -66.7kPa. The pre-consolidated stress in terms of Mandel stress is -200kPa i.e. over consolidation ratio is about 1.6. The material parameter used in the simulation is summarized in Table. 1. The results of simulations are shown in Fig. 4.

Table 1. Material parameter used in the simulation

Critical state parameter	M	1.05
Elastic compression index	$\tilde{\kappa}^*$	0.06
Elasto-plastic compression index	$\tilde{\lambda}^*$	0.20
Constant of elastic shear modulus (kPa)	μ_0^e	1000.0
Parameter for pressure dependency of μ^e	α	0.0
Reference pressure (kPa)	$\bar{P}_0$	-100.0
Reference elastic volumetric change	J_0^e	1.00
Evolution parameter of similarity ratio	u_0	10.0
Evolution parameter of similarity center	c	10.0
Evolution parameter of shear hardening/softening	μ	0.5
Stress ratio of shear boundary surface	M_d	0.7
Initial value of similarity center	$\bar{\mathbf{A}}_0$	**0**

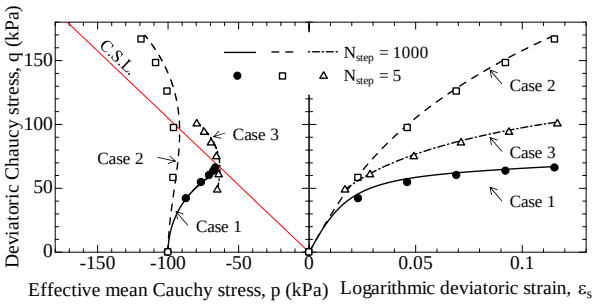

Fig. 4. Simulation results of constant volume shear test

Though the simulation results of case1, case2 and case 3, the stress updated by large deformation (5 steps) is not different from the stress updated by small deformation (1000steps). Therefore it can be said that the accuracy of the stress-update method is sufficient high for the simulation of constant volume shear test.

3.2 Simulation of cyclic loading test

The simulation of cyclic lading test with constant strain amplitude is carried out. The shear component of deformation gradient F_s is changed within the range: $-0.015 \le F_s \le 0.015$ and two cycle of cyclic loading test is simulated. The initial stress state is isotropic normally consolidated state and pre-consolidated stress in terms of Mandel stress is -100kPa. In order to validate the accuracy of the solution, two case of simulation which the total deformation is divided into 45 steps and 900 steps. The parameter used in the simulation is identical with the simulation of the constant volume shear test except elastic shear modulus. The elastic shear modulus is set to be 5000kPa in this simulation. The result of simulation is shown in Fig. 5. In the case of the cyclic loading, the stress-update method has high accuracy as well as the case of the constant volume shear.

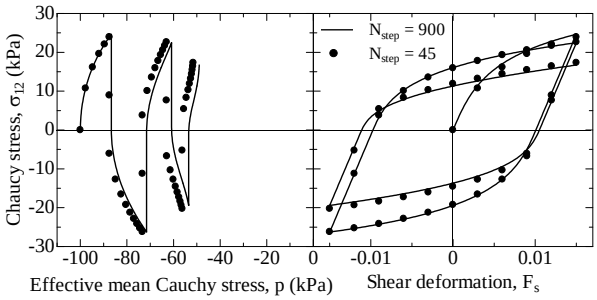

Fig. 5. Simulation result of cyclic loading with constant deformation amplitude

The simulation of cyclic loading test with constant stress amplitude is carried out. The material parameter used in the simulation is summarized in Table 2. The initial stress state is isotropic normally consolidated state and pre-consolidated stress in terms of Mandel stress is -400kPa. Initial mean stress in terms of Cauchy stress is -100kPa. The amplitude of the stress is 12kPa. The result of simulation is

shown in Fig. 6. It is found that the behavior so-called cyclic mobility can be expressed by incorporating the hardening/softening due to shear deformation to the constitutive model as plastic development rule.

Table 2. Material parameter used in the simulation

Critical state parameter	M	1.05
Elastic compression index	$\tilde{\kappa}^*$	0.025

4. CONCLUSIONS

In this paper, the implicit stress-update method by using return-mapping method for the extended sub-loading Cam-Clay model with the hardening/softening due to shear deformation is formulated in the framework of the finite deformation theory based on the multiplicative decomposition of deformation gradient. The simulations of constant volume test and the cyclic loading test are carried out by formulated stress-update method. Through the simulations, it is confirmed that the accuracy of the method is sufficient high and it is able to express the cyclic behavior of geo-material such as cyclic mobility.

Abstract: To estimate a pile's bending moment and shear force accurately, a response displacement method was developed with consideration of the seismic earth pressure and side friction acting on an embedded pile cap. Sensitivity of the coefficients of horizontal subgrade reactions for piles on the pile's shear force and bending moments and the effects of structure inertia and soil displacement on the pile's bending moment were examined using numerical parameter studies. Estimated seismic earth pressure and side friction on the pile cap, pile cap displacement, bending moment and shear force of the piles showed good agreement with the experimentally obtained results that were varied considerably with the piles' bending rigidity and relative density of soil models. The estimated shear force and bending moment at the pile head were affected slightly by variation of the coefficient of horizontal subgrade reaction. The bending moments of the low bending stiffness pile are smaller than those of the high bending stiffness pile, especially in the dense sand case.

1. INTRODUCTION

The seismic earth pressure and side friction acting on an embedded pile cap affect pile stress (Sugimura et al., 1984; Fujii et al., 1998). Therefore, the embedment effects of the pile cap, the amplitude of the resultant force of earth pressure and side friction, and the phase difference between the resultant force and the structure inertia force are important for the seismic design of pile foundations in conformity to their performance.

Garde and Dobry (1998) reported, based on cyclic lateral loading centrifuge tests with relative density of D_r=75%, that the contribution of the passive side accounts for more than half of the total capacity of an embedded pile cap. Tamura et al. (2007) demonstrated that the total earth pressure in the dense sand case plays an important role in reducing the shear force at pile heads based on dynamic centrifuge tests in a superstructure–footing model supported by piles in sand deposits of different relative densities of D_r=45%, 75% and 95%. Tamura et al. (2005) also reported that the phase difference between a structural inertia force and total earth pressure can be estimated by considering the natural period of the superstructure, the predominant period of the ground, the ground displacement, and the pile cap displacement. However, estimating pile stress with the embedment effects remains difficult.

The objectives of this study are 1) to estimate the amplitudes of the earth pressure and side friction acting on an embedded pile cap supported by pile foundation during an earthquake, 2) to evaluate the bending moment and shear force of a pile considering the earth pressure and side friction, and 3) to evaluate the sensitivity of the coefficients of horizontal subgrade reactions for piles on the pile's shear force and bending moment, and the effects of structure inertia and soil displacement on the pile bending moment. To achieve these objectives, a response displacement method was developed with earth pressure and side friction. To verify the method's effectiveness, dynamic centrifuge tests were conducted on a superstructure-footing model supported by 2×2 piles in a dry sand layer on liquefied soil. Furthermore, numerical parameter analyses were conducted.

2. CENTRIFUGE TESTS

Six dynamic centrifuge tests were conducted with centrifugal acceleration of 40 × *g* using the geotechnical centrifuge at the Disaster Prevention Research Institute, Kyoto University. A pile–footing–superstructure model was prepared in a laminar shear box with inner dimensions of 450 mm (length) × 150 mm (width) × 200 mm (height). Table 1 presents all test cases in which the piles' bending stiffness, the natural period of a superstructure, and the soil relative density were varied.

For the tests, 2×2 pile models of two types were used. Table 2 and Fig. 1 respectively present the pile conditions, the model setup, and the sensor location. The lid-shaped footing was modeled with rigid brass of 90 mm (shaking direction) × 68 mm (width) × 55 mm

(height). The pile heads were linked rigidly to the upper plate of the pile cap. Their tips were also linked rigidly to the laminar shear box. The strain gauges at the pile heads were not in contact with the soil. Four plates supported by small load cells were set up on the active and passive sides and shearing sides of the pile cap. The resultant forces of the earth pressure and side friction are defined as the sum of the earth pressure acting on the active and passive sides of the pile cap and the shearing forces acting on the pile cap's side parallel to the shaking direction. The baseline of the earth pressure and wall friction amplitudes was set to zero before the centrifuge test. Toyoura sand was pasted on active and passive sides and on shearing sides of the pile cap models to increase friction between the pile cap surface and the soil. The pile cap was embedded 44 mm into the dry sand before tests.

The natural period of the superstructure in Cases 1, 2, 5, and 6, supported by plate springs under the fixed pile cap condition, was 0.0075 s. The natural period of the superstructure in Cases 3 and 4, supported by ball bearings, was 0.125 s, which was adjusted by rubber sheets between the superstructure and the panel fixed on the pile cap. The respective masses of the superstructure and pile cap were 2.0 kg and 0.99 kg.

Dry sand was air-pluviated to prepare a uniform soil layer with relative density D_r of 30% in Cases 1–4 and 80% in Cases 5 and 6. Toyoura sand (D_{50}=0.21 mm) was used. The water table was set to 54 mm below the ground surface for all tests. Excitation for the test used Hachinohe 1968 NS. The peak acceleration was scaled to about 120 m/s^2 (3 m/s^2 in prototype scale). In addition to the earth pressure and the side friction acting on the pile cap, the horizontal accelerations of the superstructure, the pile cap, the soil and the shear box base, and the excess pore water pressure were measured. All data presented in the following sections are of prototype scale. Details of the test results were reported by Tamura and Hida (2012).

3. RESPONSE DISPLACEMENT METHOD CONSIDERING EARTH PRESSURE AND SIDE FRICTION

3.1 Analytical Model for Estimating Pile Stress with Embedment Effects

Response displacement methods for estimating pile stress incorporating the seismic earth pressure and side friction on a pile cap have been developed. Figure 2 presents the proposed analysis model. The earth pressure and side friction on a pile cap can be evaluated by the nonlinear spring between the pile cap and the free-field soil. Details of the nonlinear spring are described in Sections 3.2–3.4. To incorporate consideration of the degree of fixation at pile head and pile tip, rotation springs were set up on the pile head and pile tip. The superstructure and pile cap inertias and the soil deformation were applied to the pile–footing model simultaneously using an incremental method, considering the combination of their phase differences based on the natural period of the superstructure, the predominant period of the ground, the ground displacement, and the pile cap displacement

Table 1 Test cases

	Case 1	Case 2	Case 3	Case 4	Case 5	Case 6
Piles' bending stiffness	High	Low	High	Low	High	Low
Natural period of superstructure	0.0075 s (0.3s)		0.125 s (5.0 s)		0.0075 s (0.3s)	
Relative density of soil model	30%				80%	

(Prototype scale)

Table 2 Pile's condition

3. 2 Estimation of Seismic Earth Pressure

The relation between the total earth thrust and the relative displacement was evaluated based on the seismic earth pressure theory considering the sign (positive or minus) of the horizontal seismic coefficient, k_h. The total earth thrust acting on a pile cap, P_E, is estimated as

$$P_E = P_{EL} - P_{ER} = \frac{1}{2}\gamma H^2 B(K_{EL} - K_{ER}) \quad (1)$$

in which P_{EL} and P_{ER} respectively signify the left and right sides' earth pressure, γ denotes the soil's unit weight, H represents the embedment depth of the pile cap, B stands for the left and right sides' pile cap width, and K_{EL} and K_{ER} respectively represent the seismic earth pressure coefficients (Zhang et al., 1998) of the pile cap's left and right sides. The seismic earth pressure coefficients depend not only on the relative displacement between the pile cap and the free-field soil but also on seismic coefficient and its sign. The effect of the sign of the horizontal seismic coefficient on the seismic earth pressure can be determined by soil displacement, ΔS and pile cap displacement, ΔB (Tamura and Tokimatsu, 2005) based the assumption that the soil wedge inertia is in phase with the soil displacement because the acceleration and displacement of a sinusoidal wave have mutually opposite signs and the acceleration and horizontal seismic coefficient also have opposite signs. When the pile cap displacement is less than the soil displacement, the passive side wedge increases its size with decreasing size of the active side wedge, as depicted in Fig. 3(a). Therefore, the passive side earth pressure increases and the active side earth pressure decreases, as depicted in Fig. 3 (c). Consequently, the total earth thrust increases continuously with increasing k_h. When the pile cap displacement is greater than soil displacement, the passive side wedge decreases its size with increasing size of the active side wedge, as depicted in Fig. 3(b). Therefore, the passive side earth pressure decreases and the active side earth pressure increases as depicted in Fig. 3(d). Thus the total earth thrust decreases concomitantly with increasing k_h.

The input parameters for calculating seismic earth pressure were determined from previous studies and observed data. The minimum relative displacement requiring development of the active state was assumed as 0.5% and 0.1% of the pile cap's embedment depth for Cases 1–4 (D_r=30%) and Cases 5 and 6 (D_r =80%), respectively, based on results of a previous study (Zhang et al., 1998). The minimum relative displacement demanded development of the passive state, respectively as 4% and 2% of the pile cap's embedment depth for Cases 1–4 (D_r =30%) and Cases 5 and 6 (D_r =80%) (Fang et al., 2002; Rollins and Sparks, 2002). The respective internal friction angles for Cases 1–4 (D_r =30%) and Cases 5 and 6 (D_r =80%) were 34 deg and 42 deg. The wall friction angle between the soil and pile cap was set to 18 deg for all cases based on experimentally obtained results. The

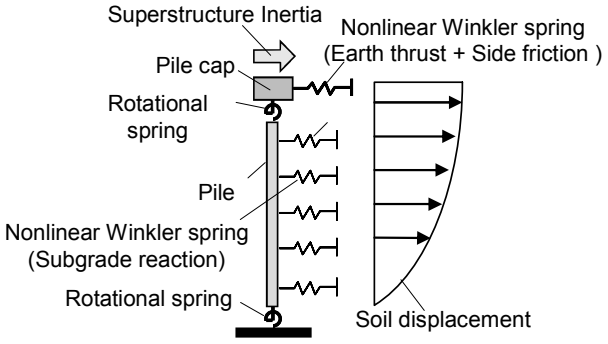

Figure 2 Analysis model for pile considering embedment effects

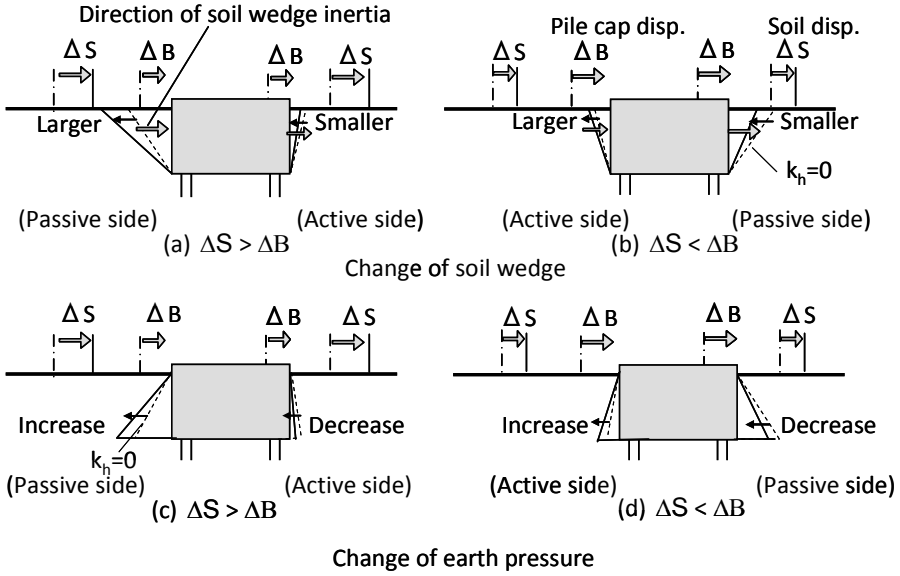

Figure 3 Effects of direction of soil wedge inertia on seismic earth pressure

horizontal seismic coefficients, k_h, were assumed to be -0.2, 0, and 0.2 in which k_h was a positive value when soil displacement was greater than the pile cap displacement.

Fig. 4 shows that the estimated total earth thrusts compared with the test results. The estimated total earth thrust with k_h=0.2 showed good agreement with the test results for Cases 1–4, which corresponded to the estimation on the effects of k_h on the total earth thrust, as depicted in Fig. 3 because the soil displacement tended to be greater than the pile cap displacement. In Cases 5 and 6, the soil displacement was less than the pile cap displacement, indicating that the total earth thrust decreases concomitantly with increasing k_h based on the proposed method. The estimated total earth thrust with k_h= -0.2, 0 and 0.2 also showed good agreement with test results because k_h had slight effects on the earth thrust for extremely small relative displacement.

3. 3 Estimation of Side Friction

Side friction was evaluated using the bilinear model considering the shear strength of soil around the sidewall (Tamura et al., 2009). The side friction, P_F was estimated as

$$P_F = \mu P_0 D_{re} / D_{\max} \qquad (D_{\mathrm{re}} \leq D_{\max}) \qquad (2)$$

$$P_F = \mu P_0 \qquad (D_{\mathrm{re}} > D_{\max}) \qquad (3)$$

$$P_0 = \frac{1}{2}\gamma H^2 L K_0 \qquad (4)$$

in which μ denotes the friction coefficient between the soil and the pile cap's surface, P_0 is the earth pressure at rest, D_{re} signifies the relative displacement between the pile cap and the soil, $D_{\max}$ represents the relative displacement at which the side friction reaches its maximum, L stands for the length of the pile cap (shaking direction), and K_0 is the earth pressure coefficient at rest, as estimated using Jaky's formula. Considering that the friction depends on the shear strength of the soil when the pile cap's surface is rough (Uesugi, 1986), the friction coefficient, μ is estimated as

$$\mu = \tan(\phi) \qquad (5)$$

where ϕ is the internal friction angle of the soil.

Fig. 5 shows that the estimated side frictions were compared with the test results to clarify the validity of the proposed method. The minimum relative displacement at which the side friction reached its maximum was assumed as 10 mm for Cases 1–4 and 3 mm for Cases 5 and 6 based on test results. The estimated side frictions agreed with the experimental data for all cases when the relative displacements were less than 2 cm, but were less than the experimental value when the relative displacements were greater than 2 cm because the positive dilatancy of sand increases the lateral pressure acting on the side when the relative displacement becomes large (Tamura et al., 2009). The effects of dilatancy demand further study, but errors are admitted in practical cases when the relative displacement is large because the side friction amplitude is smaller than the earth thrust amplitude.

3.4 Estimation of Resultant Force of Seismic Earth Pressure and Side Friction

The estimated resultant force of earth pressure and side friction, the nonlinear spring between the pile cap and the free-field soil of the proposed analysis, was verified with the test results depicted in Fig. 6. The horizontal

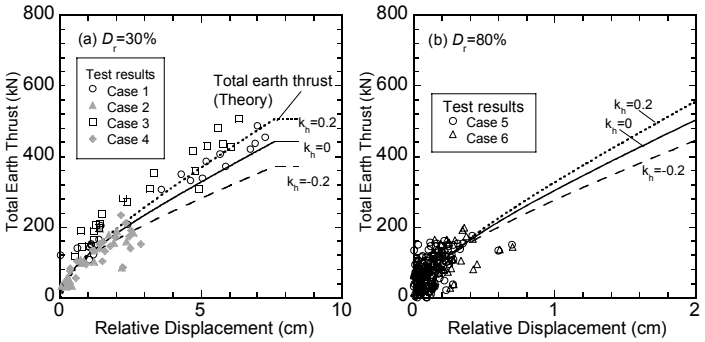

Figure 4 Relative displacement and total earth thrust

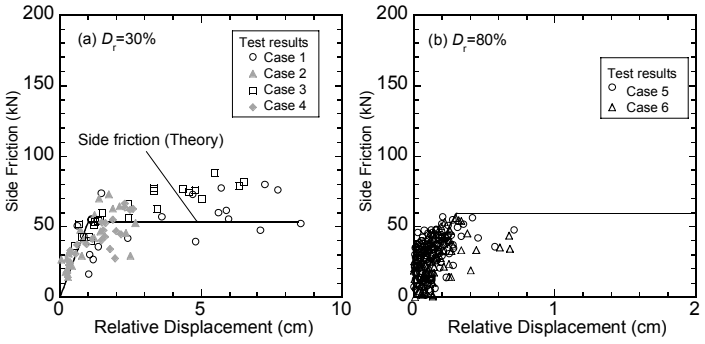

Figure 5 Relative displacement and side friction

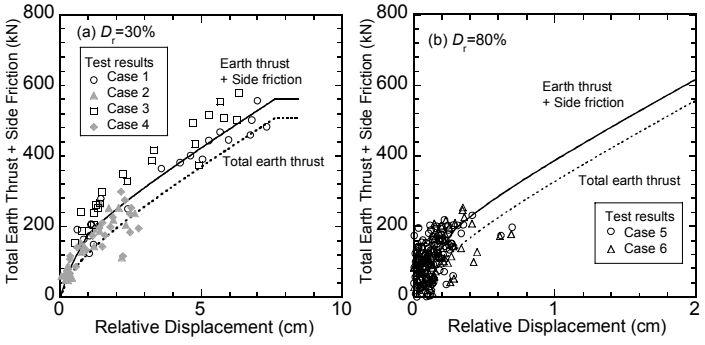

Figure 6 Relative displacement and the resultant force of earth pressure and side friction

seismic coefficients k_h were assumed as 0.2 for Cases 1–4 and -0.2 for Cases 5 and 6, considering soil and pile cap displacements. The estimated resultant force showed good agreement with the test results. The broken line in the figures shows the estimated total earth thrust (without the side friction), which was dominant in the resultant forces. The estimated resultant force (with the side friction) showed better agreement with the observed data.

4. PILE STRESS ESTIMATED USING THE PROPOSED METHOD

4.1 Calculation Conditions

The pile cap displacement, the resultant force of earth pressure and side friction, the pile's bending moment, and the shear force were evaluated based on calculation conditions as follows. The nonlinear spring corresponding to the resultant force of earth pressure and side friction was evaluated using Eqs. (1)–(5). The direction of soil wedge inertia was estimated using the soil displacement and pile cap displacement (Fig. 3). The rotation springs at the pile head and tip were 1.41×10^5 kNm/rad for the high-stiffness pile model and 1.65×10^5 kNm/rad for the low-stiffness pile model, which were evaluated using the relation between the pile cap displacement and the horizontal load acting on the pile cap based on static horizontal loading tests without soil. The subgrade reaction of a pile was evaluated using the nonlinear spring based on recommendations for design of building foundations in Japan (AIJ, 2001) using the N-value estimated from the shear wave velocities (Tamura and Hida, 2012). The soil displacements from the ground surface to GL -3 m in Cases 1–4 and GL -1 m in Cases 5 and 6 were assumed to be constant and equal to the ground surface displacement. Then the soil displacement decreased concomitantly with increasing depth as a cosine function. The superstructure and pile cap accelerations and the ground surface displacement were used as the observed values. The estimated and measured data presented hereinafter were examined when the bending moment at the pile head reached its maximum after soil liquefaction. That is because the vertical distribution of the subgrade reaction of piles and soil displacement are dramatically changed before and after soil liquefaction.

The observed superstructure acceleration, pile cap acceleration and ground surface displacement used for the numerical analyses are shown in Table 3. The minus sign of the pile cap acceleration implies that the pile cap acceleration is greater than 180 deg with the superstructure acceleration. The superstructure accelerations, where the natural period of the superstructure is greater than the predominant period of the ground surface acceleration, were much smaller than the pile cap accelerations for Cases 3 and 4. To investigate the sensitivity of the coefficients of the subgrade reaction on the numerical results, the reductions in the ultimate subgrade reaction, α and in the subgrade reaction modulus, β on liquefaction were assumed respectively to be 0.01, 0.1 and 0.2.

4.2 Estimated Pile Cap Displacement

Pile cap displacements, as estimated using the proposed method, were compared with observed data for all cases, as portrayed in Fig. 7. The observed pile cap displacements were distributed from 2.5 cm (Case 5) to 26 cm (Case 2), indicating that the pile cap displacements were markedly affected by the relative density of the soil and the bending stiffness of piles. The black circles in the figure show the observed soil displacements. The soil displacements in Cases 1–4 were greater than the observed pile cap displacement. In contrast, the soil displacements in Cases 5 and 6 were smaller than the observed pile cap displacements. The estimated pile cap displacements increased concomitantly with increasing α , β for Cases 1–4 because the soil displacements tended to be greater than pile cap's and pile's displacements. The estimated pile cap displacements showed fairly good agreement with the observed values, especially when α, β were 0.1–0.2. Estimated pile cap displacements also increased concomitantly with increasing α, β for Cases 5 and 6, although the soil displacements were smaller than the pile cap displacements because the soil displacements were larger than the pile displacements at the lower part of piles and soil layer. The estimated pile cap displacements showed excellent agreement with observed data with any α, β for Cases 5 and 6.

4.3 Estimated Earth Pressure and Side Friction

Figure 8 shows that the estimated resultant forces of earth pressure and side friction per pile are compared with the test results. The respective positive and negative

Table 3 Superstructure and pile cap accelerations and ground surface displacement when bending moments at pile head were maximum after soil liquefaction

	Case 1	Case 2	Case 3	Case 4	Case 5	Case 6
Superstructure acceleration (cm/s^2)	150	116	42	34	247	276
Pile cap acceleration (cm/s^2)	137	117	-141	-125	189	216
Ground surface displacement (cm)	20.5	26.1	18.2	25.7	2.3	6.2

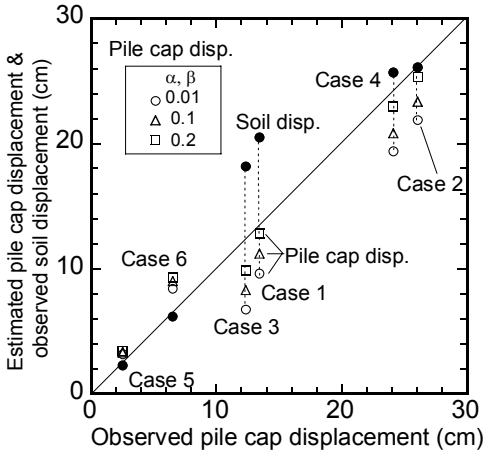

Figure 7 Estimated and observed pile cap displacement and observed soil displacement

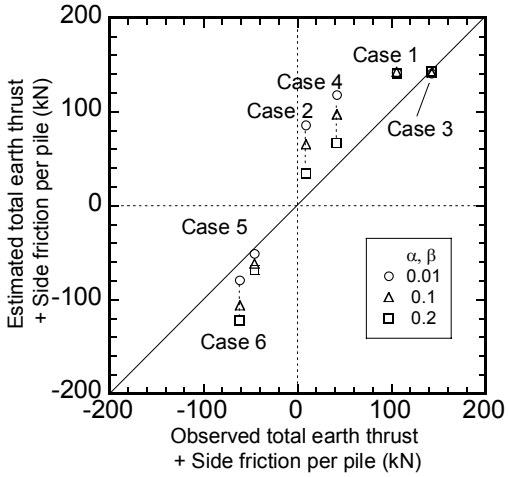

Figure 8 Estimated and observed resultant force of total earth thrust and side friction

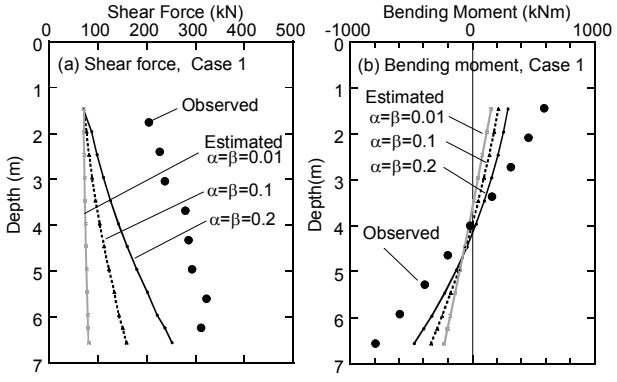

Figure 9 Vertical distribution of bending moment and shear force of pile without the resultant force of earth pressure and side friction

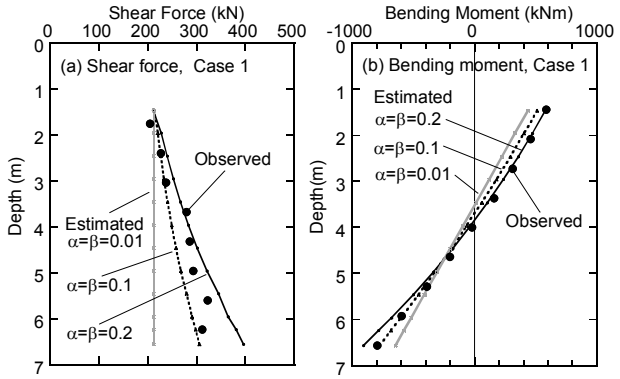

Figure 10 Vertical distribution of bending moment and shear force of pile with the resultant force of earth pressure and side friction

resultant forces show that the resultant forces are in phase and out of phase by 180 deg with the structure inertia. The observed resultant forces were in phase with the structural inertia for Cases 1–4 but were out of phase by 180 deg with structural inertia for Cases 5 and 6. The estimated resultant forces showed fairly good agreement with the experimentally obtained results, not only in terms of the amplitude but also in terms of the phase difference between the resultant forces and the structural inertia. The resultant forces for Cases 1 and 3 were unaffected by α, β because the earth pressure almost reached the passive state with any α, β. The resultant forces for Cases 2 and 4 decreased concomitantly with increasing α , β because the relative displacement between the soil and pile cap decreased. In contrast, the resultant forces for Cases 5 and 6 increased concomitantly with increasing α , β because the relative displacement between the soil and pile cap increased. These results indicate that the effects of the coefficients of subgrade reaction on the resultant force varied according to the soil, pile cap and pile displacements.

4.4 Estimated bending moment and shear force of piles

Figures 9 and 10 show the vertical distributions of pile's bending moment and shear force in Case 1, as respectively estimated without and with the earth pressure and side friction. The observed shear force increased continuously with increasing depth, indicating that the soil acted on the pile as an external force. This phenomenon resulted from the soil, for which the displacement was greater than the pile. The estimated shear force and bending moment amplitudes neglecting the earth pressure and side friction were much smaller than the test results with any α, β. In contrast, the estimated shear force and bending moments considering the earth pressure and side friction showed fairly good agreement with the observed data when α, β=0.1 and 0.2. These results indicate that the piles' shear force and bending moment cannot be estimated accurately without the earth pressure

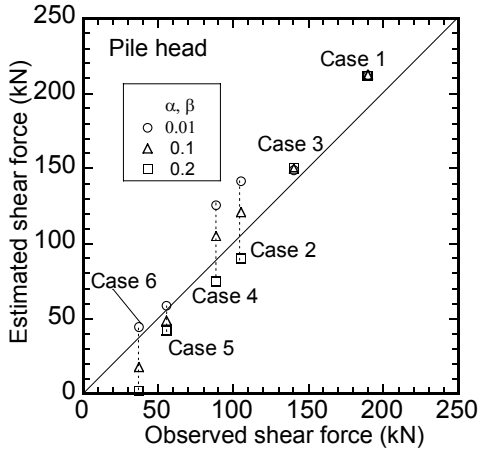

Figure 11 Estimated and observed shear force at pile head

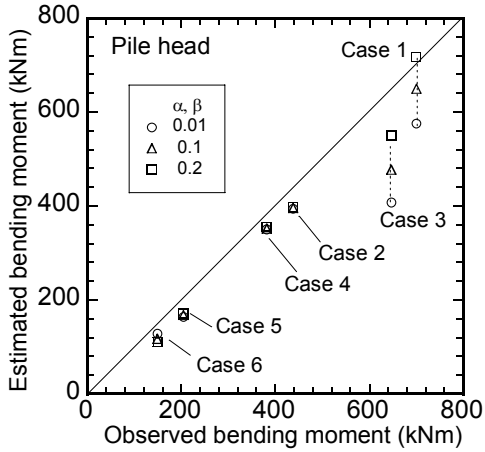

Figure 12 Estimated and observed bending moment at pile head

and side friction when a pile cap is embedded. The earth pressure and side friction are regarded as estimating the piles' stress hereinafter.

Figure 11 shows the estimated shear forces at the pile head compared with the test results. The estimated shear force at the pile head for Cases 1 and 3 did not depend on α, β because the earth pressure almost reached the passive state. The estimated shear force at pile head with α, β=0.1 and 0.2 showed good agreement with the observed data for all cases.

Figure 12 shows the estimated bending moments at the pile head compared with the test results. The estimated bending moments at the pile head with any α or β showed fairly good agreement with observed data in Case 2 and Cases 4–6. In Cases 1 and 3, the estimated bending moment with α, β=0.2 showed good agreement with the observed data.

5. EFFECTS OF STRUCTURE INERTIA AND SOIL DISPLACEMENT ON THE PILE BENDING MOMENT

The pile cap displacement, the resultant force of earth pressure and side friction and the bending moment at a pile head were examined in numerical parameter studies to investigate the effects of structure inertia and soil displacement on pile stress quantitatively. The parameters are bending stiffness of piles, relative soil density, structure inertia, and soil displacement. The pile and soil conditions for the numerical analysis are the same as those of the experiments. The reduction factors of subgrade reaction, α and β , were assumed as 0.2. The ground surface displacement D_s was assumed as 0, 10, 20, 30 cm in D_r=30% and 0, 5, 10, 15 cm D_r=80%. The soil displacement distribution was inferred using the same method as that described in Section 3.2. The horizontal equivalent seismic coefficient k_h is assumed as 0.2 for D_r=30% and -0.2 for D_r=80%. The structure inertia, assumed to be in phase with the soil displacement, changed from 0 to 300 kN. The circles in the following figure show the observed data when the pile's bending moment became the maximum for Cases 1–6. The observed and estimated data show good agreement corresponding to the structure inertia and ground surface displacement, suggesting high reliability of the numerical results.

5.1 Pile Cap Displacement

The relations between the structure inertia, the soil displacement and the pile cap displacement are presented in Fig. 13. The pile cap displacement is affected not only by the structure inertia but also by the soil displacement. For example, the pile cap displacement when the soil displacement is 30 cm and the structure inertia is 0 kN is equivalent to that when the soil displacement is 10 cm and the structure inertia is 300 kN in the case of high bending stiffness pile and D_r=30%. The inclinations of the lines showing inertia-displacement for D_r=30% are greater than those for D_r=80%, indicating that the pile cap displacements for D_r=30% are strongly affected by the structure inertia.

5.2 Earth Pressure and Side Friction

The relations between the structure inertia, the soil displacement, and the resultant force of earth pressure and side friction are presented in Fig. 14. The plus sign of the resultant force reflects that the resultant force is out of phase by 180 deg with the structure inertia. For D_r=30%, the resultant force of the high bending stiffness pile is in phase with the structure inertia except for the small soil displacement, indicating that the earth thrust and side friction tend to increase pile stress. The resultant force amplitude of D_s=30 cm is almost constant, about –150 kN, because the earth pressure reaches the passive state. In contrast, the resultant force of the low bending stiffness pile is out of phase by 180 deg with the structure

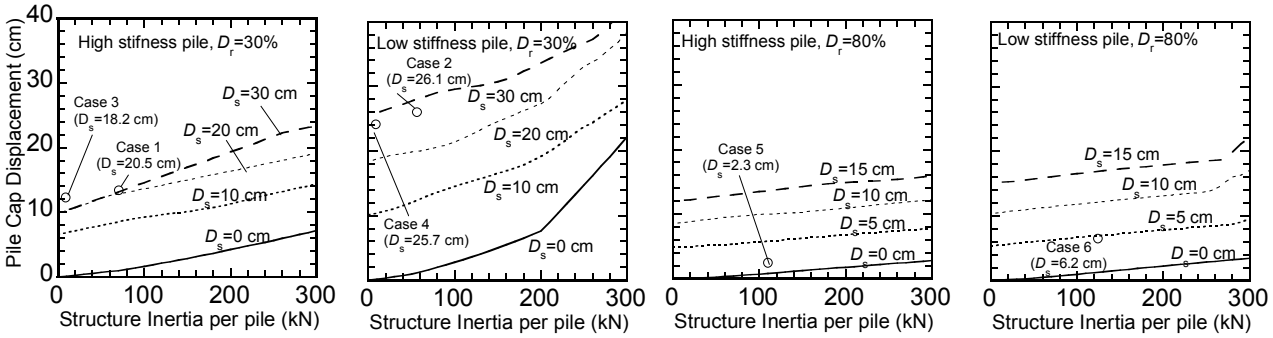

Figure 13 Effects of structure inertia and soil displacement on pile cap displacement

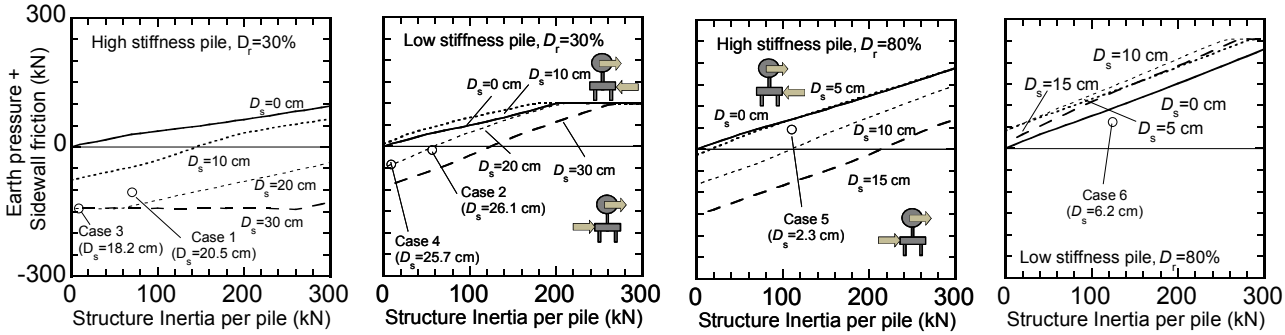

Figure 14 Effects of structure inertia and soil displacement on the resultant force of earth pressure and side friction

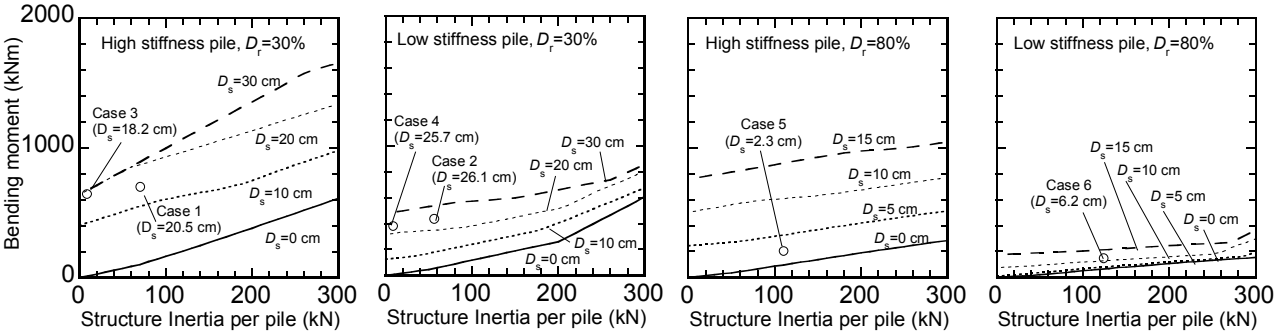

Figure 15 Effects of structure inertia and soil displacement on bending moment at pile head

inertia except for the large soil displacement and small structure inertia, indicating that the earth thrust and side friction tend to decrease the pile stress. The resultant forces when the structure inertia is large become constant, reflecting that the earth pressure reaches the passive state. The resultant force amplitude, about 100 kN, is smaller than that of the high bending stiffness pile. This difference results from the direction of the soil inertia.

For D_r=80%, the resultant force of the high bending stiffness pile is out of phase by 180 deg with the structure inertia when the soil displacement is small and the structure inertia is large, but it is in phase when the soil displacement is large and the structure inertia is small. The resultant force of the low bending stiffness pile is out of phase by 180 deg with the structure inertia with any structure inertia and soil displacement.

5.3 Bending Moment at Pile Head

The relations between the structure inertia, the soil displacement, and the bending moment at the pile head are presented in Fig. 15. The bending moment increases concomitantly with increasing structure inertia. For D_r=30%, the bending moment of the low bending stiffness pile is about half that of the high bending stiffness pile. The bending moment of the high stiffness pile is less affected by the structure inertia in D_s=20 cm than in D_s=30 cm. The resultant force of D_s=30 cm, in phase with the structure inertia, is large and almost constant for any structure inertia because the large relative displacement causes the passive state. In contrast, the resultant forces of D_s=20 cm are also in phase but decrease with the structure inertia. Therefore, the bending moment of

D_s=20 cm is less affected by the structure inertia. The bending moment of the low stiffness pile is also affected strongly by the structure inertia when the structure inertia is greater than about 200 kN because the resultant force, out of phase 180 deg with the structure inertia, reaches the passive state. It is noteworthy that the mechanism of the effects of the resultant force which reaches a passive state on the bending moment differs between the high stiffness pile and the low stiffness pile.

For D_r=80%, the bending moment of the low bending stiffness pile is about a quarter of that of the high bending stiffness pile because the resultant force of the earth pressure and side friction of the low stiffness pile reduced the shear force at pile head more efficiently than that of the high stiffness pile.

5.4 High Bending Stiffness Pile vs. Low Bending Stiffness Pile

The bending moments of the low bending stiffness pile are smaller than those of the high bending stiffness pile for both soil models, especially in the dense sand cases, because the resultant force is out of phase by 180 deg and its amplitude becomes large with small relative displacement. The pile's stress reduction effects in the loose sand case are limited when the structure inertia and/or the soil displacement are large. As described above, the effects of the structure inertia and the soil displacement on the pile's bending moment are extremely complicated, but they can be evaluated quantitatively using the proposed method.

6. CONCLUSION

A response displacement method was developed to estimate pile stress with consideration of the seismic earth pressure and side friction acting on an embedded pile cap. Sensitivity of the coefficients of subgrade reactions of piles on a pile's shear force and bending moment, and the effects of structure inertia and soil displacement on a pile's bending moment were examined in numerical parameter studies. The following conclusions were drawn.

(1) Estimated amplitudes of the resultant force of seismic earth pressure and side friction and the estimated phase difference between the resultant force and the structure inertia force showed good agreement with experimentally obtained results. The resultant forces were greater for loose sand cases but were smaller for dense sand cases with increasing coefficients of subgrade reactions of piles.

(2) Estimated amplitudes of the shear force and bending moment at the pile head agreed well with the observed results. The shear forces and bending moment were affected slightly by the variation of the subgrade reactions on piles.

(3) The bending moments of the low bending stiffness pile are smaller than those of the high bending stiffness pile, especially in the dense sand case, because the resultant force is out of phase by 180 deg and its amplitude becomes large with small relative displacement.

Abstract: An overview is presented of the authors' ongoing investigation of the performance of a railroad bridge and adjacent highway bridge during the 2010 El Mayor-Cucapah earthquake in Baja California, Mexico. A span of the pile-supported railroad bridge collapsed due to movement of a pier from lateral spreading. The highway bridge, supported on drilled shafts, suffered moderate structural damage but did not collapse. An overview of the site, structural details of the bridges, and the proposed geotechnical explorations and analyses are presented. The Pacific Earthquake Engineering Research Center (PEER) recently published "Recommended Design Practice for Pile Foundations in Laterally Spreading Ground," which synthesizes the last decade of research on the topic. Using the results from planned geotechnical investigation, the authors intend to analyze the bridges according to the PEER guidelines. The case studies will provide valuable insight for validating the recommended guidelines.

1. INTRODUCTION

On April 4, 2010, the M_w 7.2 El Mayor-Cucapah earthquake occurred southwest of Mexicali in northern Baja California, Mexico (USGS 2010). Liquefaction-related damage to irrigation and transportation infrastructure, buildings, and agricultural land was widespread throughout the region (GEER 2010). This paper focuses on an ongoing study of two parallel bridges located about 60km southeast of Mexicali that were subjected to liquefaction-induced lateral spreading and vertical settlement during the El Mayor-Cucapah earthquake.

Although the two bridges were subjected to the same level of lateral spreading demand, their performance levels were different, making this a valuable case study. An overview of the observed damage and structural details of the bridge along with the authors' planned site investigations and analyses are presented in the following sections. The primary focus of the investigation and analyses will be to model the highway bridge in an effort to understand why it exhibited desirable performance while the railroad bridge collapsed.

2. REGIONAL GEOLOGY AND SEISMICITY

The Mexicali Valley and its counterpart on the USA side of the border, the Imperial Valley, are located in the Salton Trough, an extensional basin formed by tectonic activity along the transform boundary between the Pacific and North American plates (Figure 1). To the southeast, the Gulf of California represents further extension due to divergent fault step-over at the plate margin, while movement to the northwest is primarily strike-slip along the San Andreas Fault system. The Colorado River enters the east side of the basin near the Mexico-USA border, depositing alluvium over marine deposits for a total soil thickness up to 2,400m thick (GEER 2010). High groundwater levels from the river and agricultural activity combined with the loose alluvial deposits create a high liquefaction hazard throughout the valleys.

Several faults cross the region, primarily accommodating strike-slip movement in the northwest-southeast direction and extension in the northeast-southwest direction. The El Mayor-Cucapah earthquake occurred mainly along the Pescadores and Borrego faults northwest of the epicenter and the previously unknown Indiviso Fault to the southeast, which was buried beneath sediments of the Colorado River delta prior to the earthquake. The offset was oblique with the primary component being strike-slip (GEER 2010).

The northern Baja California region is known to be seismically active, with several major earthquakes occurring in recent history. The El Mayor-Cucapah earthquake was the largest recorded event in the region since an estimated Mw 7.2 event in 1892 (Hough and Elliot 2004).

3. SITE DESCRIPTION

Immediately following the earthquake, a team of researchers from the Geotechnical Extreme Events Reconnaissance (GEER) Association visited the Mexicali and Imperial Valleys to collect perishable geotechnical data

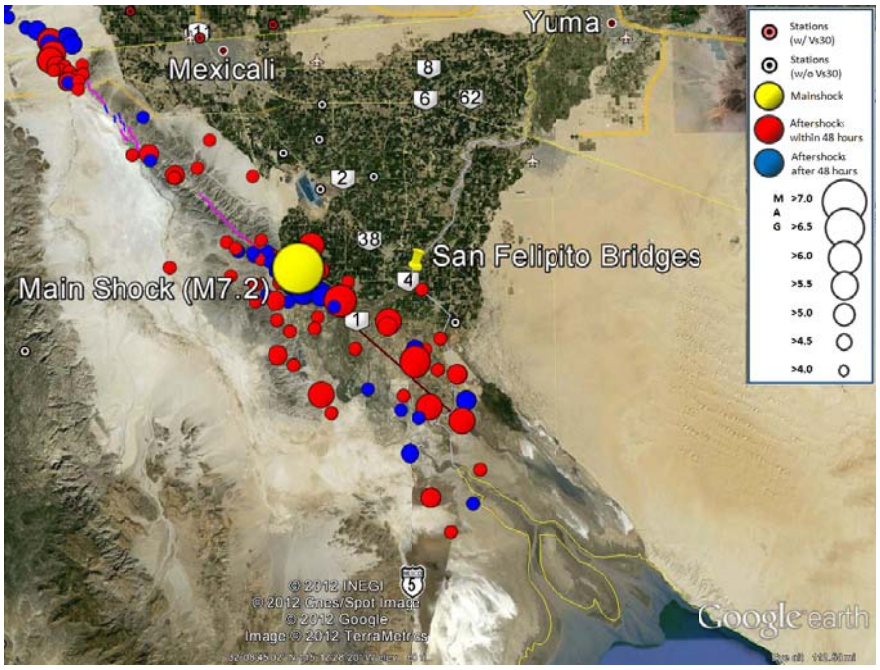

Figure 1: Regional map showing main event, aftershocks, and site location. After GEER Report (2010).

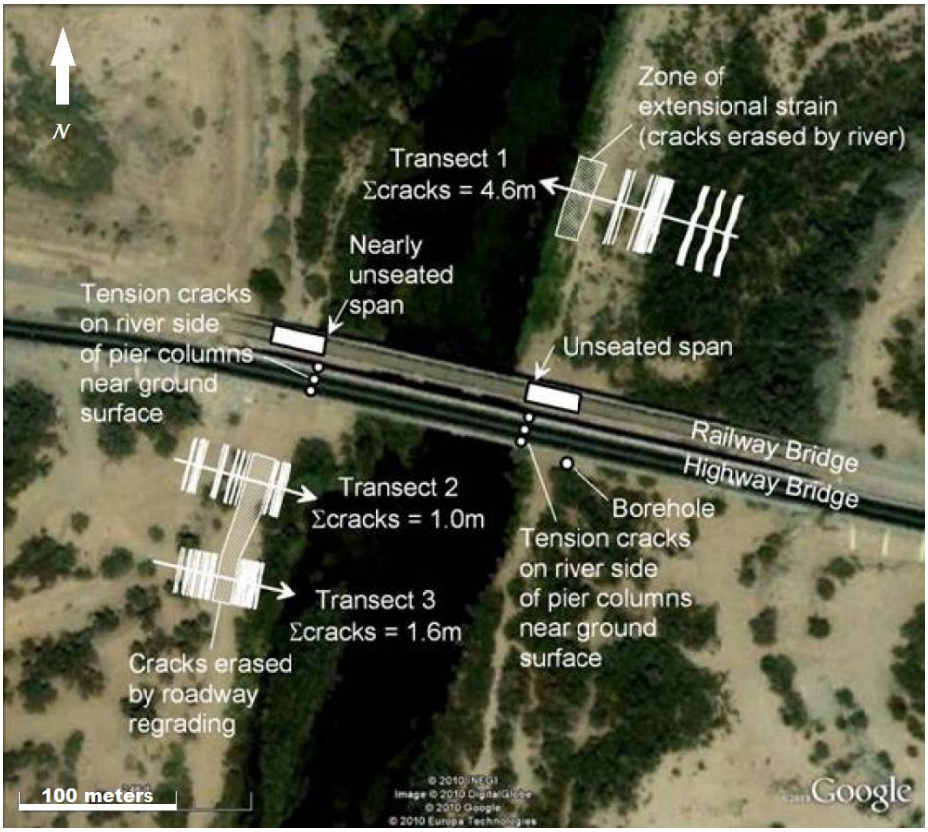

Figure 2: Site map showing lateral spreading and observed structural damage to bridges. After GEER Report (2010).

and observe structural damage associated with geotechnical issues. Except as noted, the following information in Sections 3 and 4 is adapted from the report of their reconnaissance effort, available on the GEER website (GEER 2010).

Two closely-spaced, parallel bridges span the Colorado

River at the site, a railroad bridge and a highway bridge, collectively called the "San Felipito Bridges" (see Figure 2). The river is flanked on both sides by relatively flat agricultural land with gently sloping banks. The nearest ground motion station to the site, located in Riito approximately 12km to the southeast, recorded a peak ground acceleration of approximately 0.4g.

3.1 Geotechnical Conditions

The near-surface soil profile at the site generally consists of recent alluvial deposits of loose sand with varying amounts of silt. The Secretaría de Comunicaciones y Transportes (Secretariat of Communications and Transportation) de México (SCT), the government agency with jurisdiction over the highway bridge, conducted a soil boring during the GEER reconnaissance trip. The soil profile inferred from their boring log consist of 6m of silt overlying approximately 5.5m of loose sand, underlain by dense sand, with the groundwater table at a depth of 2m. The location of the boring is shown in Figure 2. Further site investigations including subsurface testing are planned as described in Section 5.0.

3.2 Ground Failures

As shown in Figure 2, lateral spreading cracks were observed on the river banks both north and south of the bridges in the non-liquefied silt crust that overlays the liquefiable sand. It was not evident from the initial reconnaissance whether or not the approximately 4m of silt below the groundwater table liquefied during the earthquake. The sum of the measured lateral spreading cracks was as much as 4.6m along a transect about 60m north of the bridge, although not all the deformation could be directly measured due to heavy vegetation cover and erosion of cracks by the river prior to the arrival of the GEER team.

Measured lateral spreading deformation was greater on the east bank of the river than the west bank, possibly because the river currently flows along the western margin of its floodplain so the alluvial sediments on the east bank are younger and hence looser and more susceptible to liquefaction. This observation could have implications for estimates of potential lateral spreading deformations at similar sites.

Vertical settlement of up to 0.5m was observed, likely due to a combination of reconsolidation following liquefaction and deviatoric deformation. At the location of the largest measured vertical ground settlement, the bridge pier settled approximately 0.5m, likely due to static loads, down-drag forces mobilized during liquefaction, and a loss of axial resistance.

4. BRIDGE DAMAGE AND STRUCTURAL DETAILS

Both bridges have precast-prestressed concrete simply-supported spans on elastomeric bearings resting atop reinforced concrete, pile-supported piers. Although both bridges were founded on deep foundations, the railroad bridge suffered unseating collapse of one span and near collapse of two other spans, while the highway bridge suffered only moderate structural damage without collapsing. Further structural details of the bridges are provided in the following two sections.

