In this equation, T_o which is given from initial stiffness and effective mass is a key parameter but it is difficult to evaluate the initial stiffness in a timber-based structure because the load-displacement response of the structure is highly nonlinear behavior under monotonic and cyclic loading. In this study, T_o-T_e is replaced to T_{eff} which is calculated only from a peak target displacement as shown in Eq. (2). The heq in Eq. (1) which is an average of ductility factors in each cyclic loading is also replaced to an equivalent viscous damping calculated from a peak target displacement.

$$S_d(T_e, h_{eq}) = \frac{T_{eff}}{2\pi}\overline{S_{pv}}(T_{eff}) \times D_h(h_{eq}) \quad (2)$$

2.2 Determination of Effective Elastic Period, T_{eff}

The effective elastic period, T_{eff} is regarded as the elastic period obtained from the energy spectrum in nonlinear time history analysis. The detail is shown below.

STEP 1: response velocity and response acceleration is computed by nonlinear time history analysis. Total energy input is calculated from Eq. (3).

$$E_a = \int_0^{T_d} \dot{x} \cdot \ddot{y}\, dt \quad (3)$$

STEP2: equivalent velocity, V_{Ea} obtained from Eq. (4) is calculated.

$$V_{Ea} = \sqrt{\frac{E_a}{2m}} \quad (4)$$

STEP 3: time history analysis for elastic system is conducted and V_{Ea}-T spectrum is drown.

STEP 4 : T_e is calculated from effective seismic mass, m and equivalent lateral stiffness which is a tangent stiffness, k_e of a peak displacement as shown in Eq. (5).

$$T_e = 2\pi\sqrt{\frac{m}{k_e}} \quad (5)$$

STEP 5: effective elastic period T_{eff} is determined from following equation and parameters, A and B, in the equation is defined as the factors to correspond to V_{Ea}-T spectrum.

$$T_{eff} = A \cdot \left(1 + \frac{1-A}{(T_e \cdot 10)^B}\right) \cdot T_e \quad (6)$$

2.3 Determination of Equivalent Viscous Damping

In order to capture the energy dissipation characteristics of the structure at the target displacement an equivalent viscous damping ratio must be determined. For this purpose, several damping database has been established for the selected structural system from the global hysteretic behavior of the structure. During earthquake the structure behave in unstable amplitude. The story drift of the structure depends on not only the performance of the structure but also the phase and strength of the ground motions. That means equivalent viscous damping obtained from regular scheduled cyclic loading test and the testing protocol (Krawinkler et al. 2000) modeled from time history analysis does not express the energy dissipation correctly.

In this study, four equations of equivalent viscous damping were used:

$$hs = \frac{-\int_0^t \ddot{y}_0 \dot{y}\, dt}{2\omega_e \int_0^t \dot{y}^2\, dt} \quad (6)$$

$$ht = \frac{1}{2\pi} \cdot \frac{\Delta W}{W} \times 0.8 \quad (7)$$

$$h = 0.2\left(1 - 1\Big/\sqrt{\frac{\Delta_{\max}}{\Delta_y}}\right) + 0.05 \quad (8)$$

$$hp = 1/30 \cdot \Delta + 0.05 \ : \ 0 < \Delta \le 3$$

$$hp = 0.15 \ : \ 3 < \Delta \quad (9)$$

Where $\ddot{y}_0$ = ground acceleration, $\ddot{y}$ =response acceleration and ω_e = angular frequency at the tangent angle of a peak displacement

hs from Eq. (6) which is called "substitute damping" is the damping computed from non-linear time history analysis. *ht* is the damping calculated from ΔW which is energy dissipated per cycle at the target displacement Δ and W which is $ke \cdot \Delta^2$ under cyclic loading test. *h* in the Eq. (8) is the damping factor defined in the performance-based seismic code in Japan. Δ_y is the yield displacement of the structure. Then *hp* is the damping proposed by the result of the analytical study (Filiatrault 2003) and the damping was reduced in 80% as well as *ht*.

3. TIME HISTORY ANALYSIS

A series of nonlinear time history analyses were performed to determine effective elastic period, T_{eff} and to calculate substitute damping.

3.1 Histeresis Model and Seismic Mass

The EPHM model (Pnag, 2007) modified by the

authors to correspond to Japanese post-beam wood house (Hitomi and Isoda 2010) as shown in figure 1 was used in the nonlinear time history analysis. The parameters shown in Table 1 in the hysteresis model are defined by the result of shaking table test for the two story structure which has minimum requirement of the Japanese building standard law. Seismic mass is the effective mass of the two-degree of freedom system.

3.2 Ground Motions

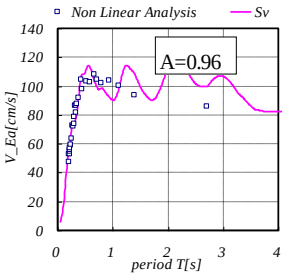

Table 2 presents the characteristic of the 31 earthquake records in this study. These records are scaled in the maximum velocity of 50cm/sec. The duration time of the earthquake is from 1% to 99% in the squared cumulative acceleration.

3.3 Definition of the parameters

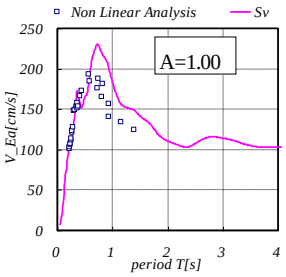

Figure 2 show the comparison of effective elastic period with energy spectrum. The variable parameter of this study is the seismic mass. The mass was divided from 0.5 to 3.0. The parameter A in Eq. (6) is shown in the figure and summarized in table 2. Note that upper limit of A is 1.00. The energy input for the structural system can be expressed by the effective elastic period although availability appears to be inconsistent. The averages of the 31 earthquake records in parameter A and B are 0.87 and 0.43, respectively.

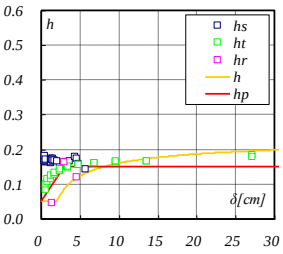

Figure 2 Distributions of effective elastic period in energy spectrum

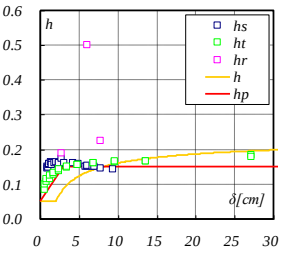
The distributions obtained from damping factor are shown in Figure 3. Note that seismic mass is the variable parameter for calculating *hs* and *hr* is the damping factor which gives the same peak displacement as time history analysis. At the calculation of *hr* the parameter of seismic mass in table 1 is divided in 0.7, 1.0 and 1.5. *ht* is also calculated from the shear wall test for plywood sheathing panel against simple step-up cyclic loading.



The damping of *ht*, *h* and *hp* remains almost constant for a given amplitude beside *hs* and *hr*. *hr* giving the actual peak displacement varies. It means that damping factor giving actual displacement can't express as the normal equation.

4. VALIDATION OF EQUIVALENT LINEAR MODEL

Figure 4 presents the comparisons of the peak displacement obtained from several equivalent linear models (ELM) and nonlinear time history analysis (NLTHA). Note that analyses are produced the combination of the system which has seismic mass of division of 0.7, 1.0 and 1.5 and 31 earthquake records. Total number of analyses is 93 cases. The parameters in Eq. (6) were used 0.87 and 0.43, respectively. Figure 5 shows the result coming from the conventional method calculated from Eq. (1) and figure 6 also shows the result of equivalent period T_e. The result from proposed effective elastic periods, T_{eff} in Eq.(6) .and constant damping expressed of h_p=15%i is equal to or more correct than that of the past method.

3. CONCLUSIONS

An outline of framework of the performance-based seismic design of timber-based structure and a validation of the peak displacement computed from proposed effective elastic period and several values of damping were describe in this paper. The peak displacement used the effective elastic period expressed only in a target displacement is equal or more accurate to the displacement used the past procedure. Although the equivalent damping depends on variety of waves and target displacement and isn't able to express to equation correctly, the constant damping factor of 15% gives almost agreement in displacement.

The numerical results confirmed the validity of this proposed direct-displacement based design procedure.

Abstract: In our previous reports, we executed the collapsing tests of three story post-and-beam wood houses by the shake table (E-Defense, NIED) and the three dimensional numerical analysis. The result of the numerical analysis based on the static element tests of seismic components of the specimens roughly agreed with experimental results. But at the detailed points, analysis model didn't correspond well with the test results and calibrated input parameters were not explained completely. In this paper, we modified the input parameters of numerical models by the result of the dynamic element tests of seismic components, and tried to trace the collapsing process at shake table tests.

1. INTRODUCTION

In our previous reports (Tsuchimoto 2010, Miyake 2010), we executed the collapsing tests of four post-and-beam wood houses by the shake table (E-Defense, NIED) and the three dimensional numerical analysis models of the specimens were verified. The two of the specimens (No.1 and No.2) have the same amount of shear walls, but the specification of the column end joints was different. The specimen No.2 didn't have sufficient tensile capacity of column end joint and No.1 have enough tensile capacity. At the shake table tests, the shear walls of No.1 failed and collapsed without no breakage of the column end joint, but the column end joints of the specimen No.2 were pull out at early stage and survive by the rocking behaviour of whole structure.

In the current seismic design method of Japanese post-and-beam wood houses, it is not considered that the column end joints are pulled out before the shear walls yield, so it is impossible to explain these shake table results. But it is necessary for further structural design to explain the ultimate collapsing behaviour like these shake table specimens.

In this paper, we executed the additional shear tests of shear walls that were seismic components of shake table specimens and the tensile tests of metal fasteners of the specimens. The displacement waves observed at the shake table test were used for the loading schedule of these element tests. The both dynamic and static loadings were carried out.

By these test results, we improved our numerical models and carried out the response analysis for shake table tests. The several variations of load displacement relationships for the springs of numerical models were used for numerical analysis. The numerical analysis uses one of these spring parameters agreed well with shake table result.

2. SHAKE TABLE TESTS

2.1 Outline of specimens

Table 1 shows specifications of shake table specimens. Four types of specimens were used for the tests. In this study, No.1 and No.2 is the target specimens for our numerical analysis. Figure 1 shows the picture of specimens No.1 and No.2. The both specimens are real-size three story wood house by post-and-beam construction. The main seismic element is bracing shear walls, gypsum board wall, and siding panel sheathed wall. The shake table tests were carried out at the E-Defence (National institute of earth science and disaster prevention) in Kobe prefecture. The two of the specimens (No.1 and No.2) have the same amount of shear walls, but the specification of the column end joints was different. The specimen No.2 didn't have sufficient tensile capacity of column end joint and No.1 have enough tensile capacity.

The column end joints of No.1 are designed to have enough tensile capacity if its shear walls reach their allowable shear force. But the column end joints of No.2 are designed to

have tensile capacity for the lateral load that is demanded at the building standard.

Figure 2, 3 shows the configuration of seismic elements All of the columns and beams were made from Glue-Lam. Cross section of columns is 105 x 105 (mm). Cross section of beams is 105 (mm) in width, 180-240 (mm) in depth. Shear walls were composed with brace, gypsum board and siding board. Braces were made from LVL with cross section of 45 x 90 (mm). The gypsum boards were set on the structural frame with screw nails as the substrate of interior walls. The siding boards were set on the structural frame with nails as the exterior walls.

The hardware for reinforcement of the column-end joints were selected from common hardware appearing on the market. 'P06' and 'P10' in Figure 2, 3 are L-shaped metal plate, 'H15', 'H20' and 'H25' are the hold-down hardware. All of the hardware was set on the structural frame with the screw nails. The allowable tensile force of 'P06' and 'P10' are 6.2 (kN) and 19.4 (kN). of 'H15', 'H20' and 'H25' are 15 (kN), 20 (kN) and 25 (kN) for each.

The horizontal plane of structure was composed with the plywood boards with the thickness of 28 (mm) which were set on the structural frame with the nails.

2.2 Input ground motion

Input seismic motion was the artificial seismic motion with acceleration spectrum which suited to the response spectrum of 2nd class of soil ruled in building standard as shown in Figure 4. The duration of the seismic motion is 20 (sec) as shown in Figure 5, The intensity of the seismic motion is approximately equal to it of the large earthquake with the return period of 400 year in Japan. The seismic motion was input to one direction of the shake table shown in Figure 1. This input wave is called "BSL" in this paper.

Table 1 Specifications of shake table specimens

Specimen	Shear walls and diaphram	Column end joints
No.1	1.25 times larger shear wall capacity than building standard requirement	adequately designed
No.2	1.25 times larger shear wall capacity than building standard requirement	inadequately designed
No.3	minimum shear wall capacity for building standard requirement and weaker floor diaphram	adequately designed
No.4	minimum shear wall capacity for building standard requirement	adequately designed

Figure 1 The photograph of shake table specimens

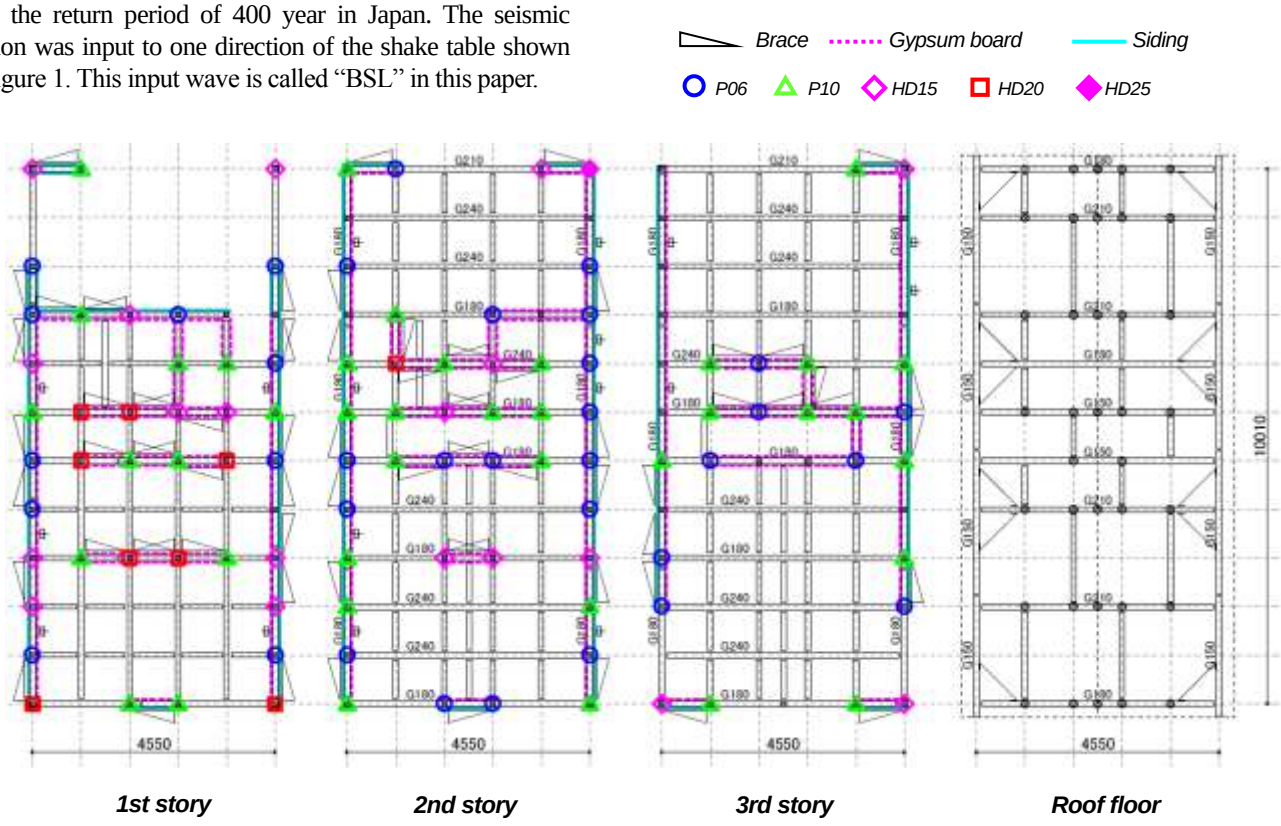

Figure 2 Configuration of shear wall and specification of column end joints at specimen No.1

2.2 Test results

At the BSL 90% level input, the maximum story drift angle of both models was approximately 1/100 (rad). There was no damage except slight cracks of the gypsum boards at the corner of the openings. The relation of the story shear and the story drift was almost linear.

At the BSL 160% level input, the story drift angle in 1st story of specimen No.1 reached 1/5 (rad) at 9.0 (sec) from the start of the seismic motion. Thereafter the story drift was kept 1/5 or less for approximately 6 (sec). Lastly, No.1 collapsed to the minus direction. On specimen No. 2, the mass of the joints of column base in 1st story fractured until 5.0 (sec) from the start of the seismic motion. All column base in 1st story in X0 axis lifted to 150 (mm) or more at 5.0 (sec) from the start of the seismic motion. Then the column bases didn't return to the original position, i.e. to the sill, but they reposed on the steel frame which was used for fixation of the model to the shake table. Thereafter, they slid in Y-direction like base-isolated building, Model 2 escaped from collapse.

Table 2 Maximum story drift of first floor (unit: mm)

Specimen	BSL input level			
	90%	112.50%	150%	160%

3. DYNAMIC AND STATIC ELEMENT TESTS

3.1 Outline of elements tests

The dynamic and static element tests of shear wall and metal fasteners were carried out to confirm dynamic behaviour of seismic components. Table 3, Table 4 and Figure 6 shows the outline of specimens. The configuration of the dynamic shear wall tests was shown in figure 7. In shear wall tests, the story shear deformation of the first story of the specimen No.1 is input to the beam of the element test specimen by the actuator. At the dynamic tests, the velocity of the actuator is controlled to fit to that of story shear observed at shake table test at BSL 160% input. In the joint tensile tests, the uplift displacement of column end joint is input to the column of the element test specimens.

3.2 Test Result

Figure 8 and Figure 9 shows the load displacement curves of shear wall tests, and joint tensile tests. At the shear tests of shear walls, the difference between dynamic loading and static loading was very small. At the tensile tests of metal fasteners, tensile forces of dynamic tests were larger than that of static loading.

Table 3 Load displacement curves of shear wall tests

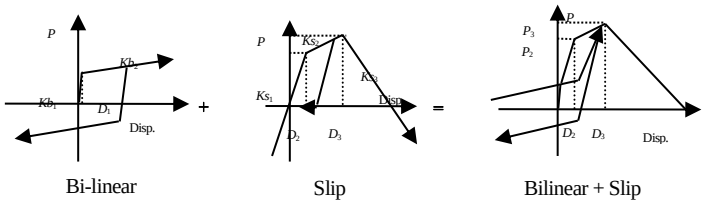
4. Numerical analysis

In our analysis, we used the three dimension frame analysis using the software "wallstat" that was developed at Building Research Institute. The fundamental analysis theory of wallstat is based on Distinct Element Method (DEM). A detailed explanation of DEM and our theory was given in our previous papers(Nakagawa 2008). DEM is a non-continuum analysing method, so the large deformation analysis of the fracture developing processes is possible.



4.1 Outline of numerical models

The analysis models used here were depicted in Figure 10. The plan of this analysis model was based on the specimen used in the shake table test. The wood frames of numerical models were modelled by beam element as indicated in figure10 (a). The moment of beam elements starts to fall once the maximum bending moment has been exceeded, with transformation into a pinned state occurring at the point in time when 0 is reached, at which point the member is adjudged to have been broken. Vertical shear walls are modelled by the replacement of braces in truss elements as indicated in figure 11(a). Hysteric characteristics are expressed according to the bi-linear + slip-type models indicated in figure 11(c). Parameters designate bi-linear and slip skeleton curves. Bracing shear walls are modelled by the positioning of two compression and tensile truss elements for each brace, as indicated in figure 11(b). As with shear wall springs, bracing spring hysteric characteristics are expressed according to the bi-linear + slip-type l models.

As indicated in figure12, joints are modelled using the rotational spring + elasto-plastic spring (for strong shearing). Hysteric characteristics of the compression / tensile elasto-plastic spring are set as per the one side elastic + one side slip-type.

4.2 Spring parameters used in numerical models

The parameters of the connections were defined according to the specifications of the target specimen, and the corresponding load-displacement relationships in figure 13 were selected for each connection respectively.

The shear wall parameters of analytical models were also selected at figure 14 according to the specifications of the target specimen. In the figure13 and figure 14, each line means the following definition.

Dynamic: The skeleton curve defined according to the dynamic loading tests in the section 3.
Static: The skeleton curve defined according to the static loading tests in the section 3.
Pre-analysis: The skeleton curve used in preliminary analysis in our previous paper (Miyake 2010).
Post-analysis: The skeleton curve defined in this paper.

In figure 15, moment frame effect means the moment resistance due to the rotation of the column end and top joint defined by the loading test at section 2. It was modelled by moment spring at numerical model.

two types. “Gypsum board” means the bracing shear walls which buckling is prevented by the gypsum board. “Siding” means the bracing shear walls which buckling is prevented by the exterior siding.

The mass of the analysis model was equalized with the actual weight of the target specimen measured by the load cell of the crane before the shaking table test. The equilibrium weight of the second floor was 103kN, and the weight of the third floor was 104kN, and the weight of the third floor was 61.2kN. The weight was distributed to the element of each floor in the analysis model.

All lateral elements against the horizontal forces in the shaking table specimen were modelled in the analytical model. The roof structure was not modelled, but accounted for as seismic weight. The damping coefficients were defined to be 2.0%. We used the instantaneous stiffness proportional damping. The damping coefficients were assumed to be zero, when the instantaneous stiffness became negative as a matter of analytic convenience.

Skeleton curves of double bracing shear walls have

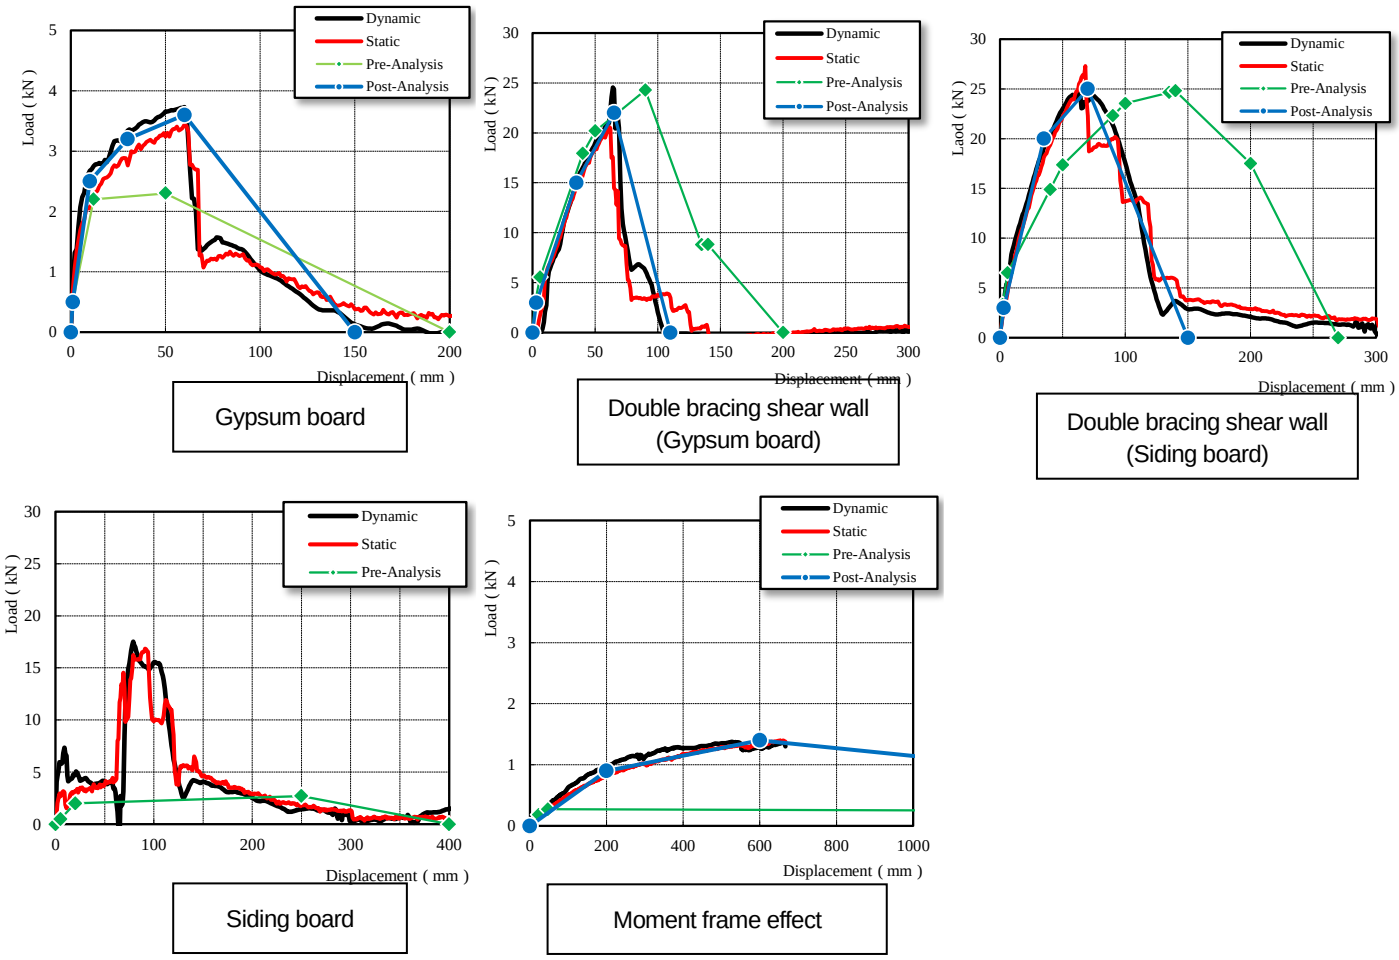

Figure 15 Skeleton curves of shear walls used in numerical analysis

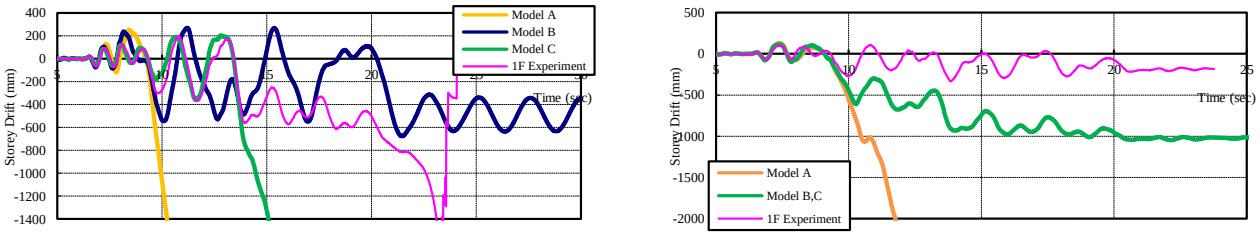
4.3. Conditons of numerical analysis

Table 5 shows the conditions of parameters for numerical analysis. In this paper, model A, model B and model C parameter sets were calculated to trace the results of shake table tests. The truss spring of shear walls were defined as post-analysis and pre-analysis skeleton curves. The moment springs of moment frame for the column end of P06 and P10 were defined 70% of post-analysis, because moment frame effect of figure15 was the experimental result of HD25.

4.4. Result and discussion

Table 6 shows the results of numerical analysis for each model. In the model A, both No.1 and No.2 collapsed. In the model B, both No.1 and No.2 didn't collapse. In the model C, No.1 collapsed and No.2 didn't collapsed.

Figure 16 shows the time history of story drift of each story of each model. Figure 17 shows the load displacement curves of first story of each model. Figure 18 shows the movie snapshot for analytical results of Model C. The rocking behaviour of No.2 was simulated in calculation. The numerical analysis uses Model C agreed well with shake table result in terms of the collapsing behaviour of No.1 and rocking behaviour of No.2.



It was found that the skeleton curves for moment frame effect were sensitive to the ultimate behaviour of numerical models

5. CONCLUSION

In this paper, we executed the additional shear tests of shear walls that were seismic components of shake table specimens and the tensile tests of metal fasteners of the specimens. By these test results, we improved our numerical models and carried out the response analysis for shake table tests. The several variations of load displacement relationships for the springs of numerical models were used for numerical analysis. The numerical analysis uses one of these spring parameters agreed well with shake table result in terms of the collapsing behaviour of No.1 and rocking behaviour of No.2.

Abstract: Horizontal displacement mode including torsion in ultimate state is clearly related to strength balance of each frame while elastic torsional vibration is characterized by stiffness balance. Therefore, this paper presents horizontal displacement mode prediction method especially focusing on timber structure having large strength eccentricity. The method is simpler than conventional ones because mechanism in ultimate state and corresponding external force distribution are assumed. The method also considers variability of response due to earthquake characteristics. The accuracy of the evaluation method is demonstrated via numerous time history analyses and shaking table test.

1. INTRODUCTION

Unbalanced distribution of shear walls leads to stiffness and strength eccentricity and results in torsional vibration. It is not desirable from a point of view of seismic resistance because of concentration of damage on particular shear wall. Such damages of timber houses were often observed in the past severe earthquakes in Japan.

As for elastic structure, horizontal displacement mode including torsion can be easily evaluated, and the method is well-established. However, evaluation methods covering inelastic structure are usually complicated and demanding non-linear pushover analysis (Hoshi et al. 2007, Fuji 2004). To apply these methods to timber houses is likely to difficult because of the huge number of them. In other words, easier solution considering non-linearity is desperately needed.

2. PRECONDITION

2.1 Conventional method and Problem

Performance based seismic design method is based on non-linear pushover analysis. As mentioned above, it is not suitable for timber houses. Similar solutions based on equivalent linearization method also require a lot of effort such as convergence calculation. Therefore, final goal of this research is to propose new method based on limit analysis, which takes less effort compared to equivalent linearization method.

In Japan, Eccentric ratio (See Equation(3c)) is used to check eccentricity between center of mass and center of elastic stiffness. The value must be less than 0.3 for timber structures and 0.15 for the other structures. This method may be reasonable for allowable stress design. However, the problem is that this confirmation is extended to ultimate state regardless of ignoring non-linearity. In addition, eccentric ratio does not consider mass distribution. Therefore, the new method we will propose should solve these problems.

2.2 Ultimate State and Mechanism

If there are not any eccentricity of mass, stiffness and strength, torsion will not occur. Then, skeleton curve of story equals to that of summation of each wall. Therefore, ultimate deformation of system is the same as that of shear wall, and evaluation is quite simple. However, if torsion occurs, deformations of each shear wall are not the same. How to define "ultimate state" is one of the problems.

In the beginning, the following two conditions are set.

i) Shear wall arrangement in one direction is eccentric. Structure is subjected to earthquake input motion along the direction.
ii) When maximum deformation of shear wall which is the most deformed reaches its ultimate deformation, the system is "Ultimate State".
iii) When system becomes ultimate state, all shear walls along earthquake motion are plastic and all shear walls perpendicular to earthquake motion are elastic.

Condition iii) is about mechanism of structure and expects that ultimate strength of story equals to that of summation of each shear wall.

3. ANALYTICAL MODEL

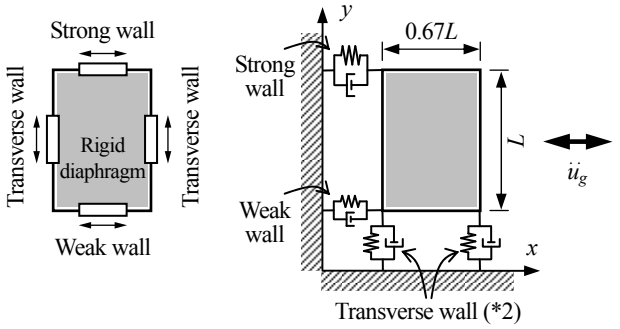
3.1 Considering Model

As shown in Figure 1, one-story wall structure is

considered, whose vibration analysis model is shown in right figure. x-directional shear walls are unbalanced, while y-directional shear walls are symmetry. x-directional earthquake motion is assumed. Floor diaphragm is infinitely rigid. The dimension of floor is $0.67L$ in x-direction and L in y-direction, respectively.

There are two shear walls in each direction; "Weak Wall" in x-direction, "Strong Wall" in x-direction and two "Transverse Walls" in y-direction, respectively.

Force-deformation curve of shear wall is approximated by elasto-perfectly plastic model. F_{xi} and δ_{xvi} are ultimate strength and yield deformation of i-th x-directional shear wall. Similarly, F_{yi} and δ_{yvi} of i-th y-directional shear wall are also defined. Ultimate deformations of each shear wall are all δ_u.



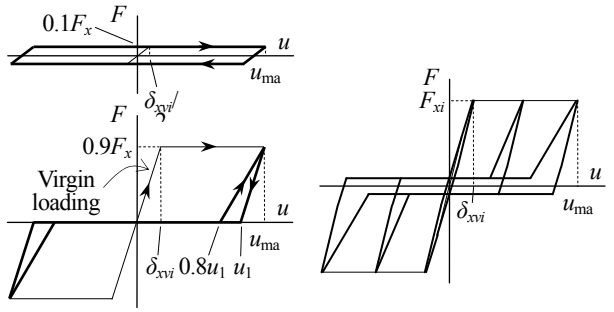


Figure 1 Considering Wall Structure and its Vibration Analysis Model

3.2 Hysteresis Model

Bi-linear + slip model is used as hysteresis model of timber shear walls (Isoda et al. 2007). In order to approach its envelope curve to elasto-perfectly plastic model, parameters are set as shown in Figure 2. Second stiffness ratio of bi-linear model is 0.001, and that of slip model is 0.02, respectively.

(a) Bi-linear Element (Upper) and Slip Element (Lower) (b) Bi-linear + Slip Element

Figure 2 Hysteresis Model

3.3 Parameters and Input Earthquake Motion

The most important parameter is strength balance between weak wall and strong wall. It is represented by strength eccentricity e_{fy}. Non-dimensional strength eccentric ratio $\bar{e}_{fy}$ is mainly used for discussion.

$$e_{fy} = \sum F_{xi} y_i \Big/ \sum F_{xi} \quad , \quad \bar{e}_{fy} = e_{fy} / r_m \quad , \quad r_m = \sqrt{I/m} \qquad \text{(1a-c)}$$

Where, m = mass, I = moment of inertia and r_m = radius of gyration, respectively. For comparison, stiffness eccentric ratio $\bar{e}_{ky}$ and eccentric ratio R_{ex} are shown as follows.

$$e_{ky} = \sum k_{xi} y_i \Big/ \sum k_{xi} \quad , \quad \bar{e}_{ky} = e_{ky} / r_m \qquad \text{(2a,b)}$$

$$K_x = \sum k_{xi} \quad , \quad K_\theta = \sum (k_{xi} y_i^2 + k_{yi} x_i^2)$$

$$R_e = \frac{e_{ky}}{\sqrt{(K_\theta / K_x)^2 - e_{ky}^2}} \qquad \text{(3a-c)}$$

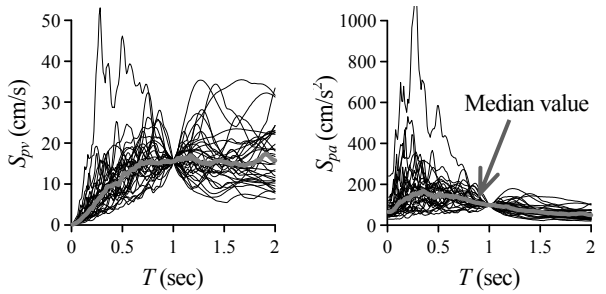
Where, k_{xi} and k_{yi} are initial stiffness of i-th x- and y-directional shear wall, respectively. They are calculated as F_{xi}/δ_{xvi} and F_{yi}/δ_{yvi}. x_i and y_i are coordinate of i-th shear wall, and the origin is set at center of mass. Eccentric ratio R_e is defined in Building Standard Law of Japan. It must be less than 0.3 for timber structures and 0.15 for the other structures, respectively.

In this study, $\bar{e}_{fy}$ will be changed from 0.1 to 0.77. Ultimate deformation of shear wall is 91mm, which means corresponding deformation angle is 1/30rad when the height of shear wall is 2730mm. The following three cases of yield deformations are considered.

Case1 : Yield deformations of all walls are 22.8mm (1/120rad)
Case2 : Yield deformations of weak wall is 30.3mm (1/90rad), strong wall is 18.2mm (1/150rad) and transverse wall is 22..8mm(1/120rad)
Case3 : Yield deformations of weak wall is 18.2mm (1/150rad), strong wall is 30.3mm (1/90rad) and transverse wall is 22..8mm(1/120rad)

In case1, stiffness is proportional to strength. However, in case2 and case3, stiffness is not proportional to strength (Table 1).

In all cases, base shear coefficient is set to be 0.38. If torsion of the system is fixed, elastic natural period is 0.49 second, and 5% viscous damping proportional to initial stiffness is added. Mass is assumed to be equally distributed in the floor.



33 earthquake motions are used. 31 motions are Japanese and world real earthquakes, and 2 motions are artificial ones provided by Building Center of Japan (Kasai et al. 2003). Their response spectra are shown in Figure 3. In Figure 3, each spectrum is scaled to S_{pa} = 98cm/s^2 in T = 1 sec. In analysis, scale factor is, however, decided through a trial and error process so that structure just reaches ultimate state.

4. PREDICTION OF ULTIMATE DISPLACEMENT MODE

Prediction method of ultimate displacement mode including torsion is presented. The important thing is to assume mechanism and external force distribution as shown

Table 1 List of Analysis Cases

	Yield deformation (angle)			Yield Force			Strength balance	Stiffness balance	Eccentric ratio
	Weak mm (rad)	**Strong** mm (rad)	**Transverse** mm (rad)	**Weak** kN	**Strong** kN	**Transverse** kN	$\bar{e}_{fy}$ —	$\bar{e}_{ky}$ —	R_{ex} —
Case 1	22.8 (1/120)	22.8 (1/120)	22.8 (1/120)	14 → 7	16 → 23	15	0.1 → 0.77	0.1 → 0.77	0.06 → 0.5
Case 2	30.3 (1/90)	18.2 (1/150)					0.1 → 0.77	0.45 → 1	0.27 → 0.72
Case 3	18.2 (1/150)	30.3 (1/90)					0.1 → 0.77	-0.27 → 0.47	-0.16 → 0.28

(a) Pseudo Velocity (b) Pseudo Acceleration

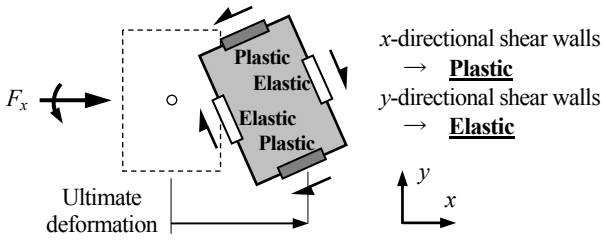

Figure 4 Assumed Mechanism and External Force Distribution

in Figure 4. It achieves easy solution without complicated calculation. In addition, variability of response due to earthquake will be considered using unique method.

4.1 Theory

In ultimate state, story shear force F_x and moment M are expressed as follows.

$$F_x = \sum F_{xi} = F_{x0} \quad , \qquad M = -F_{x0} e_{fy} + K_\theta^{(y)} \theta \tag{4a,b}$$

$$K_\theta^{(y)} = \sum k_{yi} x_i^2 \tag{5}$$

Where, θ = rotation of floor, F_{x0} = summation of ultimate strength of x-directional shear walls or ultimate strength of story. $K_\theta^{(y)}$ = rotational stiffness around center of mass contributed by y-directional shear walls.

Equation(4) also means external force distribution $\mathbf{f_{u1}}$. Therefore, we can define ultimate 1st. mode $\boldsymbol{\phi}_{\mathbf{u1}}$ and assume the following relationship using mass matrix $\mathbf{m}$.

$$\mathbf{f_{u1}} = \{F_{x0} \; M\}^{\mathrm{T}} \quad , \qquad \boldsymbol{\phi}_{\mathbf{u1}} = \{\phi_{u11} \; \phi_{u21}\}^{\mathrm{T}} \tag{6a,b}$$

$$\omega_{u1}{}^2 \mathbf{m} \boldsymbol{\phi}_{\mathbf{u1}} = \mathbf{f_{u1}} \, , \qquad \mathbf{m} = \begin{bmatrix} m & 0 \\ 0 & I \end{bmatrix} \tag{7a,b}$$

Equation(7a) means equilibrium of system having natural circular frequency ω_{u1} and displacement mode $\boldsymbol{\phi}_{\mathbf{u1}}$ in steady state. It is similar to eigen equation of elastic system. From Equation(7a), we can obtain $\boldsymbol{\phi}_{\mathbf{u1}}$ as follows.

$$\boldsymbol{\phi}_{\mathbf{u1}} = \frac{1}{\omega_{u1}^2} \mathbf{m}^{-1} \mathbf{f_{u1}} = \frac{1}{\omega_{u1}^2} \frac{1}{mI} \begin{Bmatrix} IF_{x0} \\ m\left(-F_{x0} e_{fy} + K_\theta^{(y)} \theta\right) \end{Bmatrix} \tag{8}$$

First line of $\boldsymbol{\phi}_{\mathbf{u1}}$ shows translational displacement of center of mass, and second line shows rotation. Here, we focus on the ratio of rotation to translation ϕ_{u21}/ϕ_{u11}.

$$\frac{\phi_{u21}}{\phi_{u11}} = \frac{-F_{x0} e_{fy} + K_\theta^{(y)} \theta}{F_{x0} r_m^2} \tag{9}$$

Since Equation(9) includes θ, it can be rewritten using u_x = translational displacement of center of mass in ultimate state and $\theta = u_x \phi_{u21}/\phi_{u11}$.

$$\frac{\phi_{u21}}{\phi_{u11}} = \frac{F_{x0} e_{fy}}{K_\theta^{(y)} u_x - F_{x0} r_m^2} \tag{10}$$

In this research, we should pay attention to ultimate state when deformation of the wall the most apart form center of strength reaches ultimate deformation δ_u. Therefore, the following relationship is achieved.

$$u_x (1 + l_y \phi_{u21} / \phi_{u11}) = \delta_u \tag{11}$$

Where, l_y = y-directional distance between center of mass and shear wall in ultimate state. By substituting Equation(11) into (10), we can obtain second degree equation of u_x, and it is expressed as follows.

$$u_x = \max\left(u_{x0}, \frac{\delta_u + \delta_{xv,s}}{2}\right) \tag{12a,b}$$

$$u_{x0} = \frac{F_{x0}(r_m^2 - e_{fy} l_y) + K_\theta^{(y)} \delta_u + \sqrt{\left[F_{x0}(r_m^2 - e_{fy} l_y) + K_\theta^{(y)} \delta_u\right]^2 - 4 K_\theta^{(y)} F_{x0} r_m^2 \delta_u}}{2 K_\theta^{(y)}}$$

Where, $\delta_{xy,s}$ = yield deformation of strong wall. Second part of right member in Equation(12a) ($\delta_u + \delta_{xy,s}$)/2 means lower limit of u_x promising assumed mechanism.

By substituting Equation(12a) into (10), we can obtain maximum displacement vector $\mathbf{u_{max}}$ as follows.

$$\mathbf{u_{max}} = \begin{Bmatrix} u_x \\ u_x(\phi_{u21}/\phi_{u11}) \end{Bmatrix} \tag{13}$$

4.2 Variability of Earthquake Response

In order to simulate arbitrary displacement mode of 2DOF, two independent vectors are needed. Although ultimate 1st. mode is likely to be dominant mode, another mode is required to simulate variability of earthquake response.

At first, an example of strong non-linear response is shown in Figure 5(a). This is an orbit of lateral force F_x and moment M obtained from time history analysis. The hysteresis is like a ellipse, and its slope appears to be simulated by external force vector $\mathbf{f_{u1}}$. It is also found that orthogonal vector to $\mathbf{f_{u1}}$ seems to affect variability of response. Therefore, established method to simulate variability of earthquake force is applied to this problem (Matsumori et al. 2004).

As shown in Figure 6, ultimate 2nd. mode $\boldsymbol{\phi}_{\mathbf{u2}}$ is defined as it is orthogonal to $\boldsymbol{\phi}_{\mathbf{u1}}$ through mass matrix.

$$\boldsymbol{\phi}_{\mathbf{u2}} = \{\phi_{u12}\ \phi_{u22}\}^{\mathbf{T}}, \qquad \boldsymbol{\phi}_{\mathbf{u1}}{}^{\mathbf{T}}\mathbf{m}\boldsymbol{\phi}_{\mathbf{u2}} = \boldsymbol{\phi}_{\mathbf{u2}}{}^{\mathbf{T}}\mathbf{m}\boldsymbol{\phi}_{\mathbf{u1}} = \mathbf{0} \tag{14a,b}$$

$$\mathbf{f_{u2}} = \left\{(-F_{x0}e_{fy} + K_\theta^{(y)}\theta)/r_m \quad -F_{x0}r_m\right\}^{\mathbf{T}} \tag{15}$$

$$\boldsymbol{\phi}_{\mathbf{u2}} = \frac{1}{\omega_{u2}^2}\mathbf{m}^{-1}\mathbf{f_{u2}} = \frac{1}{\omega_{u2}^2}\frac{1}{mr_m}\begin{Bmatrix} -F_{x0}e_{fy} + K_\theta^{(y)}\theta \\ -F_{x0} \end{Bmatrix} \tag{16}$$

By assuming $\boldsymbol{\phi}_{\mathbf{u1}}$ and $\boldsymbol{\phi}_{\mathbf{u2}}$ are a couple of eigen vectors, we can obtain participation function $\beta_{u1}\boldsymbol{\phi}_{\mathbf{u1}} = \{\beta_{u1}\phi_{u11}\ \beta_{u1}\phi_{u21}\}^{\mathbf{T}}$, $\beta_{u2}\boldsymbol{\phi}_{\mathbf{u2}} = \{\beta_{u2}\phi_{u12}\ \beta_{u1}\phi_{u22}\}^{\mathbf{T}}$ as follows.

$$\begin{aligned} \beta_{u1}\boldsymbol{\phi}_{\mathbf{u1}} &= \boldsymbol{\phi}_{\mathbf{u1}}{}^{\mathbf{T}}\mathbf{m}\{\mathbf{1}\}/\boldsymbol{\phi}_{\mathbf{u1}}{}^{\mathbf{T}}\mathbf{m}\boldsymbol{\phi}_{\mathbf{u1}} \\ \beta_{u2}\boldsymbol{\phi}_{\mathbf{u2}} &= \boldsymbol{\phi}_{\mathbf{u2}}{}^{\mathbf{T}}\mathbf{m}\{\mathbf{1}\}/\boldsymbol{\phi}_{\mathbf{u2}}{}^{\mathbf{T}}\mathbf{m}\boldsymbol{\phi}_{\mathbf{u2}} \end{aligned} \tag{17a,b}$$

$$\beta_{u1}\phi_{u11} = \frac{1}{1+r_m^2(\phi_{u21}/\phi_{u11})^2}, \quad \beta_{u1}\phi_{u21} = \frac{\phi_{u21}/\phi_{u11}}{1+r_m^2(\phi_{u21}/\phi_{u11})^2}$$

$$\beta_{u2}\phi_{u12} = \frac{1}{1+r_m^2(\phi_{u22}/\phi_{u12})^2} = 1-\beta_{u1}\phi_{u11}, \quad \beta_{u2}\phi_{u22} = \frac{\phi_{u22}/\phi_{u12}}{1+r_m^2(\phi_{u22}/\phi_{u12})^2} = -\beta_{u1}\phi_{u21} \tag{18a-d}$$

Where, $\{\mathbf{1}\} = \{1\ 0\}^{\mathbf{T}}$. By combining $\beta_{u1}\boldsymbol{\phi}_{\mathbf{u1}}$ with $\beta_{u2}\boldsymbol{\phi}_{\mathbf{u2}}$, the following two modes are newly defined.

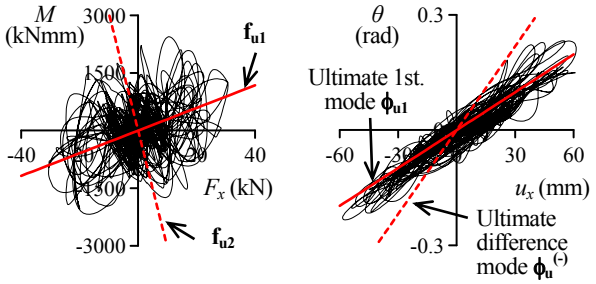
$$\boldsymbol{\phi}_{\mathbf{u}}{}^{(+)} = \begin{Bmatrix} \beta_{u1}\phi_{u11} + \alpha\beta_{u2}\phi_{u12} \\ \beta_{u1}\phi_{u21} + \alpha\beta_{u2}\phi_{u22} \end{Bmatrix}, \quad \boldsymbol{\phi}_{\mathbf{u}}{}^{(-)} = \begin{Bmatrix} \beta_{u1}\phi_{u11} - \alpha\beta_{u2}\phi_{u12} \\ \beta_{u1}\phi_{u21} - \alpha\beta_{u2}\phi_{u22} \end{Bmatrix} \tag{19a,b}$$

$\boldsymbol{\phi}_{\mathbf{u}}{}^{(+)}$ = ultimate sum mode and $\boldsymbol{\phi}_{\mathbf{u}}{}^{(-)}$ = ultimate difference mode, respectively. α is combine ratio of $\beta_{u1}\boldsymbol{\phi}_{\mathbf{u1}}$ and $\beta_{u2}\boldsymbol{\phi}_{\mathbf{u2}}$, which is originally defined as the ratio of their acceleration spectra. These two modes represent the smallest and the largest torsion situations, respectively. In this research, Equations(19) are simplified by assuming $\alpha = 1$.

$$\boldsymbol{\phi}_{\mathbf{u}}{}^{(+)} = \begin{Bmatrix} 1 \\ 0 \end{Bmatrix}, \qquad \boldsymbol{\phi}_{\mathbf{u}}{}^{(-)} = \begin{Bmatrix} 2\beta_{u1}\phi_{u11} - 1 \\ 2\beta_{u1}\phi_{u21} \end{Bmatrix} \tag{20a,b}$$

Finally, we can obtain maximum displacement vector $\mathbf{u}_{\mathbf{max}}^{(+)}$ and $\mathbf{u}_{\mathbf{max}}^{(-)}$ corresponding to $\boldsymbol{\phi}_{\mathbf{u}}{}^{(+)}$ and $\boldsymbol{\phi}_{\mathbf{u}}{}^{(-)}$ as follows.

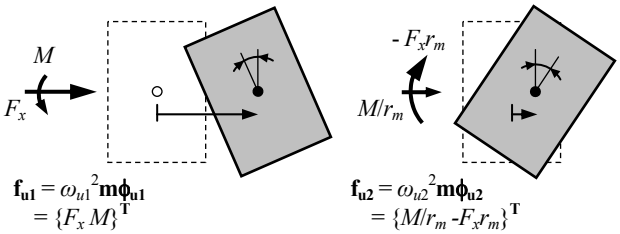
$$\mathbf{u}_{\mathbf{max}}^{(+)} = \begin{Bmatrix} \delta_u \\ 0 \end{Bmatrix}$$



$$\mathbf{u}_{\mathbf{max}}^{(-)} = \frac{\delta_u}{1 + l_y(2\beta_{u1}\phi_{u21})/(2\beta_{u1}\phi_{u11} - 1)}\begin{Bmatrix} 1 \\ \dfrac{2\beta_{u1}\phi_{u21}}{2\beta_{u1}\phi_{u11} - 1} \end{Bmatrix} \tag{21a,b}$$

Figure 5(b) shows an orbit of translation u_x and rotation θ. The slope of the hysteresis is roughly expressed by $\boldsymbol{\phi}_{\mathbf{u1}}$, and increase of θ at large u_x is simulated by $\boldsymbol{\phi}_{\mathbf{u}}{}^{(-)}$.

For comparison, 1st. mode shape and 2nd. mode shape in elastic state are shown below.



$$\omega_i^2 = \frac{IK_x + mK_\theta \mp \sqrt{(IK_x + mK_\theta)^2 - 4mI(K_xK_\theta - K_x^2e_{ky}^2)}}{2mI}$$

$$\boldsymbol{\phi}_{\mathbf{ei}} = \begin{Bmatrix} 1 \\ \dfrac{1-\omega_i^2/\omega_x^2}{e_{ky}} \end{Bmatrix}, \qquad \omega_x = \sqrt{\frac{K_x}{m}} \tag{22a-c}$$

4.3 Relationship between Strength Eccentric Ratio and Ultimate Displacement Mode

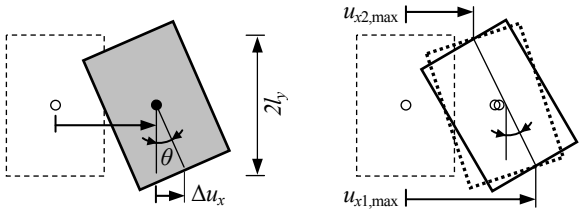
In this section, new indexes, *Torsion Ratios* Δ_1, $\Delta^{(+)}$ and $\Delta^{(-)}$ are defined. They are the ratio of increase displacement at floor edge due to torsion to translational displacement, and are defined with respect to ultimate modes ($\boldsymbol{\phi}_{\mathbf{u1}}$, $\boldsymbol{\phi}_{\mathbf{u}}{}^{(+)}$ and

$\phi_u^{(-)}$) as shown in Figure 7(a).

Although we assume *x*-directional shear walls are plastic and *y*-directional shear walls are elastic, it may not be satisfied if torsion is too large. Therefore, torsion ratios are defined as follows.

$$\Delta_1 = \min\left(\frac{\phi_{u21}}{\phi_{u11}} l_y \,,\ \frac{\delta_u - \delta_{xv,s}}{\delta_u + \delta_{xv,s}}\right)$$
$$\Delta^{(+)} = 0 \qquad \text{(23a-c)}$$
$$\Delta^{(-)} = \min\left(\frac{2\beta_{u1}\phi_{u21}}{2\beta_{u1}\phi_{u11} - 1} l_y \,,\ \frac{\delta_u - \delta_{xv,s}}{\delta_u + \delta_{xv,s}}\right)$$

$(\delta_u - \delta_{xv,s})$ / $(\delta_u + \delta_{xv,s})$ is torsion ratio when displacement of weak wall is δ_u and that of strong wall is $\delta_{xv,s}$, which is upper limit of torsion ratio.



If we obtain torsion ratio by time history analysis, maximum deformations of weak wall and strong wall do not occur at the same time. Since we are interested in distribution of maximum deformations of weak wall and strong wall, torsion ratio from time history analysis is defined as follows.

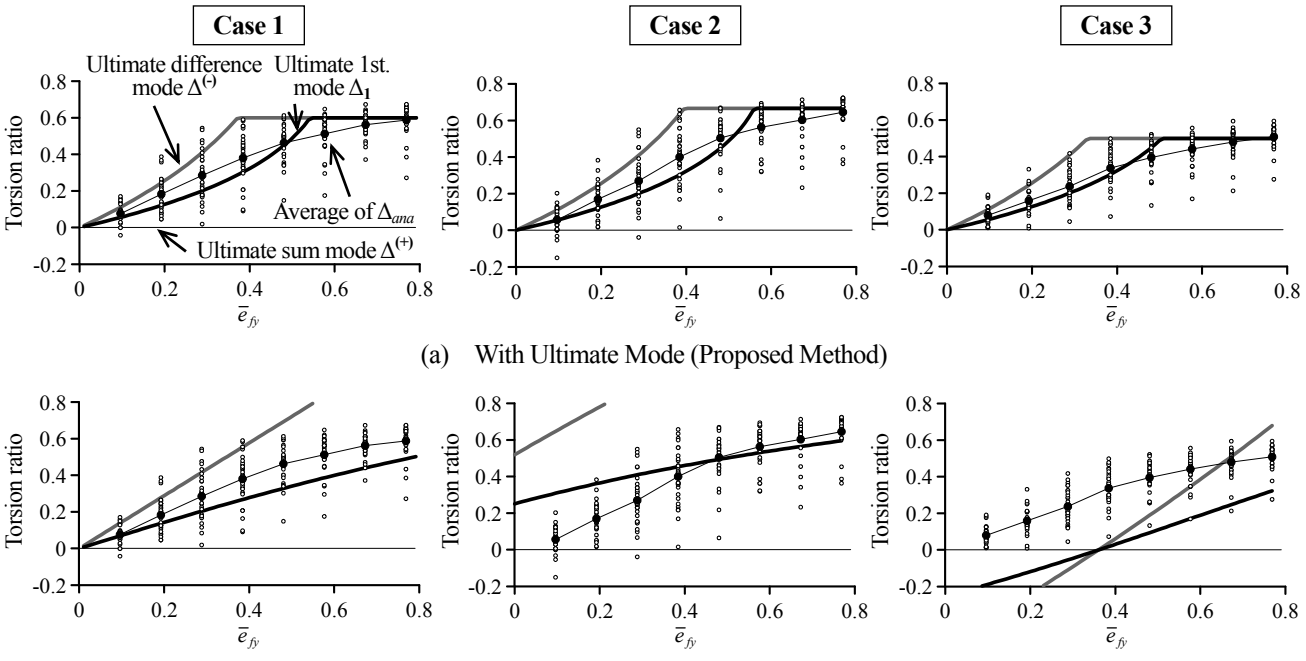
$$\Delta_{ana} = \frac{u_{x1,\max} - u_{x2,\max}}{u_{x1,\max} + u_{x2,\max}} \qquad (24)$$

Where, $u_{x1,\max}$, $u_{x2,\max}$ = maximum deformation of weak wall and strong wall obtained from time history analysis as shown in Figure 7(b).

Relationship between strength eccentric ratio $\bar{e}_{fy}$ and torsion ratio are shown in Figure 8. White plots are results of analyses, and black plots are their averaged values. Figure 8(a) is comparison between analytical results and predicted results with proposed method while Figure 8(b) shows predicted results with conventional method using elastic mode.

At first, the following tendency is confirmed. Three cases show similar relations between $\bar{e}_{fy}$ and Δ_{ana}. In other words, Δ_{ana} is close related to strength balance rather than stiffness balance. Δ_{ana} is proportionally increased until $\bar{e}_{fy}$ = 0.5, and its slope becomes loose at large $\bar{e}_{fy}$. That is why torsion ratio is limited to $(\delta_u - \delta_{xv,s})$ / $(\delta_u + \delta_{xv,s})$ in Equation(23). The upper limit of torsion ratio can simulate the tendency of analytical results.

u_x : Translational displacement
θl_y : Additional translational displacement due to torsion
$\Delta = \theta l_y / u_x$



$u_{x1,\max}$: Max. deform. of weak wall
$u_{x2,\max}$: Max. deform. of strong wall
$\Delta_{ana} = (u_{x1,\max} - u_{x2,\max}) / (u_{x1,\max} + u_{x2,\max})$

(a) Prediction Method (b) Time History Analysis

Figure 7 Definition of Torsion Ratio

4.4 Verification of Accuracy

Accuracy of prediction method is mentioned here. Predicted results using ultimate 1st. mode (bold black line) approximately trace average of analytical results. In addition, predicted results using ultimate difference mode (gray black line) and ultimate sum mode (black line) approximately show maximum and minimum curves of analytical results.

(a) With Ultimate Mode (Proposed Method)

(b) With Elastic Mode (Conventional Method)

Figure 8 Comparison of Torsion Ratio Obtained from Time History Analysis and Prediction Method
White circle: Analytical results of 33 waves Δ_{ana}, Black circle: Average of analyses, Bold lines: Prediction Δ_1, $\Delta^{(+)}$, $\Delta^{(-)}$

In contrast, predicted results using elastic mode can not simulate analytical results except for case1 when stiffness is proportional to strength.

5. APPLICATION TO SHAKE TABLE TEST OF TIMBER STRUCTURE

Ultimate displacement prediction method proposed in the former chapter is applied to shake table test of timber structure (Yamazaki et al. 2010).

5.1 Outline of test

Specimen is shown in Figure 9. It is single story timber shear wall structure having eccentric wall arrangement. One-directional input motion is applied by shake table.

Figure 10 shows force-deformation relation of each shear wall subjected to full scaled JMA Kobe motion 1995. Weak wall (hanging wall) has long elastic range compared to strong wall due to elastic flexure of column. Therefore, stiffness is not proportional to strength such as case3.

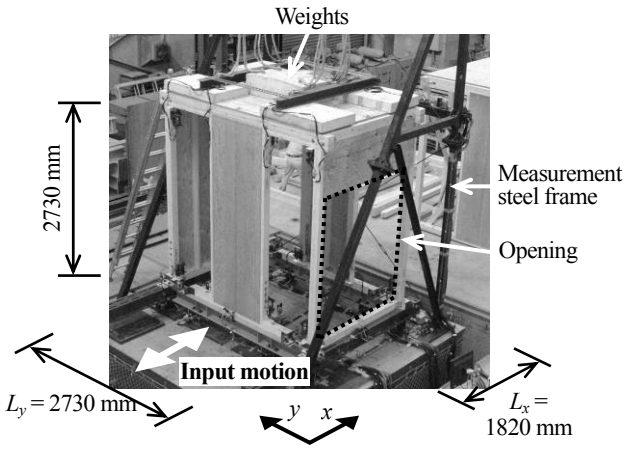


Figure 9 Setup of Specimen[21)]

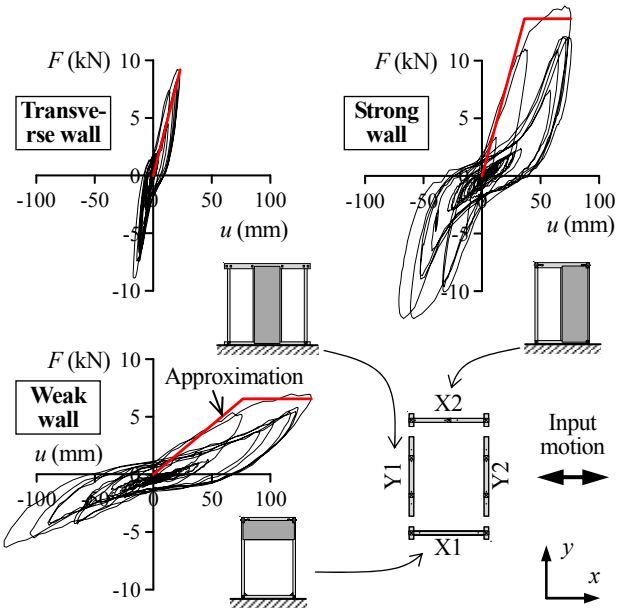

Figure 10 Force-Deformation Relation of Each Shear wall Subjected to Full Scale JMA Kobe Wave

5.2 Shear Wall Model

In Figure 10, elasto-perfectly plastic approximations of weak wall and strong wall, and elastic stiffness of transverse wall are superposed. Properties of each shear walls are summarized in Table 2. Using these values, we can obtain stiffness eccentricity e_{ky} = 859mm and strength eccentricity e_{fy} = 480mm, respectively.

5.3 Prediction of Ultimate Displacement Mode

Maximum displacement modes obtained from shake table and prediction method are compared in Figure 11 and Table 3. Ultimate 1st. mode, ultimate difference mode and elastic 1st. mode are used. Ultimate 1st. mode is the closest to test result, and ultimate difference mode and elastic 1st. mode predicts larger torsion. This is likely due to the difference between stiffness eccentricity and strength eccentricity.

Table 2 Properties of Each Shear Wall

	Stiffness kN/mm	Strength kN	Yield deform. mm	Ult. deform. mm
Weak	0.086	6.54	76.5	135.0
Strong	0.376	13.64	36.3	75.9
Transverse	0.400	—	—	—

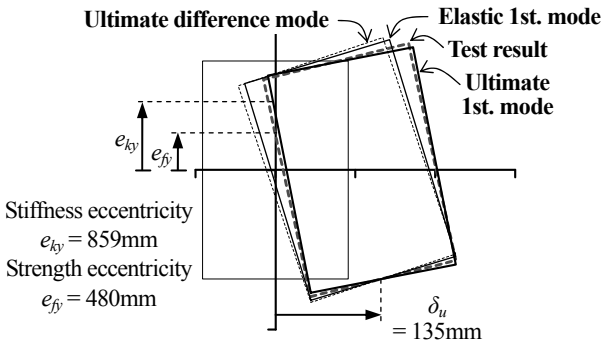

Figure 11 Maximum Displacement Mode

Table 3 Prediction of Maximum Displacement

	Test result mm	Ult. 1st. mm	Ult. diff. mm	Elast. 1st. mm
Weak	135.0			
Strong	75.9	81.5	43.9	52.1
Transverse	22.6	17.8	36.7	31.9

6. CONCLUSIONS

In this paper, the following findings are obtained.

1) Ultimate displacement mode is close related to strength balance of each shear wall rather than stiffness balance.
2) Dominant response in ultimate state can be simulated by ultimate 1st. mode, which is obtained by assuming mechanism and external force distribution.
3) Variability of earthquake response can be simulated using ultimate 2nd. mode orthogonal to ultimate 1st. mode.

4) Ultimate displacement prediction method can be applied to shake table test of timber structure.

Abstract: In order to mitigate the damage of timber houses against large earthquake, the writers developed so-called shear-link-type passive control systems having either velocity- or deformation- dependent dampers. A number of full-scale tests were conducted including from static tests of the member joints to shaking table tests of the 2-story timber frames. The dynamic characteristics of the specimens were examined, and the effectiveness of the passive control system was validated. In the next stage of this research, in order to propose the evaluation method and design method for the passive control systems, analytical study must be conducted for validations covering much wide range of applications.

This paper proposes a modeling method of simplified spring model for 1-story timber structures having energy dissipation walls which have either velocity- or deformation- dependant damper. The principal feature of this method is that it could be composed of iterated calculation of linear elasticity model so that the timber structure having energy dissipation walls are analyzed by common software. In this paper, story drift, story shear force, and the behavior of damper could be duplicated by the simplified model. The accuracy of the model will be verified through comparisons with detailed frame model.

1. INTRODUCTION

It is said that approximately 10 million wooden houses are insufficient for earthquake resistant in Japan, and those houses need to be reinforced immediately. Moreover, to design new wooden houses to be resistant to earthquakes, it is important to investigate rational methods applying the passive control scheme to wooden houses. In order to mitigate the earthquake response and damage of wooden houses, an energy dissipation wall was developed (Kasai and Sakata et al. 2005, Appendix 1) and a lot of experimental studies using the wall were carried out, such as dynamic cyclic loading tests of the energy dissipation walls (Matsuda et al. 2008), shaking table tests of 1-story and 2-story wooden frames (Sakata et al. 2007 and Matsuda et al. 2007), and so on. In addition, analytical studies also need to be carried out to develop more effective energy dissipation wall and to propose the design method. Accurate, framed analytical models for the wooden energy dissipation wall with damper and plywood shear wall were proposed (Matsuda et al. 2011 and 2012).

There are some design methods to apply the passive control scheme to wooden houses, and one of them is seismic response analysis. Although it is rare for seismic response analysis to be adopted to small wooden houses, considering the seismic response analysis of wooden houses leads to increasing options of design and research. It is desirable for wooden house model to be composed of simple models which are able to be used by generalized software. Therefore this paper proposes a simplified seismic response analysis for passively controlled wooden frame. And through comparison with a detailed frame model, accuracy verification of the simplified seismic response analysis will be discussed.

2. CONTRACTING METHOD TO SYMPLIFIED SPRING MODEL

In order to carry out the simplified seismic response analysis, degrees of freedom of the energy dissipation wall are reduced to two. The model is composed three springs, pseudo-brace, pseudo-frame and pseudo-damper (see Fig. 1). Where pseudo-brace, pseudo-frame are linear elastic springs which have stiffness K_{bs} and K_{fs}. Every damper is classified roughly into two kinds, deformation-dependent damper and velocity-dependent damper. The hysteresis of velocity-dependent damper is modeled by linear stiffness K_{ds} and viscous coefficient C_{ds} (so-called ellipse shape). The hysteresis of deformation-dependent damper is modeled by linear stiffness K_{d1s}, second stiffness ratio p_s, yield strength F_{dys} (so-called parallelogram shape, Appendix 2).

In order to create the simplified spring model, the evaluation method (Kasai et al. 2006 and 2011) could be

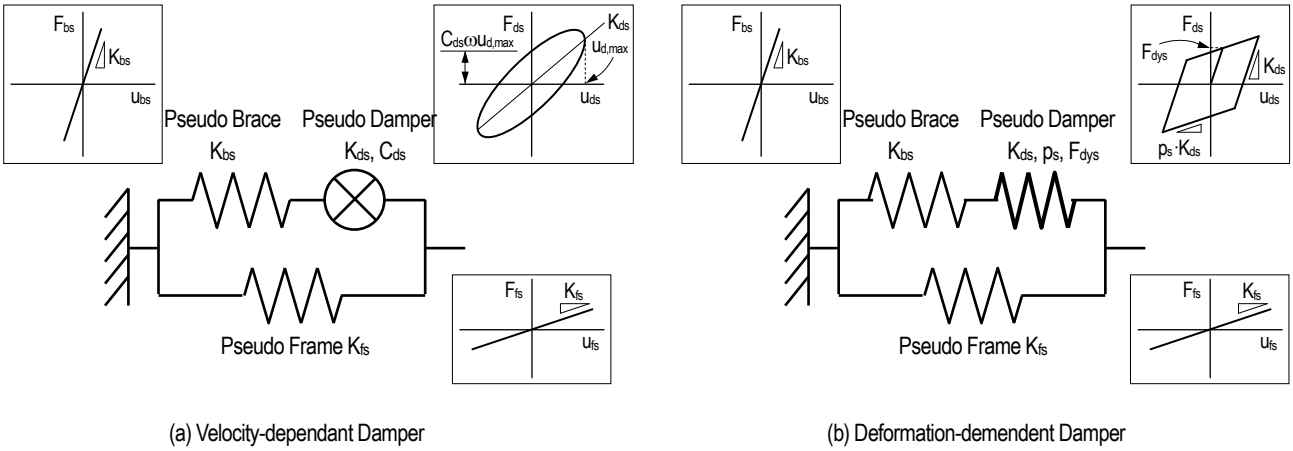

Fig. 1 Simplified Spring Model of Energy Dissipation Wall

applied. It's called "State-NR estimation". This estimation method reduces the degree of freedom of the energy dissipation wall to two by conducting twice the static analysis of the frame without dampers. As indicated Fig.2, one is State-N whose damper part is free (No-Damper), the other is State-R whose damper part is rigid absolutely (Rigid-Damper). The hysteresis of the energy dissipation wall whose damper information (hysteretic performance and quantity) had been given preliminarily could be estimated by using the two analytical results. By using this method, the performance of the energy dissipation wall for changing damper kind and/or damper quantity could be estimated properly. The simplified spring model is extremely useful for efficient time history analysis, and it also provides a new and important tool to evaluate the control effectiveness of different systems on a common scale.

Incidentally, the spring specification would be changed in each deformation since this paper is focused on timber structure which has nonlinear property. In the case of velocity-dependent damper, the spring specification also would be changed in assumed frequency.

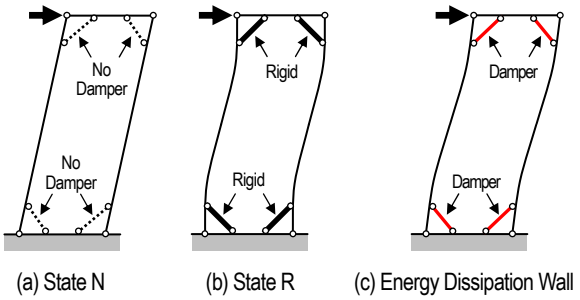

Fig. 2 Image of State-NR

3. SEISMIC RESPONSE ANALYSIS METHOD BY USING SIMPLIFIED SPRING MODEL

The relationship between system force and system deformation could be obtain for each deformation by using State-NR estimation, however seismic response analysis of

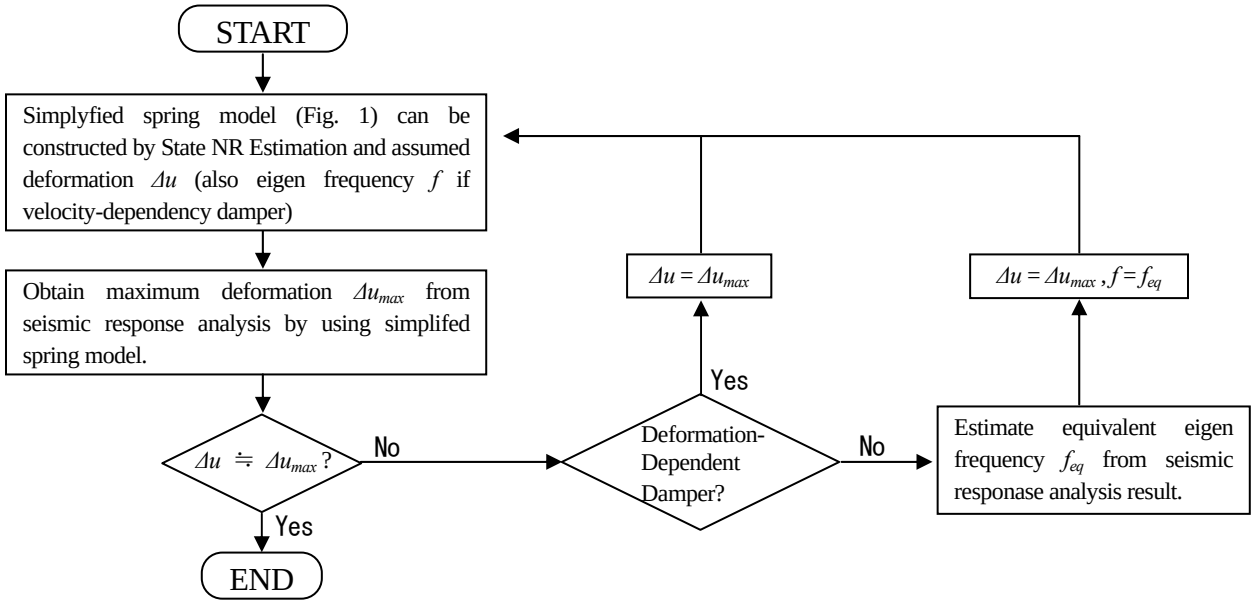

Fig. 3 Flowchart of seismic response analysis by simplified response analysis

nonlinear system is not able to be carried out since yet, since the spring specification is not equal in each deformation. Therefore, convergent calculation will be carried out in keeping with the flowchart of Fig. 3.

At first, deformation Δu is assumed, then seismic response analysis of simplified spring model is carried out by using the specification of the assumed deformation. Secondary, maximum deformation $\Delta u_{\max}$ is obtained from the previous analysis, then seismic response analysis of simplified spring model is carried out again by using the specification of the new deformation $\Delta u_{\max}$. This iteration continues until the variation of $\Delta u_{\max}$ becomes small. In the case of using velocity-dependent damper, eigen frequency f is also assumed at first. And then, eigen frequency is also included in the iteration by estimating from the seismic response analysis.

In this report, the tolerance of the convergent calculation was set to 1% variation. The first assumed Δu was set to story shear angle 1/120rad., incidentally it had been confirmed that the convergent solution became same result even if the first assumed Δu was whichever 1/480rad. and 1/30ard. The equivalent eigen frequency was derived from the equivalent stiffness which was derived from least-squares method of the relationships between system force and system deformation.

4. ACCURACY VERIFICATION

In order to confirm the accuracy of proposed seismic response analysis in chapter 3, the comparison of detailed frame model and simplified spring model will be discussed. A simplified spring model will be created by using a detailed frame model (Matsuda et al. 2011) whose accuracy is verified through comparison with shake table test. After that, comparison of seismic response analysis between detailed frame model and simplified spring model will be discussed.

4.1 Outline of Detailed Frame Model

An accurate, framed analytical model for the wooden energy dissipation wall with damper was proposed (Matsuda et al. 2011). The framed analytical model was constructed by using many kinds of nonlinear springs whose properties are derived from the test results of the joint (see Fig. 4). The joint spring between column and horizontal member consists of three types of spring, axial, rotational and shear spring. The damper is arranged at the point between the intersection of the braces and the steel plate. The frame model was able to duplicate not only global behavior but also local behavior with a high degree of accuracy in many tests of 1-story timber structure.

In this paper, viscoelastic damper is used as the velocity-dependent damper, and the viscoelastic element was proposed by Kasai et al. (2002). Basically following equations are used in viscoelastic element.

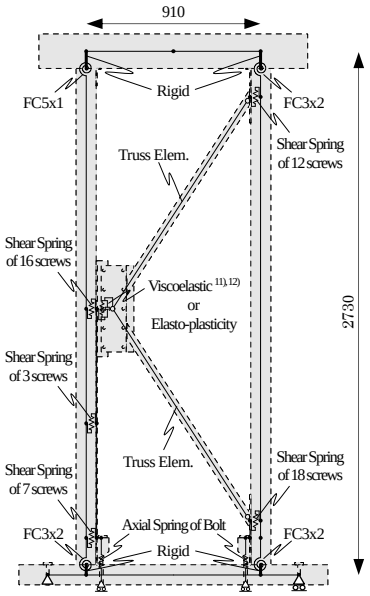

Fig. 4 Detail of Frame Model

$$\tau(t) + aD^{\alpha}\tau(t) = G\,[\gamma(t) + bD^{\alpha}\gamma(t)] \quad (1)$$

$$a = a_{ref}\lambda^{\alpha} \quad , \quad b = b_{ref}\lambda^{\alpha} \quad (2a,b)$$

$$\lambda = \exp[-p_1(\theta - \theta_{ref})/(p_2 + \theta - \theta_{ref})] \quad (3)$$

Where D^{α} is operator of fractional derivative, α is order of fractional derivative. a, b and G are parameter to depend on frequency, a_{ref} and b_{ref} are parameter to depend on temperature. In this paper, effect due to temperature raise of viscoelastic material is not considered in order to make the study simple.

In this paper, steel damper is used as the deformation-dependent damper, and improved Menegotto-Pinto model element which was proposed by Kasai et al. (2001, 2002) is used as steel damper. The improved Menegotto-Pinto model is able to duplicate the stress-strain relationship for steel material such as strain hardening, Bauschinger effect and hardening/softening effect due to repeated deformation.

4.2 Preparation of Simplified Spring Model

Fig. 5 indicates the comparison between detailed frame model and simplified spring model by State-NR estimation estimation. As for both velocity- and dependent-damper, system- and damper-hysteresis, the two curves are corresponding each other with high accuracy.

4.3 Outline of Seismic Response Ayalysis

Accuracy verification of seismic response analysis will be discussed by using the 1-Story timber frame which was modeled as the specimen of the shake table test. It was confirmed that the frame model was able to duplicate not only global behavior but also local behavior with a high degree of accuracy in many tests of 1-story timber structure. The structural part of shake table test specimen is same as Section 4.2 frame basically. In addition, mass totally 3.64ton is allocated in the beam. The damping ratio is

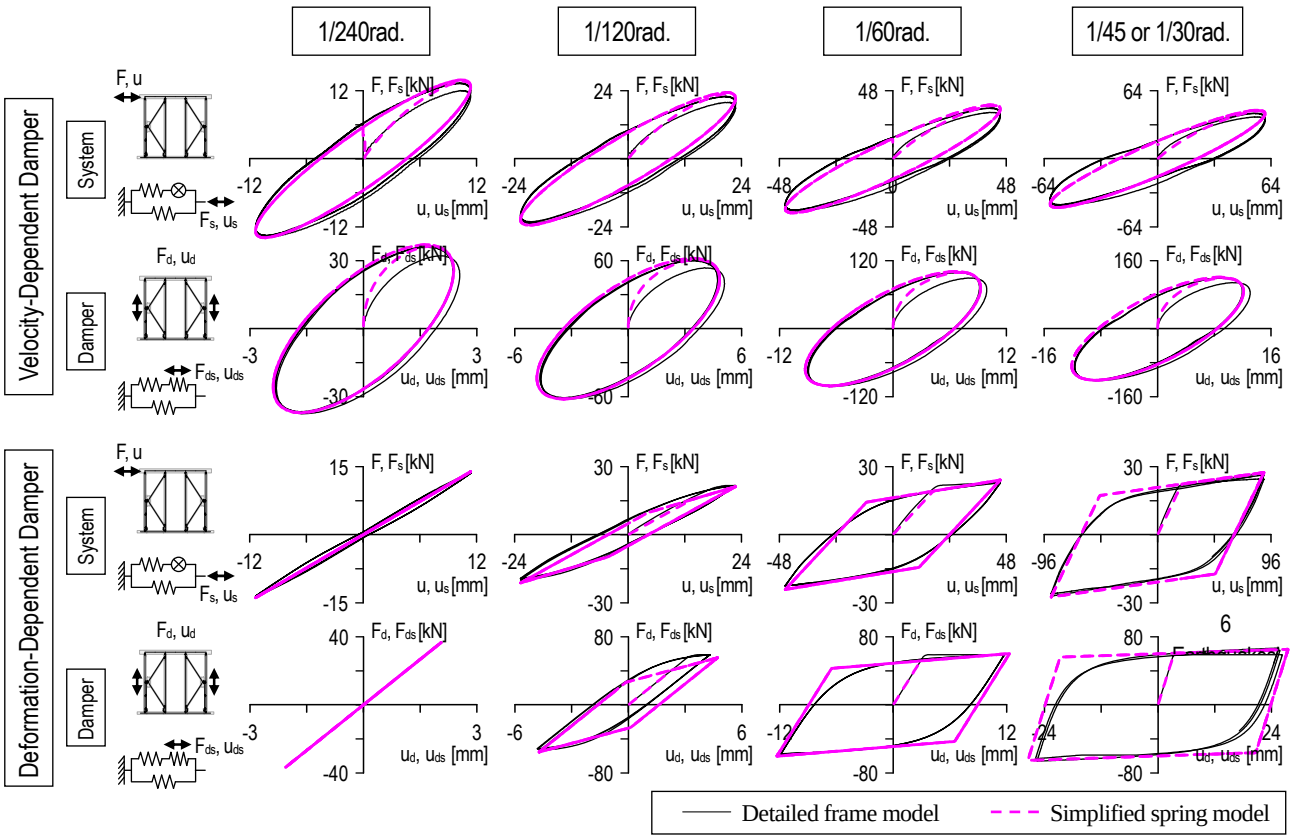

Fig. 5 Comparison between detailed frame model and simplified spring model by State-NR estimation

0.5% in both simplified spring model and detailed frame model. A seismic response analysis software, PC-ANSR, was used.

For time-history analysis, 6 artificial earthquakes are considered. These artificial earthquakes, which are scaled to Level 2, have similar spectrum characteristics. Fig. 6 shows the pseudo acceleration spectra of there earthquake (5% damping ratio).

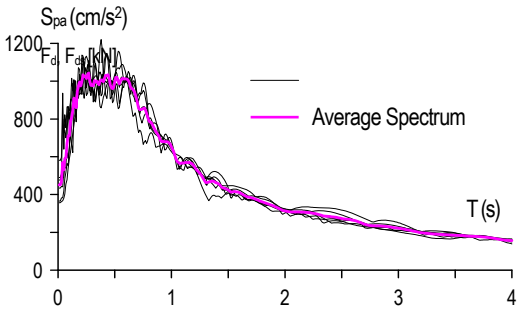

Fig. 6 Spectra of Artificial Earthquake (h = 0.05)

4.4 Results of Accuracy Verification

Comparison between detailed frame model and simplified spring model by State-NR estimation is indicated in Fig. 7. In the case of velocity-dependent damper, simplified spring model and detailed frame model are corresponding each other in both time history and force-deformation relationships.

In the case of deformation-dependent damper, linear stiffness Kd1s, second stiffness ratio ps and yield strength Fdys are basically corresponding each other in force-deformation relationships. However residual deformation and amplitude under vibration are not corresponding. The reason is that the effect of hysteresis damping due to frame yielding is not considered to pseudo-brace and pseudo-frame.

Table 1 lists summary of seismic response analysis. While there is difference in deformation range between velocity- and dependent-damper, the maximum deformation is corresponding between detailed frame model and simplified spring model in all case. Therefore it's confirmed that the simplified spring model is able to duplicate the maximum response deformation. The maximum response acceleration of simplified spring model is about 10% higher than that of detailed frame model. That's why the equivalent stiffness of simplified spring model is higher than that of detailed frame model a little, and effect of hysteresis damping due to frame yielding is not included in pseudo-brace and pseudo-frame of simplified spring model. Even if 1.5 times earthquakes are used, same tendency was obtained.

In this report, the tolerance of the convergent calculation was set to small value, 1% variation, however average number of iteration was 3.3 times. 2 times iteration approximately made the solution convergent. If design purpose is supposed to check whether maximum deformation is smaller than target deformation, it is only necessity to use specification of the target deformation to analyze.

5. CONCLUSION

A method to analyze timber frame with passive control scheme by using simplified spring model was proposed. Through the comparison with detailed frame model, the accuracy was confirmed. Major findings are;

- The hysteresis of velocity-dependent damper was modeled to linear viscoelastic element (ellipse shape) and the hysteresis of deformation-dependent damper was modeled to bilinear element (parallelogram shape) in order to be able to use generalized structural analysis software. Pseudo-brace and pseudo-frame which frame specification was summarized in were modeled to linear elastic springs.
- It was confirmed that the simplified spring model is able to duplicate the maximum response deformation of the detailed frame model. In the case of deformation-dependent damper, the accuracy of residual deformation should be improved.

Appendix 1: Outline of Energy Dissipation Wall

The feature of K-brace passive control wall is shown below (Fig. A1). When the wall deforms by horizontal force, there is vertical deformation between the brace and the steel plate and the damper is inserted in the place. The wall is classified in to a series of so-called shear link type. In order to reduce the effect of the column's bending, the edge of the brace is fixed near the joint of the column and horizontal member. There are many advantages because the contents of the wall are able to fit in inside of frames. For example it is possible to fix without an attachment of other walls. K-brace is screwed on wooden frames by a lot of screws because of high safety factor.

A stub tenon, L-type metal and bolt (hold-down metal) are allocated in the joint of the column and horizontal member. The square steel pipe is fillet-welded to steel plate B and C (Fig. A1(c)). Energy absorption capacity is increased as much as possible by allocating the bolt closer to the column, and integrating the steel plate C into the hold-down metal.

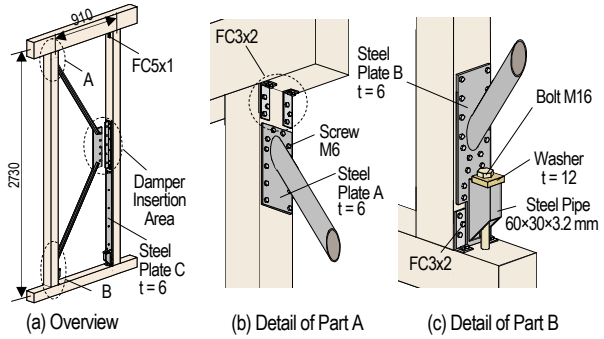

Fig. A1 Detail of Energy Dissipation Wall

Appendix 2: Modelization of Steel Damper

Hysteresis of steel damper is modeled by following step from 1) to 4). Fig. A2 indicates the example of modelization of steel damper.

Step 1) K_{d1+} is obtained from least-square method by using unloading area of the first quadrant (see Fig. A3). Likewise, K_{d1-} is obtained from least-square method by using unloading area of the third quadrant and initial stiffness K_{d1} is obtained as the average K_{d1+} and K_{d1-}.

Step 2) K_{d2+} is obtained from least-square method by using loading area of the first quadrant (see Fig. A3). Likewise, K_{d2-} is obtained from least-square method by using loading area of the third quadrant and second stiffness K_{d2} is obtained as the average K_{d2+} and K_{d2-}.

Step 3) Maximum deformation of positive and negative side are $u_{d\max+}$ and $u_{d\max-}$. $F_{d\max+}$, $F_{d\max-}$ are obtained from force at maximum deformation of positive and negative side. Maximum deformation $u_{d\max}$ and maximum force $F_{d\max}$ are obtained from the average of their two values.

Step 4) Yielding strength F_{dy} and second stiffness ratio p are obtained from following equations.

$$F_{dy} = \frac{F_{d\max} - p \cdot u_{d\max} \cdot K_{d1}}{1-p}, \quad p = \frac{K_{d2}}{K_{d1}} \qquad \text{(A1)}$$

Abstract: In this paper, moment resisting behavior of mortise-tenon joint with split wedge is examined. Flexural-shear tests for split wedge joint are conducted. Seventy-two specimens are tested, and their parameters are dimension of post, beam, tenon, notch line and wedge and tree species of members. The effect of prestressing due to wedge is also discussed. Evaluation method of moment resisting performance of split wedge joint is proposed using simplified mechanical model. It is based on the result of embedment test of wooden materials. The key techniques of the model are how to determine the location of rotation center and consideration of prestressing due to wedge. In addition, closed-form equation to evaluate moment-rotation relation of joint is also proposed.

1. INTRODUCTION

Mortise-tenon joint is one of the most typical connections of Japanese traditional wooden structure. In order to resist tensile force, wooden dowel is often used. We reported tensile tests and flexural-shear tests of mortise-tenon joint with dowel (Sakata et al. 2012). In addition, evaluation method of moment-rotation relation was proposed.

In this paper, we focused on split wedge joints, which are effective to increase initial stiffness because of prestressing due to wedge. Experimental reports on structural performance of split wedge joints are few, and its design rule is not proposed so far. Therefore, we tried to extend the evaluation method to wedge joint.

Seventy two of flexural-shear tests are carried out, and moment-rotation relation, maximum moment and failure patterns are compared. After that, evaluation method of flexural performance is proposed. The analysis model considers compatibility of deformation and equilibrium of force at the joint section and also the effect of initial stress caused by wedge. However, non-linear simultaneous equation has to be solved to determine rotation center of joint. Therefore, detailed analysis and simplified analysis are presented. Simplified approach gives closed-form solution of moment-rotation relation of joint.

2. FLEXURAL-SHEAR TEST

2.1 Outline

Specimens are shown in Figure 1. Post and beam are connected each other with mortise and tenon. Two notches are preliminary made, and wedges are inserted to the notches.

List of specimens is shown in Table 1. Their parameters are dimension of tenon, post, beam and wedge and tree species of members. Six specimens per one specification were tested. Material properties are shown in Table 2. Specimen name is determined in the following manner.

Example 120-30-CC
(1) (2) (3)

(1) Depth of beam h_b
(2) Thickness of tenon b_t
(3) Tree species of post and beam
(C=Cedar, H=Hinoki cypress)

Setup of flexural-shear tests is shown in Figure 2. Post was fixed to steel foundation beam with anchor bolts. Lateral force was applied to loading point of beam by actuator. Let γ be drift angle of beam, and it is calculated using following equation.

$$\gamma = \left(\frac{\delta_1 + \delta_2}{2} - \frac{\delta_3 + \delta_4}{2} \right) / L \quad (1)$$

Where, δ_1, δ_2 = lateral displacement of loading point, and δ_3, δ_4 = those of post. L is vertical distance between center axis of post and loading point, which was set 700 mm.

Loading schedule was controlled by γ, and static reverse cyclic loading was applied as shown in Figure 3. In

addition, relative rotation angle, uplift and shear sliding between post and beam were also measured.

2.2 Result and Discussion

Let M and θ be moment and relative rotation angle at critical section, respectively, which are shown in Figure 4. An example of M-θ hysteresis of joint is shown in Figure 5.

2.2.1 M-θ relation and failure mode

High initial stiffness was observed due to prestressing of wedge. After that, slope of M-θ relation was quite decreased. Bending failure of tenon was usually observed. As shown in Picture 1, out side of notch might get broken at first, and then moment drastically decreased due to failure of middle of tenon. Deformation of wedges was not observed. Eighteen of seventy two specimens were not broken until 1/7.5rad.

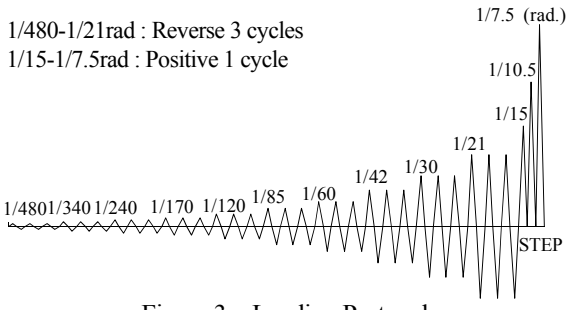

Figure 3 Loading Protocol

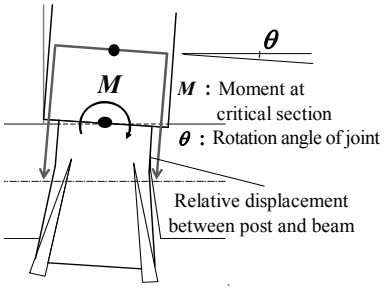

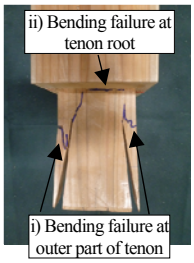

Figure 4 Definition of M and θ

Picture 1 Failure Pattern

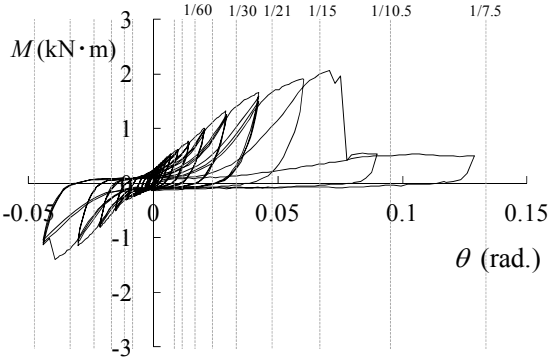

Figure 5 M-θ Hysteresis of 120-30-CC

2.2.2 Comparison of envelope curve

Envelope curves of 120-30-CC, CH and HH are shown in Figure 6(a), (b), (c), respectively. Average and standard deviation curves of six specimens are superposed.

Variation of M-θ curve in six specimens was small in the range of small θ. Rotation angle at occurrence of failure , however, were widely varied.

Maximum moment M_{max} seem to be located between $Z\sigma_s$ and $Z_0\sigma_s$. These are also superposed in the figure with lateral dash lines. Here, σ_s = modulus of rupture of tenon

identified by three-point bending test, Z = section modulus of whole section and Z_0 = that of partial section. Partial section means section from notch to notch (See Figure 6).

In addition, considering accuracy of mortise and tenon dimension, small gap between mortise and tenon might exist. This is why some envelope curves have slip in small θ.

2.2.3 Comparison of M_{max} and θ_{Mmax}

Figures 7, 8 and Table 3 show comparison of M_{max} and θ_{Mmax}. Here, θ_{Mmax} means rotation angle at $M = M_{max}$. The larger the dimension of tenon is, the larger M_{max} and θ_{Mmax} seem to be. M_{max} of CH and HH are larger than those of CC while θ_{Mmax} are not so different regardless of tree species. This means tree species of tenon has much effect on M_{max}.

3. MODELING OF FLEXURAL-SHEAR RESISTANCE

3.1 Mechanical model

Figure 9 shows equilibrium condition of joint. External forces consist of axial force N, shear force Q and moment M, and following four kinds of internal forces are considered.

F_{c1}, F_{c2} and F_{c3} are local compression forces of tenon. F_{c4} shows local compression force of post. F_{fc1}, F_{fc2} and F_{fc3} are friction forces between tenon and mortise. F_{fc4} is friction force between beam and post.

The followings are assumed in order to construct mechanical model.

1) Tenon is enough rigid except for local embedment perpendicular to the grain. Wedges are infinitely rigid.
2) Tenon rotates around rotation center determined by x_n and y_n.
3) Initial stress angle is geometrically calculated using dimension of tenon, mortise and wedge.

3.2 Local Embedment of Timber Perpendicular to the Grain

The authors have conducted rotational compression test of timber perpendicular to the grain as shown in Figure 10 (Sakata et al. 2002). We found evaluation method of moment-rotation relation using properties of parallel

Average (Upper), Coefficient of variation (Lower)

compression perpendicular to the grain. It consists of the following three steps.

Step1 : Bi-linear approximation of stress-strain curve of parallel compression perpendicular to the grain

Parallel compression tests perpendicular to the grain were carried out, and stress-strain curves were obtained. They were approximated by bi-linear model in the manner we proposed (Sakata et al. 2006), and their elastic Young's modulus E_{10}, plastic Young's modulus E_{20} and yield stress σ_{y0} were obtained. Maximum, average and minimum values of E_{10}, E_{20} and σ_{y0} are shown in Table 4.

Step2 : Conversion rule of parallel compression to rotational partial compression (Table 5)

In our previous research, stress-strain relation of parallel compression and edge stress-edge strain relation of rotational compression were compared. The results are shown in Table 6. We found that yield stress of rotational compression were about 1.5 times of σ_{y0}. Elastic Young's modulus and plastic Young's modulus seemed not to be changed.

In addition, rotational partial compression tests were also conducted. Specimen of partial compression had surplus timber along x-direction as shown in Table 5. Apparent edge stress-edge strain curves were obtained. The effects of surplus length are summarized in Figure 11 and Figure 12. If the surplus length is larger than contact length, elastic and plastic Young's modulus seems to be about 1.75 times of E_{10} and E_{20}, respectively, while yield stress is about 2.625 (= 1.5 × 1.75) times of σ_{y0}.

Step3 : Consideration of strain distribution

Although we assumed triangle strain distribution as shown in Figure 13(a), actual strain distribution on surplus timber is quite complicated. Inayama and Tanahashi used exponential function to model the distribution. However, our objective is to simulate the effect of surplus length shown in Figure 11, and we try to use simpler model, half length triangle distribution. This assumption gives easier solution, and matches tendency of test results by using properties of rotational compression without surplus timber. Therefore, we can obtain moment-rotation relation from strain distribution shown in Figure 13(b) using elastic Young's modulus $E_1 = E_{10}$, plastic Young's modulus $E_2 = E_{20}$, and yield stress $\sigma_s = 1.5\sigma_{s0}$, respectively.

3.3 Initial Stress Caused by Wedge

Kitamori has proposed evaluation method of initial stress of wedged Nuki joint (Kitamori et al. 2003). In this paper, the method is applied to split wedge joint.

Initial stress angle could be geometrically calculated using dimension of tenon, mortise and wedge (Table 1), and corresponding forces were assumed to occur as shown in Figure 14. Table 7 shows mortise angle θ_m, wedge angle θ_w and initial stress angle θ_0 of each specimen. θ_0 is defined as θ_w-θ_m from geometrical relationship.

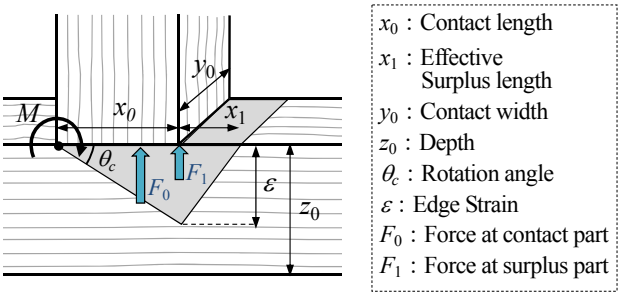

Figure 15 Definition of Local Embedment

3.4 Formulation of Local Embedment of Timber

Based on findings of section 3.2, local embedment forces F_{c1}-F_{c4} and corresponding moment M_{c1}-M_{c4} can be mathematically obtained using geometric parameters (tenon length, width and thickness and so on) and material properties (Young's modulus and yield stress).

As shown in Figure 15, formulation of local embedment force F (= F_0 + F_1) and corresponding moment M are expressed using generalized parameters : contact length x_0, effective surplus length x_1, contact width y_0, depth

z_0, rotation angle θ_c and material properties E_1, E_2 and ε_y (= σ_y/E_1).

$$\varepsilon = \frac{x_0 \theta_c}{z_0} \tag{2}$$

$$F = F_0 + F_1 \tag{3}$$

$$F_0 = F_{0e} \quad (\varepsilon \le \varepsilon_y) \qquad = F_{0p} \quad (\varepsilon > \varepsilon_y) \qquad F_{0e} = \frac{1}{2} x_0 y_0 \varepsilon E_1$$

$$F_{0p} = F_{0e}\left\{1 - \left(1 - \frac{E_2}{E_1}\right)\left(\frac{\varepsilon - \varepsilon_y}{\varepsilon}\right)^2\right\} \tag{4a-c}$$

$$F_1 = F_{1e} \quad (\varepsilon \le \varepsilon_y) \qquad = F_{1p} \quad (\varepsilon > \varepsilon_y) \qquad F_{1e} = \frac{1}{2} x_1 y_0 \varepsilon E_1$$

$$F_{1p} = F_{1e}\left\{1 - \left(1 - \frac{E_2}{E_1}\right)\left(\frac{\varepsilon - \varepsilon_y}{\varepsilon}\right)^2\right\} \tag{5a-c}$$

$$M = M_0 + M_1 \tag{6}$$

$$M_0 = M_{0e} \quad (\varepsilon \le \varepsilon_y) \qquad = M_{0p} \quad (\varepsilon > \varepsilon_y) \qquad M_{0e} = \frac{2}{3} x_0 F_{0e}$$

$$M_{0p} = M_{0e}\left\{1 - \frac{3}{2}\left(1 - \frac{E_2}{E_1}\right)\left(\frac{2\varepsilon + \varepsilon_y}{3\varepsilon}\right)\left(\frac{\varepsilon - \varepsilon_y}{\varepsilon}\right)^2\right\} \tag{7a-c}$$

$$M_1 = M_{1e} \quad (\varepsilon \le \varepsilon_y) \qquad = M_{1p} \quad (\varepsilon > \varepsilon_y) \qquad M_{1e} = x_0 F_{1e}$$

$$M_{1p} = M_{1e}\left\{1 - \left(1 - \frac{E_2}{E_1}\right)\left(\frac{\varepsilon - \varepsilon_y}{\varepsilon}\right)^2\right\} \tag{8a-c}$$

Where, ε = edge strain of triangle distribution, F_0, M_0 = contribution of contact part to local embedment force/moment, F_1, M_1 = contribution of surplus part, respectively. Indexes "*e*" and "*p*" mean elastic ($\varepsilon \le \varepsilon_y$) and plastic ($\varepsilon > \varepsilon_y$), respectively. List of generalized parameters (x_0, x_1, y_0, z_0 and θ_c) for calculation of F_{c1}-F_{c4} and M_{c1}-M_{c4} is shown in Table 8. Note that "*" means virtual force on non-contact surface. For example, F_{c1}* should be subtracted from F_{c1} as shown in Figure 9.

Table 8 Generalized Parameters of Local Embedment (Detailed Analysis)

Force, Moment	Contact length x_0	Surplus length x_1	Contact width y_0	Depth z_0	Rotation angle θ_c
F_{c1}, M_{c1}	y_n	$\frac{1}{2} y_n$	b_t	h_t	θ
F_{c1}*, M_{c1}*	$y_n - l_s$	0			
F_{c2}, M_{c2}	$\frac{h_c - y_n}{\cos\theta_m}$	$l_t - l_s - \frac{h_c - l_s}{\cos\theta_m}$			$\theta + \theta_0$
F_{c2}*, M_{c2}*	$\frac{l_s - y_n}{\cos\theta_m}$	0			
F_{c3}, M_{c3}	$\frac{h_c - y_n}{\cos\theta_m}$	$l_t - l_s - \frac{h_c - l_s}{\cos\theta_m}$			$\max.\{\theta_0 - \theta, 0\}$
F_{c3}*, M_{c3}*	$\frac{l_s - y_n}{\cos\theta_m}$	0			
F_{c4}, M_{c4}	$\frac{h_b}{2} - x_n$	$\frac{1}{2}\left(\frac{h_b}{2} - x_n\right)$	b_c	h_c	θ
F_{c4}*, M_{c4}*	$\frac{h_t}{2} - x_n$	0	b_t		

3.5 Friction Force

Friction forces F_{fc1}-F_{fc4} can be modeled on Coulomb's friction, and F_{c1}-F_{c4} are their corresponding normal forces. Moments derived from F_{fc1}-F_{fc4} are calculated as follows.

$$M_{fc1} = \left(\frac{h_t}{2} - x_n\right) \cdot \mu F_{c1}$$

$$M_{fc2} = \left(x_n + \frac{h_t}{2}\right) / \cos\theta_m \cdot \mu F_{c2}$$

$$M_{fc3} = \left(x_n - \frac{h_t}{2}\right) / \cos\theta_m \cdot \mu F_{c3}$$

$$M_{fc4} = y_n \cdot \mu F_{c4} \tag{9a-d}$$

Where, μ = coefficient of friction. In order to take into account variability of test result, both coefficient of dynamic friction and static friction are used. As for dynamic friction, $\mu = 0.17$ is used for CC, $\mu = 0.22$ for HH, and $\mu = 0.2$ for CH, respectively. As for static friction, $\mu = 0.54$ is used regardless of tree species by referring to Wood Industry Handbook.

3.6 Equilibrium of Force

Equilibrium of force in *x*- and *y*-direction and moment around rotation center is expressed as follows.

$$\sum X : -F_{c1} + F_{c2}\cos\theta_m - F_{c3}\cos\theta_m - F_{fc2}\sin\theta_m + F_{fc3}\sin\theta_m - F_{fc4} + Q = 0$$

$$\sum Y : -F_{c2}\sin\theta_m - F_{c3}\sin\theta_m + F_{c4} + F_{fc1} - F_{fc2}\cos\theta_m + F_{fc3}\cos\theta_m - N = 0 \tag{10a-c}$$

$$\sum M : M_{c1} + M_{c2} - M_{c3} + M_{c4} + M_{fc1} + M_{fc2} + M_{fc3} + M_{fc4} - Q\left\{\left(L - \frac{h_c}{2}\right) + y_n\right\} - N x_n = 0$$

If θ is given, above equations are non-linear simultaneous equations of three variables : x_n, y_n and Q. In chapter 4, convergence calculation is used to determine the unknown parameters and solve the equations. On the other hand, in chapter 5, rotation center (x_n, y_n) is assumed instead of conducting convergence calculation. Therefore, we can obtain closed-form solution.

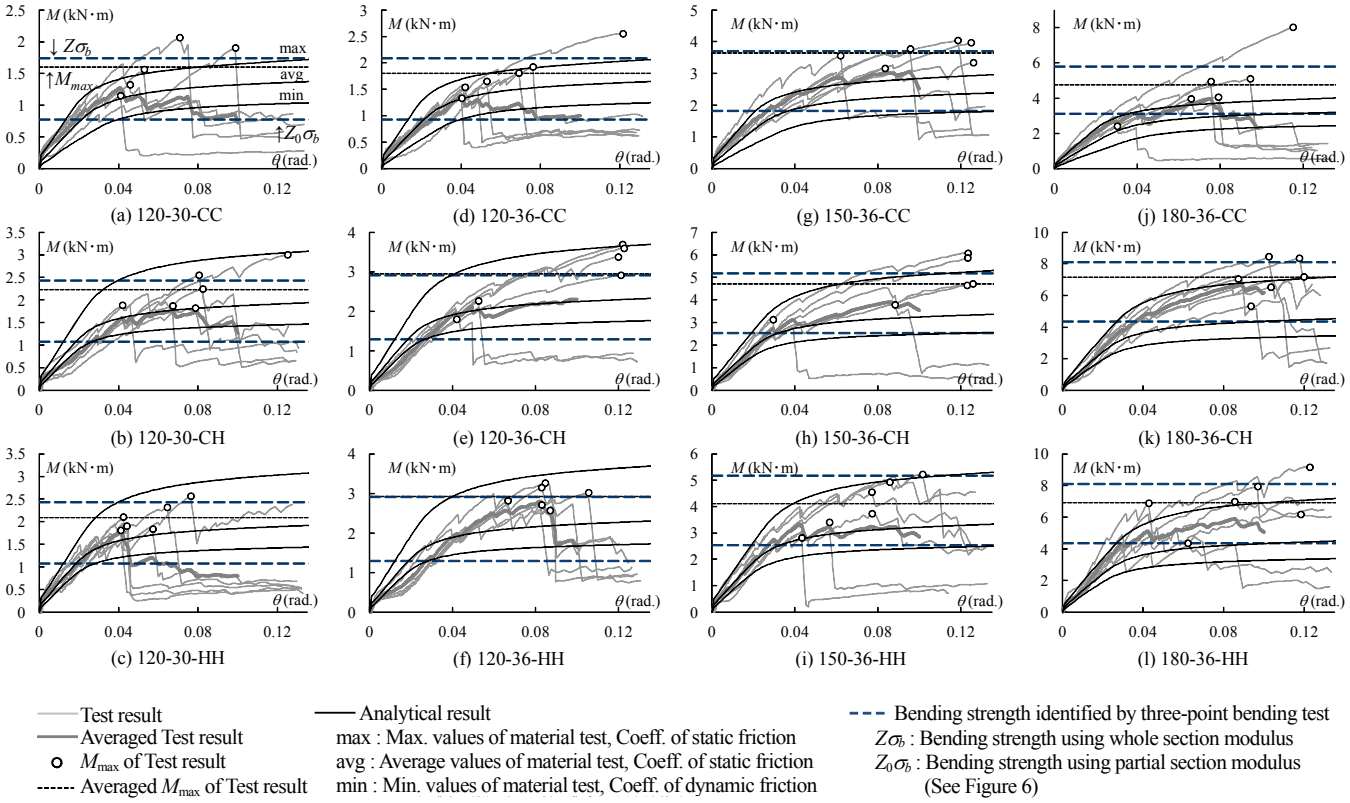
4. DETAILED ANALYSIS

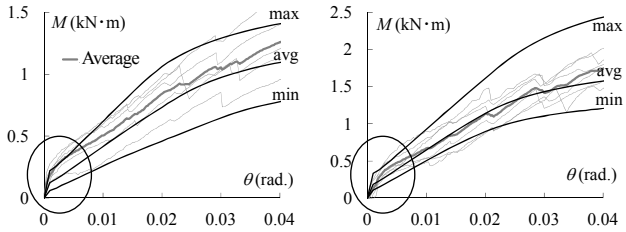
4.1 Outline

At first, arbitrary θ is applied, and three equations of equilibrium are solved, which requires convergence calculation. After that, θ is gradually increased. Above calculation leads to getting M-θ relation of joint. This procedure is named "detailed analysis".

4.2 Comparison between Test Results and Analytical Results

Accuracy of detailed analysis is confirmed. Figure 16 shows comparisons between test results and analytical results of M-θ relation. In order to take into account





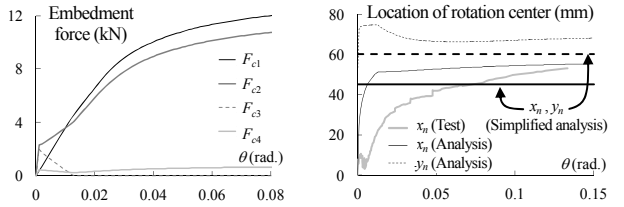


Figure 16 Comparison between Test Results and Detailed Analysis Results

(a) 120-30-CC (b) 120-30-HH

Figure 17 The Effect of Initial Stress

(a) Local Embedment Forces (b) Location of Rotation Center

Figure 18 Local Behavior (120-30-CC-avg)

variability of test result, three cases of analysis were conducted. Result of "max" is using maximum value of material test (Table 4) and coefficient of static friction. Result of "min" is using minimum value of material test and coefficient of dynamic friction. In addition, result of "avg" is using average value of material tests and average coefficient of dynamic and static friction.

avg curve seems to give good agreement with average curve of test result. In addition, test results appear to range from max curve to min curve of analysis. Therefore, variability of test results is also evaluated. Failure points are likely to range from $Z\sigma_b$ to $Z_0\sigma_b$. Figure 17 shows close-up of M-θ relation at small θ. High initial stiffness due to prestressing of wedge is also simulated.

5. SIMPLIFIED ANALYSIS

5.1 Assumption

In this chapter, rotation center x_n and y_n are determined by assuming simpler mechanical model, which means two of three unknown variables are obtained already. Therefore, Q and corresponding moment is expressed by closed-form. In addition, we set particular events to calculate M-θ relation, and M-θ curve from the event to the next event is approximated by linear relation. In this way, multi-linear M-θ curve is obtained.

As shown in Figure 18(a), F_{c1} and F_{c2} are dominant forces, and their amplitudes are nearly the same. This is why $x_n = h_f/2$ and $y_n = h_c/2$ can be assumed. Figure 18(b) shows location of rotation center identified by experiment and detailed/simplified analysis. Although simplified analysis is not able to take into account a change of rotation center according to θ, experimental and two analytical results show close values at large θ.