4.1 Railroad Bridge

Constructed in 1962, the railroad bridge consists of a single track supported on three approximately 1.0m-deep T-shaped girders. The simply-supported spans rest on elastomeric bearings atop reinforced concrete pier walls which are supported on driven pile foundations. No other positive structural connection between the girders and the pier walls was observed, e.g. shear keys and diaphragm anchorage as described below for the highway bridge. The research team has not obtained construction plans for the railroad bridge at this time, although we anticipate receiving these drawings through coordination with Mexican colleagues.

Damage to the railroad bridge consisted of collapse of a span on the eastern side of the river as lateral spreading translated and rotated the pier at the western end of the span towards the river, exceeding the lateral capacity of the elastomeric bearing and leading to unseating of the girders. The superstructure also displaced in the transverse direction relative to the pier. Similar movement of piers on the west bank of the river nearly led to collapse of two additional spans. Temporary steel trestles were erected to replace the collapsed span and support the nearly-collapsed spans.

4.2 Highway Bridge

The following structural details are based on the bridge construction plans (1998) provided to the research team by SCT.

The highway bridge consists of approach fills up to 6m thick leading to ten 20m-long simply-supported spans (Figure 3). Each span consists of seven precast-prestressed 1.15m-deep I-shaped girders spaced approximately 1.6m on-center in the transverse direction. Precast slab panels rest on the top flanges of adjacent girders, covered by a cast-in-place deck slab. The deck slabs are cast continuously across spans 1-2-3, 4-5-6-7, and 8-9-10, i.e. in three separate sections. The girders are supported on 60cm-wide concrete masonry plates on 1.6m-wide pier caps, which are in turn supported on four extended shaft columns. The elastomeric bearings are 20cm wide in the longitudinal direction.

Vertical diaphragms connect the ends of the girders in the transverse direction. A prestressing strand in the transverse direction passes through the diaphragms and ducts in the girder-ends across the entire 11m width of the bridge, forming a continuous member to provide lateral force resistance in the transverse direction.

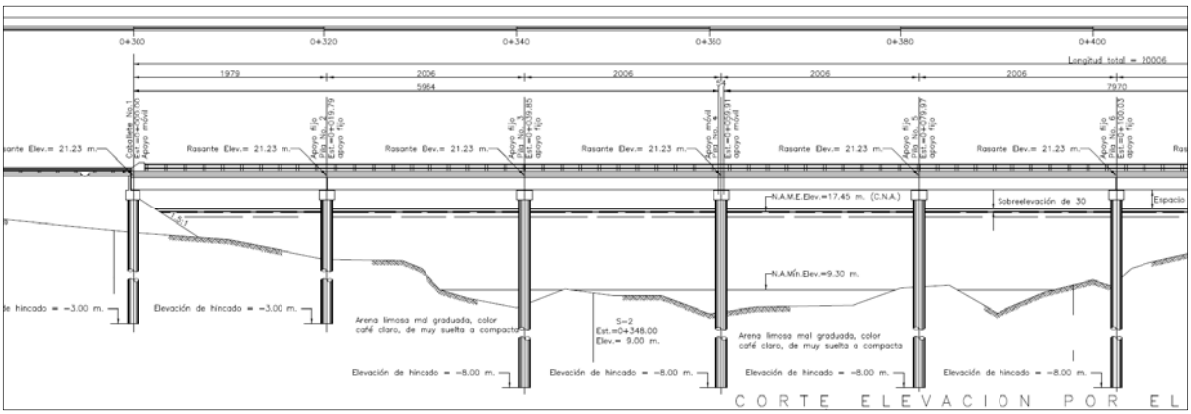

Figure 3: Western half of highway bridge, from original construction plans (SCT 1998).

(a)

(b)

(c)

Figure 4: (a) shear key damage at pier cap (photo Richard Woods), (b) vertical ground settlement relative to columns (photo Jim Gingery), and (c) column flexural concrete cracking at base (photo Richard Woods).

The girder-to-pier-cap connections are a mix of "pinned" and "roller bearing" types. At the piers between spans 3-4 and 7-8, as well as at the end supports at the abutments, the only connection between the girders/diaphragm and the pier cap is the laminated neoprene elastomeric bearing. The bearing transfers axial load and allows for rotation and translation of the girders by compressing and deforming in shear, respectively. A polymer-filled expansion joint is constructed in the deck slab at these locations to allow for thermal expansion and contraction.

At the remaining piers, the deck slab is continuous over the joint and translation of the girders is restrained by anchorage via two rectangular blocks that extend from the base of the diaphragm into the pier cap. The anchorage blocks fit into a rectangular slot cast into the pier cap such that translation is restrained in both the longitudinal and transverse directions. There is no positive connection between the diaphragm anchorage blocks and the pier cap via reinforcing bars that are continuous across the joint; an asphaltic felt pad is placed between the two elements. A

small amount of rotation is allowed at these "pinned" type connections. The end conditions of all ten spans are considered simply-supported.

The four 1.2m diameter extended shaft columns are continuous with four drilled shaft foundations of the same diameter at each pier. There are no pile caps, although the shafts are connected with a transverse beam near the ground level for the shafts in the river, likely to prevent erosion (visible in Figure 4c). The 1.5m high abutment walls are supported on three 1.2m diameter drilled shafts. The foundations in the river extend to the deepest elevation, approximately 14m below the pile cap, while the foundations nearest the abutments and beneath the eastern spans where flow is seasonal are shorter by 3m to 6m. Assuming horizontal stratigraphy at the site, the deepest foundations extend about 10m into the dense sand layer.

Three separate zones of damage were observed on the highway bridge, shown in Figure 4 (GEER 2010; Meneses et al. 2010):

1. 30-cm-tall shear key "retainers" extending up from the ends of the pier caps to provide lateral restraint of the edge girders were cracked and spalled, but did not fail, indicating that the bridge was loaded in the transverse direction. The shear keys on the western abutment pier cap were damaged in a similar manner. Transverse offset of the elastomeric bearings was also observed.
2. Flexural cracking was observed on the inward (river side) of the columns at the column-to-pile-cap connection of the piers on both sides of the river crossing. The flexural demand indicates horizontal movement of the foundations and pile cap towards the center of the river due to lateral spreading. The bridge deck was cracked above these damaged piers.
3. Vertical settlement of approximately 0.5m of one of the piers resulted in vertical displacement and cracking of the bridge deck immediately above the pier. This pier was adjacent to the span of the railroad bridge that collapsed, on the east river bank.

4.3 Performance Comparison

The desirable performance of the highway bridge appears to be due at least in part to the presence of the diaphragm anchorage blocks connecting the pier caps to the spans, which allowed the load acting on the foundations to be transferred to and resisted by the superstructure acting in compression along the longitudinal axis of the bridge. Lacking this positive structural connection, the railroad bridge piers had minimal translational restraint once the shear capacity of the elastomeric bearings was exceeded. The force exerted on the bridge foundations also differed due to the different layout and type of foundation elements. The highway bridge foundations may extend further into the dense sand layer, which would give them additional lateral resistance.

Although the reconnaissance team was not able to directly measure the lateral spreading deformation along the axis of the bridges due to ongoing repair efforts, it was visually evident that the deformation near the bridges was less than the measured deformation in the free field to the north and south. This indicates that the foundations of the bridges influenced lateral spreading soil displacements in the vicinity of the bridge. Furthermore, this indicates that the each bridge may have influenced the response of the other.

5. FURTHER RESEARCH

The authors plan to conduct cone penetration tests (CPT) at the site during the spring of 2013 in collaboration with the Mexican authorities in order to obtain detailed geotechnical data. Shear wave velocity and porewater pressure will be measured during the CPT.

The highway bridge will be analyzed using the finite element program OpenSEES (McKenna 1997) according to the Ashford et al. (2011) guidelines (i.e., the "PEER approach"), and the performance predicted by the analyses will be compared to the observed bridge performance. Foundation elements will be modeled as beam on nonlinear Winkler foundations using displaced p-y springs to model the ground deformation due to lateral spreading. The primary emphasis of the analyses will be to model the highway bridge that did not collapse.

6. CONCLUSIONS

Structural details of a pair of parallel bridges crossing the Colorado River are presented, with a description of their performance during the 2010 M_W 7.2 El Mayor-Cucapah Earthquake in Baja California, Mexico. The authors' proposed geotechnical site investigations and analyses are described. Results of the modeling will be reported in future publications.

Abstract: Traditionally, piles in seismic regions are designed to withstand horizontal loads caused by lateral spreading of liquefied soils. This is focused upon stability/safety of pile foundation against a bending failure mechanism, and is prevalent in current design codes. In contrast, recent research indicates that the bending mechanism cannot explain all historical cases of pile failure and suggests buckling failure as an alternative mechanism. A further investigation is warranted to evaluate potential failure mechanisms of piles in liquefiable soils. This study assesses dynamic behavior of liquefiable soils by using an advanced finite-element tool, which adopts a two-surface critical state plasticity sand model and implements a so-called *u-p* formulation to account for soil-fluid interaction and pore-pressure build-up realistically. Numerical simulation of pile failures (either due to bending or buckling) is conducted by considering different pile and soil parameters as well as different ground motions in terms of amplitude and frequency content. Moreover, temporal evolution of liquefaction at depth and time-varying effects of inertia and kinematic forces acting on piles are examined in detail. In general, parametric results indicate that slender end-bearing piles have potential to buckle, while in the same condition large-diameter piles remain safe against buckling (thus are likely to fail due to bending). The results are in agreement with field investigations and experimental test results.

1. INTRODUCTION

Pile foundation failure due to liquefaction was recognized as one of the most dramatic failure mechanisms of structures and bridges after the 1964 Niigata and 1995 Kobe earthquakes. Extensive investigations have been conducted to understand the main cause of pile failures (Tokimatsu *et al*., 1996, 1997; Hamada, 1992, 2000; Abdoun and Dobry, 2002). A well-established theory of pile failure is based on a bending mechanism, where lateral loads are induced by inertia of a superstructure due to ground shaking and lateral spreading of the surrounding soils. In this mechanism, piles are regarded as laterally-loaded beams, and several design criteria related to strength of piles (e.g. yield moment M_y and plastic moment capacity M_p) need to be checked to prevent bending failure of piles. For instance, the Japanese Highway code (JRA, 2002) adopted a concept of pile failure proposed by Ishihara (1997), known as 'top-down and bottom-up effects'. In this theory, in pre-liquefaction phase, the maximum bending moment along a pile is caused by inertia forces of a superstructure which are transferred to the pile head and eventually to soil (i.e. top-down effect). On the other hand, in post-liquefaction phase when pore pressure becomes excessive and soil stiffness drops dramatically, the effects due to the lateral spreading of liquefied sloped ground become dominant. In such situations, the maximum bending moment within the pile occurs at lower portion of the pile head (i.e. bottom-up effect).

The recent studies of piles embedded in liquefiable soils by Bhattacharya (2003), Knappett and Madabhushi (2005), and Kimura and Tokimatsu (2007) provided a new insight into a possible failure mechanism of piles. In cases soils surrounding a pile liquefy completely and the axially-loaded pile becomes unsupported laterally, piles may fail due to buckling. In other words, piles in liquefied soils may be better regarded as slender columns carrying axial and lateral loads, rather than laterally-loaded beams. The bucking mechanism depends on stiffness of a pile rather than strength. It could result in sudden instability, if the axial load approaches the critical value (P_{cr}), based on Euler's equation:

$$P_{cr} = \frac{\pi^2}{L_{eff}^2} EI \quad (1)$$

where L_{eff} is the effective length of the column, which depends on the length and boundary condition of the column ends, and EI is the column stiffness. The ground shaking increases pore pressure of saturated cohesion-less soils and thus effective stress of soils is decreased over the pile length. Consequently, soil skeleton loses resistance against shear and liquefied soils behave like liquid. This post-liquefaction phase renders piles laterally unsupported; with the increase of L_{eff}, piles become susceptible to buckling failure rapidly under axial loads (dead, live, and dynamic loads). It is noteworthy that the considerable force acting on structures is due to gravity; vertical load may be further amplified by ground shaking.

Recently, Bhattacharya *et al.* (2005) have proposed a simple safety assessment procedure against buckling. The assessment involves the comparison of two key parameters, critical depth of a pile against buckling (capacity) and laterally-unsupported length of a pile (demand). The former can be determined as a function of axial load, flexural stiffness, and pile boundary condition, while the latter is determined in terms of ground motion characteristics and soil profile. Furthermore, Bhattacharya and Goda (2013) have extended this procedure based on a probabilistic concept by taking into account uncertainty associated with input ground motion, liquefaction occurrence, and pile properties. The critical aspects of the procedure requiring further improvement include the effects of liquefied soils on piles in terms of lateral support and the temporal evolution of dynamic loads due to inertia with respect to liquefaction of the surrounding soils along the pile length. They have significant influence on the estimation of the critical depth of a pile against buckling.

In this study, pile bucking failure is investigated through numerical simulation of dynamic soil-pile behavior subjected to ground shaking. The focus is to provide better understanding of pile foundation failure (bending or buckling) in liquefiable soils; the key parameters involved are pile diameter, pile material, soil parameters, and ground shaking. For this, finite-element (FE) models of a single pile passing through liquefiable soils are developed (note: pile end is embedded into engineering bedrock and thus fixed). Two material types, concrete and steel, are considered for piles. Critical buckling loads of the concrete/steel piles are calculated based on Euler's buckling equation and three different masses, representing a superstructure, equivalent of $0.3P_{cr}$, $0.5P_{cr}$, and P_{cr}, are attached to the pile head to evaluate the effects of axial loads on pile performance before and after liquefaction. To account for nonlinear behavior of liquefied soils and soil-fluid interaction accurately, an advanced soil constitutive model by Dafalias and Manzari (2004), implemented in fully-coupled *u-p* elements, is adopted. Soil properties are varied by considering three different relative densities (Dr = 30%, 50%, and 80%). Depth of liquefaction and shear strength drop are assessed via FE simulations. This facilitates the better understanding of the buckling failure mechanism in comparison with previous studies (Bhattacharya *et al.*, 2005; Bhattacharya and Goda, 2013), where empirical equations were adopted to calculate the critical depth of liquefaction. Two ground motions with scaled ground acceleration amplitudes of 0.1g and 0.2g are used as input motion. They have different frequency content; thus the effects of ground motion characteristics on pile performance in liquefiable soils can be investigated. All FE models are three dimensional, and *P-Δ* effect of pile is considered. Prior to the simulations, numerical validation of the FE models is provided by considering dynamic centrifuge test data by Wilson (1998).

2. FINEITE ELEMENT AND SOIL CONSTITUTIVE MODELS

A fully-coupled *u-p* formulation is used to model soil skeleton and pore fluid interaction (Zienkiewich and Shiomi, 1984). In this formulation, variables are soil particle displacement *u* and pore fluid (water) pressure *p*. FE spatial discretization of *u-p* formulation for dynamic problems is given by:

$$\boldsymbol{M\ddot{U}} + \int_V \boldsymbol{B^T}\sigma' dV - \boldsymbol{QP} - \boldsymbol{f^{(s)}} = \boldsymbol{0} \tag{2}$$

$$\boldsymbol{Q^T\dot{U}} + \boldsymbol{HP} + \boldsymbol{S\dot{P}} - \boldsymbol{f^{(p)}} = \boldsymbol{0} \tag{3}$$

where $\boldsymbol{M}$ is the mass matrix, $\boldsymbol{U}$ is the solid displacement vector, $\dot{U}$ is the vector of relative velocity, $\ddot{U}$ is the vector of relative acceleration, $\boldsymbol{B}$ is the strain-displacement matrix, $\boldsymbol{\sigma'}$ is the effective stress tensor (derived from a soil constitutive model), and $\boldsymbol{Q}$ is the discrete gradient operator, coupling the motion and flow equations. $\boldsymbol{P}$ is the pore pressure vector, $\boldsymbol{S}$ is the compressibility matrix, and $\boldsymbol{H}$ is the permeability matrix. The vectors $\boldsymbol{f^{(s)}}$ and $\boldsymbol{f^{(p)}}$ represent the effects of external loads (and body forces) and fluxes, respectively. Newmark's algorithm is used to numerically solve the above equations, which is implemented in OpenSees (McKenna and Fenves, 2001).

Soil is a complex material that behaves non-linearly when subjected to large strain exceeding 10^{-5} (Hardin and Drnevich, 1972). It often shows anisotropic and time-dependent behavior. In addition, soil is hysteretic, behaving differently in primary loading, unloading, and reloading phases. Advanced soil constitutive models based on a concept of plasticity are able to capture important features of soil, such as nonlinearity, hardening, softening, anisotropy, pore water pressure generation, contraction, and dilation. To simulate liquefaction phenomena, a comprehensive material model proposed by Dafalias and Manzari (2004) is used; this is available from a University of California at Davis computational geomechanics toolset and is implemented in OpenSees. This model was originally proposed by Manzari and Dafalias (1997) as a two-surface critical state plasticity model for sand. It presents well-established mechanisms for predicting softening/hardening as well as dilative/contractive response of sand with different loose and dense states. The model has been updated by Dafalias and Manzari (2004). The new version incorporates the fabric-dilatancy tensor, which has a significant effect on the contractive unloading response. This version also takes into account the effect of a modified Lode angle associated with a flow rule, which produces more realistic response in non-triaxial stress conditions. The developed constitutive models and FE elements were validated extensively by Jeremic *et al.* (2008), Cheng and Jeremic (2009), and Shahir and Pak (2010). The model is well-calibrated for Nevada sand; typical model parameters are listed in Table 1. These material parameters are used throughout this study; an investigation of calibrating individual Dafalias-Manzari soil parameters for actual soil data is beyond the scope of this study.

Table 1 Dafalias-Manzari parameters for Nevada sand

Parameter	Symbol	Value
Elasticity	G_0	150
	ν	0.05
Critical state	M	1.14
	c	0.78
	λ_c	0.027
	e_0	0.83
	ξ	0.45
Yield surface	m	0.02
Plastic modulus	h_0	9.7
	c_h	1.02
	n^b	2.56
Dilatancy	A_0	0.81
	n^d	1.05
Fabric-dilatancy	z_{max}	5.0
	C_z	800

3. NUMERICAL MODEL VALIDATION

Dynamic centrifuge tests of pile-supported structures in liquefiable sand performed by Wilson (1998) are used to validate a developed FE model for a soil-pile system. The soil profile consists of two horizontal layers of saturated, fine uniformly graded Nevada sand. The lower dense layer (Dr = 80%) is 11.4 m thick, whereas the upper medium dense layer (Dr = 55%) is 9.1 m thick at the prototype scale. A highly-instrumented single steel pipe with a diameter of 0.67 m and wall thickness of 19 mm at the prototype scale is selected to model a pile. It is extended 3.8 m above the ground level and carries superstructure weight of 480 kN; the embedded length of the pile is about 16.8 m. A layout of the centrifuge test model is shown in Figure 1. The laminar box containing the soil-pile-superstructure system was spun at a centrifuge acceleration of 30g, and the pile remained elastic during the tests.

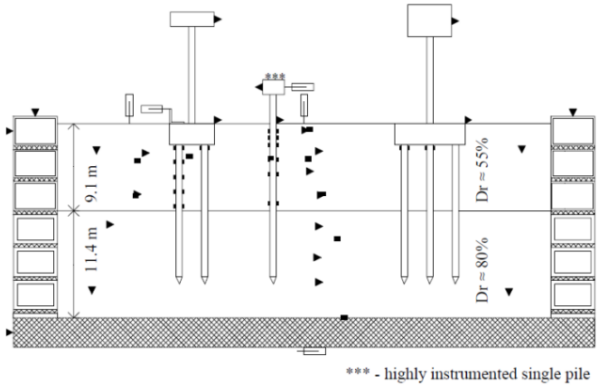

Figure 1 Layout of the centrifuge test model by Wilson (1998)

Figure 2 shows the schematics of FE meshes, consisting of 896 cubic eight-node soil elements and 16 beam-column elements. Each soil node has 4 degrees of freedom (DOFs), 3 for translation of soil skeleton and 1 for pore pressure, while the pile node has 6 DOFs. A beam-column element is used for the pile, and details of soil-pile nodal connection is shown in Figure 2, which was proposed by Cheng and Jeremic (2009). The physical modeling of the pile is implemented by using rigid connecting elements with the same material parameters of the pile. The beam-column elements connect each pile node to the surrounding nodes of a soil element at the same depth and transfer the forces from soil to pile and vice versa. Material parameters used in this validation are presented in Table 2. The modified 1995 Kobe acceleration record, scaled to peak acceleration of 0.22g, is used as a base input motion. Figure 3 shows the acceleration time history and Fourier amplitude of the input motion.

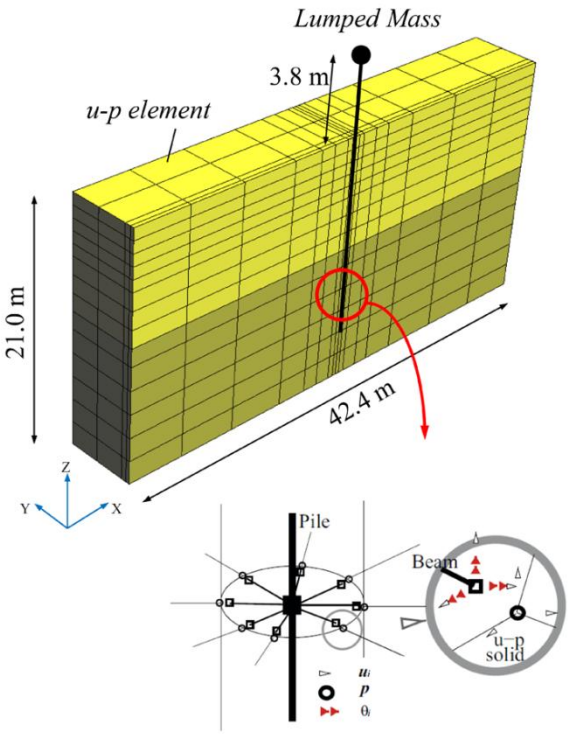

Figure 2 Finite-element mesh and diagram showing coupling of displacement DOFs of a beam-column element (pile) with displacement DOFs of *u-p* elements (soil).

Table 2 Material parameters for Nevada sand (Popesco and Prevost, 1993)

Parameter	Dr = 55%	Dr = 80%
Porosity	0.409	0.377
Saturated unit weight (kN/m^3)	19.87	20.41

Permeability coefficient at prototype scale (m/s)	1.82×10^{-4}	1.11×10^{-4}

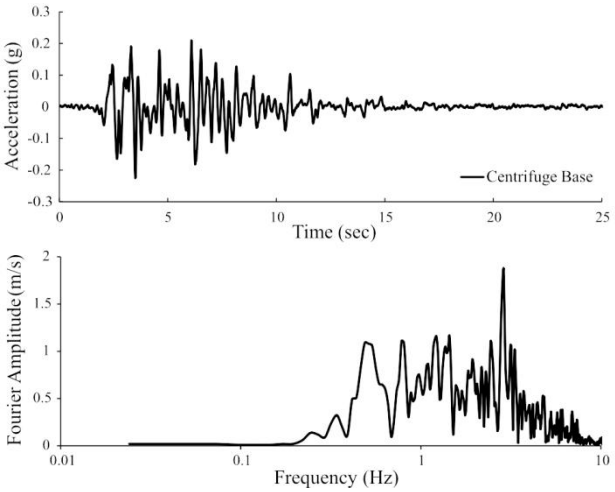

Figure 3 Acceleration time history (top) and Fourier amplitude (bottom) of the scaled Kobe record

Time histories of measured and computed acceleration of soils at different depths are presented in Figure 4. Generally, reasonable agreement between the test and simulation results is obtained, except for some spikes. It is well-known that liquefiable soil deposits show a pronounced reduction in high-frequency amplitude and increase low-frequency amplitude following the initial liquefaction. The change in frequency content corresponds to the dramatic reduction in soil stiffness and strength. However, ground motion data and soil experiments often show several isolated spikes of high acceleration. The spikes can be attributed to the influence of dilated soil above the phase transformation line (i.e. soil is stiffened), increasing transmission of high frequency motions. This also leads to the constructive interference of waves traveling upward through the liquefied soil; the resulting waves have been termed de-liquefaction shock waves (Kutter and Wison, 1999). Considering the fact that the Dafalias-Manzari model is highly dependent on position of the phase transformation line, it may overestimate the soil strength and stiffness near this line. This may be the reason for the differences between simulation and experiments, and suggests that further improvements are necessary in soil constitutive modeling.

Figure 5 shows time histories of measured and computed excess pore pressure ratios at approximately the same depths as in Figure 4. The excess pore pressure ratio (r_u) is defined as the ratio of the difference of current pore pressure and hydrostatic pore pressure over the initial effective vertical stress: $r_u = \Delta u/\sigma'_{v0}$. Comparison of the results shows that the FE model is capable of simulating the experiment accurately, except at the depth of 5 m. In the current study, permeability is considered to be constant during liquefaction, although in reality, it varies due to changes in soil skeleton; in some cases it increases up to 6-7 times greater than its initial value. The difference between the experimental and numerical results may be related to the constant value of permeability used in the analysis, noting that a variable permeability can improve the numerical prediction of excess pore pressure as well as lateral/vertical soil displacement (Rahmani and Pak, 2012).

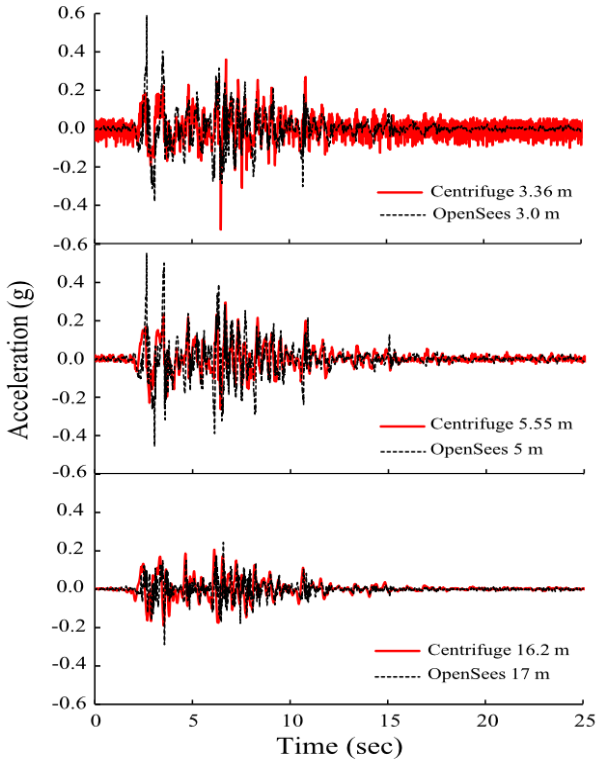

Figure 4 Comparison of simulated and measured acceleration time histories of soils at about 3 m depth (top), about 5 m (middle) and about 17 m depth (bottom)

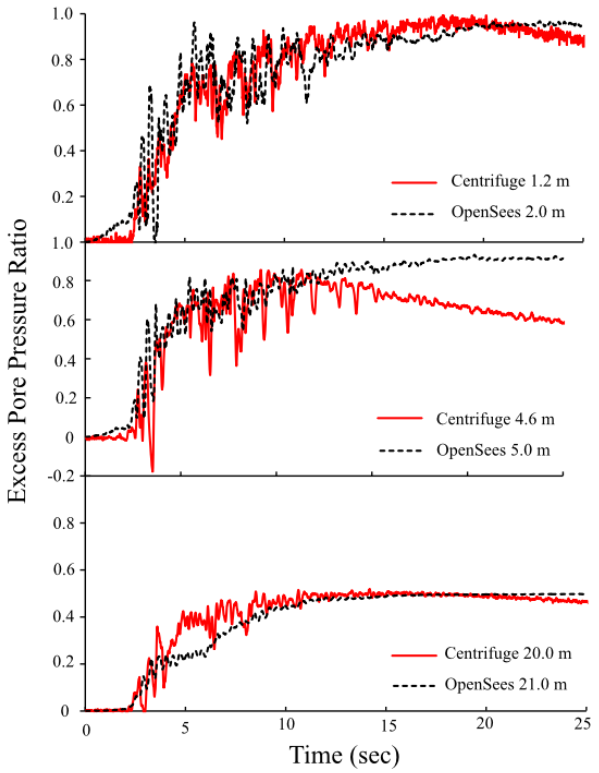

Figure 5 Comparison of time histories of simulated and measured excess pore pressure ratios at about 2 m depth (top), about 5 m (middle) and about 20 m depth (bottom)

Finally, Figure 6 shows time histories of computed and measured acceleration responses of the superstructure. The FE model is capable of predicting acceleration responses of the superstructure accurately, especially for the first few cycles (before full liquefaction). The differences between the experiment and simulation are due to temporary increase in soil stiffness, which results in large acceleration spikes transmission from ground to superstructure.

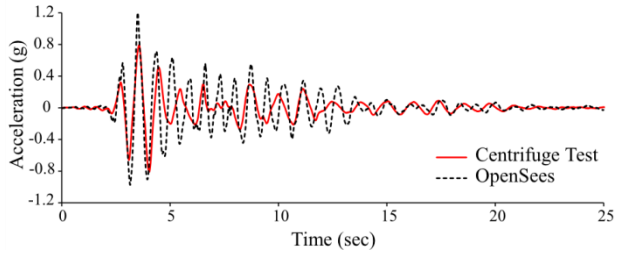

Figure 6 Comparison of time histories of simulated and measured acceleration response of superstructure

4. PARAMETRIC ANALYSIS FOR PILE FOUNDATION FAILURE MECHANISM

To investigate a pile failure mechanism in detail (e.g. temporal evolution of liquefaction at depth and time-varying effects of inertia and kinematic forces acting on piles), a parametric study is carried out by developing FE models for a pile foundation, surrounded by saturated liquefiable soils. In particular, the focus is given to axial load carried by pile, properties of pile and soil, and ground motion characteristics.

4.1 Model Set-up

A two-layer soil system is considered; a top layer represents liquefiable soil with Dr = 30% or 50%, while a bottom layer represents dense sand with Dr = 80%, providing sufficient fixity for the pile end. A single pile of 25 m long is considered with 4 m above the ground surface and 21 m below the surface. For the embedded pile part, 4 m of the pile is in the dense bottom layer and 17 m of the pile passes through the loose liquefiable layer. Figure 7 shows the geometry of the adopted model and pile boundary condition. In the FE model, soil parameters for Nevada sand (Table 1) are used. Parameter values for porosity, density, permeability, and $(N_1)_{60}$ from standard penetration tests (SPT) are listed in Table 3. Two pile material types, concrete and steel, with different diameters of 0.5 and 1.0 m are considered in the analysis. Euler's elastic buckling load P_{cr} is calculated for each case. To investigate pile performance under different axial loads, the equivalent mass on the tip of the pile, representing a superstructure, is adjusted such that the corresponding axial loads equal the critical buckling load multiplied by a factor of 0.3, 0.5, and 1.0. *P-Δ* effect is taken into account in the analysis and all models are three dimensional with 1020 *u-p* elements. The pile properties, used in the FE models, are summarized in Table 4. The values resemble materials used in practice closely. Ground motion characteristics, such as maximum acceleration amplitude and frequency, have significant effects on pile (Carvajal *et al.*, 2002; Rahmani and Pak, 2012). Two ground motions with different dominant frequencies and scaled peak acceleration of 0.1g and 0.2g are considered in the parametric analysis. Table 5 provides a summary of the two ground motion records, while Figure 8 shows unscaled input ground motion acceleration time histories and their Fourier amplitude spectra.

4.2 Soil Residual Strength

In this section, it will be shown that pile buckling in liquefiable sands occurs if the shear strength around the pile, subject to significant axial load, drops remarkably to a negligible value (i.e. loss of lateral support).

To calculate P_{cr}, the unsupported length of the pile (liquefaction depth H_L in Figure 7) needs to be calculated. Depth of liquefaction could vary depending on the relative density of soil and input acceleration.

Figure 9 shows the temporal changes of acceleration, excess pore pressure ratio (r_u), and shear strength at depths of 2, 6, and 10 m for the scaled Kobe record with the peak amplitude of 0.2g. By considering post-liquefaction as a condition where the excess pore pressure reaches 1.0, undrained residual strength of soil drops dramatically to a negligible value, leading to an unsupported pile condition. The post-liquefaction phase is identified and distinguished by a red line in Figure 9. It is noted that post-liquefaction starts at different times over depth of the pile, generally, from shallower to deeper layers.

Evaluating undrained residual strength of liquefied soils is a challenging issue in geotechnical engineering, as it involves the complex nonlinear soil behavior due to dynamic loading. Numerous investigations have been conducted to assess in-situ undrained residual strength (S_r). For example, Seed (1986) proposed a method for evaluating in-situ undrained residual strength based on SPT. He presented the results of back-analysis of several liquefaction failure case histories from which values of S_r were estimated for sites with available SPT data. The empirical correlation between S_r and $(N_1)_{60}$ is shown in Table 6. He also proposed that owing to the limited number of case studies and uncertainty associated with available information, the lower-bound of the curves should be considered. Cyclic stress-strain curves derived from FE analysis (Figure 9) show that for the specific case, the residual undrained shear strength at various depths drops near zero at post-liquefaction phase (i.e. red line); for comparison, the broken horizontal lines corresponding to S_r = +/-5 kPa are included in the stress-strain plots. This result is in agreement with the correlation of SPT data with residual undrained strength (i.e. lower bound case in Table 6). It can be concluded that a liquefiable soil deposit has potential to lose its strength and consequently piles in liquefied soils are forced to carry axial and inertial loads without sufficient lateral support from the surrounding soils.

4.3 Buckling Analysis Results

Having reliable estimates of the unsupported length of the pile, bending and buckling criteria can be checked. Timoshenko and Gere (1961) showed that in analyzing stability of elastic columns, lateral displacement caused by lateral loads is greatly amplified in the presence of axial loads. If δ_0 is the displacement of a cantilever column due to lateral loads alone, the final displacement δ is amplified due to axial load (P) by the following expression:

$$\frac{\delta}{\delta_0} = \frac{1}{\left(1-\frac{P}{P_{cr}}\right)} \quad (4)$$

Figure 10 shows amplification of lateral displacement of a column due to applied axial loads. It is evident that for P/P_{cr} = 0.33 (i.e. ratio of the applied axial load to Euler's elastic buckling load), the lateral displacement amplification is almost twice of static lateral displacement due to lateral loads alone. For axial loads exceeding $P/P_{cr} \geq 0.33$, the failure mechanism is likely to be governed by buckling. Considering this criterion, three ratios of applied axial loads to Euler's elastic buckling load are considered in the parametric analysis; the case with P/P_{cr} = 0.3 is regarded as safe against buckling, while the cases with P/P_{cr} = 0.5 and P/P_{cr} = 1.0 may be unsafe, if the top soil layer is fully liquefied. It is also noteworthy that the applied axial loads in this study do not take into account dynamic inertia effects caused by superstructure mass (note: dynamic response of the superstructure affects pile and soil responses significantly and is taken into account). Such dynamic effects can be included in the assessment by using a rigid base foundation with multiple pile rows (such that lateral motions of a superstructure are transformed into dynamic axial forces along the piles).

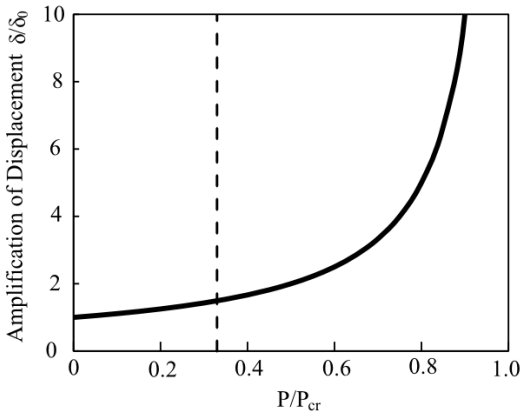

Figure 10 Amplification of lateral displacement versus normalized axial load

In addition to buckling failure mode, bending failure may occur when the maximum bending moment along the pile exceeds the yield moment of pile, ($M_{max}/M_Y \geq 1.0$). Table 4 shows the yield moment capacity for each pile. Therefore, bending-buckling interaction could occur, if both criteria are exceeded ($M_{max}/M_Y \geq 1.0$ and $P/P_{cr} \geq 0.33$), whereas the designed pile may be judged as safe if $P/P_{cr} < 0.33$ and $M_{max}/M_Y < 1.0$.

Figure 11 shows bending moment, shear force, and displacement diagrams of the 0.5 m concrete pile due to the Kobe record with the maximum acceleration scaled to 0.2g. The yield moment for this case is 215 kNm (Table 4). The predominant failure mechanism for two cases ($P = 0.5P_{cr}$ and $P = P_{cr}$) are due to bending-buckling interaction (i.e. $M_{max}/M_Y \geq 1.0$ and $P/P_{cr} \geq 0.33$). The plastic hinge is placed at about 1.0 m below the ground level where the maximum bending moment occurs along the pile. The maximum bending moment along the pile increases dramatically with greater applied axial forces. The pile with $P = 0.3P_{cr}$ is considered to be safe both under the bending and buckling criteria ($M_{max}/M_Y < 1.0$ and $P/P_{cr} < 0.33$). However, if dynamic effects due to superstructure are included, the buckling failure mechanism might be developed. Figure 11 also provides a comparison between kinematic soil-pile interaction (red line) and inertia interaction. Kinematic pile response in liquefaction is significantly different from inertia interaction, especially in terms of maximum value, location, and occurrence timing. In kinematic interaction, pile follows the imposed movement of liquefied soils, thus the maximum bending moment and shear force may dominates during post-liquefaction phase at greater depth.

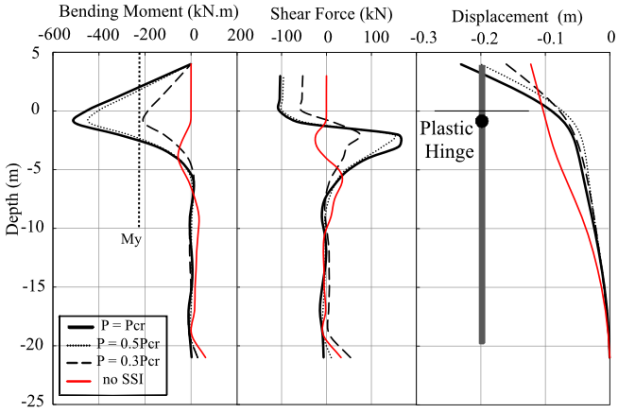

Figure 11 Bending moment (left), shear force (center), and displacement (right) of the 0.5 m concrete pile subject to the Kobe ground motion, scaled to 0.2g

4.4 Effects of pile properties and input ground motions

The detailed analysis of pile foundation failure mechanisms was presented in the previous two subsections for the 0.5 m concrete pile subjected to the Kobe record, scaled to 0.2g. In this subsection, to draw general observations/conclusions, more results are discussed by considering different pile properties and input ground motions (Tables 4 and 5).

Figure 12 shows the bending-buckling interaction diagrams for the 1999 Kocaeli and 1995 Kobe records, scaled to 0.1g and 0.2g, for 0.5 m and 1.0 m concrete and steel piles. The bending-buckling diagram plots a data point of M_{max}/M_Y and P/P_{cr} from numerical simulation of a specific analysis case (in terms of pile property and input ground motion), and is useful to identify a possible failure mode of a pile foundation. Based on the values of M_{max}/M_Y and P/P_{cr}, four domains are identified: safe domain for $M_{max}/M_Y < 1.0$ and $P/P_{cr} < 0.33$; buckling failure domain for $M_{max}/M_Y < 1.0$ and $P/P_{cr} \geq 0.33$; bending failure domain for $M_{max}/M_Y \geq 1.0$ and $P/P_{cr} < 0.33$; and buckling-bending failure domain for $M_{max}/M_Y \geq 1.0$ and $P/P_{cr} \geq 0.33$.

Figure 12(a) shows a bending-buckling interaction diagram of steel and concrete piles for the Kocaeli record with different peak acceleration amplitudes. Generally, the maximum bending moment of piles increases by applying greater axial loads (i.e. higher ratios of P/P_{cr}). This is due to elastic instability (buckling) and *P-Δ* effect. The bending capacity of a pile can be remarkably improved by increasing the flexural strength (using steel instead of concrete). However, the capacity against buckling failure is not changed significantly because it is related to the geometry of pile section. Reliable estimation of possible pile failure modes facilitates the effectiveness in seismic design of piles in liquefiable soils (i.e. selecting an appropriate combination of material strength and pile cross-section property to avoid bending and buckling failure modes). It is also noted that ground motion acceleration amplitude can have significant influence on pile performance; higher acceleration increases the inertia forces acting on pile and results in a higher maximum bending moment along the pile.

Figure 12(b) shows a bending-buckling interaction diagram for the 0.5 m concrete pile subject to two input ground motions with different peak acceleration amplitudes. It can be observed that variability of the results is significant (although the sample size of the input records is rather small). As the liquefaction induces dramatic changes of the soil properties (Figure 9), the frequency content of the input ground motion is likely to have significant influence. Different dynamic forces may be caused within pile, depending on the natural frequency of a pile-superstructure system and the properties of liquefied soils. Rigorous assessment of the bending-buckling failure modes in terms of ground motion characteristics is warranted.

Finally, Figure 12(c) represents a bending-buckling interaction diagram of concrete piles with different diameters (0.5 m and 1.0 m) subjected to the Kocaeli record (scaled to 0.1g). The result indicates that two curves for different pile diameters in the bending-buckling interaction diagram are similar. This is because in the current analysis set-up, the superstructure mass at the pile tip is determined such that a certain ratio of the axial force in terms of the critical buckling load is achieved. It is noteworthy that in real situations, the thick pile (1.0 m) has Euler's elastic buckling load 16 times greater than the slender pile (0.5 m). Hence, the result shown in Figure 12(c) may be interpreted that the pile buckling failure in liquefiable soils is less likely by using a thicker pile.

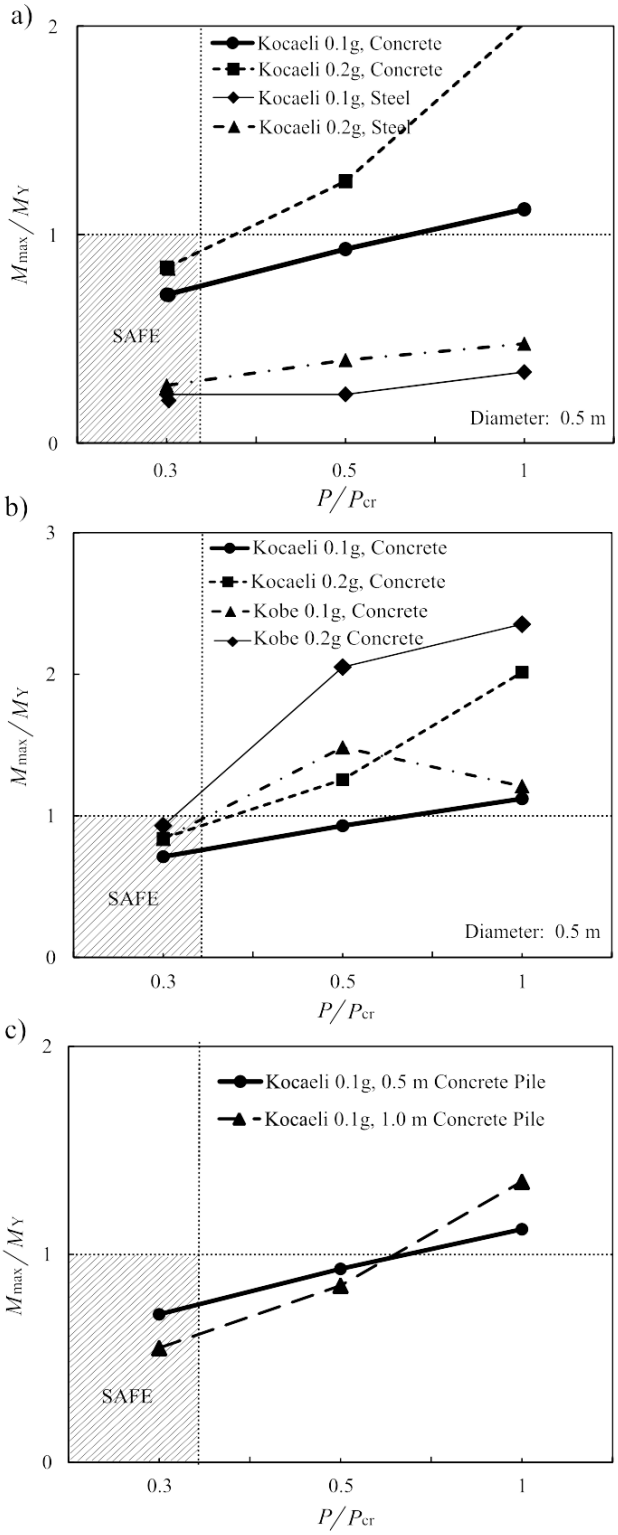

Figure 12 Bending-buckling interaction diagrams of concrete and steel piles due to the 1999 Kocaeli and 1995 Kobe records, scaled to 0.1g and 0.2g

5. CONCLUSIONS

In this paper, failure mechanisms of slender end-bearing pile in

liquefiable soils were evaluated. Historical evidences, experimental tests, and numerical results have shown that laterally unsupported piles could fail in buckling, in cases where axial loads on the pile exceed a certain fraction of Euler's critical buckling load (a factor of 0.33 is adopted in this study). Moreover, a combination of bending and buckling could be a plausible cause for actual failure mechanism of pile foundation due to liquefaction. The analysis showed that the maximum acceleration amplitude, frequency content, and pile stiffness have significant influence on the failure mechanism. Consideration of different boundary conditions of a pile, dynamic effects of superstructure inertia on axial forces, and various input ground motions is worthy of further investigations. Based on the results obtained in this study, it is recommended that the elastic instability of slender piles in liquefiable soils should be checked in addition to bending failure to achieve a safe and reliable seismic design of pile foundation.

Abstract: The earthquake reconnaissance investigations were carried out at one of the illustrative sites where the soil liquefaction induced ground deformation of cracks and subsidence as well as sand boils was observed at Gohno-ike Pond of Kamisu city during 2011 Great East Japan Earthquake. A series of Swedish weight sounding tests were carried out at this site, and the soil profiles were estimated. It was found that soil liquefaction must have occurred within the reclaimed deposits overlying the soft sedimentary "pond-bed" soil deposits.

1. INTRODUCTION

Soil liquefaction induced during 2011 Great East Japan Earthquake left a numerous number of scars on the ground surfaces, causing damages to lifelines, infrastructures and residential houses. Most of the ground failures were found associated with soil liquefaction, in Kanto region including metropolitan Tokyo. The authors' research group visited frequently to the liquefaction affected areas, and conducted a multiple series of field Swedish weight sounding tests at the areas located along the lower stream of Tonegawa river, including Sawara of Katori city, Hinode of Itako city, and Fukashiba of Kamisu city, (Tsukamoto et al. 2012a&b, Kawabe et al. 2012).

One of the illustrative sites that the authors had investigated was located at Gohno-ike pond in Kamisu city. When the authors' research group visited this site on October 14 to 16, 2011, the clear indications of soil liquefaction induced ground deformation of cracks and subsidence as well as sand boils were observed. The authors' research group decided to visit this site again on November 21 to 23, 2012, to reexamine the effects of soil liquefaction, and conducted a series of Swedish weight sounding tests. The results of the field investigations are described below.

2. SITE INVESTIGATION

Kamisu city is located at the lower stream area of Tonegawa river, as shown in Fig. 1, and is one of the areas seriously affected by soil liquefaction. The shaded zones indicated in Fig. 2 show the areas affected by soil liquefaction in Kamisu city. At the bottom-right side of Fig. 2 is located Gohno-ike pond. From the comparison with the old map of the 1880's shown in Fig. 3, (Tonegawa River Lower Stream Office 2011), the round shaded zone of soil liquefaction at the bottom-right side of Fig. 2 coincides with the old Gohno-ike pond. The old Gohno-ike pond was

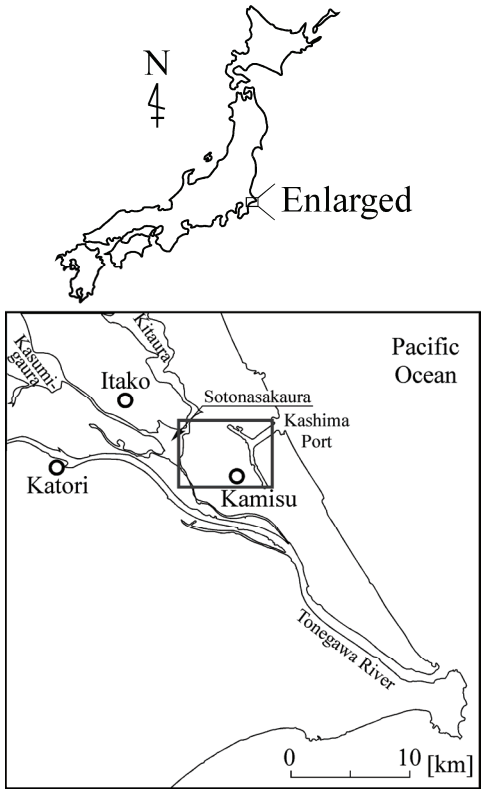

Figure 1 Location of Kamisu city

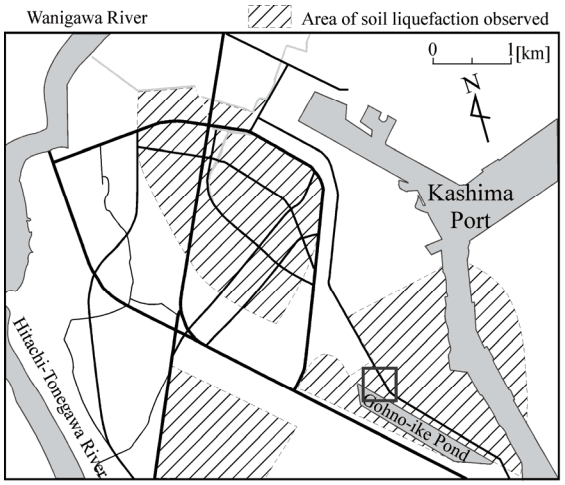

Figure 2 Location of Gohno-ike pond of Kamisu city

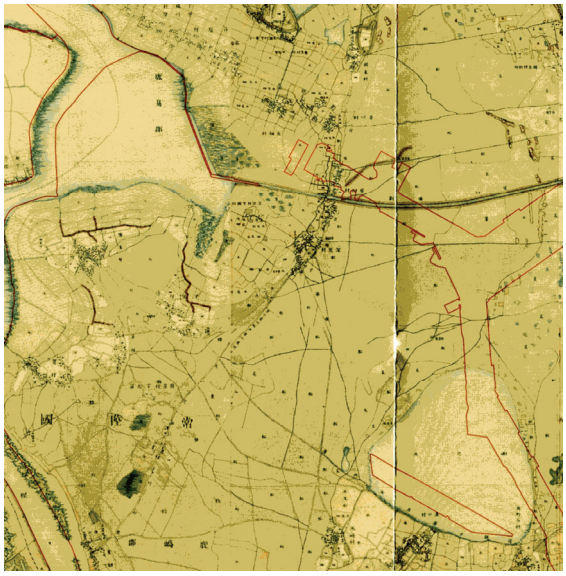

Figure 3 Old map of 1880's locating the current Gohno-ike pond, (after TRLSO 2011), (Red lines indicate current waterside lines.)

reclaimed for development of nearby industrial estates in 1969, and the current Gohno-ike pond was formed.

The authors' research group visited this area on October 14 to 16, 2011, and investigated the effects of soil liquefaction on the reclaimed land. At the foot of the steel tower for high-voltage electric cables can be observed a series of cracks on the ground surface, as shown in Fig. 4. In addition, the ground subsidence was also observed as shown in Fig. 5. At the walking street relatively close to the steel tower can be seen some remains of sand boils, as shown in Fig. 6. Some sand boils were also found near the current Gohno-ike pond, as shown in Fig. 7. The positions of ground cracks and subsidence as well as sand boils are indicated in the plan view of this area, as shown in Fig. 8.