5.2 Formulation

Generalized parameters of local embedment for simplified model are summarized in Table 9. We can

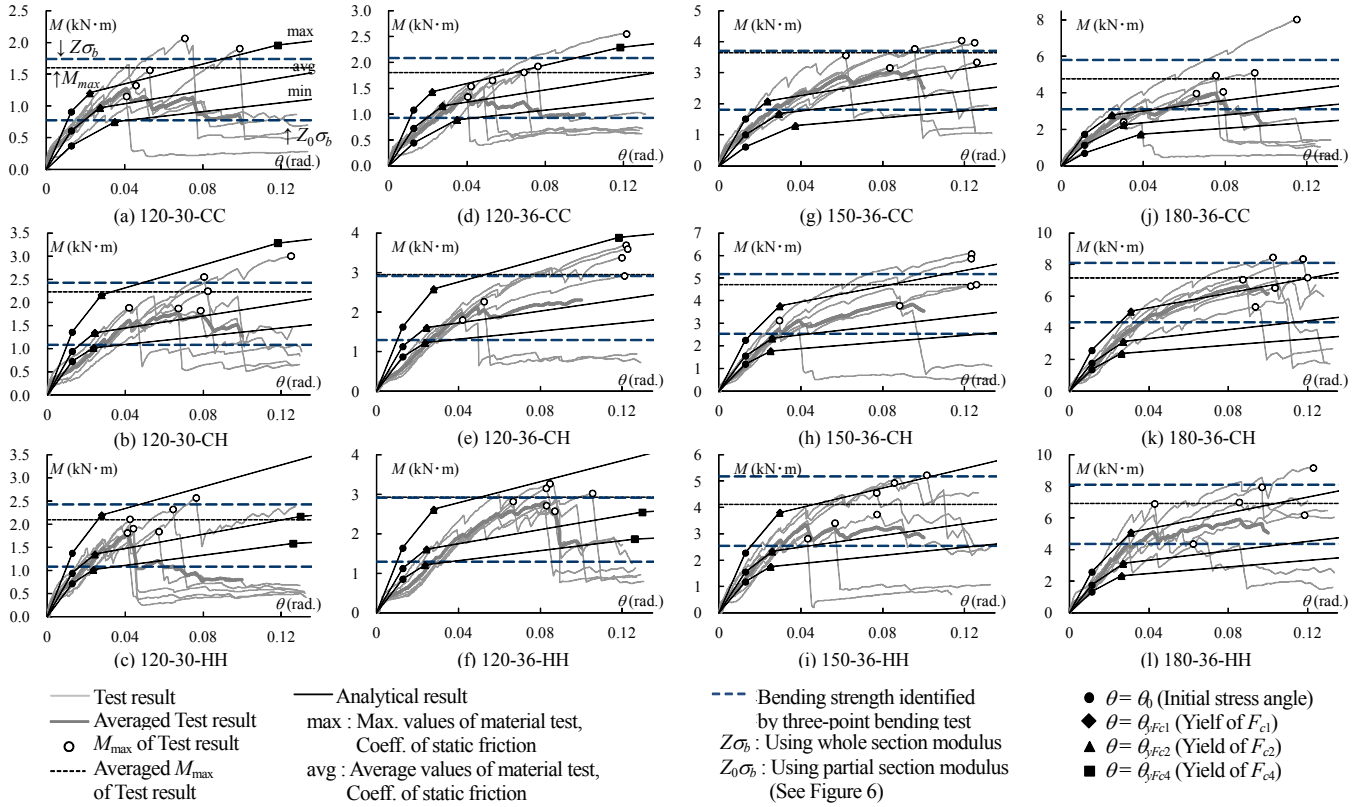

Figure 19 Comparison between Test Results and Simplified Analysis Results

Table 9 Generalized Parameters of Local Embedment (Simplified Analysis)

Force, Moment	Contact length x_0	Surplus length x_1	Contact width y_0	Depth z_0	Rotation angle θ_c
F_{c1}, M_{c1}	$\frac{h_c}{2}$	$\frac{h_c}{4}$	b_t	h_t	θ
F_{c1}^*, M_{c1}^*	$\frac{h_c}{2} - l_s$	0			
F_{c2}, M_{c2}	$\frac{h_c}{2\cos\theta_m}$	$l_t - l_s - \frac{h_c - l_s}{\cos\theta_m}$			$\theta + \theta_0$
F_{c4}, M_{c4}	$\frac{h_b - h_t}{2}$	$\frac{h_b - h_t}{4}$	b_c	h_c	θ

calculate all forces and moments without any convergence calculation. Moment at critical section is calculated as follows.

$$M = \left(M_{c1} + M_{c2} + M_{c4} + M_{fc2} + M_{fc4}\right)\frac{L - h_c/2}{L} \qquad (11)$$

5.3 Comparison between Test Results and Analytical Results

Accuracy of simplified analysis is confirmed. Figure 19 shows comparisons between test results and analytical results of M-θ relation. Analysis curve is broken at $\theta = \theta_0$, θ_{Fc1}, θ_{Fc2} and θ_{Fc4}. At $\theta = \theta_0$, prestressing of wedge at location of F_{c3} goes off (Figure 9). At $\theta = \theta_{Fci}$, local embedment force F_{ci} yields.

Simplified analysis seems to give similar tendency to detailed analysis. In other words, its mechanical model is reasonable to simulate moment-rotation relation with less effort.

6. CONCLUSIONS

In this paper, flexural-shear tests of mortise-tenon joint with split wedge were conducted, and its structural performance was shown. After that, evaluation method of M-θ relation was proposed. Its applicability was also shown. Analytical results gave close agreement with test results until the failure point.

Abstract: Conventional buildings systems can sustain heavy uneconomical to repair damage in a major earthquake. There is a lack of damage avoidance moment resisting systems in timber. A new damage avoidance system with gravity rocking and friction damping is under development. Both beams and columns are continuous through the joint in the hybrid timber-steel frame. Damage to the seismic frame and floor slab is minimized as a result. Tests at 1:20 scale have shown damage avoidance and full self-centering as expected. A simplified SAP2000 model has been developed which models the first large displacement cycles well but loses accuracy in later large displacement cycles.

1. INTRODUCTION

Major earthquakes in recent decades have resulted not only in unfortunate loss of life, but also extensive damage to infrastructure. Aseismic design is improving and the number of fatalities is gradually decreasing in developed nations. The performance threshold is being raised and damage reduction is now commonly a performance target in addition to providing for life-safety.

Capacity design principles direct inelastic action to dedicated zones in the structural system. In conventional systems, these dedicated ductile zones protect the rest of the structural system from inelastic demand and damage but sustain damage themselves. The goal of the system presented here is to minimize damage to the structural frame, floor slab and also non-structural elements. A timber-steel hybrid system is used to make best use of material properties; however, the main principles involved are largely independent of material.

2. EXISTING SYSTEMS

Energy dissipaters or dampers are often used to dissipate earthquake energy, reduce building drift and thus reduce damage. They can be added to conventional structural systems or be incorporated into advanced damage avoidance systems which are capable of large inelastic deformation without damage. Some damage avoidance moment frame systems of particular interest are described briefly here. More reading can be found in (Jamil, Quenneville et al. 2012).

The Sliding Hinge Joint (SHJ) shown in Figure 1 is a semi-rigid connection with the beam top flange effectively pinned to the column, web bolts for vertical shear transfer and a slotted bolted friction slider at the bottom flange. The SHJ remains rigid under serviceability level loads but rotates with friction sliding at the bottom flange under ultimate limit state or higher earthquake load. After the strong motion stops, the connection becomes rigid again. It has a tendency to self-center as the earthquake motion gradually stops but does not reliably fully self-center. There is also some loss of friction slider bolt tension force and hence connection strength. The addition of a ring spring (Ringfeder Gmbh 2008) for added self-centering has been investigated (Khoo, Clifton et al. 2011) but cost is an issue.

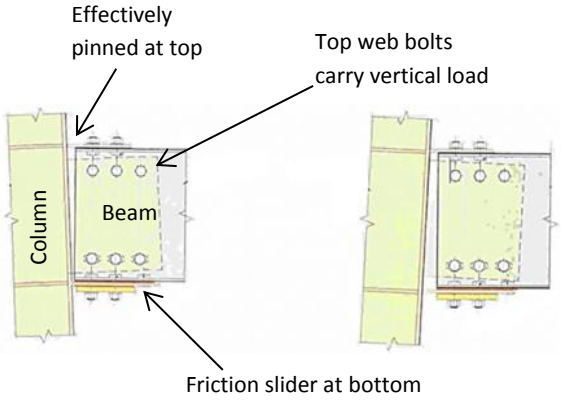

Figure 1 The Sliding Hinge Joint – copied from (Clifton 2005)

Post-tensioned connection technology was originally developed for pre-cast concrete construction under the PRE-cast Seismic Structural System (PRESSS) research program in the 1990s and is being adapted to steel and timber. The concept is illustrated in Figure 2. Un-bonded tendons clamp the joint together to provide moment strength and self-centering. Mild steel or other dampers may be added. It is difficult to use this system with timber because the post-tension force causes creep shrinkage in the timber over time. This causes a reduction in post-tension force and thus a reduction in connection strength.

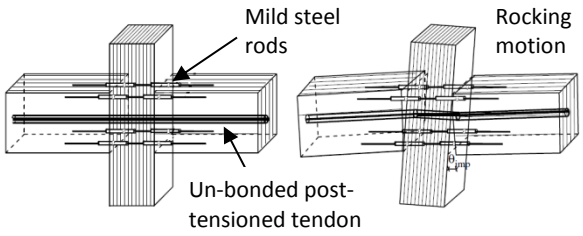

Figure 2 Post-tensioned timber moment connection – copied from (Buchanan, Deam et al. 2008)

Gravity rocking Greek and Roman masonry temples have a similar mechanism to post-tensioned systems except that the columns are non-continuous and beams may be continuous. Furthermore, normal force at the joint interface is provided by gravity instead of post-tensioned tendons. Figure 3 shows some sliding of column drum sections in addition to rocking. Japanese wood temples or pagodas have a less explicit rocking and sliding mechanism but still show structural period elongation with increased displacement (Hanazato, Minowa et al. 2010). Comparison of a typical Greek temple connection with a Japanese pagoda connection is shown in Figure 4. If columns are non-continuous, these systems are prone to soft-story formation. The new system presented here therefore has continuous columns.

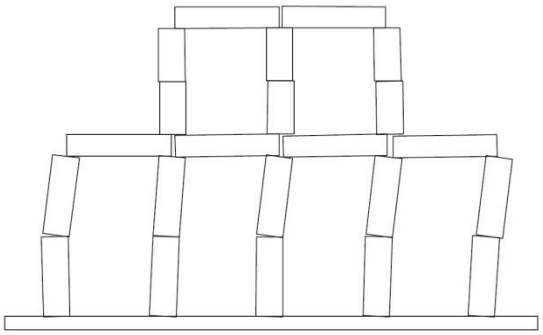

Figure 3 Gravity rocking and friction sliding in ancient Greek/Roman temples – copied from (Papaloizou and Komodromos 2011)

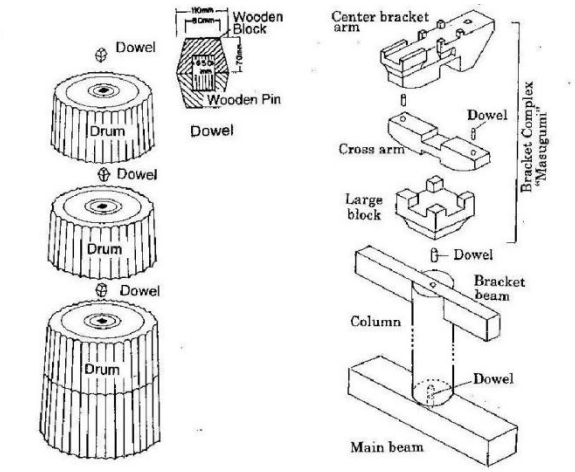

Figure 4 Comparison of connection used in Greek masonry temples with that in Japanese wood temples – copied from (Hanazato, Minowa et al. 2010)

3. NEW DAMAGE AVOIDANCE SYSTEM

3.1 Target Minimum Performance

Table 1 Minimum performance target for new system

Limit State (return period)	Mode of operation	Condition of structure	Drift residual/ peak
SLS (25 years)	Elastic	As new	0.0% / ~ 0.33%
ULS (500 years)	Inelastic connection rotation. Timber members to remain elastic	Close to as new. No wood crushing or strength/stiffness degradation. Minimal non-structural damage including partitions and floor slab	~ 0.2% / 2.5%
MCE (2500 years)	Large inelastic connection rotation. Some inelastic action may occur in the wood	Any damage economically reparable. Possible damage to non-structural elements. Structural collapse reliably avoided	No strict limit. ~ 4 to 5% expected

3.2 Connection detail

The new connection combines gravity rocking and friction damping. The concept was developed through several iterations and work is still in progress. Some detail of the development process can be found in (Jamil, Quenneville et al. 2012). A steel column / LVL beam hybrid option was chosen because the column is relatively heavily loaded with combined bending and axial actions. Furthermore, a steel column simplifies the

connection and also has a smaller foot-print. The overall connection and assembly steps are shown in Figure 5.

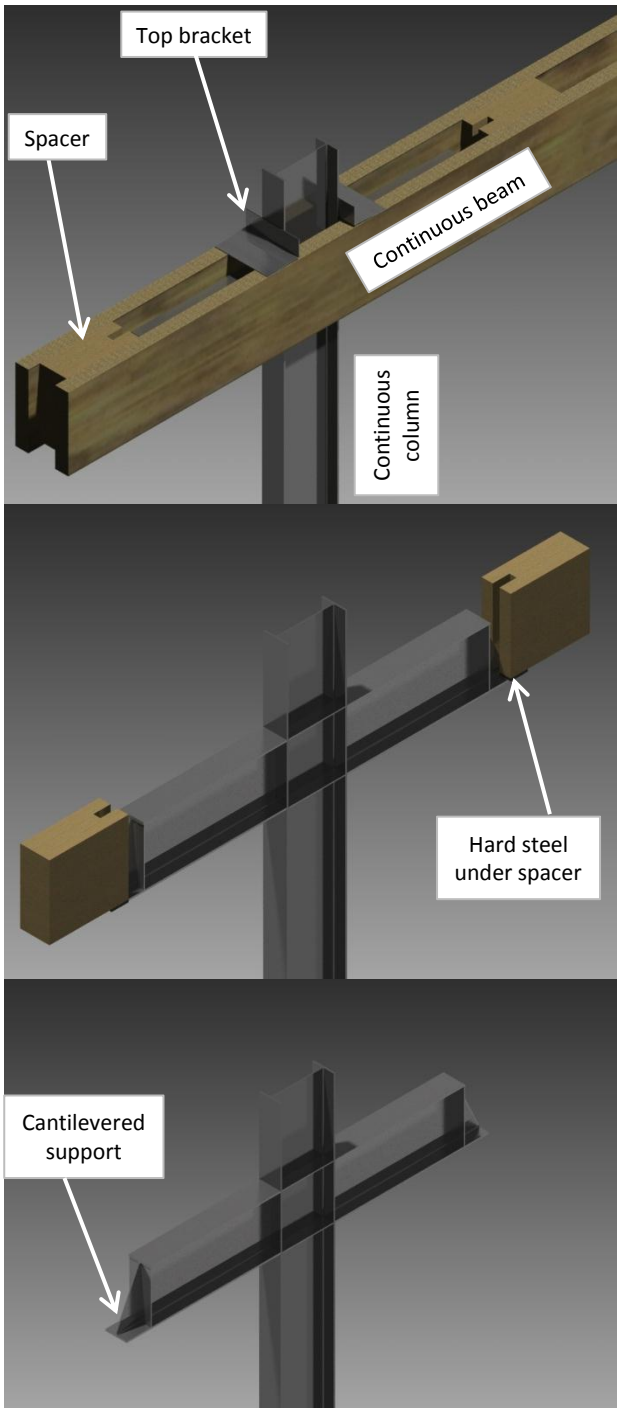

Figure 5 New connection. (top): Overall connection; (middle): construction step 2 and; (bottom): construction step 1

There are four main features: (1) gravity rocking on cantilever supports; (2) friction damping due to sliding between underside of armored spacer and cantilevered support; (3) brackets on top which restrain the beam horizontally to the column but allow the beam to uplift and (4) beam and column both continuous through the joint. One way to assemble the joint is to: (1) fabricate the column with cantilevered supports; (2) hold the spacers in place on cantilevered supports; (3) screw the two halves of the beam into the spacers; and (4) install the two top brackets.

3.3 Connection mechanics

Figure 6 shows how the connection develops moment resistance. The principal source of resistance is the gravity load carried by the joint acting at an eccentricity to the column center line. The brackets on top are bent so that the beam is restrained horizontally to the column face but can uplift upon rocking at the connection. Because the beam is restrained horizontally at the top, the bottom of the beam must slide in order for the connection to rotate. A friction force equal to the coefficient of friction, μ, multiplied by the gravity load on the joint is generated. This acts through a lever arm approximately equal to the beam depth and thus adds to moment resistance. The bracket on top has a small vertical resistance force which acts through a lever arm from the support point to the opposite column face. The other bracket has a lower moment resistance which is ignored here. Table 2 presents moment resistance calculation for an example case. Note that the calculation method is based on principles of mechanics and take no account of possible unforeseen effects.

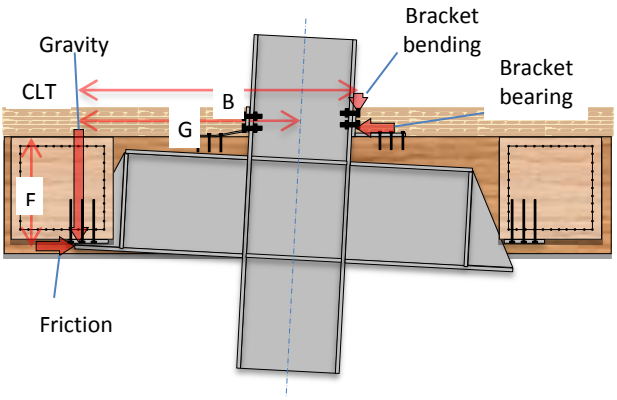

Figure 6 Connection at 50 mrad (5%) rotation. Forces are as acting onto the column

Table 2 – Example joint moment resistance calculations

	Force (kN)	Lever arm (m)	Moment (kNm)
Gravity	200 Inner column, perimeter frame, 10 m grid, 4.0 kPa	1.0 (Support point to column centre line)	200
Friction	200×0.48=70 μ=0.48	0.7	96
Top Bracket yielding	40 (depends on bracket size)	1.5+0.7/2=1.15 (support to opposite column face)	74
Total			370

4 1:20 SCALE SHAKE TABLE TESTS

4.1 Test Model

A 1:20 scale, 1 by 2 bay, 3-storey model was built following scaling similitude laws. As shown in Figure 7, Laminated Veneer Lumber was used for both the columns and beams. The test was done before switching to the steel column option. Frame members are designed to remain elastic therefore the column material has little influence on the global behavior of the model.

A length scale factor of 1:20 was used whereas acceleration and material Young's modulus were left unchanged. This resulted in a time scale factor of 1:4.47. The model was about 1000 mm long, 500 mm wide and 600 mm high overall. The total mass was about 500 kg. All connections used in the model were identical and a close up is shown in Figure 8. More detail on the model can be found in (Jamil, Quenneville et al. 2012).

Figure 7 1:20 scale model on shake table. The side frames (circled red) are not part of the model; they restrict the model to in-plane movement

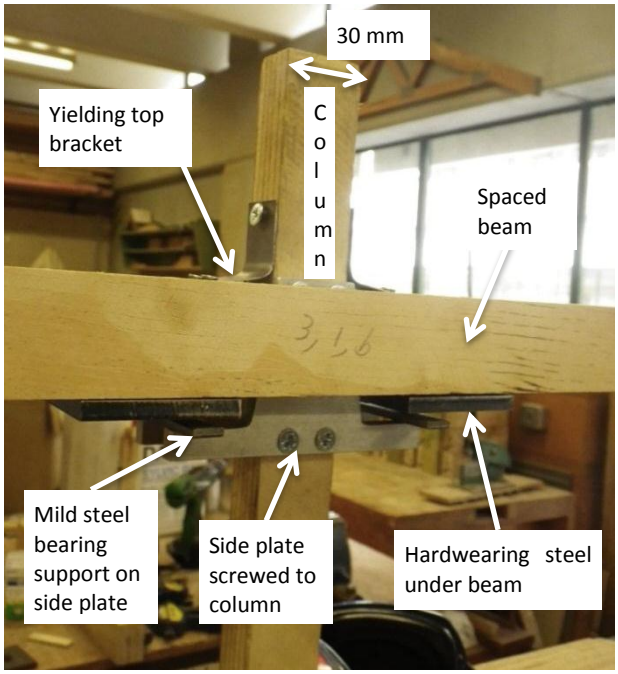

Figure 8 Connection in 1:20 scale model building

4.2 Test Results

Snap back tests were done by pulling the top of the model and releasing. Free vibration decay after releasing from a pull of 40 mm at the top is shown in Figure 9. The model returned to its original position in about two cycles showing high damping and re-centering.

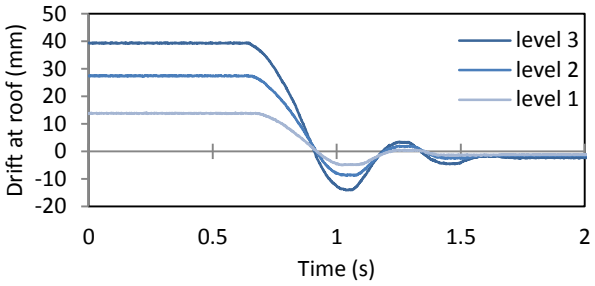

Figure 9 Free vibration decay with top floor pulled to 40 mm and released

Top floor displacement for the 1940 El-Centro earthquake displacement scaled to 0.1, 0.2 and 0.3× is plotted in Figure 10. According to similitude scaling laws, a displacement or length scale factor of 1/20 or 0.05 should have been applied. However, a stronger earthquake was used to excite the model well into the non-linear range. After about 20 earthquake tests which forced the model to a drift of over 5%, no visible damage or degradation in performance was found except minor loosening of some screws.

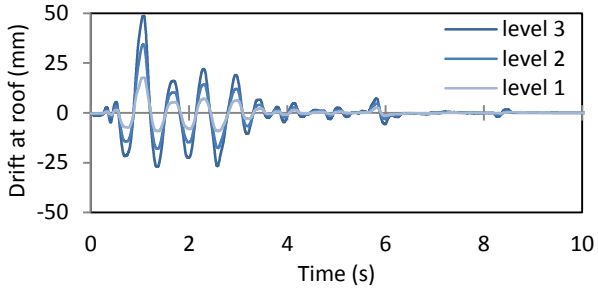

Figure 10 Top floor displacement of 1:20 scale model for scaled El-Centro 1940 earthquake

5 1:20 SCALE SAP2000 ROTATIONAL SPRING MODEL

5.1 Model setup

The SAP2000 model was setup to be the same size as the scaled down test model. A single frame was modeled as shown in Figure 11. The laminated veneer lumber (LVL) was modeled as isotropic and the material characteristic value for Young's Modulus were assumed. A uniformly distributed load was assigned to each level to match the load and self-weight of the physical model. Unprocessed shake table acceleration recorded with an accelerometer from the earthquake test reported in the previous section was used as input.

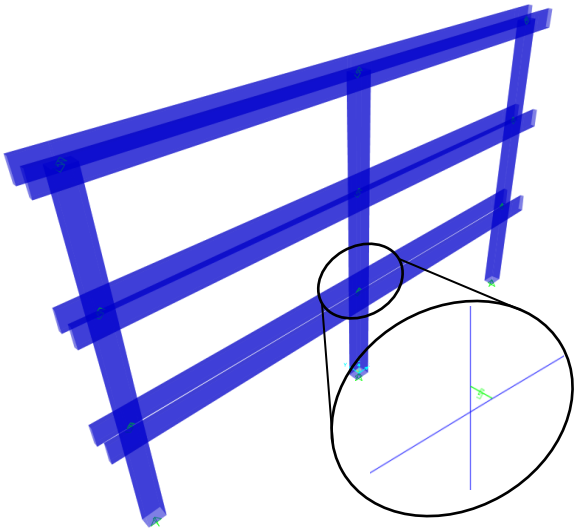

Figure 11 Overall 1:20 scale model in SAP2000. Note that line elements were used in the model but an extruded 3-D view is shown here. Close-up shows node location and rotational spring connection to nodes

Line elements were used with rotational springs at the joint. Nodes were placed at a small offset of 1mm from where the beam crosses over the column. The beam and column are not linked at the intersection but are only connected through the rotation springs. Four rotational springs were used at each joint. Spring moment-rotation curves from the shake table test described above are shown in Figure 12. A multi-linear elastic link element definition was used to represent moment due to gravity load acting at an eccentricity to the column. Multi-linear plastic link elements were used for friction damping and the two top brackets. A post-yield stiffness of 3% of the pre-yield stiffness was assumed for the brackets. A pre-yield stiffness was specified for when the bracket spring rotation exceeded the physical bracket uplift gap. This level of rotation was not reached in the simulation as can be seen in Figure 12 (c) and (d). Rotational spring strengths were calculated based on the same principles as in Section 3.3. An estimate joint elastic stiffness had to be assumed because of the difficulty in measuring the actual stiffness of the joint in the small scale model. A connection rotation of 0.01 radians to initiation of rocking and friction at the joint was specified in the SAP2000 model. Geometry and material properties were used to calculate the yield rotation of each mild steel top bracket.

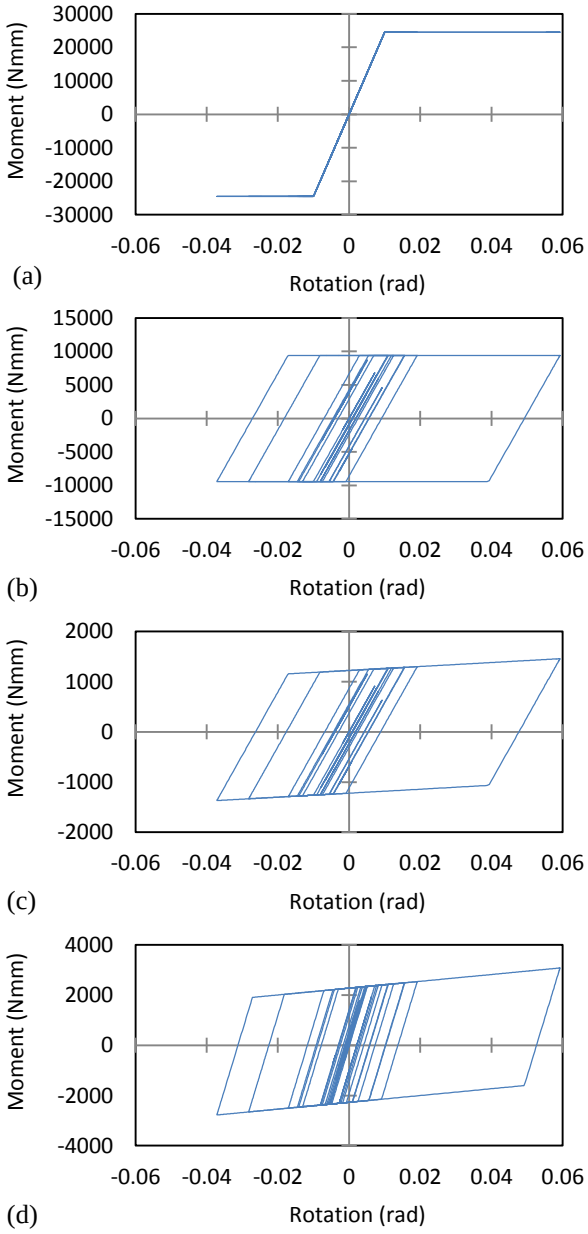

Figure 12 Moment rotation of each spring at the middle first level beam column joint of the 1:20 scale SAP2000 model subjected to the scaled 1940 El-Centro earthquake: (a) Gravity load at eccentricity to column; (b) Friction; (c) Top bracket A; and (d) Top bracket B.

5.2 Analysis method and assumptions

Hilber-Hughes-Taylor direction integration with alpha set to zero, which is the same as the Newmark method, with a maximum time step of 0.001 s was used to solve the model. A non-linear analysis with consideration of P-Delta and large displacement effects was used. First and second mode periods of vibration of 0.4 s and 0.07 s respectively were found using Ritz modal analysis. A Rayleigh proportional equivalent viscous damping of 2% was specified at these two natural periods.

A 2-D single frame model was used in SAP2000 and motion was limited to the in-plane direction. A purely pinned column base was assumed. Vertical inertia effect from uplift of the floor was not considered in the simplified rotational spring model.

5.3 Comparison of test result and SAP2000 model

Figure 13 shows the roof drift time history from the shake table test and that from the SAP2000 model. The first large motion pulse is well represented by the SAP model but drift in later cycles is under-predicted. In-accuracy of recorded shake table acceleration which was used as input for the SAP model and assumptions stated earlier are thought to be a major cause of this discrepancy.

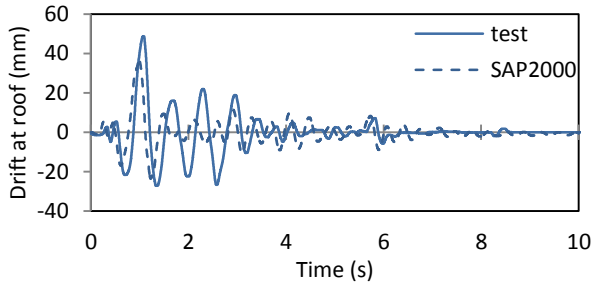

Figure 13 Drift of 1:20 scale model at top level subjected to scaled 1940 El-Centro earthquake: Test result compared with SAP2000 model

6 PLANNED WORK

Further tests on the 1:20 scale model and shake table tests on a 1:4 scale model are planned. A more sophisticated numerical model which models the actual rocking effect with contact elements is under development. The final expected outcome is a design procedure for implementing the new connection in practice.

7 CONCLUSIONS

A novel damage avoidance moment connection with gravity rocking and friction damping is under development. The system avoids post-tensioning which can cause creep issues and strength loss in the long-term when used with timber. Early 1:20 small scale testing has shown damage avoidance performance as expected with full self-centering and high damping. A simplified numerical model of the scaled physical model predicted peak drift satisfactorily but under predicted later large drift cycles. Work is underway on a more sophisticated numerical model which should capture vertical inertia effects and joint elastic stiffness. The final aim is to develop the new connection for use in low to medium rise multi-story timber-steel hybrid buildings in medium to high seismic zones.

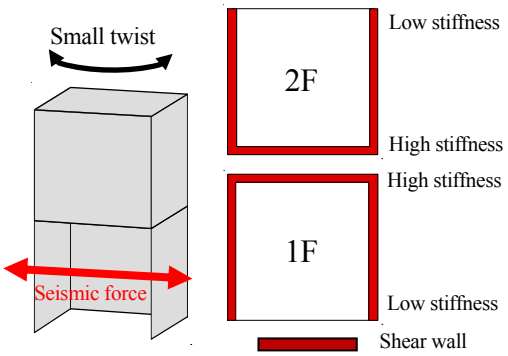
Abstract: This paper focuses on torsional behaviour of two-story timber house with eccentricity. The Japanese current design standard doesn't consider dynamic effect and torsional interaction. Therefore the rotational component of the external force is not properly evaluated. In this study, torsional behaviour of two-story timber house having rigid floor diaphragm is verified by seismic response analyses. As a result, we found that torsional deformation occurred even in the story without eccentricity, if the other story had eccentricity. When two story's eccentricities were same direction, torsional deformation increased. When two story's eccentricities were opposite direction, torsional deformation decreased. It was revealed that the transition of torsional behaviour caused by yielding of walls could be evaluated using modal shape of the equivalent linear structure.

1. INTRODUCTION



The seismic performance of timber houses in Japan has been improved especially after the 1995 Kobe earthquake. However, there are many timber houses with large opening on the south face or with opening facing to the road for garage. Such houses are likely to have unsymmetrical plan of shear walls. So these houses tend to separate the center of mass from the center of stiffness. On the other hand, most timber houses without large opening also have eccentricity. So houses without eccentricity are few.

Because of these concerns, many studies about eccentricity have been carried out. But most of them targeted on single-story buildings. In addition, the Japanese seismic design method for eccentricity is based on the rigid floor assumption and assumes the equivalent seismic force was proportional to the floor mass. Furthermore, it considers the balance of walls on each floor individually. So this method does not give enough consideration to the dynamic effect and ignores the influence of the torsional motion of a story to the other stories.

In Japan, there are many two-story and three-story timber houses. Previous studies showed that torsional behaviour of a story of a two-story unsymmetrical house can affect other stories and discussed the need to clarify the mechanism of torsional behaviour of multi-story buildings (Fig.1). Knowing the exact torsional behaviour of buildings will give valuable information not only to improve the seismic performance but also to better plan dampers for the mitigation of torsional motions.

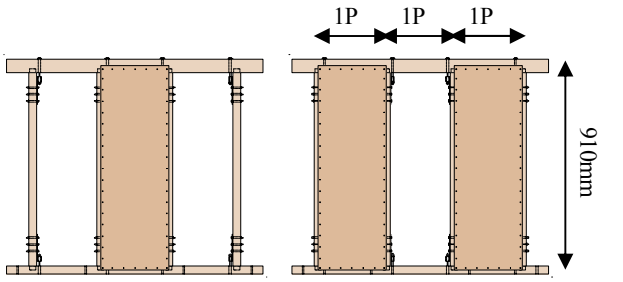
2. SHEAR WALL TESTS



2.1 Outline

Fig.2 shows specimens and Table.1 shows

specifications of elements. Specimens scaled full scale shear wall 1/3 times larger (1P=303mm). Column capitals and column bases manufactured stub tenon. In addition, column capitals and column bases were attached to the HD. Fig.3 shows set up of shear wall tests. Test was performed in accordance with 2nd references. Tests using specimens of the same specification were carried out 3 times.

2.2 Result

Fig.4 shows the relationship between shear force (Q) and the apparent shear deformation angle (θ). θ is calculated by the Eq.1. First, the failure characteristics are shown below. When θ becomes approximately 1/150rad, nail head began to lean. When θ becomes approximately 1/100rad, pull - out of nails began to be observed and nail head began to be sunk to the plywood. These destructions proceeded to approximately 1/75rad. Peeling of plywood began about a 1/50rad. Nail was completely pull - out and punching out occurred at the corner of the plywood leading up to 1/15rad. Through all the tests, most of the fracture mode was pull - out of nails. Cracking and torn off of plywood and breakage of the nail did not occurred. Next, the relationship between hysteresis and the fracture mode is shown. When nail head began to lean, stiffness was reduced gradually. Around the lifting of the plywood was observed, shear walls reached a maximum strength. After reaching the maximum strength, because the lifting of the plywood had become more pronounced, the load was reduced. In addition, specimens

structure. These characteristics are slip behaviour, pinching that were used in study had peculiar characteristics of timber behaviour and strength degradation due to cyclic loading. In other words, hysteresis and the fracture mode were similar to that of a typical full scale shear wall.

3. ANALYSIS STUDY USING 3D FRAME MODEL

3.1 Analysis Objects

Analysis objects were 1/3 scale multi-story timber houses (Fig.6). Fig.7 shows floor plans of each model. In this study, 5 type models that had difference alignment of shear walls were provided. ±00±00 model has not eccentricity. ±00+44 model has eccentricity in only 1st story. +44±00 model has eccentricity in only 2nd story. +44+44 model and +44-44 model have eccentricity in 1st and 2nd story. Position of center of rigidity of the layers of +44+44 model (hereinafter called Sequential Eccentricity model) is in the same direction for the position of the center of gravity. On the other hand, position of center of rigidity of the layers of +44-44 model (hereinafter called Reversal Eccentricity model) is in the different direction for the position of the center of gravity. There are two parameters. One parameter is the ratio ($k2/k1$) of 2F story stiffness ($k2$) for 1F story stiffness ($k1$). In this study, $k2/k1$ assumed it $k2/k1$=0.8,0.6. When $k2/k1$ was changed, $k1$ was not changed but $k2$ was changed. The other is the ratio ($m2/m1$) of 2F story's mass ($m2$) for 1F story's mass ($m1$). In this study, $m2/m1$ assumed it $m2/m1$=0.9,0.6. When $m2/m1$ was changed, total mass ($m1+m2$) was not changed. Total mass assumed it 360kg in reference to 3rd and 4th references.

3.2 Analysis Model

Analysis objects were modeled by 3D frame model (Fig.8) and shear walls were modeled by brace substitution method (Fig.9). The hysteresis model of brace was W.Stewart model. Axial springs which modeled tensile performance of the joint were placed in column capitals and column bases. Mass points were arranged on the each floor so that did not change the value of the rotational inertia (I) that was calculated when mass were placed evenly on the floor. Damping model was the proportional model of initial stiffness. Damping constant was 2%.Input motion was set to unidirectional shaking (direction X). The time axis of seismic waves was shortened to times due to the reduction of the model (the mass ratio of full scale model to 1/3 scale model was 0.111 and stiffness ratio was 0.225). The input earthquake waves were 3 types JMA-KOBE waves and BCJ-LEVEL2 (hereinafter called BCJ-L2) wave. Maximum acceleration of 2 types JMA-KOBE waves was standardized. 1st type JMA-KOBE wave's acceleration was 0.2G (hereinafter called KOBE_0.2G), 2nd type JMA-KOBE wave's acceleration was 0.6G (hereinafter called KOBE_0.6G), and 3rd JMA-KOBE wave was original wave (hereinafter called KOBE_Ori).

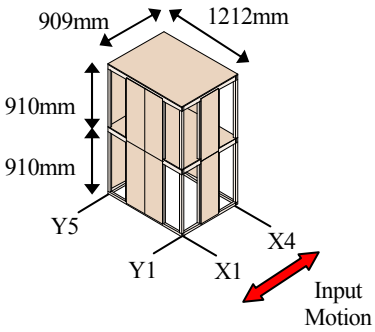

Figure 6 Analysis Objects

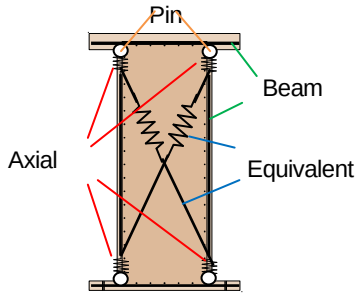

Figure 9 Frame Model of Shear Wall

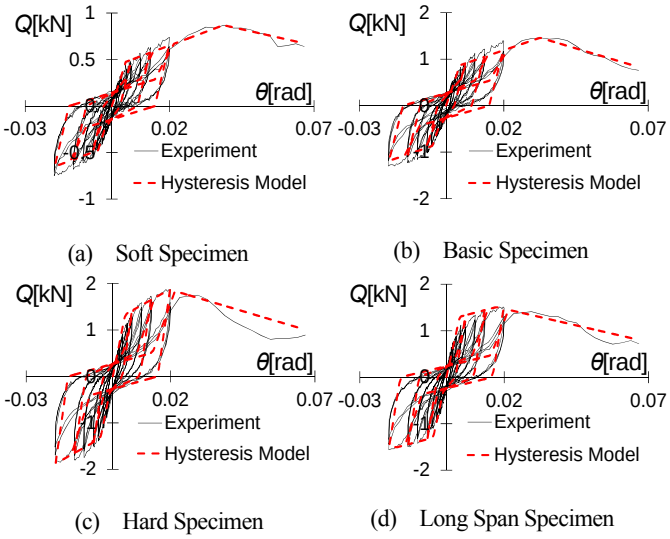

Figure 10 The Hysteresis Model of Each Wall

3.3 Result

In this paper, describes only the case of $k2/k1$=0.8 and $m2/m1$=0.9. Fig.11 shows the maximum displacement of each wall when the displacement of the center of mass of each story was maximum. Fig.12 shows the response rate of twist ($\Delta u/u_{c.m.}$). $\Delta u/u_{c.m.}$ is the ratio of the displacement that the incremental displacement caused by the torsional (Δu) for the displacement of the center of mass ($u_{c.m.}$). $\Delta u/u_{c.m.}$ means the degree of twist. Though the 1F of +44±00 model and the 2F of ±00+44 model had not eccentricity, torsional deformation occurred on the both stories. So this result shows that the existence of torsional interaction. First, make a comparison between the models for $\Delta u/u_{c.m.}$. Focus the models which have eccentricity in both stories. $\Delta u/u_{c.m.}$ of reversal eccentricity model is smaller than $\Delta u/u_{c.m.}$ of sequential eccentricity model. The reason for these results is shown below. Because 1st and 2nd stories of Sequential Eccentricity model (+44+44) twisted in the same direction, torsional deformation of Sequential Eccentricity model was got a helping hand.

On the other hand, because 1st and 2nd stories of Reversal Eccentricity model (+44-44) twisted in the opposite direction, torsional deformation of Reversal Eccentricity model was became suppressed. Next, consider the transition of the $\Delta u/u_{c.m.}$. The larger $u_{c.m.}$, $\Delta u/u_{c.m.}$ was increased once. When $u_{c.m.}$ was increased further, $\Delta u/u_{c.m.}$ was decreased. This phenomenon was considered to be due to changes in the characteristic mode shapes of each story which were caused by the damage of shear walls.

Fig.14 shows the change of characteristic mode shape which was caused by the damage of shear walls if the walls yielded in order of low stiffness wall, high stiffness wall, and orthogonal wall (Pattern1).

First, when the low stiffness walls yield, spring radius is decreased. So twist component of the mode shape is increased. Next, when the high stiffness walls yield, spring radius is increased. So twist component of the mode shape is decreased. Finally, when the orthogonal walls yield, spring radius returns to the initial state. So twist component of the mode shape returns to the initial state too.

Fig.16 shows the change of characteristic mode shape which was caused by the damage of shear walls if the walls yielded in order of low stiffness wall, orthogonal wall and high stiffness wall (Pattern2). As well, in this study, all yield patterns was (Pattern1). Then changes in the value of the characteristic mode shape and $\Delta u/u_{c.m.}$ were similar. In other words, the impact of the change of characteristic mode shape on the torsional behaviour of house with eccentricity is great.

Abstract: Since so far there is no design standard or published method that can be used to analytically evaluate the capacity of timber framed masonry buildings, an experimental study was developed having the objective to assess the mechanical behaviour of these structures.
Assessment of timber framed masonry structure's behaviour when subjected to lateral forces also involves the evaluation of each component material's contribution. The complexity of structure is given by the masonry panels and the interaction between masonry and timber frame.
The present paper presents the results of the experimental campaign developed on both component materials (first part) and timber framed masonry panels (second part). Based on the first part an evaluation of the timber framed masonry wall was made according to Japanese and Romanian design standard and was compared with the results obtained in the second part.

1. INTRODUCTION

Timber framed masonry buildings represent a special type of structure that can be found in both countries with and without seismicity. In some countries they are special for their beautiful architecture and in others for their seismic resistance, too. The structural system that consists in timber beams and columns, filled with masonry may be left visible (Figure 1) for aesthetical reasons or covered with finishing (Figure 2).

Figure 1 Timber framed masonry house in Romania

Figure 2 Timber framed masonry house in Portugal

They are spread in Europe, but they also exist in Haiti, India, and other countries in the world. For some of these countries they represent valuable heritage, but even though, the studies about them are quite scarce. The seismic design codes do not provide information on how to evaluate the behaviour of these structures when subjected to lateral loads.

2. OBJECTIVE OF STUDY

Giving these buildings' heritage value, within the Center of Urban Earthquake Engineering of Tokyo Institute of Technology, a research project was developed having as objective the efficiency analysis of a retrofitting method, using aramid fiber sheets in different layouts for timber framed masonry panels. This strengthening method aims to increase the strength, stiffness and ductility of the compound. One of the main advantages of this solution is that the intervention is low invasive, this being an important issue when retrofitting heritage buildings.

Nevertheless, in order to evaluate the retrofitting solution's efficiency, first the evaluation of non-retrofitted structure is needed. For this reason, the present paper aims to analytically evaluate the strength and the stiffness of timber framed masonry panels, and compare the results with the ones from the experimental study. Both European and Japanese design standards are used. The evaluation is especially difficult, as there is no dedicated evaluation method for this structural system. The component parts (timber, masonry) are evaluated separately.

3. DESCRIPTION OF THE STUDIED TIMBER FRAMED MASONRY PANEL

For reasons of space, capacity and economy, only a part of the structure has been chosen to be studied, namely a representative part of the wall (the frontais), taken as a reference structure the Portuguese pombaline building.

The pombaline (pombalino) building is a structure no more than four storeys high, with arcades at ground floor

level and with wood framed masonry walls (frontais) which, together with the floors' timber beams, form a cage (gaiola) (Figure 4, a) and constitute the resistant structure. They were named after the Marquis of Pombal, the man who ordered their construction after the 1755 earthquake that destroyed Lisbon, because he wanted buildings to have a seismic resistant structure (Dutu et al., 2012).

The pombaline buildings have a unique structure: external structural masonry walls; internal timber-masonry structural walls (Figure 3), and internal dividing walls.

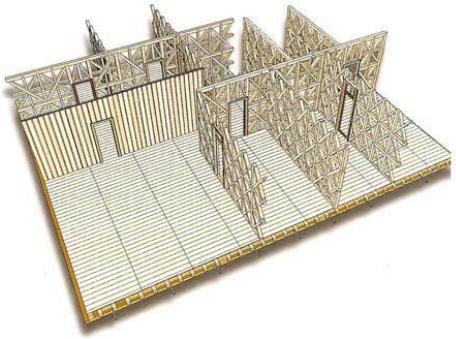

Figure 3 Pombaline building internal structural wall (Appleton J., 2003)

The specimens were chosen to have the layout in the Figure 4, without the diagonals, due to the difficulty to execute the masonry infill. Moreover, the layout without masonry it is used in other countries' timber framed masonry buildings, and the study is thought to be even more valuable, as it concerns more countries. The connections between the timber elements are cross-halving type, reinforced with screw nails.

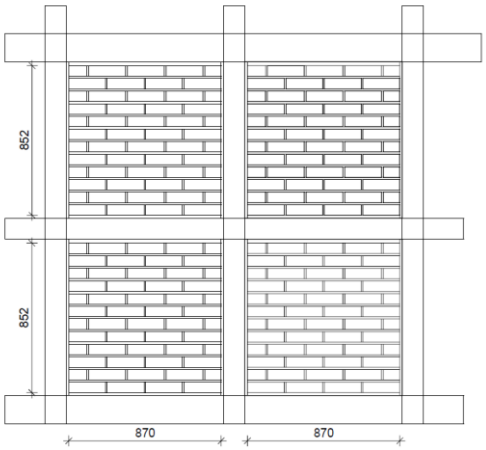

Figure 4 Timber framed masonry wall

Thus, the system is composed of the timber frame and the masonry panels, and considering the philosophy of the capacity design described by Paulay and Priestley as a chain that is as strong as its weakest link, the panels is assumed to be as strong as the shear strength of masonry or the compressive strength perpendicular to the grain of timber. So, if the masonry panels are strong, the timber may be locally crushed by compression or, if the masonry is weaker than the timber, it may present shear failure, but the timber frame would still be able to carry lateral loads, until the failure of one of its elements or joints.

The principle of this system is to have weak masonry, to fail before the timber frame, and thus, to dissipate energy through sliding of the bricks in the joints, where mortar has first failed.

4. MATERIALS TESTS

4.1 Masonry prisms

The complexity of the system is given mainly by the masonry's behavior, which is difficult to evaluate considering the fact that it consists of two different materials, mortar and bricks. Even the simple compression tests on masonry prisms showed a different behavior for each specimen, i. e. first crack occurred at the bottom or at the top brick, depending on the specimen. The elasticity modulus was also difficult to evaluate, because the results are very different between them. However, the values were calculated similar to concrete, as the 1/3 of the ratio between the maximum strength, σ, and its corresponding strain, ε (Table 1).

Table 1 Values of elasticity modulus for masonry, determined through compressive strength test on masonry prisms

No. of specimen	Young's modulus [GPa]	Compressive strength [MPa]
1	0,88	13,2
2	0,99	12,16
3	2,54	10,9
4	2,69	24,95
5	1,02	15,57
6	3,97	12,14
Average	2,01	14,82

The deformation was measured with 4 pi displacement transducers as shown in Figure 5, the total strain value being the average of the 4 values divided to the gage length.

Figure 5 Test setup of masonry prism for strain measuring

4.2 Mortar

The mortar recipe is according to Portuguese timber framed masonry buildings, 1:2:6 (cement:lime:sand). The water/(cement+lime) ratio is 1.75/2.

Uniaxial compressive and split tests were performed on mortar specimens with 50 mm diameter and 100 mm height, according to Japanese standard (JIS). Test results are shown in Table 2, respectively Table 3.

Table 2. Mortar properties after compressive tests

No. of specimen	Failure force [kN]	Strength [MPa]
1	9,2	6,87
2	11.58	8,65
3	8,77	6,55
4	0,832	6,22
5 (1st wallet)	18,8	14,05
6 (2nd wallet)	10,83	8,09
7 (3rd wallet)	7,23	5,4
8 (1st wallet)	13,16	9,83
Average		**8,21**

Table 3. Mortar properties after split tests

No. of specimen	Failure force [kN]	Tension strength [MPa]
1	5,2	0,69
2	6,28	0,84
3	5,47	0,73
4	7,77	1,04
Average	**6,18**	**0,82**

Mortar in timber framed masonry buildings is meant to be weak, as through its cracking before the bricks, bricks slide in the joints, thus more energy is dissipated.

To be mentioned that for compression tests on mortar, the 5 to 8 specimens were tested at 66, respectively 63 days after executing them and they were taken from the mortar used to build the diagonal compression test specimens, that will be discussed later in this paper.

4.3 Bricks

Compressive tests were also conducted on bricks, and the tests results are presented in Table 4. In Japan three types of burned clay bricks can be found, and according to their compressive strength given by the producer they are: 14,71, 19,61, and respectively, 29,42 MPa. Two types were selected to be tested, the 14,71 and 29,42 MPa.

For economical reasons the 29,42 MPa brick type was selected for further experimental studies.

Table 4. Compressive tests on two types of bricks

No. of specimen	Type [MPa]	Compressive strength [MPa]	Average strength [MPa]
1	14,71	38,4	41,26
2		36,8	
3		42,8	
4		42,4	
5		41,2	
6		46,0	
7	29,42	36	44,95
8		70,1	
9		38,9	
10		34,8	

4.4 Masonry wallets

Diagonal compression tests on unreinforced masonry specimens were also performed. Such "indirect" tests were preferred over "direct" shear-compression tests because of their limited cost and duration of setup preparation, and ability to provide valuable estimates of mechanical properties used in analytical models (Calvi G.M., 1996).

The diagonal compression test is the standard method in some international codes such as FEMA 356. In this paper, the results of the tests are considered according to ASTM E 519-07. This research test method is used for the purpose of evaluating the effects of variables such as type of masonry unit, mortar and workmanship, thus a smaller specimen was used. The dimensions of the specimens were chosen according to the tests conducted on timber framed masonry panels, namely to the masonry panels within the frame (Figure 4).

Thus, masonry specimens with 100x870x852 mm in size were tested. The masonry was made of burned clay bricks with dimensions 100x60x210 mm and mortar joints with 12 mm thickness (Figure 6). Diagonal compression tests were carried out on 3 specimens, built with the same characteristics.

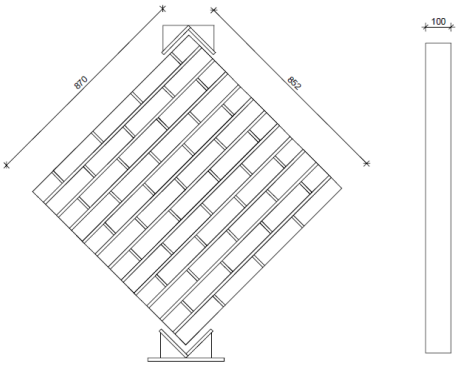

Figure 6 Dimensions of specimens

Two of the specimens suffered shear sliding involving both bed and head joints in a stepwise way (Figure 7 and Figure 9). Bed joint sliding typically produces higher energy dissipation. Specimen 2 suffered a diagonal cracking

involving both mortar joints and masonry units (Figure 8).

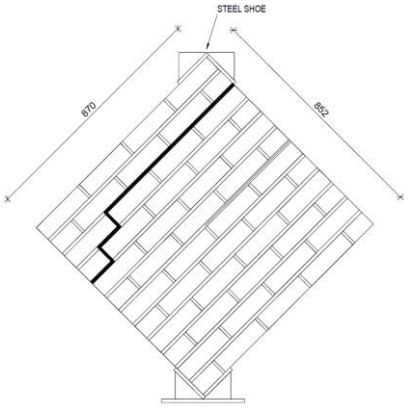

Figure 7 Specimen 1 (M1) failure mode

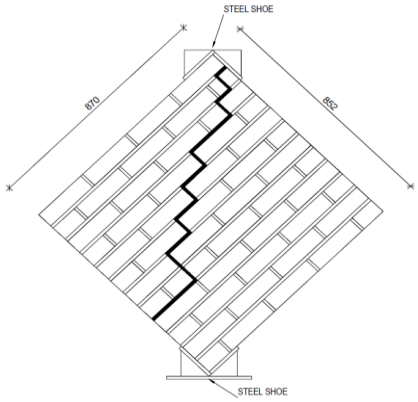

Figure 8 Specimen 2 (M2) failure mode

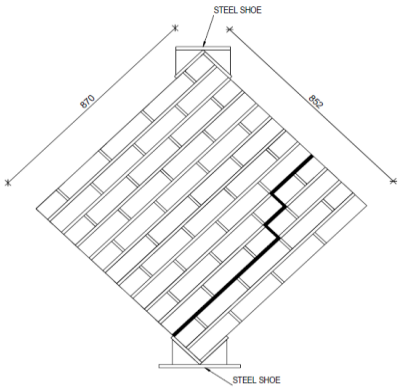

Figure 9 Specimen 3 (M3) failure mode

In ASTM E 519-07, a shear stress state at zero confining is assumed at the centre of the specimen, resulting in a shear stress equal to both tensile and compressive principal stresses. Diagonal cracking is then assumed to be caused by the attainment of masonry tensile strength f_t, which is equal to shear strength at zero confining stress τ_0. Based on displacement readings on both specimen sides, axial strains along a single direction were derived as average displacement readings divided by the gage length. The test setup is shown in Figure 10.

Figure 10 Position of displacement transducers

The stress – strain curves are shown in Figure 11 and Figure 12. The stress was calculated as the force divided by the cross sectional area.

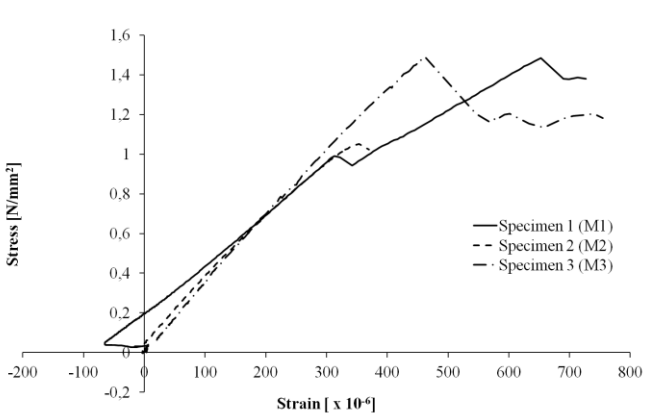

Figure 11 Stress – strain curves for compression

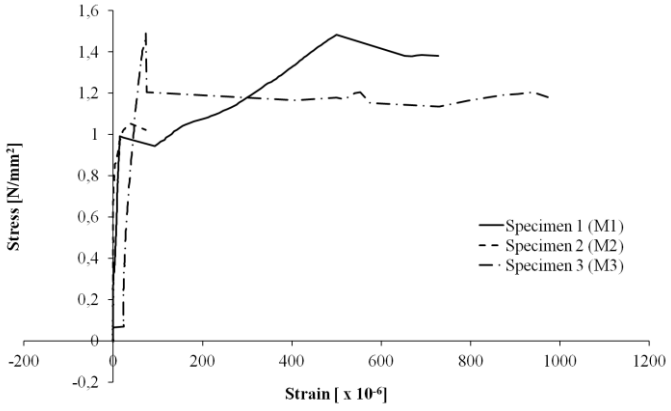

Figure 12 Stress – strain curves for tension

It can be seen that the specimens which failed through joint sliding showed higher shear strength than the one that failed through diagonal cracking.

As mentioned before, for timber framed masonry structures, mortar is weak, this being the principle of this

structural type. So the failure should occur due to mortar cracking in the joints and thus causing bricks to slide, as the assumed behaviour of the panel within the studied structure type. It can be observed that for specimens 1 and 3, the failure mode was similar to the assumed one.

Relevant parameters are shown in Table 5 where: P is the failure force; A_n is the area calculated according to ASTM E 519-07, meaning the cross-sectional area of the panel; σ_o is the shear stress; γ is the shear strain; ν is the Poisson's ratio; G is the shear modulus; and μ is the shear strain ductility as $\mu = \gamma_u / \gamma_{max,}$ were γ_u is the shear strain corresponding to the ultimate stress and γ_{max} is the shear strain corresponding to the maximum stress.

Table 5. Parameters determined according to ASTM E 519-07

Sp	P [kN]	A_n [mm^2]	σ_0 [N/mm^2]	$\gamma_{1/3}$ [x10^{-6}]	ν	$G_{1/3}$ [N/mm^2]	μ
1	129	86100	1,05	72	0,76	4896	1,11
2	91		0,75	60	0,11	416	1,05
3	128		1,05	124	0,15	2812	1,63
Av	116		0,95	85,3	0,33	2708	1,26

5. EVALUATION OF MASONRY PANEL

According to the P100-3:2008, the Romanian seismic design code for evaluation of existing buildings, the shear force associated to failure due to eccentric compression of an unreinforced masonry wall subjected to the design axial force, N_d, is calculated with:

$$V_{f1} = \frac{N_d}{c_p \lambda_p}(1 - 1{,}15\upsilon_d) \quad (1)$$

Where:

$\lambda_p = \frac{H_p}{l_w}$ is the shape factor of masonry

H_p = the height of the wall

l_w = length of the wall

c_p = coefficient depending on the support conditions of the wall (we consider $c_p = 1$, as being fixed on all edges)

$\sigma_0 = \frac{N_d}{t l_w}$ the medium compressive unit effort corresponding to the design axial force

t = width of the wall

$$\upsilon_d = \frac{\sigma_0}{f_d} \quad (2)$$

f_d = design compressive strength, determined from experimental testing on bricks = 3,51N/mm^2

The capacity of the unreinforced masonry wall in shear is given by

$$V_{f2} = \min(V_{f21}, V_{f22}) \quad (3)$$

The shear capacity according to the sliding shear mechanism:

$$V_{f21} = f_{vd} D' t \quad (4)$$

Where:

D' = the length of the compressed area in the wall

f_{vd} = design mortar joint slippage strength,

$$f_{vd} = \frac{f_{vm}}{\gamma_M CF} \quad (5)$$

$$f_{vm} = 1{,}3 f_{vk} \quad (6)$$

$$f_{vk} = f_{vk0} + 0{,}4\,\sigma_d \text{ (Eurocode 6)} \quad (7)$$

Where:

f_{vm} = shear strength of joint slippage mechanism

f_{vk} = characteristic failure strength

f_{vk0} = 0,2 N/mm^2 (according to CR6:2006)

The shear capacity according to the diagonal tension crack mechanism:

$$V_{f22} = \frac{t l_w f_{td}}{b}\sqrt{1 + \frac{\sigma_0}{f_{td}}} \quad (8)$$

b = coefficient having values $1{,}0 \le b = \lambda_p \le 1{,}5$

f_{td} = design tensile strength of masonry.

Thus, for the studied masonry panel, failure occurs due to flexure, as:

$$V_{f1} = 23{,}92 < V_{f21} = \mathbf{24{,}61\ kN,}$$

but since the tests aimed to simulate a pure shear stress state, only two failure type were considered, diagonal tension crack and sliding shear. Thus, the tests showed two shear sliding mechanisms involving both bed and head joints in a stepwise way, and the other one diagonal cracking involving both mortar joints and masonry units, as expected.

The evaluated shear strength according to the diagonal tension crack mechanism was:

$$V_{f22} = \mathbf{38{,}88\ kN}$$

The results interpretation according to (Tomazevic, 2000) and (Sheppard P., 1980) showed:

$$\sigma_0 = 0{,}83\frac{P}{A} = 1{,}10 \text{ N/mm}^2 \quad (9)$$

$$\tau_0 = \frac{\sigma_0}{0{,}98} = 0{,}84\frac{P}{A} = 1{,}12 \text{ N/mm}^2 \quad (10)$$

$$\sigma_t = -\frac{\sigma_0}{2} + \sqrt{\left(\frac{\sigma_0}{2}\right)^2 + (b\tau)^2} = 0{,}67 \text{ N/mm}^2 \quad (11)$$

$$H_{s,w} = A_w \cdot \tau = A_w \frac{\sigma_t}{b}\sqrt{\frac{\sigma_0}{\sigma_t} + 1} = \mathbf{96{,}67\ kN} \quad (12)$$

Where σ_0 is the axial compressive strength of masonry, τ_0 is the shear strength of masonry, the aspect ratio is h/d=0,98, σ_t the tensile strength of the specimen, τ is the shear strength of the specimen and $H_{s,w}$ is the lateral resistance of the plane masonry specimen.

The values above were calculated with the medium P, the force measured by the load cell of the testing machine when the failure occurred.

6. EVALUATION OF THE TIMBER FRAME

To evaluate the shear strength of the timber frame, the timber design standard issued by the Japan Housing and Wood Technology Center was used.

Thus,

$$P_a = \min(P_y, P_{150}) \quad (13)$$

$$P_{150} = K\left(\frac{1}{150} - \frac{R_0}{4}\right) \quad (14)$$

$$R_0 = \{\psi(\gamma_A - \gamma_B) + \frac{\mu}{b} \quad (15)$$

R_0 is considered 0,0095 as in the example given in the standard.

$$P_y = \frac{u \cdot v \cdot \Delta M_y}{H} \quad (16)$$

With

$$\Delta M_y = \frac{21 \cdot b^2 \cdot h \cdot F_{cv}}{55 \cdot \sqrt{1+\frac{8b}{3nh}}} \quad (17)$$

Stiffness of timber frame is calculated with the following equation:

$$k = \frac{1}{\frac{1}{K_f}+\frac{1}{K_j}+\frac{R_0}{P_y}} \quad (18)$$

$$K_f = \frac{12EI \cdot u^2 \cdot v^2}{H(uL+vH)} \quad (19)$$

$$K_j = \frac{u \cdot v \cdot k_R}{H} \quad (20)$$

$$k_R = \frac{7}{400} b^2 hE \quad (21)$$

$$I = \frac{\frac{h}{2} b^3}{12} \quad (22)$$

Where:

P_a = timber frame design shear strength

P_y = yielding strength

P_{150} = corresponding shear strength at 1/150 rad displacement

u = the number of horizontal timber elements

v = the number of vertical timber elements

ΔM_y = rotational moment of the timber elements' joint

H = the wall's height

K = the wall's stiffness

R_0 = initial deformation angle determined by initial slippage

F_{cv} = the local perpendicular to the grain compression strength of timber element having surrounding elements

h = element's cross section height

b = element's cross section width

n = coefficient taking into account compression of surrounding elements (we have considered as being 5, corresponding to the wood type)

E = Young's modulus perpendicular to the grain

I = inertial moment

L = the length of the wall

K_R = rotational stiffness of one joint

Ψ = the shrink ratio of dried wood

γ_a = moisture content of timber at the moment of building the wall

γ_b = moisture content of timber after the timber is dried

μ = working coefficient (when cut with machine or manual).

Considering F_{cv} = 0,78 kN/cm^2 according to (AIJ, Standard for structural design of timber structures, 2006) and Young's modulus of timber according to the data given by the company that provided the timber, the equations 13 to 22 are applied for the present study.

The number of horizontal, respectively, vertical elements is considered u=v=3.

The results are shown in Table 6.

Table 6. Analytical evaluation of timber frame

Case	K_f [kN/rad]	K_j [kN/rad]	K [kN/rad]	P_y [kN]	P_{150} [kN]
u=v=3	2878,93	1125,95	556,30	16,90	2,38

7. QUASI-STATIC CYCLIC TESTING ON TIMBER FRAMED MASONRY PANEL

For the cyclic test the deformation controlled CUREE-Caltech standard (CUREE) protocol was used (Figure 13). It was specifically developed for woodframe shearwall testing and is based on the hysteretic response of woodframe structures (Gatto K., 2003). The ASTM E 2126-02a standard includes the CUREE protocol as one of the loading options (Krawinkler H., 2009).

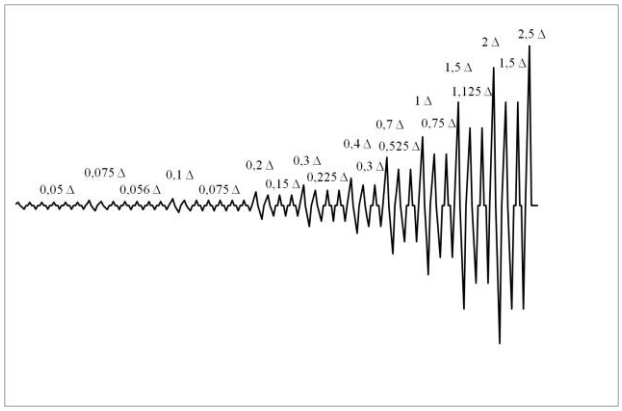

Figure 13 CUREE loading protocol

As the input deformation the shear angle, δ, was used to cancel the rocking and thus to observe the pure shear capacity of the wall, being calculated with the following equation:

$$\delta = \frac{D_1+D_2}{2} - \frac{D_3+D_4}{2} \quad (23)$$

Where D_1, D_2, D_3, D_4 are the measured displacements, as in Figure 14.

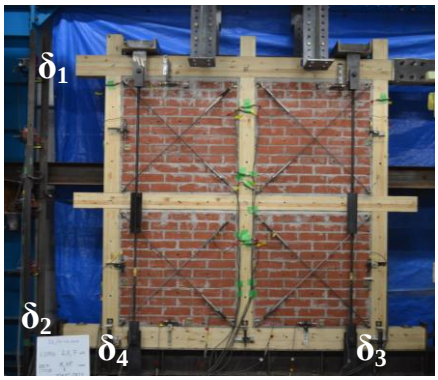

Figure 14 Parameters used to calculate δ

The hysteretic behaviour of the timber framed masonry panel (S2) is represented in terms of lateral force and lateral displacement at the top of the specimen with respect to the

height (drift) and shows an important stiffness and ductility of the system (Figure 15). The failure occurred at 5,3% drift, due to tension in the upper horizontal beam and in the same time shear in the right column (Figure 16).

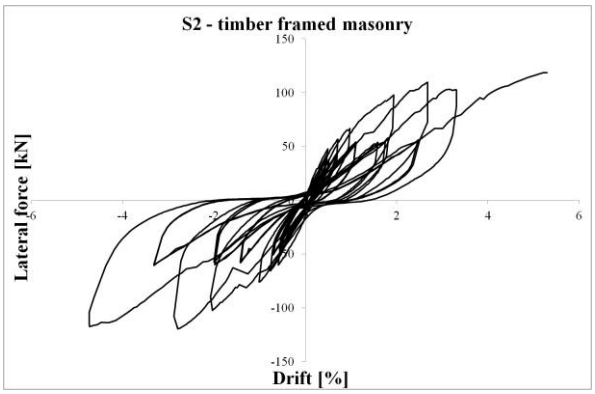

Figure 15. Lateral force – drift diagram of S2

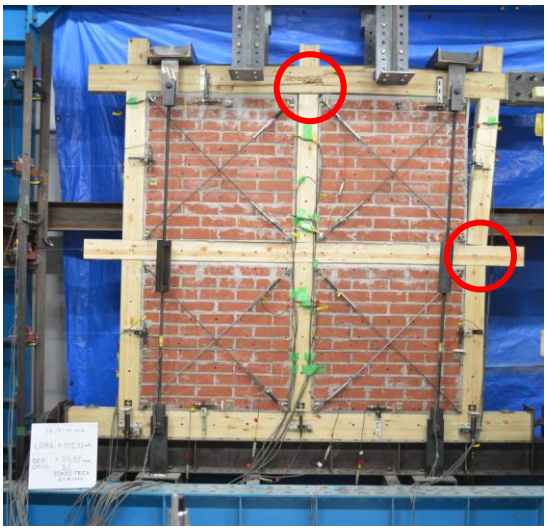

Figure 16. Failure mode of S2

Stiffness decreased direct proportional with each cycle and being strongly influenced by the reversed cycle degradation (Figure 17).

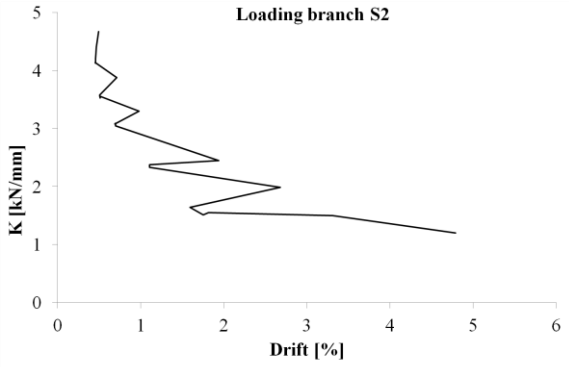

Figure 17. Stiffness degradation on the loading branch for S2

Masonry panels separated from the timber frames since first cycle.

Although the masonry failed at 1,93 % drift, at 97 kN lateral force, the masonry panels continued to ensure the system's stiffness and to dissipate energy until the timber frame's failure. The cracks of the masonry panels started appearing from the bottom and continued, with every new cycle, layer after layer, towards the top.

The upper masonry panels did not show any cracks, but near to the failure, at 4,7 %drift, the left one showed out of plane behaviour.

The middle timber joint showed important damages from 0,7 % drift and was strongly subjected to shear force, resulting in compression perpendicular to the grain of timber elements, by the masonry.

8. QUASI-STATIC CYCLIC TESTING ON TIMBER FRAME

The timber frame specimen (S1) was tested using the same loading protocol (CUREE) and the same values of the shear angle as input deformation.

The dimensions of the specimen were identical with the ones of the frame within S2 and the purpose of this test was to observe the contribution of the masonry infill.

The hysteretic behaviour (Figure 18) shows a reduced stiffness, a high ductility and important slippage in the timber connections.

The rotation angle in the connections was similar to the shear angle, this meaning that the connections are very flexible and not allowing the timber elements to bend.

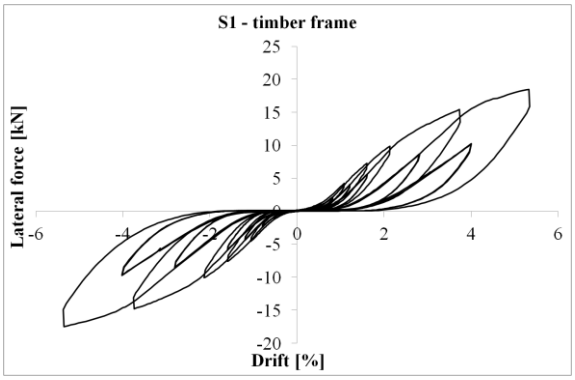

Figure 18. Lateral force – drift diagram of S1

After 5,33% drift, due to reaching the maximum stroke of the jack used to introduce the lateral force, a monotonic loading was performed until 9,4% drift.

The specimen did not show a failure mode, but the upper timber beam cracked starting from the middle connection (Figure 19).

Figure 19 Deformation of S1 at 9,4 % drift

The stiffness increased with every cycle until 2,14 % drift (Figure 20).

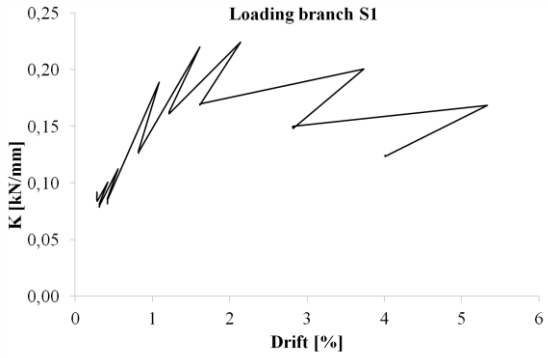

Figure 20 Stiffness degradation on the loading branch for S1

9. DISCUSSION

Comparison of S1 with S2 shows that the masonry infill has very important influence, as it determines the strength of the system.

Basically for S2, the observed principle of the system is that the masonry carries, besides the vertical forces, also lateral forces even if it presents important cracks. Considering the ratio between the ultimate displacement and the yielding displacement, a ductility factor 2,03 was determined.

Since in S1 no significant bending of the timber elements was observed, for S2 the bending was very clear for all the timber elements, except the bottom beam.

In terms of energy dissipation, S2 shows a significant higher total value, 37,69 kNm, than in case of S1, that showed a total value of 2,94 kNm. The energy dissipation, ΔW, was calculated as the area of the hysteretic curve for each specimen. In Figure 21 is shown the energy dissipation of S1 and S2 in every cycle, highlighting the initial ones.

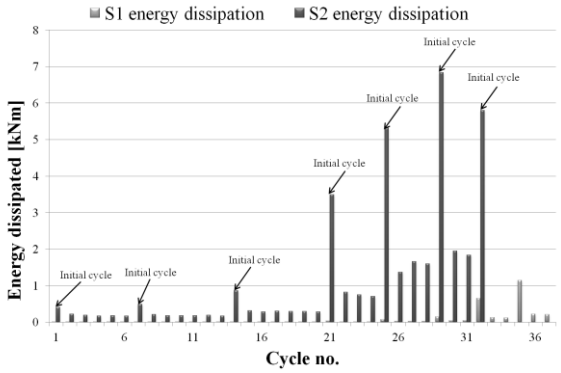

Figure 21 Energy dissipation of S1 and S2

Equivalent damping ratio h_e of system was also calculated using the formula:

$$h_e = \frac{1}{4\pi} \cdot \frac{\Delta W}{W} \quad (24)$$

Where ΔW is the total dissipated energy by the specimen under cyclic loading and W is the energy dissipated in the cycle corresponding to peak value of the force, for all cycles. The values are presented in Table 7.

Table 7. Equivalent damping ratios of all specimens according to each considered loading cycle

Cycle no.	h_e S1 [%]	h_e S2 [%]	Cycle no.	h_e S1 [%]	h_e S2 [%]
1	0,005	0,546	**20**	0,009	0,374
2	0,004	0,299	**21**	0,110	4,722
3	0,004	0,249	**22**	0,038	1,112
4	0,004	0,231	**23**	0,036	1,006
5	0,004	0,234	**24**	0,035	0,958
6	0,004	0,227	**25**	0,287	7,181
7	0,010	0,660	**26**	0,086	1,849
8	0,005	0,277	**27**	0,083	2,239
9	0,005	0,246	**28**	0,081	2,156
10	0,005	0,244	**29**	0,544	9,239
11	0,005	0,243	**30**	0,155	2,639
12	0,005	0,249	**31**	0,149	2,482
13	0,005	0,233	**32**	2,426	7,828
14	0,018	1,157	**33**	0,468	
15	0,009	0,428	**34**	0,437	
16	0,009	0,383	**35**	4,214	
17	0,009	0,406	**36**	0,833	
18	0,008	0,397	**37**	0,764	
19	0,009	0,388			

Thus, the masonry infill also produces a significant increase in damping of the timber framed masonry system.

The behavior of masonry wallets in diagonal compression tests were further compared with the behavior of masonry panels within S2 subjected to cycling loading.

Within the cyclic test it was observed that at 1, 93% drift, corresponding to a value of 97 kN for the lateral force, the bottom right masonry panel failed first due to bed joint sliding. This failure mode was also seen as predominant in the diagonal compression tests.

Moreover, according to the diagonal compression test results interpretation using (Tomazevic, 2000) and (Sheppard P., 1980) equations, the lateral resistance of the plane masonry specimen was 96,67 kN, similar to the observed failure in S2.

In Figure 22 the results of both types of tests are compared in terms of compression stress – strain relationship, highlighting the corresponding stress value for the 97 kN lateral force.

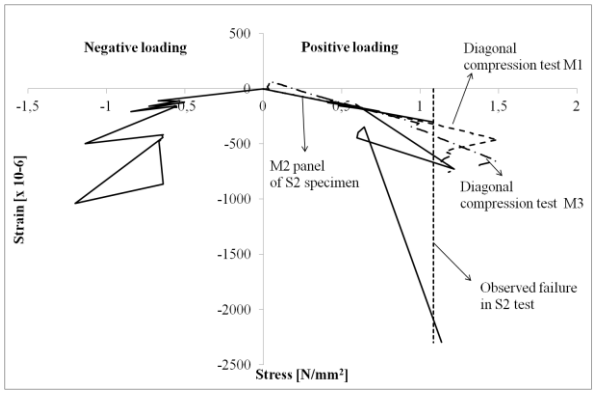

Figure 22 Comparison of Compression Stress – Strain diagrams of S2 and masonry wallets M1 and M3

Comparison of timber frame analytical evaluation with experimental results is shown in Figure 23 in terms of lateral force – lateral displacement at the top of the specimen with respect to the height (drift).

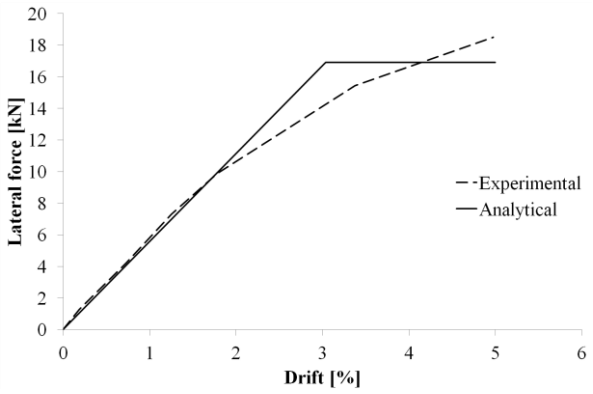

Figure 23 Comparison of analytical evaluation with experimental results for S1

The results are very similar in terms of stiffness.

However, the yielding point is difficult to be precisely determined in timber walls, where the behaviour is determined by local compression.

10. CONCLUSIONS

Present experimental study confirms the good in plane behaviour of the timber framed masonry system. It showed a significant deformation capacity and important stiffness and strength.

It is clear that the masonry infill determines the strength and stiffness of the system, while the timber frame is responsible for the high ductility.

The main purpose of the materials and diagonal compression tests was to evaluate the capacity of the masonry panel within the timber framed masonry walls, even though the boundary conditions are not the same as the actual situation, and compare the results with the ones from timber framed masonry panel test.

In timber framed masonry structures, mortar is weak, this being the principle of this structural type. So the failure of the masonry infill occurs due to mortar cracking in the joints and thus causing bricks to slide. The results of the tests confirmed this principle, the predominant failure mode in diagonal compression was bed joint sliding and the cyclic test on timber framed masonry panel also presented this type of failure of the masonry panels.

Comparing the analytical evaluation results for masonry, according to P100-3:2008 with the (Tomazevic, 2000) and (Sheppard P., 1980) equations, the latter value is almost four times higher.

Also, when further comparing the diagonal compression tests with the masonry panels within S2, it was observed that at 1, 93% drift, corresponding to a value of 97 kN for the lateral force, the bottom right masonry panel failed first due to bed joint sliding. Thus, besides confirming the failure mode shown in previous tests, it also confirmed that the use of (Tomazevic, 2000) and (Sheppard P., 1980) equations was appropriate.

The purpose of the timber frame test was to observe the contribution of the masonry infill in terms of stiffness, but it was difficult to also compare in other terms the behaviour of the two specimens as, the presence of masonry completely changes the stress state in the timber frame.

The timber frame test showed very similar results with the analytical evaluation, this indicating that the equations given in the timber design standard are also appropriate for this case.

Although the overall behaviour of timber framed masonry panel studied was good for in plane forces, the out-of-plane behaviour still needs to be considered, as even when subjected to in plane forces, the upper right masonry panel showed out of plane displacement.

The timber framed masonry structure's behaviour described in this paper corresponds to the specimen made with new materials, i.e. new timber, new bricks and new screw nails. All these materials may have higher strength than the ones used in the real situation, thus future research will also focus on retrofitting solutions to avoid out of plane behaviour and to increase capacity of timber framed masonry structures when subjected to strong motions.

Abstract: A post-earthquake investigation team observed a large building stock still standing but listed for demolition in the city of Van, eastern Turkey, half a year after two strong earthquakes hit the region in 2011. The focus point of this investigation was to observe structural and non-structural damage for several engineered reinforced concrete or masonry buildings and to apply and compare Turkish and Romanian procedures for post-earthquake investigation and seismic evaluation. This paper presents the observed damage and the seismic evaluation for a relatively new multi-storey residential building and the comparison between the damage observed and analytic damage state. The structural system of the building consists of RC frames and shear walls. The non-structural infill partitions made out of hollow bricks sustained severe damage. At the time of the inspection the building was evacuated and listed for demolition. A detailed structural analysis was carried out to understand the seismic response and the observed damage state. The results of the seismic investigation are presented in this paper together with some comments about the effectiveness of the post-earthquake quick inspection methods. The post-earthquake investigation team has been dispatched to Van with the support of the UNESCO - IPRED Platform.

1. INTRODUCTION

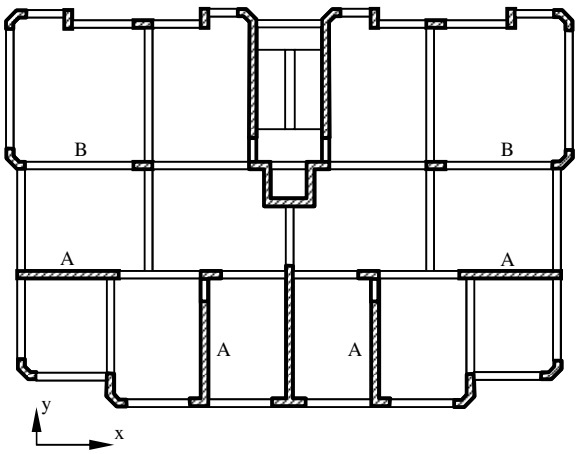
In June 2012 an investigation mission was dispatched to the city of Van strongly affected by two earthquakes in the fall of 2011, Van-Ercis, October 23, 2011, Mw=7.1 and Van-Edremit, November 09, 2011, Mw=5.6 (METU/EERC, 2011). The epicentral distances from Van downtown are 40km and 10km, respectively. Academic staff and professional engineers from Turkey and Romania participated in this mission organized with the support of the UNESCO IPRED Platform.

More than 30000 buildings were heavily damaged or collapsed after the earthquakes (EERI, 2012). A large part of the vulnerable building stock in Van consists of multistory (5-8 story) reinforced concrete frame or shear wall structures with brittle masonry infill partition walls. At the time of the mission the debris of the collapsed buildings were removed from the city. Many evacuated buildings listed for demolition still standing were observed. Most of these buildings sustained severe structural and nonstructural damage. For many buildings the nonstructural damage of exterior masonry walls was obvious from the outside.

Two identical RC residential buildings (A and B) with seven stories were investigated. This paper refers to the most damaged one, i.e. building B (Figure 1). Both buildings were designed and built in 2005. The structural system consists of cast in place reinforced concrete shear walls and frames (Figure 2). In the transversal direction the lateral resisting structure consists mainly of shear walls. Five shear walls were identified. In the longitudinal direction only two shear walls were identified so the RC frames represent an important part of the lateral resisting structure.

The structural system presents vertical regularity. No sudden changes in stiffness or strength of the structural elements occur over the building height. The transversal sections of shear walls, columns and beams are similar at each floor.

The shear walls location within the structure suggest that the building is likely to experience a strong torsional response. In the transversal direction the lever arm of the forces in shear walls to resists the building torsional moment is a merely 7,60m. In the longitudinal direction the existing shear walls are collinear so no lever arm of the shear forces in the RC walls can be considered for the torsional strength and stiffness. This particular layout of the shear walls is determined by the architectural constraints. The building has relatively large windows on each facade regularly placed in each bay and at each storey. No full masonry infills are placed in the outer frames.



The RC frames consist of rather stiff beams with height of 60cm and widths of 25 or 30cm. Most of the columns have rectangular sections of 30x60cm or 30x80cm usually aligned with the *x-x* axis of the building (longitudinal) to compensate for the reduced number of shear walls.

Relatively stiff frames were obtained in this direction. Most of the beams intersection points correspond to a column or wall end. Only two transversal beams are supported at one end by two longitudinal beams. Outer frames present beam offsets of 50...150cm from one bay to another. This unfavorable layout of the beams is caused by architectural constraints regarding the aspects of the facades. These beams are supported on thin columns that connect the beams end. The effectiveness of such layout upon the strength and stiffness of the outer frame is questionable.

A 12cm continuous slab is supported by the beams. Given the layout of the slab a rigid diaphragm assumption can be made. For many of the multistory RC buildings built in recent years in Van, infill joist system was used for the floor structural system. This resulted in shallow beams of 30-35cm not suitable for earthquake resisting frames.

Figure 1 Main façade of building B

A: Shear walls introduced during construction B: Original position of the shear walls in *x-x* direction

Figure 2 General layout of the structural system

The foundation system consists of foundation beams that connect the shear walls and columns under the basement. The basement is used also for apartments so windows are placed on the perimeter just above the ground level. No change in the vertical structural system was noticed at this level. Given the relatively weak foundation beams in comparison with the supported shear walls, uplift and even plastic hinging of the foundation beams might be expected.

Important changes in the layout of the shear walls as in blueprints of the building were observed. Shear walls in the longitudinal (*x-x*) direction were moved from one axis to another. Their web length was reduced from 6.55m to 4.55 while the width was preserved. In the transversal direction two additional shear walls were placed increasing the shear strength in the transversal direction and improving the torsional stiffness of the building as the two walls are located at 7.60m apart from each other.

Reinforcement details for beams and columns as given in the design drawings generally meet the requirements of both Turkish and European seismic codes (TERDC 2007, EN 1998-1). The columns have continuous longitudinal reinforcement from bottom to top with reinforcement ratio of around 1%. The beams have continuous reinforcement at both sides. Longitudinal reinforcement ratios ranging roughly from 0,5% to 1% could be observed.

Closed stirrups with hoops bended at 135º are used; 8mm diameter stirrups spaced at 160m or 180mm are usually provided for beams. Spacing of the stirrups in the critical regions of the beams does not meet the requirements of EN1998-1 for high ductility class.

In some elements, curtailment of the top bars in beams at the limits of the critical regions at beams ends indicates that the plastic hinges might appear closer to the middle of the beam.

At interior supports, anchorage of the bottom reinforcements is not obtained by bending the bar inside the beam-column joint. Instead, the straight bottom bars pass through the interior joints being cut in the plastic regions of the adjacent beam. Otherwise, development length of more than 40 bar diameters were used for the anchorage of the longitudinal rebars.

Masonry infills are built according to the construction practice in the region using hollow clay units. The width of the masonry panels is 30cm for exterior walls and 15cm for interior walls. Double layer masonry panels with thermal insulation in the middle have been used for exterior panels. Usually, no concrete ties were used to confine the masonry near windows or doors or to prevent out of plane failure for the large interior masonry panels. Apparently, no steel anchor ties were provided to connect the panels to the adjacent beams and columns.

2. OBSERVED DAMAGE

The analyzed buildings were inspected by IPRED mission in June 2012. At the time of the inspection both buildings were evacuated and listed for demolition. This

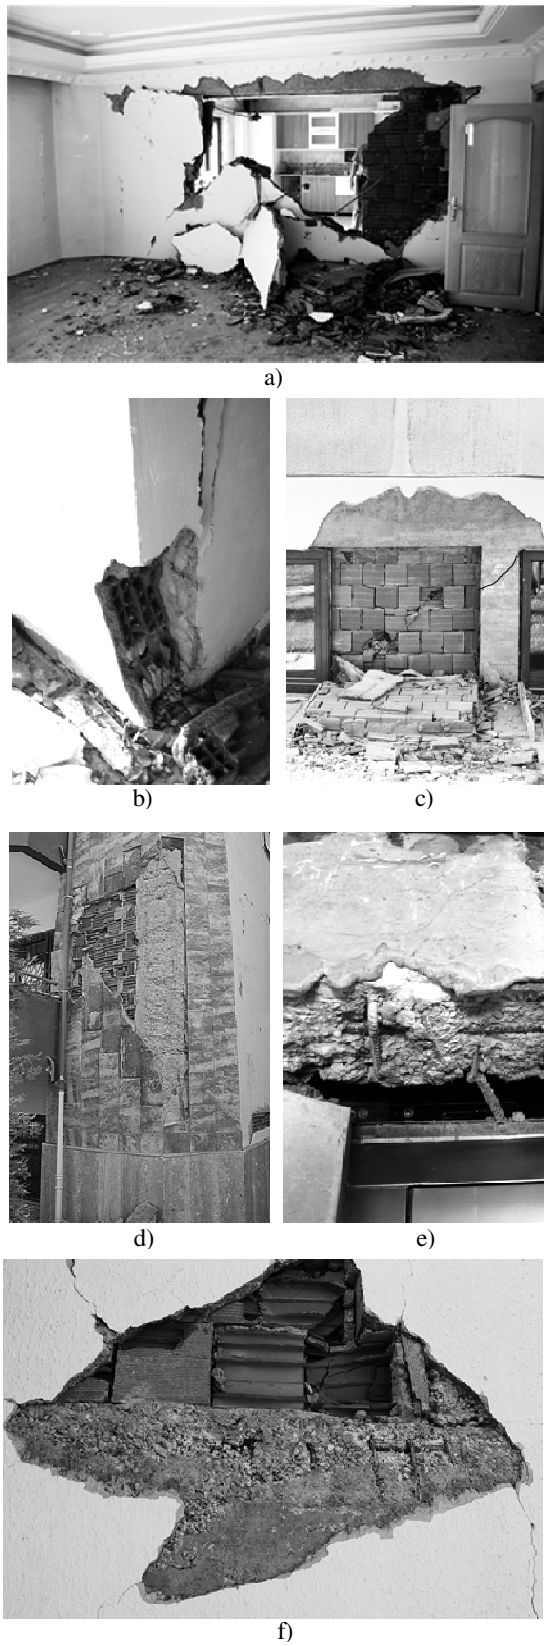
decision was made based on the rapid assessment performed immediately after the earthquakes. According to the owner, the buildings sustained limited damage after the first earthquake (October, 23) and was evacuated. The buildings suffered most of the existing damage during the second earthquake (November, 11).

For building A no major damage could be observed from the outside. Building B sustained more severe damage as reported in the following.

Most of the outer masonry panels and parapets below the windows at the lower stories were damaged. Most of the interior masonry panels at the first three stories sustained severe damage beyond reparability. Replacement of these panels is necessary for future use of the building. Full or partial collapse of some masonry panels parallel to the *x-x* direction at the first floor was observed (Figure 3, a). These masonry infills replaced the RC shear walls that were moved to the adjacent bay.

Damage to the nonstructural masonry panels with no corner bonding can be noticed in Figure 3, b. Two perpendicular panels connected using just polyurethane foam inserted in the vertical separation joint detached from each other with a vertical crack. The panel oriented in the *x-x* direction of the building crashed at the bottom corner.

Overturning of an exterior leaf of a double layer masonry panel can be observed in Figure 3, c. No connectors between the leaves were noticed on the site; In the same figure the shear crack developed in the captive column between the basement windows can be observed.



No major structural damage has been noticed. Shear and flexural cracks occurred in the critical regions of the beams. Inclined shear cracks occurred in beams due to the interaction with the masonry infills as well.

Inclined shear cracks were observed in the columns and shear walls. The largest crack width measured in the shear walls was 0,3mm. Thinner cracks could be observed in the L shaped columns on the building perimeter.

Despite the shallow structural damage the site inspection revealed the low quality of structural concrete. Removal of the finishing layers exposed the members' concrete surfaces (Figure 3, d). In some members even the steel reinforcements were exposed as can be seen in the case of the coupling beam that connect the two wings of the shear walls around the elevator shelf (Figure 3, e). Ready mix concrete for building construction is available in Van area since 5-7 years ago (EERI, 2012). Inspection showed that the construction quality of the RC structure was rather poor. The low concrete quality is further illustrated in Figure 3, f. Improper water/cement ratio, improper combination of gravel sorts, segregation, lack of vibration, and concrete settlements under steel rebars can be noticed.

Samples of the concrete extracted from the columns and shear walls revealed a very low compressive strength of 6-7MPa for B building and 12MPa for A building.

No severe settlement could be observed around the building perimeter or at the basement floor. An uplift of the building of 3cm from the sidewalk level was measured at one corner of the building.

3. STRUCTURAL ANALYSIS

3.1 Analytical model

Structural analysis was performed using ETABS (CSI, 1995). Static nonlinear analysis (pushover) is used to investigate the structural response in the nonlinear range. The main objective of the structural analysis was to determine the lateral yielding force and, consequently, the displacement demand.

A 3D computer model which accounts for the nonlinear response of the structural system is developed. Beams and columns are modeled using frame elements. Shear walls having length of the transversal section smaller than 1,5m (including) are modeled using frame elements. Shear walls having length of the transversal section larger than 1,5m are modeled using shell elements.

Within the boundaries of the columns sections the longitudinal and the transversal beams are considered rigid. If the transversal beam axis, the longitudinal beam axis and the column axis did not intersect in a single point a stiff beam link is considered to model the connection. The equivalent "elastic" stiffness is taken equal to half of the gross stiffness for each structural member.

Foundation beams are supported on springs with homogenous elastic behavior in vertical direction. The translation of the foundations in *x-x* and *y-y* direction is restrained. No other external restraints are applied.

Horizontal rigid diaphragms are considered at each level.

Gravity loads, other than the dead weight of the structure, are applied as uniform load on the slabs at each floor. An equivalent uniform load of 12.8 kN/m^2 is obtained for the entire building.

Nonlinear M3 hinges are introduced at the end of each beam. Nonlinear P-M2-M3 hinges are introduced at the bottom of each column, directly above the foundation beams. Nonlinear P hinges are introduced at the boundary columns of shear walls. Nonlinear P hinges are used to simulate the yielding of the vertical reinforcement in the web of the shear walls, as well (Figure 4).

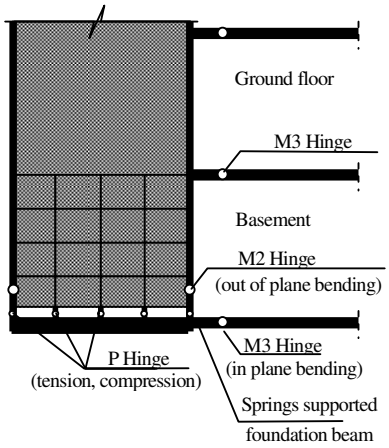

Figure 4: Modeling assumptions

Pushover analysis is performed in both *x-x* and *y-y* direction. Two lateral load distribution patterns are considered for each direction: uniform (mass proportional) and triangular (acceleration proportional).

3.2 Masonry infills

Regarding the contribution of the masonry infills to the lateral strength and stiffness of the building the following comments are made:

- Interior masonry panels are just 15cm thick.
- Double layer masonry panels with a glass wool layer in the middle are used for exterior walls. No connectors could be observed between the masonry layers.
- All masonry panels are made using hollow masonry units. These are multi-cell clay blocks with large rectangular holes, with the holes oriented in the horizontal direction. The vertical interior walls of the bricks have out of plane defects that significantly reduce their strength and stiffness for diagonal stresses in the vertical plane (Figure 5).
- Most of the exterior masonry panels have large openings for windows. Most of the interior infill panels have door openings usually located at one end. The formation of the compression diagonal is prevented as the small lateral drifts are usually accommodated by the door opening.

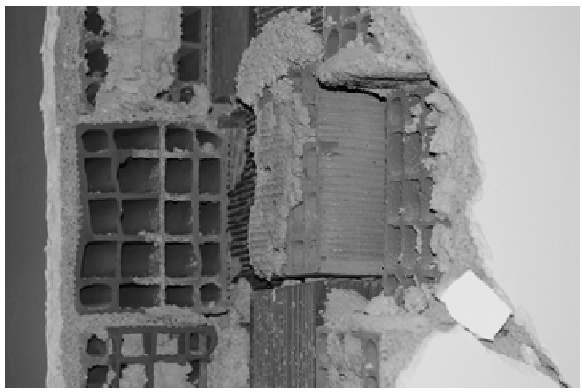

Figure 5: Typical masonry work in the building

All these comments suggest that the contribution of the infill masonry panels upon the lateral strength and stiffness of the building is questionable. As the main objective of the structural analysis was to determine the peak lateral drift demand using the capacity spectrum method, the contribution of the masonry infills is not accounted for directly. A sensitivity study to account for the influence of the masonry infills by changing the lateral stiffness of the structure to the dynamic response of the building is performed using time-history linear analysis. Further studies will be performed to account for this contribution using time-history nonlinear analysis.

3.1 Push-over analysis

The modal analysis of the building revealed a strong torsional response. The modal participating mass ratios are listed in Table 1.

The second and the third vibration modes are considered to determine the seismic demand for the equivalent lateral load method in the Turkish Earthquake Standard (TERDC, 2007). The required lateral seismic coefficient in the longitudinal direction results:

$$C^x = \frac{A(T)}{R} = \frac{A_0\, I\, S(T)}{R} = 0.108 \qquad (1)$$

considering an effective ground acceleration coefficient A_0=0.3, a spectrum coeficient S(T)=1.42, an importance factor I=1 and a reduction factor R=4. For the transversal direction S(T)=1.80 and C^y=0.135.

Based on the simplified representations of the force-displacement capacity curves as presented in Figure 7, the normalized yield strength of the structure in x and y directions can be estimated:

$$R_y^x = \frac{F_y^x}{W} = \frac{8700}{39000} = 0.22 \qquad (2)$$

$$R_y^y = \frac{F_y^y}{W} = \frac{12000}{39000} = 0.31 \qquad (3)$$

The calculated values of the R_y are larger than the required lateral seismic coefficient. Resulted values of the overstregth factors are 2.03 in the longitudinal direction and 2.30 in the transversal direction, considering the characteristic steel strength. To account for a partial safety coeficient γ_S=1.15 for the steel strength, lower-bound values of the lateral overstregth of 1.77 and 2.00 are obtained.

The Capacity Spectrum Method (ATC 40, 1996) is used to determine displacement demand for the structure. Two levels of the effective ground acceleration are considered:

- 0.25g, corresponding to the recorded earthquake of November 11, 2011, Van Merkez Station, E-W direction
- 0.4g, corresponding to the design acceleration of the updated version of the Turkish Earthquake Standard. This value was selected for Van region after the earthquakes of 2011.

Considering a control period of the acceleration response spectrum of 0.4s the following coefficients results: C_a=C_v=0.25 for a_g=0.25g and C_a=C_v=0.4 for a_g=0.4g.

The performance points determined using capacity spectrum method are presented in Figures 8...11. For the effective ground acceleration of 0,25g peak lateral displacements of 46mm in *x-x* direction and 36mm in *y-y* direction are determined. These values correspond to maximum lateral drifts in the longitudinal direction of approximately 0.25% at the first story. Such values of the lateral drift suggest an essentially elastic response of the structure. The same comment is valid noticing the location of the performance points in Figures 9 and 11.

For the design acceleration of 0.4g peak lateral displacements of 74mm and 56mm are determined for the longitudinal and transversal direction of the building. Even under the design earthquake limited structural incursion in nonlinear range are expected.

These relatively low values of the lateral displacement demand can be explained by the short control period of the acceleration response spectrum for the building site and the relatively high lateral strength of the building. Regarding the strength of the building, a lateral overstrength factor of 2,0 corresponding to a reduction factor R=4 suggest that limited nonlinear behavior is expected.

Table 1: Modal participation mass ratios

Mode	Period	Participating mass ratios

3.4 Linear time-history analysis

To determine the amplification of the lateral displacement caused by the structural torsional response, linear time-history analysis is performed. The low lateral displacement demand determined using capacity spectrum method suggested that time-history considering a linear response of the building represents a suitable method of analysis. Unscaled ground motions recorded in Van Merkez station on November 11, 2011, on N-S and E-W direction are simultaneously used in the analysis. E-W component was considered in the longitudinal direction of the building while N-S was considered in the transversal direction.

This is consistent with the real location of the building as the longitudinal façade is roughly aligned with E-W direction. The Van Merkez seismic station is located in the Van downtown at around 1.5 km from the building site.

The inelastic displacement response spectra for E-W component of the recorded ground motion showed that for any single degree of freedom system with relatively high lateral strength the inelastic displacements is roughly equal to the displacements of the elastic system with same vibration period. This is consistent with the Newmark rule for relatively flexible systems. This remark makes the results obtained using the linear time-history analysis more credible.

A damping ratio of 5% is considered in the analysis.

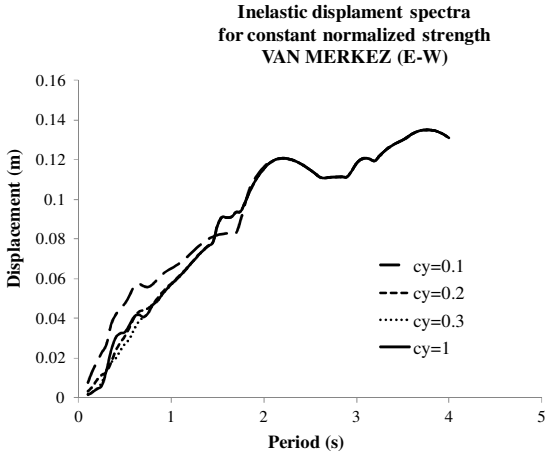

Figure 12: Inelastic design spectra

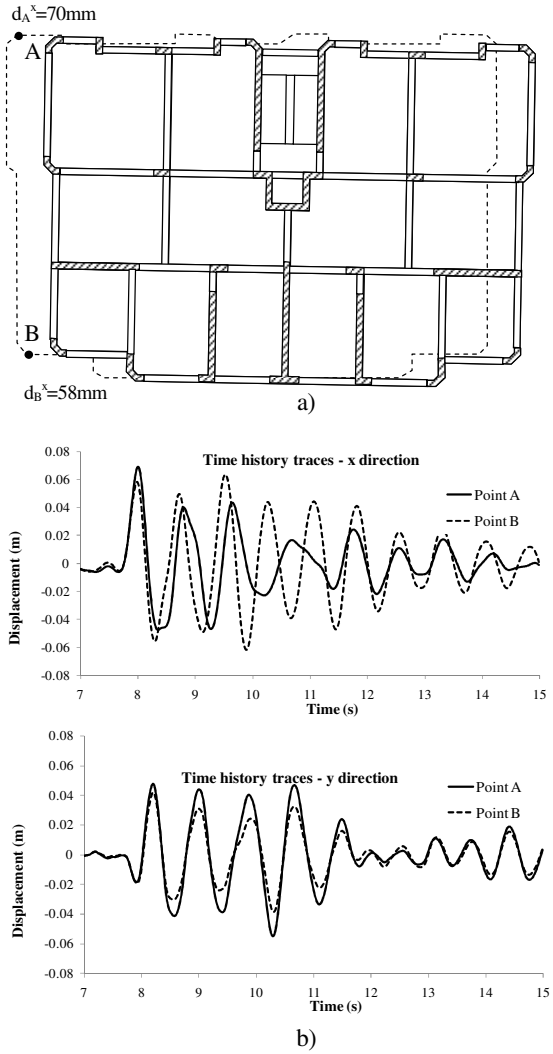

Figure 13: Amplification of the lateral displacement caused by torsion and time history traces at the roof level

The time history analysis revealed that the building might experience a relatively strong torsional response. Only the inherent torsion caused by the eccentricity between the center of mass and center of rigidity is considered in the analysis. Accidental torsion is not accounted for. Peak displacements in the longitudinal direction at roof level vary from 58mm to 70mm on the building perimeter (Figure 13, a). This represents a 10% amplification of the perimeter displacements in comparison with the displacement calculated in the center of mass. This amplification increases in the following cycles but the absolute value of the displacement decreases (Figure 13, b).

An additional time history analysis carried out using the unscaled El Centro ground motion record showed that at the time step when the peak lateral displacement at the roof level of 10,3cm was reached in the main façade in the rear façade the displacement was close to 0. That means that the maximum lateral displacement on the building perimeter is twice as large as the displacement in the center of mass. This analysis clearly shows the torsional sensitivity of the structure. Interaction with the nonstructural infilled masonry walls can further increase this torsional instability.

Time history analysis confirmed the low values of the lateral displacement obtained using the capacity spectrum method. For the Van Merkez station record, maximum base shear forces of 8000kN and 6900kN were determined in the longitudinal and transversal direction. This proves that the structural response was essential elastic behavior with limited incursions in the nonlinear range.

The lateral stiffness of the structure is difficult to be precisely assessed due to the scattered and uncertain quality of the concrete and interaction with the masonry infills. The dynamic characteristics of the building are related to the lateral stiffness and directly influence the displacement demand. In this respect, a sensitivity analysis was carried out. The variation of the peak displacement demand at the roof level is determined for different values of the vibration period of the building in the longitudinal direction. The concrete modulus of elasticity was varied from 5000Mpa to 22500Mpa to determine a variation of the vibration period from 1,43s to 0,68s. The calculated peak displacement increased with the vibration period (Figure 14) as revealed by the displacement spectrum as well. This shows that a change in the lateral stiffness of the structure is not likely to significantly modify the conclusions of this analysis. Such variation of the lateral stiffness might occur the masonry infills are accounted for or the assumed concrete modulus of elasticity is reduced.

A similar sensitivity study was performed to determine the variation of the peak displacement demand with the stiffness of the linear springs that vertically supports the foundation beams. The results presented in Figure 15 showed that the stiffness of the support springs have little influence on the calculated peak displacement demands at roof level.

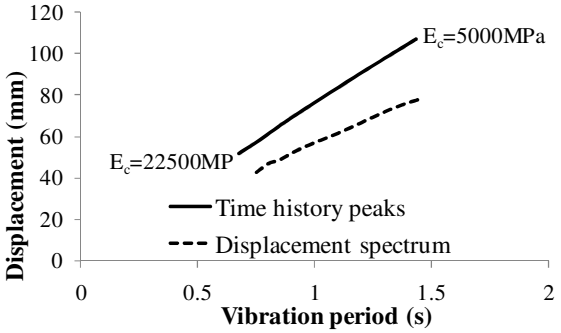

Figure 14: The variation of the peak displacement with the vibration period of the structure

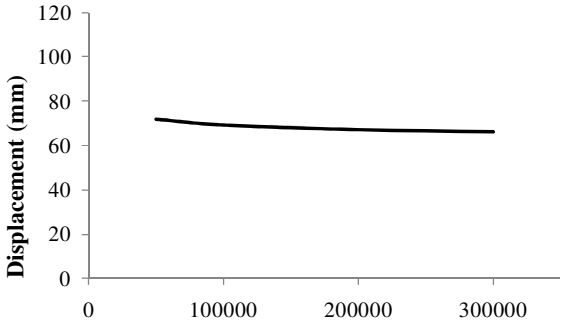

Figure 15: The variation of the peak displacement with the stiffness of the support springs

4. RETROFITTING SOLUTION

The structural analysis proved that the buildings have suitable lateral strength and deformation capacity. Retrofitting of the buildings for future use is feasible. Some retrofitting solutions are presented in this paragraph but other options can be considered as well.

Retrofitting work should address mainly the lateral stiffness of the building and its torsional sensitivity. The lateral stiffness should be increased especially in the longitudinal direction. The masonry panels severely damaged aligned with x-x direction (position B in Figure 2) shall be replaced at all stories with structural infills such as RC panels or steel braces. These panels shall be connected with the outer RC frame using post-installed anchor bolts.

Solid units masonry infills can be an option if adequate strength can be obtained but special attention should be paid to possible shear failure of the adjacent concrete members. The connection of the infills with the outer frame is weak so most of the shear force is supported through the bracing action of the masonry. Since several shear cracks were noticed in beams and columns due to the interaction with the existing weak masonry infills it is questionable if the use of stronger infills represents a reliable option.

If two effective shear resisting elements are created, parallel to the existing shear walls in x-x direction, the torsional sensitivity of the building is reduced.

Retrofitting work shall be preceded by repairing of the existing structural members. Resin injection of the wider cracks might be necessary. Such cracks were noticed especially in some beams at the first three stories.

To obtain a ductile response of the building it is necessary to prevent the local brittle failure modes. These include the shear failure of the captive columns on the basement perimeter. Their shear strength can be increased by steel jacketing. Another option is to replace some of the exterior masonry walls with RC panels properly connected to the existing frame.

Furthermore, in order to reduce the building mass it is recommended to replace the existing damaged partition walls with light and deformable partitions. Plasterboard panels represent a relatively cheap solution for interior partitions. Special care should be taken to prevent the occurrence of soft story type of failures. If a masonry infill is replaced in the ground floor it should be replaced in the upper stories as well.

The proposed retrofitting works can be done using construction materials locally available and require moderate skills of the workers. Engineer supervision is mandatory.

4. CONCLUSIONS

The IPRED post-earthquake investigation mission was dispatched to Van in June 2012, six month after two severe earthquakes hit the region. Ten engineered reinforced concrete and masonry buildings were investigated to observe the damage and to check the applicability of the rapid assessment techniques. Subsequently, detailed structural analyses were carried out for some of these buildings to evaluate their seismic vulnerability.

The results obtained for two of these buildings are reported in this paper. The structural system consists of reinforced concrete shear walls and moment resisting frames. Infilled masonry walls made out of hollow, multi-cell, clay units were used for exterior walls and interior partitions.

At the time of the inspection both buildings were evacuated and listed for demolition.

Nonstructural masonry walls were severely damaged at the first three stories of the building. Some of these walls partially collapsed. Most of the masonry infills had multiple diagonal cracks in both directions. Limited structural damage consisting mainly in shear cracks in beams, columns and shear walls was observed.

A very low concrete quality was observed, especially in one of the buildings. A low quality of the masonry works could be observed as well. During the construction the design prescriptions were not followed as some shear walls were erected in different positions. However this did not affected strongly the general structural layout.

The structural design solution meets most of the

requirements of current advanced seismic design codes. The main shortcoming refers to the torsional sensitivity of the structure and the details for local ductility.

The structural analysis showed that building have enough strength according to the provision of the Turkish earthquake standard at the time of construction. Lateral overstrength factors of around 2,0 were determined. After the earthquake the design acceleration was increased with 25% but the lateral strength of the buildings is still enough.

The lateral displacement demand are relatively low with peak lateral drifts of around 0,5%. These include the amplification caused by the torsional response observed using linear time history analysis.

The structural analysis proved that the buildings have suitable lateral strength and deformation capacity. Retrofitting of the buildings for future use is feasible.

The rapid assessment of these buildings failed to converge to this rather positive conclusion. Nevertheless, the results of the rapid assessment are justified by the low quality of concrete and the noncompliance with the blueprints of the design.

Quality of the construction works represents the main reason for the damage suffered by this building during the earthquakes. The structural works presented major deficiencies opposite to the relatively good quality of the finishing's. Special attention should be paid to the quality of the retrofitting works as it strongly influences their effectiveness.

The post-earthquakes investigation techniques applied worldwide proved to be not always successful because they did not incorporate parameters regarding the local construction techniques, materials, social and economic climate and the expectations of the residents at risk. The lack of methodologies adapted to the regional constraints might lead to overwhelming social problems and misguided decisions of the engineers. Further developing of credible, reliable custom made post-earthquake investigation techniques incorporating parameters regarding the local construction techniques, materials, social and economic climate and the expectations of the residents at risk such as to alleviate the social and economic impact and to improve the decision of engineers is desirable.

PERFORMANCE OF SANDWICH COLUMNS UNDER ECCENTRIC CYCLIC LOAD

H.-L. Hsu [1] and C.-Y. Zhan [2]

Abstract: This paper investigated the performance of sandwich columns subject to eccentric cyclic load. A series of cyclic loading tests were conducted to evaluate the flexural-torsional response of the members. It was found from the tests that the member strength decreased when the magnitude of torsion was increased. It was further observed from the tests that the member strength was higher for sandwich column with larger sectional void ratio. However, the member's energy dissipation capacity was decreased when the member's sectional void ratio was increased. Therefore, it is recommended that composite member with adequate sectional void ratio be adopted should higher member performance be expected. Finally, a simplified expression for the strength interaction was proposed for engineering references.

1. INTRODUCTION

Composite members, such as concrete-filled tubes, possess high strength and significant ductility, thus are suitable structural forms for earthquake-resistant purposes (Kitada 1998). However, for structures subject to extreme loads, the dimensions and the weight of the structures might increase dramatically that reduces the efficiency of the design. In order to improve the design efficiency, a modified structural form, namely sandwich column, was proposed in this study. The sandwich columns were composed of double steel tubes and in-filled concrete between the double tubes. The advantages of adopting sandwich included higher strength and lower structural weight, compared with the concrete-filled tubes with similar dimensions.

For sandwich columns subject to earthquakes, combined loads coupled with torsion due to load eccentricity are usually observed. It has been indicated in several investigations (Han et al. 2009, Tao et al. 2004, Uenaka et al. 2008) that the presence of torsion will significantly affect the flexural strength of the member. Therefore, the structural performance of sandwich columns under combined loading coupled with torsion must be evaluated so that structural safety can be assured. This paper focused on the experimental investigation of sandwich column performance under combined bending and torsion. A series of combined loading tests were conducted to evaluate the member strength under combined loads. Energy dissipation of members was evaluated to correlate the relationship between member performance and sectional compositions.