3. SWEDISH WEIGHT SOUNDING TESTS

A series of Swedish weight sounding (SWS) tests were carried out at this area when the authors' research group

Figure 4 Cracks observed near the pylon

Figure 5 Subsidence observed near the pylon

Figure 6 Sand boils observed on the reclaimed hill

Figure 7 Sand boils observed near Gohno-ike pond

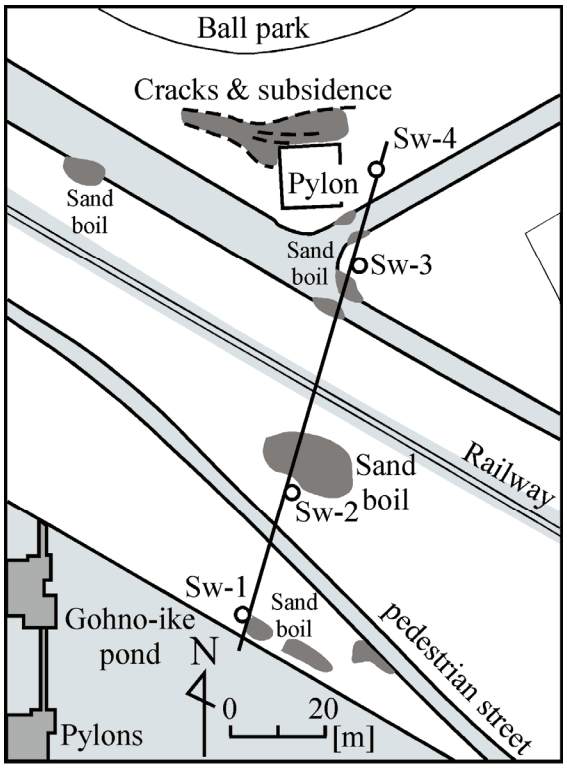

Figure 8 Location of SWS tests and ground deformation

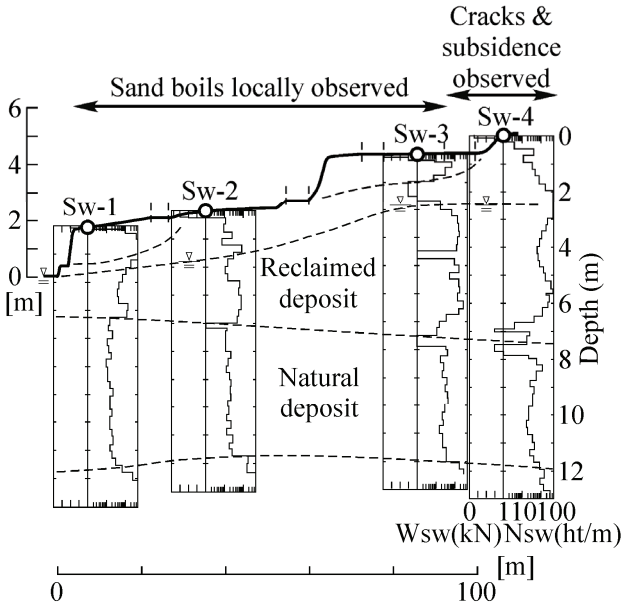

Figure 9 Results of SWS tests and estimated soil profile

revisited this site on November 21 to 23, 2012. The positions of SWS tests are shown in Fig. 8. The details of the testing equipment and procedure and the data reduction for SWS tests are described by Tsukamoto et al. (2004) and Tsukamoto (2009).

The results of SWS tests are summarized as a cross section, as shown in Fig. 9. The groundwater level was not monitored during the SWS tests, and the estimated level of the groundwater is shown in Fig. 9. The reclaimed deposit might be found overlying the loose "old pond"-bed deposit, which should have been reclaimed in 1969. The area that the

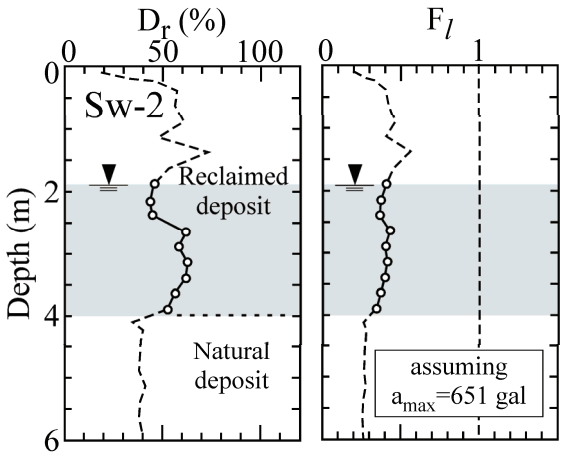

Figure 10 Estimated depth-wise profile of relative density D_r and factor of safety against liquefaction F_l at the position Sw-2

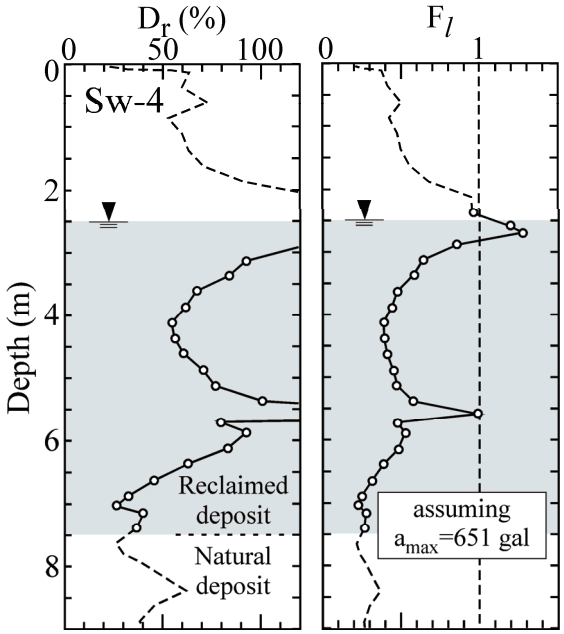

Figure 11 Estimated depth-wise profile of relative density D_r and factor of safety against liquefaction F_l at the position Sw-4

sand boils were observed is indicated on top of Fig. 9, so is indicated the area that the cracks and subsidence were observed. When the authors' research group revisited this site on November 21 to 23, 2012, the remains of sand boils had already been removed, and it was not possible to retrieve any samples of sand boils. Therefore, any physical properties of sand boils were not obtained. However, since the authors' research group had obtained the sand boil samples at the other end of Gohno-ike pond when they visited this site on October 14 to 16, 2011, it would be reasonable to assume that the physical properties of this sand boil sample are similar to each other at this site. By holding this bold assumption and employing the soil liquefaction analysis proposed and exercised by Tsukamoto et al. (2011), the depth-wise profiles of relative density D_r and factor of safety against liquefaction F_l are estimated as shown in Figs. 10

and 11. The profile for Sw-2 is shown in Fig. 10 ,and that for Sw-4 is shown in Fig. 11. Herein, the maximum ground surface acceleration of as high as 651 gal at east-west component was assumed, which was observed at the K-Net station of Kashima.

4. CONCLUSIONS

The earthquake reconnaissance investigations were conducted at Gohno-ike pond in Kamisu City, where the liquefaction-induced ground deformation and sand boils were observed. A multiple series of Swedish weight sounding tests were carried out and the subsurface soil profiles were estimated. The liquefied soil layers responsible for surface exposed ground deformation were identified.

Abstract: Dynamic centrifuge tests were conducted to investigate the effects of drainage and dewatering as remedial measures to mitigate damage to wooden houses founded on liquefiable soils. The results showed that: (1) drainpipes, if properly installed, can maintain the tilting angle of wooden houses less than 6/1000; (2) dewatering the groundwater level from G.L.-1.0m to G.L.-4.0m can reduce absolute structure settlement by about 50% and relative settlement by almost 100%; (3) combined method using both drainage and dewatering could have significant effects on reducing differential settlement of houses.

1. INTRODUCTION

In off the pacific coast of Tohoku Earthquake on March 11, 2011, many single-family houses built on reclaimed land of Tokyo Bay and the Tone River basin were suffered from differential settlement and tilting of their foundations due to liquefaction (Tokimatsu et al., 2011). In particular, about 9000 single-family houses were damaged in Urayasu city in Chiba Prefecture (Urayasu city, 2012). The same type of damage to single-family houses built on reclaimed land occurred in the Hyogoken-Nambu Earthquake on January 17, 1995 (Editorial Committee for the Report on the Hanshin-Awaji Earthquake Disaster, 1998). Since then, many types of liquefaction remedial measures have been developed and used in construction of new buildings and structures. Liquefaction remedial measures for existing buildings and single-family houses, in contrast, have not been widely developed and used because of the cost. The national and local governments have, therefore, been developing inexpensive liquefaction countermeasures for existing single-family houses since the Tohoku Earthquake.

Urayasu city and other local governments, together with residents, have developed new system for liquefaction remediation of a district rather than a single house, in which governments implement countermeasures for roads, and residents implement countermeasures for their houses.

New liquefaction countermeasures for existing houses using both drainage and dewatering have been proposed. It is difficult to lower groundwater level greatly, because settlement and tilt of houses occurs due to consolidation of the deep clay layer. Thus, lowering groundwater level is not sufficient on its own. Therefore, a combined method using both dewatering and drainage seems promising.

This paper presents a study on liquefaction countermeasures using both dewatering and drainage method. Dynamic centrifuge tests were conducted to investigate the effects of dewatering and drainage on settlement and tilt of wooden houses founded on liquefiable soils.

2. OUTLINE OF CENTRIFUGE SHAKING TESTS

Figure 1 shows the centrifuge test models with the positions of measuring instruments within a laminar box (inside dimensions of length L=700mm, width W=220mm, and height H=300mm). The shaking table tests were carried out under a centrifugal acceleration of 50 g. Structures were set on upper dry and lower saturated sand layers with relative density of about 50%. Figure 2 shows grain size distribution curves of silica sand sizes No. 7 and No. 8. The upper dry sand layer comprised silica sand size No. 8 and the lower saturated sand layer comprised silica sand size No. 7. Horizontal and vertical acceleration, horizontal and vertical displacement in structures, horizontal acceleration, excess pore water pressure and vertical displacement in ground were measured.

The test cases are shown in Table 1. In the shaking table tests, the two types of liquefaction countermeasures, drainage and lowering of groundwater level, were tested. Two structural models, small and large, were used in the tests. Two of the same structures were set on both the left side (I-side) and right side (N-side). Groundwater was set to three levels, 20mm, 50mm and 80mm (1.0m, 2.5m and 4.0m

in prototype scale) for the small models, and to two levels, 20mm and 50mm (1.0m and 2.5m in prototype scale), for the large models. Two drain types, large and small, were used in the tests. The drains were set 5mm (0.25m in prototype scale) from the models and 100mm (5.0m in prototype scale) below ground level. For the small models using 12 drains and the large models using 24 drains, the drains were set at a pitch of 30mm (1.5m in prototype scale). For the large models using 12 drains, the drains were set at a pitch of 60mm (3.0m in prototype scale). For the small models using 4 drains, the drains were set at the four corners. For the models with groundwater levels at 50mm and 80mm, the sensors in the ground were set a little lower than that with groundwater level at 20mm, as shown in Figure 1. Measurements were conducted in the same way.

Photo 1 shows the two types of structural models and Table 2 shows the physical properties. The structures were made of MC nylon and composed of superstructure, foundation, flat spring and eccentric mass. The flat spring connected the superstructure with the foundation. A metallic mass was set on the foundation to induce differential settlement as eccentric load. The large and small structural models imposed the same contact ground pressure. The mass and natural frequency of the structural models were about the same as those of common single-family wooden houses in Japan.

Photo 2 shows the two types of drain models. They were made of stainless-steel mesh (100 wires per inch, wires 0.1mm in diameter), rolled into cylinders. In order to adjust the amount of water dissipation due to liquefaction, two drain models were used. The large one was 5.0mm in diameter (250mm in prototype scale), and the small one was

Case-L4	Large	G.L.-50mm (-2.5m)	12 Drains (Small)	No

※ Model (Prototype)

2.5mm in diameter (125mm in prototype scale). In order to examine the countermeasure effect of drainage, shaking table tests were carried with various numbers and diameter of drains.

Figure 3 shows the test procedure. First, a dry sand layer of relative density 50% was made by air pluviation from the bottom of a laminar box to groundwater level. Second, sand was saturated by slowly pouring in silicon oil with 50 times the viscosity of water from the bottom of the laminar box in a vacuum. After that, drains were set in the saturated sand as shown in Photo 3, and the dry sand layer was made by the same method. Finally, two structures were set on the ground.

The artificial earthquake wave shown in Figure 4 was applied as the input acceleration wave (Niwa et al., 1993). First, the test model was shaken using a maximum acceleration of 400cm/s^2 as a main shock. Next, a maximum acceleration of 200 cm/s^2 was used as an aftershock after

Table 2 Physical properties of model structures

excess pore water pressure due to the main shock completely dissipated. After that, the maximum acceleration of 400 cm/s^2 was used once or twice again.

Photo 4 shows the view before the first shaking for Case-S1. The structure in the front in photo 4 is on the I-side. The drains can be seen sticking up from the ground. Photo 5 shows the view after the third shaking for Case-S1. In Photo 5, the structure without drains on the N side was significantly tilted, but the structure with 12 large drains on the I side was only slightly tilted and settled down only after the third shaking.

In this paper, we show only the result of the first main shock in prototype scale.

3. TEST RESULTS

3.1 Soil and Structure Responses for Case-S1

As an example of response results for the small structure, Figure 5 shows the time histories of Case-S1 with 12 large drains and without drains. Input acceleration of shaking table, horizontal acceleration of center ground surface, and horizontal acceleration of superstructure and foundation in both I and N side are shown on the left side of Figure 5. Excess pore water pressure of the center ground and just under the structures at G.L.-4.5m, absolute settlement of the ground and both structures, and rotation angle of both structures are shown on the right side of Figure 5. All histories in Figure 5 are shown for 120 seconds after the start of vibrations.

Excess pore water pressure at G.L.-4.5m was constant after about 15 seconds, indicating that the saturated sand layer liquefied. The peak accelerations were about 80cm/s^2 on the ground surface and both foundations, and about 180cm/s^2 on both superstructures at about 10 seconds. The amplitudes of those accelerations were smaller than the input acceleration after 10 seconds. There was little difference between the acceleration time histories of the superstructures and foundations for the structure with 12 large drains on I side and the structure without drains on N side. However, there was a difference between the excess pore water pressures just under the structures. The drains were very effective because excess pore water pressure on I side was smaller than the others. Excess pore water pressure on N

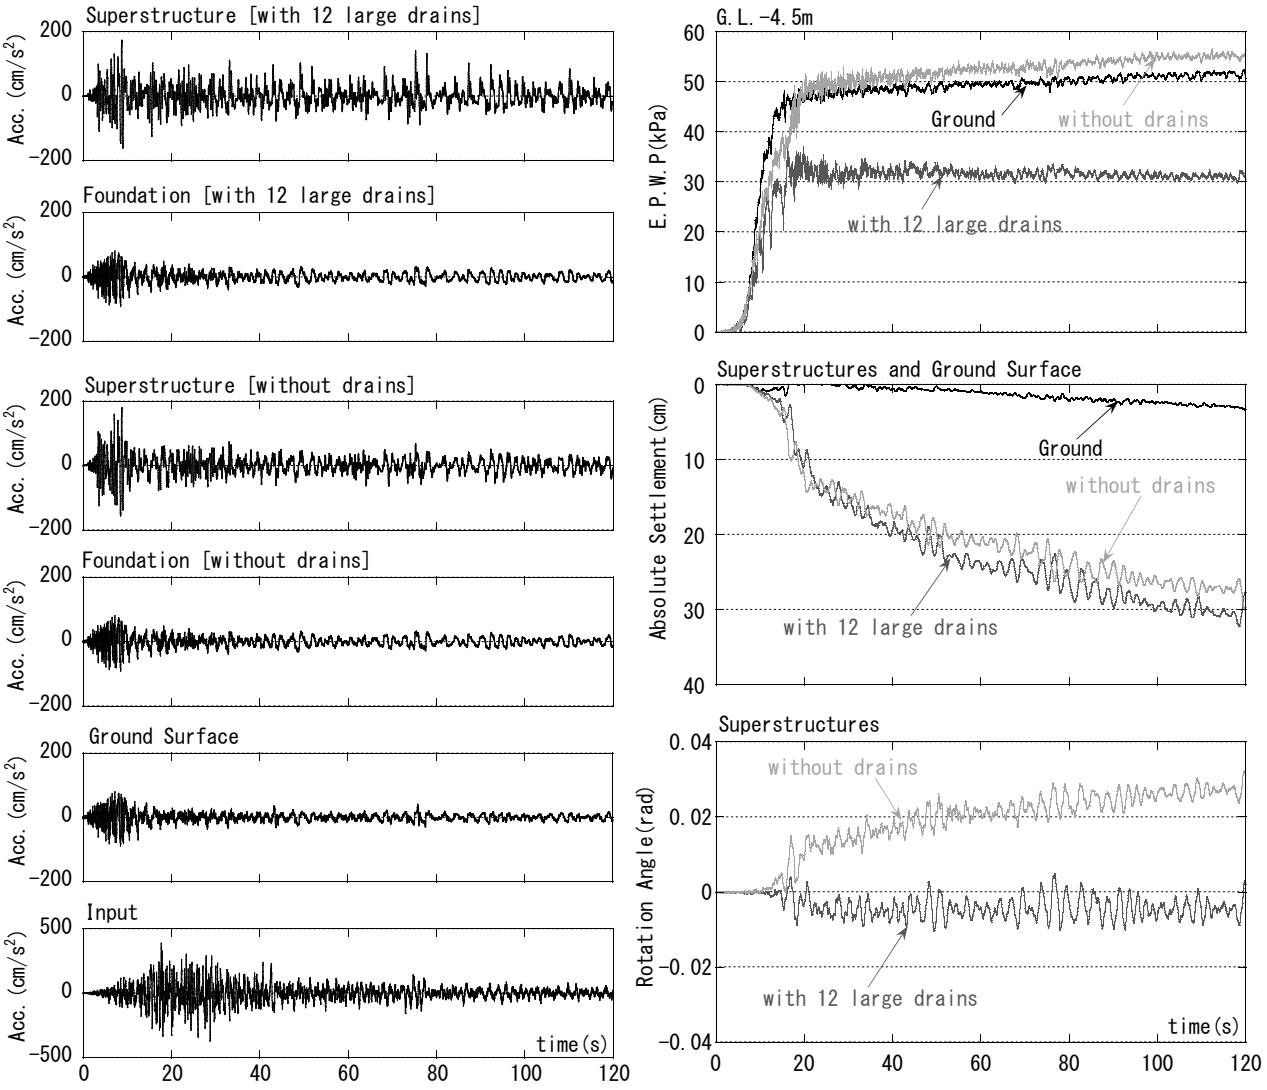

Figure 5 Time histories of structures and soil response for Case-S1

side was larger than that of the center ground because of increasing confining pressure of the ground by the weight of the structure.

Absolute settlements of both structures were clearly larger than that of the ground surface. The absolute settlement of the structure with 12 large drains on I side was slight larger than that of the structure without drains on N side, because excess pore water pressure on I side was dissipated to the ground surface more rapidly by the drains. However, the settlement on N side was subsequently slightly larger than that on I side as shown in Figure 7.

Although the rotation angle of the N-side structure increased in the direction of the eccentric mass during shaking, the rotation angle of the I-side structure was suppressed. Because the effective stress of the ground was maintained by the effect of dissipation by the drains, one-way structure tilt due to dynamic rocking motion could be suppressed simultaneously.

3.2 Soil and Structure Responses for Case-L1

As an example of response results for the large structure, Figure 6 shows the time histories of Case-L1 with 24 large drains and without drains in the same form as Figure 5.

Excess pore water pressure at G.L.-4.5m was constant after about 15 seconds, indicating that the saturated sand layer liquefied. The peak accelerations were about 80cm/s^2 at ground surface and at both foundations, and about 300cm/s^2 in both superstructures at about 10 seconds. The amplitudes of those accelerations were smaller than the input acceleration after 10 seconds. The ratio of peak accelerations of the large and small superstructures was nearly equal to their structure height ratio. Although the responses of the large structures were larger than those of the small structures, they showed similar responses under liquefaction as Case-S1. As for Case-S1, there was little difference between the acceleration time histories of the superstructures and the foundations for the structure with 24 large drains on I side and the structure without drains on N side. However, there was a difference between the excess pore water pressures. The drains were mostly effective, because the excess pore water pressure on I side was smaller than those of the others. However, the effect of the drains for Case-L1 was smaller

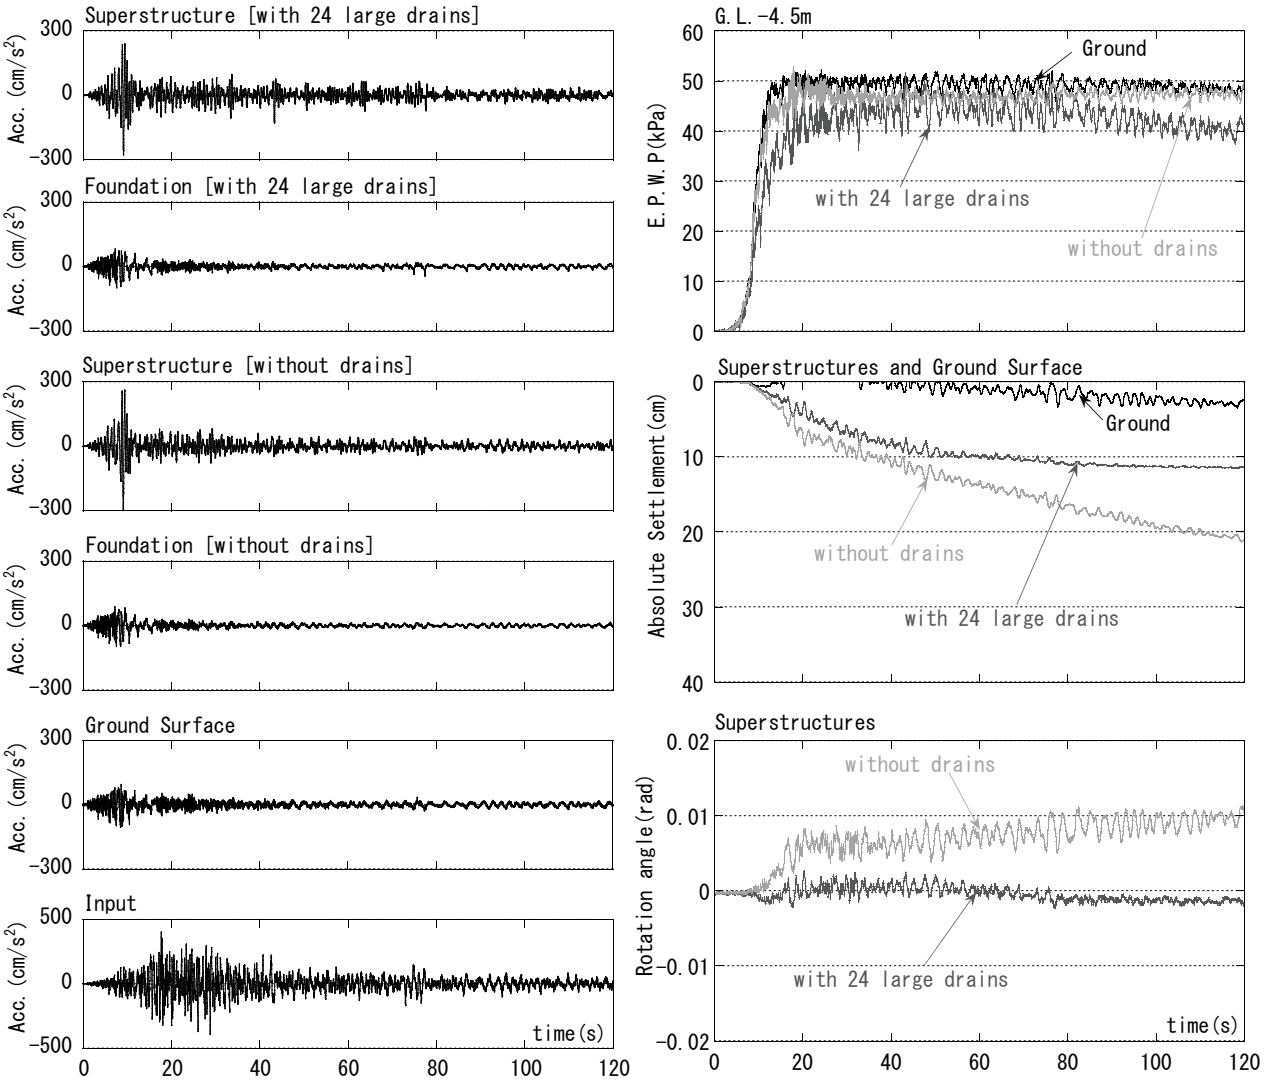

Figure 6 Time histories of structures and soil response for Case-L1

than that for Case-S1.

As for Case-S1, the absolute settlements of both structures were larger than that of ground. However, the difference between them was smaller than for Case-S1. The absolute settlement of the structure with 24 large drains on I side was remarkably smaller than that of the structure without drains on N side, in spite of the smaller dissipation effect due to drains compared with Case-S1. That was a different phenomenon from Case-S1.

Although the rotation angle of the N-side structure increased in the direction of the eccentric mass during shaking, the rotation angle of the I-side structure was suppressed. As for Case-S1, because the effective stress of the ground was maintained by the dissipation effect of the drains, one-way structure tilt due to dynamic rocking motion could be suppressed simultaneously.

3.3 Effect of Drains for Small Structural Model

Figure 7 shows the results of different numbers and diameter of drains with groundwater level -1.0m using the small structural model in Case-S1, Case-S4 and Case-S5. This figure shows excess pore water pressure at G.L.-4.5m, absolute settlement of ground surface and structures, and rotation angle of structures for 600 seconds. The excess pore water pressure of the ground under the center of the structures is shown at the upper left, and that under the end of structure near the drains is shown at the upper right.

The excess pore water pressure of the ground rose rapidly for about 10 seconds in each case, remained almost constant until the end of shaking, and then dissipated. The maximum excess pore water pressures under the center of the structure with drains were smaller than that without drains during shaking. In particular, the maximum excess pore water pressures with 12 drains reduced to about 60% of that without drains, and it also tended to dissipate faster. The maximum pore water pressure using 12 large drains was less than that using 12 small drains. The maximum excess pore water pressures using 4 drains were almost the same. The maximum pore water pressures under the end of the structure near the drains were slightly smaller than those under the center of the structure.

The absolute settlements of the structures were larger than that of the ground in each case. The absolute settlements of the structure with drains were larger than that without drains, because the excess pore water pressure dissipated to the ground surface more rapidly. However, the absolute settlement of the structure without drains was larger than that with drains at the time of 600 seconds because a complete liquefaction state was maintained for a long time in the case without drains.

The rotation angle of the structure with 4 small drains was similar to that of the structure without drains. The rotation angle of the structure with drains in other cases was remarkably small.

3.4 Effect of Drains for Large Structural Model

Figure 8 shows the results for different numbers and diameter of the drains with groundwater level -1.0m using the large structural model for Case-L1 and Case-L3. This figure has the same form as Figure 7.

Excess pore water pressure of the ground rose rapidly for about 10 seconds in each case, remained almost constant

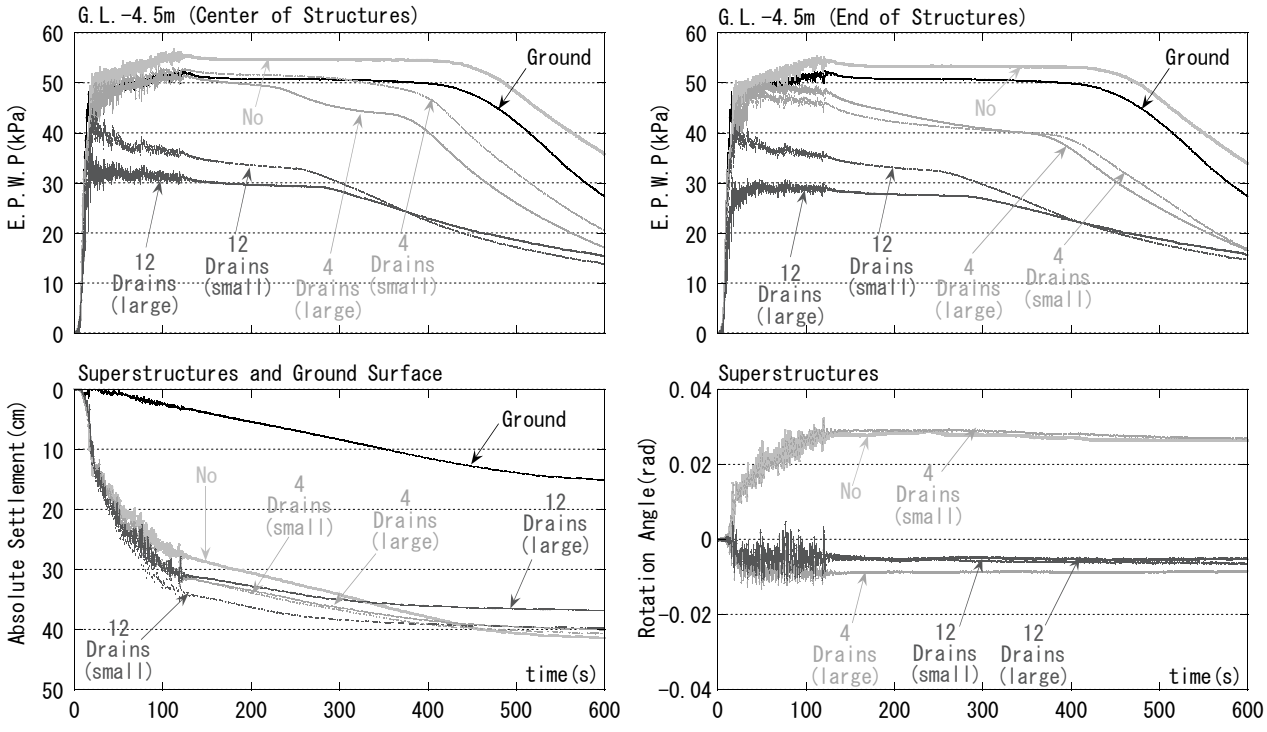

Figure 7 Time histories of excess pore water pressure, absolute settlement and rotation angle for small structure models with groundwater level -1.0m

for a period and then dissipated. However, this effect was less remarkable than that shown in Fig.7 using small structural models. The maximum excess pore water pressure of the ground under the center of the structure with 24 large drains was slightly smaller than for the other cases. The dissipation of excess pore water pressure under the center of the structure with drains was faster than that without drains. However, the excess pore water pressure and its dissipation in the ground under the end of the structure near the drains were varied with number and diameter of drains, because the distance between the center and end of the structure was about twice that for the small structural models.

The absolute settlements of the structures were larger than that of the ground in each case. The absolute settlements of the structure with drains and without drains were initially almost the same in each case. However, the difference between the absolute settlements increased with number and diameter of drains after a period of shaking.

The rotation angle of the structure with 12 small drains was similar to that of the structure without drains. The rotation angle of the structure with drains in other cases was very small.

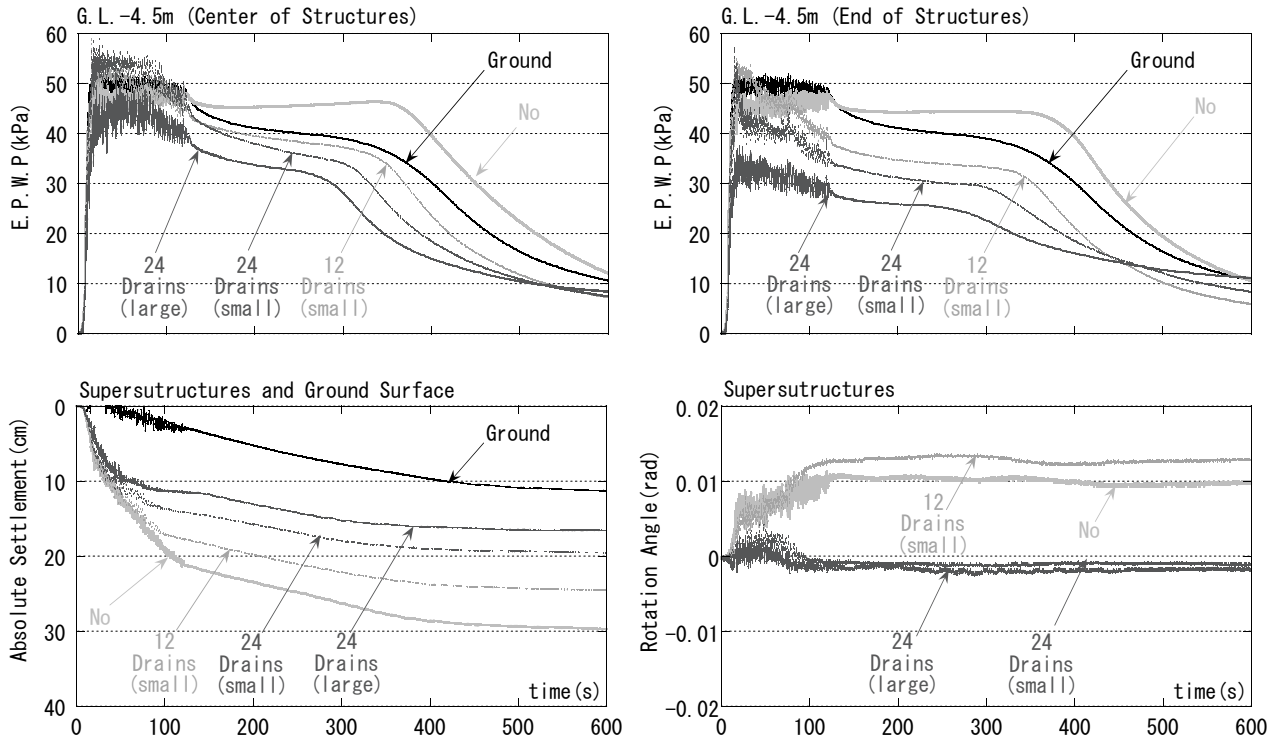
4. STRUCTURE SETTLEMENT AND ROTATION

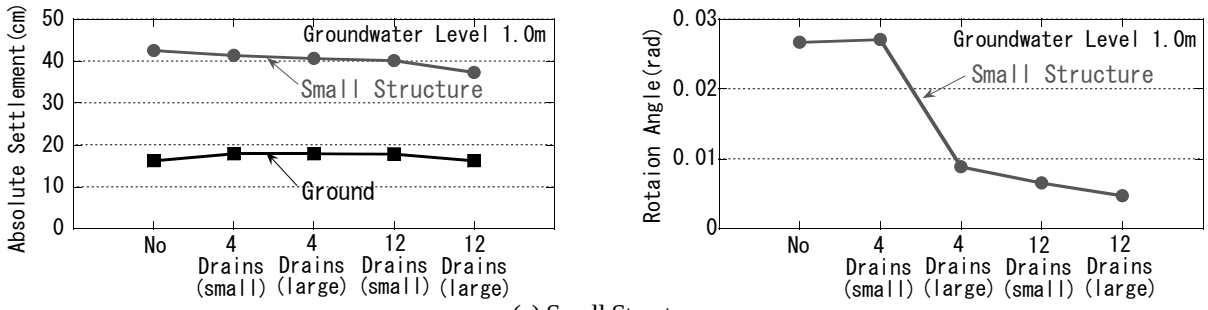
The relationships between the absolute settlements and rotation angles of structures, and the numbers and diameter of drains, are shown in Figure 9 for the time 1200 seconds from the start of vibration. The test cases are shown on the horizontal axis in the increasing order of the drainage effect. Test results for the small structure with groundwater level -1.0m are shown at the top of Figure 9, those for the large structure with groundwater level -1.0m are shown at the middle, and those for the large structure with groundwater level -2.5m are shown at the bottom.

The suppression of the absolute settlements and rotation angles of the structure depends on the numbers and diameter of the drains. There was a large difference between the small structure rotation angles with 4 small drains and with 4 large drains. There was also a large difference between the large structure rotation angles with 12 small drains and with 24 large drains. Thus, the effect on the structure rotation angle was clearly reflected by the numbers and diameter of drains, i.e., the dissipation capacity.

The relationships between absolute structure settlements and rotation angles, and the groundwater level are shown for the small and large structural models in Figure 10. These values are shown for a time of 1200 seconds from the start of vibration.

The ground settlements were almost constant regardless of groundwater level. The structure settlements decreased with lowering groundwater level. It was possible to suppress about 50% of the absolute structure settlement or almost 100% of structure settlement relative to the ground by lowering the groundwater level from G.L.-1.0m to G.L.-4.0m. For the large structural model, the settlements of the structure with drains were smaller than those without drains, and were almost the same as those of the ground. The rotational angles of the structures with drains were smaller than those without drains for both small and large structural models. It is therefore possible to suppress the differential





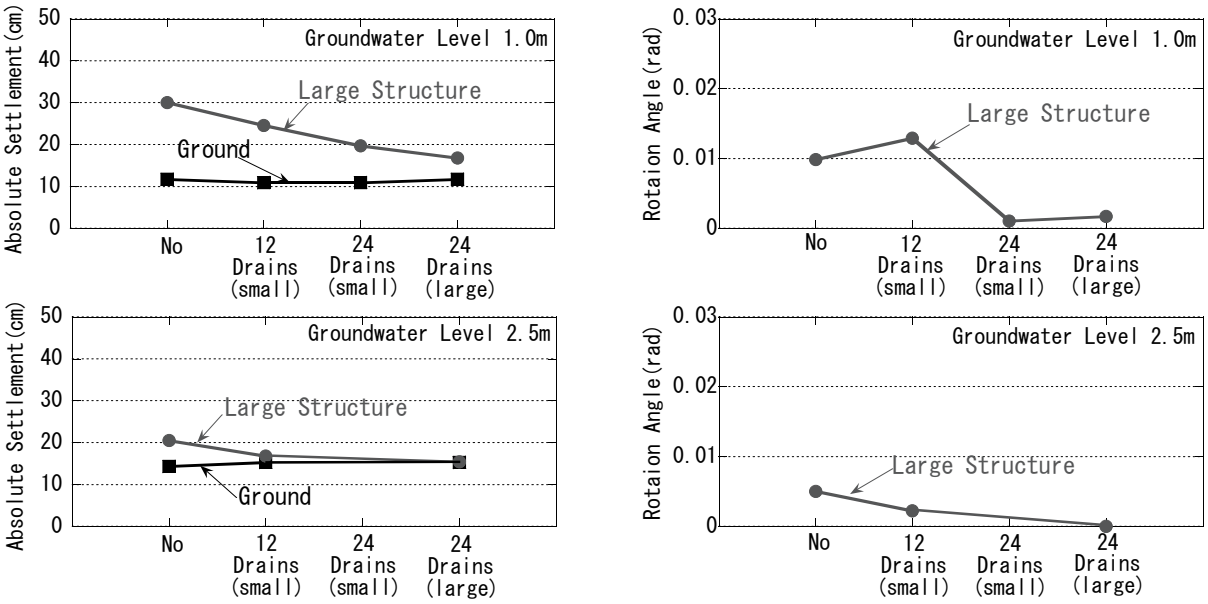


Figure 8 Time histories of excess pore water pressure, absolute settlement and rotation angle for large structure models with groundwater level -1.0m

settlement by reducing to less than 6/1000 the rotation angle of the structure. Therefore, the combined method using both drainage and dewatering could be an effective measures to mitigate differential settlement of houses founded on liquefiable soils.

5. CONCLUSIONS

Dynamic centrifuge tests were performed to investigate the effect of dewatering and drainage on liquefaction induced damage to structures such as single-family houses. The conclusions drawn from this study may be summarized as follows.

1) The relative settlement and tilting angle of a structure due to soil liquefaction decrease with lowering groundwater table, regardless of the size of the structure.

2) The relative settlement and tilting angle of a structure due to soil liquefaction decrease with increasing number and diameter of drainpipes installed around the structure, probably because the excess pore water pressure below the structure generated by earthquake shaking can dissipate rapidly and the ground stiffness was maintained due to the presence of drainpipes. The effects appear more pronounced as the size of the structure increases.

3) The combined method using dewatering and drainage could be effective for reducing damage to wooden houses founded on liquefiable soil.

NUMERICAL MODELING ISSUES IN PREDICTING POST-LIQUEFACTION RECONSOLIDATION STRAINS AND SETTLEMENTS

Katerina Ziotopoulou[1], and Ross W. Boulanger[2]

Abstract: Volumetric strains and settlements that develop during post-liquefaction reconsolidation of sand are difficult to numerically model using the conventional constitutive separation of strains into elastic and plastic components since a large portion of the post-liquefaction reconsolidation strains are due to sedimentation effects which are not easily incorporated into either the elastic or plastic components of behavior. Single element simulations using various constitutive models show that they generally predict post-liquefaction reconsolidation strains that are an order of magnitude smaller than observed in various experimental studies. Accurate prediction of post-liquefaction volumetric strains can also be important for numerically simulating post-shaking pore pressure redistribution and its effect on slope deformations. This paper describes modifications to the bounding surface plasticity constitutive model PM4Sand that provide a means for improved modeling of post-liquefaction reconsolidation strains after the end of strong shaking in a nonlinear deformation analysis. The methodology of the approach along with the calibration is presented, followed by a comparison of the response computed for a field case history.

1. INTRODUCTION

Settlement caused by one-dimensional reconsolidation of liquefied soils, along with any settlement caused by lateral spreading, is an important possible consequence of liquefaction. Settlement caused by post-liquefaction reconsolidation results from volumetric strains that develop throughout the underlying soil profile. Such volumetric strains are not easy to numerically model. The conventional numerical separation of strains into elastic and plastic components cannot capture post-liquefaction volumetric strains that are due to sedimentation under essentially zero effective stress. For this reason, it is common for numerical models to underestimate liquefaction-induced one-dimensional settlements.

The ability to numerically model post-liquefaction reconsolidation strains can also be important for predicting deformation and stability of slopes. Diffusion of the earthquake-induced excess pore water pressures leads to outward seepage from zones that are reconsolidating. If this transient seepage is impeded by an overlying lower permeability soil layer, the accumulation of water near such an interface can lead to void redistribution and subsequent localized loosening, strength loss and possibly water film formation (e.g., Kokusho 1999, Kulasingam et al. 2004). These mechanisms can all locally diminish the shear resistance in a loosening zone leading to greater deformations and possibly instability.

In this paper, modifications to an elastic-plastic constitutive model are presented for improving the numerical prediction of post-liquefaction reconsolidation strains and settlements. The modifications were made to the PM4Sand model (Boulanger and Ziotopoulou 2012) as implemented in the numerical platform FLAC (Itasca 2011). PM4Sand, like other elastic-plastic models, significantly underestimates post-liquefaction reconsolidation strains. A phenomenological modification was added to PM4Sand that enabled the constitutive model to reproduce realistic volumetric strains during the post-liquefaction reconsolidation phase. The following sections of this paper provide: a review of laboratory data, a description of the constitutive equations, results of direct simple shear single element simulations, and the analysis of a case history.

2. LABORATORY DATA

Ishihara and Yoshimine (1992) observed that the volumetric strains that occur during post-liquefaction reconsolidation of sand samples were directly related to the maximum shear strains that developed during undrained cyclic loading and to the initial relative density (D_R) of the sand. They compiled laboratory results and developed the relationships shown in Figure 1. The experimental data show post-liquefaction reconsolidation volumetric strains ranging from 1 to 4% for most relative densities. Their results also showed that a significant portion of the reconsolidation strains occurred early in the reconsolidation phase when the effective stresses were still small.

Other laboratory studies of post-liquefaction reconsolidation strains (e.g., Tokimatsu and Seed 1987, Sento et al. 2004) produced results similar to those of Ishihara and Yoshimine (1992). Sento et al. (2004), however, showed that post-liquefaction reconsolidation strains are more uniquely related to

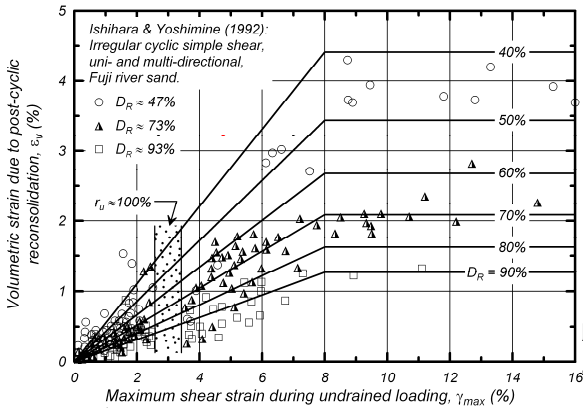

Figure 1 Relationship between post-liquefaction volumetric strain and the maximum shear strain induced during undrained cyclic loading of clean sand (after Ishihara and Yoshimine 1992; redrawn in Idriss and Boulanger 2008).

the accumulated shear strain (summing the absolute magnitude of shear strain increments) that develops during the undrained cyclic shearing process than to the maximum shear strain that develops during undrained shearing. In practice, experimental results for post-liquefaction reconsolidation strains are unlikely to be available for an individual site but any numerical model should at least give results that are consistent with the range of experimental data in the literature.

3. CONSTITUTIVE MODELING

3.1. Elastic – Plastic Component

Constitutive models are most often based on the additive decomposition of strains (or strain rates) into elastic and plastic components. For example, volumetric strain increments $d\varepsilon_v$ are composed of an elastic volumetric strain increment $d\varepsilon_{vol}^{el}$ and a plastic volumetric strain increment $d\varepsilon_{vol}^{pl}$:

$$d\varepsilon_{vol} = d\varepsilon_{vol}^{el} + d\varepsilon_{vol}^{pl} \tag{1}$$

Elastic strains are computed from Hooke's law and the stress increment, and plastic strains are computed from the yield criterion and flow rule. For PM4Sand, the elastic volumetric strain increment $d\varepsilon_{vol}^{el}$ is equal to the mean effective stress increment dp' divided by the bulk modulus K and the plastic volumetric strain increment $d\varepsilon_{vol}^{pl}$ is equal to the dilatancy D multiplied by the plastic shear strain increment $d\gamma_{vol}^{pl}$:

$$d\varepsilon_{vol} = d\varepsilon_{vol}^{el} + d\varepsilon_{vol}^{pl} = \frac{dp'}{K} + D \cdot \left| d\gamma^{pl} \right| \tag{2}$$

One-dimensional post-liquefaction reconsolidation strains are the result of integrating volumetric strain increments as the vertical effective stress σ_v' recovers from zero (i.e., the liquefied state) to its initial value prior to cyclic loading (σ_{vo}'):

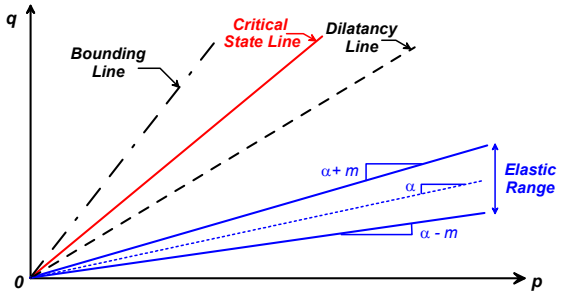

Figure 2 Schematic of the yield, critical, dilatancy, and bounding lines in q-p space (after Dafalias and Manzari, 2004)

$$\varepsilon_{vol-1D} = \int_0^{\sigma_{vo}'} \left(\frac{d\varepsilon_{vol}}{d\sigma_v'} \right) d\sigma_v' \tag{3}$$

The nature of this integration depends on the details of the constitutive model.

3.1.1. Stress-Ratio Based Models

Stress-ratio controlled models, like PM4Sand, use a narrow open cone-type yield surface with its apex at the origin and obeying rotational hardening. This means that only changes of the stress ratio (i.e. the ratio of deviatoric stress q over the mean effective stress p') can cause plastic shear and volumetric strains, while constant stress-ratio loading induces only elastic strains. The stress-ratio based dilatancy, critical state and bounding surfaces of the Dafalias and Manzari (2004) model, upon which PM4Sand was developed, are illustrated in Figure 2. Other examples of stress-ratio based models include the ones developed by Papadimitriou et al. (2001), Andrianopoulos et al. (2010) and Yang et al. (2003).

In simulations of one-dimensional reconsolidation of a liquefied sand, the stress-ratio will remain constant for a stress-ratio based constitutive model with a constant Poisson's ratio v. Reconsolidation strains, as computed using Equation 3, will therefore be integrated along the K_o consolidation line. The bulk modulus K will vary with confinement and thus, the reconsolidation response will be non-linear elastic.

The one-dimensional post-liquefaction reconsolidation volumetric strains obtained by constitutive models using the above framework are illustrated by the following analytical calculation. One-dimensional volumetric strain increments are equal to the vertical stress increment $d\sigma_v'$ divided by the constrained modulus M:

$$d\varepsilon_{vol} = \frac{d\sigma_v'}{M} \tag{4}$$

The constrained modulus M is related to the shear modulus G and Poisson's ratio v as:

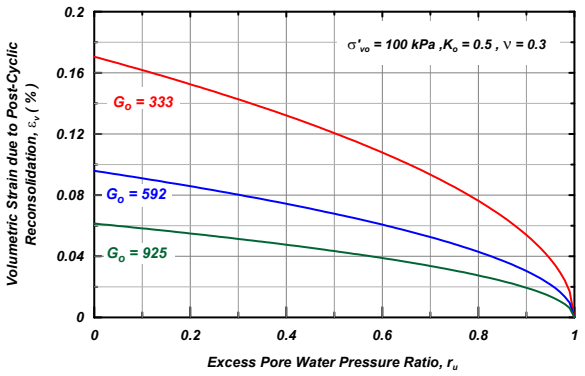

Figure 3 Volumetric strain versus r_u curves with different G_o's obtained through analytical integration of elastic volumetric strain increments.

$$M = \frac{2G(1-\nu)}{(1-2\nu)} \tag{5}$$

The shear modulus G of sand is approximately proportional to the square root of the confinement p' and thus can be expressed as:

$$G = G_o P_{atm} \sqrt{\frac{p'}{P_{atm}}} \tag{6}$$

where G_o is the shear modulus coefficient and P_{atm} is the atmospheric pressure.

The above equations can be used to analytically solve for the volumetric strains that are obtained as the vertical effective stress is recovered during reconsolidation. For example consider reconsolidation from a liquefied state ($\sigma'_v = 0$, $r_u = 1$) back to an initial vertical effective stress of $\sigma'_{vo} = 100kPa$ ($\sigma'_v = \sigma'_{vo}$, $r_u = 0$). The Poisson's ratio is assumed to be constant at a value of 0.3. G_o values of 333, 592, and 925 are considered, which would correspond to in-situ shear wave velocities V_s of 120, 160 and 200 respectively prior to earthquake loading. The volumetric reconsolidation strains computed for these values of G_o are plotted versus r_u in Figure 3. The final volumetric strains range from 0.06 to 0.17% which is about an order of magnitude lower than expected based on experimental data (e.g., Figure 1). This simple example illustrates the order of magnitude of the discrepancy that is often observed in the reconsolidation strains computed using a number of different sand constitutive models.

3.1.2. Other model considerations

Other constitutive models include plastic strains during mean stress increases at a constant stress ratio by the introduction of additional plastic loading mechanisms, such as a cap type of loading surface or a more generalized yield surface (e.g., Taiebat and Dafalias 2008; Wang et al. 1990). These features may, or may not, improve predictions of post-liquefaction volumetric strains because they are not necessarily formulated to account for sedimentation strains. In any event, single element simulations can be used to evaluate the ability of these models to reproduce the range of post-liquefaction volumetric strains observed in laboratory element tests.

3.2. PM4Sand (Boulanger and Ziotopoulou 2012)

The sand plasticity model PM4Sand presented and modified herein for the effects of post-liquefaction reconsolidation follows the basic framework of the stress-ratio controlled, critical state compatible, bounding-surface plasticity model for sand presented by Dafalias and Manzari (2004). The Dafalias and Manzari (2004) model extended the previous work by Manzari and Dafalias (1997) by adding a fabric-dilatancy related tensor quantity to account for the effect of fabric changes during loading. Dafalias and Manzari (2004) provide a detailed description of the motivation for the model framework, beginning with a triaxial formulation that simplifies its presentation and then followed by a multi-axial formulation. Boulanger and Ziotopoulou (2012) provide detailed descriptions of all PM4Sand constitutive equations and terms, along with simulated element responses for a broad range of conditions. PM4Sand follows the conventional additive decomposition of strains, so that it cannot naturally capture reconsolidation settlements.

Modifications to PM4Sand were performed by developing an approximate phenomenological method of accounting for sedimentation strains during reconsolidation. The method has been incorporated in the model to provide more realistic estimates of reconsolidation strains by reducing the post-earthquake elastic shear modulus G (and hence the elastic bulk modulus K). Reducing the elastic moduli increases the post-liquefaction reconsolidation strains (e.g., Equations 2 and 4), thereby compensating for the sedimentation strains which are not explicitly modeled. The user may activate this feature after the end of strong shaking, such that post-liquefaction reconsolidation strains are better approximated in the remainder of the simulation.

The elastic shear and bulk moduli's reduction is based on the maximum fabric parameter z_{max} (a model input parameter), the cumulative fabric z_{cum} (a damage measure), the current stress-ratio M_{cur} and the slope of the dilatancy line M_d. Detailed descriptions of these parameters are given in Boulanger and Ziotopoulou (2012). A sedimentation mean effective stress p'_{sed} is introduced which controls the range of mean effective stresses over which reconsolidation strains are enhanced (i.e., elastic moduli are reduced):

$$p'_{sed} = p'_{sed_o} \cdot \left(\frac{z_{cum}}{z_{cum} + z_{\max}} \right) \cdot \left\langle 1 - \frac{M_{cur}}{M_d} \right\rangle^{0.25} \tag{7}$$

where the MacCauley brackets return zero if the argument is negative, and the sedimentation coefficient p'_{sedo} was calibrated to 20 kPa.

The elastic moduli reduction factor F_{sed} is calculated as a function of p' and p'_{sed}:

$$F_{sed} = F_{sed,min} + (1 - F_{sed,min}) \cdot \left(\frac{p'}{20 \cdot p'_{sed}} \right)^2 \leq 1 \quad (8)$$

where the constant $F_{sed,min}$ represents the smallest value that F_{sed} can attain. The value of F_{sed} progressively reduces from unity toward the value of $F_{sed,min}$ as z_{cum} progressively increases and provided that M_{cur} is less than M_d. The constant $F_{sed,min}$ was calibrated to a value of 0.04 for the results shown later.