2. EXPERIMENTAL PROGRAM

2.1 Specimen Details

Sixteen composite members, including 12 sandwich columns and 4 concrete-filled tubes, were fabricated for testing. The sandwich columns were composed of double steel tubes with concrete filled in-between. All specimens were composed of identical outer tubes and the sandwich members were fabricated with inner tubes of various dimensions. The sandwich columns were distinguished by the various inner tubes that used to form the hollow composite sections. Figure 1 shows the dimensions and sectional details of the specimens. The yield stress of the steel tubes was 300 MPa. Concrete strength was 48 MPa, determined from cylinder test after 28-day curing. The details of the specimens are listed in Table 1. The effective height of all specimens was 1650 mm. The diameter and thickness of the outer tube were 318.5 mm and 6 mm, respectively, that resulted in a diameter-to-thickness ratio (D_o / t_o) of 53. Three inner tubes with diameter-to-thickness ratios (D_i / t_i) equaling to 31, 36, and 42, were used for the sandwich columns. They were labeled series B, C, and D, respectively. The normalized member weights of sandwich columns with respect to that of the concrete-filled tube, ranged from 0.91to 0.79, as listed in Table 1.

2.2 Test Setup

The specimens were tested under constant axial load and cyclically eccentric load. Each specimen was rigidly fastened to a pair of stiffened platforms at the member bottom. A stiffened loading beam was attached to the top of the specimen so that the combined loads could be applied. Constant axial load was generated using a hydraulic jack acting on a stiffened reaction beam. The eccentric load was generated by a servo-controlled actuator through a series of increasing displacement commands. The servo-controlled actuator was attached to the loading beam with three eccentricities (e), 0 mm, 460 mm, and 920 mm, respectively, so that various combinations of bending and torsion could be

generated. Parameters considered in the tests included the sectional void ratio (η) and the eccentric ratio of loading (χ). Table 1 listed the specimen details and the loading arrangements. The test setup and the loading history were shown in Figures 2 and 3, respectively.

3. EXPERIMENTAL RESULTS

3.1 Failure Modes

The failure mode of members subject to bending was governed by the alternating local buckling and tensile fracturing of the outer tube, as shown in Figure 4. It should be noted that, for all specimens, the local buckling of outer tubes occurred at the inelastic stages. Once the tube reached the buckling state, alternating elongation of the steel tube was observed. Strength deterioration was observed when the drift of the member increased. For members subject to combined bending and torsion, failure was governed by the coupled action of the flexural stress and the torsion-induced stress. Inclined deformation on the steel tube was observed during the test. The angle of the inclined deformation increased when the ratio between torsion and bending increased. Figure 5 showed the flexural-torsional failures of sandwich columns subject to various load combinations.

3.2 Member Strength

Figures 6 and 7 showed the typical hysteretic loops of composite members subject to various combined loading. It could be observed from the figure that the strength of sandwich columns was higher than that of the concrete-filled tube. Strength enhancements for the sandwich columns over the corresponding concrete-filled tube ranged from 11% to 23%. Further enhancement in strength for the sandwich columns was achieved when the structural weight was considered. The further strength enhancement was 22% to 56%, respectively. It was found from the test result comparisons that the ultimate strength of the sandwich members increased when the members' sectional void ratios increased. However, higher strength deterioration was also exhibited in such members, thus indicating the necessity to optimize the sectional compositions should higher seismic performance in sandwich column design be desired.

3.3 Strength Interaction

In order to evaluate the member's performance under combined bending and torsion, the achievable strength of member was compared. It could be found from the tests that the member strength decreased when the magnitude of eccentricity increased. Figure 8 shows the relationship between the strength deterioration and the applied load eccentricity. It can be further observed from the normalized strength of sandwich columns with various sectional compositions that the relationship, as shown in Figure 9, could be approximated by a linear expression as shown below:

$$\frac{M}{M_{u0}} = 1 - 0.228\left(\frac{e}{h}\right) \tag{1}$$

This expression provides a simple yet effective estimation of the member strength under combined loads, and can be used for engineering design purpose.

3.4 Energy Dissipation

Figure 10 shows the relationship between the cumulative energy and the member strength. The energy dissipation was evaluated by the areas of the hysteretic loops. In order to define the member performance, the member's energy dissipation was compared at the state when member strength dropped to 95% of the member's ultimate strength. Figure 11 compared the energy dissipation of members with various sectional compositions. It could be found from the comparison that the strength of sandwich columns was larger than the corresponding concrete-filled tube. It was also observed from further comparison that the energy dissipation capacity of sandwich column decreased when the sectional void ratio of the member increased. Therefore, it is recommended that composite member with adequate sectional void ratio be adopted should higher member performance be expected.

4. CONCLUSIONS

This study investigated the performance of sandwich columns subject to various combinations of torsion and bending. A series of cyclic loading tests were conducted to evaluate the flexural-torsional response of the member. It is justified from the tests that the sandwich columns possessed significant strength and energy dissipation capacity. It was found from the tests that the member strength decreased when the magnitude of torsion was increased. It was further observed from the tests that the member strength was higher for sandwich column with larger sectional void ratio. However, the member's energy dissipation capacity was decreased when the member's sectional void ratio was increased. Therefore, it is recommended that composite member with adequate sectional void ratio be adopted should higher member performance be expected. Finally, a simplified expression for the strength interaction was proposed for engineering references.

Abstract: In urban areas, structures interact with each other through the surrounding soil. This phenomenon is referred to as structure-soil-structure interaction (SSSI). Theoretical, numerical and experimental work has shown that SSSI effects can be important for certain types of structure pairs. To date, however, few parametric studies have been performed to elicit specific SSSI effects. In this paper, parametric studies involving soil-foundation-structure modeling properties are conducted using the direct differentiation method to understand which modeling properties, if any, control the interaction between structure pairs. Steel, moment-resisting frames are considered. The structural response is examined in terms of roof displacement. Preliminary results show that SSSI effects are minimal for the adjacent steel, moment-resisting frames investigated.

1. INTRODUCTION

Within a city block in densely populated urban areas there are different types of structures (i.e., different height, different building materials, etc.), which is exhibited in Figure 1. During an earthquake, the adjacent structures within the city block will interact with each other through the soil. This phenomenon, whereby adjacent structures interact through the soil, is generally referred to as structure-soil-structure interaction (SSSI). SSSI effects are not well understood by earthquake engineers. Accordingly, earthquake engineers must work to understand which scenarios lead to detrimental, beneficial and/or neutral SSSI effects. The purpose of this paper is to present some analyses that progress our understanding of SSSI effects.

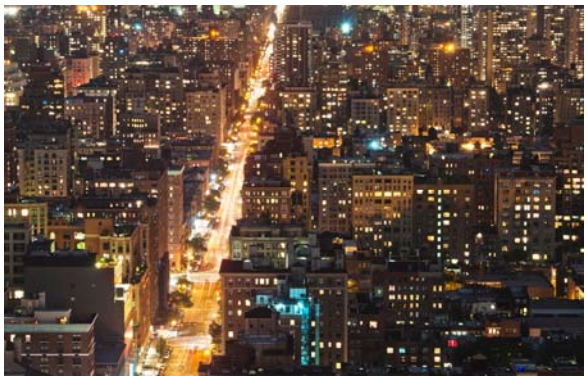

Figure 1. The Upper West Side of New York City, which shows the complex building arrangements (city blocks) of an urban area (photo courtesy of Ben Leshchinsky).

Steel, moment-resisting frame structures are considered herein. Parametric studies are undertaken to understand which modeling parameters control the interaction between adjacent pairs of frame structures. The parametric studies are performed using the direct differentiation method (DDM), which is a very efficient method for performing many parametric analyses. The results are presented for only one earthquake motion. In future efforts, a suite of 100 earthquake motions will be used for the parametric studies.

A short literature review is first presented, which frames the subsequent methodology and results sections. The focus of this paper is on the methodology section. For brevity, the results of only one pair of adjacent structures will be presented. Future publications by the authors, including the second author's M.S. thesis (released June 2013), will include more results and findings. It should be stated up front that pounding (i.e., adjacent buildings hitting one another during an earthquake) was not considered during any of the analyses presented in this paper.

2. LITERATURE REVIEW

2.1 Structure-soil-structure interaction

During an earthquake, seismic waves from a source eventually reach the ground surface. In urban areas, the waves interact with the foundations of buildings. In turn, the waves travel through the foundations and into the supported superstructure. The superstructure vibrates, and the vibrational energy propagates downwards into the foundation and eventually into the surrounding soil. These complex interactions encapsulate the phenomenon of

soil-foundation-structure interaction (SFSI) or soil-structure interaction (SSI). The impedance contrast between the various system subcomponent materials (i.e., soil to foundation to superstructure) as well as the vibrational characteristics of the system subcomponents, makes SFSI a complex phenomenon. However, SFSI effects have been investigated for many years, as reported by Kausel (2010), and earthquake engineers and scientists have developed a good understanding of these effects for individual buildings.

SSSI is a phenomenon related to SFSI. As noted, SSSI effects are not well understood; however, they have been shown to be significant for various soil-foundation-structure (SFS) systems (e.g., Luco and Contesse 1973; Lee and Wesley 1973; Wong and Trifunac 1975; Mason 2011). Menglin et al. (2011) contains a literature survey of SSSI research.

Incorporating SSSI effects into engineering design is a novel concept, and to the authors' knowledge, is currently not widely considered outside the nuclear industry (the results from nuclear industry research are usually either classified and/or proprietary). Theoretical studies from the 1970s exist (e.g., Luco and Contesse 1973; Lee and Wesley 1973; Wong and Trifunac 1975). These theoretical studies focus on solutions to governing partial differential equations. To make the solutions tractable, a number of simplifying, and often unrealistic assumptions are made. These researchers have generally focused on understanding the displacement response of two adjacent rigid shear walls using a plane strain assumption. Some numerical SSSI studies, which rely on using finite-element, finite-difference, or boundary-element methods, have been developed since the 1970s (e.g., Qian and Beskos 1995; Mulliken and Karabalis 1998; Padron et al. 2009). The first two references were only concerned with the response of two adjacent, shallowly-embedded footings, and the third reference was concerned with the response of advanced structures founded on pile foundations. More recently, researchers have performed centrifuge experiments to investigate SSSI effects (e.g., Mason 2011; Mason et al. 2013; Trombetta et al. 2013).

2.2 Direct differentiation method

Exhaustive parametric analyses are usually employed to answer outstanding earthquake engineering questions. This strategy is time consuming. The direct differentiation method (DDM) is a more efficient alternative. In the DDM, model parameters are identified and the gradient of time history response is computed with respect to each parameter. Considering a nonlinear dynamic analysis, the sensitivity of a nodal response is calculated by solving the following system equation, which is obtained by differentiation of the equation of motion with respect to a model parameter, θ:

$$\tilde{\mathbf{k}}_T \frac{\partial \mathbf{u}}{\partial \theta} = -\frac{\partial \mathbf{m}}{\partial \theta}\left[\ddot{\mathbf{u}} + \iota \ddot{u}_g(t)\right] - \frac{\partial \mathbf{c}}{\partial \theta}\dot{\mathbf{u}} - \left.\frac{\partial \mathbf{p}_r}{\partial \theta}\right|_{\mathbf{u},\dot{\mathbf{u}}} \quad (1)$$

where $\tilde{\mathbf{k}}_T$ is the effective stiffness matrix, $\mathbf{u}$ is the lateral nodal displacement vector, $\mathbf{m}$ is the mass matrix, $\ddot{\mathbf{u}}$ is the lateral nodal acceleration vector, ι is the influence vector, $\ddot{u}_g(t)$ is the acceleration-time series of the ground, $\mathbf{c}$ is the damping matrix, $\dot{\mathbf{u}}$ is the lateral nodal velocity vector, and $\mathbf{p}_r$ is the static resisting force vector (Franchin 2004; Kleiber et al. 1997).

The DDM is performed using OpenSees (the Open System for Earthquake Engineering Simulation; McKenna et al. 2000). OpenSees provides a nonlinear finite element framework in which SSSI problems can be modeled efficiently. In addition, OpenSees is fully equipped for computing nonlinear dynamic response sensitivity by the DDM (Scott and Haukaas 2008).

3. METHODOLOGY

3.1 Soil-foundation model

Figure 2 shows a schematic of a soil-foundation model. As shown in the figure, the flexibility of the soil-foundation interface is modeled by a series of translational springs. The stiffness values of these translational springs were determined using formulas and charts in Gazetas (1991), and the values were checked based on guidance in Wolf (1985). In addition, the "structure-soil-structure" link is also modeled as a translational spring in this initial work. Calibrating and validating this newly defined structure-soil-structure spring will be one of the contributions of this ongoing work. Simplified values of the spring coefficient are chosen, which are based on the work of Mulliken and Karabalis (1997) and Qian and Beskos (1995). The translational springs are modeled in OpenSees using "zero length elements," which allows the user to define a stiffness between two nodes. In future work, complex springs, which also include damping (as shown in Figure 2), will be used to model the soil-foundation interface (i.e., Winkler springs; Allotey and Naggar 2007).

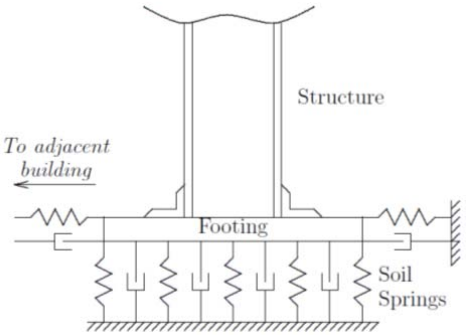

Figure 2. The soil-foundation model represented as a series of springs and dashpots.

Reasonable assumptions for the shear modulus and Poisson's ratio of the soil, as well as the geometry of the foundations, were made to estimate the stiffness of the soil springs. In this paper, the underlying soil was assumed to be a dense sand with shear modulus of about 35 MPa and

Poisson's ratio of about 0.33 (Budhu 2011). All moment-resisting frame structures were assumed to have square spread footings at the base of each column resting on the surface of the soil. Adjacent footings were assumed to be immediately adjacent. The 4-story structure shown in Figure 3 was assumed to have a footing width of 1.8 meters, and the 8-story structure shown in Figure 4 was assumed to have a footing width of 2.4 meters.

3.2 Moment-resisting frame model

The models used for moment-resisting frame structures were largely based on a previously developed proof of concept model; accordingly, the models presented in this paper are not based on an established structure. The models presented herein have wide-flange sections and are either four or eight stories tall. Shallower W12x or W14x shapes were used for the columns and deeper W21x or W24x sections were used for the beams. All steel sections were assumed to have a modulus of elasticity, *E*, of 207 GPa. The steel section models, in combination with the force-based beam-columns, allow for non-linear analysis of the structural model. Building models of 3.0-m story height and 3.7-m base width were constructed for each combination of 4-story and 8-story buildings. A typical floor mass of 89 kN was divided in half and placed at the nodes of each floor on either side of the structure. The depth of the columns, was user-defined and was found suitable to be varied in order to determine the sensitivity to building stiffness. Although the models presented herein were not based on established designs, the authors were careful to choose realistic geometric and material properties.

In the first iteration of the analyses, the structures were initially fixed at the far ends and allowed to translate laterally at the near end, where the structure-soil-structure spring was placed. Figure 3 is an example of this model for the 4-story by 4-story system. Using this model, it was found that buildings with the same number of floors and identical floor masses translated in harmony, resulting in zero sensitivity to the structure-soil-structure spring stiffness. For analysis of these systems, the Secondary structure was assigned a mass equal to three-quarters that of the Primary structure. The Primary and Secondary nomenclature is adopted for convenience.

After further consideration, the first iteration model was thought to be too restrictive, because a structure is not usually constrained against lateral motion at one of its foundations. The only restraint against lateral motion is applied by the rigidity of the foundation and the underlying soil. As a result, the lateral constraint was removed from the far end of the Secondary structure and soil springs were placed at each of the column bases to reflect the actual behavior of structures placed on a flexible soil medium. The far end of the Primary structure was left fixed with the knowledge that the displacements experienced by both structures would be relative to the far end of the Primary structure. The improved structure-soil interface model is depicted for the 8-story by 4-story system in Figure 4.

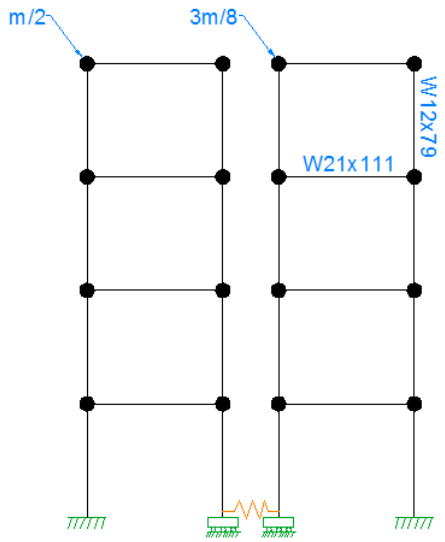

Figure 3. Four-by-Four system with lateral constraint on far end of Secondary structure. Each floor mass (m) is divided in half and placed at either end of the floor.

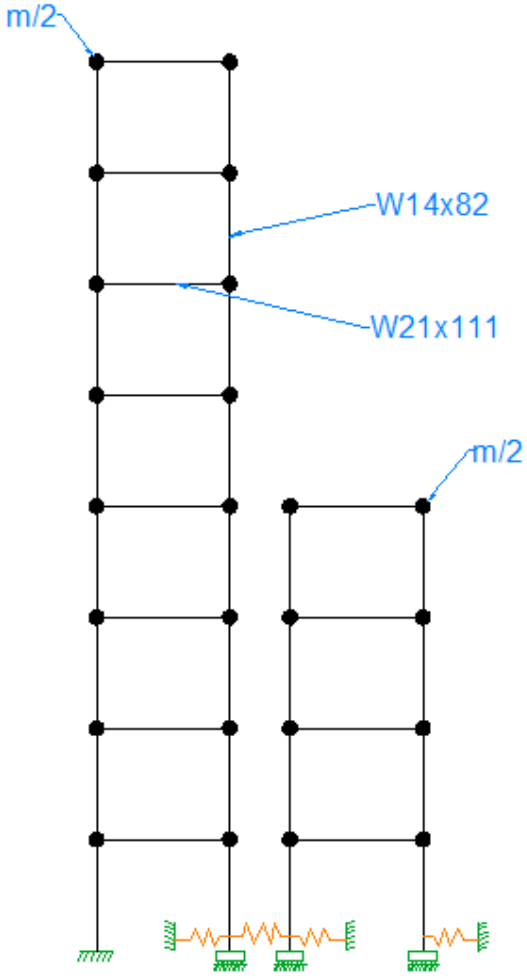

Figure 4. Eight-by-four system with column bases restrained by structure-soil springs.

4. RESULTS

To date, the structural models previously described have only been subjected to the north-south component of the earthquake motion recorded at the El Centro station during the 1940 Imperial Valley, California. Figure 5 shows the roof displacement response of both the Primary and Secondary structures throughout the duration of the motion. The configuration of the Primary and Secondary structures for this analysis is identical to that shown in Figure 4, with an 8-story building adjacent to a 4-story building. The floor mass used was 89 kN.

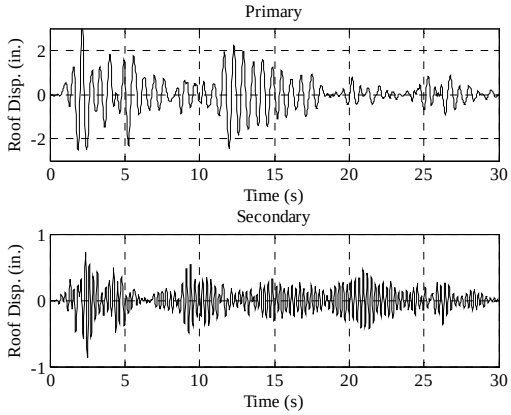

Figure 5. Roof displacement response time series of both Primary and Secondary structures subject to the 1940 El Centro earthquake motion.

In addition to the mean displacement response, sensitivities to structural stiffness, structure-soil-structure spring, and floor mass are calculated and compared to the mean values. Figure 6 shows the mean roof displacement response, *u*, and the responses when the story stiffness of the Primary structure is increased or decreased by 10 percent, from t = 2 s to t = 6 s. Likewise, Figure 7 shows the roof displacement responses when the mass of the 7th floor of the Primary structure is varied by 10 percent.

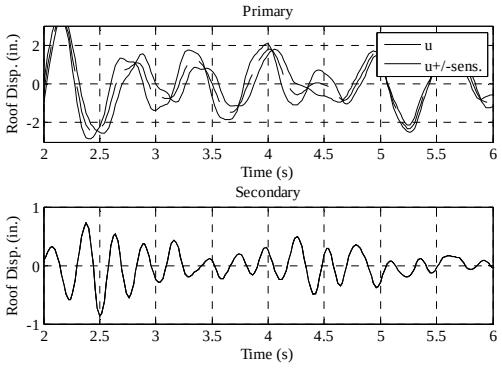

Figure 6. Roof displacement response with sensitivity to the story stiffness of the Primary structure.

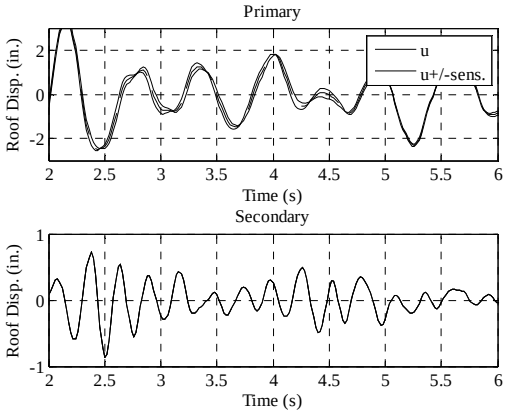

Figure 7. Roof displacement response with sensitivity to the 7th floor mass of the Primary structure.

Based on the presented analyses, the sensitivity of the roof displacement response of the Secondary building to changes in the Primary structural properties and soil parameters appears to be minimal. As expected, the response of the Primary building was sensitive to changes in its own story stiffness and floor mass. However, the response of the Secondary structure, even with 10-percent changes in design parameter values, remained almost identical. This result implies that there is negligible interaction between the two building models through the structure-soil-structure spring. Even as the response of the Primary structure changes with changes in the design parameters, the response of the Secondary structure remains constant.

5. CONCLUSIONS

The DDM has been found to be an efficient method for analyzing the response sensitivity related to SSSI effects. This method allows 100s of analyses to be performed within the OpenSees framework. With tools such as batch processing, and parallel computing, many analyses can be performed efficiently.

For the specific case of an 8-story by 4-story building system subject to the 1940 Imperial Valley earthquake motion, the response of the Secondary structure is not particularly sensitive to changes in the model parameters of the Primary structure. The roof displacement response of the Secondary structure was practically unchanged with 10 percent changes in both the story stiffness and floor mass of the Primary structure. These results suggest that structure-soil-structure interaction is not significant in this particular case and may not be significant in other steel frame buildings. It should be noted that these results are contingent upon the stiffness of the structure-soil-structure spring; however, preliminary analyses shows that SSSI effects are minimal for this case when the stiffness of the structure-soil-structure spring varies between reasonable values.

The lack of structure-soil-structure interaction seen in the particular case presented in this paper is likely

attributable to one of three causes: (1) the employed earthquake motion did not elicit significant response in either structure; (2) the model of simple, horizontal springs is not sufficient to model SSSI effects; and (3) steel, moment-resisting frame structures are sufficiently flexible to prevent SSSI effects that might occur in more rigid structures (Luco & Contesse 1973).

The methodology and results shown in this paper represent a very initial effort of ongoing work. Future contributions of this work will include: (1) more guidance for modeling the structure-soil-structure spring; (2) more advanced spring models (i.e., Winkler springs) to account for the damping and flexibility of the interfaces; (3) inclusion of more DDM results to investigate the design optimization and reliability of adjacent structures in urban areas; (4) an examination of more earthquake motions; and (5) a finite element model of the soil with a proper constitutive model. In closing, it must be noted that finding that SSSI effects are potentially unimportant for a given scenario is still an important finding. Future efforts will try to find scenarios where SSSI effects are detrimental; however, finding scenarios where SSSI effects are beneficial or neutral is also valuable for earthquake engineers.

DAMAGE ASSESSMENT OF BUILDINGS. CASE STUDY OF AN EDUCATIONAL BUILDING

Claudiu-Sorin Dragomir[1), 2)]

1) Senior Researcher, Laboratory of Seismic Risk Assessment and Action in Constructions, National Institute for Building, Development and Urban, NIRD URBAN-INCERC, Bucharest, Romania
2) Lecturer, Department of Environmental, Faculty of Land Reclamation and Environmental Engineering, U.S.A.M.V. Bucharest, Romania
dragomircs@incerc2004.ro, claudiu.dragomir@fifim.ro

Abstract: Due to the time evolution of the design provisions, in Romania there are buildings that were designed decades ago, after the less stringent provisions. Thus, when the earthquake is produced there are many cases where the buildings are badly damaged. Some buildings were rehabilitated, but most of them maintained the original appearance. In addition to the historical or heritage value they reflect the conception and economic power of their time. According to the modern approach of the post-seismic investigation the damage building assessment should be clearly foreseen and properly planned in order to obtain dynamic parameters for the analysis. In this context, determining the fundamental period of building oscillation and comparison with the original data is a first comprehensive method for assessing the variation of rigidity building due to the earthquake. The paper is emphasis the need for extensive seismic instrumentation of national interest buildings so that information on the behavior of structural categories is available in a limited time from the occurrence of an earthquake. All the aforementioned ideas are illustrated through a study case of an educational building.

1. INTRODUCTION

In Romania, Vrancea earthquakes occur every few decades, and approximately 60% of territory is affected by them. There are buildings that were designed decades ago, after the less stringent provisions. Thus, when the earthquake occurs there are many cases where buildings are badly damaged.

The university centres shelter large concentrations of young intellectuals which in the near future are assumed to take over most the society duties. Besides education, in universities are carried out scientific research activities for the modern technology of society. For that reason, seismic protective measures of the university buildings according to the new requirements are necessary as well as drawing up some assistance strategies and interventions for emergency situations similar with those already existing in the technologically advanced countries. The priority for the university centres is to respect the clause 1.1.2 of the Romanian Code P100-1:2006 which provides avoiding of human loss, maintenance of the activities and limitation of damages.

Currently, there are no specific programs for university building inspection to verify the compliance with new requirements of safety standards and no organized programs in emergency areas such as in countries like U.S.A. and Japan. For this reason the paper tries to present a method for assessing the vulnerability of university buildings through a case study for the building that houses the Faculty of Land Reclamation and Environmental Engineering in Bucharest.

2. MODERN CONCEPT FOR POST-SEISMIC ASSESMENT OF BUILDINGS

The experimental model presented in the case study was conducted in 1990-1991 in the seismic Hall of INCERC Bucharest, in view of full-scale tests.

The construction is based on a modular square grid 3.90 x 3.90 m and a floor height of 2.75 m, consisting of two openings and two bays, which comprises a single structural wall.

At the intersection of axes, constant cross-section poles are placed, 500 x 500 mm, covering the entire height of the building. Pillars are prefabricated for two-story height, with a non-concrete portion in the middle of 350 mm, which includes reinforcement of strips of plate. Full-scale tests were conducted as follows (Vlaicu, 1999):

- The first step of testing the experimental system was to load the tare weight and more concrete weights.
- In 1995 took place the first test with lateral loading forces, using presses, while in 1996 post-elastic horizontal loads were applied, in 8 cycles (incremental loads).
- In 1997 the experimental model testing was resumed, aiming at the evaluation of the behavior to breaking stress.

To simulate the behavior of a future earthquake damaged building, the following steps were followed:

- Determination of the own vibration periods by

microseism measurements and their processing;

- Modeling a spatial structure identical to that found in seismic Hall; noting that the model was created with five levels unlike the existing one that had four levels (being tested at the top- -floor - terrace to simulate the loading of an extra floor).

- The time-history analysis to determine the structure response spectrum using accelerograms recorded in the earthquakes in from the '77, '86 and '90.

Following the above steps, microseism measurements were made on the experimental model, following two sensor placement schemes presented in Fig. 2. Measurements were made both by applying shocks in the center of the 2nd floor and the microseism movement from the site.

Microseism measurement results obtained in the case of the full-scale experimental model, with GF+3 floors are presented in Table 1. These values of own periods of vibration are determined from the Fourier spectrums. Processing the records made at this stage of cracking of the model are presented in Fig. 4 (Dragomir et al. 2012).

3. SOLUTIONS TO STRENGTHEN THE MASONRY PANELS IN RC FRAMES STRUCTURES

To highlight the efficiency of carbon fiber reinforcement, the full-scale attempts made in the INCERC Bucharest laboratories are presented. The masonry panels presented are made of ceramic blocks with vertical hollows.

3.1 Strengthening with carbon fiber strips

The basic concept of the experiments was to use a standardized test - the diagonal test – on the same specimens of masonry in two situations: in the initial state, masonry made according to usual procedures and after applying a reinforcement with carbon fiber plates attached to specific adhesives (Dragomir, 2009).

The results indicated that the tested systems are effective, with the clarifications that it is also advisable to apply the strips on the diagonal of the panels in two directions close to the main efforts, so that the strips work on stretching. In this case, it would be reasonable to recalculate the size and arrangement of the strips used, for cost optimization.

Figure 14 Making specimens, by applying the carbon fiber plates

Since parametric testing was done in one direction, in static stress, monotone increasing, while the real seismic application is dynamic in nature, it is necessary to extend the research, to highlight the differences in behavior. It is advisable to symmetrically apply the strips on both sides of the specimens, as consolidation on only one side can cause failure by bending in a direction normal to the sample plane, at forces below the original test. The application process can be done on masonry with superior resistance characteristics, thus ensuring the entry into work and working together between the two materials during the stress application, avoiding crushing masonry in the nodes areas. From this point of view, because in practical applications two diagonal strips are applied, at higher levels of alternating stress, it is possible that masonry work stop of the corners of the frame may occur successively, where the grip is redundant, the rest of the strip remaining as active zone, on the long direction, but with some contribution of the strips from the other direction. These considerations should be taken into account in determining the actual size of the strips area of contact with the masonry, in relation to the computing area. If anchoring the strips to concrete slabs on the contour, some of these effects may be compensated, the strips may work efficiently throughout the whole stress application. Additional tests are needed to clarify the concrete behavior particularities and the strips adherence to concrete in the node zone.

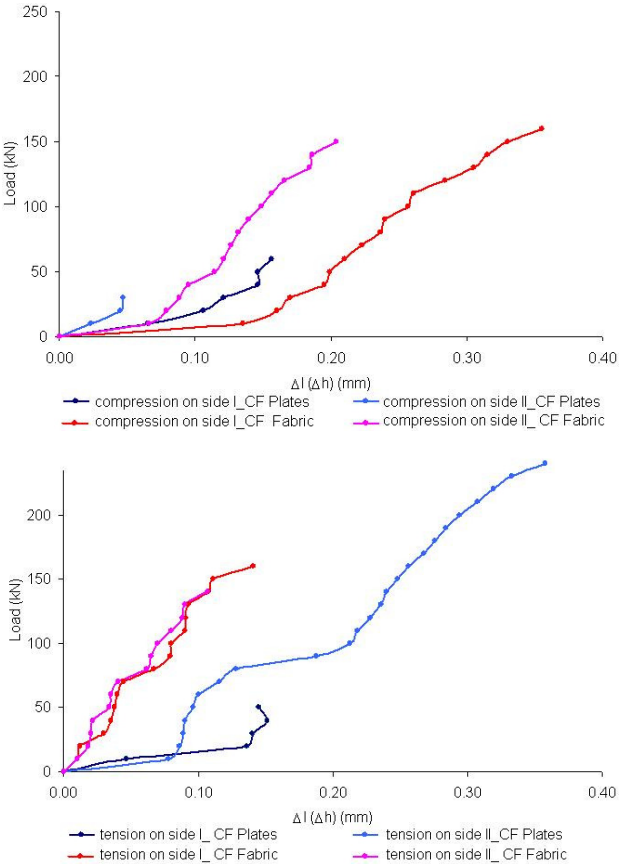

Figure 15 Relationship between effort - relative compression / relative elongation corresponding for two of the samples tested

3.2 Strengthening masonry panels with carbon fiber fabric

The aim of the trials carried out at INCERC was to test for bending four models of masonry made of ceramic blocks, with the same plan dimensions 1.50 x 1.00 m, but with different thickness: 2 models with 30 cm thickness (M30) and 2 models with 38 cm thickness, M38 (Dragomir et al. 2009).

Attempts have been made at various stages, as follows:

- In the first stage two models of simple masonry (different thickness) were tested;

- In the second stage the other two models were tested, but this time they were consolidated on the side with fabric from reinforced carbon fiber. The test results of the two

stages will be presented in comparison to highlight the effectiveness of consolidation.

The two models tested in the second stage were consolidated on the side with carbon fiber fabric. To apply this fabric, a bicomponent Epoxy resin was used.

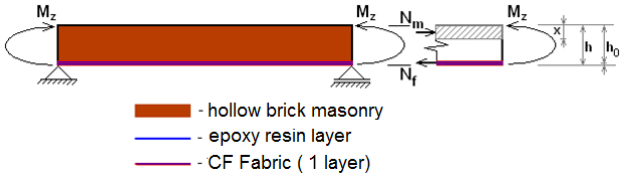

Figure 16 Analysis scheme of rectangular sections under bending stress

To emphasize the need to strengthen with a larger or smaller number of carbon fiber fabric layers, the model with 30 cm thickness was coated with two layers of fabric overlapping on a width of 20 cm, while the model with 38 cm thickness was coated on the side with only one layer. In Fig. 16, a calculus scheme to determine the required reinforcement area at stretched fiber.

The balance equations obtained on the basis of scheme emphasized in Fig. 16 are:

$$M_z = N_m h_m \quad (1)$$

$$N_f = N_m \quad (2)$$

where

$$N_f = A_f f_f; \quad N_m = bxf_m \quad (3)$$

N_f is tensile stress into carbon fiber fabric layer;
N_m is compression stress into hollow brick masonry.

From this equations was resulted the height of the compressed zone (neutral axis position), as follow

$$x = \frac{A_f f_f}{bf_m} \quad (4)$$

From Eq. 1 was obtained a second degree equation,. The accepted solution for this equation is:

$$A_f = \frac{bh_0 f_m}{f_f}\left(1 - \sqrt{1 - \frac{2M_z}{bh_0^2 f_m}}\right) \quad (5)$$

where A_f = area of the carbon fiber fabric.

In Fig. 18 and Fig. 19, the force-arrow diagrams are shown in comparison, with the two versions of the M30 model: unconsolidated and consolidated.

Figure 17 The M30 model after failure

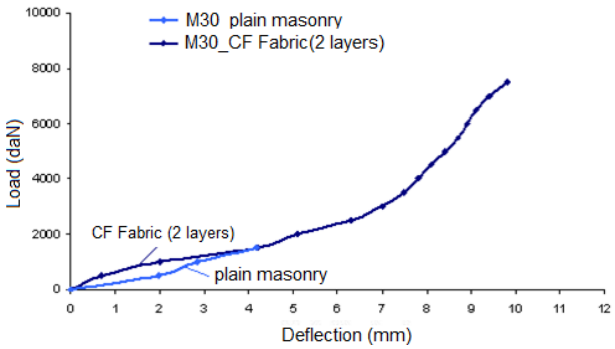

Figure 18 Force-arrow diagram for the M30 masonry model (30 cm thick)

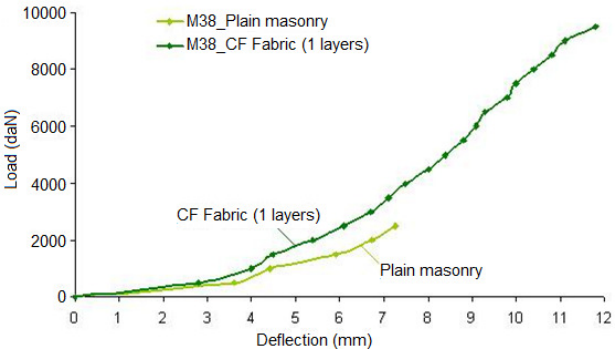

Figure 19 Force-arrow diagram for the M38 masonry model (38 cm thick)

Comments:

- Results demonstrate the efficiency obtained for the application of layers of carbon fiber fabric on the model stretched fiber.
- After the failures of the two modules, was found that the masonry failed, as expected, because it exceeded the compressive resistance on the compressed side.
- Under the conditions of these tests, the contribution to the rigidity conferred by the blocks size was greater than the contribution given by applying a double number of layers of carbon fiber fabric;
- Because the failure point doesn't appear in the zone of

the stretched fiber, where for fabric is applied, but in the compressed side with simple masonry, a single layer of fabric is enough, because the advantage of an increased number of layers may not be exploited.

4. CASE STUDY OF AN EDUCATIONAL BUILDING

The method for assessing the vulnerability of university buildings is illustrated through the case study of the Faculty of Land Reclamation and Environmental Engineering (F.L.R.E.E.) in Bucharest.

The F.L.R.E.E. building has resistance structure of reinforced concrete frames designed in the '70s, according to the Code P13-70 (see Fig. 20).

Figure 20 The F.L.R.E.E. building from Bucharest

Although the height is low (H = 20.33 m) and the shape in plane is regular, the earthquake of 4 March 1977 have caused damage, especially to non-structural elements due to insufficient stiffness for the protection of subdivision elements.

In Figure 21 is shown the time evolution of part A's own periods of Faculty of Land Reclamation and Environmental Engineering in Bucharest, with records made available by INCERC Bucharest between 1986-1998.

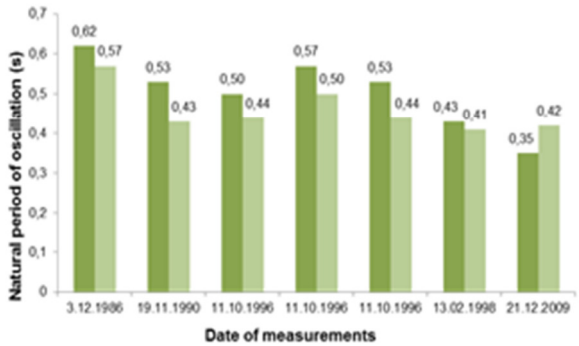

Figure 21 Time evolution of own periods of part A of F.L.R.E.E.

By determining the dynamic characteristics of part A of the Faculty of Land Reclamation and Environmental Engineering, from December 2009, and then in 2012, it was found that the period of oscillation of the building was reduced by approximately 19% compared to values determined in 1998.

The recordings made after the entry into force of the new design code P100-1: 2006 are presented. Recordings were made on the 4th floor of part A of building F.L.R.E.E.

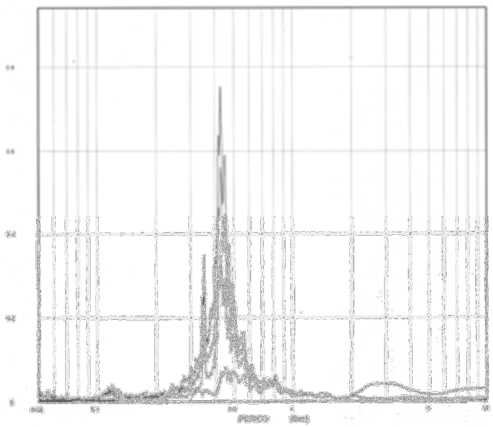

Figure 22 Fourier Spectra obtained from processing of recorded data

It is estimated that this reduction is due to the collaboration processes of the various parts of old and the new structure and to earthquake of magnitude Mw = 6.0, which took place on October 27, 2004, in Vrancea seismic zone, which may contributed to structural transfer efforts from the four concrete caissons to the structure.

Following the changes made in the composition of the building, either to the structural or non-structural elements, through the interventions to strengthen the building from damage caused by earthquake or other causes, the building suffered significant changes both in terms of both mass and own periods.

All those three types of calculation for that comparative study was performed (initial structure before the 1977 earthquake; structure after consolidation in 1986; structure after consolidation in 1996) are shown in Figure 23.

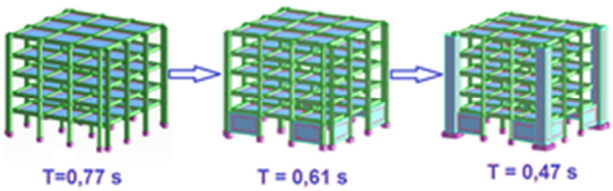

Figure 23 Oscillation periods of FLREE determined by dynamic analysis

From the image shown in Fig. 23, it can be seen that the two consolidations have brought an decreases in the period of fundamental mode of oscillation (39% compared to initial version). This demonstrates the effectiveness of interventions to strengthen applied throughout the period of

life of the structure, but they have become inadequate because of changes occurring over time with the introduction of new design codes.

Basically, the building interventions to strengthen were designed to increase the rigidity of structure that is obtained by increasing the size of structural elements and/or adding other structural elements.

However, while reducing their periods of oscillation for the T…Tc of the spectrum (Tc is in this case under the Code P100-1/2006 equal with 1.6s) not reduces the design forces due to the covering adoption of a constant value (landing) for spectral acceleration in this area, removal of the resonance conditions T = Tc is a goal of always watching.

Based on the results of the presented structural calculations, can be made the following comments:

- In any of the situations, permissible value of the relative displacement at the service limit state has not been exceeded and the allowable amount of relative displacement at ultimate limit state has been exceeded in a single statement in the version I of calculation; this would have contributed to serious damage to the building in the earthquake of 1977 (according to the P100-1/2006, the value of $SLU_{r\,ad}$ = 0.025 h and $SLS_{r\,ad}$, = 0.008h).
- After the first consolidation, the relative displacement was decreased by 38% and after the second by 40% compared to the previous consolidation, representing 63% compared to the relative displacement in the initial situation. In this way, the structure fulfills the conditions imposed by the current seismic design code, code P100-1/2006 from the point of view of the relative displacement.

Although, despite the increased rigidity of the building after the building interventions, the bending and twisting ratio remained less than 1.5, which means that the danger of coupling between the three modes of oscillation remained.

Thus, the results of calculation in ROBOT program were validated through the dynamic parameters of the structure, i.e. the periods and the frequencies determined by measurements.

In comparison calculation were taken into account the two structural assumptions: 1. the parts were separated by virtual seismic joints, and, 2. the parts were linked together without seismic gaps. These assumptions were applied to both rigid and elastic soil.

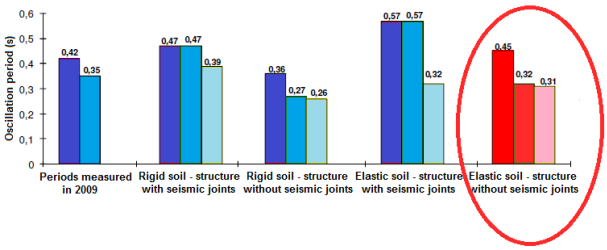

Figure 24 Oscillation periods of the first three modes obtained from analysis performed in the 4 assumptions compared with recently measured oscillation periods

From the point of view of their periods of oscillation, the comparative analysis shows (Fig. 24) that the real behavior of the structure corresponds to the elastic structure hypothesis (there is a ground-structure interaction) without seismic joints, which is the real situation at this moment (Dragomir and Calin, 2011).

In Figure 25 are shown the periods measured by INCERC for some specimens of the existing buildings of reinforced concrete frame made in Bucharest in different periods.

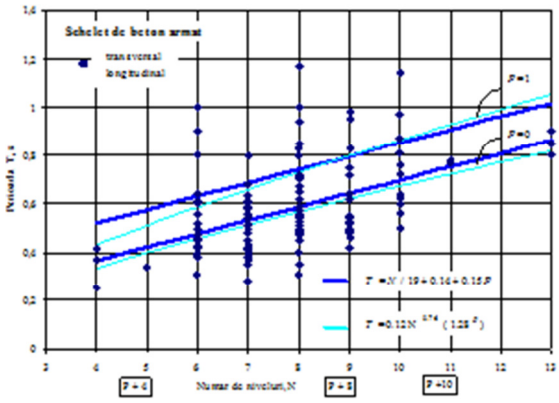

Figure 25 Periods measured by INCERC for RC structures

Two regression models (other than those presented in previous sections): linear and nonlinear (UBC format, Eurocode) are sized. The exponent of 0.76 determined for the reinforced concrete frame structures is closed to value 0.75 specified in UBC and Eurocode8.

Based on the formulas established by INCERC, the value of the period of vibration of the fundamental mode, obtained by temporary seismic instrumentation is:

$$T = 0.12N^{0.76} => T = 0.41s \qquad (6)$$

5. CONCLUSION

The concept of investigating the performance of a building proposes the validation of calculations with a program dedicated to structural analysis using instrumental data processing techniques.

The tests made on masonry panels confirmed the usefulness of using composite materials. Tests proved that it is possible a successive strengthening of clay blocks with plates and fabrics and avoiding demolition of cladding when structure is not damaged. Application to existing buildings is feasible, although some cost-benefit analysis must be done.

Based on the results obtained on site with throught temporar seismic instrumentation, a structural model with identical dynamic characteristics can be modeled and thus the behavior of the existing structure to strong earthquakes in Romania can be studied.

It can say that in this way one can predict how certain structures that have experienced earthquakes in the last century will respond to future earthquakes.

Abstract: The modularized construction method applying SC (steel plate concrete) structure as the measure to reduce the construction period of nuclear power plants (NPP) has been developed. SC structure applied to the nuclear power plants requires a seismic design and thus the dynamic properties of SC structures need to be decided for accurate designing. The damping ratio of dynamic properties is an important design parameter governing the seismic response of structures. This paper has compared the damping ratios of SC structures suggested in the design criteria and the regulatory guide. To identify the damping ratio of SC shear walls, SC wall specimens without shear reinforcement were manufactured and cyclic loading tests and vibration tests were conducted. During the tests, SC walls exerted large ductility while its load increased due to the confining effect by the steel plates and the damping ratio increased continuously to the moment of failure. The experimental results showed that the damping ratio of SC walls increased by about 6-20% depending on the amplitude of the load.

1. INTRODUCTION

The SC structures arrange steel plates on both sides and/or single side of walls to replace the reinforced steel bars of RC structures and places concrete inside. In other words, SC structure complements the concrete tensile strength and flexural strength by installing the steel plates instead of the reinforcement steel bars used in the previous RC structures and performs a role as a formwork, which shortens the construction period and ensures the systematic quality management. Recently, the major countries with nuclear power plants try to apply SC structures to the safety structures of nuclear power plant. Thus, there is a need to analyze the dynamic behaviors of the composite structure and study the mechanical properties of that. SC structure has been recently developed, thus the research history is rather short and there is a lack of studies to secure the structural safety. To apply the SC structures to nuclear power plant structures, the studies on dynamic characteristics and seismic performance as well as the characteristics of stiffness due to the composite action between the steel plate and concrete are additionally required. The studies on SC structures are conducted mainly in Japan and the research results started being published since the early 2000s. Japan Electric Association has announced the steel plate concrete seismic design provisions in 2008. Kashiwa nuclear power plant has constructed a solid waste incinerator building as a demonstration building by applying SC structure and conducted a research on the dynamic characteristics of the building through vibration tests. Some research cases that performed a load analysis on this building and analyzed the in-plane behavior due to the composite action of SC structure have been reported.

The studies on the behavioral characteristics of SC structures conducted in Korea include the static experimental researches on the ductility of concrete and steel composite columns; an analytical research on compressive strength and failure mode according to width-thickness ratio; an experimental research on the lateral load performance of wall and the strength characteristics by producing non-reinforced steel concrete specimen. As a research that used an analytical method, a research to develop equivalent plate element model of SC structure was conducted. The researches on the dynamic characteristics of SC structures have seldom been conducted in Korea. Lee, Seung Joon et al, in his study, has suggested the damping ratio for SC structure seismic design by analyzing the results of a free vibration analysis, yet has analyzed the damping ratio in the stress state lower than the yield stress level of structures. In the seismic design of nuclear power plants, the damping ratio is defined at the level of the yield stress level of structures and 1/2 of the damping ratio of the yield stress. This study has organized the damping ratio regulations applied to NPP structures and compared them in order to analyze the damping characteristics of the dynamic characteristics of SC structure; furthermore performed transverse cyclic load tests and vibration tests using impact hammers after manufacturing SC shear wall specimen

without shear reinforcement. The acceleration signals measured from experiments and load-displacement curves were analyzed and the natural frequency and damping ratio of the target specimen were analyzed. The values of the damping ratio of SC structure identified by experiments were compared with the values suggested in the design regulations.

2. Damping Ratio of Structures

2.1 Methods to Determine Damping Ratio

Damping ratio refers to a phenomenon of energy loss and the response reduction in structures due to natural resistance, and is divided into material damping and friction damping. Material damping is refers to the damping due to the relation between the molecules that comprise the materials of structures, and friction damping refers to the damping at the joints of structures due to the structural members and the friction between components. Damping is one of the variables influencing the dynamic behaviors of structures significantly and is expressed in the equation of motion representing the dynamic system,

$$\ddot{u} + 2\xi\omega_n\dot{u}(t) + \omega_n^2 u(t) = f(t) \qquad (1)$$

Where, u is the displacement of the structure, ξ is damping ratio, ω_n is natural frequency, f(t) is external load.

The damping of structures is difficult to measure and the cause of its occurrence is uncertain. The report of the U.S. Nuclear Regulatory Commission (NUREG/CR-6011) suggests the ways to obtain the vibration response of the structure and calculate the damping ratio from that. The experimental methods to measure the damping of structures are divided into a forced vibration method and a free vibration method. Damping ratio of structures can be identified in several ways. National Center for Earthquake Engineering Research (NCEER) in the US introduces the ways to determine the damping ratio of concrete frame specimens: a way using a transfer function, a way using the half-power bandwidth, and a way to determine the damping ratio by using logarithmic decrement. Furthermore, to obtain the damping ratio in the state of huge load inducing the yield stress in structures, ways to measure the force-displacement hysteresis curve through a harmonic motion experiment and determine the equivalent viscous damping from the area of the hysteresis curve are used..

2.2 Techniques to Extract the Damping Ratio of Measurement Signals

(1) Half-Power Bandwidth Method

Even if the characteristics of the load is unknown, it is possible to calculate the damping ratio from the results of a forced vibration test by using half-power bandwidth. As known well, this method determines the damping ratio as shown in equation (2) by using the values of the left and right frequency corresponding to the $1/\sqrt{2}$ of the value corresponding to the top of the dynamic amplification factor curve.

$$\boldsymbol{\xi = \frac{\beta_b - \beta_a}{2}} \qquad (\mathbf{2})$$

(2) A Method Using Logarithmic Decrement

This method estimates the damping ratio from the time history displacement records in the system vibrating freely. Logarithmic decrement represents the reduction rate of the amplitude after the one period of free vibration. ξ value of the exponential equation in the graph represents the value of the damping ratio of the structure.

To calculate the damping ratio, the logarithmic decrement after n periods can be expressed in the following equation.

$$\delta = \frac{1}{n}\ln\left(\frac{u_1}{u_{n+1}}\right) = 2\pi\xi\frac{2}{\sqrt{1-\xi^2}} \qquad (3)$$

where, u, in the first displacement amplitude of free vibration curve, and u_{n+1} is the u_{n+1}–th amplitude.

When the amplitude decreases by half, the period of ($u_1 / u_{n+1} = 2$) can be expressed in equation (4).

$$n = \ln 2\frac{\sqrt{1-\xi^2}}{2\pi\xi} \qquad (4)$$

The period of half-bandwidth can be calculated by using above equation, which will calculate the damping ratio.

(3) Polynomial Regression Analysis

Equation (1) can be expressed in the following transfer function, after the extension with multi-degree freedom and Laplace transformation

$$\{X(s)\} = [H(s)]\{F(s)\} \qquad (5)$$

Where s is Laplace variable; [H(s)] is transfer function matrix, {X(s)} is the Laplace transform of displacement, {F(s)} is the Laplace transform matrix of load, The following transfer function matrix can be deployed in the form of a fraction partial fraction part.

When the evaluation of transfer function is made along the vibration contraction in s-plane, the frequency response function is obtained. Thus, by substituting $s = i\omega$, the frequency response function $H(i\omega)$ is generated.

$$H_k(i\omega) = \frac{r_k}{(i\omega - p_k)} + \frac{r_k^*}{(i\omega - p_k^*)} \qquad (6)$$

When polynomial curve fitting technique is applied for the regression analysis of transfer function, the transfer function can be developed as shown in equation (7)

$$H_k(i\omega) = \frac{r2_k\sigma_k + r1_k\omega_k + ir2_k^{\omega}}{\sigma_k^2 + \omega_k^2 - \omega + 2i\sigma_k^{\omega}} + A0 + A1(i\omega) + A2(-\omega^2) \quad (7)$$

where $\omega_k, \sigma_k, r_k = r1_k + i2r_k$ represent kth mode natural frequency, mode attenuation value and the dynamic characteristic values obtained as a result of the regression analysis as complex residue number, respectively. And A0, A1, A2 are the constants of the rest functions obtained in the course of calculation.

(4) Equivalent Viscous Damping

Damping has the feature that dissipates energy. Thus, by using this feature, it is possible to estimate the damping. By assuming that the dissipation energy (E_D) per one period, the area of the general hysteresis curve obtained by vibration tests by harmonic load is equivalent to the area of an ellipse in hysteresis loop representing the dissipation energy by equivalent viscous damping, the equivalent viscous damping can be obtained.

The dissipation energy per one period E_D can be obtained in the following equation.

$$E_D = \pi c_{eq}\omega_d A^2 = \pi\left(2m\xi_{eq}\omega_e\right)\omega_d A^2 = 2\pi\xi_{eq}\beta kA^2 \quad (8)$$

Here, c_{eq} is equivalent viscous damping, ξ_{eq} is equivalent viscous damping ratio, ω_d is damping natural frequency, ω_e is forcing frequency, β is vibration ratio($= \omega_e/\omega_d$).

When substituting static strain energy (E_{S0}) in the above equation, the equivalent viscous damping ratio at resonance (β = 1) can be calculated as shown in the following equation

$$\xi_{eq} = \frac{1}{4\pi\beta}\frac{E_D}{E_{S0}}\Big|_{\beta=1} = \frac{1}{4\pi}\frac{E_D}{E_{S0}} \quad (9)$$

$$\text{Where } E_{S0} = \frac{1}{2}kA^2 \quad (10)$$

2.2 Regulations on the Damping Ratio of SC Structure

Damping ratio of Korean NNPs follows the regulatory standards published by the U.S. Nuclear Regulatory Commission (USNRC). The damping ratios applied to NNP are defined after being classified into Operating-Basis Earthquake (OBE) and Safe-Shutdown Earthquake (SSE) and also being classified depending the types of structures in use. Korea's KEPIC-SNG suggests the damping ratio in the design of SC structures on the basis of the results of the recent studies; Japan's JEAC-4618 also suggests the damping ratio in the design of SC structures. However, the United States Nuclear Regulatory Commission do not suggests the damping ration of SC structures until now and thus the damping ratio between reinforced steel concrete (RC) and pre-stressed SC structures were compared.

As shown in Table 1, regarding the RC structures in the regulatory standards of the United States and Korean power industry technical standards, the damping ratio is decided at 7% and 4% in case of SSE standard and OBE standard, respectively. Furthermore they suggest that the damping ration can be decided by estimating the dissipation energy by viscous damping in cases other than the structures suggested. Korea's KEPIC SN nuclear structure and SNG steel plate concrete structure define the damping ratio of RC structure as 4% equivalent to the damping ratio suggested by the United States Nuclear Regulatory Commission in OBE standards and 6% which is smaller than RC structures by 1% in RC standard. Seismic design provisions of steel plate concrete structure issued by the Standards Committee of the Japan Electric Association (JEAC 4618-2009) defines the damping ration of RC structure as 5% equivalent to steel concrete. It is because they regard the damping ratio of SC structure to be equivalent to RC structure based upon concrete damping mechanism.

Table 1. damping ratio of each code

code	type	SSE	OBE
USNRC (KEPIC STB)	RC	7%	4%
	PSC	5%	3%
KEPIC-SNG	SC	6%	4%
JEAC-4618	SC	5%	

3. Damping Ratio Estimation Tests

In this study, in order to investigate the damping ratio of SC structure, simple unreinforced SC wall specimens were manufactured and then vibration tests and cyclic loading tests were conducted. The transfer function obtained through shock hammer vibration tests was analyzed by polynomial curve fitting method and then the natural frequency and damping ratio of specimens were calculated. In addition, the dissipation energy by period in cyclic loading was calculated from force-displacement curve obtained through cyclic loading tests and then the damping ratio was determined.

3.1 SC Wall Specimens

The specification of the specimens used in the tests is shown in Figure 1. The size of specimen is 1100mm x 400mm x 150mm (Height x Length x Thickness).

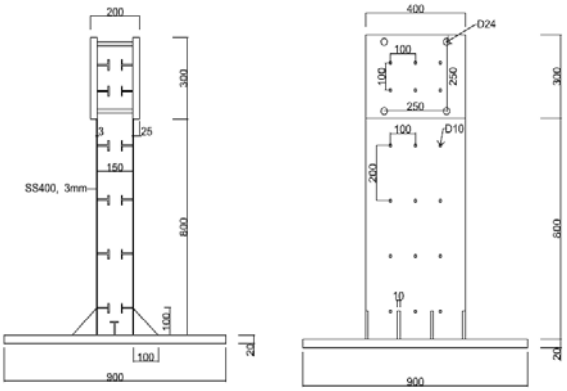

Fig. 1. size of specimens

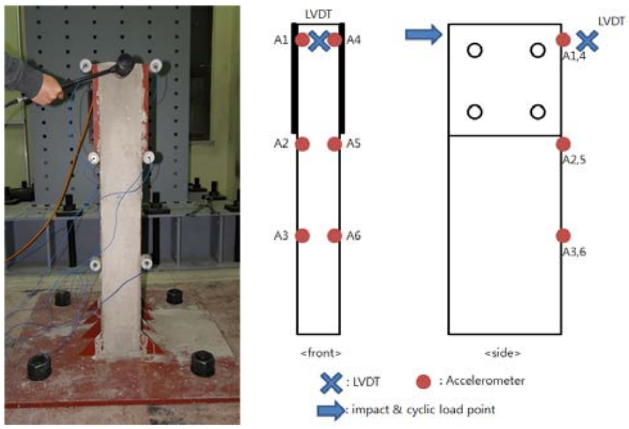

Fig. 2. Impact hammer test and measuring points

The specimen with 2 steel plates with studs is designed compositely at compressive strength of 35MPa and concrete was placed. The material of the steel plate attached to the specimen is SS400 steel plate with 3mm thickness. As for studs, 6 lines were welded to both steel plates in the length direction (3 lines each along to the height of wall). 20mm thick steel plate are attached on the bottom of the specimen to fix the specimen and 3 studs attached to the base plate connect the plate to the walls. To the bottom of walls, 4 ribs are welded on the left and right side for the reinforcement. The size of the studs used in the specimen is 8mm x 45mm (diameter x length). On the top of the specimen, 25 mm steel plates are reinforced on both sides of the walls to add the mass and fix an actuator, considering the dynamic characteristics of wall. The name of each specimen is decided as shown in Table 2.

Table 2. names of specimens

	Specimen 1	Specimen 2	Specimen 3
name	SXC1	SXC2	SXC3

3.2 Impact Hammer Test

To analyze the vibration characteristics of the SC walls and examine the damping ratio at low levels of stress, a vibration test was conducted by using impact hammer. The specimen was the same as that used in cyclic load tests and tightly fixed to mass foundation, and a test was conducted as shown in Fig.2. impact hammer used in the test was DYTRAN's Model 5802A with the head weight of 1.36kg (3 lb) and 6 x PCB PIEZOTRONICS's 1-axis accelerometer (PCB 393B04) were used to measure the acceleration response. OROS's FFT Analyzer was used to analyze the signal. In the impact test, 6 acceleration measuring devices were attached to the specimen on the left and right of specimen (bottom, middle, top). And then, the average acceleration response transfer function signal was recorded after striking the top-center of specimen in the back.

3.3 Cyclic load Test

Cyclic load was performed in the direction of specimen's length. The loading equipment used in the test was hydraulic servo loading equipment with the capacity of 500KN. The specimen was fixed tightly on mass foundation and abutment test walls by using bolts. Fig 3 exhibits the diagram of the experimental apparatus and the test scenes.

Load was applied on the wall through displacement control as shown in the graph in Figure 4 and the displacement was increased gradually up to about 110mm. The loading was repeated in the forward and backward direction. To measure the displacement of the target specimen, 2 LVDTs were additionally installed on the specimen on both sides and whether there was the displacement of the specimen in to the sides was monitored

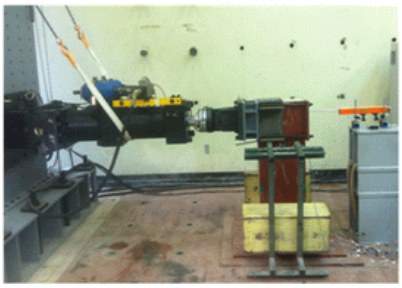

Fig. 3. cyclic load test apparatus

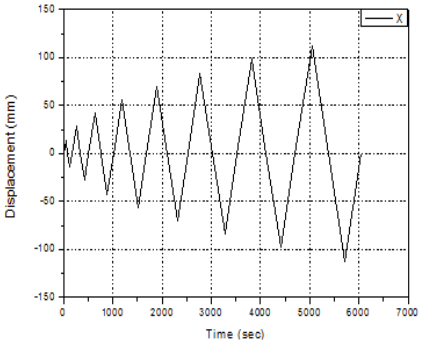

Fig. 4. input load of cyclic load test

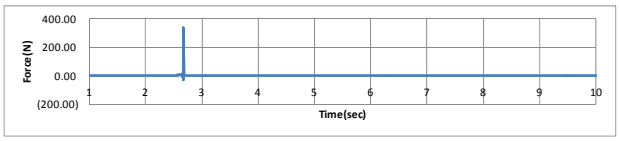
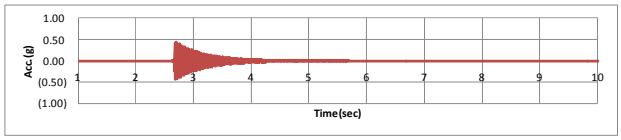
3.4 Test Results



(1) Impact Hammer Test

The acceleration time history measured through impact hammer test was converted into response acceleration transfer function for loading load and expressed in Figure 5 and 6. As shown in Figure 7, the vibration characteristics of SC wall specimens can be identified by using a polynomial curve fitting method. The damping ratio and natural frequency of each specimen is summarized in Table 3.



The results of test showed there is a difference of natural frequency even though the specimens have the same shape and weight. It is likely because the degree of the attachment of concrete and steel plate inside the specimens varies depending on specimen due to the effect of dry contraction. As a result of the analysis of damping ration, every specimen had about 1% the damping ratio. This damping ratio is low in low-stress state and thus it will rise in real earthquake vibration.

Fig. 5. time history response

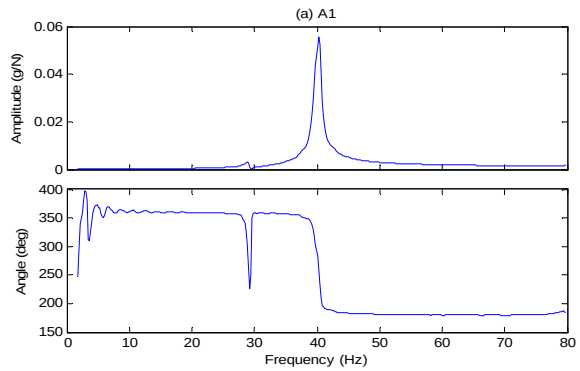

Fig. 6. transfer function of SXC1 top location

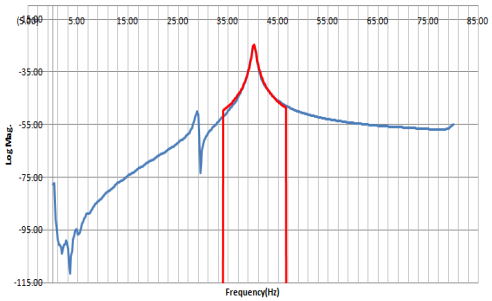

Fig. 7. Polynomial Curve Fitting

(2) Cyclic Load Test

The load-displacement hysteresis curve of each specimen by cyclic load tests is shown in Fig 8.

As a result of cyclic loading tests of SC wall specimens, the average of the forward maximum load was 130.4kN; the average displacement was about 46mm; the average of the backward maximum load was 118.8kN; the average displacement was 45mm. Damping ratios shown in Table.5 were identified from the each cyclic loop of Fig. 8. The results from analyzing the damping ratio demonstrate that the size of ellipse increases and the damping ratio increases from 6% to about 20% as the cycle of loading load increases. In the first cycle, 60kN, about 50% of the maximum specimen load, is loaded and the damping ratio at this moment is about 6%. After the 3rd cycle, the load is greater than yield strength and ductile fracture occurs during this interval. After the 3rd cycle, loading load gradually decreases, whereas the damping ratio continues to increase gradually. It is because the internal concrete cracks increase and the binding force continue to increase due to the steel plate arranged on both sides and as a result the internal friction forces increase, which results in a continued increase of damping ratio.

4. CONCLUSIONS

To find out the damping ratio which is one of the dynamic characteristics of the SC structure wall, specimens were manufactured and static and dynamic tests were conducted. The test results are as follows:

1) As a result of cyclic loading tests, the damping ratio of SC structure specimen was about 7% when the steel plates yielded. Furthermore, there is a large ductility capacity in the length direction after the concrete yields due to the composite action between concrete and steel plates, and a binding force occurs in both steel plates installed outside the concrete due to the attributes of SC structure. Due to this, the frictional effect increases due to an increase of binding force as the cracks of internal concrete increases, which results in an increase of damping ratio as tests progress and loading load increases.

2) Seismic design code on steel plates in Korea prescribes the damping ratio as SSE 6%, explaining SC structure incurs less cracks than RC structure. However, as a result of the test, it is not possible to check the cracks that occur inside due to effect of steel plates and the damping ratio rather increases due to the binding force of the steel plates installed outside. Thus, there is a need to conduct further studies and tests to suggest reasonable damping ratio regulations.

3) As the dynamic characteristics through impact tests, the values vary depending on specimen. It is because the bonding between steel plate and concrete varies depending on specimen due to the curing condition.

4) As a result of vibration tests using impact hammers, very small damping ratio was calculated compared to the cyclic loading test using a hydraulic loading device. It is because the compliance energy of vibration tests using impact hammers is relatively smaller than the compliance energy using a hydraulic loading device. Thus, a large scale vibration test like a shaking table test is considered to be needed to evaluate the damping ratio of structure.

Abstract: In this study, lateral force resistance capacity and failure mode of steel plate concrete (SC) wall element were evaluated based on the static push-over tests. Seismic capacity and stiffness characteristics of unstiffened SC shear walls under lateral force were investigated from the test result. Failure modes, sectional strength, and stiffness characteristics of SC structures under lateral loads were investigated by analyzing the experimental results. One of the main failure of unstiffened SC shear walls were found to be the type of bending shear failure due to the debonding of steel plate at the concrete interface. In addition, finite element model of the specimen was also created and nonlinearly analyzed for the static load. The failure modes of the SC wall due to the lateral force were analyzed and compared with those identified by the test. The initial stiffness and displacement due to the lateral load which were analyzed by the finite element model were in good agreement with the experimental results. Overall patterns of structural behavior identified by analysis showed very similar to those obtained from the test.

1. INTRODUCTION

Nuclear power plant (NPP) is formed of reinforced concrete buildings with shear walls for seismic resistance effectively. Steel plate Concrete (SC) structure is the alternative to Reinforced Concrete (RC) structure of NPP. The researches on SC structures for the modularization of nuclear power plants have been performed recently in Korea. In order to design the SC element to be rational, its structural behavior should be clearly investigated.

Unlike general industrial facilities, to adopt SC member to the safety-related major structures, various research on structural behavior and mechanical characteristics is required. To date, experimental research on SC type has been actively performed. However, research results on the development of analytical model, which can apply in the design practice, and the prediction technique of performance are uncommon.

Research (Chen, 1999; Mello et al., 2008) using finite element analyses (FEA) on composite action between concrete and steel plate has been trying for a lone time. To date, it is increasingly becoming the development trend owing to the improvement of analytical program. Chaudhary et al. (2011) studied, for bridge structures, the behavior characteristics considered the nonlinearity of each material on composite structures composed of concrete and steel plate. Based on these fundamental researches, the study (Ahmer et al., 2011) on the effectiveness of SC walls after comparing RC and SC shear walls was carried out. However, they are not only research qualified practically based on the actual test results but also the comparison research between FEAs based on the theory.

In this paper, to qualify the practicality of a static analytical technique for applying to the practice, FEA for targeting the test results of RC shear walls were performed. The reliability of static analytical technique for the length direction of walls was qualified and mechanical behaviors were predicted by comparing stiffness and failure modes with test results.

2. STATIC PUSH-OVER TEST

This study was performed based on Cho et al.'s (2012) published in recent year. All data including the spec of specimens were referenced from the research (Cho et al., 2012).

To confirm the mechanical behavior of SC shear walls, a total of three specimens were fabricated and the monotonic increasing load (Figure 1) were applied. Concrete design strength is 35MPa. SS400 having a thickness of 3mm was used and 36 numbers of studs was installed in the steel plate. And, concrete was placed inside the steel plates. All tested specimens were 150 mm x 400 mm rectangular sections and the height was 1100 mm as shown in Figure 2. To anchor the static loading device, the steel plate having the holes was welded to the upper part of the specimen. Lateral direction loading tests were carried out using a hydraulic universal

testing machine (UTM) with a capacity of 500 kN.

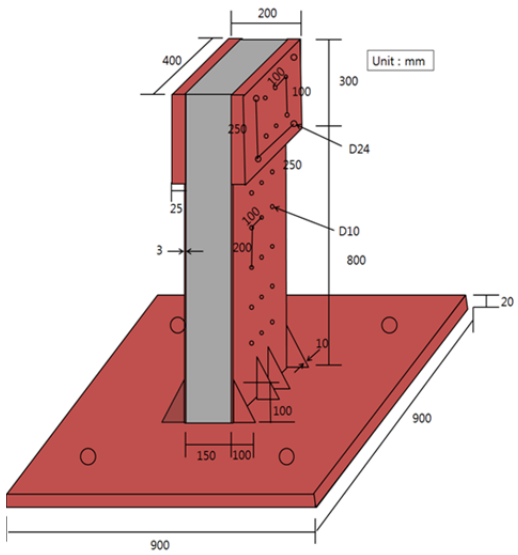

Figure 1. Specification of specimen

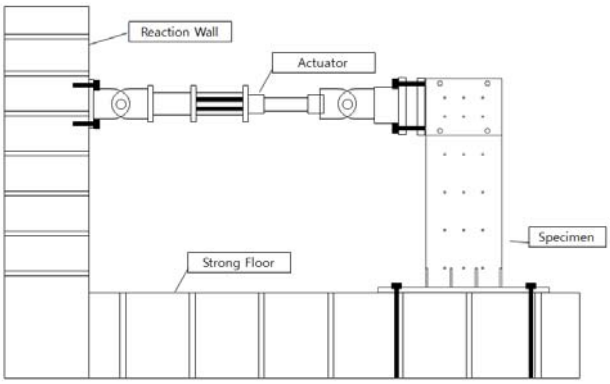

Figure 2. Test set-up

To measure the strain distribution of specimens, eight three-axial steel strain gauges (for example, ST21) and four concrete gauges (for example, CON1) were attached in the tensile and compressive surfaces of the steel and concrete. Linear variable differential transducers (LVDTs) were installed at the opposite side center of point applying the force and two sides of each specimen to clarify the existence of torsion. Overall view of test set-up and details of attachment locations of LVDTs and strain gages are shown in Figure 3.

Monotonically increasing loads on the specimens put the pressure on slowly increasing the lateral displacement loading was displacement-controlled. Lateral load tests were performed for each specimens the longitudinal direction, the name of the longitude direction of the wall specimen SXP1, SXP2 and SXP3 as were classified.

The average maximum load on the specimen is about 115.25kN, when the average displacement reached of about 66mm. As shown in Figure 4 was compared of the load-displacement graph of each specimen.

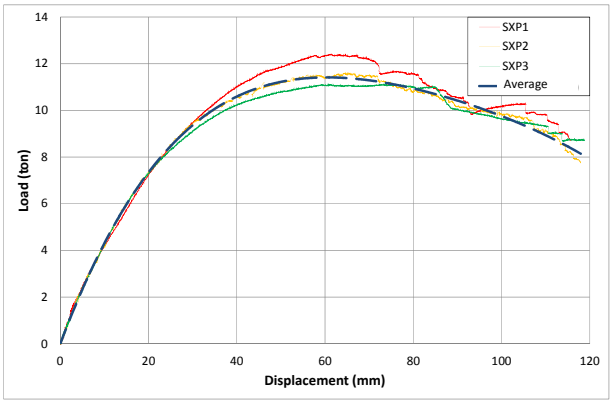

Figure 4. Load-displacement curve obtained result of test

3. FINITE ELEMENT ANALYSIS

To predict the behavior of SC walls, finite element analyses (FEA) was performed using the actual size and materials of specimens from ahead performed research (Cho et al., 2012). For the analyses, the universal structure analysis program (ABAQUS Ver. 6.10 (2011)) was used. Steel plate, concrete, and studs were considered to be perfectly bonded. The load was applied to the center of upper part of the specimen using the displacement control. 3-dimensional nonlinear static-analyses considering the

nonlinear behavior between concrete and steel plate were performed and the relationships between load and displacement and crack patterns of concrete were evaluated.

3.1 Modeling

As shown in Figure 5, target structures were modeled using 3-dimensional finite elements (solid elements of Mesh Tools of ABAQUS) based on the real size considering the nonlinear behavior of the concrete. Compressive strength of concrete was 35 MPa and yield strength of steel plate was 400 MPa. To prevent the shear locking phenomenon, which does not present the shear deformation of solid elements, the reduced integration technique was applied. As the boundary condition, the lower part of bottom plate of the steel plate was fixed.

As the model applied to the concrete solid element, concrete damaged plasticity model to confirm the failure behavior in concrete of the compressive and tensile stage was used. This model is an appropriate model to predict the damage behavior of concrete and contains the characteristics of tensile hardening, compressive softening, stiffness damage, and plastic expansion under the restrained compression condition.

As the constitutive model applied to three-dimensional element of the steel plate, Von Mises plasticity model was used considering the non-linearity of the steel plate. Drucker-Prager plasticity model is an appropriate one for materials showing the volumetric plastic strain such as concrete. On the other hand, Von Mises plasticity model is a proper one for ductile materials showing the plastic incompressibility like metal and steel plate.

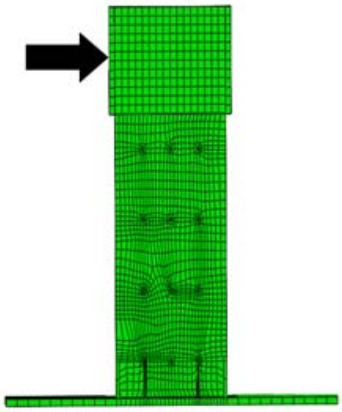

Figure 5. Load point of specimen

3.2 Analysis Method

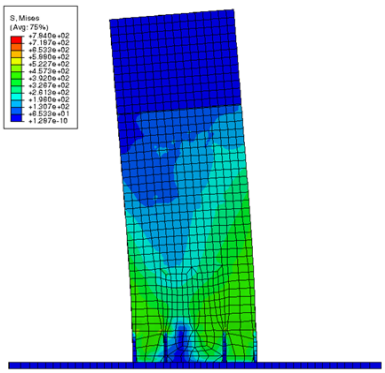
Pushover analysis was conducted by applying displacement load on the top as shown in Figure. 5. Pushover analysis is effective in identifying the behaviors and limit state of structures after the yield, by considering the material nonlinear characteristics can establish the target performance of structures and accomplish that. Pushover analysis calculates load-displacement relation curves, by gradually applying the pre-set static load to the performance point that can be expected in structures. It is possible to compare the performance of specimens by comparing the calculated load-displacement curves. Thus, pushover analysis aims to identify the vulnerability of specimens by analyzing the behaviors of specimens and identifying the stress distribution of steel plates.

4. ANALYSIS OF RESULTS

Actual specimens are modeled into an analytical program in actual scale and a pushover analysis was conducted by applying displacement load to the top-center. After the analysis, concrete crack distribution and steel stress distribution of specimens were confirmed and load-displacement and failure mode between tests and analysis were compared.

4.1 Stress of Specimens

Results of Stress distribution acting on the steel plate of the specimen are shown in Figure 6. Displacement increase concentrates the stress of specimens on the mid-bottom and the consequential flexural crack and shear crack progress from the front to the rear. The cracks are concentrated on the mid-bottom of the front of concrete. Due to the failure of concrete because of these cracks, the analysis stopped even though the steel plates did not yield. V-shaped failure occurred on the bottom in the rear. It is likely because the concentration of stress on the bottom in the rear incurs V-shaped failure.



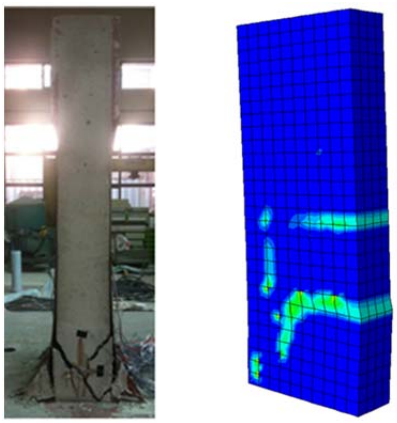


Figure 6. Stress distribution of specimen

4.2 Failure Mode of Specimen

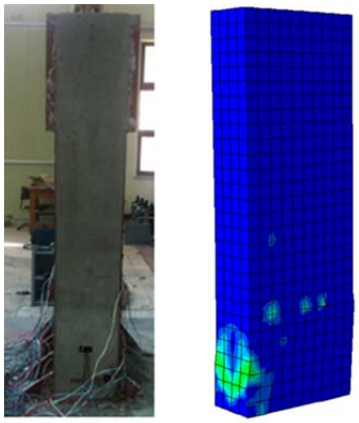

Figure 7 & 8 shows the comparisons of failure patterns between experiments and analyses for length direction of the wall. There is a little difference because the failure mechanism was changed. Namely, due to studs and reinforcement attached to the bottom of side and foundation, the stress concentration in the tension part compared to that of analyses excessively occurred. In addition, the reinforcement was failed and concrete went overall on. Finally, it can be concluded that the failure of concrete of was controlled by the tension. Figure 9 & 10 shows the buckling phenomenon of steel plates obtained from experiments and analyses. As the displacement increases, the junction between steel plate and concrete in the front and rear parts of the specimen was separated and, accordingly,

the buckling phenomenon was happened. It shows the similar pattern with experimental results.

Figure 9. Comparison of buckling of (a) test and (b) analysis on front.

(a) (b)

Figure 10. Comparison of buckling of (a) test and (b) analysis on back

4.3 Load-Displacement Curve

Figure 11 shows the displacement in accordance with the experimental and analytical load. In experimental and analytical results, the initial rigidity and displacement agree with each other and behavioral modes are very similar to each other. ABAQUS curve in Figure 11 represents the specimens modeled by attaching stiffener and abacus-x/o stiffener curve represent the specimens without stiffener.

The specimens except SXP3 have the similar results strength to that of the specimens without stiffener and the results strength was smaller than the specimens with stiffener. With respect to the results of the specimens with stiffener, the strength increased more than the tests due to the effect of the attachment between steel plates and concrete and the assumptions applied to weld model of stiffener attached to the floor. Thus, it was expected that more accurate modeling of welding zone of stiffener and steel pate-concrete modeling would lead to the improvement of analysis results.

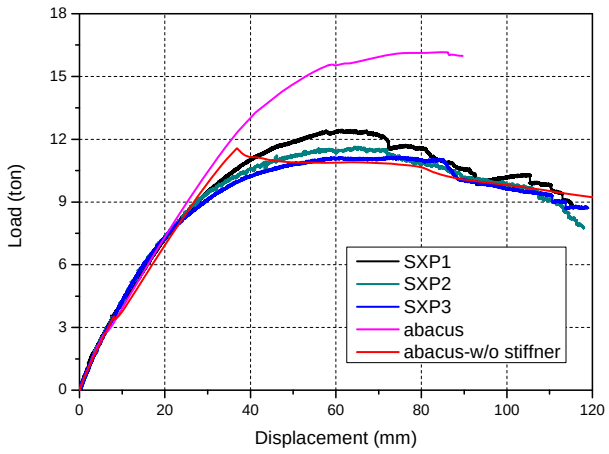

Figure 11. Comparison of load-displacement by test and analysis

5. CONCLUSIONS

In this study, to predict the behavior of SC shear wall structure accurately, by analysis SC shear wall specimens were manufactured and a lateral load test on specimens was conducted. In addition, a finite element analysis was conducted by modeling the specimens in real scale. The stress distribution, failure mode, buckling modes and load-displacement curve of specimens and the safety test results and analysis results of SC structure were compared. The following conclusions have been reached.

(1) As a result of the comparison between test results and analysis results regarding SC shear walls, it is known that the results of nonlinear analysis of stress, failure mode and buckling mode by three-dimensional elements depicts the actual behaviors of specimens accurately.

(2) As a result of the analysis of load-displacement by tests and analysis, the displacement and initial strength appear relatively similar to each other. Furthermore the result of the comparison of load-displacement curves show similar results in tests and analysis when specimens yield, which indicates that a finite element analysis of SC shear walls in fact depicts the actual behaviors well.

(3) In case of finite element analysis, the presence of reinforcement materials changes the strength interpretation. Thus, more accurate depiction of the attachment between concrete and stiffener and welding zone modeling is expected to produce more accurate analysis results.

(4) The attachment between steel plates and concrete in SC structure relies on studs and the gap between studs and the length of studs influence the behavioral characteristics of SC walls, which require careful attention. The reliability of the behavioral analysis of SC structure is expected to improve though further studies on the gap between studs and the length of studs.

Abstract: The approach as proposed in this paper is based on predicting the diagonal cracking strength, considered as the shear capacity of the brick panel and an amount of shear coming from the tie-columns due to dowel mechanism. In this type of structural members, tie-columns are used mainly to provide post-cracking deformation capacity by maintaining the integrity of the masonry after diagonal cracking.
Two analytical models (linear and non linear) are used to compute the dowel action coming from longitudinal reinforcements. To access the influence of the two models an experimental study is carried out on a half scale confined brick wall. The general applicability of the proposed approach regarding the maximum lateral resistance was confirmed by a good correlation between experimental data and calculated values which obeys to the linear model.
Keywords: Confined masonry, brick wall, tie-columns, dowel action, lateral resistance.

1. INTRODUCTION

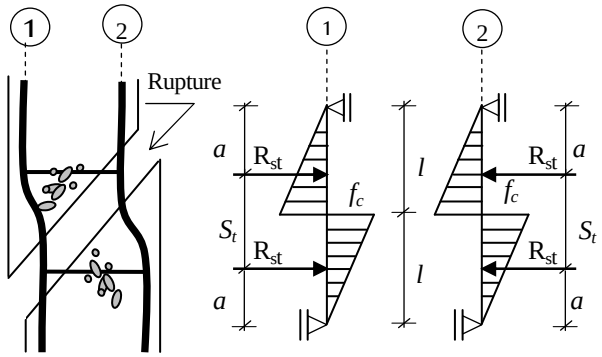
During earthquakes, when, the drift storey of confined masonry wall becomes large, tension in tie-columns' reinforcement dominates on both directions of imposed lateral displacements. At such level, the cracked masonry panel pushes the tie-column sideward inducing tension in the reinforcing bars. In other words, the RC confining elements prevent the collapse of the masonry and cause additional compression stress in the vertical and horizontal directions; hence a certain amount of additional shear can be transmitted by dowel action of the vertical bars. This mechanism occurs mainly at wall corners.

2. ANALYTICAL DEVELOPMENT

The dowel effect (Dowel action) in RC column and/or RC tie-column is a very complex phenomenon involving the shear resistance of longitudinal bars and their interaction with stirrups and concrete see Figure.1-a.

The problem can be reduced to a pure calculation of strength of materials, where, the flexion of longitudinal steel bars, the compression of the concrete surrounds them and tensions created by stirrups are considered together, see Figure.1-a and Figure.1-b.

The vertical tie-columns significantly improve the ductility of masonry walls, but have a little effect on the lateral shear resistance (≈20%, Umek 1971), then, it is more economic to reduce the web reinforcement ratio in tie-columns by increasing S_t the distance between two successive stirrups. S_t is usually considered equal to (3/4)*t* (Yoshimura *et al.,* 1996) or simply to "*t*" (Yoshimura *et al.*, 1996 & Goto *et al.*,1993), where "*t*" is the width of the tie-columns. It is also known that the shear cracks in the RC tie columns occurs at the four corners of the wall inclined by an approximate angle $\alpha = 45^{o}$ (Pillai and Kirk, 1988).



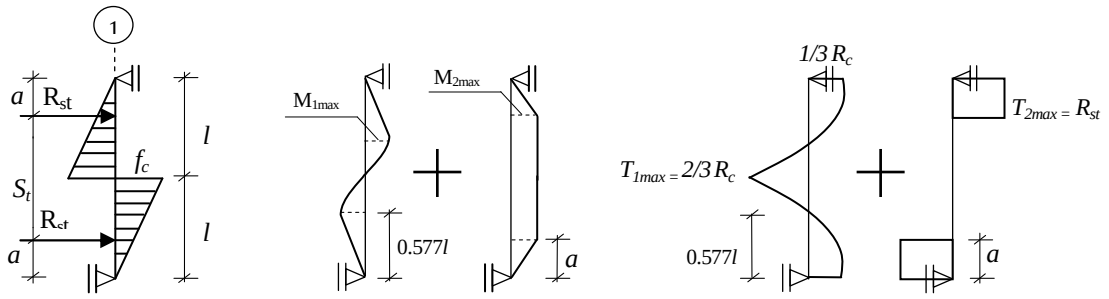


Figure 1-a Reactions on main bars which causes the dowel effect

According to the above reasoning, the shear crack would cross 1 or 2 stirrups at maximum (the stirrups are supposed positioned symmetrically from the inflection point of the bars presenting dowel action). The appropriate presentation of the dowel action phenomenon is clearly shown by the Figure1-a. This will result in moment and shear force distributions of the form shown in Figure1-b.

1) Flexural moment diagrams 2) Shear diagrams

Figure1-b Flexural and shear diagrams resulting from the dowel-action model

From the bending moment equilibrium:

$$M_{\max} = \frac{0.256}{f_c \phi} R_c^2 + \frac{2R_{st}}{f_c \phi} R_c - \frac{R_{st} S_t}{2} \qquad (1)$$

Where,
M_{max} = maximum external moment on the main bar.
$R_c = f_c \phi l /2$ = reaction of the concrete on the main bar.
f_c = compressive strength of concrete
ϕ = the main bar diameter
$R_{st} = f_{yt} A_{st}$ = reaction of the stirrup on the main bar.
(f_{yt} and A_{st} are the yield stress of stirrup and its section, respectively).
S_t= distance between two successive stirrups.

The internal moment in the main (longitudinal) bar is equal to:

$$M_{\max,b\,e} = z_e\ f_y = \frac{\pi \phi^3}{32} f_y \quad \text{for linear case} \qquad (2\text{-a})$$

$$M_{\max,b\,p} = z_p\ f_y = \frac{\phi^3}{6} f_y \quad \text{for nonlinear case} \qquad (2\text{-b})$$

$M_{max,b,e}$ and $M_{max,b,p}$ = maximum internal moment in the main bar for both cases linear and nonlinear, respectively. .
f_y = yield stress of the main bar.
Z_e and Z_p = Plastic and elastic section modulus, respectively (Figure 2)
f_y = yield stress of the main bar.
Equalizing the Eqs. (2-a) and (2-b) consecutively to the Eq. (1) gives:

$$\frac{0.256}{f_c \phi} R_c^2 + \frac{2 f_{yt} A_{st}}{f_c \phi} R_c - \frac{16 f_{yt} A_{st} S_t + \pi \phi^3 f_y}{32} = 0$$

for linear model (3-a)

$$\frac{0.256}{f_c \phi} R_c^2 + \frac{2 f_{yt} A_{st}}{f_c \phi} R_c - \frac{3 f_{yt} A_{st} S_t + \phi^3 f_y}{6} = 0$$

for nonlinear model (3-b)

After solving Eqs. (3-a) and (3-b) i.e (determination of the value of R_c), the maximum value of shear resistance due to the dowel action of one single bar is obtained by the superposition of shear force diagrams shown in Figure1-b, where:

$$T_{\max,b} = \max\left(\tfrac{2}{3} R_c, \tfrac{1}{3} R_c + R_{st}\right) \qquad (4)$$

$T_{max,b}$ = The maximum value of shear resistance due to the dowel action of one single bar on the dowel length 2l

Taking into account that, $R_c = f_c \phi\, l /2$, the value of the dowel length 2l is then deduced.

In case $2l \leq S_t$ (stirrups positioned outside of the dowel length), the stirrups will not contribute to the shear resistance due to dowel mechanism ($R_{st} = f_{yt} A_{st} = 0$), however, only the effect of concrete would be considered and the reaction of the concrete R_c will be recalculated consequently.

The shear resistance H_{cf} of 2n vertical bars, which represents the total lateral resistance induced by the tie-columns, is equal to:

$$H_{cf} = \sum_{i=1}^{2n} T_{\max,bi} \qquad (5)$$

n = the total number of longitudinal bars in each tie-column.

As a result, the maximum shear or lateral resistance of a confined masonry wall H_{wall} is then:

$$H_{wall} = H_m + H_{cf} \qquad (6)$$

Where;

1- Failure of the wall by diagonal splitting:

$$H_m = A_m \frac{f_{t1}}{b} \sqrt{\frac{\sigma_V}{f_{t1}} + 1} \quad \text{if} \quad \sigma_V \leq 0.5 \text{ MPa} \qquad (7.a)$$

(Bourzam et. al, 2008)

$$H_m = \frac{A_m}{b\left(1+\frac{f_{t2}}{f_m}\right)}\sqrt{f_{t2}^2+\sigma_V f_{t2}\left(1-\frac{f_{t2}}{f_m}\right)-\sigma_V^2\frac{f_{t2}}{f_m}}$$

if $\sigma_V > 0.5$ MPa (7.b)

2- Mortar-joint separation in stairs shape along the strut of the wall:

$$H_m = A_m(\tau_0 + \mu\sigma_V) \quad (8)$$

Where,

H_m = the shear resistance (lateral resistance) of masonry panel.

σ_V = the average compression stress on the brick panel due to vertical (axial) load V.

b= the shear stress distribution factor depends of the height to length ratio h/l of the brick panel (b= 1 for $h/l \le 1$, $b = h/l$ for $1< h/l <1.5$ and b=1.5 for $h/l \ge 1.5$) (Tomaževič, 1999).

A_m = the horizontal cross-section area of the masonry panel.

f_{t1} and f_{t2} = tensile strengths of masonry, where:

$f_{t1}=0.519P_d/A$ the average masonry tensile strength, obtained by diagonal compression test as specified by ASTM C1391) (P_d and A are the maximum diagonal compressive load and the test panel section, respectively).

$f_{t2} = 0.5187\, f_m \frac{P_d}{\left(f_m A - 1.683 P_d\right)}$ obtained by Mohr's failure theory (Yokel, 1976 and Sucuoglu, 1991).

f_m = the masonry compressive strength obtained by testing stack bonded prisms of five bricks according to the specifications of LUMB1, (1994).

τ_0 = the shear strength at zero pre-compression.

μ = the friction coefficient in mortar-brick interface.

The Coulomb failure mode (refer to Eq. (8)) is then valid for lower axial stresses σ_V or low quality of mortar joints. In case of lower axial loading, it is recommended to calculate the brick panel resistance H_m by both Eqs. (7-b) and (8) where the greater value of H_m will be considered in the rest of calculations.

3. EXPERIMENTS AND RESULTS

The test specimen is a 1/2 scale of a common confined masonry bearing wall with h/l ratio equal to 1.5 surrounded by RC tie-columns.

The panel of the wall is composite of Japanese solid clay brick units with 210x100x60 mm of nominal dimensions. The bricks are laid with plain cement mortar, with a joint thickness of 10 mm.

The surrounding frame which serves to confine the brick panel is made by reinforced concrete. Mechanical characteristics of used materials, details of dimension, arrangement of reinforcement and member sections are summarized in Table 1 and Figure 3.

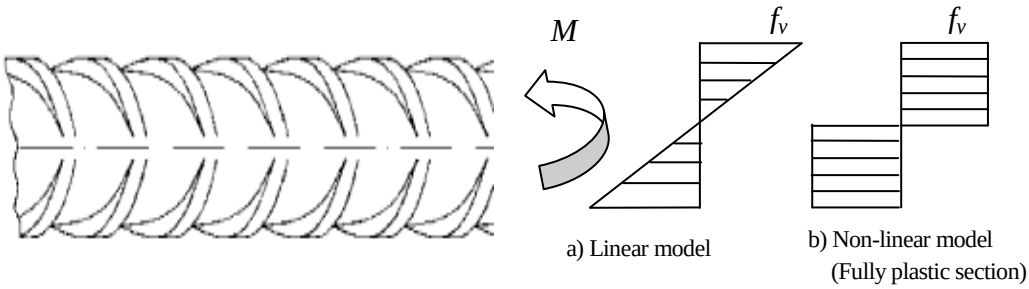

Figure 2 Internal repartition of stresses of main bars due to bending moment of linear and non linear models

The confined wall was tested in the laboratory of structural members of Kanazawa University by the loading system as shown in Fig.ure 4. The constant vertical load to simulate the dead load was represented by the weight of the top RC gravity beam which offered an axial stress of 0.1MPa.

The specimen was subjected to a quasi-static horizontal cyclic loading applied to the center of the top-beam by the mean of a horizontal hydraulic jack. The specimen was designed as a cantilever vertical structural element. The lateral displacement at the top of the wall was measured by two transducers of LVDT type.

Increasing the drift angle (displacement) gradually from 1/5000 the maximum resisting force of specimen was attained

4. CONCLUSIONS

It is concluded in the case of the linear model the contribution of tie-columns to the total shear capacity represents an average value of 38.1%. This ratio is greater when the non-linear model is adopted (44.5%). According to Umek (1971) almost 20% of the total resistance is attributed to both confinements, which means the linear model is more representative.

In the other hand, the analysis of the correlation of the theoretical predictions to the experimental values have shown that the linear model overestimates the real shear resistance (experimental value) by only 24.90% but the nonlinear model pushes this value to 32.45%.

In conclusion, in this type of structural member, confinements or tie columns do not acquire the possibility to be plastically hinged. The linear model is then the best representative.

Abstract: The Los Angeles Tall Buildings Structural Design Council and PEER Tall Buildings Initiative performance-based design guidelines for shear design of structural walls are reviewed. Provisions in the two documents are identical, except for the recommended capacity reduction factor ϕ, which is 1.0 for the LATBSDC document and 0.75 for the PEER document. Shear wall failure modes, test results, ACI 318-11 code provisions, and modeling approaches are reviewed to assess the current design approaches and to propose changes.

1. INTRODUCTION

Performance-based design of tall buildings is commonly based on the comparison of analysis demands and capacities for at least two hazard levels, service-level earthquake (SLE) and maximum considered earthquake (MCE). Service-level analysis is typically accomplished using a linear model of the building and a site-specific response spectrum analysis for a 43-year return period earthquake (50% probability of being exceeded in 30 years), although use of a nonlinear analysis is generally permitted. Three dimensional, nonlinear models of the building system are developed and subjected to seven or more pairs of earthquake records at the building base for the MCE analysis; MCE ground motions are defined in Chapter 21 of ASCE 7-05.

Acceptance criteria for various response parameters, including demand-to-capacity ratios for force-controlled components, plastic rotations and strain demands for deformation-controlled components, and story and residual drift limits are used as a basis to judge whether a building design complies with the expectation that the building performance will be equal to or better than the performance of a building meeting prescriptive code requirement (ASCE 7-05, Section 12.2.2). Consensus documents such as the Los Angeles Tall Buildings Seismic Design Council Guidelines (LATBSDC, 2011) and the PEER Tall Buildings Initiative Guidelines (Peer TBI, 2010) include example acceptance criteria for both SLE and MCE analyses. In the following paragraphs, example acceptance criteria for MCE are briefly reviewed.

Global Acceptance Criteria: Global acceptance criteria include story drift and residual drift are commonly expressed as (LATBSDC, 2011, Section 3.5.4.2; PEER TBI, 2010, Section 8.7):

$$\begin{aligned} \bar{\theta}_{max,\ transient} &\le 3.0\% \quad & \bar{\theta}_{max,\ transient,\ residual} &\le 1.0\% \\ \theta_{max,\ transient} &\le 4.5\% \quad & \theta_{max,\ transient,\ residual} &\le 1.5\% \end{aligned} \tag{1}$$

Where $\bar{\theta}$ is the mean of the maximum absolute values obtained from seven or more pairs of earthquake records applied to the building and θ is the maximum absolute value obtained for a single pair of earthquake records applied to the building.

Deformation-controlled Acceptance Criteria: Criteria for deformation-controlled components are typically take the form of:

$$\begin{aligned} \bar{\theta}_{plasitc,\ max,\ transient} &\le \theta_{limit} \\ \bar{\varepsilon}_{max,\ transient} &\le \varepsilon_{limit} \end{aligned} \tag{2}$$

where $\bar{\theta}$ and $\bar{\varepsilon}$ are the mean of the maximum absolute values of plastic rotation and total axial strain obtained from seven or more pairs of earthquake records applied to the building and θ_{limit} and ε_{limit} are a limiting values of plastic rotation and axial strain. Limiting values of rotation and demand are determined using available test data and judgment, e.g., as included in ASCE 41-06 (2013) for reinforced concrete columns, beams, and slender structural walls. The value of limiting concrete compressive strain depends on how the strain value is obtained (e.g., as an average value over a height that is selected to be approximately equal to the plastic hinge length), and how modeling uncertainty is treated (e.g., the potential bias in the model strain value). Commonly used values are in the range of: $\bar{\varepsilon}_{max,\ t} \le 0.05$ and $\bar{\varepsilon}_{max,\ c} \le -0.015$.

Force-controlled Acceptance Criteria: Acceptance criteria for force-controlled components can be represented as:

$$(1+\beta)\bar{F}_u \le \phi F_{n,e} \quad (3)$$

where β accounts for uncertainty in the maximum mean force demand $\bar{F}_u$, and strength reduction factor ϕ accounts for uncertainty in nominal strength for expected material properties $F_{n,e}$. Nominal strengths are typically computed using ACI 318-11 provisions. Values for β and ϕ depend on the whether the element is a "critical" on "non-critical". The LATBSDC and PEER TBI Guidelines define critical actions as those "*in which the failure mode poses severe consequences to the structural stability under gravity and/or lateral loads*". Ideally, the β-value could be determined directly from the variation in the maximum values obtained from the analysis results; however, because it is common to use only seven (and certainly less than 15) pairs of earthquake ground acceleration histories applied at the base of the building, little confidence can be placed on the computed values of the mean and standard deviation. Studies (PEER, TBI, 2010) have shown that the true coefficient of variation in force-controlled actions due to record-to-record variability is on the order of 0.4; therefore, both the LATBSDC and PEER TBI Guidelines recommend using β = 0.5. The slightly higher value (0.5 vs 0.4) is used to account for modeling uncertainties and uncertainty in the mean value. The LATBSDC (2011) and PEER TBI (2010) Guidelines are effectively identical, except for the recommended value of ϕ; with the LATBSDC Guidelines (2011) recommend ϕ = 1.0, whereas the PEER TBI Guidelines (2010) recommend using the ϕ-value from ACI 318. For wall shear design, the ACI 318 ϕ-value for shear is 0.75; therefore, shear design of a structural wall according to PEER TBI will be 1.0/0.75 = 1.33 times thicker than the LATBSDC designed wall. For the relatively thick walls required for tall buildings, e.g., 1m to 1.33m thick, a 33% increase in wall thickness is significant.

Given the difference in the ϕ-values for the LATBSDC and PEER TBI Guidelines, and the significant impact this difference has on wall design, a study is undertaken to review shear design of structural walls using a reliability-based approach.

2. SHEAR DESIGN OF STRUCTUAL WALLS

2.1 Strength Design Requirements

Code based shear design of structural walls is based on satisfying:

$$\phi V_n \ge V_u \quad (4a)$$

Where V_n is calculated using the ACI 318-11 nominal shear strength equation:

$$V_n = A_{cv}\left[\alpha_c \lambda \sqrt{f_c'} + \rho_t f_y\right] \le A_{cv}\left[0.67\sqrt{f_c'}MPa\right] \quad (4b)$$

Where f_c' is specified compressive strength of concrete, f_y is specified yield strength of reinforcement, A_{cv} is gross area of concrete section bounded by web thickness and length of section in the direction of shear force considered, α_c is coefficient defining the relative contribution of concrete strength to nominal wall shear strength, and ρ_t is ratio of area of distributed transverse reinforcement to gross concrete area perpendicular to that reinforcement. Coefficient α_c is 3.0 for $h_w/l_w \le 1.5$, is 2.0 for $h_w/l_w \ge 2.0$, and varies linearly between 3.0 and 2.0 for h_w/l_w between 1.5 and 2.0. ACI 318-11 also limits the maximum shear stress on any one wall to $v_n \le 0.83\sqrt{f_c'}MPa$ and the average shear stress on all walls providing lateral force resistance to $v_n \le 0.67\sqrt{f_c'}MPa$. Shear demand V_u is determined using ASCE 7-05 provisions using either the equivalent lateral force procedure (Section 12.8), modal response spectrum analysis (Section 12.9), or seismic response history procedures (Chapter 16).

The ACI 318-11 Equation for V_n is a relatively simple expression and does not include factors that are known to have an impact on shear strength, such as axial load and the quantity of boundary transverse reinforcement. However, until more comprehensive relations are developed and validated, use of the current ACI 318 equation, which has remained effectively unchanged since it was introduced in ACI 318-83, is common (LATBSDC, 2011; PEER TBI, 2010). As is common with code equations used to determine nominal strength for design of new buildings, the ACI 318 wall shear strength equation tends to produce a low estimate of the actual shear strength to ensure a low probability of wall shear failure in the Design (Basis) Earthquake. For design of new buildings using prescriptive design approaches, nominal material properties are used and code specified strength reduction factors are applied, i.e., $\phi = 0.75$.

As noted in the introduction, for performance-based seismic (or non-prescriptive) design, the LATBSDC (2011) and PEER TBI (2010) documents use Equation (3), which is a slightly modified form of Equation (4a) to account for use of a response history analysis procedure. Equation (3) is restated here as:

$$\phi \bar{F}_{n,e} \ge \gamma \bar{F}_u \quad (5)$$

where γ accounts for uncertainty in the maximum mean force demand $\bar{F}_u$, and strength reduction factor ϕ accounts for uncertainty in mean nominal strength for expected material properties $\bar{F}_{n,e}$.

Equation (5) is used as a basis to apply reliability-based design approach to assess shear design of structural walls. The objective is to evaluate the probability of shear failure given distributions and uncertainties in demand and capacity, and to determine if it exceeds a limiting value, taken as 10% for MCE demands.

2.2 Wall Failure Modes, Capacities, and Demands

Reliability-based design requires a review of shear wall behavior (failure modes), wall capacities, both force and deformation using available test data, and wall demands determined from response history analysis. Each of these topics is reviewed in the following subsections.

(a) Wall behavior: Three structural wall failure modes, similar to those proposed for columns by Elwood and Moehle (2008), are depicted in Fig. 1; (a) shear, (b) flexure-shear, and (c) flexure. Flexural failures are typically characterized by concrete crushing followed by buckling of boundary vertical reinforcement and eventual fracture of boundary vertical reinforcement. Shear failures, in the absence of sliding shear failures, are typically characterized by either diagonal tension failure or crushing of concrete along diagonal compressive struts within the wall web (or web crushing). For flexure-shear failure, as nonlinear flexural deformation (ductility) increases, flexural and bond crack widths grow and the expectation is that shear resistance will degrade, leading to shear failure. Flexural-shear failures are likely to look like flexural failures, i.e., concrete crushing followed by buckling of boundary vertical reinforcement and/or diagonal tension failures (Tran, 2012). For both flexure and flexure-shear failures, the compressed boundary region may buckle in - or out-of-plane depending on the ratio of wall thickness to concrete side cover, axial load, and shear demand (Tran and Wallace, 2012).

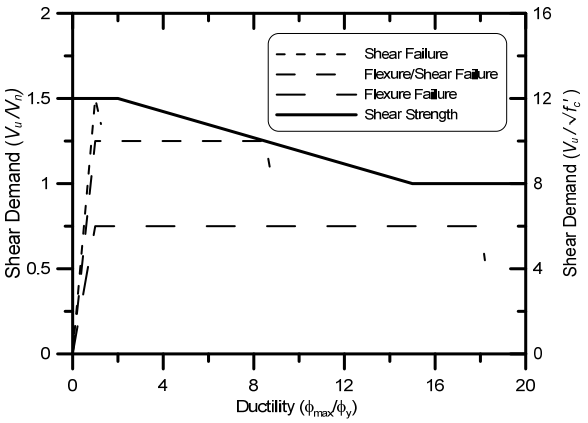

Figure 1 Wall Shear Behavior: (a) Shear, (b) Flexure-shear, (c) Flexure

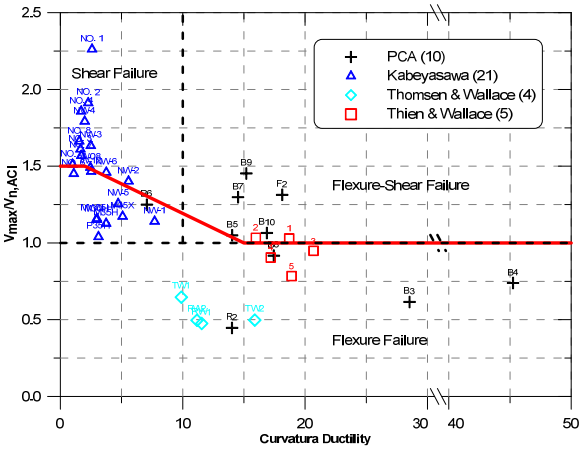
(b) Wall Capacity (Test Data): Test data for relatively slender, well-detailed, walls were compiled to assess the relationship shown in Fig. 1. For this study, well-detailed walls were defined as walls with area of boundary transverse reinforcement at least equal to one-half of that required by ACI 318-11 and ratio of vertical hoop/crosstie spacing to vertical boundary bar diameter (s/d_{bl}) less than 8 (ACI 318-11, 21.9.6.4 limits this ratio to 6). Failure modes for each test also are characterized based on information reported in the literature. Plastic rotation θ_{pl} and curvature ductility $\mu_\phi = \phi_u/\phi_y$ for each test were calculated using the following relation (e.g., see Wallace, 1994):

$$\delta_u = \delta_y + \theta_{pl}\left(h_w - l_p/2\right) = \delta_y + l_p\left(\phi_u - \phi_y\right)\left(h_w - l_p/2\right) \quad (6)$$

where δ_u is the lateral displacement at significant strength loss, δ_y is the yield displacement, ϕ_u is the ultimate curvature, ϕ_y is the yield curvature, h_w is the wall height, and l_p is the plastic hinge length. Values for δ_u, δ_y, and ϕ_y are determine directly from test data; plastic hinge length for the well-detailed walls was taken as one-half the wall length $(l_w/2)$.



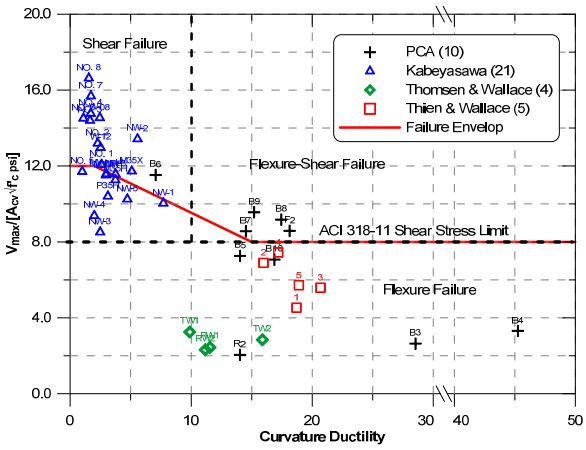


Fig. 2(a) Wall curvature ductility versus $V_{u,test,max}/V_n$

Fig. 2(b) Wall curvature ductility versus $V_{u,test,max}/\sqrt{f'_c}$

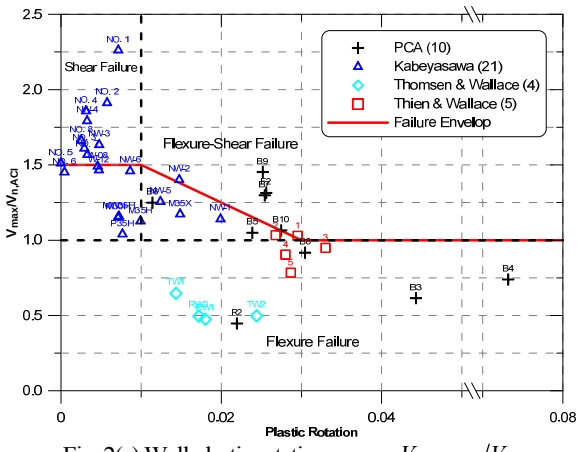

Fig. 2(c) Wall plastic rotation versus $V_{u,test,max}/V_n$

Results for the test database are presented in Fig. 2, with V_{max} is the maximum shear measured in the test. For the 22 test specimens with $\mu_\phi = \phi_u/\phi_y < 10$, the following observations are noted from Fig. 2(a): (a) mean value and

coefficient of variation of V_{max}/V_n are 1.47 and 0.21, (b) mean value and coefficient of variation of μ_ϕ are 3.2 and 1.8, and (c) majority of data points below the shear strength trend line were for walls with barbell cross sections subjected to biaxial loading which failed due to web crushing. For the 11 test specimens with $V_{max}/V_n \le 1.0$ and $\mu_\phi = \phi_u/\phi_y \ge 10$ all failures except B6 were characterized as "flexure". Test specimens in the transition region (flexure-shear failures) with $V_{max}/V_n > 1.0$ consist primarily of barbell-shaped wall cross-sections designed according to ACI 318-95 or earlier codes in which web-crushing failures were observed (e.g., B5-B9, F2). Such walls typically have substantial flexural overstrength, resulting in higher wall web shear demands than were used for design (Wallace and Orakcal, 2002). Current US construction practice is to use rectangular (versus barbell) wall cross sections and for ACI 318-99 and later versions, code provisions were changed to reduce flexural overstrength and thus the potential for web crushing failures.

Test results are presented in a slightly modified format in Figures 2(b) and 2(c), with vertical axis is normalized shear stress $V_{max}\Big/\left(A_{cv}\sqrt{f_c'}\right)$ for Fig. 2(b) and plastic rotation θ_{pl} on the horizontal axis for Fig. 2(c). Trends observed for Fig. 2(b) are similar to Fig. 2(a), with shear failures observed for walls with demands substantially above the ACI 318-11 limiting shear stress of $V_{max}\Big/\left(A_{cv}\sqrt{f_c'}\right) = 0.67$ and flexure failures displaying modest to large curvature ductility μ_ϕ for demands less than the ACI limiting shear stress. Results presented in Fig. 1(c) indicate modest plastic rotation θ_{pl} capacity even for walls with shear failure and plastic rotation capacities of 0.02 to 0.03 for most walls with flexure failure. Top drift ratios at yield for wall tests with $1.5 \le h_w/l_w \le 3.0$ were typically 0.005 to 0.01, resulting in roof drift ratios at significant strength loss of 0.025 to 0.035; larger roof drift ratios are likely for more slender walls in very tall buildings.

Test parameters and results for walls with shear failure are examined more closely to evaluate their relevance to current US practice for tall buildings. Since shear strength is not impacted significantly by the detailing provided at wall boundaries, the restriction that the wall boundary be "well-detailed" is relaxed; the database used here is the same as that used by Wallace (1998) and includes 37 wall tests. Ratios of the test measured maximum shear V_{max} to the computed ACI 318-11 strength V_n using equation (4b) and plotted versus $\rho_t f_y / f_c'$. Mean test shear strength is $1.57\,V_n$ with a coefficient of variation of only 0.20. Results presented in Fig. 3 reveal that ACI 318-11 Equation (21-6), Equation (4b) in this paper, significantly underestimates wall shear strength, with a slight trend for less conservatism as the ratio of $\rho_t f_y / f_c'$ increases from 0.02 to 0.16.