The elastic shear G and bulk K moduli that will be applied to the soil during the post-liquefaction reconsolidation modeling phase are calculated by multiplying the reduction factor F_{sed} by the corresponding elastic moduli of the soil computed using the original constitutive relationships:

$$G_{(reduced)} = F_{sed} \cdot G \quad (9)$$

$$K_{(reduced)} = F_{sed} \cdot K \quad (10)$$

4. SINGLE ELEMENT SIMULATIONS

Performance of the PM4Sand constitutive model has been evaluated using single element and boundary value problem simulations. PM4Sand has been implemented as a user defined material for use with the commercial finite difference program, FLAC 7.0 (Itasca 2011). PM4Sand's numerical implementation scheme was developed to comply with the mixed discretization scheme used in FLAC's architecture (Marti and Cundall 1982). The goal of the generalized calibration of the model has been to produce drained and undrained, monotonic and cyclic responses under a broad range of stress conditions that are reasonably consistent with the range of behaviors observed for numerous sands as described in the technical literature and embodied in engineering design correlations (e.g., as commonly correlated to in-situ test data such as SPT, CPT and V_s data). The constitutive model has been shown to be relatively easy to calibrate and provide reasonable responses.

A similar calibration approach was followed for the modifications presented herein. Single element simulations of direct simple shear tests with a post-cyclic loading reconsolidation phase were used to calibrate the p_{sedo} and G_{sed} parameters so that the model provided a reasonable approximation of the progressive accumulation of volumetric strains during the post-cyclic reconsolidation phase and provided final reconsolidation strains that are consistent with the ranges observed experimentally (e.g., Figure 1). The resulting ability of the model to produce reasonable relationships between volumetric strains and maximum shear strain experienced during cyclic loading is illustrated in Figure 4 where results are presented for two cases: the first case was using the implementation of PM4Sand described in Boulanger and Ziotopoulou (2012), which does not include the modifications described in this paper, while the second case included the modifications presented in this paper. For both cases, Figure 4 illustrates the ultimate volumetric strain plotted versus the maximum shear strain γ (%) experienced during the undrained cyclic simple shear loading for three different relative densities of D_R = 35%, 55%, and 75%. Using the original PM4Sand implementation, the computed reconsolidation strains shown in Figure 4 are about an order of magnitude smaller than the laboratory results of Ishihara and Yoshimine (1992) presented in Figure 1. Using the modifications presented herein, the reconsolidation strains are in reasonable agreement with the laboratory results presented in Figure 1, both in their trends and magnitudes.

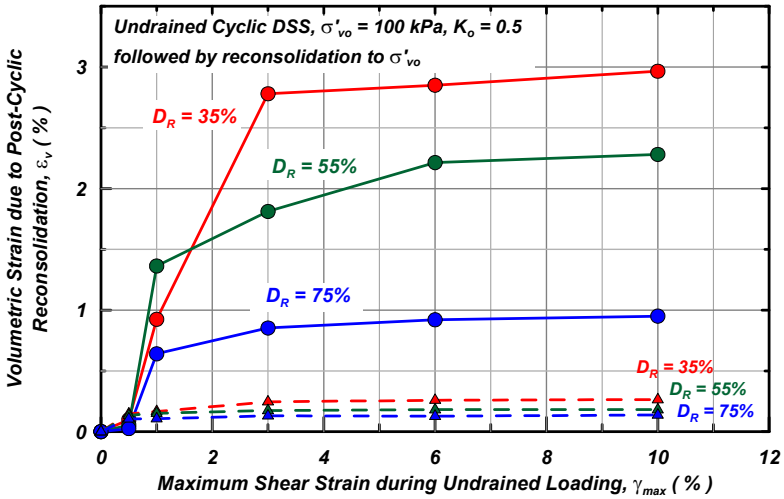

Figure 4 Volumetric strain due to post-cyclic reconsolidation versus the maximum shear strain induced during undrained cyclic DSS loading. Dashed lines correspond to PM4Sand before any modifications and solid lines correspond to PM4Sand implemented with the modifications for post-liquefaction volumetric reconsolidation strains.

5. RESPONSE OF PORT ISLAND LIQUEFACTION ARRAY

Port Island is a man-made island in Kobe city that experienced liquefaction damage during the 1995 M=6.9 Kobe earthquake (e.g., Ishihara et al. 1996). The soil profile and the SPT blowcounts N reported by Ishihara et al. (1996) are shown in Figure 6. The liquefiable layer was the approximately 18-m-thick Masado soil (decomposed granite). The water table was located at a depth of 3 m. Damage included ground surface settlements ranging from 20 to 50 cm across the island (Ishihara et al. 1996). Peak horizontal accelerations of 0.35g and 0.58g were recorded at the ground surface and at a depth of 16 m during the earthquake.

One-dimensional site response analyses of the site subjected to the north-south component of motion were performed using PM4Sand with the modifications presented in this paper in the program FLAC (Itasca, 2011). The liquefiable layer (i.e., submerged Masado fill) was modeled with PM4Sand while all other soil layers were modeled with a hysteretic damping model in FLAC. All model input parameters are reported in Ziotopoulou (2010).

Results are presented in Figure 6 for two analysis cases: the first case was using the implementation of PM4Sand described in Boulanger and Ziotopoulou (2012) which does not include the modifications described in this paper. The ground surface settlements versus time are shown in Figure 6 and the final reconsolidation volumetric strains are plotted versus depth in Figure 5. The final ground surface settlement of 0.03 m after the full dissipation of the earthquake-induced excess pore water pressures is about an order of magnitude smaller than what was observed. This final settlement corresponds to volumetric strains that are about 0.01% to 0.04% in the saturated Masado fill, which are consistent with the corresponding element simulations shown in Figure 4, which in turn are an order of magnitude smaller than commonly observed in laboratory element tests (Figure 1).

The second analysis case included the modifications to PM4Sand presented in this paper. The reduction in elastic moduli was applied to the PM4Sand materials at the end of strong shaking (at 46 sec). The ground surface settlements are shown in Figure 6 versus time and the final reconsolidation volumetric strains are plotted versus depth in Figure 5. In this case the settlements up to the end of shaking (at 46 sec) are identical to the ones obtained in the first analysis case because the reduction to the elastic moduli was not applied until that time. The settlements before 46 sec are limited by the rate at which water can seep out of the soil profile during shaking. The

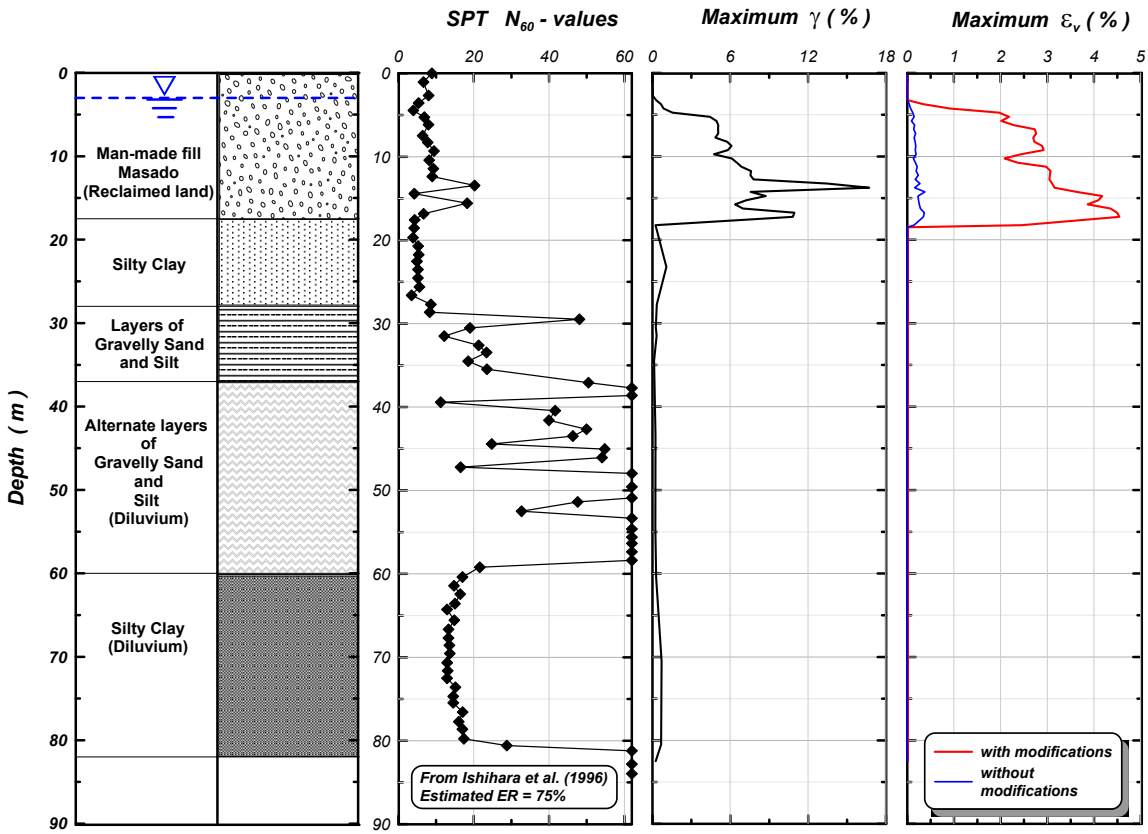

Figure 5 Port Island Array profile. Depth plots of SPT blow count N values (Ishihara et al. 1996) and distribution of maximum shear strains and maximum volumetric strains that developed during the dynamic and the post-liquefaction reconsolidation analyses respectively of the profile with and without the modifications presented in this paper.

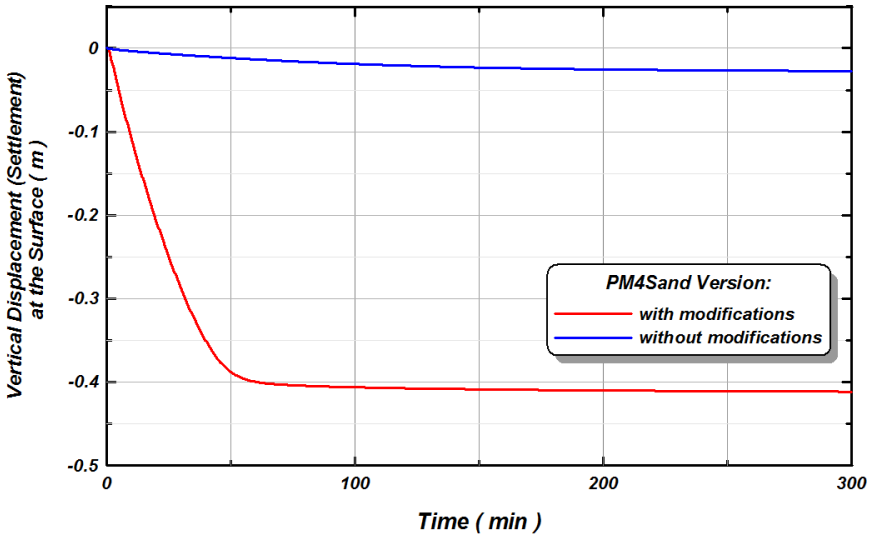

Figure 6 Comparison of vertical displacement time histories at the ground surface of the Port Island liquefaction array for PM4Sand with and without the modifications presented in this paper.

final ground surface settlement of 0.41 m after the full dissipation of the earthquake-induced excess pore water pressures is consistent with the observed settlements of 0.2 to 0.5 m. This final settlement corresponds to volumetric strains that are about 2.0% to 4.5% in the saturated Masado fill, which are consistent with the corresponding element simulations shown in Figure 4, which in turn are consistent with the ranges observed in laboratory element tests (Figure 1).

6. CONCLUSIONS

Modifications were implemented to the bounding surface plasticity constitutive model PM4Sand that provide a practical means for improved modeling of post-liquefaction reconsolidation strains after the end of strong shaking in a nonlinear deformation analysis. The modifications involve a reduction of elastic moduli (shear and bulk modulus) at low effective stresses by a factor that accounts for the soil's loading history through a cumulative fabric term; the reduction is elastic moduli is applied after the end of strong shaking (or cyclic loading) at a time specified by the user. The modified and calibrated model was shown to provide reconsolidation strains that are consistent with the ranges observed experimentally (e.g., Ishihara and Yoshimine 1992), and thus overcomes a common limitation of elastic-plastic soil models. The modified model was applied to a case history and shown capable of significantly improving predictions of liquefaction-induced ground surface settlements. Additional work is needed, however, to develop constitutive and numerical modeling approaches that can more mechanistically simulate post-liquefaction reconsolidation strains without distinguishing between the strong-shaking and post-strong shaking portions of a simulation.

Abstract: Tunnels buried in liquefiable sand deposits may suffer uplift following a major earthquake. Numerical modeling supported with centrifuge experiment on shallow circular tunnels were conducted and have shown to be capable of replicating such uplift failure mechanism with similar excess pore pressure and uplift displacement of a circular buried structure. The uplift of the tunnel was initiated following the rapid excess pore pressure generation. After the soil had liquefied, the rate of uplift came to a constant value despite further uniform cyclic shearing produced by the shaking. This substantiates the presence of a shear modulus degradation limit. Minimal uplift displacement of the tunnel was observed after shaking despite the retention of high excess pore pressure. This implied that the duration of cyclic shearing has a direct influence on the accumulation of uplift displacement of the tunnel. In addition, this refutes the hypothesis that liquefied soil can be assumed as a viscous fluid. Soil dilation near the face of the tunnel as observed in the centrifuge experiment was successfully produced in the numerical analysis. Given the general matching results between the numerical and centrifuge models, it is evident that the constitutive soil model was effective in replicating the floatation response of the structure in the centrifuge test.

1. INTRODUCTION

Faced with the growing demand for effective transportation network, coupled with the scarcity of land in urban areas, underground highway and railway construction has been increasingly popular in the past few decades. Many of these transportation facilities, such as the George Massey Tunnel in Vancouver and the Bay Area Rapid Transit (BART) Tunnel in San Francisco lie in soil deposits which are highly susceptible to soil liquefaction in the event of a major earthquake. Each of these large scale underground structures carries thousands of commuters and evidently poses extreme concerns to public safety. Large diameter natural gas pipelines in New Mexico, Japan and Canada are similarly confronted with likelihood of damage following an earthquake. It is therefore imperative to conduct in-depth research to ensure such seismic risks are mitigated.

This paper presents a section of the numerical and experimental studies carried out on the uplift of tunnels buried in liquefied sand deposits. Verification on the performance of the constitutive soil model was also conducted based on the Wildlife Liquefaction Array recording of the 1987 Superstition Hills Earthquake.

2. SIMPLIFIED UPLIFT MECHANISM

Underground structures such as tunnels are generally subjected to a buoyant force due to their lower submerged unit weight than the surrounding soil. This buoyancy force (F_B) governed by Archimedes Principle is counteracted by the weight of the tunnel (F_T), effective surcharge of the overlying soil (F_{WS}) and the shear resistance from the soil (F_{SP}). The force equilibrium is illustrated in Figure 1.

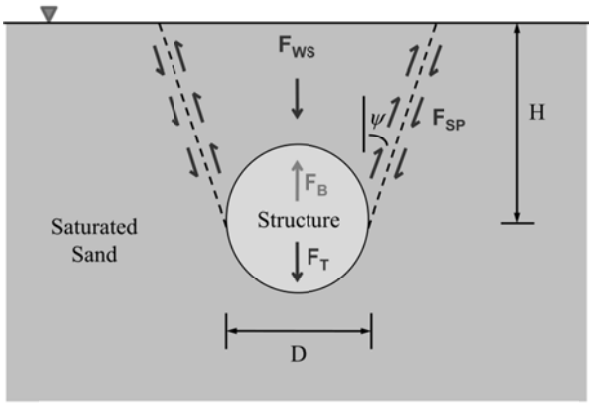

Figure 1 Forces Acting on Tunnel at Static Condition

In the event of soil liquefaction, the shear strength of the soil is significantly reduced, which in turn decreases the shear resistance from the soil inhibiting the uplift of the tunnel. In addition, the generation of excess pore pressure may also induce an upward force at the invert of the tunnel which encourages the floatation of the tunnel.

3. NUMERICAL MODELLING

3.1 Background

Numerical analyses were performed using FLAC (Fast Lagrangian Analysis of Continua), a finite difference program code developed by Itasca Consulting Group. The program has been widely used in various geotechnical problems such as slope stability, embankment, deep excavation and tunneling. It is also capable of simulating yielding and flow of materials at large strain (Itasca, 2011), and hence suitable for soil liquefaction problems.

A user-defined continuum soil model, Wang model (Wang *et al.*, 1990) was applied to the analysis to simulate soil liquefaction properties and response. The Wang model is a non-linear, fully-coupled bounding surface plasticity constitutive model for sand, specifically formulated to capture the contraction and dilation induced by shear stress applied to the soil. Figure 2 illustrates the failure surface, maximum pre-stress surface and phase transformation line considered in the model.

The constitutive model-dependent parameters, namely the modulus coefficient defining the small strain elastic shear modulus (G_0), the reduction of shear modulus with increasing strain amplitude (h_r) and the blow count related parameters (k_r and d) were calibrated to produce similar contractive and dilative responses as typical cyclic laboratory tests of loose saturated sand (e.g. Toyoura sand). Details of the calibration procedure and conformance of the constitutive model with cyclic laboratory tests were discussed by Wang *et al.* (1990, 2006) and Wang and Makdisi (1999).

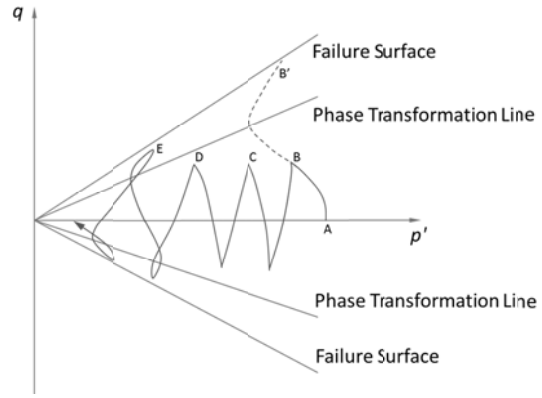

Figure 2 Effective Stress Paths under Monotonic (Path ABB´) and Cyclic Undrained Triaxial Loading (Path ABCDE) (from Wang *et al.*, 1990).

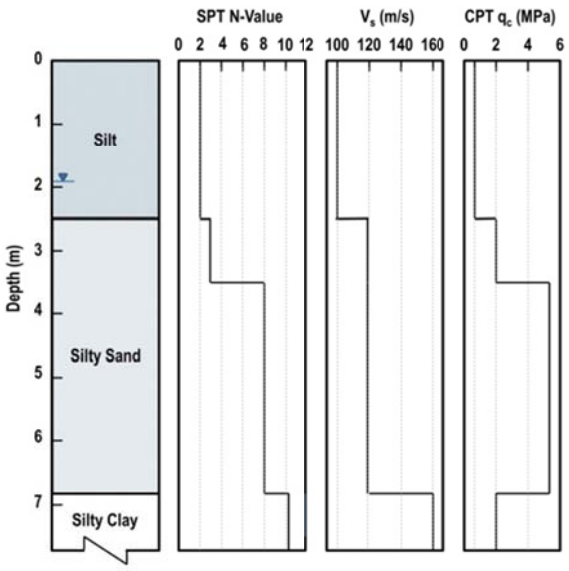
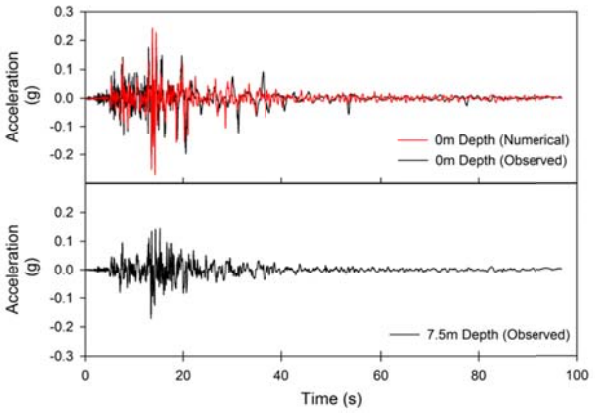
The numerical analyses presented in this paper were carried out as a plane strain condition and the tunnel lining was assumed as rigid. The boundary condition at the sides of the model must account for the semi-infinite free-field condition. Given the application of only a simple 1-D input wave, the free-field condition was achieved by applying a one-dimensional free-field calculation in parallel with the main-grid analysis, and applied to the sides of the main-grid analysis. Absorbing boundaries were also applied to the sides of the main-grid to ensure minimal seismic wave reflections (Cundall *et al.*, 1980).

3.2 One-Dimensional Soil Analysis

In order to verify the suitability of the constitutive soil model for soil liquefaction analysis, the site response of the Wildlife Liquefaction Array was simulated. The Wildlife Liquefaction Array is located in the Imperial Valley desert of southern California. The most significant recording was the soil liquefaction following the 1987 Superstition Hills Earthquake (Holzer and Youd, 2007). Figure 3 illustrates the soil profile of the site. The soil profile was kept simple as the key objective of this simulation was to assess the soil response between a liquefied and non-liquefied site produced by the constitutive model, rather than to obtain accurate depiction of the observation on site. The absence of Love waves in the numerical analysis, which contributed 13 to 35% of the excess pore pressure generation following the earthquake (Holzer and Youd, 2007), also meant that it was even more difficult to obtain exact replication of the observations on site. As such, the soil profile was merely used as a basis for the numerical simulation on a real site. The input acceleration to the numerical model was based on the deepest accelerometer recording at 7.5m depth of soil in the NS direction. In order to assess the response of a non-liquefied soil deposit, an identical numerical model was subjected to a weaker input acceleration of 0.1 times the amplitude of the former input acceleration. Figures 4 and 5 show the results obtained from the above mentioned simulations.





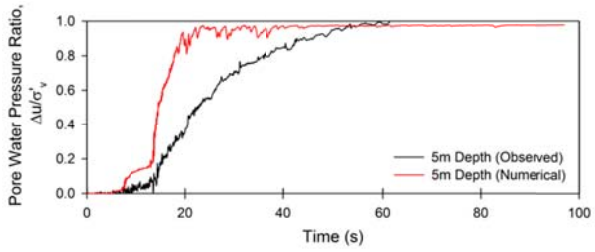


Figure 3 Simplified Wildlife Liquefaction Array Soil Profile and Properties (adapted from Bennett *et al.*, 1984)

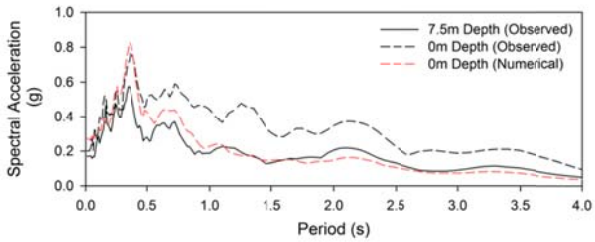
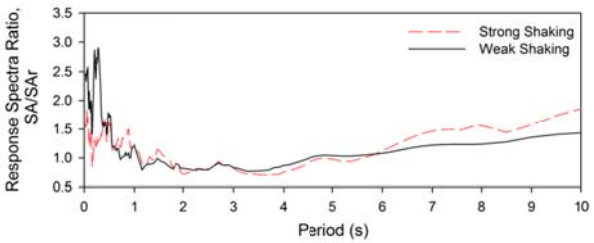
In Figure 4, soil liquefaction was achieved in both the numerical analysis and observed data sometime past 20 seconds of earthquake shaking. This was supported by the presence of sharp spikes of acceleration spaced at long periods and excess pore pressure ratio near 1.0. The differences between the observed and numerical results were likely due to the simplified soil profile and the absence of long period Love waves in the numerical analysis. Nevertheless the numerical analysis was able to replicate the response spectra especially at the period range before 0.5 seconds where the natural period of the site lies



(approx. 0.28 seconds). The lower spectral acceleration predicted at longer period could possibly be due to absence of the long period Love waves which produced large (approx. 1.5%) cyclic shear strains after the strong shear wave abated (Holzer and Youd, 2007) as discussed earlier . Such significant cyclic shear strain would also affect the process of soil softening and thereby altering the long period response of the soil. Such hypothesis was inferred by several publications which similarly predicted lower than observed response spectra at long periods of the response spectra (Youd and Carter, 2003; Ziotopoulou *et al.*, 2012).

(a) Acceleration

(b) Excess Pore Pressure Ratio



(c) Response Spectra

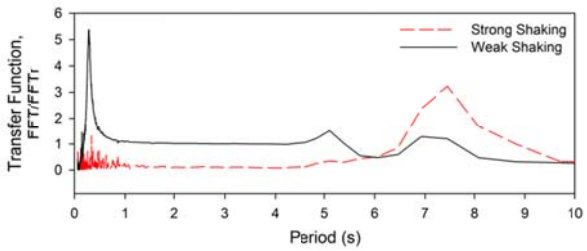


Figure 4 Wildlife Liquefaction Array Simulation on the 1987 Superstition Hills Earthquake

The constitutive soil model was further verified with response spectra ratio and transfer function plots in Figure 5. In the case of the site response between liquefied and non-liquefied soil, it was anticipated that shear wave propagation through a liquefied soil would be inhibited due to the loss of shear stiffness of the soil. As such, low period wave recordings at the soil surface would be attenuated. This is portrayed in the numerical analysis between a strong shaking (the actual 1987 Superstition Hills Earthquake) and a weaker shaking (0.1 times of the same Superstition Hills Earthquake) as shown below in Figure 5. A lower response spectra ratio at the initial natural period of the site (approx. 0.28 seconds) was produced in the case of the strong shaking. The loss of shear stiffness due to soil liquefaction also amplified the longer period waves, hence indicating a shift in the dominant peak of the response spectra ratio plot as evident in Figure 5a.

The above findings were further substantiated by the transfer function which was computed as the ratio of the Fast Fourier Transform at the surface and the base of the numerical models. The weaker shaking produced a natural period of about 0.26s for the 7.5m thick soil deposit (shear wave velocity, V_s of 115m/s) as indicated at the dominant peak in Figure 5b. However, the peak was no longer obvious in the case of the strong shaking. Instead, the dominant peak was located at about 7.4s (V_s of approx. 4m/s), hence confirming a sensible effect of soil liquefaction.

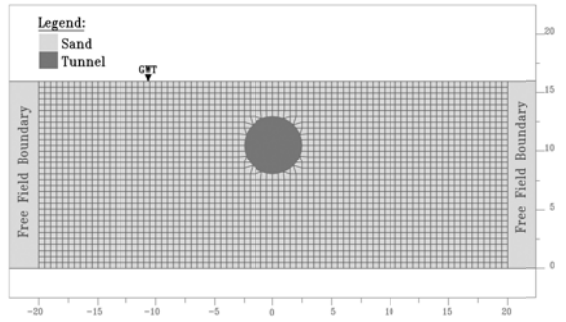
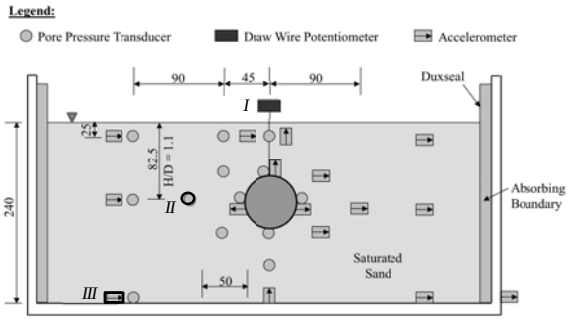
4 NUMERICAL AND CENTRIFUGE SIMULATION OF TUNNEL UPLIFT IN LIQUEFIABLE SOIL



Based on the above Wildlife Array simulation, the FLAC program accompanied with the Wang constitutive soil model has demonstrated its suitability in simulating soil liquefaction condition. A numerical analysis on the uplift of tunnel was subsequently carried out and supported with a centrifuge experiment. The material properties of the sand in centrifuge test are shown in Table 1. Figure 6 shows the soil model layout for the numerical analysis and the centrifuge test.

In order to reduce reflecting incident stress waves due to the rigid boundary of the centrifuge model container, 25mm of moldable Duxseal was placed on the sides of the container to



reduce reflecting incident stress waves by at least 65% (Steedman and Madabhushi, 1991), as well as achieving semi-infinite boundaries given its compressibility properties (Cheney *et al.*, 1988). The Duxseal remained stable and did not show any unusual deformation after each centrifuge testing. This substantiates optimum molding of the Duxseal to achieve the desired boundary condition.

Table 1 Material Properties of Hostun Sand

(a) Numerical Model

(b) Centrifuge Test

Figure 6 Soil Model Layout: for Numerical and Centrifuge Models

An automatic sand pourer, which relied on the concept of sand pluviation by gravity, was used to achieve a 45% relative density of the sand. A circular hollow structure with closed ends was buried in the sand at a depth of 1.1 times of its diameter. The sand was subsequently saturated with high viscous fluid of kinematic viscosity (in cSt) equivalent to the centrifuge g-level. By increasing the viscosity of the pore fluid in the sand, the rate of excess pore pressure generation (due to earthquake loading) and the rate of dissipation (due to soil consolidation) are both matched. Centrifuge g-level of 66.7g was used to scale the model tunnel of 75mm in diameter to the prototype scale of 5m in diameter. The mass of the tunnel including attached instruments at prototype scale was about 6 tons (specific gravity, G_s of 0.3). Near sinusoidal earthquake shaking of about 27 seconds at 0.75 Hz at prototype scale was applied at the base of the soil model while it was in-flight.

Figure 7 shows the results obtained from the numerical analysis and the centrifuge test. It was observed that both results were comparable. Excess pore pressure was generated rapidly with the application of shaking and attained near full liquefaction in about 4 cycles of shaking. As discussed earlier, the simplified theoretical floatation mechanism suggests that a buoyant structure may float when the soil's shear strength from its inter-particle frictional contact is reduced with the generation of excess pore water pressure. Floatation of the tunnel is hence assumed to be initiated due to build-up of high pore water pressure. This is substantiated with the commencement of the uplift as observed in the numerical analysis and centrifuge test in Figure 7.

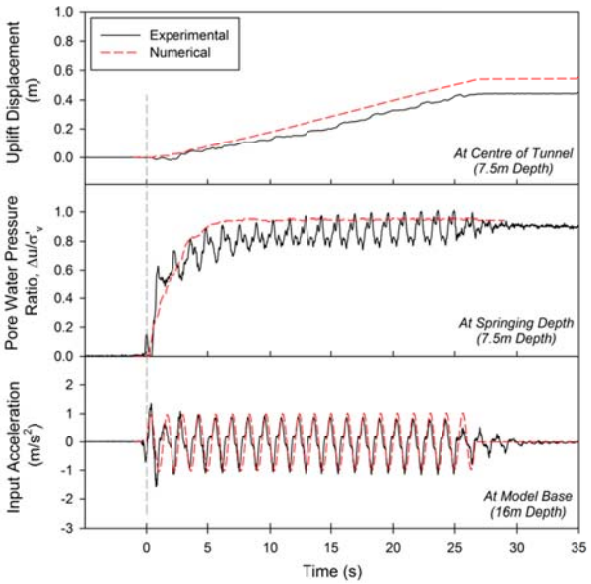

Figure 7 Tunnel Uplift Displacement (*I*), Far Field Pore Water Pressure Ratio (*II*) and Input Acceleration (*III*) Time Histories

Some differences were present between the numerical analysis and centrifuge test result. The far field excess pore pressure obtained from the numerical analysis was slightly higher than the mean values from the centrifuge test after the initial few cycles of shaking. This led to the higher rate of uplift of the tunnel during that time frame, thereby resulting in a higher final uplift displacement of the tunnel. This infers that the rate of uplift of the tunnel was highly dependent on the excess pore pressure. The generation of excess pore pressure leading to soil liquefaction was due to cyclic shearing of the soil which also led to degradation of the soil's shear modulus. A lower shear modulus encourages the uplift of the tunnel. However, a limit of the shear modulus degradation exists where cyclic degradation no longer takes place with further shearing (Lo Presti *et al.*,

2004). As such, the rate of uplift of the tunnel would arrive at a constant value after the soil had liquefied. This is supported by both the numerical analysis and the centrifuge test result in Figure 7. Given the general matching results between the numerical and centrifuge models, it is evident that the constitutive soil model was effective in replicating the floatation response of the structure in the centrifuge test.

After the end of the shaking, minimal uplift displacement of the tunnel was observed in both the numerical analysis and centrifuge experiment, despite retaining high excess pore pressure. This implied that the duration of cyclic shearing has a direct influence on the accumulation of uplift displacement of the tunnel, in addition to the liquefied soil condition. As such, the uplift displacement of an underground structure can be estimated based on the knowledge of the cyclic shear modulus degradation, excess pore pressure generation and the duration of the shaking.

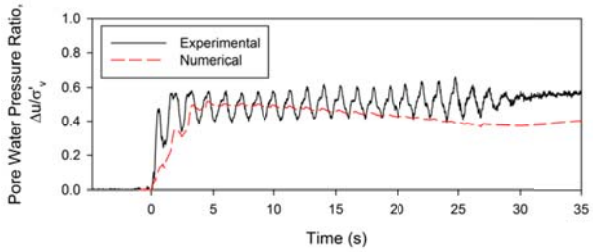

Figure 8 Near Field Pore Water Pressure Ratio at Springing Depth of Tunnel

At the near field (i.e. face) of the tunnel, studies have shown that soil dilation arising from the cyclic displacement of the tunnel relative to the surrounding soil exists around an uplifting tunnel (Chian and Madabhushi, 2012). Figure 8 shows the near field pore water pressure ratio measured at the springing (i.e. mid-depth) of the tunnel. In the figure, soil liquefaction was not pronounced at the face of the tunnel despite attaining near full liquefaction in the far-field as shown in Figure 7. In addition, the numerical analysis produced a decreasing pore water pressure ratio as compared to the centrifuge test as shown in Figure 8. Such reduction in pore pressure is likely due to the increased shearing of the soil at the tunnel interface. This hypothesis is supported by the higher rate of uplift of the tunnel after 5 seconds of shaking in the numerical analysis as observed in Figure 7. These observations clearly demonstrate that the numerical analysis was capable of producing the dilative effect inferred by the lower excess pore pressure. Such reduction in excess pore pressure near the tunnel would inevitably have consequences in the design and performance of underground structures against seismic uplift in liquefiable soil deposits.

5. CONCLUSIONS

Liquefaction induced uplift failure of tunnels was investigated with numerical and centrifuge modeling. The FLAC program accompanied with the Wang constitutive model for soil liquefaction was applied to the study. The performance of the numerical package was assessed with the Wildlife Liquefaction Array case study and has shown to be capable of producing soil liquefaction responses and properties. The uplift of shallow circular tunnels was investigated with numerical modeling and centrifuge testing. Both modeling techniques were capable of replicating such uplift failure mechanism with similar excess pore pressure and uplift displacement of a circular buried structure. Rapid excess pore pressure generation was followed by the uplift of the tunnels. The rate of uplift of the tunnel was found to be highly dependent on the excess pore pressure, and came to a constant value after the soil had fully liquefied. This substantiates that a limit of the shear modulus degradation exist where cyclic degradation no longer takes place with further shearing. Minimal uplift displacement of the tunnel was observed after shaking despite retaining high excess pore pressure, thereby implying that the duration of cyclic shearing has a direct influence on the accumulation of uplift displacement of the tunnel. This observation also refutes the hypothesis that liquefied soil can be assumed as a viscous fluid. Soil dilation near the face of the tunnel as observed in the centrifuge experiment was produced in the numerical analysis. These consistencies undoubtedly demonstrate and pave the prospects of applying similar numerical analyses and centrifuge tests for geotechnical problems associated with the uplift of underground structures in liquefiable soil deposits.

Abstract: Natural sand deposit normally consists of many sub layers with different soil particles and properties, ranging from soft sand lenses to stiff cohesive clay and coarse sand layers, referred as non-homogeneous soil deposits. The actual soil profile characterized by various patterns of layering and lensing is very complex, which may have great effect on geotechnical engineering problems at a site. The effects of non-homogeneity on liquefaction in stratified soil deposits are investigated by carrying out a series of dynamic centrifuge tests and numerical simulations. Non-homogeneity in the tests is incorporated by including the periodically distributed silt patches. The centrifuge tests were also conducted on uniform homogeneous and continuous layered soil deposits for the comparison purposes. Two dimensional finite element analyses based on extended sub-loading surface model are carried out. Simulation results are compared to the centrifuge test measurements and observations. The experimental and numerical results shows that more excess pore water pressure remains for a longer period of time at discontinuous region in non-homogeneous soil deposits compared to the uniform and continuous layered soil deposits. The dissipation of excess pore water pressure becomes the dominant mechanism for non-uniform settlement after the seismic excitation as the pore pressure generation ceases the supply of new mass of water. The rapid dissipation of excess pore water pressure through the discontinuous part in the non-homogeneous soil deposits manifest a larger settlement at the corresponding part, causing non-uniform settlements.

1. INTRODUCTION

Liquefaction has been reported as a cause of severe damage to foundations of buildings, bridges and other structures, as well as to ports and buried lifelines during past major earthquakes. During earthquakes, saturated sandy soils are characterized by substantial rise in excess pore water pressure, leading to dramatic loss of strength and stiffness. When this excess pore pressure reaches a value equal to the initial effective stress, soil particles do not support each other, referred to as a zero effective stress condition; a state of initial liquefaction (NRC 1985; Ishihara and Yoshimine 1992; Fiegel and Kutter 1994; Kramer 1996; Brennan and Madabhushi 2005). Following the two devastating earthquakes viz. the 1964 Niigata and 1964 Great Alaska Earthquakes, many geotechnical earthquake engineering research programs on liquefaction were initiated in Japan and North America. These have provided researchers with better insight into the liquefaction phenomenon and associated failures. Initially, the study was only focused on assessing the triggering factors for liquefaction in clean, sandy soils. As the years passed, physical model studies on layered soil deposits evolved. Various experimental studies based on the physical model tests, such as one dimensional column tests (Kokusho 1999; Tohumcu Özener et al. 2008), shaking table tests (Liu and Qiao 1984; Kokusho 1999), and centrifuge model tests (Dobry and Liu 1992; Fiegel and Kutter 1994; Balakrishnan and Kutter 1999; Kulasingam et al. 2004; Brennan and Madabhushi 2005) as well as site investigations (Kokusho and Fujita 2002) and numerical analyses (Yoshida and Finn 2000; Seid-Karbasi and Byrne 2007; Lu and Cui 2010) have been conducted to examine the effects of liquefaction in stratified sands. All of the studies concluded that the presence of relatively impermeable layer (silt) within the liquefiable deposits results in the formation of a water film beneath it. The excess pore water squeezed from the liquefied sand is trapped by a relatively impermeable sub-layer and forms a water film beneath it, which has a key role in the extent of lateral deformations in the sloping surface (Kokusho 1999; Kokusho 2000; Kokusho and Kojima 2002).

It is noted that the real soil profile is complex and a soil deposit is neither uniform nor consists of continuous layers. Natural sand deposit normally consists of many sub-layers with different soil particles and properties, ranging from soft sand lenses to stiff cohesive clay and coarse sand layers. Ghosh et al. (2005) performed a series of centrifuge tests to analyze the effects of localized loose sand in a dense sand deposit subjected to seismic loading. It was found that the soft layer has significant influence on the overall response of the layered strata. Chakrabortty and Popescu (2012) also conducted a series of centrifuge tests on homogeneous and heterogeneous soil deposits followed by numerical simulation, where the heterogeneous model consisted loose pockets of same sand with lower relative density. The results showed more excess pore water pressure is generated in a heterogeneous soil deposits than in corresponding

homogeneous soil. However, the stratification of soil profile is not only limited to soft layers involving one type of soil material as considered by Chakrabortty and Popescu (2012); it consists of many discontinuous layers ranging from highly permeable liquefiable to impermeable non-liquefiable layers. The patterns of layering and lensing in an actual soil profile can be extremely complex and have great effect on geotechnical engineering problems at a site (NRC 1985). In order to systematically predict the earthquake response of saturated porous media it is essential to correctly simulate the generation, redistribution, and dissipation of excess pore water pressure during and after earthquake shaking, which are the major mechanisms in case of real soil profile (Taiebat et al. 2010). To the best knowledge of authors, numerical or experimental studies related to the presence of discontinuous less permeable layer in the liquefiable soil have not been carried out. Therefore, liquefaction potential of non-homogeneous soil profile is not well understood, though many liquefaction case histories exist.

In this study, the effects of non-homogeneity in stratified soil deposits are investigated by carrying out four dynamic centrifuge tests and numerical simulations. Two of the model tests were conducted on non-homogenous soil deposits. Non-homogeneity was incorporated by including periodically distributed silt patches with a lower permeability than the liquefiable soil specimen with the same length of discontinuities in each layer, which will be referred as drainage layer hereafter. For reference, tests on a uniform soil deposits and continuous layered soil deposit were also conducted. Laminar containers were used in all the tests to properly simulate the boundary conditions. Two dimensional finite element analyses based on extended sub-loading surface model were carried out. Simulation results are compared to the centrifuge test measurements and observations. The main objective of the study is to enhance the understanding of liquefaction mechanism in non-homogenous soil deposits and to systematically study the effects of non-homogeneity of the soil deposit on the amount of excess pore water pressure, drainage path, and settlement of the liquefiable soils.

2. CENTRIFUGE MODEL TEST PROCEDURES AND CONDITIONS

2.1 Soil and pore fluid

Toyoura sand and Silica sand No.8 were used in all four centrifuge tests (Table 1). The difference between the permeability of the sands is of order 1; Silica sand No. 8, referred as silt, being less permeable, was employed to create the continuous relatively impermeable layer in Model 2 and discontinuous relatively impermeable layer in Models 3 and 4, creating non-homogeneity in soil deposits.

The models were saturated with a viscous fluid in order to ensure accurate simulation of prototype soil permeability. The viscous fluid was a mixture of water and 2% Metolose (Hydroxypropylmethyl cellulose from Shin-Etsu Chemical Company) by weight of water to achieve a viscosity of about 40 times the viscosity of water. It has also been shown in previous research that this type of viscous fluid neither disturbs nor adversely affects the dynamic properties of cohesionless soil (Okamura et al. 2001). The density and surface tension of this solution is practically identical to that of water. Therefore, the highly viscous Metolose solution ensured accurate simulation of prototype soil permeability of a fine sand and silt when the models were tested at centrifugal acceleration of 40g.

Minimum void ratio, e_{min}	0.609	0.703
Permeability, k (m/s)at Dr=50%	2×10^{-4}	2×10^{-5}

2.2 Model preparation

Models were constructed in a flexible laminar container with dimensions of 500×200×450 mm in length, width, and height, respectively, which allows the container to deform dynamically with the soil layer. The models were prepared by air pluviation method to the depth of 225 mm in model scale, where sand was poured from a hopper which was moved manually back and forth along the longest dimension of the box, and the falling height was kept constant to obtain the desired relative density. Accelerometers and pore pressure transducers were installed at the desired locations during model preparation. The colored noodles 'somen' were placed at the sand-silt interface to trace the deformation pattern. During the preparation of non-homogeneous soil deposits, Toyoura sand was deposited first by the help of two light weighted blocks placed on both sides (Fig. 1). Then, the remaining parts were filled with Silica sand No.8 by air pluviation method. The de-aired Metolose solution was dripped slowly from the top of the container under a vacuum of 760 mmHg until the solution level reached the desired elevation. The saturation process for all the tests required approximately 30 hours. After saturation, the sand was again poured by air pluviation method to make the total height equal to 245 mm in model scale so that the water table was 20 mm below the surface in model scale and finally laser displacement transducers and potentiometers were placed at the surface. After preparation, the models were placed in Tokyo Tech Mark III centrifuge (Takemura et al. 1999) and spun at centrifugal acceleration of 40g.

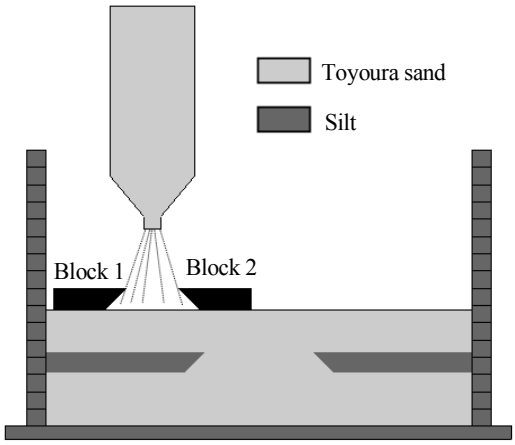

Figure 1 Model preparation of non-homogeneous soil deposits.

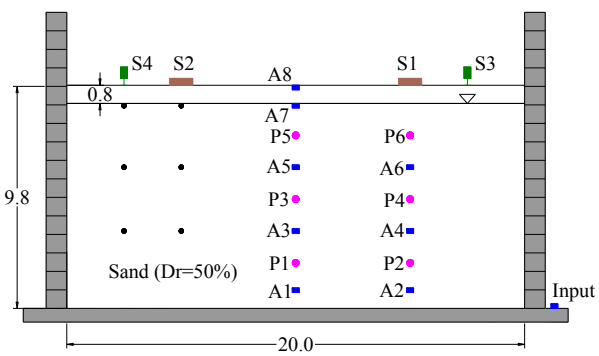

2.3 Test conditions

Four dynamic centrifuge model tests were conducted on the Tokyo Tech Mark III centrifuge (Takemura et al. 1999) at a centrifugal acceleration of 40g. The model configurations and the entire test results are presented and discussed in prototype scale units, unless indicated otherwise.

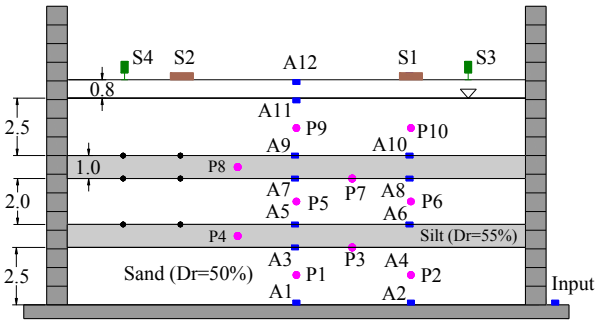

Table 2 Model configurations

Test code	Model series	Model details
Model 1	Uniform sand	D_{r1}=50-55%
Model 2	Continuous silt interlayered sand	D_{r1}=50-55%
		D_{r2}=55-60%, H_{silt}=1 m
		No discontinuity
Model 3 and Model 4	Discontinuous silt interlayered sand	D_{r1}=50-55%
		D_{r2}=55-60%, H_{silt}=1 m
		Drainage length = 5 m

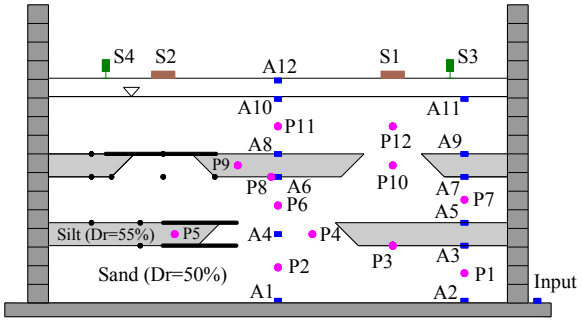

Figure 2 and Table 2 depict the model configurations. Model 1 is a homogeneous uniform sand profile, consisting of Toyoura sand only (Fig. 2(a)); Model 2 is a five layered homogeneous soil profile, consisting of three layers of sand and two continuous sandwiched silt layers of thickness 1.0 m (Fig. 2(b)); Model 3 and Model 4 are non-homogeneous soil profiles consisting of sand layers with two discontinuous silt layers of thickness 1.0 m (Fig. 2(c)). (d)). In Model 3, lower silt layer consists of one 5.0 m long (referred to as

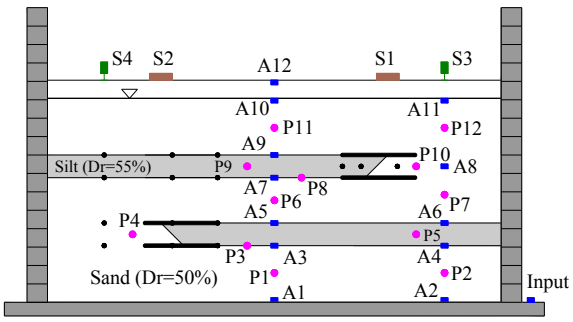

(a) Model 1

(b) Model 2

(c) Model 3

(d) Model 4

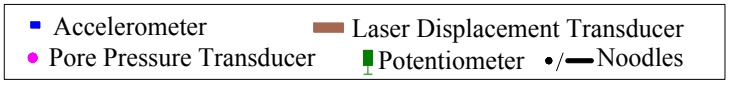

Figure 2 Model test configurations. All the units are in m in the prototype scale.

average length of discontinuity) i.e. the drainage layer is 5.0 m, dividing the silt layer into two equal portions of length 7.5 m each, and upper silt layer consists of two discontinuities at the quarter line of average length, i.e. drainage layer is 2.5 m each (Fig. 2(c)). In Model 4, lower and upper silt layers consist of only one average length of discontinuity in each layer at the edge near the left and right boundary, respectively (Fig. 2(d)).

For the entire centrifuge model tests, earthquake ground motion recorded at the Hachinohe Port in 1968 Tokachi-Oki earthquake (NS component) was applied at the base of the model parallel to the long sides of the container (Fig. 3). The ground motion applied to the shaker is plotted with a dotted line, and the input motions recorded at the base of the laminar container for each tests are plotted with solid lines. During the experiments, the accelerations were recorded by accelerometer and pore pressure transducers installed at different locations measured excess pore water pressures generated during dynamic loading. Laser displacement transducers and potentiometers measured the surface settlements.

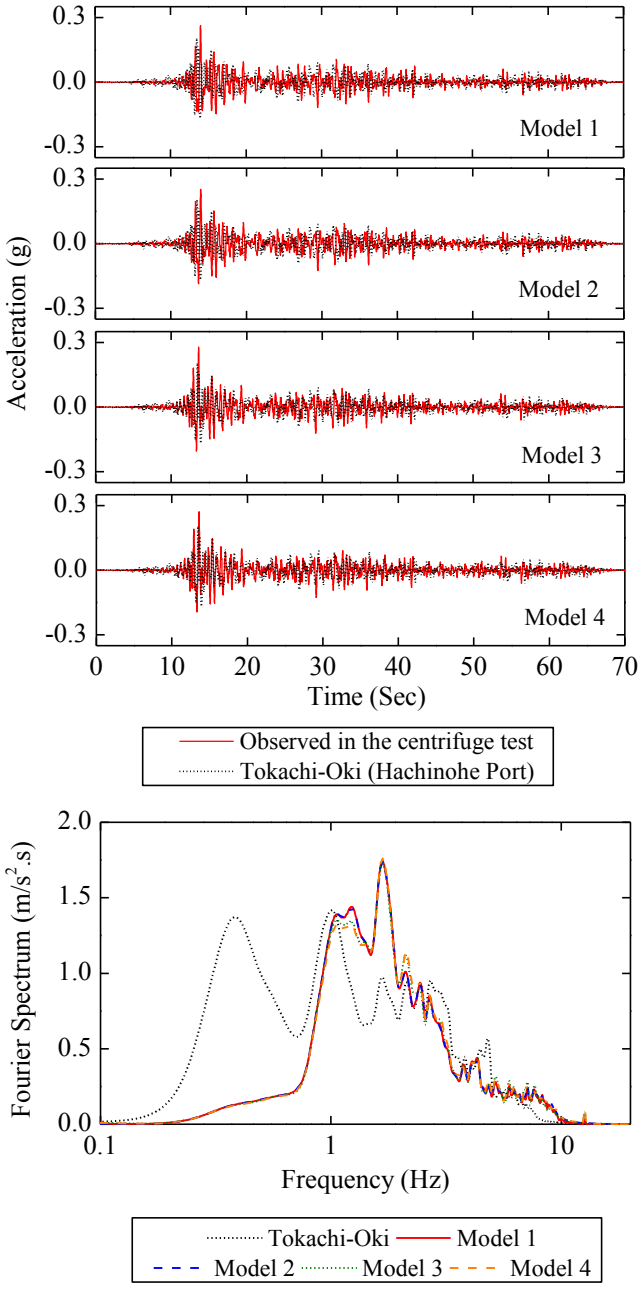

Figure 3 Acceleration time histories and Fourier spectra of input waves for Hachinohe Port record of 1968 Tokachi-Oki earthquake (NS component).