The test results presented in Fig. 3 include tests with quantities of web reinforcement that significantly exceed that required by ACI 318-11, i.e., the value of $\rho_t f_y / f_c'$ exceeds the value required to reach the ACI 318-11 limiting shear stress of $V_n \le A_{cv}\left[8\sqrt{f_c'}\,psi\right]$. To assess the potential bias in the mean and COV associated with including these data, the test results were sorted to into bins with $V_n \le 1.1\left[0.67\sqrt{f_c'}\,MPa\right]A_{cv}$ and $V_n > 1.1\left[0.67\sqrt{f_c'}\,MPa\right]A_{cv}$. Mean and COV for the entire database and the two bins, along with information on concrete strength, are given in Table 1 and indicate no significant bias.

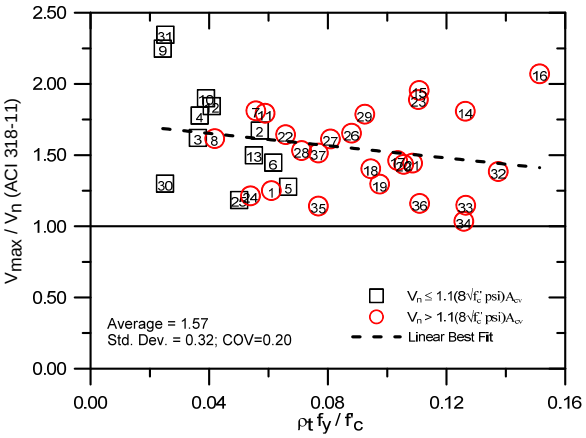

Figure 3 Wall tests with shear failure – $V_{test}/V_{n,ACI}$ Wall shear strength versus $\rho_t f_y / f_c'$

Table 1 Wall Shear and Concrete Strength

Database	Tests	$V_{test,max}/V_n$		f_c'	
	#	Mean μ	COV σ	Mean μ	COV σ
All	37	1.57	0.20	11.05	0.23
$V_n \le 1.1\left[0.67\sqrt{f_c'}\right]A_{cv}$	12	1.68	0.22	10.81	0.21
$V_n > 1.1\left[0.67\sqrt{f_c'}\right]A_{cv}$	25	1.52	0.19	11.27	0.24

It is noted that the mean values of concrete compressive strength and reinforcement yield strength for the 37 tests were $\mu_{concrete} = 1.1 f_c'$ and $\mu_{steel} = 1.05 f_y$. Mean and coefficient of variation reported by Nowak et al (2008) for concrete compressive strengths of 8 to 10 ksi (55.2 to 69.0 MPa) in the range of 1.1 to 1.16 and 0.09 to 0.12, whereas values for reinforcement reported by Bournonville et al (2004) for #7 to #10 bars (22.2mm to 32.3mm diameter bars) are about 1.12 to 1.14 and 0.02 to 0.03.

(c) Nonlinear Wall Modeling for Response History Analysis and Wall Shear Demands: Common practice is to model axial-bending behavior independent of shear behavior using beam-column fiber (BC-Fiber) elements with concrete and rebar fibers with defined uniaxial material relations. Use of BC-Fiber models is attractive because: (1) element yield moment and bending stiffness automatically vary with level of axial load, (2) element overstrength depends directly on element demands and defined material relations, (3) migration of the neutral axis along the wall cross-section during loading and unloading varies with applied P-M, (4) wall axial growth or shortening are captured, and as a consequence of (1) through (4), (5) interactions with connecting elements (e.g., beams and slabs), both in the

plane of the wall and perpendicular to the wall, are captured. Nonlinear shear behavior is typically modeled using multi-linear segment backbone relation defined by shear strength associated with inclined cracking, yielding, and degrading strengths (e.g., ASCE 41 backbone relations).

As noted in the introduction, values for $\gamma = (1 + \beta_{tot})$ and ϕ depend on the whether the element is a "critical" on "non-critical". Studies (PEER TBI, 2010) have shown that the true coefficient of variation in force-controlled actions due to record-to-record variability is on the order of 0.4; therefore, both the LATBSDC and PEER TBI Guidelines recommend using γ = 1.5. The slightly higher value (1.5 vs 1.4) is used to account for modeling uncertainties and uncertainty in the mean value.

The PEER TBI notes that: "*The use of use of 1.3σ, where σ is the standard deviation obtained from Maximum Considered Earthquake response analysis is permitted for specific cases, such as beam shear in a moment-resisting frame, where localized or global mechanisms may limit the force value to a rather stable maximum value and inflation to 1.5 times the mean value may be too large. This would not, in general, apply to shear in structural walls*". The last sentence is included despite the fact that nonlinear modeling of axial-bending behavior over the entire wall height, nonlinear modeling of coupling beams, and nonlinear modeling of outrigger slabs (if they are included in the model) provide a fuse to limit wall shear demands (Salas, 2008). Additional studies are needed to assess wall shear dispersion for tall buildings utilizing structural walls for lateral-force resistance (i.e., core wall buildings) using appropriate sets of ground motion records; until additional information is available, continued use of *1.5σ* on force-critical elements is likely to continue. The appropriate multiplier on capacity, ϕ, is examined using a reliability-based analysis is the following section.

2.3 Reliability-Based Design

A framework is developed for reliability-based assessment of structural wall failure based on Equation (5) using Monte Carlo Simulation. The objective of this preliminary study, given a mean demand multiplier of $\gamma \bar{F}_u = (1 + \beta)\bar{F}_u$, what is the appropriate multiplier ϕ on mean capacity $\bar{F}_n$ mean ($\phi \bar{F}_n$) to limit collapse probability to an acceptable level (90% reliability against collapse) under MCE demands. For this preliminary study, all random variables associated with capacity and demands are assumed to be normally distributed (it is noted a Beta-distribution is more appropriate for reinforcement).

Wall shear strength is based on ACI 318-11 requirements, i.e., using Equation (4b). Assuming negligible variability in cross-section properties (i.e. A_{cv} and ρ_t constant), mean overstrength associated with the 37 shear-controlled tests are:

$$\begin{aligned} \mu_{vn} &= V_{\max,test}/V_n = 1.73 \qquad \beta_{vn} = 0.22 \\ \mu_{vne} &= V_{\max,test}/V_{ne} = 1.57 \qquad \beta_{vne} = 0.20 \end{aligned} \tag{7}$$

Where μ_n and μ_n are the mean values for nominal and expected material properties, respectively, and β_{vn} and β_{vne} are the coefficients of variation (cov). For the 37 tests, expected material properties were approximately $f'_{ce} = 1.10 f'_c$ and $f_{ye} = 1.05 f_y$; therefore, the mean values are related by:

$$\mu_{vn} = \left(\sqrt{1.1}\right)(1.05)(\mu_{vne}) \tag{8}$$

The square root on the concrete term is because wall nominal shear strength (V_n) according to ACI 318-11 is related to $\sqrt{f'_c}$. The dispersion values of 0.20 and 0.22 for expected and nominal properties, respectively, is relatively low for brittle failure modes of reinforced concrete members; therefore, for this preliminary study, dispersion values β_{vn} and βvne are assumed to be 0.3. Examination of a larger test database is needed to resolve this issue for typical materials used for tall buildings.

As discussed previously, for collapse assessment, shear demands in PEER TBI and LATBSDC are taken as:

$$(1 + \beta)\bar{F}_u = 1.5\bar{F}_u \tag{9}$$

With the design objective of:

$$\phi V_n \geq 1.5\bar{F}_u \tag{10}$$

Therefore, for the purpose of this reliability study, demand is defined as:

$$\bar{F}_u = \frac{\phi V_n}{1.5} \quad and \quad \bar{F}_{ue} = \frac{\phi V_{ne}}{1.5} \tag{11}$$

Nominal material properties are used to define $\bar{F}_u$ and expected (mean) material properties are used to define $\bar{F}_{ue}$.

For capacity, mean values and dispersion are described by Equation (7), with expected concrete and steel strengths treated as random variables. Given these distributions, the reliability analysis assesses the following relation using Monte Carlo Simulation:

$$Reliability = P\left[V_{\max} \geq \bar{F}_u\right] \tag{11}$$

Monte Carlo Simulation is used to predict the reliability. By determining an adequate distribution for each of the random variables that make up the capacity and demand as described above, random sampling may be performed over an acceptable number of iterations to obtain dependable results. Dependable results are determined by convergence of a solution as the number of iterations is increased.

2.4 Application: Shear Reliability Assessment

Reliability analysis is performed on the following rectangular wall using the following values: f'_c=8 ksi (55.2 MPa), f_y=60 ksi (414 MPa), ρ_t= 0.011, and A_{cv} = 30" x 360" = 10,800 in^2 (0.76m x 9.14m = 6.97 m^2).

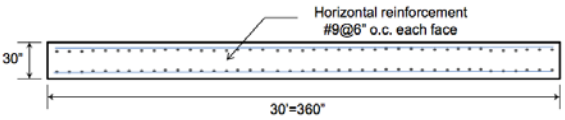

Figure 4 Wall Section for Reliability Analysis (#9@6" or 28.7mm diameter bar @152.4mm)

Reliability results are summarized in Table 2 for various criteria. Values for expected concrete compressive $\left(f_{ce}^{'}=1.13f_{c}^{'}\right)$ and reinforcement yield $\left(f_{ye}=1.13f_{y}\right)$ strengths, along with COV (0.10 and 0.02) are taken based on results presented by Nowak et al (2008) and Bournonville et al (2004), and are slightly higher than reported for the shear-controlled tests. The results presented in Table 2 indicate that reliability exceeding 94% can be achieved for all cases. It is noted that, expected material properties used in the LATBSDC (2011) or PEER TBI Guidelines are higher, i.e., $f_{ce}^{'}=1.3f_{c}^{'}$ and $f_{ye}=1.17f_{y}$. Assuming dispersions (cov) of 0.2 and 0.1 for concrete and steel, respectively, the reliabilities are lower slightly lower for Design Cases II and IV in Table 2. To obtain a reliability factor of 90% for Design Case IV requires use of $\mu_{vne}=V_{\max,test}/V_{ne}=1.35$, which is a low overstrength value Equation (4b).

Table 2 Wall Shear Reliability

	DESIGN CASE			
PARAMETER	I	II	III	IV
CRITERIA	$\phi F_n=1.5\bar{F}_u$	$\phi F_{n,e}=1.5\bar{F}_u$	$\phi F_n=1.5\bar{F}_u$	$\phi F_{n,e}=1.5\bar{F}_u$

3. CONCLUSIONS

The Los Angeles Tall Buildings Structural Design Council and PEER Tall Buildings Initiative performance-based design guidelines for shear design of structural walls are reviewed. Provisions in the two documents are identical, except for the recommended capacity reduction factor ϕ, which is 1.0 for the LATBSDC document and 0.75 for the PEER document. Shear wall failure modes, test results, ACI 318-11 code provisions, and modeling approaches are reviewed to assess the current design approaches and to propose changes. Based on the study, the following conclusions are reached:

- Flexure failures with curvature ductility capacity exceeded approximately 15.0 and plastic rotation capacity exceeding nearly 0.025 were reported for all well-detailed walls with ACI 318-11 $V_n \le 0.67A_{cv}\sqrt{f_c^{'}}$ MPa. Walls not achieving these deformation capacities, the walls tested by Thomsen and Wallace (2004), had approximately one-half the area of boundary transverse reinforcement required by ACI 318-11.
- Thirty-seven wall tests were categorized as shear failures. In all tests, $V_{test,max}/V_{n,ACI}>1.0$, with mean nominal shear strength of $1.57V_{n,ACI}$ and coefficient of variation of 0.20. For all walls, $V_{max,test}>0.67A_{cv}\sqrt{f_c^{'}}$ MPA. Curvature ductility for all tests were less than 10.0 (and generally less than 5.0) and plastic rotation capacities were less than 0.01.
- Tests categorized as flexure-shear failures all had $V_{test,max}/V_{n,ACI}>1.0$. Curvature ductility for these walls was generally between 5.0 and 15.0 and plastic rotations were generally between 0.01 and 0.025.
- Continued use of demands equal to $1.5\bar{F}_u$ is likely until studies are conducted to assess the role of various wall modeling parameters (e.g., component stiffness, reinforcement yield, material overstrength, and redistribution) and ground motion parameters (e.g., number of records used and scaling process). It would appear that use of a lower multiplier on mean demand is appropriate for walls that yield in flexure with shear demands $V_n \le 0.67A_{cv}\sqrt{f_c^{'}}$.
- Material overstrength values should modified to depend on design concrete compressive strength, with expected values of $f_{ce}^{'}=1.2f_{c}^{'}$ for $f_{c}^{'}<6$ ksi (48 MPa) and $f_{ce}^{'}=1.10f_{c}^{'}$ for 6 ksi (48 MPa) $<f_{c}^{'}<12$ ksi (83 MPa).
- Use of $\phi F_{n,e}=1.5\bar{F}_u$, with ϕ=1.0, $f_{ce}^{'}=1.3f_{c}^{'}$, and $f_{ye}=1.17f_{y}$, as recommended by the LATBSDC Guidelines, along with the assumption of normally-distributed random variables, produces the highest probability of failure, but it is still significantly less than 10%. Use of ϕ=0.75 appears excessively conservative.
- Data presented in Figures 2(a) through 2(c) provide valuable information for modeling wall behavior. Efforts are needed continue and expand data sharing to enable rapid progress to mitigate losses in earthquakes.

Abstract: Static loading tests of RC shear walls with diagonally arranged two openings were carried out to grasp the seismic performance. Specimens were designed to be the flexural failure mode and the variable investigated was the opening layouts. In this paper, the experimental results on failure mode, hysteresis characteristic and deformation capacity are compared with the shear failure mode specimens tested by the authors in 2010, which have the same configuration, opening layout and bar arrangement but the different shear-span ratio. As the result, the deformation capacity of RC shear walls with openings arranged adjacent to the boundary column failing in flexure was lower than that failing in shear because the shear failure occurred at bottom of the column adjacent to the opening.

1. INTRODUCTION

In Japan, the shear strength of reinforced concrete (RC) shear walls with openings is estimated by multiplying the strength of the shear walls without opening by a reduction factor based the opening details. However, according to the existing experimental results and the actual damages under real seismic forces, the behavior of RC shear walls with multi-openings is very complex. Especially, the shear strength, hysteresis characteristics, failure mode and deformation capacity of RC shear walls with several opening layouts are more significantly influenced than specified by the simplified methods in the AIJ standard for RC buildings (2010). Moreover, little quantitative evaluation for the seismic performance of the shear walls with multi-openings has been done so far.

The main objective of this study is to propose the quantitative evaluation for RC shear walls with multi-openings. Therefore, static loading tests of RC shear walls were carried out to investigate basic performance under seismic loadings from 2006 to 2009 (Sakurai et al. 2008, Sakurai et al. 2008 and Sakurai et al. 2010). As a result, their seismic performances were clarified when failing in shear. On the other hand, there are few studies on RC shear wall with openings when failing in flexure.

The static loading tests of RC shear walls were carried out to grasp flexural failing behavior. Comparing specimens in 2009, the specimens in 2010 had the same configurations, opening layout and bar arrangement but the different shear span ratios. In this case, the result showed that the specimen without opening had flexural failing behavior. While the specimen with multi-openings failed in shear because its shear strength deteriorated under the influence of openings.

In this paper, the results of static loading tests of RC shear walls with multi-openings designed to have flexural failure mode are described. Then the experimental results on failure mode, hysteresis characteristic and deformation capacity were compared with those of shear walls failing in shear tested in 2010.

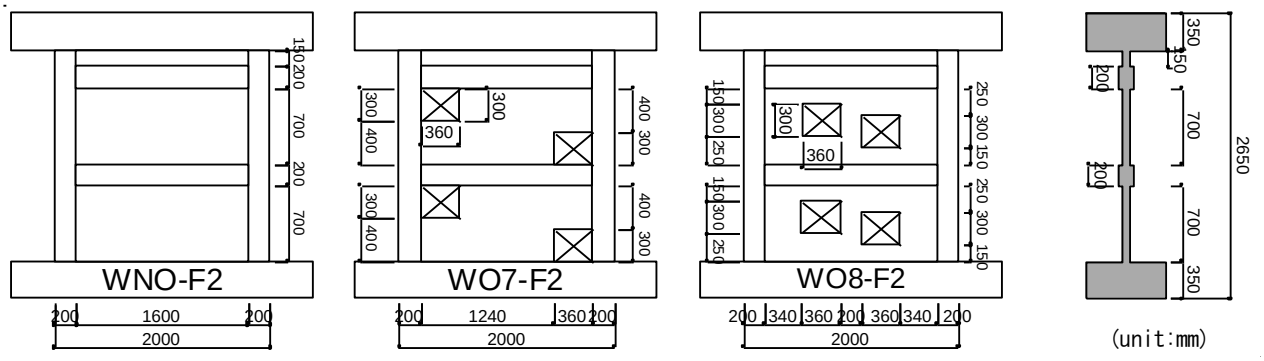

Figure 1 Specimens

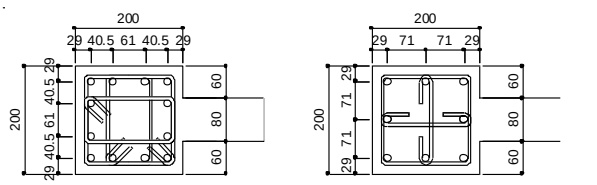
2. EXPERIMENTAL PROGRAM

2.1 Specimens



A total of three specimens of RC shear walls without or with opening were tested, which were one-third scale models simulating the lower 2.3 stories of multi-story shear walls in a medium-rise RC building. Details of the section and configuration of specimens are shown in Table 1 and Fig.1. Each specimen was based on previous test by the authors (Sakurai et al. 2008, Sakurai et al. 2008 and Sakurai et al. 2010). Variables investigated were the layout of the openings. Specimen WNO-F2 without opening was the standard specimen and Specimens WO7-F2 and WO8-F2 had two openings located diagonally. As shown in Fig.1, the diagonal openings in Specimen WO7-F2 were located at the boundary column while those in Specimen WO8-F2 were located at the center of the wall. The equivalent perimeters ratios of openings were almost the same for all specimens, i.e. about 0.4.

The experimental results of RC shear walls with multi-openings in 2010 showed shear failing behavior. Therefore, in this test, the number of longitudinal bars as well as their specific yield strength was reduced compared with the specimens tested in 2010 to have flexural failure mode.

The mechanical properties of materials used are listed in Tables 2 and 3.

2.2 Loading Method

The loading apparatus used in this test is shown in Fig.2. The wall specimens were loaded with horizontal shear reversals applied by a manual jack of 1,000kN capacity and a constant axial force of 442kN by two vertical manual jacks of 2,000kN capacity for each. During the testing, an additional moment was also applied to the top of specimens using vertical jacks to keep the prescribed shear-span ratio of 1.80. The loading was conducted by controlling the relative wall drift angle, R, given by the ratio of the height of corresponding to the measuring point of horizontal displacement at the top of the specimen, h, to the horizontal deformation, δ, i.e. R=δ/ h.

unit: mm, Fc=27MPa, The steel grade of all bars is SD295A.

2.3 Measurement

Displacement transducers were used to measure horizontal displacement of the upper stub, longitudinal deformation of column and deformation of wall panel. The strain of longitudinal and transverse reinforcement of columns and walls were measured by using strain gauges. In addition, the crack widths were measured by using crack scale at the peak of each loading and unloading cycles.

3. EXPREIMENTAL RESULT

3.1 Damage Process and Hysteresis Loop

Cracking patterns of each specimen after the loading cycle of 1/100 rad. are shown in Fig.4. The loading toward the north direction (Fig. 3) is defined as the positive loading while the loading toward the south direction is the negative loading. The shear force versus drift angle relationships of specimens are shown in Fig.5. In this figure, the ultimate flexural strength calculated by Eq. (1) is shown by horizontal line. The results of specimens tested in 2010 failing in shear are also shown to compare in Figs.4 and 5.

$$Q_{mu} = (a_t \cdot \sigma_y \cdot l_w + 0.5a_w \cdot \sigma_{wy} \cdot l_w + 0.5N \cdot l_w) / h_w \quad (1)$$

For each specimen, the initial crack occurred at the wing wall and column in the first story in the loading cycle of 1/800 rad. The flexural cracks increased at the column in

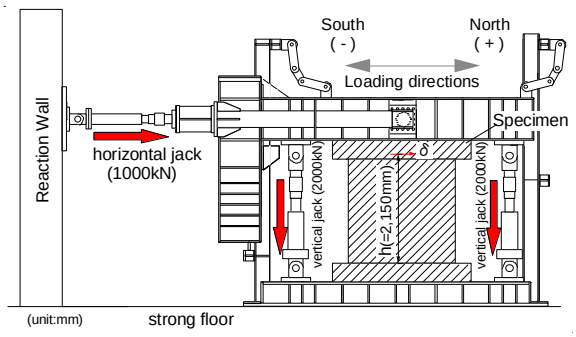

Figure 3 Loading apparatus

Table 2 Properties of steels

Steel bar		Yield strength (MPa)	Young's modulus (GPa)	Ultimate strength (MPa)
D6 (SD295A)	Wall reinforcement, Tie, Stirrup	338	160	384
D10 (SD295A)	Beam reinforcement, Bar around opening	347	185	408
D13 (SD295A)	Column reinforcement	343	199	483

Table 3 Properties of concretes

Concrete		WNO-F2	WO7-F2	WO8-F2
σ_B (MPa)	1st story	27.7	27.2	29.6
	2nd story	25.6	26.5	28.4

the first story in the loading cycle of 1/400 rad., and new cracks occurred in wing wall of the second story. In the loading cycle of 1/200 rad., the cracks propagated throughout the wall and the column and the longitudinal bars of the tensile column were yielded.

In Specimen WNO-F2 without opening, the flexural cracks at middle of the tensile column of the first story were propagated for the loading cycle of 1/100 rad., and the shear cracks at bottom of the compressive column of the first story occurred for loading cycle of 1/67 rad.. Then, the maximum shear force reached 375.5kN at R of 1/50 rad., and -379.5kN at R of -1/50 rad., and shear strength deterioration occurred by failing in shear and buckling of the longitudinal bars at the column in compression for the loading cycle of 1/40 rad.. In Specimen WNO-F tested in 2010, the longitudinal bar at the columns yielded at R of 1/200 rad., and the maximum shear force reached 481.5kN at R of 1/100 rad., and -477.0kN at R of -1/100 rad.. Then, the wall panel at the first story failed in shear and the shear strength deterioration occurred for the loading cycle of 1/67 rad.. Comparing specimen WNO-F, it was suggest that the deformation capacity of Specimen WNO-F2 was enhanced by reducing the amount of the longitudinal bars.

In Specimen WO7-F2 in which diagonal openings were arranged adjacent to the boundary columns, the maximum shear force reached 315kN at R of 1/200 rad., and -349.5kN at R of -1/100 rad.. Then, the flexural cracks at middle height of the tensile column propagated in the first story, and the shear failure occurred at bottom of the north column in compression in the first story. The maximum shear force in

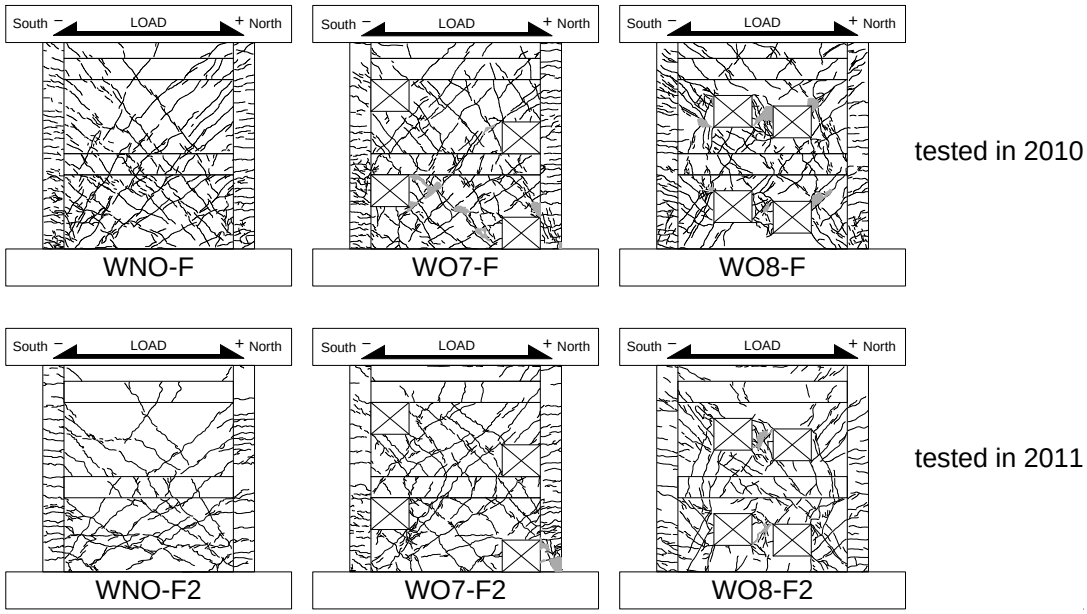

Figure 4 Cracking patterns R of 1/100 rad.

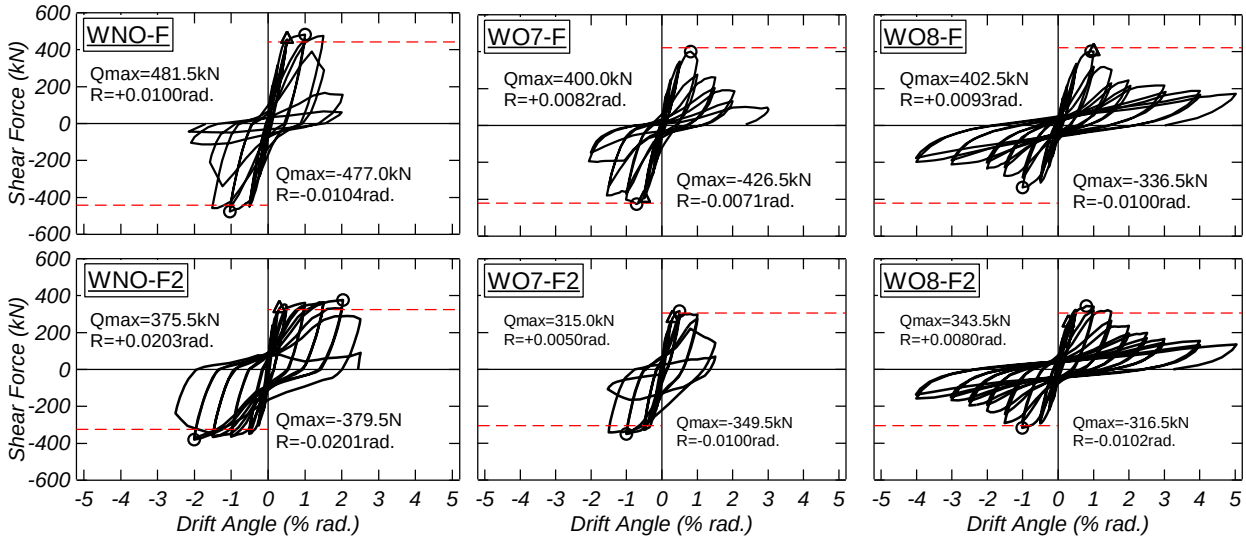

Figure 5 Shear force versus drift angle relationships

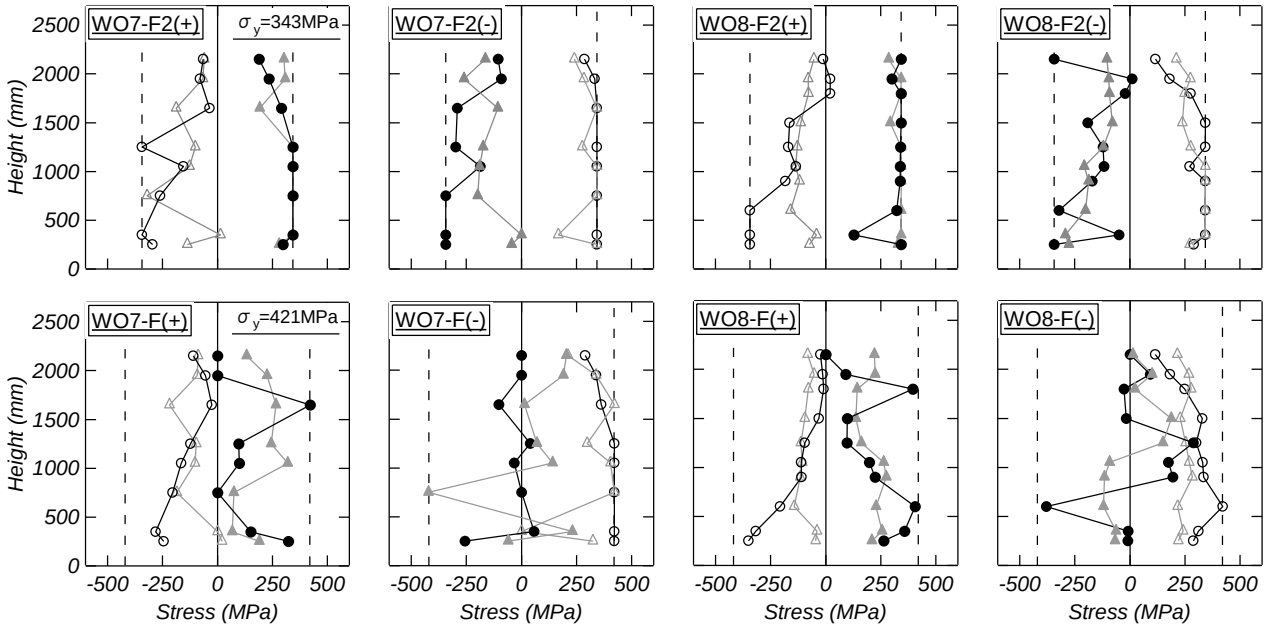

Figure 6 Stress distribution at columns (R=1/200 rad.)

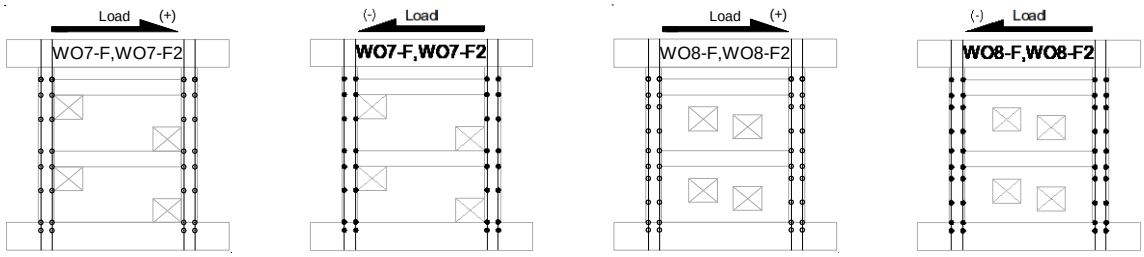

Figure 7 Locations of measuring strain

positive loadings was smaller than that in negative loadings because there was opening arranged adjacent to the bottom of the north column and the transferring stress from top of the wall was not concentrated at bottom of the north column. In the loading cycle of 1/67 rad., compression failure of the central wall panel, and buckling of longitudinal bars at bottom of the north column occurred in the first story were observed. In Specimen WO7-F tested in 2010, shear strength deterioration occurred by failing of concrete around the south side opening. On the other hand, Specimen WO7-F2 showed shear strength deterioration because the buckling of the longitudinal bars at bottom of the north column occurred before compression failure of the concrete at the wall panel.

In Specimen WO8-F2 in which diagonal openings were positioned close to each other, in the loading cycle of 1/200 rad., the failing of concrete at the central panel occurred in the second story, and the maximum shear force reached 343.5kN at R of 1/100 rad., and -316.5kN at R of -1/100 rad.. After the loading cycle of 1/100 rad., the failing of concrete at the central panel and wing walls in the first story. Finally, it was showed that the shear strength of columns maintained about 200kN until R of 1/20 rad. with damages at bottom of the beam in the first story. The failure mode of Specimens WO8-F2 and WO8-F tested in2010 were similar regardless the difference of the amount of longitudinal bars.

3.2 Deformation Capacity

(a) Stress distribution at columns

The stress distribution at each column at the R of ± 1/200 rad. for Specimens WNO-F, WO7-F, WO8-F, WNO-F2, WO7-F2 and WO8-F2 are shown in Fig.6 (plus = tension, minus = compression). The locations of measured stress on the specimens are also shown in Fig.7. On the assumption that the stress - strain relationship of a steel bar is bilinear curves, the stress was calculated using strain measured by the strain gauge.

In Specimens WO7-F and WO8-F tested in 2010, the stress at the south column in tension was small in the first story. However, in Specimens WO7-F2 and WO8-F2, the yielding of longitudinal bars occurred along the whole the first story column.

In addition, in Specimens WO7-F and WO8-F, the stress distributions at the column in compression showed that the stress varied widely whole columns. On the other hand, in Specimens WO7-F2 and WO8-F2, the stress concentrated at bottom of the column, and yielding occurred at the compression side.

As described above, in RC shear wall with openings, regardless the opening arrangement, longitudinal bars in the tensile column yielded in the whole length of the first story, and that in the compressive side at bottom of the column.

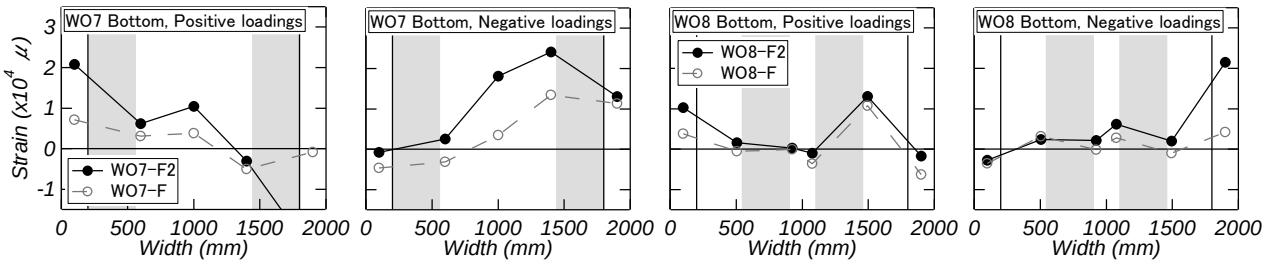

Figure 8 Stain distribution at bottom of walls (R=1/100 rad.)

Figure 9 Locations of measuring displacement (Bottom of walls)

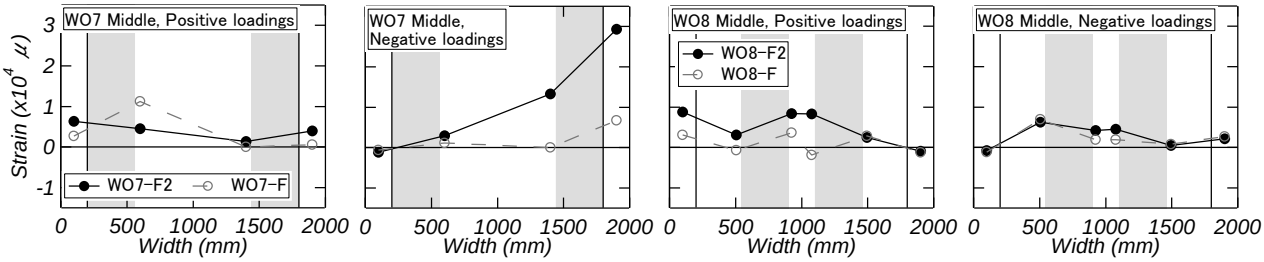

Figure 10 Stain distribution at middle height section of walls (R=1/100 rad.)

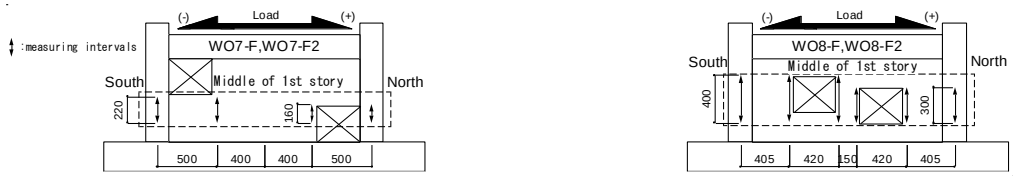

Figure 11 Location of measuring displacement (Middle height of walls)

(b) Strain distribution at bottom and middle height of walls

The strain distributions at the bottom section of walls at the R of ± 1/100 rad. for Specimens WNO-F, WO7-F, WO8-F, WNO-F2, WO7-F2 and WO8-F2 are shown in Fig.8 (plus = tension, minus = compression). Strains calculated using the displacement measured by transducer divided by its measuring intervals. The locations of measured displacement on the specimens are shown in Fig.9.

In Specimen WO7-F2, the strain at bottom of the south column increased in tensile and that of the north column increased in compressive by failing in shear at the north column in the positive loadings.

In Specimen WO8-F2, although the strain at bottom of the north column increased in tensile, the strain distribution at bottom of the wall showed similar tendency of Specimen WO8-F. In the test, the flexural crack in each specimen propagated at bottom of wall as well as middle height of walls in the first story. Then, the following passages describe the strain at middle section of walls.

The strain distributions at the middle height section of walls at the R of ± 1/100 rad. are shown in Fig.10 (plus = tension, minus = compression). The locations of measured displacement on the specimens are shown in Fig.11.

In Specimen WO7-F2, the strain at middle height of the north column and the wall panel increased widely in tension compared with Specimen WO7-F in the positive loadings. This is a reason why the failing in shear at bottom of the north column in tension progressed in the positive loadings, and the flexural cracks at middle height of the north column and the wall panel propagated instead of bottom of the north columns in the negative loadings.

On the other hand, in Specimen WO8-F2, although the strain at middle height of the wall panel slightly increased in tension, the strain distribution of Specimen WO8-F showed similar tendency.

As described above, in Specimen WO7-F2, the deformation at bottom of the north column adjacent to the openings increased early because Specimen WO7-F2 had few amount of steel at the columns compared with Specimen WO7-F. Therefore, the deformation capacity of Specimen WO7-F2 was not enhanced as compared with Specimen WO7-F.

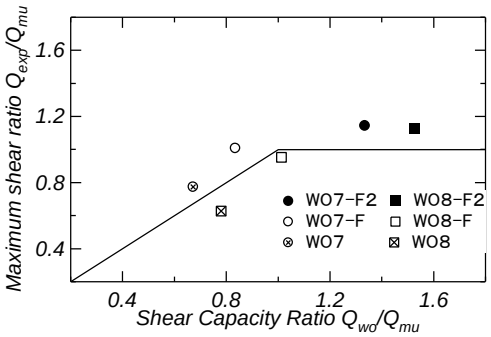

Figure 12 Maximum shear ratio – shear capacity ratio relationship

4. FAILURE MODE ESTIMATION

The shear capacity ratio of calculated flexural strength and shear strength of the specimens are shown in Fig. 12. The calculated flexural strength Q_{mu} is given by Eq. (1) (Japan Building Disaster Prevention Association, 2001) The calculated shear strength, Q_{wo} (Eq. (2), Eq. (3) and Eq. (4)), is proposed by the authors, where Q_{wo} was considered on the basis of shear transferring struts in RC shear wall and can estimate the difference of shear strength depending on the opening arrangement. The shear resisting model proposed by equations Eq. (2), Eq. (3) and Eq. (4) are shown in Fig.13, and the assumptions of boundary columns are also shown in Fig.14.

In Fig.12, the experimental value used for the maximum shear ratio is the absolute value among the positive and negative loading values. The test result of Specimens WO7, WO8 tested in 2010, which have the same configuration, opening layout and bar arrangement but the different shear-span ratio of 1.2 are also shown in Fig.12.

$$Q_{wo} = \sum_{i=1}^{n+1} Q_{wi} \tag{2}$$

$$Q_{wi} = \nu\sigma_B \cdot \cos\theta_i \sin\theta_i \cdot 0.5 l_{p_i} \cdot t_i \tag{3}$$

$$\nu = -0.016\sigma_B - 0.16\frac{M}{QD} + 0.36\frac{N}{bD\sigma_B} + 0.27 p_W + 1.23 \tag{4}$$

where, n: number of openings
σ_B: concrete cylinder strength (MPa)
θ_i: the angle of strut at wall panel
l_{pi}: wall panel length (mm)
t_i: wall panel width (mm)

For the details of the equation, see the reference (Sakurai et al. 2012)

In Fig.12, although the calculated the shear capacity ratio Q_{wo}/Q_{mu} of Specimen WO8-F slightly exceeds 1.0 in the calculation, the failure mode in the test was in shear failure. However, the calculated shear strengths of Specimens WO7-F2 and WO8-F2 which failing in flexure were over 1.3 respectively and it certified that the calculated

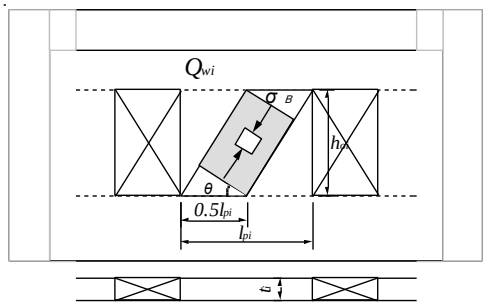

Figure 13 Proposed shear resisting model in wall panels

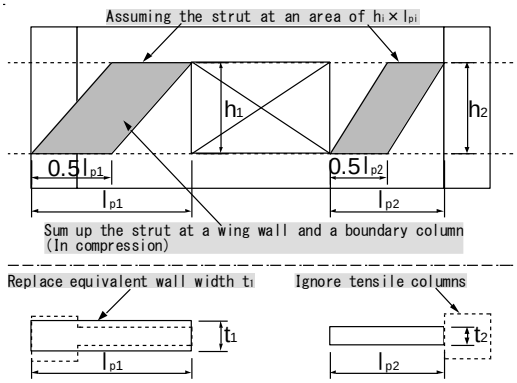

Figure 14 Assumption of boundary columns

shear strength is in accordance with the failure mode in test. In addition, the calculated the shear capacity ratio Q_{wo}/Q_{mu} of Specimens WO7, WO8 and WO7-F which failed in shear were under 0.8, it was showed similar tendency.

As described above, using the shear capacity ratio given by Q_{mu} (Japan Building Disaster Prevention Association, 2001) and Q_{wo} proposed by the authors, the failure mode of RC shear walls with openings can be estimated. However, due to the small number of specimen tested so far, additional tests are necessary for further validation.

5. CONCLUSIONS

In this paper, static loading tests of RC shear walls with multi-openings designed to have flexural failure mode were carried out to grasp the seismic performance. Then the experimental results in terms of failure mode, hysteresis characteristic and deformation capacity were compared with those of shear walls failing in shear tested by the authors in 2010. The following conclusions are obtained.

1) RC shear wall with opening decreased the deformation capacity compared with that without opening regardless the difference of the failure mode.

2) The failure mode and hysteresis loop of RC shear walls in which diagonal openings were positioned close to each other failing in flexure showed similar tendency of that failing in shear.

3) The deformation capacity of RC shear walls with openings arranged adjacent to the boundary column failing in flexure was lower than that failing in shear because the

shear failure occurred at bottom of the column adjacent to the opening.

4) In RC shear walls with openings failing in flexure, the stress distribution at longitudinal bar of the columns showed similar tendency regardless opening arrangement.

5) Using the shear capacity ratio calculated by Q_{mu} and Q_{wo} proposed by authors, it is possible to estimate the failure mode of RC shear walls with openings in case of the static loading test.

Abstract: This paper compares the experimental and estimated seismic performance using the results of scaled three-story steel frames tested on a shaking table, excited with artificial and earthquake waveforms, and formulations based on the capacity spectrum method and the substitute damping model, such as the equivalent damping ratio and the response reduction ratio. For each specimen, the elastic and inelastic behavior is reproduced; in the last, the specimen was excited by the mainshock, and then the maximum expected aftershock in order to analyze the residual seismic performance.

1. INTRODUCTION

The collapse of structures, in many cases, is not caused by the mainshock, but it may be caused by the subsequent aftershocks due to the seismic capacity degradation of the building during the mainshock. Entry into a damaged building at earliest is often indispensable for different emergency reasons. Thus the estimation of the seismic performance due to the maximum expected aftershock is very much important in order to determine if the building may or may not survive.

This paper presents an instrument to conduct this estimation; it is based on the capacity spectrum method and the substitute damping model; by means of formulations, such as the equivalent damping ratio and response reduction ratio given for the life-safety limit state. This limit is established for earthquakes motions whose return period is approximately 500 years, as prescribed the Japanese Building Standard Law Enforcement Order.

The equivalent damping and response reduction ratios are prescribed by Notification No. 1457-6 (2000) of Ministry of Land, Infrastructure, Transport and Tourism of Japan (MLIT). They are used to estimate the seismic performance due to the mainshock.

On the other hand, the equation of the equivalent damping ratio for the seismic performance estimation due to aftershock proposed in previous work by Kusunoki et al. (2006) and Diaz et al. (2012) is used in this paper. Additionally, a new equation of the response reduction ratio proposed by Diaz et al. (2012) which holds good for mainshocks and aftershocks is also used.

Thus the seismic performance due to mainshocks and aftershocks from the shaking table tests are compared with the estimated seismic performance using the formulations of equivalent damping and the response reduction ratios. Ten specimens were tested under one artificial waveform and two earthquake waveforms; properties such as period, equivalent damping and response reduction ratios due to mainshocks and aftershocks are analyzed.

2. RESIDUAL SEISMIC PERFORMANCE

2.1 Aftershock assumption

The aftershock is defined as the subsequent shakes after a significant earthquake with a magnitude less than the given earthquake (mainshock).

Generally, a magnitude of the largest aftershock is smaller by 1 than that of the mainshock. The largest aftershock, in many cases, occurs within 3 days after the occurrence of the mainshock in the case of inland earthquake. As for those occurred in sea area, the largest aftershock generally occur within about 10 days (Japan Meteorology Agency).

The energy released by earthquake is proportional to its magnitude. Thus, a rough approximation may suppose that the energy released by the maximum expected aftershock is relatively close to that by the mainshock.

Therefore, if a given earthquake and its subsequent aftershocks are considered as one-long duration earthquake from the beginning of the mainshock toward the end of the maximum expected aftershock; the motion of the maximum expected aftershock can be supposed same as that of the

mainshock, then neglect the inner shakes, because they do not produce larger responses than the maximum expected aftershock.

Using this assumption, the total motion to conduct the residual seismic performance analysis is given by the earthquake inputted twice, mainshock and aftershock, and a gap between both. The duration of this gap is set in the measure that the system vibration converges to zero, as shown in Figure 1.

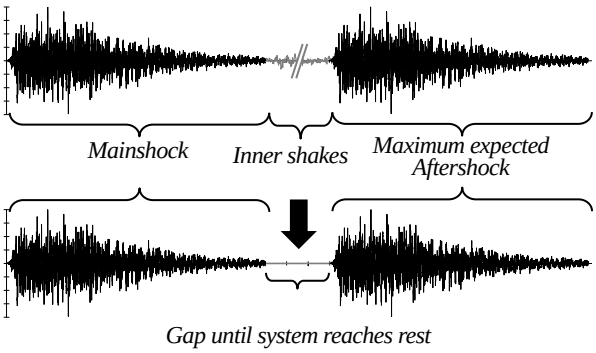

Figure 1 Aftershock assumption

2.2 Equivalent damping ratio

The equivalent damping ratio for yielding structures can be determined by the hysteresis damping in terms of the elastic strain energy of a structure by means of the geometric stiffness method (Jennings, 1968).

Notification No. 1457-6 (2000) prescribes the equivalent damping ratio ${}_mh_{eq-i}$ of a structural member i in Eq. (1) for the life-safety limit state.

$$ {}_mh_{eq-i} = \gamma \cdot (1 - 1/\sqrt{\mu}) \tag{1} $$

The coefficient γ in Eq. (1) is assumed as 0.25 in case of material which constitutes the member, and the joint connected to the adjacent member are rigid; and as 0.20 in cases of members or braced members where the buckling strength is degraded by the compressive forces when seismic forces acts (member exhibits a slip-type characteristic), as prescribed Notification No. 1457-6 (2000).

The coefficient γ in Eq. (1) may hold good for the estimation of the equivalent damping ratio due to mainshocks; otherwise the energy dissipation (or equivalent damping) due to the aftershock is less than or equal to that due to its corresponding mainshock. Therefore, this coefficient can be conveniently reduced in order to obtain larger responses, such as responses during an aftershock, since the response reduction ratio in Eq. (3) is inversely proportional to the equivalent damping ratio in Eq. (1). Thus, the coefficient γ is reduced to 0.12 and 0.08 by an appropriate curve fitting based on a series of nonlinear simulations obtained for systems under aftershocks (Diaz et al., 2012).

Eq. (2) is also prescribed by Notification No. 1457-6 (2000), based on the substitute structural method (Shibata and Sozen, 1976). It estimates the equivalent damping ratio of an equivalent SDOF system as the weighted average respect to the strain energy with a viscous damping ratio of 0.05 for the first-mode at the damaged-initiation limit state, since at this stage the building behavior remains elastic. ${}_mW_i$ is the strain energy dissipated in member i.

$$ h_{eq} = \frac{\sum {}_mh_{eq-i} \cdot {}_mW_i}{\sum {}_mW_i} + 0.05 \tag{2} $$

2.3 Response reduction ratio

The response reduction ratio reduces the elastic spectral response to the inelastic response. Notification No. 1457-6 (2000) also prescribes the response reduction ratio as Eq. (3), which guarantees the life-safety limit state.

$$ F_h = \frac{1.5}{1+10 \cdot h_{eq}} \tag{3} $$

Additionally, previous work by Diaz et al. (2012) proposes a new equation of the response reduction ratio, given by Eq. (4). It is developed solving the equation of motion under the stationary vibration, and then adapting it to the non-stationary vibration, such as earthquake motions, by means of curve fitting to analytical response of a series of nonlinear simulations.

$$ F_h{}^* = \sqrt{\frac{1.1+\alpha \cdot h_{eq}{}^2}{1+(40+\alpha) \cdot h_{eq}{}^2}} \tag{4} $$

The Japanese Building Standard Law Enforcement Order requires that spectral acceleration of a structure at a limit state should be higher than the corresponding acceleration of the reduced demand spectrum using the equivalent damping ratio at the same limit state.

2.4 Seismic performance evaluation

During a damaging earthquake, some buildings may survive, but the subsequent aftershocks may or may not cause the building collapse; that's why, it is desirable to recognize the building state (seismic performance) after a mainshock, and to estimate the seismic performance due to the maximum expected aftershock in order to anticipate if the building may or may not survive, and so safeguard life.

The seismic performance of a building due to a given earthquake motion is examined by comparing the capacity curve and demand spectrum in terms of $S_a - S_d$ relations, as shown in Figure 2. The intersection between the capacity curve and the demand spectrum for an appropriate equivalent damping ratio which represents the inelastic response under the given earthquake, is called the performance point (ATC-40, 1996).

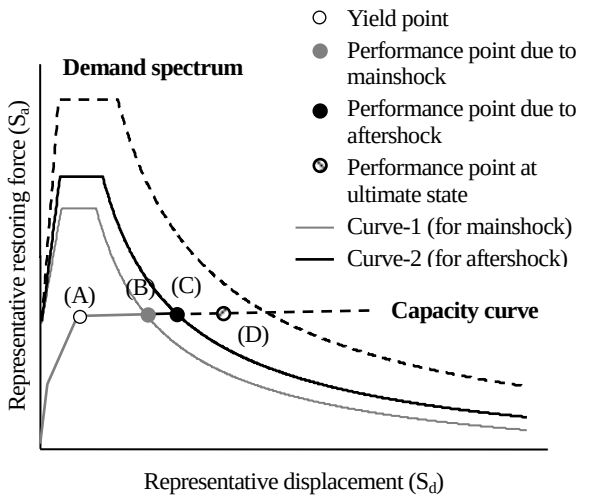

Figure 2 Scheme of the seismic performance evaluation

The concept of the seismic performance evaluation method is represented by the scheme shown in Figure 2. The performance point due to the mainshock is represented by the point (B) on the capacity curve, in this figure; the demand spectrum is reduced by increasing the viscous damping ratio until it intersects the point (B). Thus the reduced demand spectrum is represented as curve-1 in Figure 2, and the converged viscous damping ratio is defined as the equivalent damping ratio for mainshock.

The maximum response during the maximum expected aftershock, represented by the performance point (C) on the capacity curve in Figure 2, is larger than or equal to that during the mainshock, represented by the performance point (B) in the same figure. Thus the equivalent damping ratio for aftershock is less than or equal to that for mainshock, as observed in Figure 2, because the energy dissipation (or equivalent damping) during the maximum expected aftershock is less than or nearly equal to energy dissipation during its corresponding mainshock. Then the demand spectrum is again reduced until it intersects the performance point (C) in Figure 2; the reduced demand spectrum is represented as curve-2 and the converged viscous damping ratio is defined as the equivalent damping ratio for aftershock.

3. SHAKING TABLE TESTS

The experimental tests are based on the assumption described in Section 2.1. The testing program consists in four series of excitation. The first excitation was produced by the white-noise in order to evaluate the dynamic properties. The second excitation was the test using the input motion with small acceleration amplitude to induce an elastic response. The third excitation was the test using large acceleration amplitude, so that the specimen was within the inelastic range (mainshock). And, the fourth excitation was the test using the previous acceleration amplitude (or slightly less) to produce the maximum expected aftershock.

3.1 Tests specimens

The specimen consists in a scaled three-story and one-bay steel plane frames; their members are connected by bolts to a rigid joint, as shown in Figure 3.

The bay width is 1000 mm, the first-story height varies from 805 mm to 1005 mm, and the second and third stories heights are 700 mm. The beams are rectangular bars of 100×6 mm widened at the middle to support the accelerometer on each level. The first-story is constituted by rectangular bars as columns without braces; the second and third stories are braced frames with rectangular bars of 100×6 mm as columns, and circular bars M10 as braces (a pair in each front).

The design of the specimen supposed that the columns of the first-level would be only affected during the tests, due to the soft-story behavior of this structure. The sections of these columns were reduced in 50% at the bottom in order to provide to the specimen a plastic hinge to control the failure mechanism.

Thus, the properties of the specimen depend on the dimensions of first-story columns (thickness and height); the second, third braced frames are preserved for all tests. However, the second and third braced frames are also observed by the measurement system.

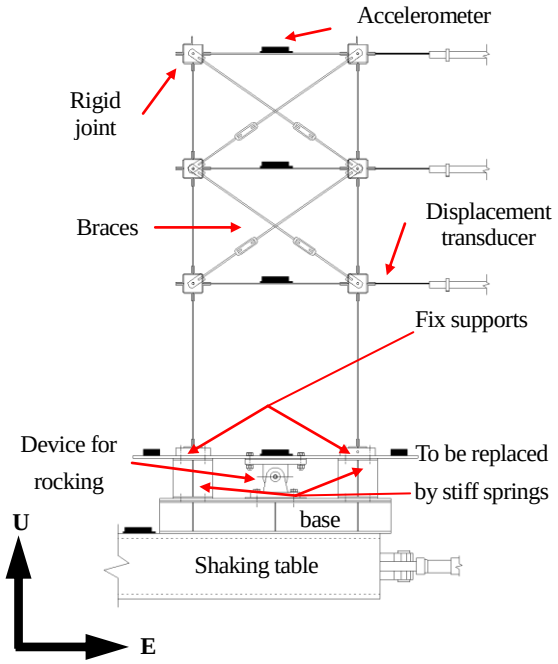

Figure 3 Configuration of specimens

The specimens Frame1a, Frame2a,b and S-F01,02,03 are fixed support; while specimens S-S01,02,03,04 are also fixed support, but the base (ground) includes a small rocking effect due to the adding of stiff springs (K_{spring}=500 N/mm) between supports and base, as shown Figure 3. The initial compressive deformations of springs were 1 mm and 7 mm for S-S01,02 and S-S03,04, respectively. Members of these specimens consisted of SS400 (326 MPa). Table 1 presents characteristics of these specimens.