3. FINITE ELEMENT MODELING AND ANALYSIS

Two dimensional finite element analyses were conducted under the plain strain condition (Takahashi 2002). The extended sub-loading surface model proposed by Hashiguchi and Chen (1998) was adopted for the soil layers. Geo-material parameters of the soil layers are listed in Table 3 where G_S, specific gravity; e_0, initial void ratio; κ and λ, tangent of swelling and compression line; ν, poisson's ratio; σ_{ij0}, initial stress; $\sigma_{m0} = \sigma'_{ij}(1+\chi_0^2)/3, \delta_{ij}$, Kronecker's delta, K_0, coefficient of earth pressure at rest; k, hydraulic conductivity, and the other parameters represent the specific parameters for the constitutive model used. These parameters were determined so that numerical simulations on a single element fitted cyclic undrained triaxial test results. The acceleration recorded during the centrifuge tests were applied as earthquake motion. In order to

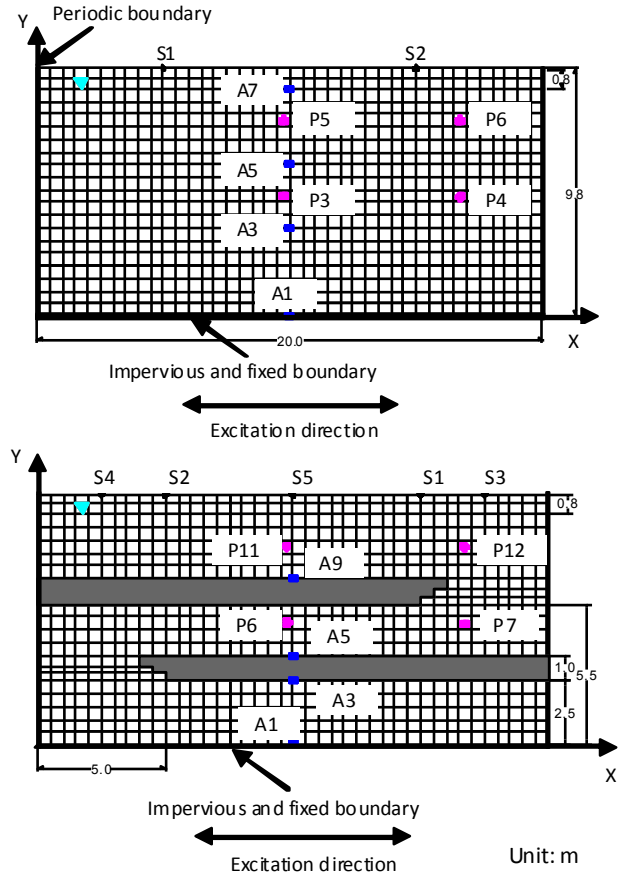
obtain the numerical solution, the differential equations were integrated along time. System damping was represented by stiffness proportional damping, and the damping ratio used was 1% in the first mode of free vibration of the system

Numerical simulations of the centrifuge model tests were carried out. Modeling and results of Model tests 1 and 4 are discussed here for brevity. Figure 4 shows the finite element discretization and boundary conditions of the test specimens. Model 1 and Model 4 consist of 800 and 880 quadrilateral elements, respectively. During the numerical simulations, acceleration time histories were sampled at A3, A5, and A7 locations for Model 1 and at A1, A3, A5, and A9 locations for Model 4, excess pore water pressure time histories were sample at P3, P4, P5, and P6 locations for Model 1 and at P6, P7, P11, and P12 locations for Model 4 and settlements were sampled at S1 and S2 locations for Model 1 and at S1, S2, S3, S4, and S5 locations for Model 4 (Fig. 4). P6, P7, and P12 were selected for Model 4 to observe the pore water pressure responses along the drainage path and are compared with the responses at P11, which lies far from the drainage path. At these key locations, computed accelerations, pore pressures and vertical settlement are compared to the corresponding experimental measurements.



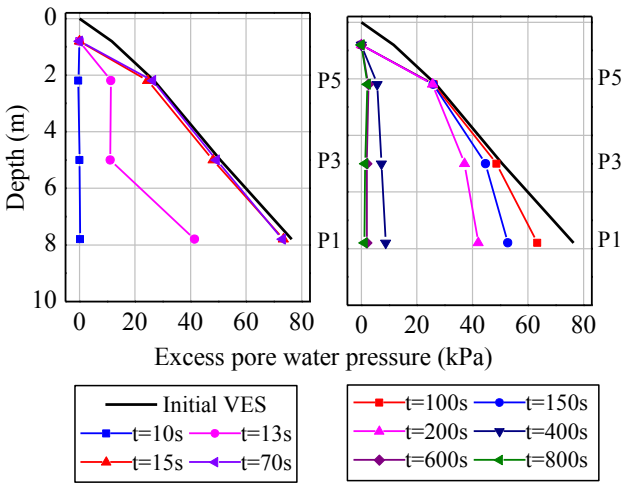


Figure 4 Finite element discretization and boundary conditions of centrifuge model test: (a) Model 1; and (b) Model 4).

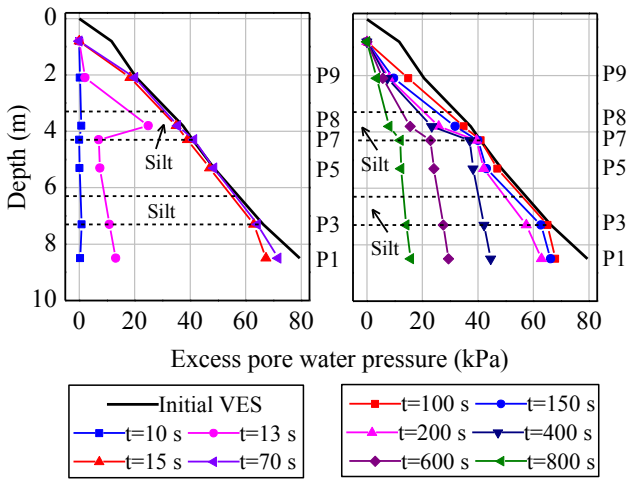
4. EXPERIMENTAL RESULTS



4.1 Excess pore water pressure (EPWP) responses

The excess pore water pressure, when reaches a value equal to the initial vertical effective stress (VES), indicates the occurrence of liquefaction; a state of initial liquefaction. The changes of excess pore water pressure at the centerline during shaking and after shaking for Models 1 and 2 are illustrated in Figs. 5 and 6. Results are also presented for PPTs located at centerline and quarter line after shaking for Models 3 and 4 (Figs. 7 and 8). Also shown in these figures are the positions of silt layers with dashed lines. In case of uniform homogeneous profile, excess pore water pressure generated rapidly, reaching liquefaction between 13-15 s at all the depths followed by rapid dissipation, shown by changes of excess pore water pressure isochrones for PPTs P1, P3, and P5 aligned at the centerline in Fig. 5.

(a) During shaking (b) After shaking

Figure 5 Excess pore water pressure isochrones measured on centerline in Model 1.

(b) During shaking (b) After shaking

Figure 6 Excess pore water pressure isochrones measured on centerline in Model 2. Dotted lines distinguish the sand and silt layer in the model.

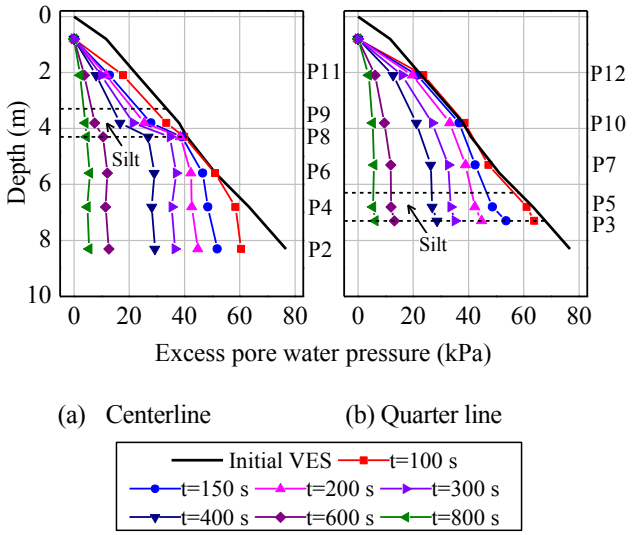


Figure 7 Excess pore water pressure isochrones measured in Model 3 after shaking.

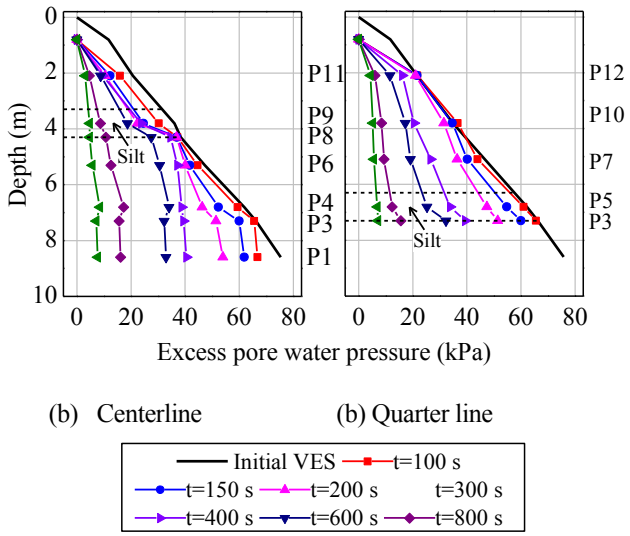

Figure 8 Excess pore water pressure isochrones measured in Model 4 after shaking.

The elapsed time for complete dissipation of excess pore water pressure is about 400 s (Fig. 4(b)). Excess pore water pressure generated rapidly in sand and silt in case of continuous and discontinuous layered soils, but the elapsed time for dissipation is quite different. The excess pore water pressures beneath the upper silt layer remain equal to the initial effective stress for a longer time even after the cessation of dynamic motion, indicating the trapping of pore water as shown by PPT P7 for Model 2 and PPT P8 for Models 3 and 4 (Figs. 6-8). It can be seen that the excess pore water pressures measured below the upper silt layer have nearly the same rate of dissipation after a certain time, which is about 400 s for continuous layered and 300 s for discontinuous layered soils (Figs. 6-8). The faster dissipation in discontinuous layered soils might be due to the presence of discontinuity in silt layer, allowing the pore pressure at high pore pressure region easily find a path to be drained out and transmit to the low pore pressure region through that path.

When the pore water pressures build-up during shaking, dissipation starts mainly towards the ground surface through the shortest path as possible (Ishihara and Yoshimine 1992). The silt layer being relatively impermeable hinders the upward movement of pore water, thus the possible shortest drainage path being the path through P4, P6, P10, and P12 for Models 3 and 4 (see Figs. 1(c) and 1(d)) and finally towards the ground surface. A comparison between EPWP for PPTs lying along the drainage path (i.e., P6, P10, and P12) and those lying away from the drainage path (i.e., P7, P9, and P11) for Models 3 and 4 is shown in Figs. 7 and 8. Excess pore water pressure is larger at PPTs lying along the drainage path than PPTs away from the drainage path. The difference in EPWP between PPTs lying along the drainage path and away from the drainage path is more pronounced at the shallow depths (for example at 2.1 m depth in Figs. 7 and 8). The difference in EPWP around the discontinuous region and below the upper silt layer creates a hydraulic gradient pointing towards the discontinuous region which led to the migration of pore water towards the discontinuity region. This causes the excess pore water pressure at discontinuity in silt layer, i.e., drainage layer remain larger for a longer period of time during its dissipation. As a result, the excess pore water pressure responses at P12 for Models 3 and 4, which lies above the discontinuity at 2.1 m depth, is significantly larger than that at P11, above the silt layer at the same depth (Figs. 7 and 8). Excess pore water pressure dissipates as soon as shaking stops at P11 while it remains equal to the initial vertical effective stress until 200 s at P12 (Figs. 7 and 8). The excess pore water pressure at P12 remains equal to the initial vertical effective stress until t=150 s for Model 3 and until t=200 s for Model 4. This is due to the effect of length and number of discontinuities in the silt layer. Model 4 consists of only one discontinuity in silt layer at the right part of length 5 m in upper silt layer, i.e., drainage layer of length 5 m, while Model 3 consists of two discontinuities in upper silt layer of length 2.5 m each. The presence of several discontinuities can accelerate the rate of dissipation. The excess pore water can easily transmit from the liquefied sand beneath silt layer (high pore pressure region) to the upper sand layer through the highly permeable discontinuities in silt layer (i.e., both drainage layers) due to seepage flow or migration of pore water.

4.2 Settlement responses

Settlement time histories at the surface measured by laser displacement transducers (LDTs) and potentiometers for all the tests are presented in Fig. 9. Two LDTs and two potentiometers were aligned along the centerline at the surface. An acrylic base plate was used as a target for LDTs so that they would not sink into the liquefied sand. Similarly, plexiglass was used to support the potentiometers. Potentiometers for the Models 1 and 4 malfunctioned; therefore, the records are not presented. A significant part of settlement takes place in all the tests during the initial process of pore pressure build-up, at the time when seismic

shaking is applied (up to 70 s). Nonetheless, a part of the settlement during seismic shaking might also be due compression of dry sand and penetration of target base plates, which was observed during the tests. The dissipation of excess pore water pressure becomes the dominant mechanism after seismic loading as the pore pressure generation ceases the supply of new mass of water, which is manifested as settlement. Therefore, the settlement induced during dissipation of EPWP after shaking is of great importance for assessing the uneven settlement induced by non-homogeneity of soil deposits and therefore is further compared in terms of rate of settlement.In case of homogeneous continuous profile, the rate of settlement is nearly the same at different locations (see for example, S1 and S2, Fig. 10(a)). In case of non-homogeneous soils, the rate of settlement is significantly larger above the discontinuity part than that above the silt layer (S1 and S2 Fig. 10(b)).

Figure 11 shows the rate of settlement after shaking at S1 for all the model tests for different time windows. It can be seen that the rate of settlement is presumably greater in Model 1 until 160 s. This reveals the rapid dissipation of excess pore water pressure within a shorter period of time due to a large value of permeability of Toyoura Sand and consequently more settlement is induced in Model 1. The continuous dissipation of excess pore water pressure in Model 3 and 4 for a longer period of time causes the rate of settlement quite significant for a longer period of time. Moreover, the rate of settlement for Model 3 and 4 is significantly larger for all the time windows than that for Model 2. In Model 3 and 4, there is a continuous supply of pore water pressure at the discontinuous part due to seepage flow or migration of pore pressure from the surrounding soil of high pore pressure, resulting in dissipation of excess pore water pressure for a longer period of time (P12, Figs. 7 and 8) and finally causing the rate of settlement greater at S1 in Model 3 and 4. It can be concluded that soil settlement is incorporated by the increment in the amount of pore pressure generation and drainage. However, the rate of

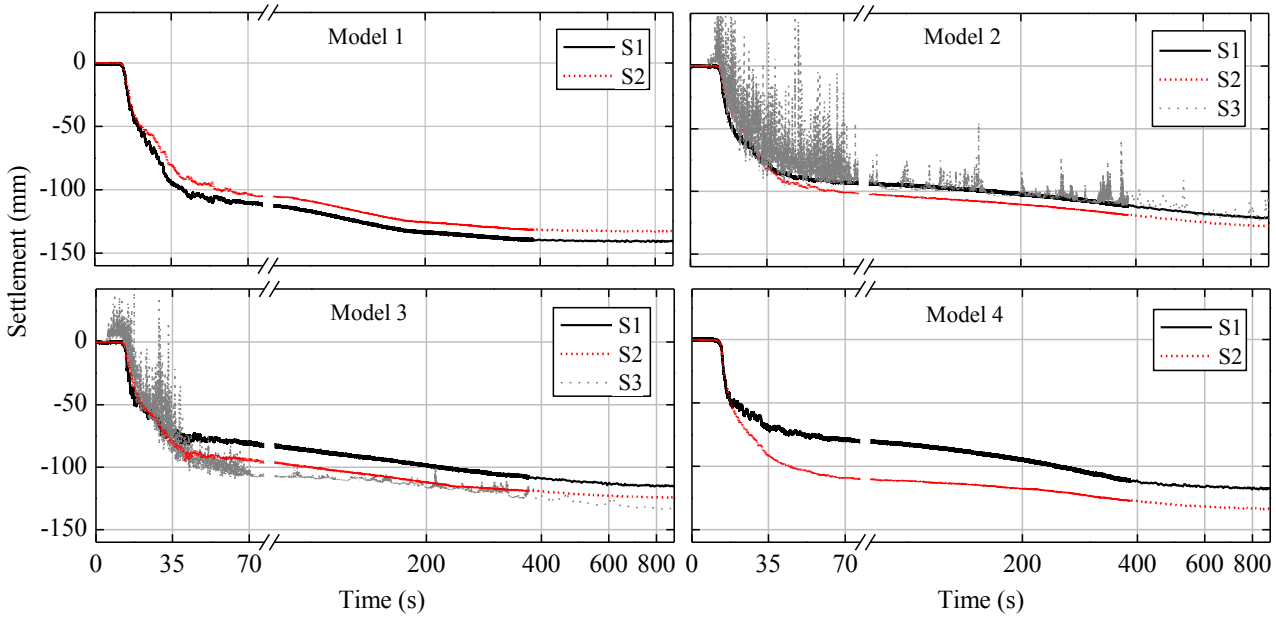

Figure 9 Settlement time histories for all the model tests.

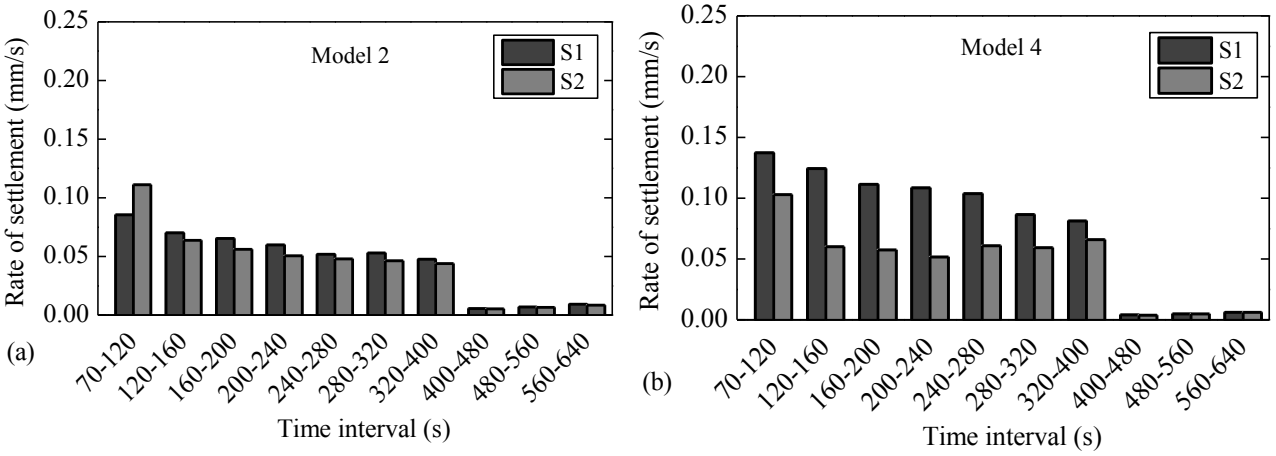

Figure 10 Variation of rate of settlement: (a) Model 2 and (b) Model 4

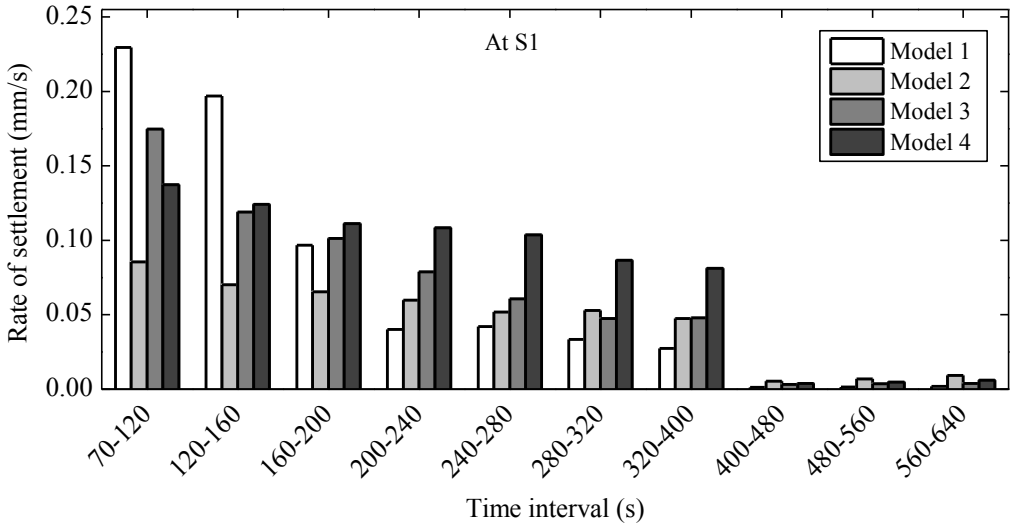

Figure 11 Variation of rate of settlement at S1 for all the tests.

settlement for Model 4 and Model 3 is fairly the same until 200 s, while it is substantially larger after 200 s for Model 4 than that for Model 3, indicating the larger rate of dissipation of excess pore water pressure at P10 in Model 4 (Figs. 8 and 11). The presence of only one discontinuity in silt layer concentrates the flow of excess pore water pressure from high pore pressure region to the permeable drainage layer.

The settlement induced by seepage flow after the earthquake at S1, S2, and S3, lying on the ground surface for all Models is presented in Table 4. The settlements at S1, S2, and S3 for Models 1 and 2 indicate the uniform settlement. The larger settlements at S1 and S2 for Model 3 and S1 for Model 4 and the smaller settlement at S3 for Model 3 and S2 for Model 4 indicate the uneven settlement. Meanwhile, the settlement at S1 is significantly larger for Model 4 than that for Model 3 and the settlement at S2 for Model 4, which is above the silt layer, is significantly smaller than that for Models 2 and 3. This shows that in Model 4, the excess pore water pressure is forced to drain through only one discontinuity layer, inducing the larger settlement at the discontinuity region, while in Model 3, the excess pore water is drained out through two discontinuities, reducing the volume of dissipation, inducing the smaller settlement difference.

Table 4 Settlement induced by seepage

Test code	S1 (mm)	S2 (mm)	S3 (mm)
Model 1	30.6	30

Model 3	35	32	27
Model 4	39.5	24.9	

5. NUMERICAL RESULTS

During liquefaction, a significant increase in soil permeability occurs by seismic excitation (Taiebat et al. 2010; Shahir et al. 2012). It is important to take an account of the permeability increase in the course of simulation of liquefaction. The actual variation of permeability incorporates the accurate simulation of excess pore water pressure generation and dissipation. Assuming a constant increased permeability is a common method for taking permeability variation into consideration in the process of liquefaction modeling (Shahir et al. 2012). Balakrishnan (2000) and (Taiebat et al. 2010) increased the permeability coefficient equal to 3.67 and 4 times the initial value, respectively for the simulation of the centrifuge experiment. In order to determine the effects of permeability of sand on the responses of excess pore water generation and dissipation and consequent settlement during liquefaction in non-homogeneous soil deposits, several numerical analyses were conducted by varying the coefficient of permeability of both liquefiable soil and relatively impermeable soil, i.e., constant permeability values of liquefaction of $k_{initial}$, 2.5 $k_{initial}$, and 5 $k_{initial}$. The coefficient of permeability ($k_{initial}$) of Toyoura sand and Silica No. 8 are 2×10^{-4} and 2×10^{-5} m/sec, respectively. The permeabilities of both soils were increased by 2.5, and 5 times the value mentioned above. The computed excess pore water pressures for all the permeabilities are similar to the centrifuge model tests in terms of the generation of excess pore water pressure, while the dissipation of excess pore water is quite different for differentpermeabilities. It can be seen that the dissipation of excess pore water pressure is quite faster with the increase in permeabilities. Moreover, the overall excess pore water pressure response was adequate when the permeability of $2.5k_{initial}$ was used.

Figure 12 shows the time histories of the excess pore

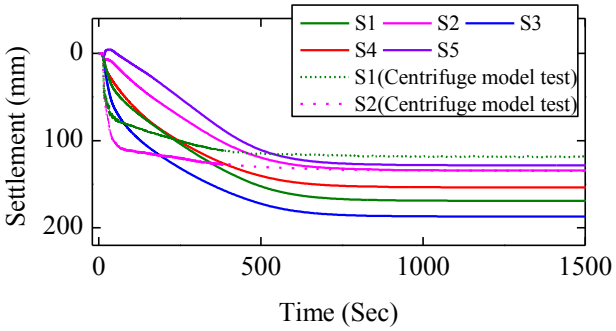

Figure 13 Settlement time histories for Model 4.

water pressure for P11 and P12 computed from numerical analysis when $2.5k_{initial}$, and centrifuge model tests for Model 4. Both numerical analysis and centrifuge model tests indicate that the excess pore water pressure is larger for longer period of time after shaking at the discontinuity part. Figure 13 presents the time histories of the vertical displacement at the selected locations for the numerical analysis when $k=2.5k_{initial}$ and the centrifuge model tests for Model 4. The final settlement is larger at S3, which lies completely above the discontinuity region, while the settlement at S1, which is at the adjacent of the discontinuity region, is also larger than that above the silt layer (S2, S4, and S5).

The permanent deformations of the model ground computed from numerical analysis along with the contours of excess pore water pressure distribution at t=354 sec are presented in Figure 14. The deformation at the discontinuity part is larger than that in the silt layer at the sand silt interface. The colored noodles placed at the sand-silt interface in the centrifuge model tests also showed the same deformation pattern. The permanent vertical displacement above the discontinuity part at the ground surface was found to be larger than that above the silt layer. Moreover, the contours of excess pore water pressure distribution shows the larger amount of excess pore water pressure above the discontinuity region.

6. CONCLUSIONS

This paper presents the centrifuge model test results and

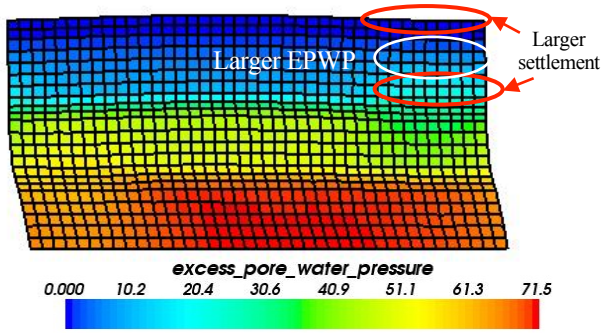

Figure 14 Permanent deformations of model ground with contours of excess pore water pressure distribution.

numerical simulation results, which investigated the effects of non-homogeneity on liquefaction in stratified soil deposits. Stratified soil consists of many sub layers of soil of different properties, which was defined by including periodically distributed discontinuous silt patches with lower permeability than the surrounding soil during centrifuge model tests. For comparison purposes, tests were also conducted on a model of continuous layered soil deposit and a model of uniform soil deposit.

It was found that, in stratified soil deposits the pore water was trapped beneath or within less permeable siltpatches due to the local migration of pore water and difference in permeability of the soils, restricting its upward movement. This indicates that the pore water finds a path to drain from high pore pressure region to low pressure region, which reveals that the presence of the discontinuous less permeable layer can have significant effects on the pore water pressure dissipation mechanism and drainage. It is determined that the presence of discontinuity of higher permeability in the less permeable soil layer can act as the drainage layer, through which the excess pore water pressure can be drained out during shaking and dominantly after shaking, as the dissipation of pore water becomes the dominant factor for settlement. Excess pore water pressure was accumulated for a longer period of time after shaking in non-homogeneous soil deposits compared with the uniform and continuous layered soil deposits, especially at shallow depths. The settlement induced by seepage at the surface above the discontinuity part was found to be larger than that above the silt layer, resulting in non-uniform settlements.

The modeling of liquefaction in field is complicated by the various uncertainties in stratigraphic details and geological non-uniformities. It is impossible to model the real soil profile exactly the same considering all the geological non-uniformities and taking into the account of uncertainties and various soil properties. Attempts have been made to model the multi-layered soil profile consisting of discontinuous relatively impermeable layer in order to enhance the understanding of the complicated mechanisms of liquefaction in non-homogeneous soil during earthquake loading and to improve the ability to account for them in practice.

Abstract: A series of centrifuge model tests has been carried out to study the effects of tunnel-induced soil movements of both surface and subsurface area by Potentiometers and Particle Image Velocimetry (PIV) software respectively. The tunneling process was simulated by reducing the diameter of the model tunnel for various ground loss values in 100g centrifugal acceleration. Two model acrylic pile groups which consist of four piles each with the different lengths were embedded in a dry sandy ground at either side of a tunnel. The effects of the horizontal distance between pile and tunnel (Xp), the relative pile tip position and tunnel (Zpe), and cover depth ratio (C/D) were investigated in this study. The horizontal and vertical movements and inclination of the pile cap, together with the observed soil movements is discussed.

1. INTRODUCTION

Ground settlements and movements are inevitably caused by the tunnel construction in soft ground and are the vital concern especially in urban areas. Therefore, the tunneling-induced soil movements have been long studied by many researchers not only ground surface settlement, but also subsurface settlement (Mair (1996)). The potential effects of the ground movements associated in the tunnel construction must be properly considered in the design and construction of tunnel to avoid the adverse effects, i.e., damages of the adjacent structures.

Several researchers have proposed numerical methods for evaluating the behavior of existing piles and inverse effects of nearby tunneling on them. However, there are still some uncertainties and the validation of the proposed methods are required, especially for the effects of many factors, such as, types of soil, types of tunneling and imposed soil movement or ground loss by tunneling, tunnel depth, types of piles (single and group piles), pile construction methods, depth and location of piles, initial pile bearing resistance, load supported by piles, and so on (Chen et al. (1999)).

Physical modeling, especially centrifuge modeling is a useful tool to tackle these problems with its capability of creating the similar stresses in a small scale model to those of the full scale prototype. This similitude is the critical condition in a model in which most of stresses and their changes are caused by weight of soils, e.g., excavation of soil in tunneling process. In the early stage of tunneling study using the centrifuge, rubber bags with air pressure or liquid pressure were mainly used to investigate the stability of tunnel and deformation of soils (Mair (1979) & Takemura et al. (1999)). The rubber bag method has some uncertainty in the induced tunnel deformation and pressure acting on the tunnel. To control the tunnel perimeter displacement more accurately, mechanical tunneling simulator was developed in which a tapered inner core is pulled to decrease the diameter of outer tunnel (Katoh et al (1998)).

In this study, a series of centrifuge model tests were carried out to scrutinize the tunneling induced soil movement and its effect on adjacent group pile. In the tests, mechanical type 2D tunneling machine was used to impose the ground deformation in dry sand. From the observed bending moment and axial force of the piles, and the horizontal and vertical movement and inclination of the pile cap, together with the observed ground displacements, the tunnel-soil-pile interaction is discussed.

2. CENTRIFUGE MODEL TESTS

2.1 Shield model tunnel

To simulate tunneling process in a centrifuge models, various techniques have been applied. Loganathan and Poulos (2000) described an oil volume control technique. A syringe pump was fabricated to control the volume of silicone oil in the aluminum. Similarly, Mair (1979) introduced the air pressure method by using the reinforced rubber bag. This rubber bag can maintain its diameter and circular shape before the air pressure was lowered to reduce the model tunnel diameter.

Table1 Specification of model piles

Properties	Model	Prototype
Material	Acrylic	RC Concrete
Diameter	10mm	0.5m
Thickness	1mm	Solid
Young's Modulus	3.2 Gpa	20-28 Gpa
Embedment depth	140mm 210mm	14m 21m
Bending rigidity EI (GNm^2)	$9.3x10^{-10}$	$(6.2\text{-}8.6)x10^{-2}$

In this study, the Mechanical type of shield tunneling machine is employed. This machine is composed of a steel ring and a wedge shaped shaft as shown in Figure 1. The ring is divided longitudinally into six parts, and covered with a steel sleeve (t=0.5 mm) and a rubber membrane (t=0.2mm). The machine is located at the central part of a model container. The wedge shaped shafts are connected to a screw jack behind the container, which can move horizontally inward and outward. This process will change the position of the ring in the radial direction.

As a result, this model tunnel covered with rubber can expand or contract its diameter. This rubber is used for a consistent circular shape transformation of the tunnel when it reduces or increases the diameter. Moreover, this rubber membrane also prevents sand intrusion inside the model tunnel. The initial diameter of the shield model is 70 mm. The diametrical velocity of expansion and contraction is controlled from 0.1 mm/sec to 1.3 mm/sec.

2.2 Model pile and pile cap

Model piles were designed to replicate a circular concrete pile (Table1). By using the relation of flexural rigidity of prototype (E_pI_p) equal to N^4 of the model (E_mI_m), where N is the model linear scale (in these tests N = 100), or the centrifuge acceleration ratio, E is Young's modulus, I is the area moment of inertia, and the subscripts m and p denote prototype and model respectively.

(a) (b)

Figure 1 Group piles model : (a) Short pile ; (b) Long pile

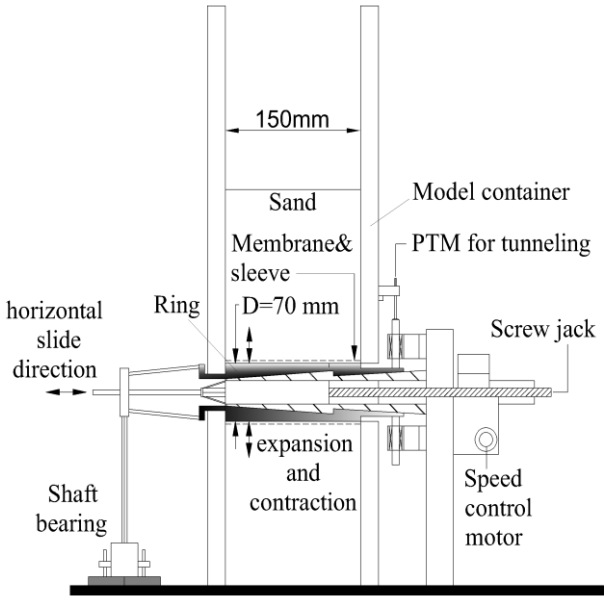

Figure 2 Shield tunneling machine equipped in the model

An acrylic material with Young's modulus of 3.2 GPa was selected to make model piles of 10 mm outer diameter and 8 mm internal diameter with an embedded length of 210 mm and 140 mm (Figure 3). One group pile consists of two strain gauges piles in the front row and two dummy piles in the rear row as described in Figures 2&3. Inside the hollow acrylic pile, three types of strain gauge were placed, namely, axial strain type (to directly measure axial strain at the pile end), bending strain type (to directly measure bending strain along a pile) ,and strain gauge which can measure both axial forces and bending moment as shown in Figure 3.

20 mm thick stainless steel made pile cap rigidly held the piles vertically at a center-to-center spacing of 50 mm. Acrylic or aluminum made plate was fixed on top of the pile cap to add an extra-weight on the pile group.

2.3 Sample preparation

Tokyo Tech Mark III Centrifuge was used for the experiments.

Models were placed and tested in an aluminum box which had an internal plan area of 150 mm by 550 mm and an internal height of 600 mm. Front wall of the container is made of acrylic plate, through which the ground movement can be observed.

Two assemble group piles were placed on either side of the tunnel at the predetermined vertical and horizontal locations. Dry Toyoura sand (Table 2) was pluviated with a hopper at a constant falling height and flow rate. The sand was poured by layers in 20 mm thickness each until it reached the designed depth. The target relative density (D_r) of the sand was about 80%. The minimum distance between container sidewall and the model pile is 120 mm which is considered adequately enough to minimize the boundary effects (Lee and Chaing (2007)).

Table2 Specification of Toyoura sand

Specific gravity (G_s)	2.65
Mean particle diameter (D_{50})	0.19
Coefficient of uniformity	1.62
Maximum void ratio (e_{max})	0.973
Minimum void ratio (e_{min})	0.609

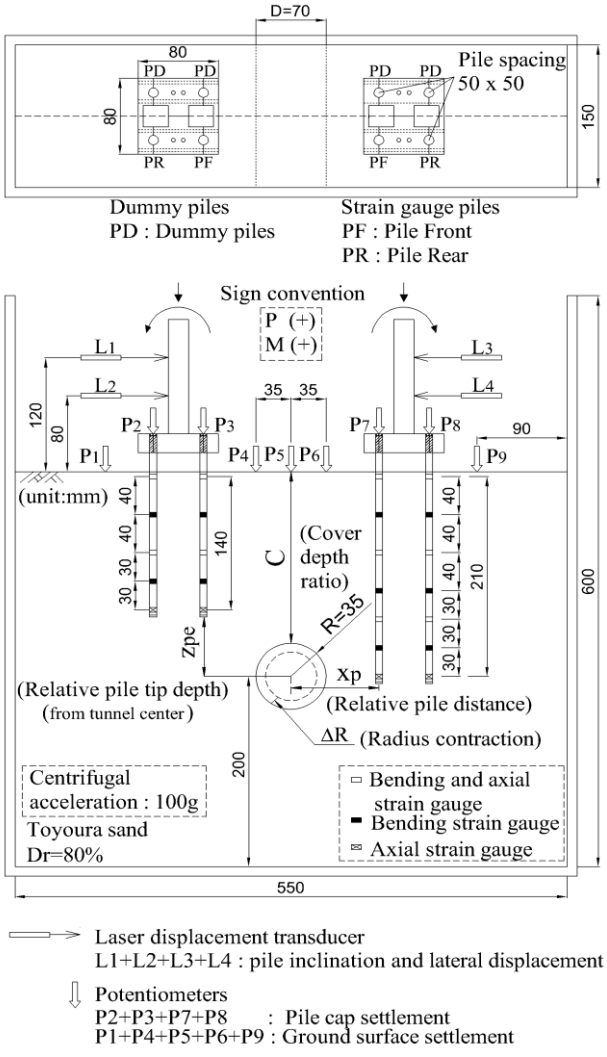

Figure 3 Test setup and instrumentations

After the sand preparation, the box was mounted on the centrifuge platform. Pair of potentiometers and laser displacement transducers were placed to measure the displacement (horizontal and vertical movements, and inclination) of each pipe cap and potentiometers were placed on the sand surface to measure the surface settlements as shown in Figure 3. A digital camera was fixed at the front of the box to capture the image of ground surface movement.

2.4 Test procedures and test conditions

Centrifuge model was accelerated to 100g. After confirming the steady condition of each measurement, the tunneling test was started reducing the diameter from 70 mm to 60 mm for simulating the tunneling process two dimensionally.

Particle Image Velocimetry (PIV) technique was used (White et al. (2003)) to measure the soil movements. Geo-PIV was applied for the data processing (White (2003)). The radius contraction of the tunnel was measured by potentiometer, which is converted to ground loss ratio ($\Delta V/V_o$), where ΔV is a volume of tunnel contraction, and V_o is an initial volume of model tunnel (D=70 mm).

Under 100g centrifugal acceleration, the model used in this study has a tunnel model of 7m diameter and pile group with the length of 14m and 21m depths in a prototype scale at either side of the tunnel.

In the following section, test results are presented using model scale. The displacement, axial force and bending moment of the prototypes are 100, 10^4, and 10^8 times those of the model.

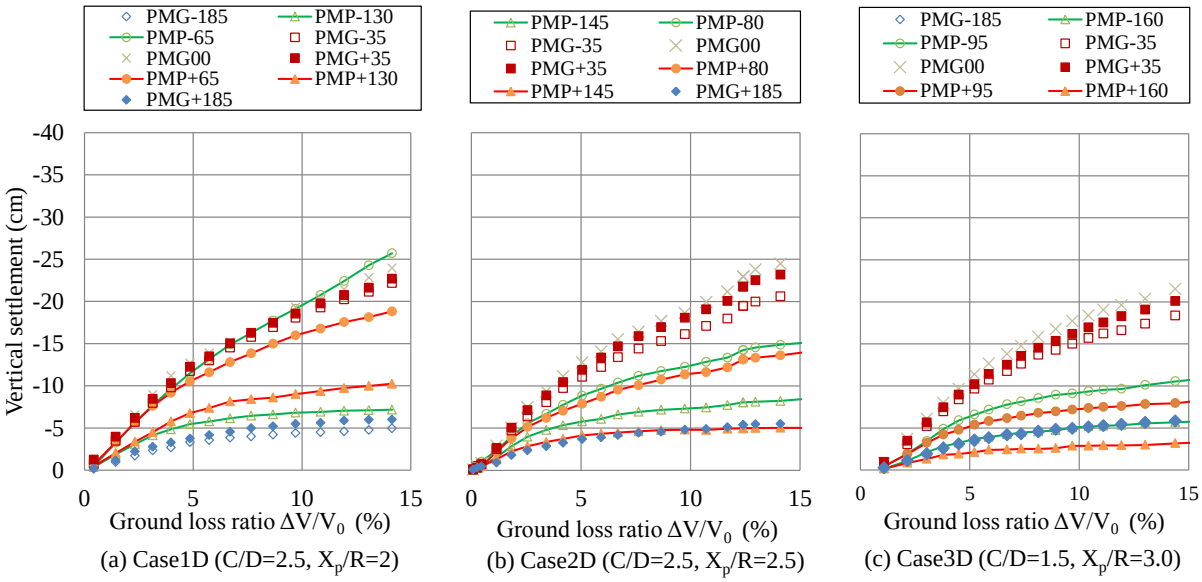
The series of tests can be divided into three series (Table 3). The test conditions of the eleven cases are the distance of piles from the tunnel (X_p), the relative pile tip position and tunnel (Z_{pe}), and the tunnel cover depth (C/D),which determines the relative depth of pile to the tunnel for the given pile length. In Table 3 the test conditions are given by normalized values, C/D, X_p/R, Z_{pe}/R, where R is the tunnel radius as shown in Figure 3.

3. TEST RESULTS AND DISCUSSIONS

3.1 Soil surface settlement

Surface settlements was measured by potentiometers resting on the pile cap and soil surface of the dry Toyoura sand sample. The ground surface settlement is slightly different by the cases.

In the Figure 4, PMG and PMP mean potentiometer on the ground surface and on the pile cap respectively. The value after these abbreviations denotes a horizontal location of potentiometer from the center line of the model tunnel. The positive and negative values mean the position of potentiometers are on the right-hand side and left-hand side respectively. The settlement increases with increasing the ground loss ratio. In addition, the graph displayed nonlinearity between the settlement and ground loss ratio. In the small value of ground loss ratio less than (5 %), rate of increment is higher than a large number of ground loss ratio. The pile group models tend to show less settlement in the case in which a horizontal distance is far from the tunnel model (Figure 4b). In addition, when a pile tip level of long pile below the model tunnel, the pile cap settlements were reduced (Figure 4c).



3.2 Shield model tunnel

By using PIV technique, soil subsurface movement is able to investigate. The sequence pictures which were captured during the reduction of tunnel diameter were used in GeoPIV program. This program was computed by module in matlab software.

The soil layers above a tunnel model were divided by the center of patches in GeoPIV software as shown in Figure 5(a).

Table 3 Test conditions

Figure 4 Ground surface settlement and pile cap settlements in various ground loss ratio measured by potentiometer

The displaced vector (Figure 5 (b)) show a corresponding trend for Gaussian distribution profile where the highest movement is concentrated in the center-line above the tunnel. The resolution from digital camera of canon power-shot G7 is 180 pixels per 1 inch. Therefore, this range is converted to 0.14 mm/pixels in real object displacement. The patch size which used in this analysis was 128 pixels or 18 mm In addition, the search zone length area between sequence images was imposed to 12 pixels. The first layer was at 12 mm from the ground surface level and the deepest layer was at 138 mm and 84 mm for C/D ratio of 2.5 and 1.5respectively.

The settlement profile slightly decreased as a position of potentiometers far from the tunnel axis. Furthermore, the deepest layer showed the highest vertical soil movement into opening tunnel

3.3 Pile displacement and ground loss ratio

The safety of structure is one of the most important for designation of all buildings. For this reason there is highly recommend for predicting the movement of the structure not even the vertical settlement but also the lateral movement and the inclination of the designed building.

The effect from a relative horizontal distance (X_p) is showed in Figure 6 in which this parameter is divided by radius of tunnel. The induced settlement is significantly influenced by the position of pile and tunnel.

The rate of settlement profile significantly increased in the interval value of X_p/R equal to 2.0 - 2.5. In contrast, the interval value of X_p/R equal to 2.5-3.0 showed small settlement value. In the small ground loss value, the induced settlement showed a small value compare to the large ground loss value.

This result is different from Lee and Chaing (2007) who propose that the settlement of single pile is significantly large even a small magnitude of ground loss value.

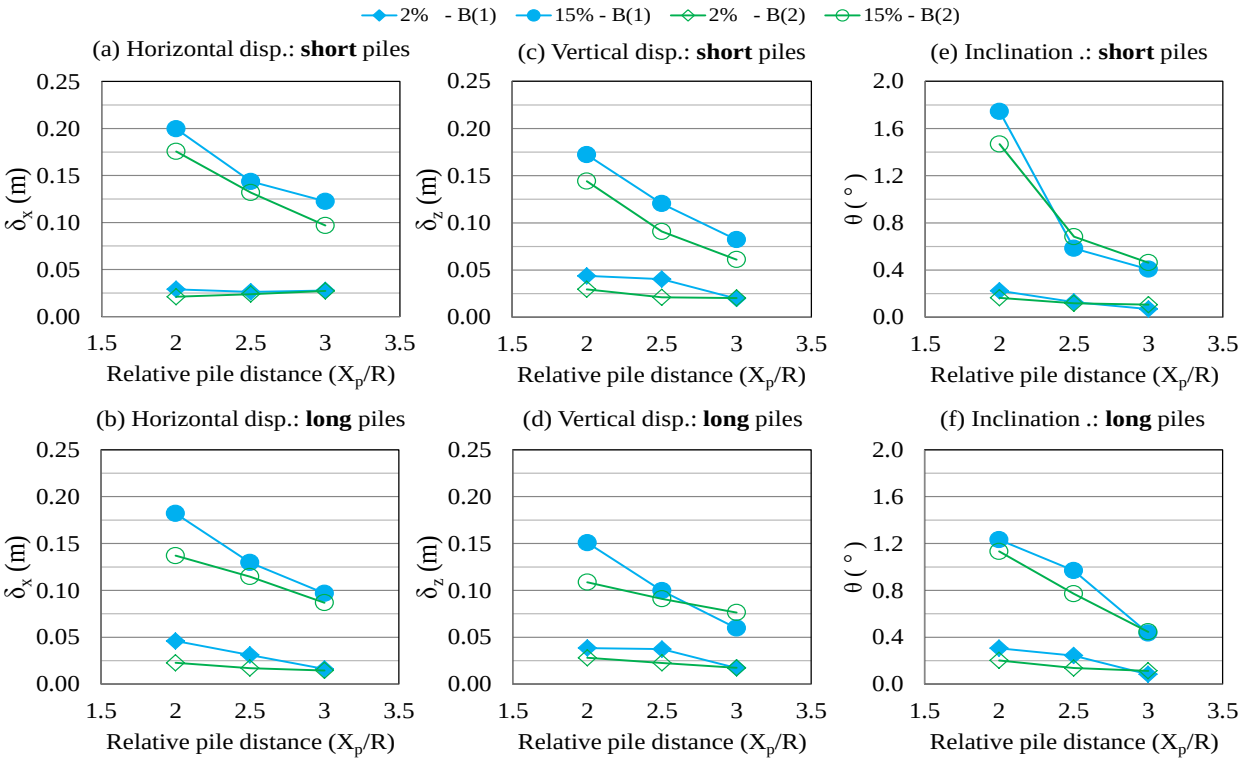

Figure 6 Comparison of displacement in term of relative distance (X_p/R): (a).(b) horizontal displacement; (c),(d) vertical displacement; (e),(f) inclination angle

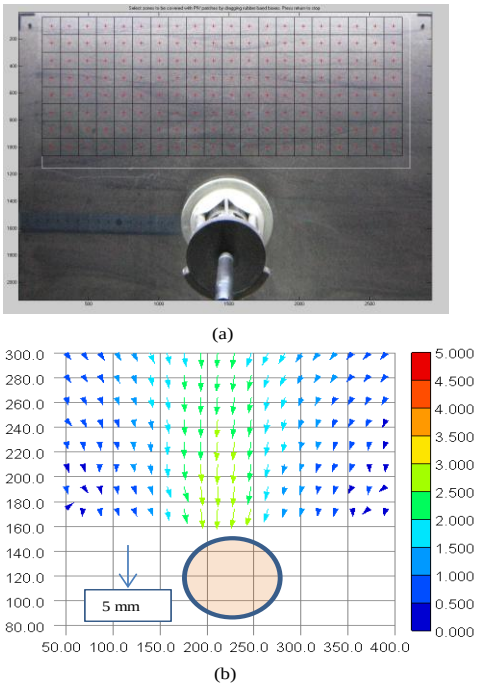

Figure 5: PIV analysis: (a) divided patches of series pictures; (b) vectors of soil movement

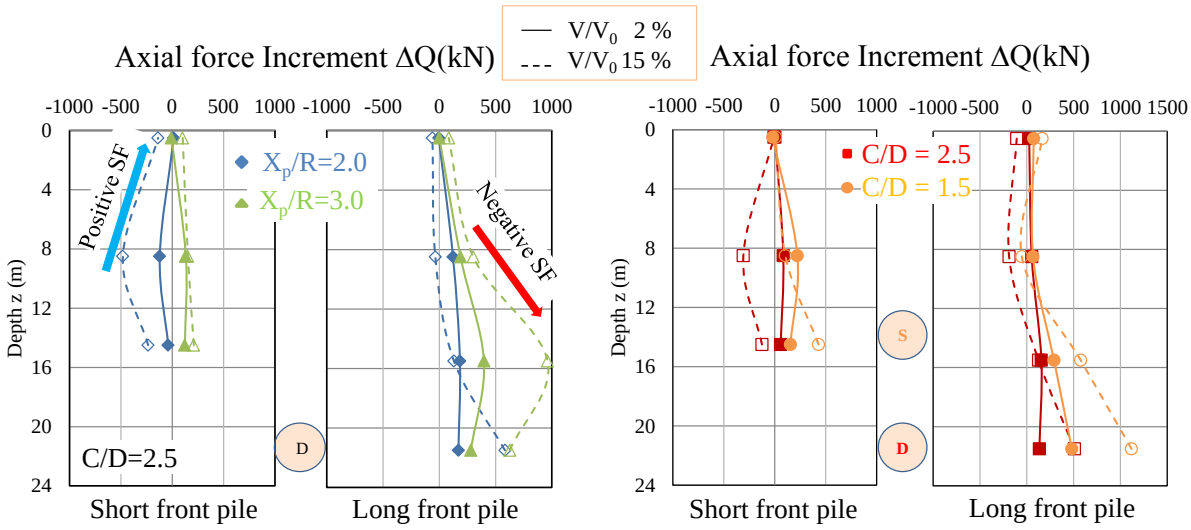
The result may come from the pile group which can distribute extra loads to another pile reducing the settlement into small value. The short group pile of different working load showed the normal trend of settlement.



3.4 Axial force and bending moment

Tunneling process causes the soil movement which reacts with the pile foundation. As a result, the existing pile will develop extra bending moments and extra axial forces on the pile. Ground loss ratio of 2% and 15% were selected for working load and failure conditions respectively. The axial loads on the pile are attributed to the mobilization of the relative displacements between the surrounding soil and the pile during tunneling process. The upper part of pile in the nearest case, with $X_p/R=2$, showed a positive skin friction which is caused by larger pile settlement than the subsurface settlement. Although, this magnitude become less when the pile is far from the tunnel as shown in Figure 7(a). Pile groups which have cover and depth ratio equal to 1.5 develop negative skin friction since a pile settlement become less when the value of relative pile tip level is increased (Figure 7(b)).

4. CONCLUSIONS

The following conclusions were summarized in this study.

1.) Tunnel induced subsurface settlement can be approximated by a Gaussian distribution curve. The settlements above the tunnel are larger for the deeper depth than the shallower depth, but the settlements at outside from the tunnel are smaller for the deeper depth than those of the shallower depth.

(a) (b)

Figure 7 Comparison of axial force development at front pile positions with 2% and 15% ground loss: (a) horizontal distance effect; (b) relative pile tip depth effect

2.) The pile groups embedded above the tunnel shows large displacements, which increase as the pile closes to the tunnel. The inclination rapidly increase for the horizontal distance of the front pile from the tunnel center less than 2.5 tunnel radius, especially for the large ground loss.

3.) The mobilized pile shaft friction is negative due to the large soil movement relative to the pile, except of the front pile with shallower depth than the tunnel and closer to the tunnel.

4.) The fixity of pile by the cap of pile group creates the largest bending moment at the pile top.

Abstract: In order to verify seismic performance of a structure, it is necessary to evaluate the effect of dynamic soil-structure interaction appropriately. One of the reliable models that can account for basemat uplift as well as soil yielding is the macro-element model for shallow foundations. This paper studies stress reduction effects induced in structures (such as bridge piers) due to basemat uplift and soil yielding by the use of a macro-element model for foundations placed on sands. A superstructure is modeled by a lumped mass and Bernoulli-Euler beam. A foundation-soil system is modeled as four cases; (1) fixed base, (2) elastic soil, (3) elastic soil with basemat uplift and (4) elasto-plastic soil with basemat uplift. Time histories that have different frequency characteristics are considered as input motions to the models. Response comparisons of the models show remarkable reduction of section force due to basemat uplift and soil yielding. Therefore, it may be concluded that the degree of base shear reduction depends on the frequency characteristics of the input motions relative to the system.

1. INTRODUCTION

As the design method shifts to performance-based design, it becomes more important to accurately estimate the response of superstructure accompanied by foundation rotation and basemat uplift. Basemat uplift is reportedly induced even by weak to medium ground motions (Fukui et al., 1999), hence, it is necessary to incorporate the effect of basemat uplift into a design code.

Hayashi (1996) assessed slightly damaged buildings standing on the most severely damaged area during the 1995 Hyogoken-Nanbu Earthquake. By using numerical simulation, he has studied damage reduction effect due to basemat uplift of buildings which were subject to strong ground motions, and showed that the damage reduction effect sometimes becomes remarkable depending on structural parameters and input motions. The finite element model was used in his analysis treating soil as a linear or equivalent linear medium.

This paper studies the reduction effect of a section force induced in the structure due to basemat uplift and soil yielding by the use of a macro-element model considering four kinds of foundation-soil models such as (1) fixed base (2) elastic soil (3) elastic soil with basemat uplift and (4) elasto-plastic soil with basemat uplift. Time histories which have different frequency characteristics are considered as input motions in the model.

2. MACRO-ELEMENT MODEL

In this study, a macro-element model developed by Nakatani et al. (2008) is employed to study stress reduction effect of structures due to basemat uplift and sand soil yielding. A brief overview is described in this section. Details can be referred to in Shirato et al. (2008).

2.1 Relationship between displacements and loads of a macro-element model

In the macro-element model, the foundation is assumed to be rigid, and foundation-soil model which is subjected to combined loads is modeled as one element. Displacements and loads at the center of the footing are defined as shown in Figure 1 and the following equations.

$$x = \begin{pmatrix} v & u & \theta \end{pmatrix}^T \tag{1}$$

$$F = \begin{pmatrix} V & H & M \end{pmatrix}^T \tag{2}$$

where the superscript T stands for transposition. The relationship between incremental displacements and loads is expressed by

$$dF = \left(D^{el} + D^{up} + D^{pl} \right)^{-1} dx \tag{3}$$

where D^{el}, D^{up} and D^{pl} are elastic compliance, uplift compliance and plastic compliance, respectively.

2.2 Elastic compliance

In order to determine elastic compliance, equivalent elastic spring coefficients corresponding to the vertical, translational, and rocking component are used based on Gazetas(1991). The coefficients for a rectangular foundation are expressed by

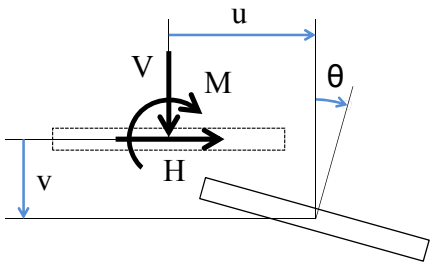

Figure 1 Definition of displacements and loads for the macro-element model

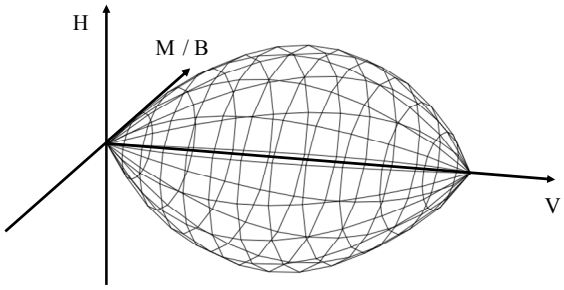

Figure 2 Schematic of bearing capacity surface

$$K_v = \frac{4.54G(B/2)}{1-v} \tag{4}$$

$$K_h = \frac{9G(B/2)}{2-v} \tag{5}$$

$$K_r = \frac{3.6G(B/2)^3}{1-v} \tag{6}$$

where G and v are shear modulus and Poisson's ratio of the underlying soil and B is the footing length. Frequency dependence of the coefficients is ignored.

2.3 Uplift compliance

Uplift compliance is determined based on the following model for uplift. $\theta^{up} - M$ relationship is expressed by

$$\theta^{up} = 0 \ \ (M \le M_\alpha) \tag{7}$$

$$\theta^{up} = \left\{ \frac{4}{(3 - M/M_\alpha)^2} - \frac{M}{M_\alpha} \right\} \theta_0 \ \ (M > M_\alpha) \tag{8}$$

where M_α and θ_0 are moments that are influenced by soil plasticity and rotation at which the uplift initiates. Then $v^{up} - M$ relationship is expressed by

$$v^{up} = 0 \ \ (M \le M_\alpha) \tag{9}$$

$$v^{up} = -\frac{B}{2} \left\{ \frac{4}{(3 - M/M_\alpha)^2} - \frac{4}{(3 - M/M_\alpha)} + 1 \right\} \ \ (M > M_\alpha) \tag{10}$$

2.4 Plastic compliance

In order to determine plastic compliance, bearing capacity surface is used. A schematic diagram of this is shown in Figure 2 Shirato et al. (2008) assumed following expression for bearing capacity surface.

$$f_{cr} = h^2 + m^2 - \xi^2 (1 - \xi)^{2\zeta} = 0 \tag{11}$$

where $\xi = V / V_m$, $h = H / (\mu V_m)$, $m = M / (\psi B V_m)$ and V_m is bearing capacity in terms of centered vertical loading. Parameters μ and ψ are tangents at the origin on the $V - H$, $V - M$ planes, respectively. To describe plastic deformations, a yield function is defined based on Nova and Montrasio (1991) as follows:

$$f_y = h^2 + m^2 - \xi^2 (1 - \xi / \rho_c)^{2\zeta} = 0 \tag{12}$$

where ρ_c is the hidden parameter that specifies instantaneous size of the yield surface and translates instantaneous combined loads into the norm of an equivalent vertical force. In order to relate size of the yield surface and incremental displacements, the hardening rule and flow rule are required. As for the hardening rule, isotropic hardening, which defines similar bearing capacity surface and yield surface, is assumed. The hardening function is expressed by

$$\rho_c = 1 - exp\left(-\frac{R_0 v_c}{V_m} \right) \tag{13}$$

where R_0 is initial gradient of the $V - v^{pl}$ curve. v_c is expressed by

$$v_c = \left\{ \left(v^{pl}\right)^2 + \left(\alpha_M u^{pl}\right)^2 + \left(\gamma_M B \theta^{pl}\right)^2 \right\}^{0.5} \tag{14}$$

where α_M and γ_M are non-dimensional parameters that incorporate the contribution of horizontal displacement and rotation into hardening. As for the flow rule, a non-associated flow rule is adopted. Regarding such a non-associated flow rule, a plastic potential function is defined as follows:

$$g = \lambda^2 h^2 + \chi^2 m^2 - \xi^2 (1 - \xi / \rho_g)^{2\zeta} = 0 \tag{15}$$

where $\lambda = \mu / \mu_g$, $\chi = \varphi / \varphi_g$, μ_g and φ_g are parameters that

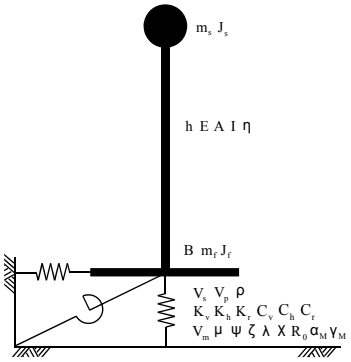

Figure 3 Schematic of structure-foundation-soil system

Table 1 Parameters of structure-foundation-soil system

Parameter	Unit	Value

Parameter of hardening function γ_M		1.7

specify the shape of the plastic potential surface.

3. STRESS REDUCTION AGAINST A REAL EARTH QUAKE

Here, stress reduction effects of a structure-foundation-soil system against real earthquakes is reviewed. The system was subjected to different types of acceleration-time histories. A foundation-soil system is modeled as four cases; (1) fixed base, (2) elastic soil, (3) elastic soil with basemat uplift and (4) elasto-plastic soil with basemat uplift.

3.1 Structure-foundation-soil system

Schematic and parameters of the structure-foundation-soil system is shown in Figure 3 and Table 1. The parameters were set based on Nova and Montrasio (1991) and Nakatani et al. (2008). A superstructure was modeled by a lumped mass and Bernoulli-Euler beam. The total degrees of freedom of the system were six; consisting of three degrees of lumped mass and three degrees of the macro-element. A foundation-soil system is modeled as four cases; (1) fixed base, (2) elastic soil, (3) elastic soil with basemat uplift and (4) elasto-plastic soil with basemat uplift. Frequency dependence of elastic compliances was ignored.

3.2 Stress reduction against a real earthquake

The degree of stress reduction effects of a structure was studied. The aforementioned structure-foundation-soil system is subjected to input motions in the time domain. Two kinds of ground motions are considered as the input motions here; subduction type earthquake (acceleration time history that was recorded at a port in Hachinohe during the 1968 Tokachi-Oki Earthquake) and inland type earthquake (acceleration time history observed at JR Takatori station during the 1995 Hyogoken-Nanbu Earthquake). These time histories are shown in Figure 4 and 5. For conducting nonlinear analysis with the macro-element model, time step for seismic response analysis was set at 0.0001 seconds by interpolating the input time histories which were originally recorded at 0.02 second intervals. A linear acceleration method was used for the numerical integration.

The time history of base shear that occurred in the structure for subduction zone type earthquake is shown in Figure 6. The thin black line, the thin blue line, the thick red line and the thick green line correspond to responses for fixed base case, elastic soil case, elastic soil with basemat uplift case and elasto-plastic soil with basemat uplift case, respectively. The case (1) show different time responses from other cases (this difference implies the wave radiation effect). However, linear case and nonlinear cases show similar time responses. This means that significant stress reduction effect due to basemat uplift and soil yielding are not apparent in this case.

Secondly, an inland type earthquake is considered as input motion into the system. Calculated responses are shown in Figure 7. Meanings of curves are the same as Figure 6. Responses show significantly different waveforms. The fixed base case and elastic soil case show similar time responses (this difference implies the wave radiation effect). However, when basemat uplift is considered, the base shear becomes significantly different from linear cases. Nonlinear cases show drastic reduction of base shear, thus longer period motions are implied. When soil yielding is considered, the period of the motion becomes even longer.

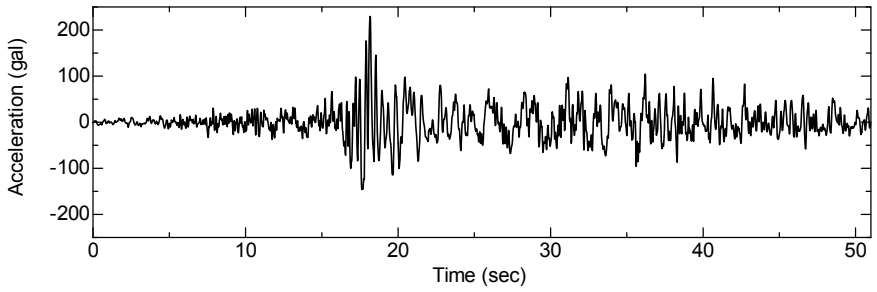

Figure 4 Acceleration time history

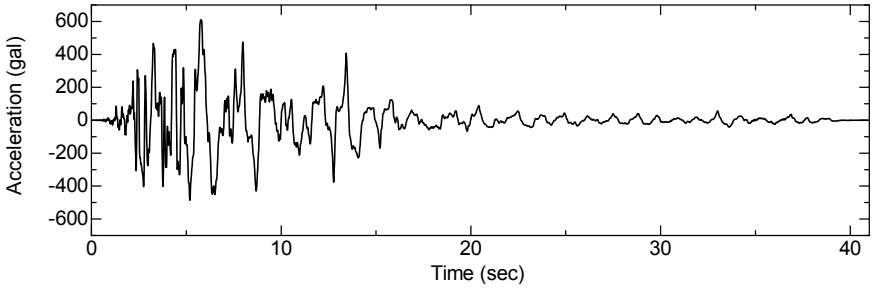

Figure 5 Acceleration time history

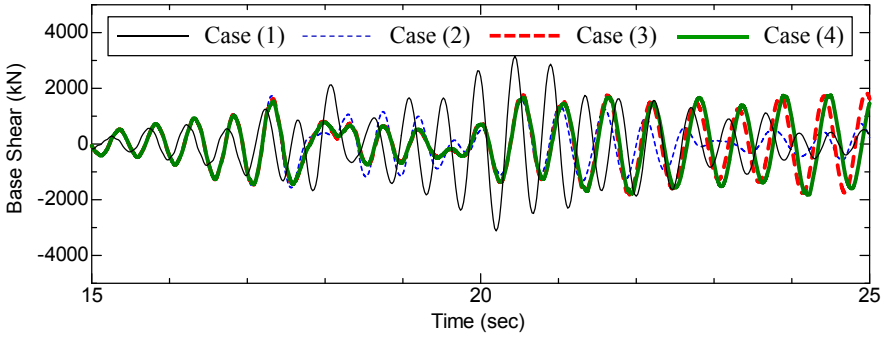

Figure 6 Base shear time history

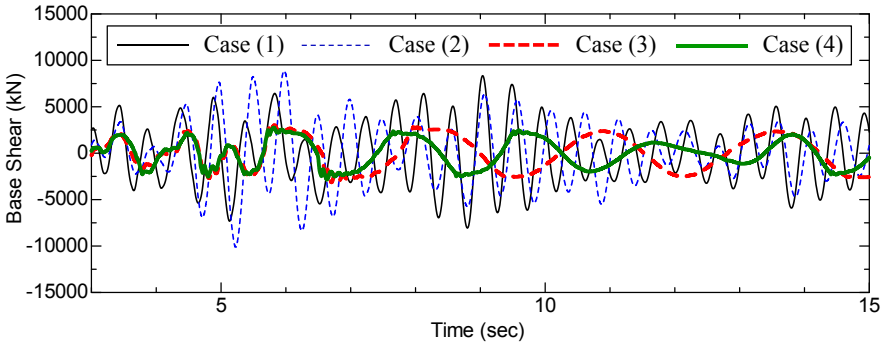

Figure 7 Base shear time history

We can recognize from these results that stress reduction of structures due to basemat uplift and soil yielding can occur in some cases depending on input ground motions. In order to examine factors that might bring a differences in the level of stress reduction, some artificial input motions that have different frequency characteristics are considered in the next section.

4. STRESS REDUCTION OF STRUCTURE FOR INPUT MOTIONS OF DIFFERENT FREQUENCY CHARACTERISTICS

The same structure-foundation-soil system is considered. As the input motion, harmonic waves that have different frequency characteristics are given. An example of the harmonic seismic wave which has a natural frequency of 1.78Hz is shown in Figure 8. The amplitude gradually increases until it reaches to the amplitude of 500gal. As the former section, foundation-soil system is modeled as four cases; (1) fixed base, (2) elastic soil, (3) elastic soil with basemat uplift and (4) elasto-plastic soil with basemat uplift. Three cases of different excitation frequencies are considered: (a) excitation frequency fe is lower than the natural frequency of the elastic soil system fn (fe/fn=0.9) (b) excitation frequency is the same as the natural frequency of the elastic soil system (fe/fn=1.0) and (c) excitation frequency is higher than the natural frequency of the elastic soil system (fe/fn=1.1). The natural frequency of the elastic soil system is 1.98(Hz).

4.1 Stress reduction for case (a)

The time history of base shear induced in the structure is shown in Figure 9. The meanings of the curves are the same as before. The base shear responses of fixed base and elastic soil model are larger than nonlinear cases. When basemat uplift effect is incorporated in the model, the base shear reduced significantly. Any clear difference can not be seen by the soil yielding effect.

4.2 Stress reduction for case (b)

Calculated responses are shown in Figure 10. In this case, the base shear of the elastic soil model becomes much larger than others. This is because the elastic soil system reached resonance with excitation frequency becomes system frequency. Compared to the elastic soil case, base shear of the models that incorporated basemat uplift effect reduced significantly.

4.3 Stress reduction for case (c)

The result is shown in Figure 11. In this case, excitation frequency is higher than the elastic soil system and closer to the fixed base model. For this reason, base shear of the fixed base model is largest. Owing to radiation damping effect, base shear of the elastic soil model reduced significantly. Furthermore, basemat uplift effect

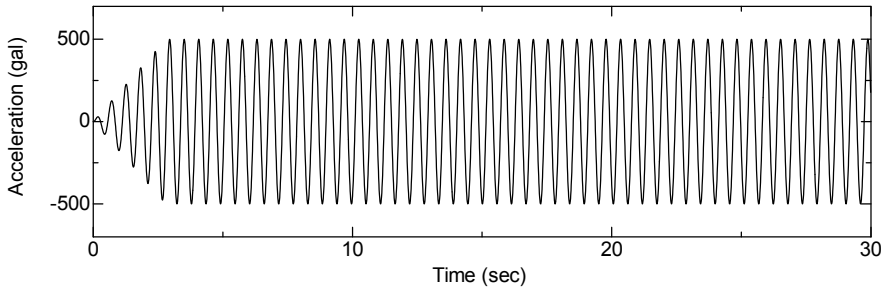

Figure 8 Acceleration time history

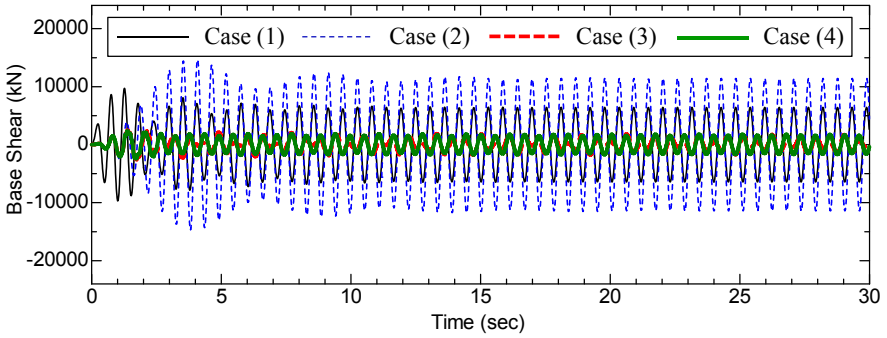

Figure 9 Base shear time history (Case (a))

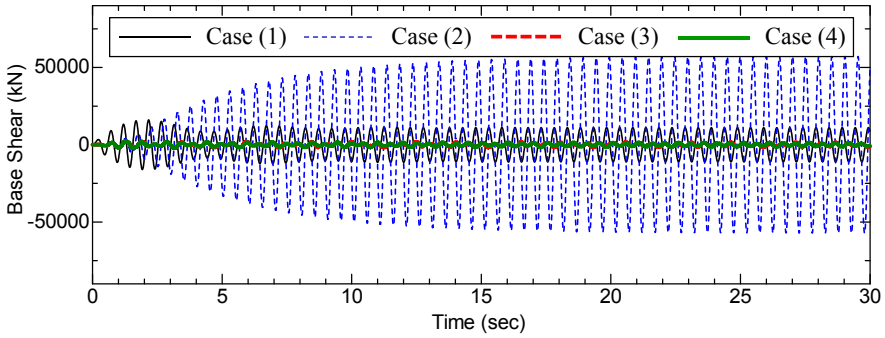

Figure 10 Base shear time history (Case (b))

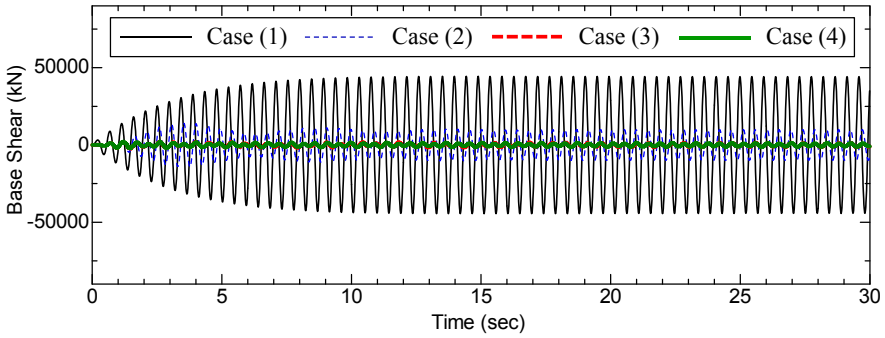

Figure 11 Base shear time history (Case (c))

works to drastically reduce the base shear of the structure in this case.

5. CONCLUSIONS

This study examined stress reduction effects induced in a structure due to basemat uplift and soil yielding by the use of a macro-element model for foundations placed on sands. The foundation-soil system is modeled as four cases; (1) fixed base, (2) elastic soil, (3) elastic soil with basemat uplift and (4) elasto-plastic soil with basemat uplift. Time histories with different frequency characteristics were considered as input motions to the models. Comparisons of responses for the models showed remarkable reduction of section force due to basemat uplift and soil yielding. Therefore, it may be concluded that the degree of base shear reduction depends on the frequency characteristics of the input motions relative to the system.

Abstract: Numerical techniques commonly used to compute the response of soil and rock media under earthquake shaking are investigated by analyzing the observations provided by instrumented borehole arrays. Using a selected subset of the Kiban-Kyoshin (NIED KiK-net, Japan) database along with recordings from the La Cienega (California) and Lotung (Taiwan) arrays, site amplification predictions using 1-D linear elastic analysis, equivalent linear (EQL) analysis and equivalent linear analysis with frequency-dependent soil properties (EQL-FD) are compared with borehole observations. Specifically, 13 sites are investigated using over 800 recorded ground motions characterized by low (less than 0.05 g) to high (greater than 0.3 g) recorded peak ground accelerations at the downhole sensor. Low intensity motions are used to investigate the appropriate boundary conditions at the base sensor, as well as to quantify the average misfit (i.e. bias) between the simulations and observations. Larger intensity motions are used to investigate the ability of the numerical models to predict site amplification at moderate to large strain levels. Our analyses indicate that the appropriate boundary conditions for analysis of a borehole array depend on the depth of the borehole sensor. Comparisons with the observed motions indicate that the misfit of simulations can be significant. However, at low intensities, the average bias across all sites analyzed is close to zero, indicating that 1-D wave propagation does not systematically over-predict or under-predict site amplification. However, at large intensities the EQL approach generally under-predicts site amplification at periods less than 0.4 s due to over-damping at large strains. On the contrary, the EQL-FD approach over-predicts of site amplification, due to the utilization of small strain damping values at high frequencies.

1. INTRODUCTION

Local soil conditions play a significant role in the nature and characteristics of ground shaking during earthquakes. The influence of local soil conditions on ground shaking is typically evaluated using numerical modeling techniques, all of which involve the propagation of earthquake waves from the base rock through a model of the soil layers to the ground surface. The various properties of the soil layers are the primary input into the modeling process, while the surface motion, in terms of an acceleration time series or response spectrum, is the primary output. The existing site response approaches differ from each other based on the way they address: 1) the complexity of the seismic wave propagation pattern, and 2) the nonlinearity of the soil response. Thus, 1-D, 2-D and 3-D models have been developed to simulate the directional effects of the passing seismic waves on the soil response, while equivalent-linear (EQL) and fully nonlinear (NL) models provide the numerical tools by which the nonlinear soil behavior may be approximated.

In cases where major topographic and basin effects are minimal, one-dimensional ground response analysis has been considered adequately representative of the actual wave propagation conditions (Figure 1). That is, it can be reasonably assumed that all boundaries are horizontal and extend infinitely, and thus, the response is dominated by vertically propagating and horizontally polarized shear waves (SH-waves). Moreover, in engineering practice the nonlinear and inelastic soil behavior is approximated most commonly by the equivalent-linear approach. That is, once the modeling parameters such as the shear wave velocity profile and shear modulus reduction and damping curves have been specified, linear analysis is performed with iteratively adjusted soil properties. Within the general framework of an equivalent-linear analysis, two major formulations are prevalent. The most widely accepted approach is the traditional equivalent-linear formulation (EQL), as first introduced by Schnabel *et al.* (1972). Based on this approach, the shear modulus and damping are iteratively adjusted to be consistent with an effective level of shear strain induced in each soil layer (Figure 1). More recently, a new formulation, namely an equivalent-linear analysis with frequency dependent soil properties (EQL-FD) (e.g. Assimaki and Kausel, 2002; Yoshida *et al.*, 2001) has been proposed. These phenomenologically-based algorithms address the inability of the traditional EQL formulation to accurately predict site amplification at high frequencies at large input intensities. The EQL-FD iterative procedure, instead of targeting a single-valued effective shear strain to select strain-compatible soil properties, takes advantage of the complete shear strain frequency spectrum to select strain-compatible properties at each frequency (i.e. frequency-dependent properties, Figure 1).

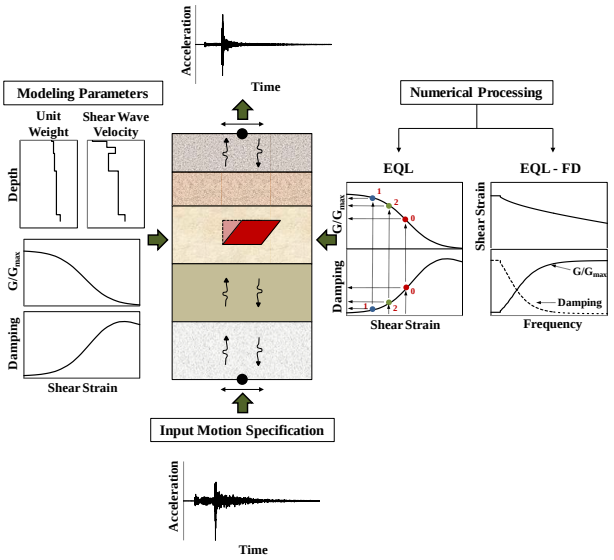

Figure 1 Schematic of the aspects associated with 1-D equivalent-linear (EQL, EQL-FD) numerical models

In this study, one-dimensional linear-elastic (LE) analyses are performed initially to evaluate key assumptions associated with one-dimensional site response. Then, using the obtained information, we investigate the ability of both 1-D equivalent-linear formulations (EQL and EQL-FD) to accurately predict the ground response under moderate to strong shaking. This evaluation is achieved by comparing the theoretically computed response with observations obtained from vertical strong motion borehole arrays. Our ultimate goal is to: 1) evaluate the performance of the numerical algorithms at different levels of earthquake shaking, and 2) quantify the uncertainty associated with the theoretical models.

2. SITE AND GROUND MOTION SELECTION

2.1 Data from strong motion borehole arrays

Geotechnical strong motion borehole arrays consist of vertically distributed, strong-motion accelerometers and they have been installed in numerous locations around the globe. Borehole arrays provide critical information to better understand the physical mechanisms associated with the response of soil and rock media under earthquake shaking. The continuously increasing number of strong-motion recordings from these arrays has been driving more rigorous studies on the assumptions and accuracies of numerical models commonly used to compute site response (e.g., Borja *et al.*, 1999; Kottke, 2010; Kaklamanos *et al.*, 2012).

Specifically, the Kiban-Kyoshin (NIED KiK-net) network in Japan is one of the largest sources of strong motion recordings from borehole arrays. It consists of more than 650 sites where surface-borehole pairs of sensors are available. For each site, shear and compression wave velocity profiles are provided along with basic soil and rock classifications and descriptions. Despite the fact that the site characterization is not extensive, the breadth and the number of strong motion recordings is large and diverse, something that makes the database suitable for the evaluation of site response methodologies.

2.2 Factors for site selection

Towards an effort to select the most suitable sites and associated strong ground motion recordings for the purposes of the present study, site characterization information and strong motion data obtained through the KiK-net database were processed and classified. For each site in the database, information was compiled regarding the time-averaged shear wave velocity over the top 30 m (V_{s30}) of the array, the number of recorded motions, their respective peak accelerations, and the depth to the downhole sensor. In Figure 2, the distribution of sites relative to their NEHRP site classification and the distribution of recordings relative to their peak ground acceleration at the downhole sensor (PGA_{base}) are shown. These data show that the majority of sites are Site Class C (V_{s30} = 360 - 750 m/s) and the majority of the recordings have PGA_{base} < 0.1 g. Specific criteria were established to select appropriate KiK-net sites for further investigation. These factors included: 1) the stiffness of the site based on the available in-situ shear wave velocity measurements, 2) the number of the recorded motions, 3) the range of PGA_{base} values, and 4) the availability of high intensity motions as recorded at the downhole sensor. Sites characterized by low V_{s30} were preferred due to the fact that these sites typically exhibit strong nonlinearity during intense ground shaking. Understandably, sites with such a characteristic along with the availability of high intensity recordings represent the ideal combination.

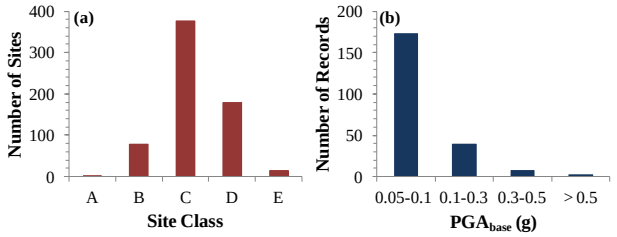

Figure 2 a) Number of sites per NEHRP site classification, and b) number of records per PGA_{base} range

Consequently, 11 KiK-net sites were identified to be most suitable for this study. The selected sites are presented in Tables 1 and 2, where information on the site characteristics and the number of the recorded motions can be found. To supplement this study in terms of softer sites with smaller V_{s30}, we also made use of two additional vertical borehole arrays, namely the La Cienega and Lotung arrays. The V_{s30} for the 13 selected sites ranges from 184 m/s to 371 m/s, while the depth to the downhole sensor varies from "shallow" (≤ 100 m) to "deep" (> 200 m). In Figure 3, the V_S profiles of the selected sites are presented, as reported by the KiK-net database and by Kottke (2010) for the La Cienega and Lotung sites. The KiK-net profiles, obtained through in-situ suspension logging measurements, often do not extend to the depth where the downhole sensor is located and thus extrapolation of the measured shear wave velocity profile was required. Some of the sites (FKSH19, IBRH11, IBRH13 and KSRH10) also exhibit a strong impedance contrast within the top 50 m of the profile (Figure 3).

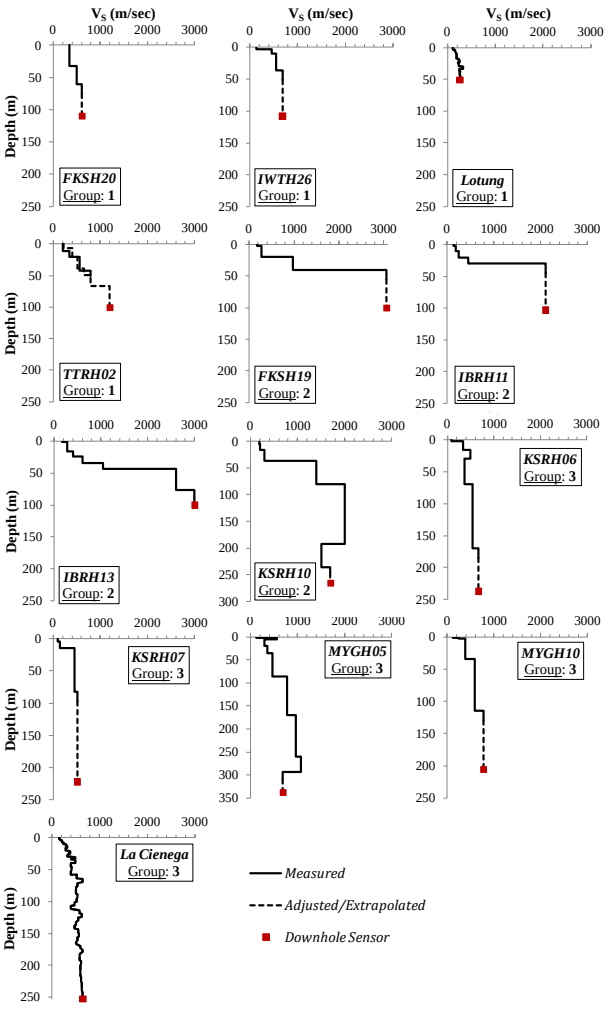

Figure 3 Shear wave velocity (V_S) profiles of the borehole arrays used in this study

2.3 Signal processing of recorded motions

After the borehole arrays were selected, the horizontal (East-West and North-South) components of the recorded motions, both at the downhole sensor and the ground surface, were processed in a unified manner. A fifth-order Butterworth, time-domain, acausal filter with a low-pass cut-off frequency of 30 Hz and a high-pass cut-off frequency of 0.15 Hz was applied to all motions. Subsequently, the recordings were baseline corrected and post-processed, i.e. response and Fourier amplitude spectra were calculated. The obtained transfer functions, i.e. the ratios of surface to "base" Fourier amplitude spectra, were smoothened using a logarithmic triangular window with a width equal to one-fifth of a decade.

3. IDENTIFICATION OF BOREHOLE WAVEFIELD

3.1 Uncertainty in the borehole wavefield

In a one-dimensional layered model, the wave propagation pattern typically consists of an up-going (A) and a down-going (B) seismic wave (Kramer, 1996), as shown in Figure 4. These waves are complex valued and differ from each other within each layer, except for the free surface layer. A certain degree of uncertainty exists in the actual wave propagation field (i.e., boundary condition) present at the depth of base recording within a borehole array (e.g., Bonilla *et al.*, 2002). That is, the down-going (B) wave may or may not be present at the base of the borehole, a remark that leads to two potential assumptions regarding the motion recorded at depth. One possible assumption is that the dowhole response includes both up-going and down-going waves (A+B). This assumption is often referred to as a "within" motion. The alternative assumption, namely an "incoming only" motion, refers to wavefields where only the up-going (A) wave is present. The assumption that best simulates the actual wave propagation conditions at a site of a borehole array is not known a priori. Therefore, a separate set of analyses was performed for each borehole array to evaluate the wavefield that best models the observed responses.

3.2 Evaluation of appropriate borehole wavefield

Identification of the most suitable borehole wavefield is achieved by comparing the observed frequency domain transfer function swith the theoretical transfer functions computed based on the velocity profile and the different wavefield assumptions. The assumption yielding results most similar to the observations can be considered to be most representative. In the past, other researchers (Bonilla *et al.*, 2002; Thompson *et al.*, 2009) have

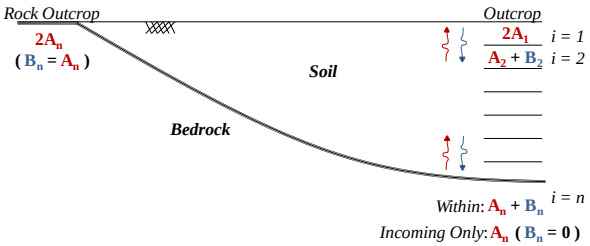

Figure 4 Common assumptions regarding wavefield pattern throughout a 1-D layered system (after Kottke, 2010)

made similar efforts to investigate and explain the physical mechanisms associated with the selection of the appropriate wavefield for a given borehole array.

Within the framework of the present study, 1-D linear-elastic analyses (LE) were performed assuming both "within" and "incoming only" wavefields at the base of the arrays. The observed transfer functions for the lowest levels of shaking (PGA_{base} < 0.05 g) were compared with the computed transfer functions for the two boundary conditions. The soil layers at the sites were modeled as linear-elastic with damping values assigned in two ways. First, a minimum damping (D_{min}) value, as obtained by the Darendeli (2001) model for the modulus reduction and damping curves, was assigned to each layer. The Darendeli (2001) model models damping as confining stress dependent, with larger damping values (generally ~ 1.0-1.5 %) close to the ground surface and smaller values (~ 0.5 %) at depth. Because the damping values from Darendeli (2001) are based on laboratory testing, they only account for material damping and do not account for other mechanisms of energy dissipation in the field such as wave scattering. To investigate the influence of incorporating these other mechanisms of energy dissipation, an increased damping value of 2.5 % was considered. The utilization of two different damping profiles was essential in order to address the uncertainty concerning: 1) the assumed level of damping experienced by soil materials at low levels of induced shear strain, and 2) the potential attenuation of the down-going seismic wave (B).

Analyses assuming both wavefields and damping profiles were performed. In Figure 5, theoretical transfer functions computed based on both the "within" and "incoming only" assumptions are compared with the observed transfer functions. Because the "within" transfer functions using D_{min} generally had excessively large peaks, the "within" transfer functions in Figure 5 are shown with damping values set to 2.5 %. The "incoming only" transfer functions are shown for damping profiles based solely on D_{min}. In general, the "within" wavefield produces very peaked transfer functions, even with the increased damping, due to the destructive interference between the upgoing and downgoing waves at the modal frequencies of a velocity profile. This phenomenon is more profound at lower frequencies, which are related to the response of deeper strata of the soil profile. The "incoming only" transfer functions are much smoother than the "within" transfer functions because the downgoing wave is ignored. It is clear from Figure 5 that some sites are better modeled by the "within" transfer function while others are better modeled by the "incoming only" transfer function.

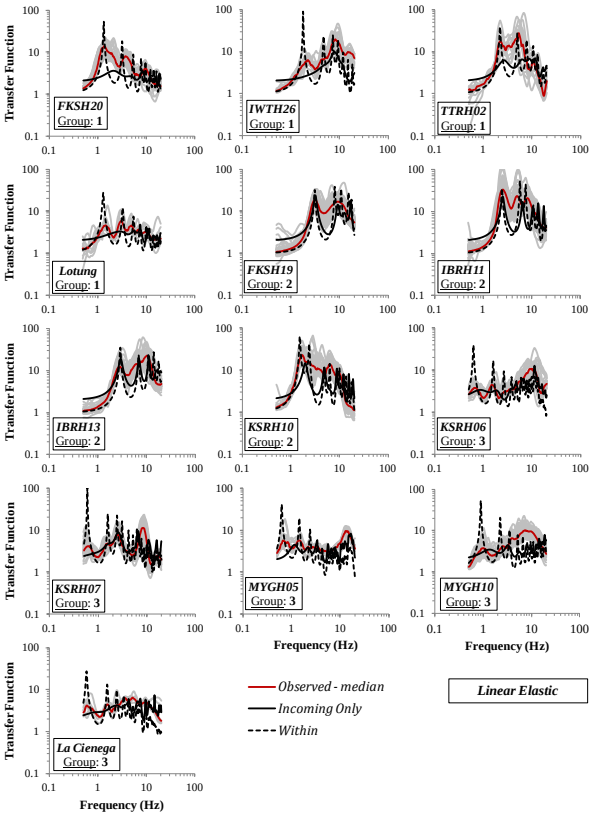

Figure 5 Comparison of theoretical linear-elastic transfer functions and observed transfer functions for low intensity motions

Based on these observations, the borehole arrays can be subdivided into three groups based on the appropriate wavefield and the physical justification for this wavefield (Table 3). Group 1 sites are best-fit by the "within" wavefield, most likely because the downhole sensor is positioned at relatively shallow depths (i.e., ≤ 100 m) such that the downgoing wave is present at the downhole sensor. Group 2 sites are best-fit by either the "within" or "incoming only" wavefields because both wavefields produce similar responses (Figure 5). The similarity in the transfer functions for the two wavefields is caused by a strong shear wave velocity contrast within the top 50 m of the profile (Figure 3) which traps the downgoing wave in the softer layers near the surface. Because the "within" boundary condition is most commonly used in engineering practice when analyzing borehole arrays, subsequent analyses of Group 2 will utilize the "within" wavefield boundary condition. Finally, Group 3 sites are best fit by the "incoming only" wavefield. This wavefield provides the best fit because the borehole sensor is relatively deep (i.e., ≥ 200 m), such that the downgoing wave is not present at the borehole sensor due to attenuation/damping in the upper layers. It should be noted that the theoretical transfer functions are not able to fully capture the observed transfer functions at all frequencies. The discrepancies are most likely attributed to simplifications associated with 1-D wave propagation, as well as to potential bias in the utilized material properties.

Table 3 Grouping of arrays based on site characteristics and appropriate wavefield boundary condition

Site	Downhole Sensor depth (m)	Selected Wavefield	Damping for LE analyses (%)	Group*

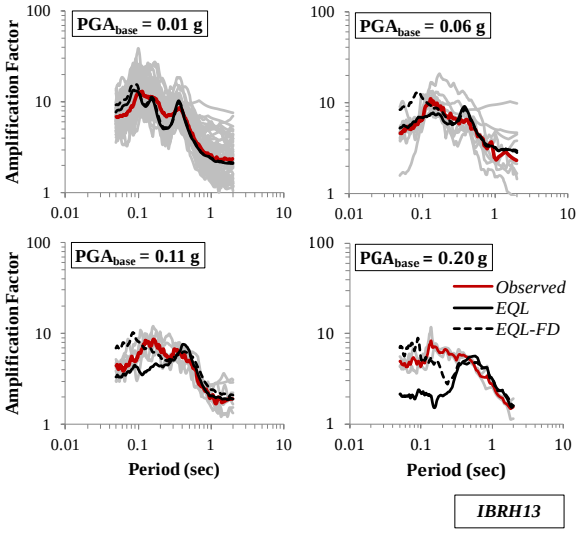

Figure 6 Observed and computed Amplification Factors for the IBRH13 borehole array

4. ASSESSMENT OF SITE RESPONSE METHODS

4.1 General framework

The assessment of the performance of the 1-D equivalent linear site response methodologies (EQL and EQL-FD) is based on site amplification factors, defined as the acceleration response spectrum of the surface motion divided by the acceleration response spectrum of the recorded base motion. This evaluation is different than used for the evaluation of boundary conditions in Section 3, but it is deemed appropriate because most site response analyses are aimed at producing acceleration response spectra rather than Fourier Amplitude Spectra. Analyses were performed using the selected wavefield assumption for each site (Table 3). Modulus reduction and damping curves based on the Darendeli (2001) model were assigned to all soil layers. Subsequently, the results from the analyses were classified according to their corresponding level of shaking, as depicted by the peak acceleration of the input motions (PGA_{base}). Because the PGA_{base} values range from low (less than 0.05 g) to high (greater than 0.3 g), the effect of input intensity on the accuracy of the predictions is investigated.

Figure 6 illustrates the comparison between observed and computed *median* amplification factors for borehole array IBRH13 at different input level intensities. Results are shown for four ranges of PGA_{base}, with median values of 0.01 g, 0.06 g, 0.11 g, and 0.20 g, respectively. The performance of both the EQL and EQL-FD models strongly depends on the level of shaking, and thus implicitly on the magnitude of the induced shear strains. At low intensity levels, namely for PGA_{base} less than 0.05 g, there is strong agreement between observations and theoretical results at all frequencies. A slight over-prediction occurs at periods less than 0.1 s and a slight under-prediction at a period of about 0.25 s, but still the agreement is quite good. As input intensity increases, the computed amplifications factors from the EQL and EQL-FD methods deviate from each other, as well as from the observations, at periods less than about 0.3-0.4 s. In general, the EQL model strongly under-predicts amplification at shorter periods because of over-damping of high frequencies due to the large peak strain used to select the frequency-independent properties (i.e. damping). The EQL-FD analysis seems to better predict the response at periods between 0.1 s and 0.3 s, with the exception of highest input intensities (PGA_{base} ~ 0.20 g). Here, some under-prediction is observed. However, at periods below 0.1 s the EQL-FD approach systematically over-predicts the site amplification. At these very high frequencies, which are associated with very small strains during unloading-reloading cycles, the EQL-FD approach utilizes damping close to or equal to the minimum damping values incorporated in the damping curve. Consequently, the EQL-FD analysis predicts a near-linear-elastic response and high amplification at these frequencies. This is an attribute of the model that can be seen throughout our analyses.

The discussion above involves only one out of the thirteen sites analyzed, although many of the observations are valid for the other borehole arrays. To compare results across sites and quantify the accuracy and uncertainty of the different approaches, a unifying framework is used. The framework is based on a model developed by Abrahamson *et al.* (1990) for the quantification of the goodness-of-fit between seismological ground motion observations and simulations. Abrahamson *et al.* (1990) quantified the misfit between numerically simulated and recorded strong ground motions in terms of the natural log of the response spectral values. In the present study, we quantify the misfit (or bias) as the difference between the natural log of the observed and calculated amplification factors (AF) at each frequency. This modification is solely semantic, because the calculated bias is the same in either case. Therefore, for the i^{th} site and j^{th} recording, the residual (y) between the natural log of the observed amplification factor ($\ln AF^{obs}$) and the natural log of the theoretically calculated amplification factor ($\ln AF^{calc}$) is given by:

$$y_{i,j}(f) = ln\ AF_{i,j}^{obs}(f) - ln\ AF_{i,j}^{calc}(f) \quad (1)$$

where f is frequency. Positive bias represents under-prediction by the model, while negative bias represents over-prediction by the model. For example, residuals with values 1.0, 0.5, -0.5 and -1.0 correspond to ratios of AF^{obs}/AF^{calc} equal to 2.71, 1.65, 0.61 and 0.36, respectively. Figure 7 presents the calculated residuals for IBRH13 site. The results in Figure 7 are the direct equivalent of the results in Figure 6, with the EQL approach producing large positive residuals (i.e., under-prediction) at high frequencies and large input intensities and the EQL-FD producing negative residuals (i.e., over-prediction) at high frequencies and large input intensities.

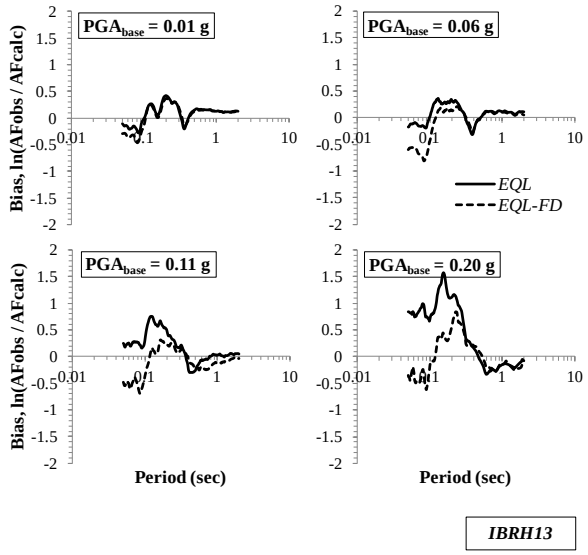

Figure 7 Calculated bias for EQL and EQL-FD methods for IBRH13 borehole array

4.2 Identification of sources of uncertainty

Examining site response models for a specific site gives us insight into the effects of particular site characteristics. However, uncertainty assessment requires the combination of observations from several sites, such that statistically significant measures can be established and evaluated. Within the framework of our efforts, we tried to identify sources of uncertainty by using models proposed by several researchers in the context of either ground motion prediction equations (GMPEs) (e.g., Lin *et al.*, 2011; Rodriguez-Marek *et al.*, 2011) or site response analysis (e.g., Kaklamanos *et al.*, 2012). In this study, the notation utilized by Kaklamanos *et al.* (2012) is adopted.

Assuming that the observation residuals at a specific frequency, $y_{i,j}$, as previously introduced, represent a normally distributed random variable with mean μ_y and standard deviation σ_y, we can separate the residuals into different components, as:

$$y_{i,j} = \alpha + \eta_{s,i} + \varepsilon_{i,j} \quad (2)$$

where α is the "fixed effect", $\eta_{s,i}$ is the inter-site residual, and $\varepsilon_{i,j}$ is the intra-site residual. The "fixed effect", α, represents the mean bias across all sites and recordings. The inter-site residual, $\eta_{s,i}$, quantifies the "site-specific" bias and is assumed to be a normally distributed random variable with, ideally, a zero mean ($\mu_{\eta_s} = 0$) and standard deviation τ_s. For the i^{th} site, $\eta_{s,i}$ represents the misfit between the mean residual of the site and the "fixed effect", α. The intra-site residual, $\varepsilon_{i,j}$, expresses the "within-site" variability and is a normally distributed random variable with zero mean ($\mu_\varepsilon = 0$) and standard deviation σ. $\varepsilon_{i,j}$ represents the difference between a single observation, $y_{i,j}$, and the site-corrected mean residual ($\alpha + \eta_{s,i}$).

Considering the model of equation (2), the mean (μ_y) and standard deviation (σ_y) of the observation residuals can be split into three components, namely: the fixed effect, α; the inter-site standard deviation, τ_s; and the intra-site standard deviation, σ. Specifically, the uncertainty measures of $y_{i,j}$ are given by:

$$\mu_y = \alpha \quad (3)$$

$$\sigma_y = \sqrt{\tau_s^2 + \sigma^2} \quad (4)$$

The mean inter -site residual (μ_{η_s}), could have been included in equation (3) to fully represent the actual linear model, as developed based on the observations of the present study. However, although μ_{η_s} has been assumed to be zero-valued, this assumption is not fully achieved in this study because the number of borehole arrays considered is relatively limited (13) and the number of recordings is not evenly distributed among the sites. Therefore, the computed values of μ_{η_s} are not zero, although generally they were close to zero (~0.1).

4.3 Uncertainty evaluation across sites

As shown in the evaluation of single-site bias (Figures 6 and 7), one of our main goals was to examine the effect of increasing levels of shaking on the site response predictions. When evaluating a single site, PGA_{base} was an appropriate parameter upon which to classify the different responses. For the uncertainty analysis across sites with different shear wave velocity characteristics, the maximum calculated shear strain (γ_{max}) was established as a more appropriate parameter to use. The magnitude of the induced shear strains is the parameter mostly influencing the results because it directly influences the damping used in the site response analysis. Five different ranges of γ_{max} values were considered; γ_{max} < 0.01 %, 0.01-0.1%, 0.1%-0.3%, 0.3%-1.0%, and > 1.0%. The number of sites and number of input motions yielding γ_{max} values within each of these shear strain ranges varied substantially. For example, 407 motions from 13 sites are included in the γ_{max} < 0.01 % bin, 24 motions from 9 sites are included in the γ_{max} of 0.1%-0.3% bin, and 25 motions from 8 sites are included in the γ_{max} > 1.0 % bin. It should be noted that γ_{max} is computed as part of the analysis and thus is not an independent assessment of the strain that can be predicted a priori. Nonetheless, the computed γ_{max} best explains the deviations of the site response results from the observations and it should be proportional to the actual induced strains in the soil deposit.

By combining the observations and numerical results from all borehole arrays using equation (2) and grouping the results

based on the computed γ_{max}, we are able to quantify the across-site accuracy of the EQL and EQL-FD methods at different strain levels and provide estimates of the uncertainty associated with the site amplification predicted by these models. Figures 8 and 9 summarize the uncertainty modeling for the EQL and EQL-FD methods, respectively. Figures 8a and 9a illustrate the mean residuals, while Figures 8b and 9b present the corresponding standard deviations. Results are shown for calculated maximum shear strain ranges of: $\gamma_{max} \leq 0.01\%$, $0.1\% < \gamma_{max} \leq 0.3\%$, and $\gamma_{max} > 1.0\%$. The mean observation residuals (μ_y) are represented by the "fixed effect" α, while the total standard deviations (σ_y) include inter and intra-site standard deviations (τ_s and σ, respectively).

Figure 8a, demonstrates that the accuracy of the EQL approach strongly depends on the level of the induced strains. At small strain levels ($\gamma_{max} \leq 0.01\%$), the EQL yields mean residual values (μ_y) relatively close to zero across almost the entire frequency range. When the induced strain level increases, the responses from the EQL approach deviate from observations, with μ_y becoming large and positive. Indeed, at periods smaller than approximately 0.4 s, the EQL approach under-predicts the response by as much as factors of 1.5 to 3.0. Under-prediction

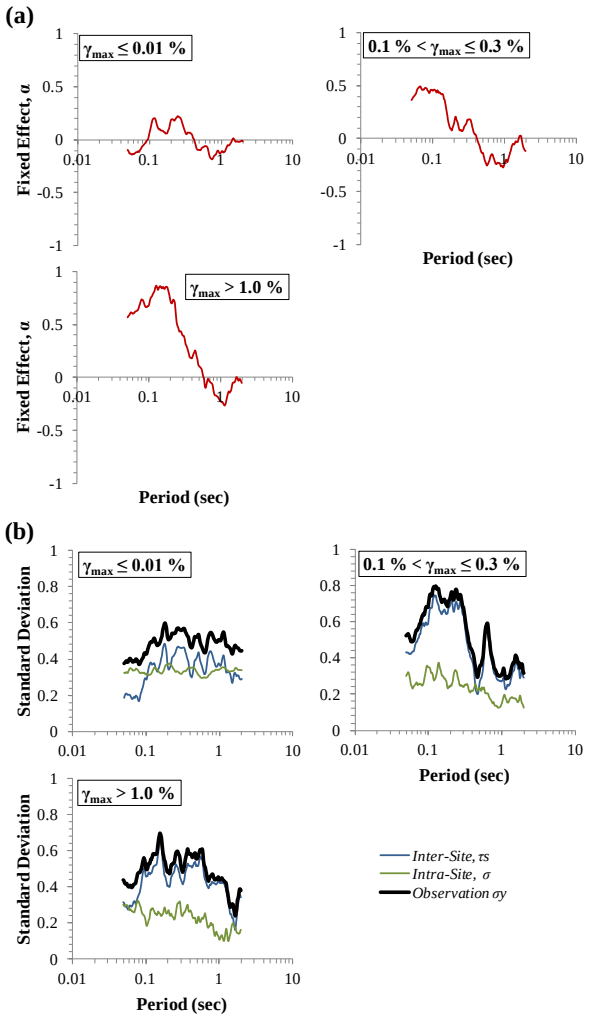

Figure 8 (a) Mean residuals, and (b) standard deviations for amplification factors computed by the EQL approach

of the response can be attributed to the inability of the numerical model to deal with excessive nonlinearities caused by strong shaking. The total observational standard deviation (σ_y, Figure 8b) at small strains is approximately 0.4 at periods less than 0.1 s and it is about 0.55 at larger periods. The inter-site and intra-site standard deviations contribute almost equally (~0.3 to 0.4) to the total standard deviation. At larger strains, σ_y increases to about 0.65-0.8 at periods less than about 0.4 s, and the inter-site component dominates with the intra-site standard deviation being relatively small (0.2-0.3). At these levels of shaking the calculated maximum strain, and not input motion characteristics, predominantly influences the performance of the theoretical model, which may explain the observed low intra-site variability. Moreover, the greater contribution of the inter-site variability (τ_s) to the total variability (σ_y) is most likely attributed to the fact that analyses resulting in large shear strains include fewer sites and motions per site, making the estimate of τ_s unreliable.

As shown in Figure 9, at low strain levels ($\gamma_{max} \leq 0.01\%$), the residuals and standard deviations from the EQL-FD approach are very similar to those for the EQL approach. This similarity occurs because the soil properties do not vary significantly with frequency at small strains. In contrast, as the magnitude of the induced strains increases, the mean residuals for the EQL-FD approach become systematically negative at periods less than about 0.3 s. These residuals indicate an over-prediction of the amplification by factors as large as 1.5 to 2.0. As previously discussed, the over-amplification of high frequencies is caused by the utilization of the minimum damping value at high frequencies. In terms of the variability in the calculated residuals for the EQL-FD approach (Figure 9b), the total standard deviation at small strains is similar to that for the EQL approach. At larger strains there is some increased variability across some periods but the effect is not clearly identified. As for the EQL method, at larger strains the inter-site variability is the primary contributing factor to the total standard deviation, with the corresponding intra-site standard deviation taking relatively small values (0.2-0.3). However, the fewer number of sites and motions included in the analyses at large strains makes the computed inter-site standard deviation less reliable.

Figure 10 summarizes the mean observation residuals (μ_y) and total standard deviations (σ_y) for the EQL and EQL-FD approaches across the five shear strain bins considered. For the EQL approach, the mean residual stays close to zero (+/- 0.1 which represents +/-10%) across all periods for strains less than about 0.1%. At strains larger than 0.1%, the residuals become increasingly positive for periods less than 0.4 s and indicate an under-prediction of the response. For the EQL-FD approach, the residuals become increasingly negative for periods less than 0.4 s at strains greater than 0.01%, which is a smaller strain threshold than for the EQL approach. Nonetheless, the over-prediction by the EQL-FD approach appears to be generally less than the under-prediction by the EQL approach. With the exception of slightly lower values at small strains, total standard deviations (Figure 10b) seem to be unaffected by the level of

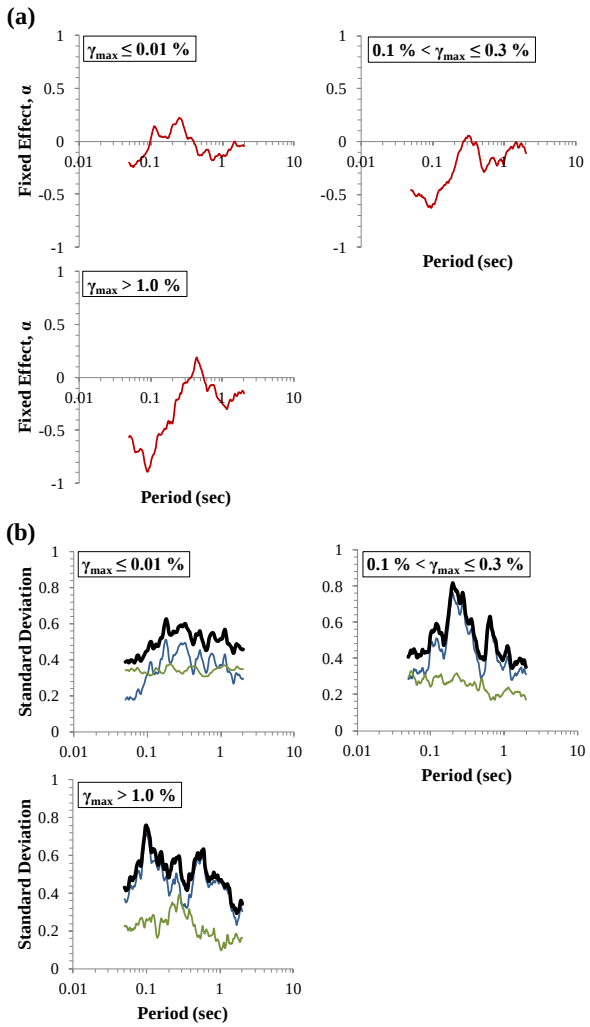

Figure 9 (a) Mean residuals, and (b) standard deviations for amplification factors computed by the EQL-FD approach

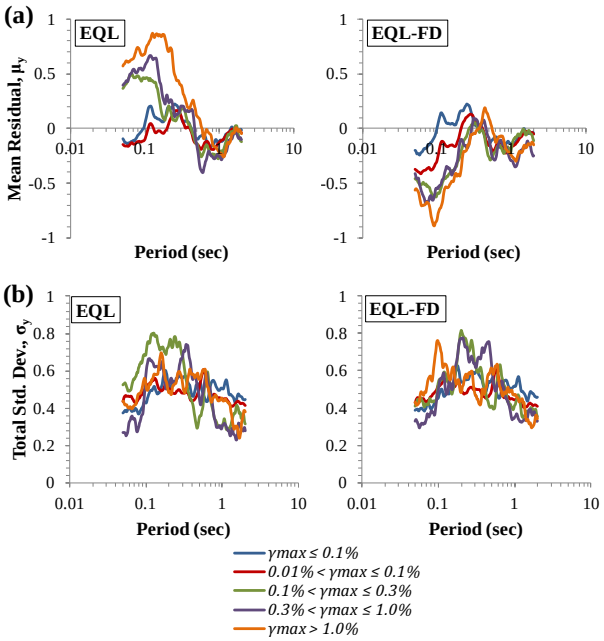

Figure 10 (a) Mean residuals, μ_y, and (b) total standard deviations, σ_y, across different induced shear strain levels

shaking. Moreover, they are, for all practical purposes, similar for both numerical models. Site response variability seems to be smaller at periods less than 0.1 s and periods greater than 1.0 s.

5. CONCLUSIONS

Observations from 13 selected strong-motion borehole arrays have been studied and compared with results from numerical site response analysis. Site response analyses were performed using two main approaches: equivalent-linear (EQL) and equivalent linear with frequency-dependent soil properties (EQL-FD). Using the recordings and theoretical calculations we evaluated the appropriate boundary conditions at the base of each borehole array, the accuracy of the site amplification computed by the two site response approaches, and the associated variability in the computed site amplification.

Results from linear-elastic analyses were utilized to identify the boundary conditions (i.e., borehole wavefield) as captured by the recordings at each array. The borehole wavefield that most accurately models the recorded surface motions strongly depends on the depth to the downhole sensor. Sites with depths to the base sensor greater than about 200 m are better analyzed using an "incoming only" assumption, while sites with shallower base sensor depths (less than about 100 m) seem to be better characterized by a "within" wavefield. Borehole arrays with a strong impedance contrast within the upper 50 m of their profile can be analyzed using either wavefield assumption.

Amplification factors computed by the EQL and EQL-FD approaches were compared with those observed, both on a site-by-site basis as well as within an across-site context. At low levels of shaking and induced shear strain levels, both the EQL and EQL-FD methods yield mean residuals across all sites close to zero, indicating no systematic bias in the site amplification predictions at small strains. As input intensity and the induced shear strain increases, the computed responses from both the EQL and EQL-FD methods deviate from the observations. The misfit is typically exhibited at periods less than 0.4 s. In this frequency range the EQL approach systematically under-predicts the response, while EQL-FD method consistently over-predicts site amplification. In both cases, the differences can be as large as a factor of 1.5 to 3.0.

A model was used to quantify the variability associated with both EQL and EQL-FD methods. Inter and intra-site contributions to the total variability were evaluated. Both approaches appear to be characterized by similar levels of variability. When performed at a single site, the intra-site standard deviation is generally frequency-independent with values on the order of 0.2 to 0.3. When evaluated across sites, the total standard deviations are larger with values around 0.5 to 0.7 and are practically independent of the level of shaking.

Abstract: The present study aims to examine thoroughly the relation between the local site effects and the local subsurface conditions in Lima city, due to the fact that there is little information related to the seismic amplification in this city. Using ground motion records, the amplification effects are studied empirically, in the frequency range from 0.1 to 20 Hz. This study analyzes the seismic events observed along the Pacific coast of Lima city, which were recorded by 10 stations. Because of the limitation in data, site amplification factors are evaluated by using three different methods: the standard spectral ratio, the spectral inversion method and the H/V ratio, so as to identify the significant peaks and troughs at all sites. Results show that most of the stations present relatively large amplifications in the high-frequency range over 3 Hz, moreover RIN station. Nonetheless, CAL site has a different behavior of amplification.

1. INTRODUCTION

A future large earthquake is expected to occur in Lima city, the capital and most densely-populated city of Peru. According to several works (Okal et al. (2006) and Pulido et al. (2010)) the seismic gap that has been identified near coast of Lima city might generate a gigantic magnitude ~9.0 Mw event, which could occur any time within the next 20 years.

During the 1974 October 3 Mw8.0 earthquake – the last event of considerable magnitude that Lima city has been subjected – with focal depth about 13 km, few areas outside of Lima center were severely damaged, such as La Campiña (Chorrillos), La Molina and Callao – La Punta (Repetto et al. 1980). Works described by Husid et al. (1977), Espinoza et al. (1977), Repetto et al. (1980) and Stephenson et al. (2009) refer that these areas were affected by the influence of local surface conditions. For example, in La Molina district it was possible to observe the collapse of reinforced concrete structure during the October 3, 1974, earthquake.

The present study uses ground motion records observed along the Pacific coast of Lima city, Peru, in which the seismic events were recorded by 10 stations, including stations installed both at La Molina and Callao districts. The relation between local subsurface conditions and the local site effect in some areas of Lima city are discussed based on the results obtained from three empirical methods.

2. GROUND MOTION DATA AND ACCELEROMETER STATIONS

Data from 2003 to 2008 was used in this study so as to analysis the site effects at 10 stations. Table 1 gives pertinent information on the 17 events used in this work, and Figure 1 shows their locations relative to our recording sites. These seismic events are superficial and intermediate earthquakes, with Local Magnitude ML from 3.8 to 7.0. The epicentral distances range between ~55 and ~200 km. Because the PGAs were mostly small, we can assume linear site responses, even during the 2007 August 15th Pisco earthquake (Mw 8.0) the influence of non-linearity on the site response was not detected (Quispe 2010).

In addition, from the ten stations used in this work, four stations (CSM, CAL, MOL and CDLCIP) are maintained by CISMID Accelerometer Network, nonetheless MOL site was removed after Pisco earthquake struck, three stations (CER, RIN and PUCP) deployed by the South American Regional Seismological Centre (CERESIS) and three stations (MAY, LMO and NNA) deployed by the Geophysical Institute of Peru (IGP).

All the observation sites are shown in Figure 1 on the geological map of Lima city (Martinez et al. 1975). According to this map, basically most of the stations (sites MAY, CER, RIN, CAL, CDLCIP, CSM, MOL and PUCP) are located on alluvial soil deposits belonging to the Quaternary Holocene (Figure 1), however sites LMO and NNA are located on cretaceous intrusive rock (Figure 1).

Source parameters were determined by the Geophysical Institute of Peru (IGP)

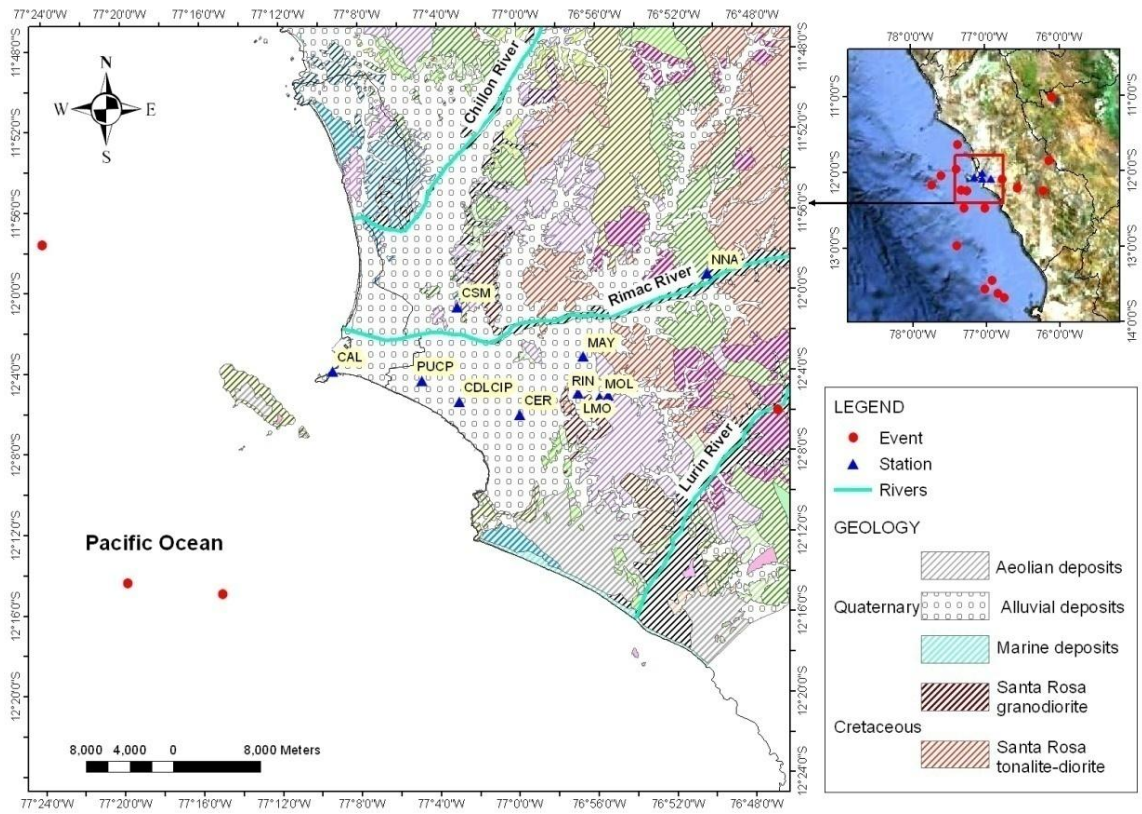

Figure 1 Red circles show the epicenter of events used for this work. Blue triangles represent the stations which are located on the geological map of Lima city (Martinez et al. 1975).

All the observation sites are shown in Figure 1 on the geological map of Lima city (Martinez et al. 1975). According to this map, basically most of the stations (sites MAY, CER, RIN, CAL, CDLCIP, CSM, MOL and PUCP) are located on alluvial soil deposits belonging to the Quaternary Holocene (Figure 1), however sites LMO and NNA are located on cretaceous intrusive rock (Figure 1).

3. SITE RESPONSE ESTIMATION TECHNIQUES

Because of the fact that not all the analyzed events were recorded at all the ten sites as well as the limitation on data, three different empirical methods have been applied in order to get reliable information about the relevant frequencies on seismic amplification factors, such methods are the standard spectral ratio technique (Borcherdt 1970), the spectral inversion method (Iwata and Irikura 1988) and the horizontal-to-vertical spectral ratio technique (Nakamura 1988, Lermo and Chavez-Garcia 1993, Field and Jacob 1995).

The traditional spectral ratio assumes that the site response is estimated by a simple division of the amplitude spectrum calculated from a record at the analyzed station with the amplitude spectrum from a record of the same component at the reference site. However from a practical point of view, the spectral inversion method offers the advantage that records from some events can be included in the inversion even if records at the reference site are not available. This offers the advantage of a more complete exploitation of the data set (Riepl et al 1998). In addition, the inversion method simultaneously gives source, path, and site factors; nonetheless in this article, our concern is to determine the site factor and not to go into details on the other effects. The horizontal-to-vertical spectral ratio in comparison to the other techniques estimates the empirical transfer function using spectral ratios between horizontal and vertical components of motion, so no reference site is needed. For this study, NNA rock site was used as the reference site, because its spectral response shows lesser amplification levels in comparison to LMO site (Cabrejos 2009). As a constraint condition for the spectral inversion method, we set the site amplification factor for NNA to be 2, irrespective of frequency.

The processing sequence for the data set to compute the spectral ratios relative to a reference site or relative to the vertical component was as follows. From each record we selected a window of 20 sec, beginning at the shear-wave arrival. In order to recognize the onset time of S-wave, particle motion plots for two components of motion, EW component on the horizontal axis and NS component on the vertical axis (Figure 2), and Husid plots (Husid et al. 1969), where the horizontal axis is the time and vertical axis is the accumulated horizontal component square for each horizontal component (Figure 3), are realized. After that, the time window of 20 sec was cosine tapered (10%), using the same criterion took by Takemura et al. (1990), and Fourier transformed. The spectral amplitudes were then smoothed by Parzen windows of 0.6-Hz widths. Both for the standard spectral ratio and the horizontal-to-vertical spectral ratio, horizontal value is calculated by taking the geometrical average of the north-south and east-west components. For the inversion method, the Fourier acceleration amplitude spectra of two horizontal components are computed and summed vectorially.

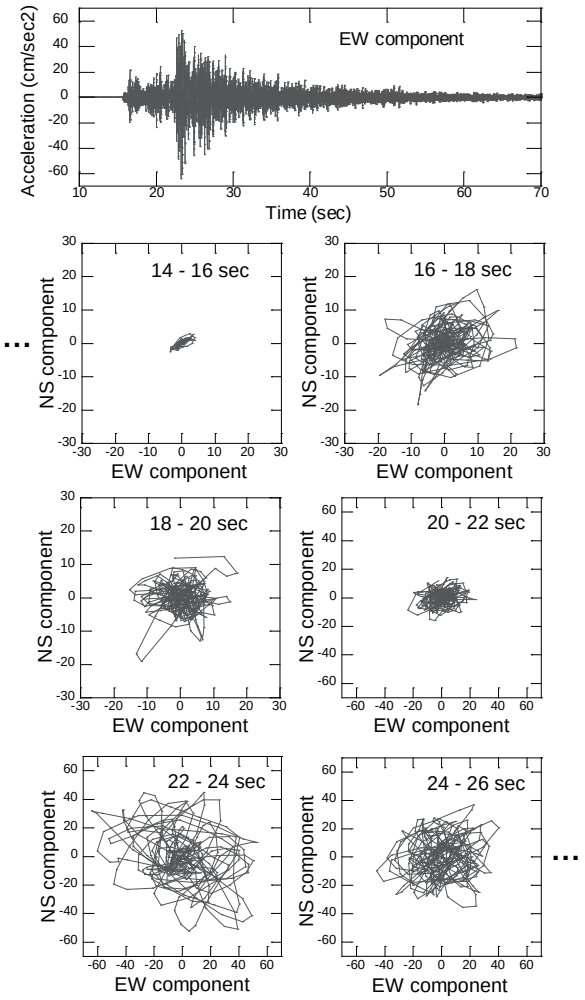

Figure 2. Particle motion plots for two components of motion (CSM station, seismic event 2008/03/29 12:51).

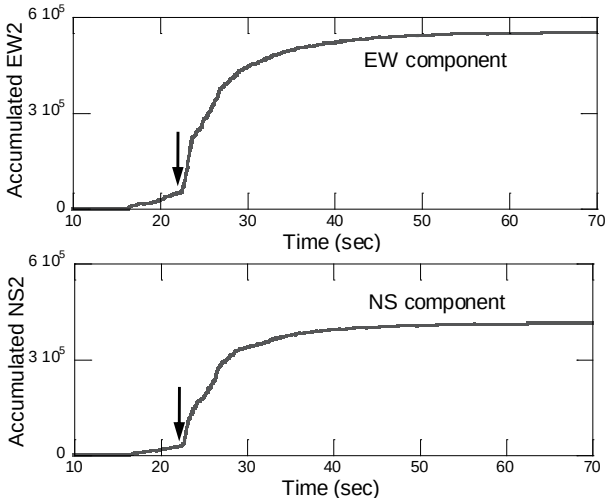

Figure 3. Husid plots to recognize the onset time of S-wave. Black arrows indicate the S-wave onset time (CSM station, seismic event 2008/03/29 12:51).

In order to take advantage that the rupture process of Pisco earthquake was composed of two major events, separated by 60 to 70 seconds (Bernal and Tavera 2007), the

first and the second main events are analyzed for this work, nonetheless the 2nd main event was not recorded by LMO station. For taking a window of 20 sec starting just before the direct S-wave arrival for these two major events, the same procedure as we previously explained was applied.

4. COMPARISON AMONG DIFFERENT EMPIRICAL METHODS

The different estimates of site amplification factors for the stations are compared in Figure 4. Those obtained from the Standard Spectral Ratio (SSR) are shown by thick solid lines, site factors estimated by Spectral Inversion Method (SIM) are shown by thin lines, and amplitude factors calculated from the Horizontal-to-Vertical Spectral Ratio (HVSR) are shown by dotted lines. The SSR for LMO site is not presented for this work given that we do not count on enough seismic events that were simultaneously recorded both for LMO and NNA sites.

According to Figure 4, the geometrical averages of SSR are very similar with inversion results in the analyzed frequency range from the analysis of small and large events. Results show that the amplification level obtained by the SIM are slightly larger in comparison to the traditional approach introduced by Borcherdt (1970) as we can see for CSM, MAY, CDLCIP, PUCP, CAL, and LMO sites. This may be due to the time window of 20 sec that tend to increase slightly the inversion results with the length of the time window because of the effects of later arrivals of surface waves in the case of a long time window (Uetake and Kudo 2005), since as part of this work but results do not show, a time window only taking the S-wave portion was analyzed and inversion results coincided with SSR at many sites in the frequency range higher than 1 Hz.

On the other hand, the geometrical averages of HVSR are also compared with the reference site methods by using the same time window. Results indicate a similarity in the shape of the curves, but HVSR fails for the estimation of the amplification level, since according to Figure 4 most of the sites have much lower amplification in comparison to the other methods. This method assumes that vertical component is expected to be free of amplification, however results obtained by other studies show that subsurface structure influences the vertical component in the same order of magnitude as the horizontal components (Riepl et al. 1998).

For CSM, MAY, CER and CDLCIP stations, even though the amplification level does not fit very well among the analyzed empirical methods, the same peaks and troughs can be identified by the three methods for these four stations. Site effects on these curves (Figure 4) show several peaks of amplification between 3 and 8 Hz as well as a small bump that occurs between 1 and 2 Hz, which is more evident for CER station. Furthermore, relatively large ratios at high frequencies of 10 Hz, moreover for CSM station that has the highest amplification in comparison to the other three sites. There is also a significant trough at about 9 Hz, for CDLCIP site the prominent trough varies in the frequency range between 6 and 10 Hz.

The different estimates for PUCP station show that several peaks of amplification can clearly be distinguished in the frequency range between 1 and 8 Hz, at least four peaks, as well as a trough at about 9 Hz as the previously mentioned stations.

For MOL station, the amplification level both for the SSR and the inversion method are in good agreement for the frequency range investigated. Higher amplifications occur at frequencies larger than 3 Hz as we can see in Figure 4. Amplification effects evaluated by the HVSR do not coincide well with the other methods, however the shape of the site spectra is similar, even a prominent trough at about 12 Hz is identified. This result suggests that the frequency response of vertical component at this site amplifies at the same level as the horizontal components.

The site response at RIN site is dominated by three prominent peaks which are well predicted in the three methods, even though the HVSR predicts lower amplitude in comparison to the reference site methods. The strongest peaks of amplification occur between 3-4 Hz, 7-8 Hz, and frequencies larger than 10 Hz.

For CAL station in comparison to the other sites which amplification levels are larger at higher frequencies, this site shows clearly that strongest amplifications appear at frequencies lower than 3 Hz for the three methods, however amplifications at higher frequencies also occur but are comparatively low. In addition, a trough at about 9-10 Hz has also been detected.

The station located on a rock outcrop, LMO site, has relatively small variations against frequency given that rock sites have local site response (Uetake and Kudo 2005).

Finally, the result of horizontal-to-vertical spectral ratio for NNA site, the reference station, shows that the average transfer function is flat for frequencies lower than 3 Hz, nonetheless no significant trends appear but values are around one. Furthermore, the frequency response at NNA site has a trough, and the trough makes the peaks at frequencies larger than 10 Hz for soft soil sites. That is why, sediment sites show peaks at frequencies larger than 10 Hz that are attributed to the spectral response of NNA given that a relatively strong trough is found.

5. EVALUATION OF LOCAL SURFACE CONDITIONS AND LOCAL SITE EFFECTS

According to the Figure 1, most of the stations are located on Quaternary alluvial deposits with the exception of the rock sites LMO and NNA. CSM, MOL, CER and CDLCIP sites are installed on alluvial gravel deposits that cover a large portion of Lima city, and present a good geomechanic behavior locally named “Lima Conglomerate” (Repetto et al. 1980 and Aguilar 2005). The site response at these stations are characterized by relatively large peaks at around 3-8 Hz, which represent the resonant modes between the poorly graded gravel deposit and other shallow materials that overlie this deposit. PUCP site is also placed on alluvial gravel deposits (Figure 5) nonetheless this site shows several

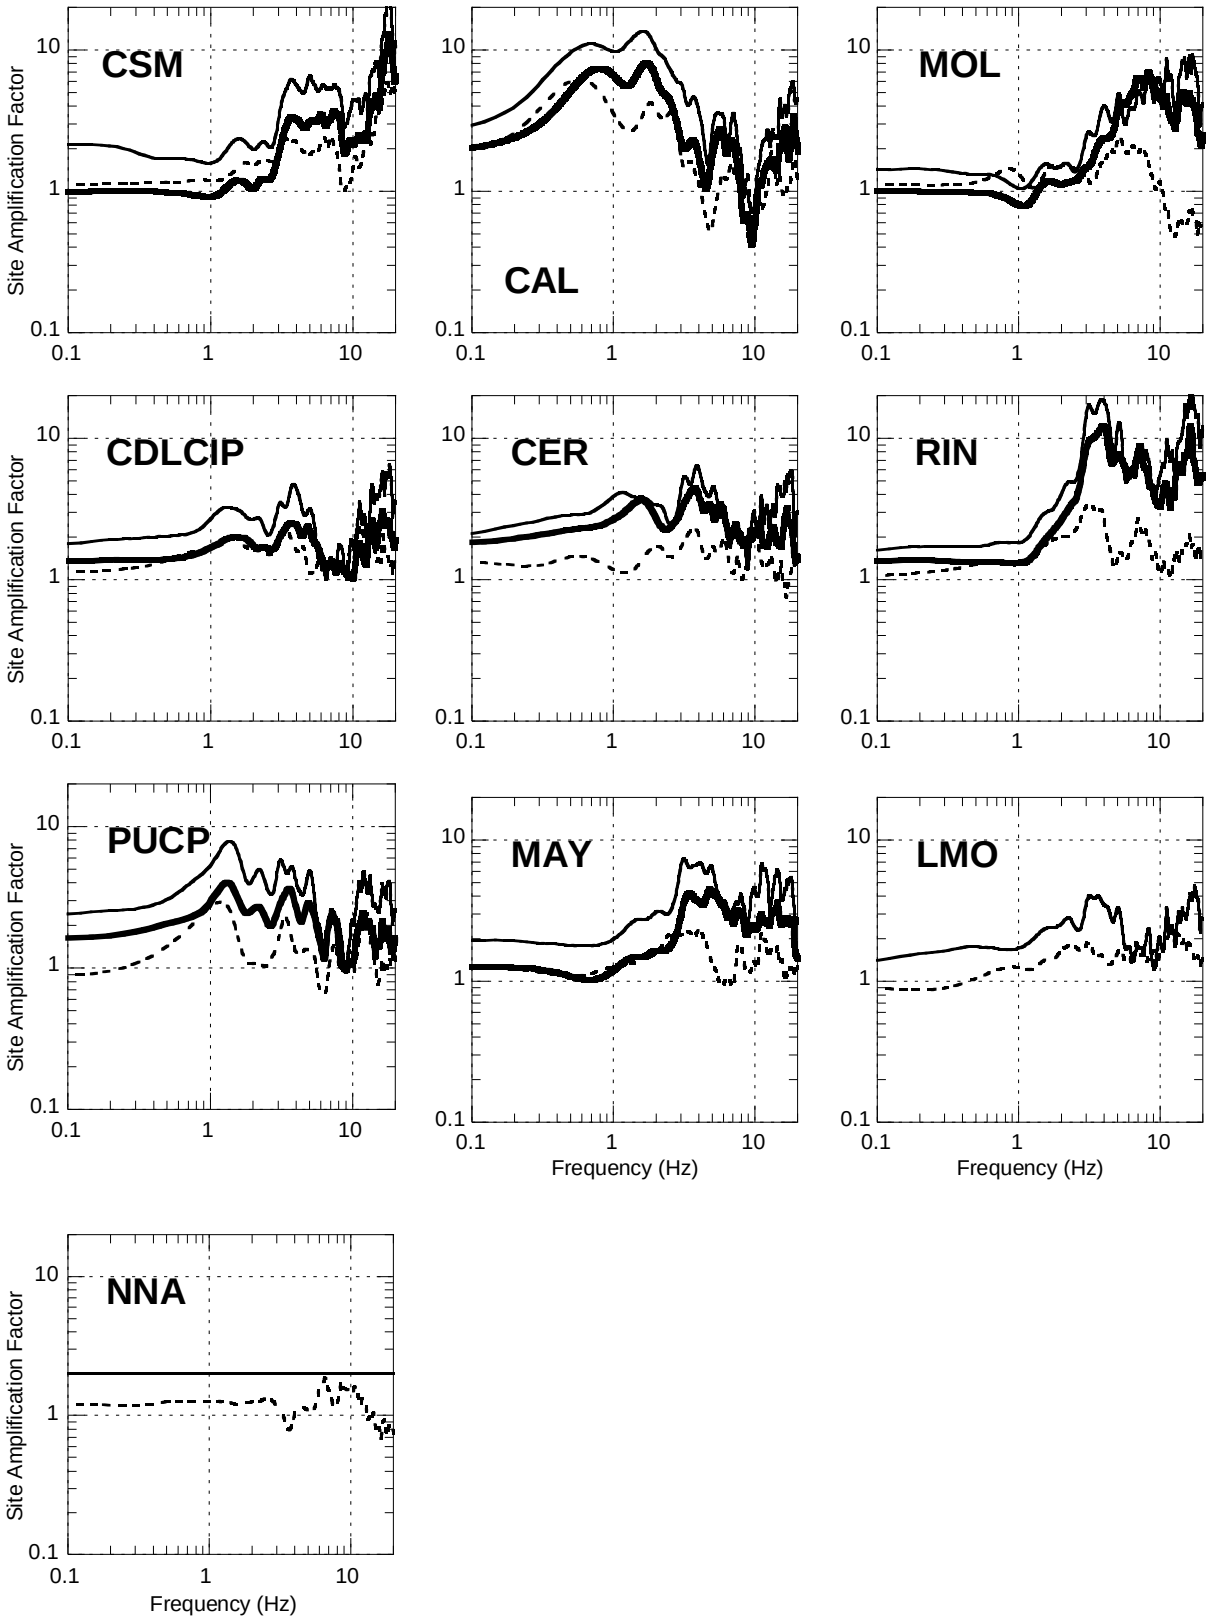

Figure 4. Comparison between spectral ratios from the horizontal components with reference to NNA, the Spectral Inversion Method and the Horizontal-to-Vertical Spectral Ratio. Thick solid lines show the geometrical average of two horizontal spectral ratios. Thin solid lines represent the results obtained by the Spectral Inversion Method. Dotted lines show the geometrical average estimated by applying the HVSR.

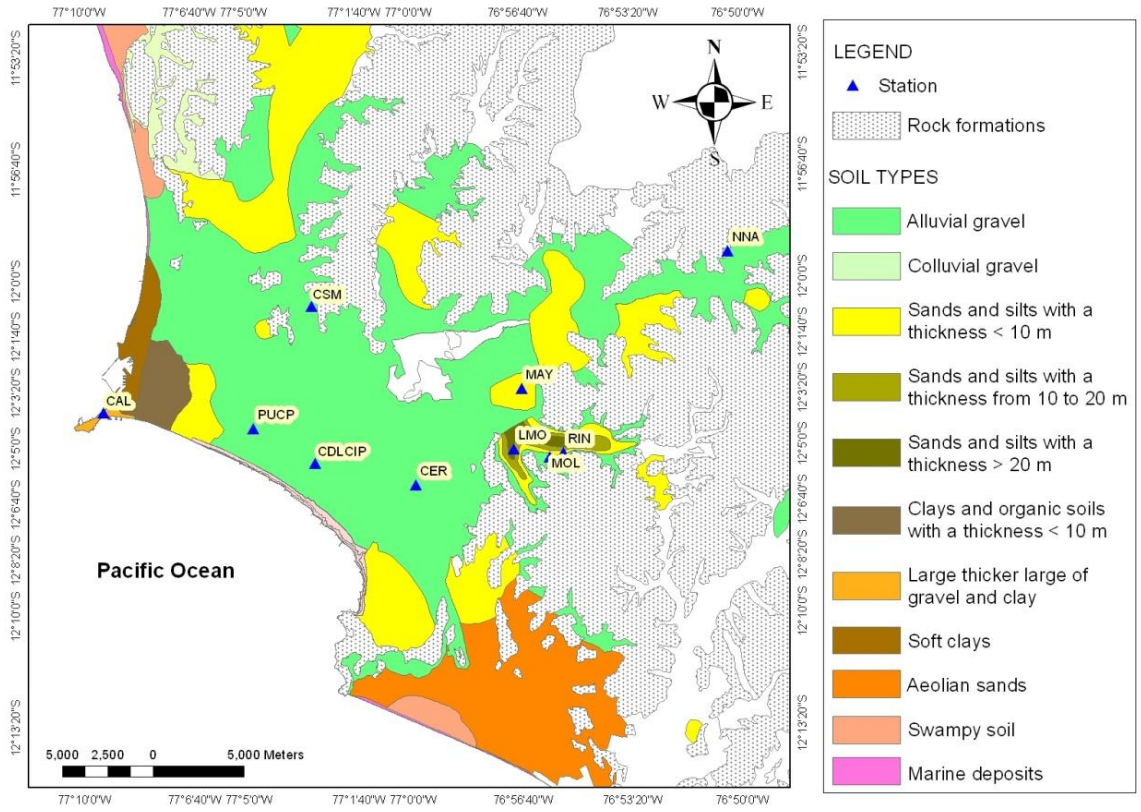

Figure 5. Soil type map of Lima city.

prominent peaks being the most significant at about 1-2 Hz (Figure 4). Our results suggest the presence at the surface of relatively softer soil layers that might contribute to the local response at this site, so it is required to carry out further studies in order to have a better understanding.

MAY and RIN sites are installed on sand and sill deposits with a thickness less than 10 m (Figure 5). At MAY station, spectral ratios show slightly large amplitudes at about 3-5 Hz due to the presence at the surface of these relatively soft layers but with a thickness less than 5 m that overlie on alluvial gravel. However, the site response at RIN station is dominated by a prominent peak between 3 and 4 Hz, which represents the first resonant mode at this site. This station shows the largest amplification factor in comparison to the other sites in this frequency range due to the medium dense sand deposits with a thickness larger than 5 m according to a soil pit near at this site. This significant peak that responds at about 3 Hz has also been detected by Stephenson et al. (2009) but by analyzing velocity response spectra.

On the other hand, CAL station shows a different behavior of amplification since important amplifications appear in the range frequency lower than 3 Hz due to the fact that this station is placed on gravel layer that overlies on a thick clay deposit.

6. DISCUSSION

Even though most stations are located on alluvial soil deposits belonging to the Quaternary Holocene, the presence of thin soft layers that overlying the Lima Conglomerate influence in the site response, dominated by several relatively small peaks in the frequency range between 3 and 6 Hz, as we can see in the CSM, MOL, CER and CDLCIP sites (Figure 4). However, RIN station has the highest amplification levels in the same frequency range because of the fact that this site is located in La Molina district, place that back in time has been reported to be affected by the influence of local subsurface conditions (Repetto et al. 1980 and Stephenson et al. 2009).

Works developed by Lee and Monge (1968) and Stephenson et al. (2009) report that this place has a complex subsurface structure that might contribute to the local site response at La Molina. In terms of our results, the horizontal-to-vertical spectral ratio for both stations present much lower amplitudes in comparison to the reference site methods, Riepl et al. (1998) reports that it is probably the complex subsurface structure that influences the vertical component in a similar manner to the horizontal components, that makes the amplification level lower.

On the other hand, small peaks at about 6-10 Hz are commonly found for all the sediment sites, which we interpret this amplification as the predominant frequency of Lima Conglomerate. Calderon (2012) gathered information about the one-point microtremor measurements (Figure 6), and such points represent the H/V ratio peak period. So on the basis of this information, we interpret that Lima Conglomerate has a dominant period of ~0.1 sec, period or frequency that has also been identified in our results. Several

researchers have pointed out that Lima city underlies by a deposit consisting of a medium dense to very dense coarse gravel and sand with cobbles, extending from the ground surface to rock, with a thickness larger than 80 m (Repetto et al 1980, Le Roux et al. 2002, Martinez A. 2007 and Aguilar et al. 2009).

The site response for CAL station shows highest amplifications for frequencies lower than 3 Hz in accordance to the gravel layer that overlies by a thick clay deposit. Our results are also consistent with the H/V peak period distribution map (Figure 6). According to this map, the predominant period at Callao-La Punta district lies in the range of 0.41 to 0.6 sec.

In addition, MOL, RIN and CSM sites show strong peaks at frequencies larger than 10 Hz, this may be because these stations are installed very close to a hill, so further studies are needed to have a better understanding.

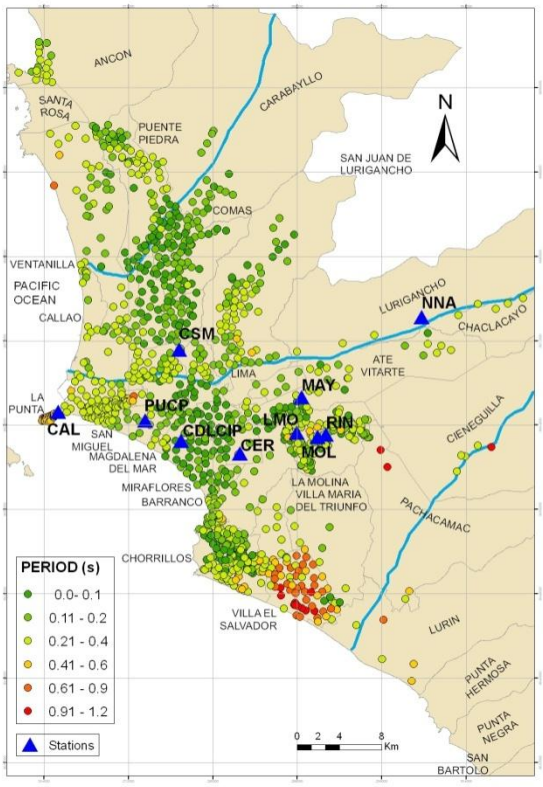

Figure 6. Location of seismic stations over the predominant period distribution map obtained from the H/V spectrum of single-point microtremor measurements (Calderon 2012).

7. CONCLUSIONS

In spite of the limitation of data, the application of the three empirical methods has allowed to evaluate the site effects on examined sites, since information about frequencies at which important amplification might appear have been provided for the study area.

Our results indicate that sediment sites show prominent peaks in the frequency range at 3-6 Hz, due to the surface layers that overlie on the alluvial gravel deposits. Most of these stations show relatively high amplification levels. Nonetheless, CAL site shows a different behavior of amplification because of soft clay layer that underlies on this site.

Last but not least, according to our results and the predominant period distribution map (Calderon 2012), we conclude that one the dynamic site characteristics of soils in Lima city is its predominant period of ~0.1 sec.

Abstract: In this study the stability of undercut slopes subjected to pseudo-static loading was investigated through centrifugal modeling, in which pseudo-static horizontal load was applied by a tilting table. Moist Edosaki sand was used as the modeling material with a series of miniature pressure cells and accelerometers embedded into the model. Furthermore the movement of the slope was monitored through a series of potentiometers placed at the top edge of the slope model. Special attention in this study was focused on the failure mechanism of the undercut slopes and redistribution of the earth pressure in the model due to arch action. Model deformation was monitored and analyzed using particle image velocimetry (PIV) and image processing software. It was concluded that the failure mechanism in the undercut slopes involves a passive condition where the major principal stresses dominate the force supporting the arches over the excavated area.

1. INTRODUCTION

Excavation in front of a slope can cause some slope stability problems especially in the existence of a potential failure plane through the slope body. The potential failure plane may be a clay seam or an oblique fault exists in the soil/rock mass or any other type of weak planes which initiates the failure of the slope. This kind of problem can be arisen during excavation stage for various kinds of geotechnical projects such as, foundations, cutting through a mountain for road or railway construction and surface mining. The most unstable case is that the potential failure plane be exposed totally along the excavated area. Some of the huge slope failures during coal mining reported by Electricity Generating Authority of Thailand (EGAT, 1985) are evidences of this kind of problem. Doing more research on the above mentioned coal mining projects, Pipatpongsa et al. (2009) reported that stable scarps observed on the slopes after a failure. They explained that those stable scarps remained stable because of the passive arch action on the slope body. The phenomenon of arch action has been initially defined by Terzaghi (1936), as a load transfer mechanism from the yielding part of the material to the adjacent stationary parts.

The problem of undercut slopes was investigated and studied through theoretical, numerical and physical considerations (Khosravi et al. 2011, Khosravi et al. 2012a, Leelasukseree et al. 2012, Pipatpongsa et al. 2012). The existence of passive arch action was confirmed by the authors through a series of 1G physical model tests (Khosravi et al., 2011). They confirmed a performance of counterweight balance on the two sides of the excavated area (Khosravi et al. 2012a) in an attempet to stabilize the undercut slopes. Later the instability phenomena of undercut slopes were developed by the authors (Khosravi 2012) based on the Jenike's (1961) theory of cohesive arching in hoppers. The problem of undercut slopes under pseudo-static loading was studied later considering the effect of earthquakes (Khosravi et al. 2012b).

Pseudo-static slope stability method is a simple method for simulation of dynamic loads of an earthquake applying on a slope by assuming additional static loads. This first application of this method is attributed to Terzaghi (1950). The pseudo-static load then has components in both horizontal and vertical directions; however, the vertical component has insignificant effect on the stability of slope and is ignored usually in stability analysis (Kramer 1996). A well known experimental apparatus for applying a pseudo-static horizontal body force to the model is a tilting table in which the horizontal seismic coefficient (k_h) can be calculated from the tilted angle of the model.

In this study the stability of undercut slopes is investigated through centrifugal tilting table model tests. Moist Edosaki sand was used as the modeling material. Change of pressure distribution inside the model body was measured by a series of earth pressure cells. Furthermore the slope deformation was monitored and analyzed using particle image velocimetry (PIV) and image processing software.

2. MATERIAL PROPERTIES

Edosaki sand as a well graded material was used in this study with the grain size distribution shown in Figure 1.

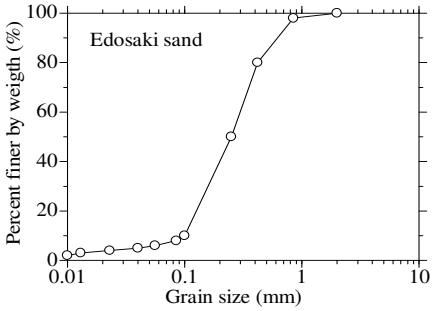

Figure 1 Grain size distribution of Edosaki sand

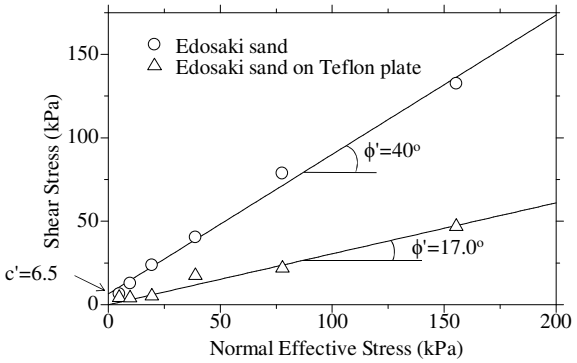
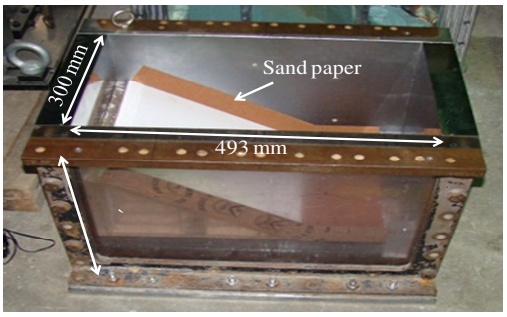
Moist sand with an optimum water content of w=15.4% was compacted inside the model container to achieve a bulk density of ρ=1630 kg/m^3. The basic properties of moist Edosaki sand are shown in Table 1.

Table 1 Basic properties of moist Edosaki sand

Average particle diameter (D_{50})	0.25 mm
Uniformity coefficient (Cu)	3.1
Specific gravity (G_s)	2.69
Optimum water content (w)	15.4 %
Unit weight (γ)	16 kN/m^3
Relative density (D_r)	92 %
Maximum void ratio (e_{max})	1.29
Minimum void ratio (e_{min})	0.87

In the undercut slope model, a Teflon sheet was used to simulate the potential failure plane due to its relatively low surface friction. A direct shear apparatus was employed to measure the shear strength parameters of moist Edosaki sand as well as the interface shearing resistance of sand and Teflon sheet. As shown in Figure 2, internal friction angle and cohesion for moist Edosaki sand was obtained 39.9^o and 6.5 kPa respectively. Interface friction between the sand and Teflon sheet was obtained 17^o with almost zero adhesion.





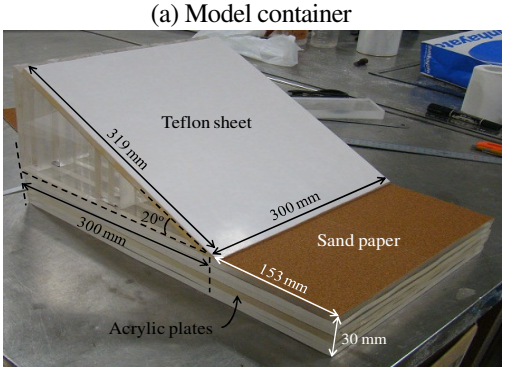


Figure 2 Shear strength parameters of moist Edosaki sand and its interface with Teflon sheet

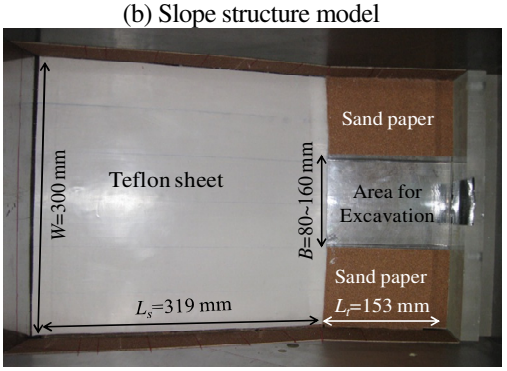
3. EXPERIMENTAL SETUP



A strong metallic model container with a transparent side was used as the container of the model (Figure 3(a)). The slope structure model was made from rigid Acrylic plates as illustrated in Figure 3(b). The slope was covered by Teflon sheet to simulate a low friction interface as a potential failure plane beneath the sand layer. The part in front of the slope was covered with sandpaper to make a fully rough base surface. Furthermore, in order to realize to the assumption of fully rough side supports, the sides of both slope and base parts were covered with sand papers as shown in Figure 3(a-c).

(a) Model container

(b) Slope structure model

(c) Slope structure model inside the container

Figure 3 Model container and the slope structure

The model container was placed on a tilting table which is installed on the platform of the centrifuge as shown in Figure 4. The tilting table used in this study was developed by Nikken Sekkei Nakase Geotechnical Institute in 1995 (Saitoh et al., 1995). The specifications of this tilting table are listed in Table 2.

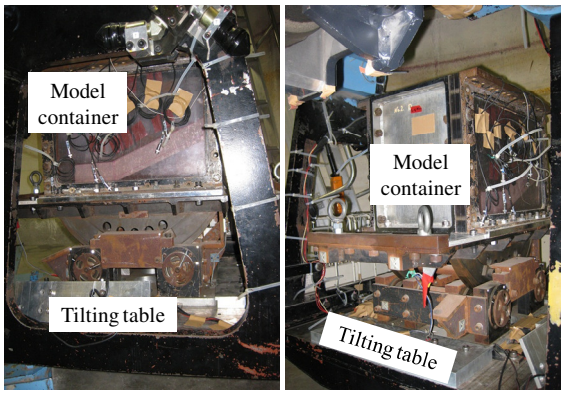


Figure 4 The model container and the tilting table placed on the centrifuge platform

Table 2 Specifications of this tilting table (Izawa & Kuwano, 2010)

weight	230 kg
Max. pay load	80 ton
Table size	
Width	920 mm
Beneath	450 mm
Max. tilting angle	20° (Corresponding k_h=0.36)
Max. tilting velocity	5°/min
Electric motor (Oriental motor, MSM590-501K)	
Voltage	AC 100 V
Power current	2.3 A
Max. power	90 W
Speed controller (Oriental motor, MSP301 N)	

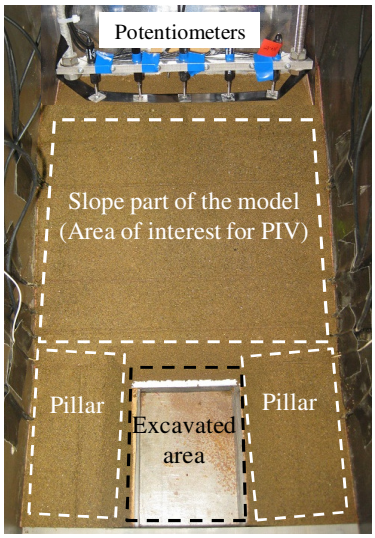
Mark 3 centrifuge of the Tokyo Institute of Technology (Takemura et al., 1999) which is a beam type in-house centrifuge machine was used in this study. This type of centrifuge has two arms which one of them holds the platform for the model container and the other one holds a weight equal to the model container for counterbalance.

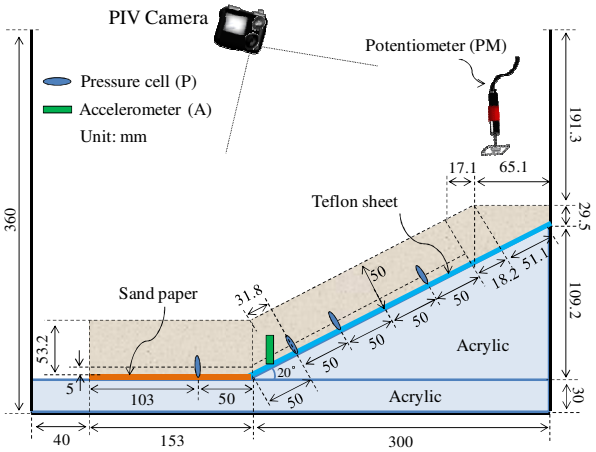
4. MODEL PREPARATION AND INSTRUMENTATION

Moist Edosaki sand was compacted inside the model container with a uniform relative density of 92%. Depending on the model test an area was excavated in front of the slope to make an initial undercut span as shown in Figure 5. Two model tests were conducted in this study where the geometry of the slope model is summarized in Table 3.

Table 3 Geometry of the slope model

Model test		1	2
Slope angle (α)		20°	
Slope length (L_s)		319 mm	
Pillar length (L_t)		153 mm	
Width (W)		300 mm	
Height (H)		50 mm	
Undercut span (B)	Bottom	80 mm	120 mm
	Top	120 mm	160 mm
	Average	100 mm	140 mm





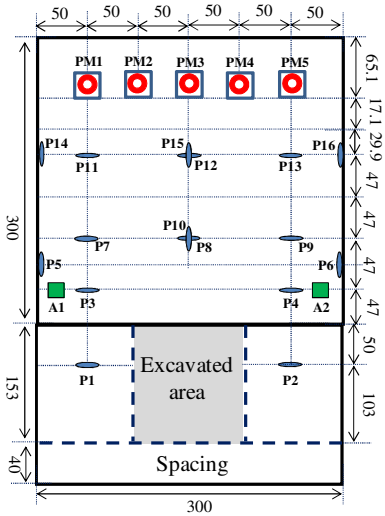


Figure 5 Moist Edosaki sand prepared in the model container

A total number of 16 pressure cells are buried in the moist sand during model preparation as illustrated in Figure 6.

(a) Side view

(b) Plan

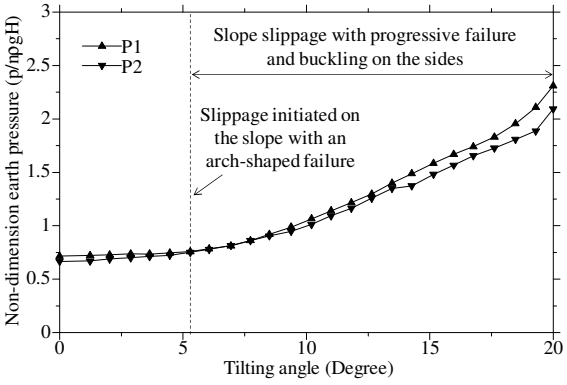
Figure 6 The instrumented undercut slope model

Pressure cells type PS-1KC, class ZC with the capacities of 100kPa and 200kPa are used for this model. All of the pressure cells are buried 5 mm above the bottom of the sand layer, in other words, underneath a 45 mm-thick layer of sand. Furthermore, a row of 5 potentiometers type MLT-38000201 with the range of 60 mm installed at the top edge of the slope to record the slope movement during the test as shown in Figures 5 and 6.

5. EXPERIMENTAL RESULTS AND DISCUSSIONS

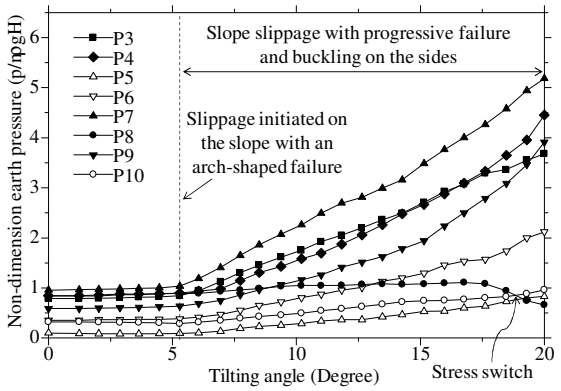
By tilting the table during the test a pseudo-static horizontal body force was applied to the model. The maximum tilting angle of the table was 20° corresponding to a horizontal seismic coefficient of 0.36 where the horizontal seismic coefficient was calculated by the following equation (Izawa & Kuwano, 2010). where k_h is horizontal seismic coefficient and β is the tilting angle.

$$k_h=\tan\beta \quad (1)$$



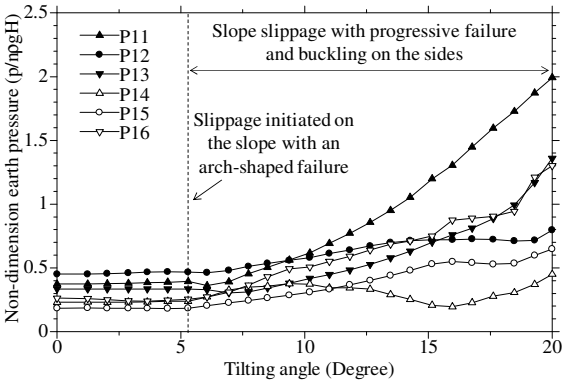
In this study the tilting velocity of the tilting table was about 3°/min and digital images for deformation analysis were captured every 20 second. Therefore, for every one degree of tilting the model, one image was captured. The results of earth pressure distribution in the model through pressure cells and deformation analysis through particle image velocimetry (PIV) are discussed individually in the two following subsections.

5.1. Earth pressure distribution



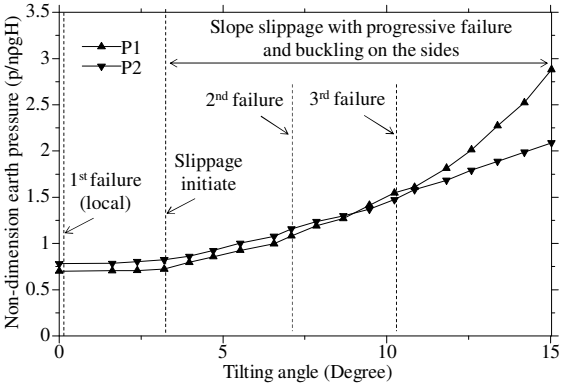
During the model tilting, the earth pressures inside the model were monitored and recorded by pressure cells. This data are normalized by $n\rho gH$ and plotted as a function of tilting angle in Figures 7 and 8 respectively for model tests 1 and 2. Where n is centrifugal acceleration, ρ is a bulk density of the sand, g is a gravity of Earth and H is a height of the model. In these figures, data measured along the dip and transverse directions are shown in close and open symbols respectively. By tilting the model, earth pressure in the pillars started to increase by slippage initiation of the slope and steadily increased until the total failure of the model (Figure 7(a) and 8(a)). The earth pressure on two sides of the slope model (P3, P4, P7 and P9) also increased gradually while the earth pressure at the center of the slope (P8) decreased. This behavior is consistent with that of 1G undercut slope physical model tests reported by authors which shows the development of passive arch action in the slope model as explained in details in Khosravi et al. (2011).

Due to symmetric geometry of the model, the centerline of the model can be assumed as a zero shear line where there is no relative displacement along the two sides; therefore, the dip and transverse directions along the centerline of the slope can represent the directions of principal stress.

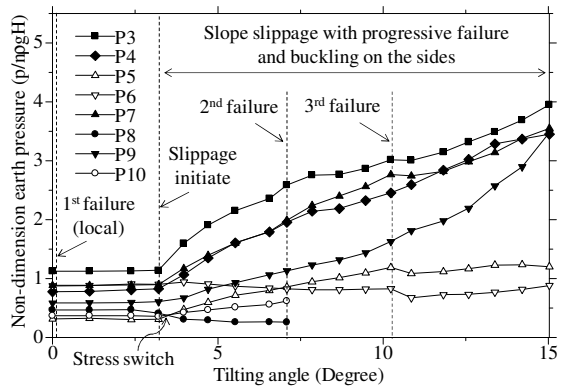


According to Figures 7 and 8 at the initial condition, where tilting was not started yet, the slope was in active condition as shown schematically in Figure 9(a). That's because the earth pressure along the dip direction (P8 and P12) was larger than that along the transverse direction (P10 and P15) at the centerline initially. By tilting the model, the status of the earth pressure along the center at the lower portion of the slope was gradually changed to passive condition where the earth pressure in dip direction (P8) became smaller than that along the transverse direction (P10). The intersection of P8 and P10 signify the isotropic stress condition where the state of earth pressure switched from active to passive. These intersections are indicated in Figures 7(b) and 8(b) as stress switch. Therefore the state of stress at the lower part of the slope was gradually changed to passive condition as shown schematically in Figure 9(b).

(a) Pillars



(b) Lower portion of the slope



(b) Upper portion of the slope

Figure 8 Measured earth pressure vs. tilting angle (Test 2_ B/W=0.47)

In model test 1, where undercut span was relatively narrow (*B/W*=0.33), the slope slippage was initiated with an arch-shaped failure in front of the slope (Figure 10(a)). By tilting the model progressive failures were observed in front of the slope. As shown in Figures 10(b) and 11, sand buckled on the sides on the lower portion of the slope while the upper portion of the slope slipped down along the Teflon sheet almost uniformly. On the other hand in model test 2, where undercut span was relatively larger (*B/W*=0.47), an initial arch-shaped failure occurred in front on the slope just when the centrifuge acceleration reached to 50G before tilting the model (Figure 12(a)). Figure 9 obviously indicates that after this failure and even until the tilting angle of about β=3°, the pressure cells did not record any movement for the model. Therefore, this initial failure did not trigger the slope slippage and can be considered as a local failure. At the tilting angle of about β=3°, the slope slippage was initiated while pressure cells record changes in earth pressures. By tilting the model, progressive failures were occurred in the model with buckling on the sides and two noticeable stacks of arch-shaped failures in the center part of the slope (Figures 12 and 13).

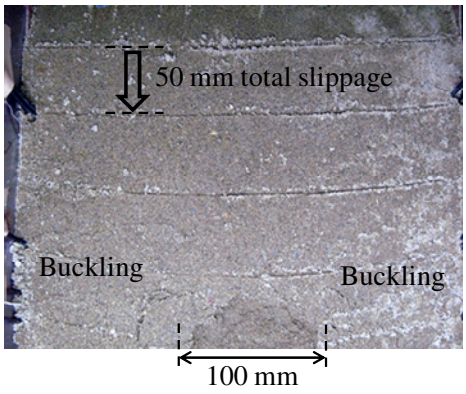
5.2. Slope deformation



Particle image velocimetry (PIV), as a non-destructive optical method (White et al., 2003), was used in this study. Sequential digital images were captured during tilting of the model and used to determine the model's deformation through GeoPIV software (White & Take, 2003).

Results of PIV analysis for the model tests 1 and 2 are shown in Figures 14 and 15 respectively in the form of displacement vectors and contours of volumetric and deviatoric strain. Figure 14 shows the deformation in the model test 1 from when the tilting was started until a failure observed on the slope. In the model test 2 the first failure occurred before tilting started. Furthermore, as explained in the previous section, this failure did not trigger the slope slippage and was considered as a local failure. Then the

images for PIV analysis were captured from tilting initiation until the second failure occurred.

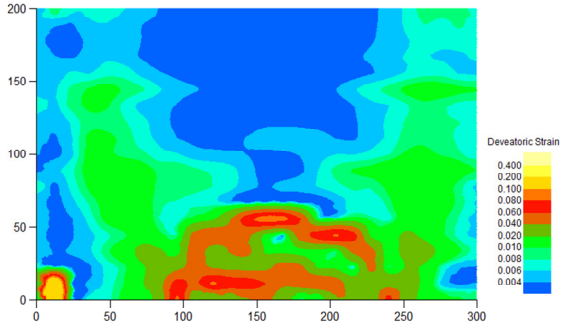

Figure 14 Results of PIV analysis (Model tests 1)

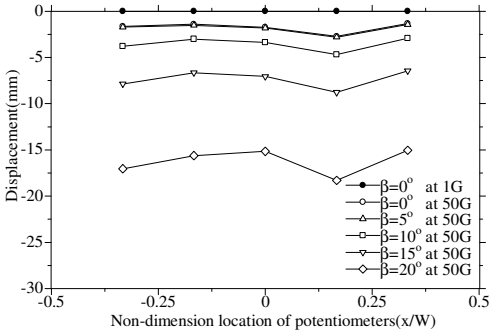
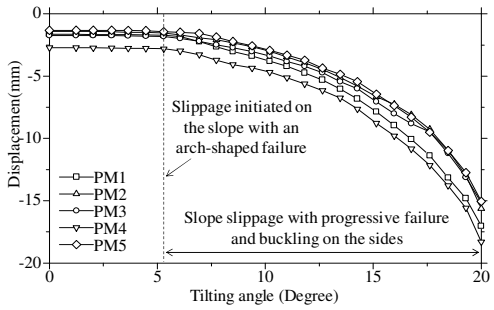
(a) Displacement vectors

(b) Volumetric strain



(c) Deviatoric strain

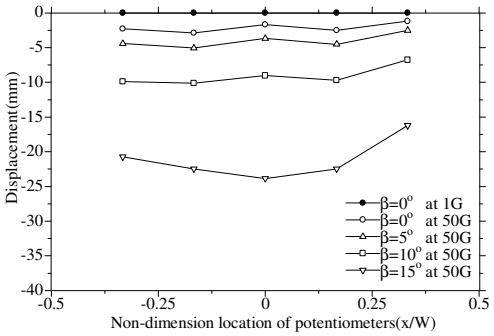
Figure 15 Results of PIV analysis (Model tests 2)



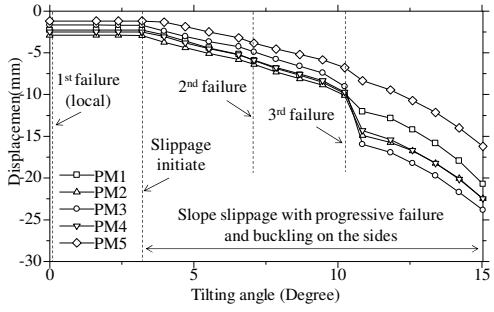
The negative values in volumetric strain (Figure 14(b) and Figure 15(b)) indicate dilation while the positive values indicate compression in the soil. From changes in volumetric strain even before failure, it can be seen that by tilting of the model the soil immediately above the excavated area dilate while the soil on the sides compress. This behavior is consistent with the earth pressure analysis explained in previous chapter where by tilting of the model the load from center part gradually transfers to sides.

The maximum values of deviatoric strain (Figure 14(c) and Figure 15(c)) indicate the part of the model with the maximum deformation in which the failure may be initiated from. Note that the holes existing in down left corner of Figures 15(b) and 15 (c) are considered as analysis error and should be ignored.

Furthermore displacements recorded by potentiometers for model tests 1 and 2 are plotted in Figures 16 and 17 respectively.



(a) Profile of the slope top edge



(b) Slope displacement vs. tilting angle

Figure 16 The slope displacement monitored by potentiometers (Model test 1)

(a) Profile of the slope top edge

(b) Slope displacement vs. tilting angle

Figure 17 The slope displacement monitored by potentiometers (Model test 2)

Attention is paid to Figure 16 (a), in model test 1. By increasing the centrifugal acceleration up to 50G, potentiometers showed some small relative displacements; however, the profile of the slope top edge during tilting of the model hardly changed. This implies that no relative displacements found between potentiometers and the slope top edge wholly moved down. It is also noticeable that during tilting process, until the tilting angle of β=5° there was no displacement recorded. After that, an arch-shaped failure occurred in the lower portion of the slope and the whole slope started to slip down on the low friction Teflon sheet.

In the model test 2, as shown in Figure 17 (b), the first failure happened when the centrifugal acceleration reached to 50G before tilting the model. However, this failure seems to be a local failure because subsequent slope failure was not observed. By increasing the tilting angle, the slippage was initiated on the slope at a tilting angle of β=3° as shown in Figure 17 (b). Later, two more failures occurred on the slope at tilting angles of about β=7° and β=10°. The relative displacement between the potentiometers gradually increased and the maximum displacement occurred at the center part of the slope top edge as shown in Figure 17 (a).

6. COMPARE TO THEORY

For the problem of a undercut slope under pseudo-static loading the relation between the slope angle (α_f) and the undercut span (B_f) at failure and the horizontal pseudo-static seismic coefficient (k_h) was defined through the following equation (Khosravi et al. 2012b).

$$\alpha_f = \phi_i - \tan^{-1} k_h + \sin^{-1}\left(\left(k\frac{\sigma_c}{\gamma B_f} + \frac{c_i}{\gamma H}\right)\frac{\cos\phi_i}{\sqrt{1+k_h^{\,2}}}\right) \qquad (2)$$

Where

σ_c: unconfined compressive strength of the material (σ_c=2c(1+sin(ϕ))/cos(ϕ))

ϕ: internal friction angle of the material

c: internal cohesion of the material

ϕ_i: interface friction angle

c_i: interface adhesion

γ: bulk unit weight of the material

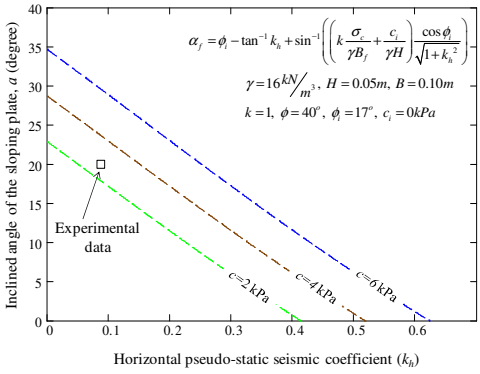
H: thickness of the material

k: arching coefficient (k=1 for mild undercut slopes (α<45°) and k=4/π for steep undercut slopes (α>45°))

The horizontal pseudo-static seismic coefficient (k_h) is obtained for every model test by using of Eq. (1). Where the values of tilting angle (β) at the instant of first arch-shaped failure on the slope were used. Note that, as explained in the previous section, the first failure in model test 2 occurred before initiation of the slope slippage and also did not trigger the slope slippage; therefore, this local failure is unlikely to be the first failure in test 2 but the second failure was considered as the real first arch-shaped failure.

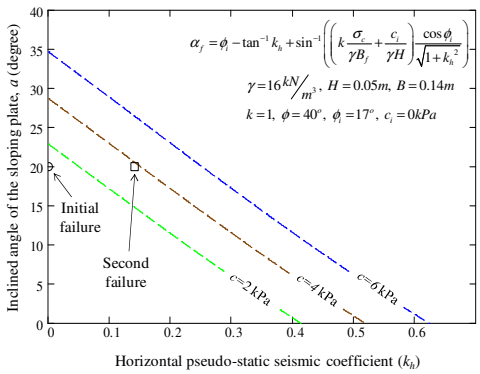
It was difficult to measure an accurate value for the internal cohesion of moist sand. A value evaluated from the free

standing height of the moist soil under 50G of centrifugal acceleration was compared to the value obtained from direct shear test (Figure 2). The stable height of the material was observed at least 3 cm which is equivalent to 1.5 m at prototype. For this free standing soil height, the internal cohesion of 3kPa was obtained through limit analysis solution (Hsai-Yang Fang 1991) which is almost the half of the value obtained from direct shear tests (6.5 kPa).



The experimental data are compared with the theory for various values of cohesion in Figures 18 and 19. It can be concluded from these figures that a value of the material's internal cohesion back calculated from the free standing height of the moist soil under centrifugal field is more reliable that the value obtained from direct shear test.

In order to show all the experimental data in a unique plot the horizontal pseudo-static seismic coefficient (k_h) removed from Eq. (2) and instead the tilting angle (β) was added as in Eq. (3).



$$(\alpha+\beta)_f = \phi_i + \sin^{-1}\left(\left(k\frac{\sigma_c}{\gamma B_f}+\frac{c_i}{\gamma H}\right)\cos\phi_i\right) \qquad (3)$$

Where $(\alpha+\beta)_f$ represents the inclined angle of the slope at failure including the initial slope angle plus the tilting angle.

Figure 20 compares all the experimental data with theory where for comparison, the result of a previous centrifugal undercut slope test under static condition (Khosravi 2012) was also shown.

7. CONCLUSIONS

This work describes the pseudo-static stability of undercut slopes using centrifuge tilting table tests. Slope models with a specific undercut span were subjected to pseudo-static loading under a centrifugal acceleration of 50G. The earth pressure distribution inside the model was recorded through a series of earth pressure cells. The deformation of the slope was monitored through analysis of sequential digital images captured during the test by particle image velocimetry technique. A row of potentiometers were also placed at the top edge of the slope to record the slope displacement.

By applying a pseudo-static loading to a certain level, the slope initiated to slip down and the earth pressure transferred from the center to sides. Furthermore, the stress condition in the slope was changed from active to passive gradually. These results are in agreement with those reported by authors on a series of 1G undercut slope model tests (Khosravi et al. 2011) conforming that arching effect in undercut slope is a scale-independent phenomenon.

An acceptable agreement between the experimental data and the theory under pseudo-static approach convinces that the concept of passive arching effect can assess the seismic stability of undercut slopes. Though arching typically involves a monotonic loading, the undercut slopes subjected to a cyclic loading could be considered by means of shakedown analysis because both phenomena of arching and shakedown are associated to the adaptation of load bearing structure.

Abstract: To increase the pullout resistance of geocell, a square-shaped geocell was developed and pullout tests were conducted on small scaled models placed in gravelly soil backfill. A preloading method was applied to enhance a high initial stiffness of square-type geocell. Significant effects of in-plane geometry and height of geocell on the pullout resistance were found. Analysis of the tests results indicates noticeable particle size effects that can be explained by a conceptualized pullout interaction mechanism. It is shown that the pull-out resistance is composed of two factors: the shear resistance along the shear bands developed at the top and bottom interfaces between the geocell and the adjacent backfill and the anchorage resistance induced by passive pressure inside the aperture of the geocell, which increases and becomes more dominant in the total pull-out resistance with an increase in the height of geocell.

1. INTRODUCTION

Geosynthetic-reinforced soil structures are now widely used for different civil engineering applications, including earth retaining walls, bridge abutments, slopes, embankments, pavements and erosion control. Geocell, as a three-dimensional soil confinement system, has more attractive features than other planar geosynthetic reinforcements such as geotextles and geogrids (Yuu and Han, 2008).

Most of the previous studies of geocell were mainly focused on the function as base reinforcements subjected to vertical loads, such as roads, embankments, light houses. The influencing factors for the performance of geocell-reinforced bases, such as geometric structures and dimensions, properties of geocell material and properties of infilled soil, loading methods, etc., were investigated by many researchers including Rea and Mitchell (1978), Shimizu and Inui (1990), Mhaiskar and Mandal (1992b, 1994), Dash et al. (2001a, 2001b, 2003, 2004), etc.

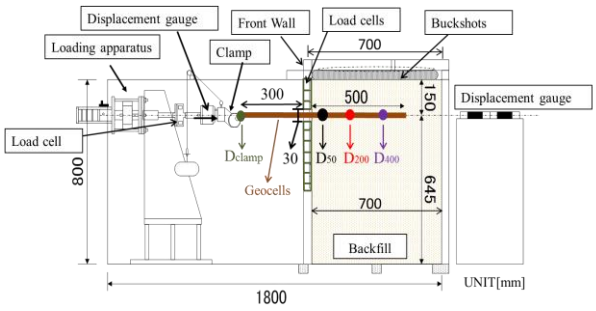
For the last two decades, geosynthetic-reinforced soil retaining walls (GRS RWs) with a stage-constructed full-height rigid (FHR) facing have been constructed for railways, highways and other facilities and have shown greater seismic resistance than conventional retaining wall structures (Tatsuoka et al., 2009). Geogrids and geotextiles are commonly used as planar reinforcements to tensile-reinforce the backfill of RWs, embankments and other soil structures. However, the application of geocell as tensile reinforcement to these soil tructures is relatively new due to the lack of related research. Ling et al. (2009) investigated the seismic performance of several soil RWs having a geocell facing by shake table tests. The results showed that walls having a geocells facing are flexible exhibiting much better seismic performance than conventional type RWs. In addition, the performance of a RW with the backfill reinforced with geocell layers was better than a RW with the backfill reinforced by geogrid layers.

One of the important advantages of geocell is an ability of three-dimensionally confining large particles in the cells exhibiting a large anchorage capacity when pulled laterally. Kiyota (2009) and Kuroda (2012) conducted a series of pullout tests using diamond-shaped geocell models and several different types of geogrid to investigate whether or not the geocells can be used as tension reinforcement. It was found that, although the diamond-type geocell shows higher pullout resistance than geogrids, the global stiffness is not better than the geogrids due to progressive large deformation of diamond-shaped cells. In the present study, in order to increase the initial stiffness and pullout resistance of geocell, a new type geocell having square cells were developed and evaluated by pull-out tests.

2. TEST APPARATUS, PROCEDURES AND MATERIALS

2.1 Pullout test apparatus

Figure 1 shows the schematic diagram of pullout test apparatus that was developed at Tokyo University of Science (TUS). The tests were carried out on under plane strain conditions. The sand box was 700 mm (length) ×400mm (width) × 800mm (height). The main part of the apparatus was made of steel, while the longitudinal side walls were made of hard glass plates to reduce sidewall friction. The front wall to retain the backfill was composed of separate plates accommodating small load cells to measure the lateral earth pressure activated to the back face of the front wall. An opening with a height of 30 mm was provided at the front wall for pulling out the geocell specimen from the backfill.



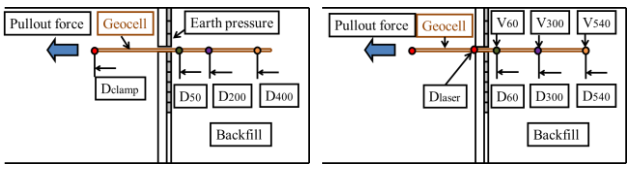


Figure 1. Pullout test apparatus at TUS

A similar apparatus was also developed at the University of Tokyo (UT).

2.2 Pullout test procedures

Gravels were poured into the soil box and compacted in 30 cm-thick sub-layers arranging a geocell model at the prescribed level in the backfill. The target relative density of the backfill was 90%. As listed in Tables 1 and 2 and indicated in Figure 2, the pullout displacements at the clamping device of the geo cell (D_{clamp}) were measured with two displacement gauges and the displacements at distances of 50 mm (D_{50}), 200 mm (D_{200}), and 400 mm (D_{400}) from the back face of the front wall were measured with three displacement gauges. In addition, the vertical displacements at distances of 60 mm (V_{60}), 300 mm (V_{300}), and 540 mm (V_{540}) from the back face of the front wall were also measured with three displacement gauges in UT. A surcharge of 1 kPa of lead shots was applied on the crest of the backfill. The tests were conducted by pulling out the geocell at a constant speed of 5 mm/min using a precision jack driven by a motor. The pullout force was measured with a load cell.

2.3 Backfill and geocells

The backfill soils used in this study are poorly graded sub-round gravelly soils, Gravel No.1 and Gravel No.3 (Figure 3). Their particle sizes are 3~5 mm and 7~10 mm, respectively. As shown in Figure 4, the geocell reinforcement was 480 mm (length) × 350 mm (width), having eight cells in the longitudinal direction and seven cells in the transverse direction. The geocell was made of polyethylene terephthalate (PET) covered with PVC for protection, having a square aperture of 60 mm (length) ×50 mm (width) and a thickness of 1 mm. The longitudinal members have a common height which is 20mm higher than transversal members. The ultimate tensile strength of the material is 56 kN/m at a strain of 20 %. Four geocell models with different heights were prepared. The full height (H) of transverse members is 25 mm (SG-1); 12.5 mm (SG-2); 40 mm (SG-3); and 60 mm ((SG-4). The test cases are summarized in Table 3.

3. RESULTS AND DISCUSSIONS

3.1 Effects of geometry of geocell

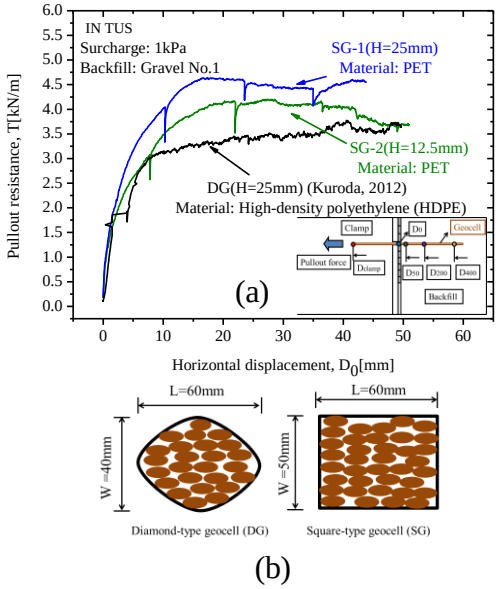

Figure 5. a) Relationships between pullout force and displacement D_0 for various types of geocell; and b) schematic diagrams of single geocell

Figure 5a shows the relationships between the pullout force (T) and the displacement (D_0) of square-shaped geocells (SG-1and SG-2) and diamond-shaped geocell (DG), which has the same height as SG-1, from the tests conducted on the same conditions (Kuroda, 2012). Geocell DG starts obvious yielding at the smallest displacement (8 mm) and does not exhibit strain-softening. Geocells SG-1 and SG-2 exhibited higher peak strengths at larger displacements, followed by noticeable strain-softening. This difference is due likely to the different geometries of the geocells, in particular the shape of aperture (Figure 5b). The fact that, despite a lower peak strength, geocell DG has the nearly the same initial stiffness as geocell SG-1 and SG-2 may be due to much thicker therefore much stiffer members of geocell DG (by a factor of >>1/6).

Figure 6 compares the results of earth pressures on the front wall during the pulling out of the geocells from soil. As shown in Figure 6, the earth pressure induced by geocell DG was higher than that by geocell SG-1 and SG-2. This fact indicates that the confining pressure developing around geocell DG was higher than those developing around geocell SG-1 and SG-2, despite that the peak strength is smaller.

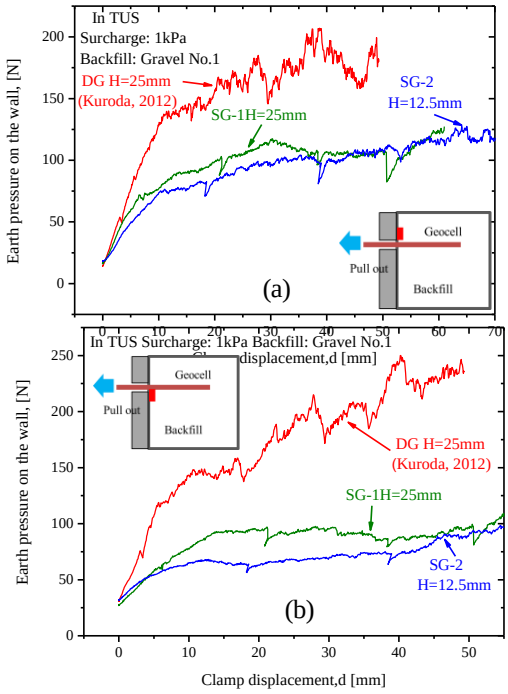

Figure 6. Earth pressures on the front wall: (a) above; and (b) below the opening

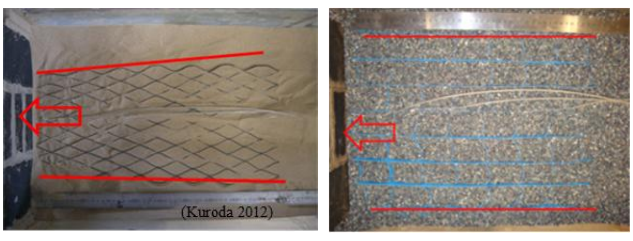
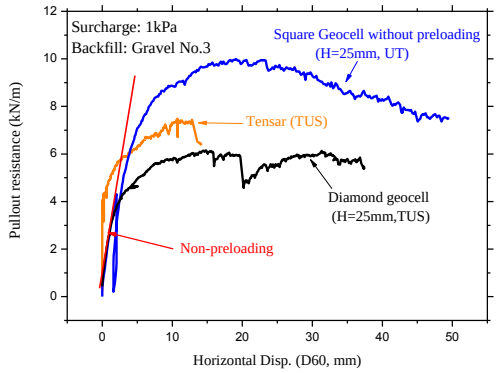
The complicated trends of behavior described above may be due to a larger deformability of the whole structure of geocell DG due to its specific shape of aperture despite thicker and stiffer members. That is, the soil in the diamond-shaped cells can be pushed out much more easily than with the square-shaped geocells, which results in a more progressive deformation of geocell DG than geocells SG-1 and SG-2, as shown in Figure 7.





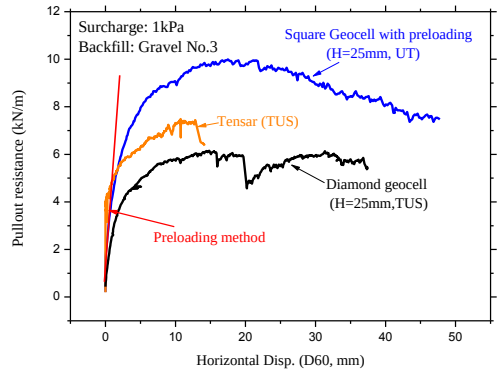


Figure 7. Deformation characterics of geocell: (a) diamond-type geocells; (b) square-type geocells

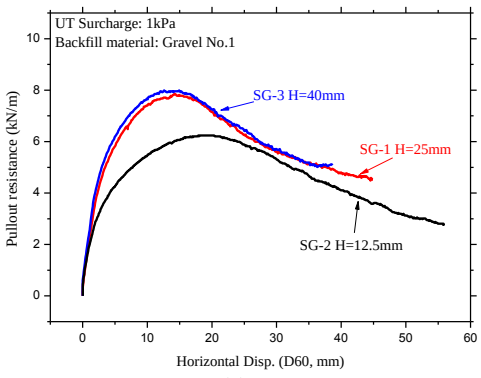
3.2 Enhancement of initial stiffness

With square-shaped geocells, the initial stiffness increases with an increase in the stiffness of transverse ribs. Tensar has a very high value of this stiffness, therefore it exhibits a very high initial stiffness as seen from Figure 8. It may also be seen from Figure 8 that, with geocell SG-1, the initial stiffness increases by applying preloading of pull-out load up to 4.3kN/m. This may be due to that preloading decreased the slackness of the initial arrangement of the transversal ribs.

(a)



(b)

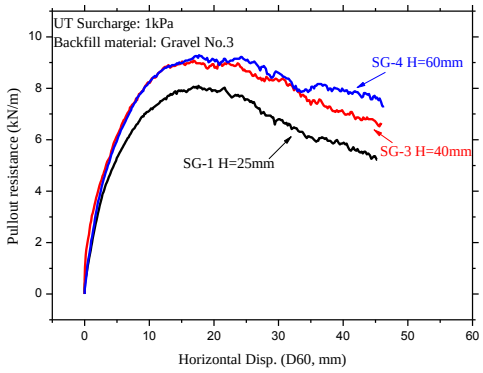


Figure 8. Relationship between pullout force and horizontal displacement among square- and diamond-shaped geocells and Tensar: (a) without and (b) with preloading

3.3 Effects of particle size relative to aperture size

The relative particle size effect was investigated by using square-type geocells with different heights arranged in backfill Gravels No.1 (the particle diameter is 3~5 mm) and No. 3 (7~10 mm). It may be seen from Figure 9 that, with an increase in the particle size, the peak strength increases while the amount strain softening decreases: i.e., the residual strength increases with an increase in the particle size to a more extent than the peak strength.

(a)

(b)

Figure 9. Pullout behavior of square-type geocells with different heights: (a) Gravel No.1; (b) Gravel No.3

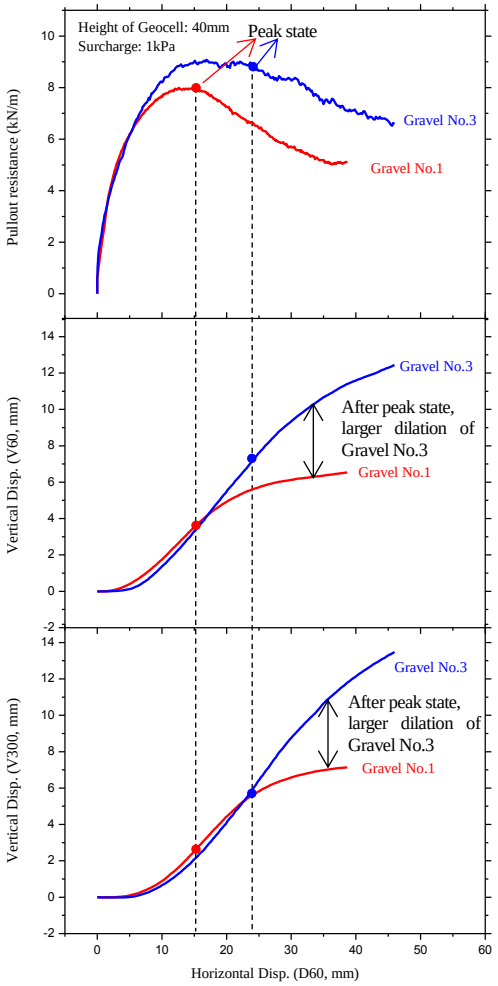

Figure 10. Relationship between horizontal displacement and pullout resistance, local vertical displacement (V_{60} and V_{300}) of SG-3 (H=40mm)

Figure 10 compares the effects of backfill particle size on the pull-out resistance and the local vertical displacements (i.e. V_{60}, V_{300}) measured above the geocell SG-3 (shown in Figure 2-b) plotted against the pullout displacement (D_{60}). In the post-peak regime, the rate of

dilatancy per horizontal displacement was larger while the strain-softening was smaller with Gravel No.3 (larger particles) than with Gravel No.1 (smaller particles). This result indicates that, with an increase in the backfill particle size, the shear band that develops at the interfaces between the geocell and the backfill becomes thicker, therefore the ultimate amount of dilatancy becomes larger, which results in a larger increases in the local vertical stress activated to the geocell, therefore larger pull-out resistance at large pull-out displacements.

The pull-out resistance increases with an increase in the rib height from 12.5 mm to 25 mm in Figure 9a and from 25 mm to 40 mm in Figure 9b. However, with further increase in the rib height, the pull-out resistance exhibits only a very small increase in both cases. To analyze this trend, Figure 11a summarizes the pull-out resistance of square-shaped geocells SG-1, SG-2, SG-3 & SG-4 embedded in Gravel No.1 and Gravel No.3 and diamond-shaped geocells DG embedded in Toyoura sand (Kuroda et al. 2012). It may be seen that, under otherwise the same conditions, the pull-out resistance increases with an incease in the rib height with the square-shaped geocells or the member height with the diamond-shape geocells. However, there exists an upper limit with the pullout resistance that is reached when the height of rib or member becomes a certain value that increases with an increase in the backfill particle diameter. The line presented in Figure 11a indicates this upper-limit state.

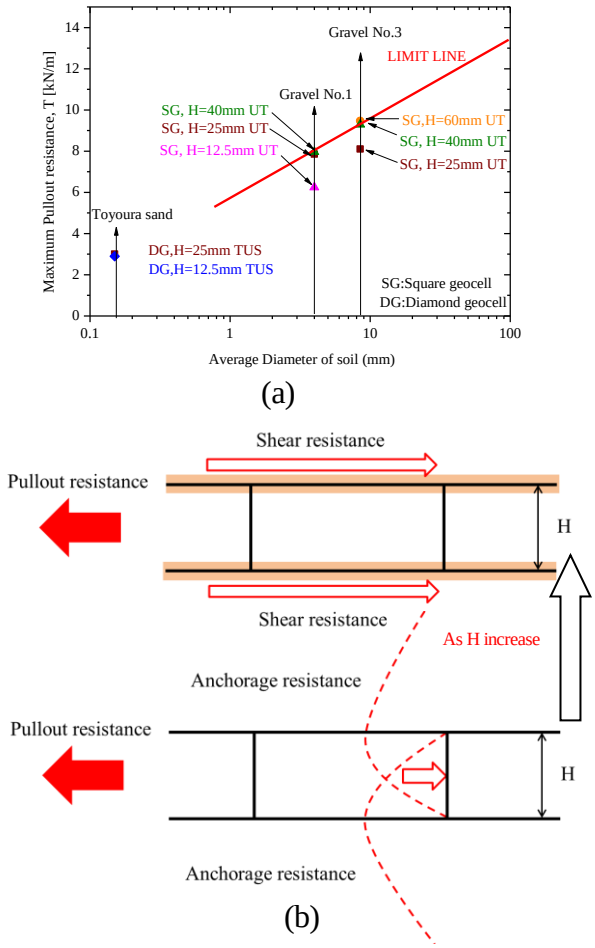

Figure 11. (a) Particle size effect on maximum pullout resistance; and (b) two mechanism of pullout resistance of reinforcement embedded in the backfill

These test results suggest the following fundamental mechanism. As shown in Figure 11b, the pullout resistance is equal to the smaller one of the following two types of resistance: 1) the shear resistance of the shear bands that develop along the upper and bottom faces of a geocell and the backfill, which is independent of the height of rib or member (i.e., the height of geocell); and 2) the anchorage resistance induced by passive pressure developing inside the cells, which increases with an increase in the height of geocell. Therefore, as the height of geocell increases, the total pullout resistance is first determined by the anchorage resistance and increases with an increase in the height of geocell. When the height of geocell reaches a certain value, the anchorage resistance reaches the shear resistance. Then, the pull-out resistance does not increase with further increase in the height of geocell. Both shear resistance and anchorage resistance increase with an increase in the backfill particle size, therefore the pull-out resistance does so. This trend becomes stronger at larger pull-out displacements. The test results show that the limit of the height of geocell at which the two types resistance become the same increase in the backfill particle size.

4. CONCLUSIONS

A geocell having square-shaped apertures was developed to increase the pull-out resistance. A series of pullout tests were conducted on small scaled models of square-shaped geocell arranged in backfill of gravelly soil. By analyzing the data from these tests and previous tests, the effects of the shape of cell and the height of transversal members (ribs) and the backfill particle size on pullout resistance were evaluated. The main conclusions from this study are as follows:

1. The effects of cell shape increases with an increase in the pull-out displacement. Under otherwise the same conditions, the square-shaped geocell exhibit higher peak pull-out resistance than the diamond-shaped geocell and higher residual strength to a more extent.
2. The initial pull-out stiffness of a geocell increases by reducing the initial slackness of the geocell by preloading.
3. The pullout resistance is equal to the smaller value of: the shear resistance of the shear bands along the upper and bottom faces of a geocell, which is independent of the height of geocell; and the anchorage resistance induced by passive pressure developing inside the cells, which increases with an increase in the height of geocell. Therefore, as the height of geocell increases, the total pullout resistance is equal to the anchorage resistance and increases with an increase in the height of geocell. When the height of geocell reaches a certain value, the pull-out resistance becomes the same as the shear resistance and does not increase with further increase in the height of geocell. Both shear resistance and anchorage resistance, therefore the pull-out

resistance, increase with an increase in the backfill particle size.

The tests results presented in this paper are rather limited. More tests to evaluate the effects of the stiffness and height of geocell and the particle diameter of backfill, the vertical pressure and so on should be tested in the future.

Abstract: Cement stabilized soil is characterized by the brittle property in which high compression strength and small strain at failure and low tensile strength. It has been well recognized that the failure pattern of the stabilized soil is quite different from those of ordinary cohesive soils. A series of centrifuge model tests was conducted to investigate the failure pattern and stability of cement stabilized clay ground having an unsupported vertical slope. The model ground was subjected to monotonically increasing centrifugal acceleration until it failed due to the enhanced self-weight. It was found from the test results that the model ground failed with a combination of a vertical tensile crack and a straight shear failure plane, which was much different from the failure phenomenon of sandy or clayey ground. A new calculation incorporating the failure pattern of stabilized soil should be necessary to investigate its critical height and the failure zone precisely.

1. INTRODUCTION

Because of economical and environmental concerns it has become more difficult in recent years to obtain enough soil to make reclamation for airports, electric power plants, manufacture plants and so on. On the other hand, it has become difficult to find and construct disposal sites for waste subsoil or dredged soil. These circumstances have caused geotechnical engineers at present to use these poor quality materials as filling materials more than they were used one or two decades ago. Several soil admixture methods have been developed to improve their properties and to manufacture high quality fill materials. Actually, Horiuchi *et al*. (1992) and Kawasaki *et al*. (1992) manufactured fly ash and cement mixtures as a fill material to construct a man-made island for a bridge in Hokkaido, Japan. Tsuchida *et al*. (1996) manufactured lightweight soil, a mixture of dredged clay, cement and fine air form, to fill behind a sea revetment. Recently a cement soil mixture manufactured by the Pneumatic Flow Mixing Method as shown in Fig. 1 has been used to construct a man-made island for a new international airport (Kitazume *et al*., 2000, Kitazume and Sato, 2002).

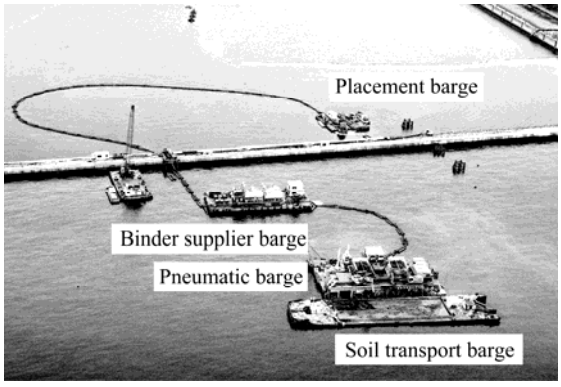

Fig. 1. Pneumatic Flow Mixing Method.

The deformation and strength characteristics of cement stabilized soils have been investigated in Japan, which have revealed that the stabilized soil is characterized by a brittle behavior with quite high compressive strength and quite small strain at failure, and the stabilized soil with relatively high strength shows tensile failure instead of shear failure, as exemplified in Fig. 2. Regarding to evaluate the stability of structures adjacent to or buried in the stabilized ground, Kitazume (1998) and Kitazume et al. (2003) investigated the earth pressure of cement stabilized ground by the centrifuge model tests. And The emphasized that the failure pattern of the cement stabilized ground was much different from that of ordinary ground. After the Hyogoken-Nambu earthquake in 1995, many design codes for the seismic stability were revised in Japan, so that seismic stability must be evaluated more precisely. The dynamic earth pressure of ordinary grounds is usually calculated by a pseudo-static limit equilibrium method based on the Mononobe-Okabe's method (Okabe 1924, Mononobe and Matsuo 1929). This calculation method is also applied to the cement stabilized ground, although its applicability has not been thoroughly clarified.

(a) relatively low strength (b) relatively high strength

Fig. 2 Failure pattern of cement stabilized soil.

In order to investigate the failure pattern of cement stabilized ground, the authors started a research project where a series of model tests and analyses is carried out on the above subject. In this paper, the failure pattern of the cement stabilized clay ground subjected to monotonic increase of self-weight was investigated in the Tokyo Institute of Technology Mark III geotechnical centrifuge apparatus. A series of centrifuge model tests was carried out on the cement stabilized clay ground having an unsupported vertical slope. The model ground was subjected to monotonically increasing centrifugal acceleration until it failed due to the enhanced self-weight. The applicability of the conventional limit equilibrium method based on Coulomb method to the cement stabilized ground was examined based on the model test results, where the calculated critical height of the ground did not coincide well with the model test results. A new calculation incorporating the failure pattern of stabilized soil should be necessary to investigate its critical height and the failure zone precisely.

In this paper, the model test procedure and test results are briefly introduced.

2. CENTRIFUGE MODEL TESTS

Centrifuge Apparatus

A static loading technique has also been employed to investigate the stability and failure pattern of cement stabilized ground where the model ground is subjected to enhanced self-weight. The centrifuge used for the tests was the Tokyo Institute of Technology Mark III Geotechnical centrifuge. The centrifuge has a maximum acceleration of 150 G, a maximum effective radius of 2.3 m and a maximum payload of 330 kg.

Model ground preparation and testing procedure

The model ground set up for the test is schematically shown in Fig. 3. A rigid specimen box had inside dimensions of 70 cm in length, 15 cm in width and 45 cm in height. The box had a Polycarbonate resin window to observe the model ground behavior. The inner surfaces of the box were lubricated with a mixture of silicone grease and silicone oil to minimize the friction between the box and the model ground.

The model ground was prepared as follows. Kaolin clay was thoroughly mixed with de-aired water for 60 minutes to make a uniform slurry with a water content of 120%, whose physical properties are summarized in Table 1. Then, binder factor *aw* of 5 or 10% of normal Portland cement was added to the slurry and mixed for 10 minutes, where the cement factor, *aw* was defined as the ratio of dry weight of cement to that of soil. The soil cement mixture was poured into the specimen box. Three mold specimens were also prepared with the same stabilized soil as the model ground for the unconfined compression test. The model ground and the mold specimen were sealed tightly to minimize water evaporation from the model ground and cured for the prescribed days in the laboratory. After curing, the model ground thus prepared was mounted on the centrifuge, and a potentiometer was placed at the crown of the model ground to measure the vertical displacement during the loading. The ground was subjected to monotonically increasing centrifugal acceleration until it failed due to the enhanced self-weight. During the flight, the vertical displacement at the crown of the model ground was measured and the ground deformation was observed by the TV camera mounted on the centrifuge. After the test, the failure pattern of the ground was carefully observed. At each test, unconfined compression tests were conducted on the mold specimen to estimate the unconfined compressive strength of the model ground. Three model tests were conducted by changing the strength of the model ground, as summarized in Table 2.

Curing days, *t* (day)	7	12	13
Unconfined compressive strength, q_u (kPa)	142.6	46.2	120.9
Height of ground (cm)	34.6	34.0	33.5
Unit weight (kN/m^3)	13.5	13.6	13.7
Centrifuge acceleration at failure (G_f)	46.5	17.7	46.5

3. TEST RESULTS

Displacement and centrifugal acceleration

During the test, the vertical displacement of the model ground was measured at its crown. Figure 4 shows the ground settlement, *S* in a model scale against the centrifugal acceleration *G* measured in the CASE3, where the unconfined compressive strength of 120.9 kPa. It can be seen that the *S* value increases very slightly at first as the *G* increases but suddenly jumps up to around 40 to 50 mm due to ground failure just after *G* reaches about 46 *G*. Similar test results were obtained in the CASEs 1 and 2. This phenomenon indicates that the entire ground failure suddenly took place without an pre-failure progressive deformation.

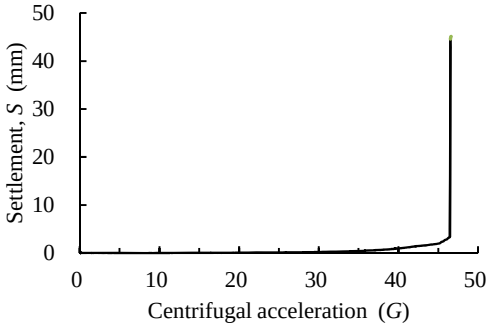

Fig. 4. Displacement and centrifugal acceleration curve (CASE3)

Failure pattern of ground

A typical failure pattern of the ground is shown in Fig. 5, which was obtained in the CASE3. For ease of detecting the failure pattern, the side surface of the model ground was painted as a grid pattern. In the figure, a tensile crack developed almost perpendicular to the ground surface. A shear failure plane also developed from the bottom end of the tensile crack toward the bottom of the ground base immediately after the tensile crack formed. A similar failure pattern was also found in the cement stabilized fly ash ground (Kitazume 1998). The failure pattern obtained in this study is much different from those of soft clayey ground or sandy ground (e.g. Japanese Soil Mechanics Society 1994, Zeng 1998). The features of the failure pattern is due to the considerably small ratio of tensile strength to compressive strength of cement stabilized soil.

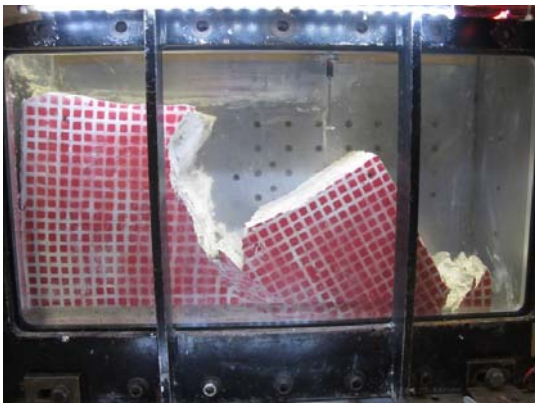

Fig. 5. Model ground failure (CASE3)

4. DISCUSSIONS

Critical height

The centrifugal acceleration at ground failure, G_f, was defined as the acceleration when the ground settlement jumped up as shown in Fig. 4. The G_f values thus obtained are summarized in Table 2 together with the test condition. The normalized critical height, H_c of the ground is calculated by Eq. (1) and plotted against the unconfined compressive strength, , q_u in Fig. 6.

$$H_c = \frac{\gamma \cdot H_m \cdot G_f}{q_u} \quad (1)$$

where

G_f : gravity at failure (*G*)
H_c: normalized critical height of model ground
H_m: height of model ground (m)
q_u : unconfined compressive strength of model ground (kN/m^2)
γ: unit weight of model ground (kN/m^3)

In the figure, similar test results (Kitazume *et al*., 2003) are plotted together. Although there is a scatter in the data, it is found that the normalized critical height, H_c decreases gradually with the strength of stabilized ground. The critical height calculated by the static limit equilibrium method, Coulomb theory, is plotted as chain line in the figure. The calculation gives a constant value of 2 irrespective of the strength of model ground. It can be seen that the calculation

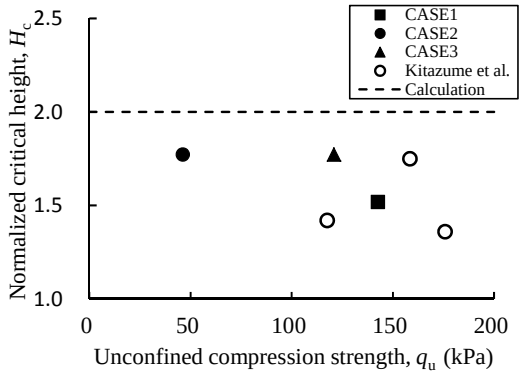

Fig. 6. Normalized critical height and strength of ground.

overestimates the measured values and the overestimation increases with increasing strength. This is because the failure pattern assumed in the theory, a straight shear failure plane alone, is much different from that obtained in the tests.

Failure zone

The normalized failure zone B_m/H_m is plotted against the G_f in Fig. 7, where B_m is the horizontal distance of the tensile crack plane measured from the front face of the ground. Again, the measured data by Kitazume *et al.* (2003) and the calculation of Coulomb theory are plotted together in the figure. The calculation is constant of 1.0 along the q_u, while the B_m/H_m value is smaller than the calculation and decreases with the increasing q_u. This difference also suggests that the conventional static limit equilibrium method cannot evaluate the failure zone of the cement stabilized ground. A new calculation incorporating the failure pattern of stabilized soil should be necessary to investigate its critical height and the failure zone precisely.

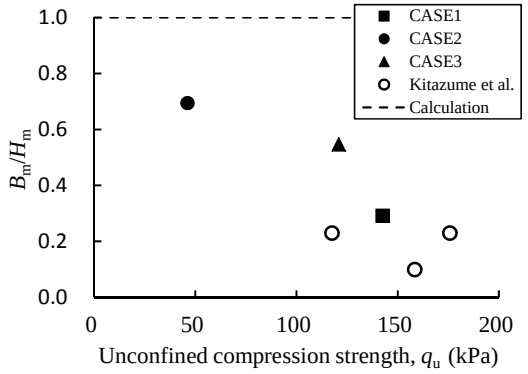

Fig. 7. Normalized failure zone and strength of model ground.

5. CONCLUSIONS

A series of model tests was conducted on the geotechnical centrifuge apparatus to investigate the stability and failure pattern of cement stabilized ground having an unsupported vertical slope. The test results show the unique feature of failure pattern that is characterized by a combination of a vertical tension crack and a shear failure plane. The conventional static limit equilibrium method based on Coulomb theory cannot evaluate the critical height and the failure zone of the ground obtained in the tests accurately. new calculation incorporating the failure pattern of stabilized soil should be necessary to investigate its critical height and the failure zone precisely.