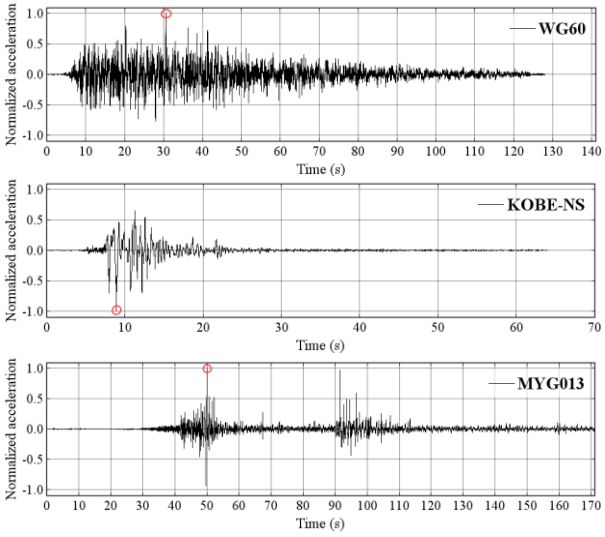
Table 1 Characteristics of specimens

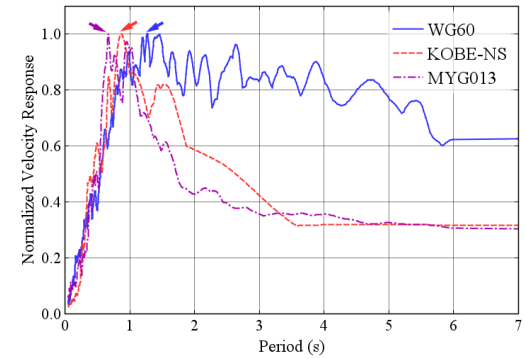
Specimen	Thickness 1st F column (mm)	Height 1st F (mm)	Total weight (kN)	Natural period (s)	Yield. Disp. (mm)
Frame1 a	4.5	805	1.450	1.03	66
Frame2 a, b	4.5	1005	1.464	1.66	101
S-F 01, 02, 03	6.0	1000	1.485	0.93	71
S-S 01, 02	6.0	1000	1.485	0.99	73
S-S 03, 04	6.0	1000	1.485	0.98	73

The measurement system was given by accelerometers at the base and beams of each level, and displacement transducers connected at each eastern rigid joint, as shown in Figure 3.

3.2 Input waveforms

The input motions to conduct this study were one artificial wave: the WG60, and two earthquake records: the KOBE-NS (Kobe, 1995) and the MYG013 (Tohoku, 2011). The input motions were scaled in order to induce different performance levels on the specimen within elastic and inelastic ranges, both mainshocks and aftershocks. Figure 4 shows the WG60, the KOBE-NS and the MYG013 waveforms.





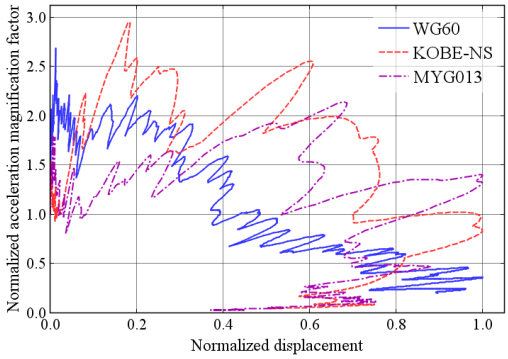


Figure 4 Input waveforms

Figure 5 shows their respective a) normalized velocity response spectra respect to the maximum spectral velocity, and b) normalized response spectra respect to peak ground acceleration (PGA) and maximum spectral displacement. The maximum spectral response with viscous damping ratio of 0.05 was obtained at periods of 1.27 seconds, 0.87 seconds and 0.67 seconds for the WG60, the KOBE-NS and the MYG013 waveforms, respectively (Figure 5a).

a) Velocity response spectra

b) Displacement and acceleration response spectra

Figure 5 Response spectra

3.3 Equivalent SDOF

In order to conduct the residual seismic performance analysis, it is necessary to transform the capacity curve of the specimen in terms of $S_a - S_d$ relations.

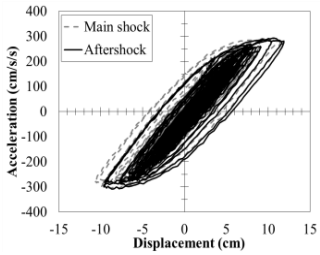
The probable value of the maximum response is usually given by the square root of the sum of square (SRSS) of the maximum modal response components. Then the maximum displacement at i-th story and the base shear force can be expressed approximately by Eq. (5) and Eq. (6) (Shibata, 2010), respectively; where ${}_sS_d$, ${}_sS_a$ is the spectral displacement and spectral acceleration for the s-th mode. The base shear force of N-DOF is given by Eq. (7).

$$|\delta_i|_{max} \approx \sqrt{\sum_{S=1}^{N} \left| {}_s\beta \cdot {}_su_i \cdot {}_sS_d \right|^2} \quad (5)$$

$$Q \approx \sqrt{\sum_{S=1}^{N} \{ \sum_{i=1}^{N} m_i \cdot {}_s\beta \cdot {}_su_i \cdot {}_sS_a \}} \quad (6)$$

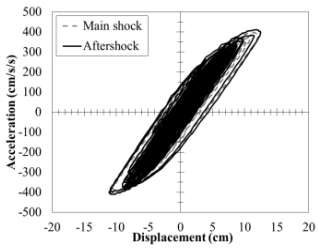
$$Q = \sum_{i=1}^{N} m_i \cdot (\ddot{x}_i + \ddot{x}_g) \quad (7)$$

Particularly, the specimens can be assumed as 3-DOF systems. Their configuration allows that second and third participation factor can be neglected, and the first-mode distribution can be assumed as the unit $\{ {}_1u \} \approx \{1\}$. Then Eq. (5) is rewritten as Eq. (8) to calculate the spectral acceleration, and Eq. (7) into Eq. (6) is rewritten as Eq. (9) to calculate the spectral displacement.



$$ {}_1S_d \approx \frac{|\delta_i|_{max}}{{}_s u_i} \quad (8) $$

$$ {}_1S_a = \frac{\sum_{i=1}^{3} m_i \cdot (\ddot{x}_i + \ddot{x}_g)}{\sum_{i=1}^{3} m_i} \quad (9) $$



3.4 Tests results

The representative response or spectral response is calculated by Eq. (8) and Eq. (9), using experimental data such as the displacement from transducers and the absolute acceleration from accelerometers on each level. The responses during mainshocks and aftershocks, in terms of $S_a - S_d$ relations, with different maximum acceleration amplitudes of waveforms are plotted in Figure 6, Figure 7 and Figure 8, where g is the acceleration of gravity.

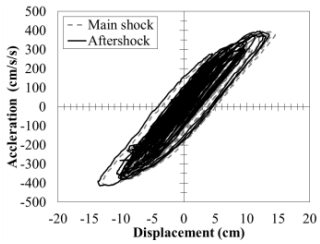


Figure 6 shows the response during the WG60 waveform for four specimens, namely: Frame1a, S-F01, S-S01 and S-S04 with maximum acceleration amplitude of waveform of 0.36g, both mainshock and aftershock.

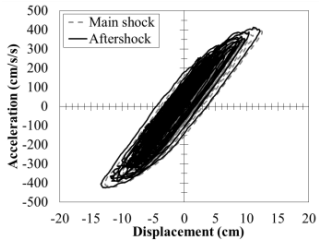
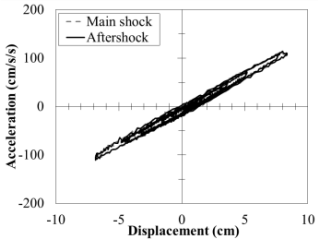


a) Frame1a (0.36g)

b) S-F01 (0.36g)

c) S-S01 (0.36g)



d) S-S04 (0.36g)

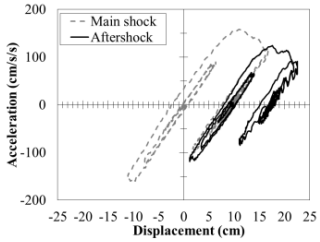


Figure 6 Response during the WG60 waveform

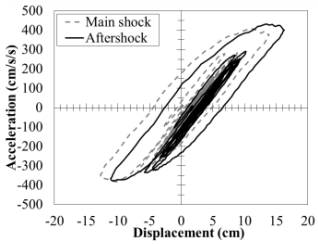
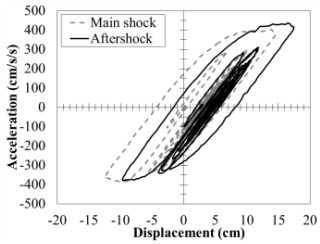
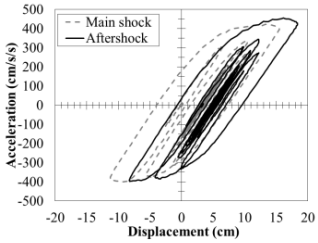
Figure 7 shows the response during the KOBE-NS waveform for five specimens, namely: Frame2a with maximum acceleration amplitude of waveform of 0.17g (mainshock and aftershock), Frame2b with 0.33g for mainshock and 0.25g for aftershock; and S-F02, S-S02 and S-S03 with 0.38g, both mainshock and aftershock.



In Figure 7b, a negative slope arose in the representative acceleration; it is because the specimen Frame2b is slender and long-period frame (see Table 1), and suffered the P-Δ effect (its capacity is reduced in front of the gravity effect). The maximum response within the inelastic range was larger than the elastic spectral response with damping ratio of 0.05.

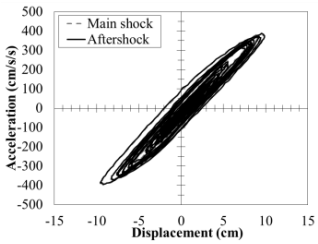


a) Frame2a (0.17g)



b) Frame2b (0.33g→0.25g)

c) S-S02 (0.38g)



d) S-S03 (0.38g)

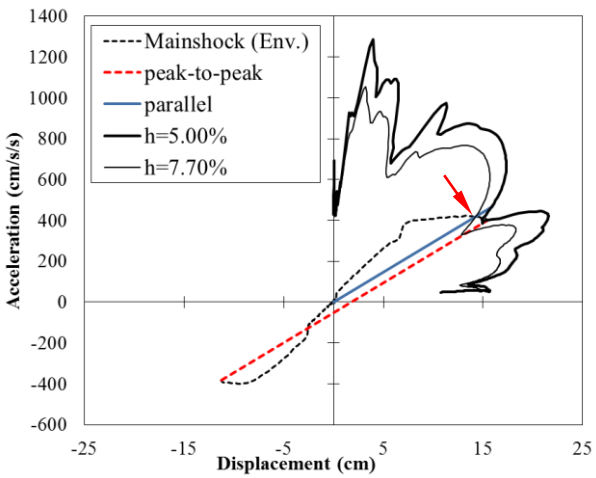
e) S-F02 (0.38g)

Figure 7 Response during the KOBE-NS waveform

Figure 8 shows the response during the MYG013 waveform for the specimen S-F03 with maximum acceleration amplitude of waveform of 0.39g, both mainshock and aftershock.

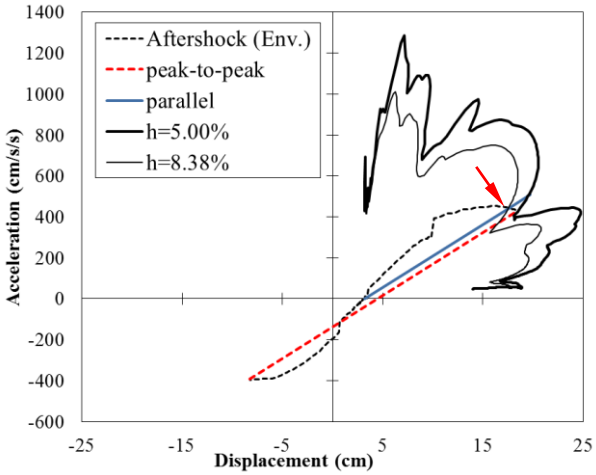
a) S-F03 (0.39g)

Figure 8 Response during the MYG013 waveform



In the previous experimental study (Diaz, Kusunoki and Tasai, 2012), the equivalent damping ratio was estimated using the maximum response amplitude, negative or positive, to estimate the equivalent damping ratio; by increasing the damping ratio until the resulting demand spectrum is intersected with this maximum response amplitude, as described Section 2.4 in Figure 2.

Those results showed that some responses such as those from specimens S-F02, S-S02 and S-S03 were unsafely



estimated using the formulations of the equivalent damping and response reduction ratios presented in this paper. It is because the fundamental period of these specimens are close to the predominant period of the corresponding input waveform (KOBE-NS). Also, the specimen Frame2b could not be used because it suffered the P-Δ effect and its maximum response amplitude is larger than the elastic spectral response with damping ratio of 0.05.

On the other hand, the equation of equivalent damping ratio given in Eq. (1) is developed by the geometric stiffness method which supposes that the positive and negative amplitudes of the hysteresis loop are equal. Although, as shown in Figure 6a, 6c, 7b, 7c, 7d and 7e, the hysteresis loops are shifted in many cases toward negative or positive direction, and amplitudes (negative and positive) turn out to be quite different; this shifting is intensified during aftershocks, where a residual deformation due to the mainshock may occur.

Thus the energy dissipation, or equivalent damping, is represented much closer to the true value when both amplitudes, negative and positive, are used to estimate an equivalent period (peak-to-peak), and then defining the equivalent amplitude.

a) Response during mainshock

b) Response during aftershock

Figure 9 Estimation of parameters using the equivalent amplitude

An important characteristic is that the envelope of the spectral response during the mainshock maintains the same shape during the aftershock, but moved toward one direction or another, and the residual deformation becomes the new origin. It means the capacity curve preserves the same shape until the structure sustains major damage (large deformation). This phenomenon can be observed in Figure 9, the envelope of the response during mainshock looks like moved toward positive direction during the aftershock, and the new origin is relocated at 3.2 cm.

Therefore, the equivalent damping and response reduction ratios are calculated after defining the equivalent amplitude as the intersection between the line parallel to the resulting line of joining the peak amplitudes (peak-to-peak) which crosses the origin and the negative or positive branch of the envelope of the spectral response (Figure 9a). In case of the response during the aftershock (Figure 9b), the parallel line crosses the new origin (residual deformation).

After defining the equivalent amplitude, the equivalent damping ratio is calculated by reducing the demand curve toward the equivalent amplitude, as describe in Section 2.4. Then the response reduction ratio is calculated as the ratio of the equivalent amplitude to the elastic response. The elastic response corresponds to the intersection between the parallel with the demand spectrum with damping ratio of 0.05, as shown in Figure 9a. In case of aftershocks, the demand spectrum is moved toward the residual deformation as shown in Figure 9b.

4. ANALYSIS OF RESULTS

Figure 10 shows the relation between the ductility factors due to mainshocks and aftershocks, using the absolute maximum displacement (maximum amplitude), and the negative and positive maximum displacement (equivalent amplitude).

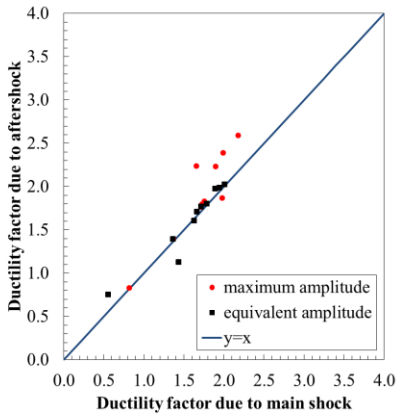


Figure 10 Relation between ductility factors

Table 2, Table 3, Table 4 and Table 5 show the ductility factor (μ), the equivalent damping ratio (h_{eq}) and the response reduction ratio (F_h) obtained from the experimental tests, and the estimated response reduction ratio. In order to

estimate the response reduction ratio, the ductility factor is evaluated into Eq. (2) to estimate the equivalent damping ratio and then it is evaluated into Eq. (3) and Eq. (4), F_h and $F_h{}^*$, respectively.

Table 2 and Table 3 show results due to mainshocks and aftershocks, respectively, using the maximum absolute displacement. As shown in these tables, the equivalent damping and response reduction ratios are not calculated for the specimen Frame-2b, because the inelastic response is much larger than the spectral response with damping ratio of 0.05, both mainshock and aftershock.

Table 2 Results due to mainshock using the maximum absolute amplitude

Specimen	waveform	Experimental			Estimated	
		μ	h_{eq}	F_h	F_h	$F_h{}^*$

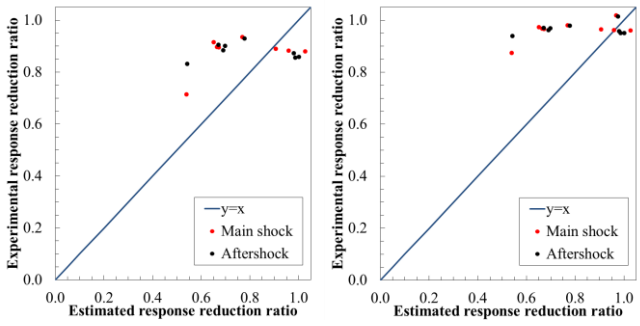
Figure 11 shows the relationship between the ductility factor and the equivalent damping ratio from the experimental test using the maximum absolute amplitude and the equivalent amplitude due to a) mainshocks and b) aftershocks.

a) mainshocks b) aftershocks

Figure 11 Estimation of equivalent damping ratio

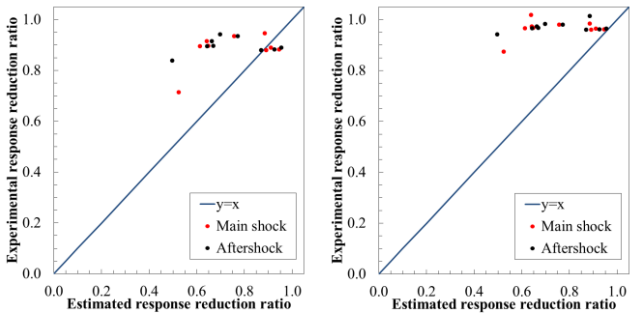
Results in Figure 11 are compared with the estimated equivalent damping ratio which is defined by the curve heq-0.25 and heq-0.12, for mainshock and aftershock,



respectively. It corresponds to coefficients γ 0.25 and 0.12 in Eq. (1), because the hysteretic behavior is quiet close to the perfect elasto-plastic bilinear model.

The equivalent damping ratio becomes larger using the equivalent amplitude than using the maximum absolute amplitude, it is observed in Figure 11. It means that the equation of the equivalent damping ratio can be estimated more safely these values using the equivalent amplitude.

In order to compare the experimental and estimated response, the response reduction ratio is calculated from the shaking table tests and formulations. The response is safely estimated when the actual response reduction ratio (experimental) is less than or equal to the estimated response reduction ratio using the formulations presented in this paper, both mainshock and aftershock, whichever is applicable.



$$F_h^{experimental} \leq F_h^{estimated} \tag{10}$$

The comparison between the estimated response reduction ratio and the experimental response reduction ratio due to mainshocks and aftershocks is presented in Figure 12 and Figure 13, using Eq. (3) and Eq. (4), respectively. These figures show this comparison using a) the maximum absolute amplitude and b) the equivalent amplitude. Here, the response safely estimated are represented by points above the line (y=x).

a) maximum amplitude b) equivalent amplitude

Figure 12 Response reduction ratio by F_h , Eq. (3)

a) maximum amplitude b) equivalent amplitude

Figure 13 Response reduction ratio by $F_h{}^*$, Eq. (4)

5. CONCLUSIONS

From the analysis conducted for the experimental and estimated results, the following conclusion can be drawn:

- Ten scale three-story steel frames were tested on a shaking table, seismic performance is determined from the experimental results and compared with the estimated values.
- The definition of the equivalent amplitude allows calculating responses where the maximum absolute amplitude exceeds the elastic spectral response, even for the specimen which suffered the P-Δ effect.
- The equivalent damping ratio can be more safely estimated when the equivalent amplitude is defined instead of the maximum absolute amplitude.
- The formulations estimated safely the equivalent damping ratio and then the response reduction ratio due to mainshocks and aftershocks using the peak amplitudes to define the equivalent amplitude. The response reduction ratio is more safely estimated using Eq. (4) than Eq. (3).

However, this technique would become safer for the seismic performance estimation if an equation to estimate the shifting displacement is incorporated.

Abstract: Aging of castle masonry walls in Japan after 400 years since their construction has become problematic. The application of restoration works is examined when bulging phenomena are confirmed. However, methods to evaluate stability before and after repair of aged castle masonry walls have not been established. Hence, the effect of restoration has not been clarified.

The variation of dynamic stability of castle masonry walls before and after restoration was investigated by stability analyses using the distinct element method, which is one of discontinuous analyses, focused on actual repair works. The effect of repair was well represented by the analyses.

1. INTRODUCTION

In Japan, there are a lot of castle masonry walls being of historically and culturally inestimable value. It is important to appropriately maintain these walls because most of the castle ruins are used as historical places and parks where many people visit. Recently, aging of these walls has become problematic in terms of structure stability and functions.

Many restoration works of castle masonry walls have been conducted. It is required to sustain the authenticity of the walls and use traditional materials and techniques in principle for repair works of cultural heritages having historical values.

It is a present condition that the effect of repair works of castle masonry walls cannot be known because it is difficult to evaluate stability of these walls behaving complicatedly as discontinuous structures. Stability analyses by using the distinct element method which is one of discontinuous analyses (Kasa et al. 2007) were conducted to quantitatively evaluate the improvement of stability after restoration works of these walls.

In the present study, quantitative evaluation of stability of castle masonry walls before and after restoration works were conducted by referring to measures of actual restoration works of these walls. The restoration work of Takamatsu castle which is one of examples referred in this investigation is shown in Photo 1.

Dynamic analyses by means of distinct element method were conducted by using models before and after restoration works. The model before the works has the bulging phenomenon. On the other hand, rearrangement of stones, improvement of the thickness of cobble layers and ground, and arrangement of frames were reflected in models after the works.

Photo 1 Restoration work of castle masonry wall in Takamatsu castle

The variation of dynamic stability of structures before and after works was investigated. The effect of reinforcement of the bottom parts of stones by arrangement of frames was especially focused on.

2. MODELING IN ANALYSES

2.1 General restoration work

General castle masonry walls have the recurvate stone arrangement. This arrangement changes to arch shape in the front direction because of earthquakes, weather, and growth of roots of trees. This is called the bulging phenomenon. Restoration works are often conducted when this phenomenon is confirmed.

In general restoration works, castle masonry walls are dismantled to rearrange stones into the original shape. Rearrangement of stones is reconstruction of bulged stone parts into the original gradient of stone parts which is determined by using inclination of existing castle masonry walls or ancient texts such as Goto family texts (Nishida et al. 2003). Improvements of the thickness of the cobble layer and back ground are also conducted in some cases when the thickness of the cobble layer and the strength of the ground are not enough. Lime powder is used in the ground improvement as traditional material.

2.2 Frame in Takamatsu castle

Frame works modeled as one of restoration measures in this investigation were used in the restoration works of castle masonry walls in Takamatsu castle from 2009 to 2011.

Frame works are shown in Figure 1. Pine piles are constructed in front of the bottom stones and stones are filled to constraint the deformation of the bottom stones under water surface in the front direction. This work seems to contribute to the improvement of structural stabilitiy of castle masonry walls (Nishida et al. 2009).

2.3 Outline of castle masonry wall model

Referring to the above, the cross-section of castle masonry walls used in analyses was decided and shown in Figure 2. The cross-section of castle masonry walls before restoration works has a bulging part and the thickness of cobble layers is inconstant in the vertical direction. Rearrangement of stones, uniformalization of the thickness of the cobble layer, improvement of the ground, and the frame were incorporated into the cross-section of walls after works. The height of models of castle masonry walls is from 10 to 15 m. The model after works is not only with rearrangement of stones but also with the frame used in Takamatsu castle as actual works. The effect of reinforcement by the frame is especially investigated in the following analyses.

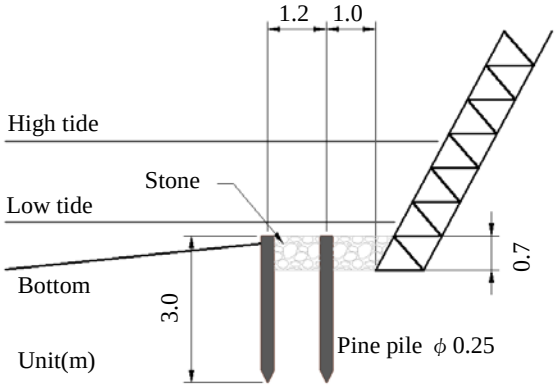

Figure 1 Arrangement of frame (Modified figure of Nishida et al. 2009)

3. INVESTIGATION OF DYNAMIC STABILITY

3.1 Outline of analysis

Analytical cases are shown in Table 1. Case 1 assumes the bulging castle masonry wall before restoration works. Case 2 and 3 consider walls after works and application of measures shown in Table 1 was took into account. The difference between Case 2 and 3 is with or without the frame.

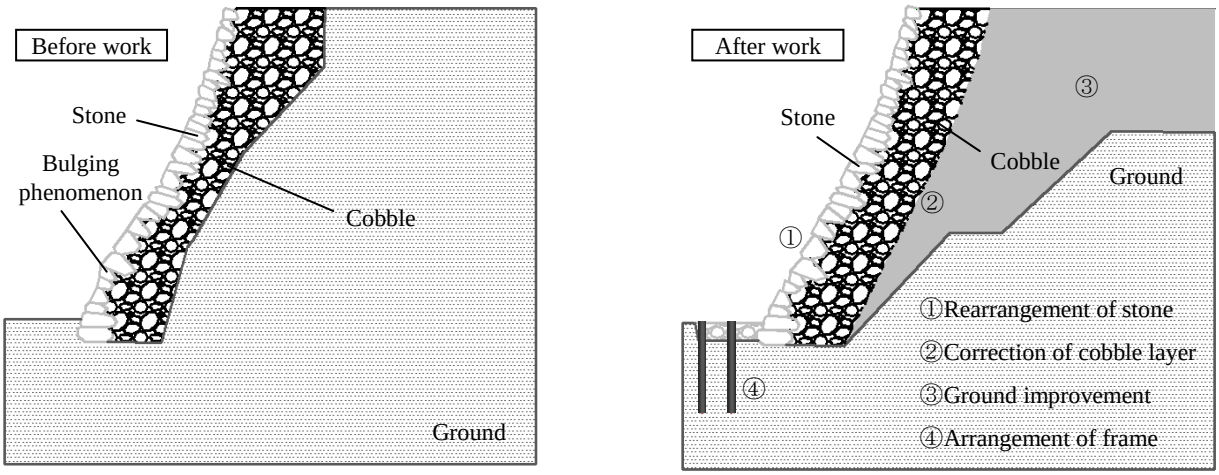

Figure 2 Pattern diagram of cross-section of castle masonry wall before and after restoration work

PFC2D which is one of versatile analysis codes of the granular distinct element method is used in the analyses. Input parameters used in the analyses are shown in Table 2. Each material is modeled as a shape shown in Figure 3 by clumped elements assembled with circular elements. Sizes of stone and cobble elements are decided by sizes of stone (500～1500 mm) and cobble (100～300 mm) of walls in Takamatsu castle. Particle frictions of the ground and the improved ground are calibrated to satisfy ϕ=40° and ϕ=45° respectively (Noma et al. 2011). The particle friction of the stone was determined by using analytical results of shear analyses to satisfy ϕ=25～35° . Input parameters of the frame are the same as the stone because stones are filled inside the frame.

Analytical models after obtaining static stability for each case are shown in Figure 3. The height of models is 14 m from the bottom stone because the height of the castle masonry wall of Takamatsu castle is about 13.5 m. Cross-sections of stones are similar to the shape of actual stones and simplified. The upper line of the ground is modeled as flat and the height is the same as the upper stone. The frame is modeled by considering stones and pine piles (embedded length is 3 m).

Takamatsu castle has experienced several large-scale earthquakes such as Hoei Nankai Earthquake (M8.6) in 1707, Ansei Nankai Earthquake (M8.4) in 1854, Showa Nankai Earthquake (M8.0) in 1946, and Hyogoken Nanbu Earthquake (M7.3) in 1995. 20 times sinusoidal waves whose frequency is 3 Hz and the amplitudes of 400 and 800 Gals are used in dynamic analyses. This frequency is decided by eigenvalue analyses and in-situ inspection of castle masonry walls. These amplitudes are determined by referring the above earthquakes and assuming seismic intensities of about 4 and 6.

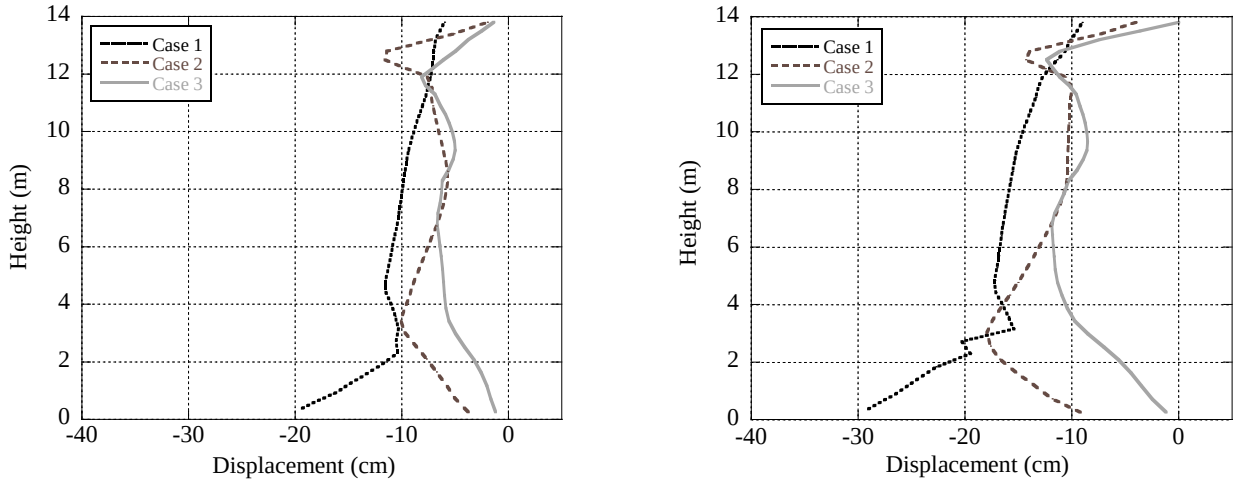
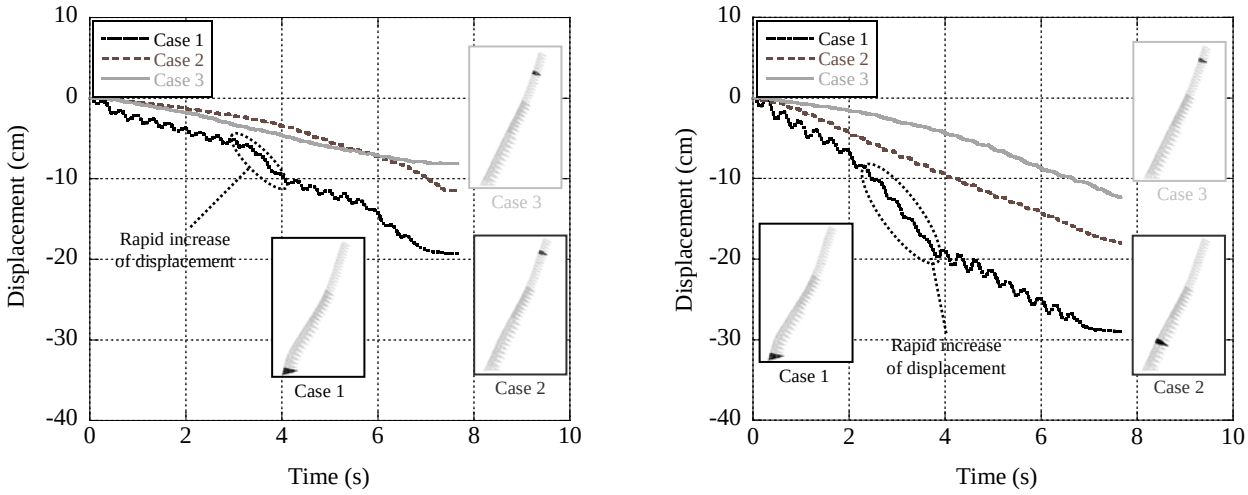
Figure 3 Analytical model



3.2 Analytical result

Displacement distribution of stones at the end of analyses, the relationship between time and displacement of stones showing the maximum displacement and deformation diagrams are shown in Figure 4, 5, 6 and 7. Displacements in the front direction of walls show negative values.

Maximum displacement of about 18 cm is confirmed at the bottom stone of Case 1 in the dynamic analytical result with amplitude of 400 Gals. However, Maximum displacements of about 8～12 cm are confirmed near the upper stone of Case 2 and 3. Maximum displacement of about 28 cm is confirmed in Case 1 in the dynamic analytical result with amplitude of 800 Gals. However, maximum displacements of about 18 cm in Case 2 and about 13 cm in Case 3 are confirmed. From these results, it is confirmed that dynamic stability is improved by conducting repair works. Especially, deformation of stones near the bottom stone becomes smaller by using the frame.



Rapid increase in displacement of stones can be confirmed in analytical results with amplitude of both 400 and 800 Gals in Case 1 as shown in Figure 5. This shows the deformation changed from continuous behavior to discontinuous behavior and is progressive. On the other hand, time histories of displacement do not change in Case 2 and 3, and continuous behavior can be confirmed from these cases.

The above results can also be confirmed in Figure 6 and 7. Slips of stones near the bottom stone and irreversible behavior as a discontinuous structure can be observed and displacements of stones become large in Case 1. In Case 2, bulging phenomenon and changes from continuous behavior to discontinuous behavior can be confirmed. However, performance of a continuous structure is sustained because only small deformation near the upper stones and no bulging phenomenon are observed in Case 3.

3.3 Evaluation of dynamic stability

Pattern diagrams related to dynamic stability of castle masonry walls before and after restoration works assumed from analytical results of this study are shown in Figure 8. Slips of lower stones in the front direction are confirmed in dynamic analyses in bulging castle masonry walls before works. This indicates that the collapse of castle masonry walls is caused by the movement of lower stones in the front direction and fall of upper stones in earthquakes. On the other hand, only small deformations are observed in dynamic analyses in castle masonry walls after works. It can be considered that the effect of earthquakes is moderated and seismic resistance is improved by the restoration works.

4. CONCLUSIONS

Dynamic stabilities of castle masonry walls before and after restoration works are evaluated for a model of aged walls and restoration works in Takamatsu castle by using the distinct element method in this study. As a result, it is indicated that displacement of stones become smaller by conducting repair works. Especially, it is considered that frames arranged in front of the bottom stone contribute to the improvement of seismic performance from analytical results.

Abstract: A large number of the historical structures in Turkey are under high seismic risks. Since the knowledge on the traditional masonry walls and masonry constituents of the historical structures in Turkey is scarce, particularly from the structural engineering perspective, this study intends to enlarge the experimental data concerning the behavior of the Ottoman period multi-leaf stone masonry walls under cyclic in-plane loads that represent the seismic effects. For this purpose, four stone masonry walls, representative of the investigated wall typology, were constructed with similar materials and construction techniques. A well-known local limestone (Küfeki limestone), widely used in ancient structures in Istanbul, was utilized during the construction of the wall members with dry joints. The Küfeki units were interconnected to each other via metal cramps as also done in the past practice. The main parameter of the tests was the level of pre-compression stress that was kept constant during the lateral cyclic loading. The experimental study provided data on the failure mode, lateral load capacity and load-displacement response of the investigated walls and showed the influence of pre-compression stress level on these characteristics.

1. INTRODUCTION

Most of the historical structures in Turkey are under high seismic risk since the overall seismicity of the region is considerably high. Particularly, in and around the old imperial city of Istanbul, where numerous monumental structures from the Roman, Byzantine and Ottoman periods exist, this risk is even more solid. Although a number of studies on seismic behavior of stone masonry walls exist in the engineering literature (such as Lorenço et al. 2005, Corradi et al. 2008, Vasconcelos and Lourenço 2009 and Galasco et al. 2010), the knowledge on the traditional masonry walls and masonry constituents of the historical structures in Turkey is scarce. Consequently, new experimental and analytical studies are needed for development of well-established assessment and intervention procedures. This study intends to enlarge the experimental data concerning the behavior of the Ottoman period multi-leaf stone masonry walls under cyclic in-plane loads that represent the seismic effects.

In order to achieve this purpose, the mechanical characteristics of multi-leaf stone masonry walls of classical era Ottoman Imperial structures are investigated through an experimental campaign carried out at the Structural and Earthquake Engineering Laboratory of Istanbul Technical University Civil Engineering Faculty. A prototype wall, representative of the investigated walls is designed, scaled down and wall specimens produced accordingly are subjected to combined vertical and in-plane lateral forces. Two typical structures from Ottoman period, Edirnekapı Mihrimah Sultan (16^{th} century) and Fatih (initial construction 15^{th} century, reconstructed in 18^{th} century) Mosques, and their multi-leaf walls can be seen in Figure 1.

Figure 1 Ottoman period structures in Istanbul and their multi-leaf stone masonry walls

2. EXPERIMENTAL STUDY

2.1 Experimental Program

The experimental study carried out on multi-leaf stone masonry that represent the walls used in the Ottoman Period multi-leaf walls in and around the Istanbul city were subjected to in-plane quasi-static displacement cycles. The main parameter of the study was the level of vertical stress level acting on the walls. The shear compression tests aimed to obtain failure modes and lateral force-displacement hysteresis loops that can be used to evaluate a number of parameters such as ductility, energy dissipation and stiffness variation. Please note that more details of this study can be found in Demir (2012).

2.2 Specimen Characteristics

A survey of the existing literature and site observations on the main aspects of the historical masonry walls of Ottoman period structures reveal that it is generally typical for monumental structures in and around Istanbul to have thick ashlar external leaves made of limestone (local Küfeki stone) that cover the inner rubble masonry core. Limestone blocks are generally connected to each other via metal cramps (and in some cases with pins), which are fixed to the stone units with molten lead, in case no mortar is used between the units. The inner rubble masonry mainly consists of lime based mortar mixed with stone and brick pieces. Illustration of a typical three-leaf wall can be seen in Figure 2.

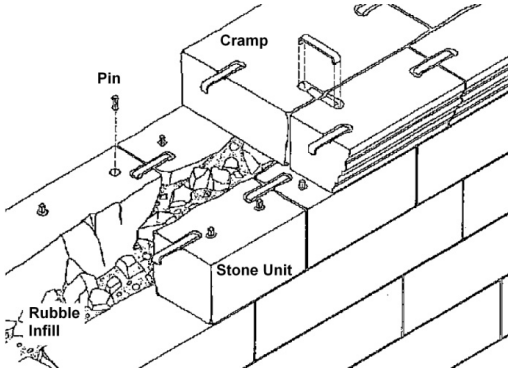

Figure 2 Typical wall configuration (modified from Tanyeli, 1990)

Considering the actual dimensions of walls and stone units together with the capabilities of the available testing facilities of Istanbul Technical University Structural and Earthquake Engineering Laboratory, an approximate scale factor of 1/3 was preferred that led to wallet dimensions of 1.20×1.20×0.30 m in length, height and thickness, respectively (as seen in Figure 3). Width of each leaf along the thickness of the wall was about 100 mm, however, at alternating stone courses the units of the external leaves were protruding into the rubble core for about 30 mm from both side, leaving a clear core thickness of 40 mm.

During the construction of the specimens, in order to replicate the main characteristics of the multi-leaf walls in the heritage structures around Istanbul, special attention was paid to apply similar materials and techniques. For this purpose, prior to the laying of the stone units, holes and channels required for the attachment of the cramps were prepared on the top surfaces of machine sawn limestone blocks. The Küfeki stone blocks were obtained from a quarry near Istanbul and sawn into desired dimensions. After laying and leveling the first course of stone units, U-shaped cramps were inserted into their slots. In the next step, lead melt in a pot was poured into the cramp slots, fixing them to the adjacent stone units as seen in Figure 4. After laying two rows of stone units of external leaves, rubble masonry was used to fill the gap between them. The rubble masonry was prepared by using the Albaria Struttura ready-mix mortar (from BASF Construction Chemicals) and irregular stone pieces obtained by crushing Küfeki stone blocks. Since the compressive strength of the ready-mix mortar was relatively high (approximately 20 MPa at 28 days), after a number of trials, sand and water was added to the ready-mix mortar to achieve a mortar compressive strength in the order of 5 MPa to replicate the actual mortar quality for the examined type historical structures more realistically. Steps described above were repeated until a height of 1200 mm was achieved. Construction steps indicated above can be seen in Figure 4.

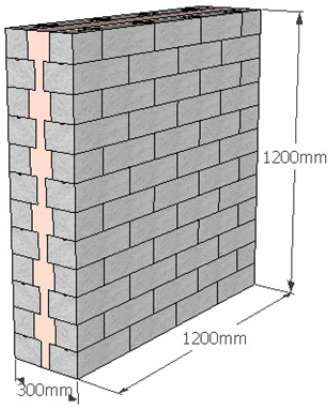

Figure 3 Dimensions of the tested walls

Figure 4 Construction of the specimens

During the application of lateral displacement cycles, normal stress level was kept constant as one of the following values: 0.25, 0.50, 0.75 and 1.00 MPa. Since it was the main parameter of the study, the names of the constructed walls were designated with respect to the targeted normal stress level of each specimen. Accordingly; M-25-C wall was tested under 0.25 MPa normal stress level; while M-50-C, M-75-C and M-100-C specimens were tested under 0.50, 0.75 and 1.00 MPa normal stresses, respectively. These stress levels were decided by considering the results of structural analyses available in literature for Ottoman period structures with multi-leaf walls and they represent normal stresses at different elevations of a structure.

2.3 Material Characteristics

Several material tests were also undertaken for defining the mechanical characteristics of materials used for construction of the shear compression test specimens. This stage of the experimental campaign included tests such as compression and modulus of rupture tests on Küfeki stone units; compression and splitting tests on rubble masonry standard cylinders; tension tests on steel material used for production of cramps; and initial shear tests on ashlar masonry dry joints. By utilizing these material tests, mechanical characteristics such as compressive strength, Young's modulus, tensile strength, friction coefficient, and stress-strain diagrams of the constituent materials were obtained. Accordingly, the mean compressive strength of the Küfeki stone material was 18 MPa (with a coefficient of variation of 29.6%) and mean modulus of rupture was 3.2 MPa. The rubble masonry material, that was formed by a mortar matrix and randomly distributed stone pieces placed without compaction had a mean compressive strength of 3.3 MPa at 28 days that dropped to 1.7 MPa at 180 days. Tensile strength of rubble masonry obtained from cylinder splitting tests was around 0.3 MPa at 28 and 90 days. The yielding stress of the mild steel used for the cramps was 250 MPa while the tensile strength was about 350 MPa. Finally, the friction coefficient of dry joints formed between the units of the ashlar external leaves was obtained as 0.76. It should be noted that more information on material characteristics can be found in Demir and Ilki (2013)

2.4 Test Setup and Loading Pattern

The in-plane lateral displacement cycles and the constant vertical load were applied to the walls by using the test setup shown in Figure 5. Test rig and the reaction frame were strictly fixed to the 1.20 m thick strong floor (reaction slab) of the laboratory via post-tensioned rods. Two 20 mm thick steel plates, stiffened with steel ribs, were used to restrict the horizontal sliding at the support level (first course) of the walls. Specimens were carefully positioned and aligned between these reaction plates that were located at both ends of the walls.

Lateral force required for displacement cycles was exerted by a ±990 kN force and 400 mm displacement capacity TDG actuator that was fixed to a reaction frame. A 600 kN capacity hydraulic jack pressurized by an electric pump was used for acting the vertical load. This hydraulic jack was coupled with a 1000 kN capacity loadcell for monitoring and keeping of the vertical load at the desired vertical load level. Both the hydraulic jack and the loadcell were placed between the test rig, which supplied a closed reaction frame for applying the vertical force, and a stiff steel beam. The in-plane translation of the upper end of the walls was eased by using steel cylinders placed between a steel encased reinforced concrete bond beam resting on the top surface of the specimen and the stiff steel beam. In addition to distributing the vertical load, the bond beam was also used for attachment of the lateral actuator. Although the measurements did not indicate a noticeable out-of-plane translation, as an additional precaution, walls were supported by two steel beams and wheels attached to them.

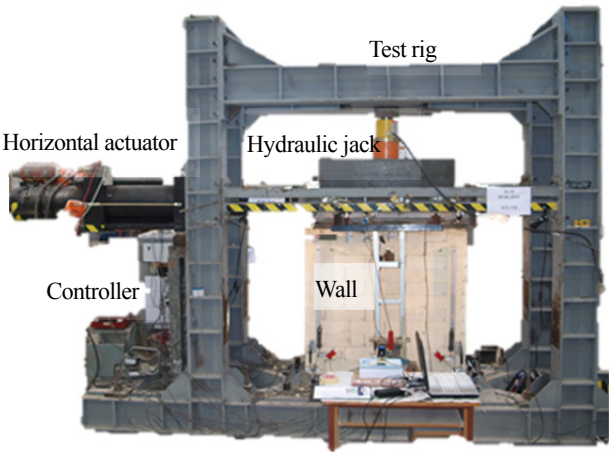

Figure 5 Test setup of the shear compression tests

The displacements, deformations and loads were measured by using different types of sensors. A total of 43 data collection channels; 35 linear variable differential transformers (LVDTs), two loadcells and six strain gauges; were installed on each shear compression test specimen. Data collected from all sensors were transferred to the computer by a TML TDS 302 Data Logger.

Loading of the walls was performed at two steps. At the first step, the axial load was applied until the desired pre-compression stress level (0.25, 0.50, 0.75 or 1.00 MPa) and then unloaded. These loading and unloading cycles were repeated for three times. Simultaneously data was collected from all sensors, so that variation of deformations under axial loading and unloading cycles could be recorded.

After completing the first step, all sensor channels were initialized and the axial load was increased to the targeted load level for the last time and lateral loading started. During the tests, axial force acting on the walls was carefully monitored and necessary adjustments were made to keep it at the desired value.

In all tests, reversed cyclic in-plane loading was applied under displacement control. All lateral displacement cycles targeted prescribed drift ratios, which progressively increased in amplitude: 0.05, 0.10, 0.25, 0.50, 0.75, 1.00, 1.25, 1.50 and 2.00%. Certain cycles near the peak load and in the post-peak region (0.5, 1.0 and 2.0%) were applied for

three times while the rest of the cycles were applied only once. The loading of the walls continued until peak load dropped in both directions at least by 20% or extensive damage occurred with an indication of loss of stability. Please note that a schematic representation of the applied loading pattern can be seen in Figure 6.

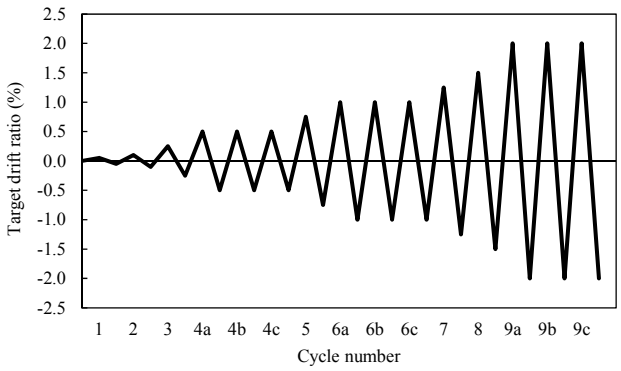

Figure 6 Loading pattern

3. RESULTS OF SHEAR COMPRESSION TESTS

3.1 Evolution of Damage and Failure Modes

All specimens exhibited failure types mainly dominated by the shear effects. However, depending on the level of axial stress level, differences in the behavior of the walls could be observed during the tests. For instance, bending effects as well as sliding of stone units were also observed, particularly for walls with relatively lower axial stress levels, whereas shear and compression effects were more dominant for walls with higher pre-compression loads. The damage distributions of M-25-C, M-50-C, M-75-C and M-100-C walls, observed during the shear compression tests and photographs taken after the tests can be seen in Figure 7.

The damage evolution generally started with vertical cracks passing through the stone units. These vertical cracks were mainly concentrated in the compression zones. Except the M-100-C specimen (with the highest level of axial stress considered in this study), horizontal flexural cracks appeared on rubble masonry between the initial stone courses at the lower halves of the specimens. Since the dry bed joints had zero tensile strength in the vertical direction, only the tensile strength of the rubble masonry resisted the tensile stresses at the tension side of the neutral axis.

Further increase of the lateral displacement caused formation of shear cracks along the diagonals of the walls. As also seen in Figure 7, due to the low tensile strength of the lime stone used in the specimen production and the restraining effects of the cramps interconnecting the head joints of adjacent units, these cracks were crossing the stone units rather than the head joints. The first diagonal cracks generally appeared near the 0.50% drift ratio.

Majority of the vertical and diagonal cracks crossing the stone units were generally, either at mid-length of the units or near the anchorage sockets of the cramps. Due to the existence of the cramps, that were transferring tension forces from one unit to adjacent one at singular points, diagonal cracks were wide spread across the wall faces. It should be noted that, number of cracks was higher in the case of specimens with relatively higher axial stresses, but crack widths were relatively smaller.

After opening of the wide spread diagonal cracks and failure of some of the cramp anchors (due to cracking of stone units), the concentrated compressive stresses around the toes caused crushing of these zones. In M-25-C and M-50-C walls, where the vertical compression stress levels were rather small, sliding at some of the stone courses were also observed.

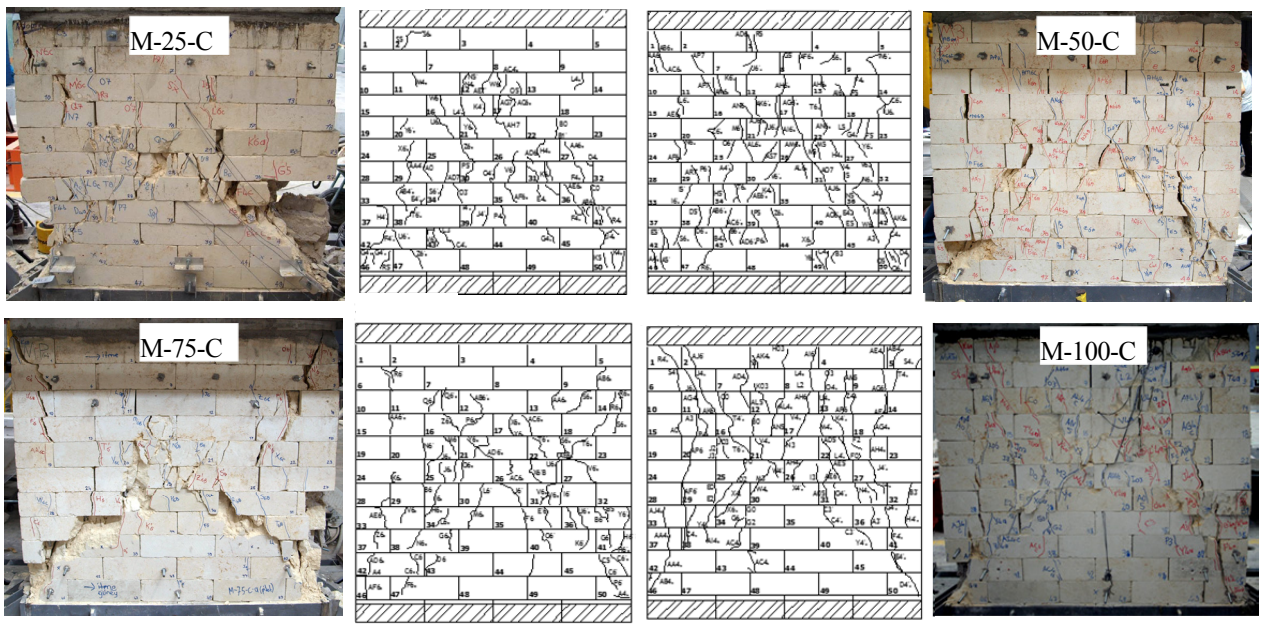

Figure 7 Damage patterns of tested walls

3.2 Test Results

Typical lateral load-displacement diagrams of specimens subjected to the lowest and highest constant normal stresses (0.25 and 1.0 MPa) are presented in Figure 8. Data points corresponding to first flexural cracking ($H_{f,cr}$), first diagonal cracking ($H_{dia,cr}$), maximum lateral resistance (H_{max}), 20% strength loss ($H_{0.8max}$) and ultimate displacement ($H_{d,max}$), are also marked in the same figure. The upper horizontal axes of these diagrams indicate the drift ratio values that correspond to displacement values of the lower horizontal axes.

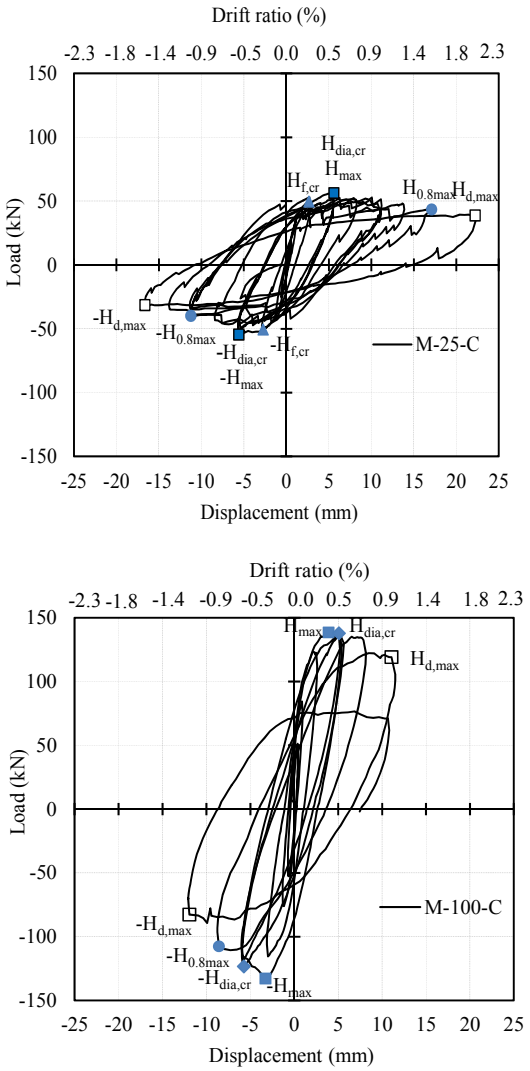

Figure 8 Lateral load-displacement diagrams for M-25-C and M-100-C walls

From the lateral load-displacement hysteresis diagrams, it can be observed that, at small displacement levels (i.e. at target drift ratios less than 0.50%) the walls exhibited elastic behavior and showed negligible residual displacement upon the reversal of the applied horizontal load. With the increase in the achieved lateral displacement, the walls exhibited a highly nonlinear response with significant residual displacements after each load reversal, which is typical for shear-controlled behavior of masonry walls. With the substantial loss in the horizontal load capacity and due to formation of extensive damage, the specimens reached their ultimate stages.

It should be noted that the tests were resumed until formation of extensive damage (namely, $H_{d,max}$ point), which could cause safety problems during the implementation of the tests. However, in order to define a uniform failure condition, during the interpretation of experimental results of this study, the ultimate state will be assumed as the critical state that corresponds to 20% strength degradation ($H_{0.8max}$ point on the hysteresis diagrams). Assumption of 20% strength loss for ultimate state has also been made by other researchers such as Magenes and Calvi (1997) and Frumento et al. (2009). Envelope curves derived from the hysteresis diagrams by considering this ultimate state definition are presented in Figure 9 for the pushing direction.

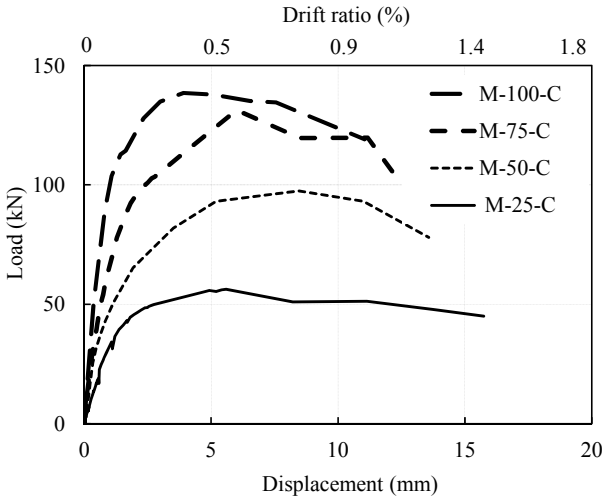

Figure 9 Envelope curves for the pushing direction

Comparison of lateral load-displacement envelope curves clearly shows that the variation of the pre-compression stress level has remarkable effect on the behavior. When submitted to low and moderate axial compression stresses, as in the case of M-25-C and M-50-C walls, larger displacement capacities can be achieved with lower lateral strengths. On the other hand, walls with higher axial pre-compression stresses (walls M-75-C and M-100-C) may reach higher lateral force capacities with less displacement capacities.

Tested walls reach their maximum resistance values (H_{max}) between 0.30 and 0.70% drift ratios (DR_{Hmax}). Assumed ultimate state, which corresponds to 20% strength loss ($H_{0.8max}$), is generally achieved between 0.80 and 1.50% drift ratios. Drift ratios corresponding to 20% strength loss ($DR_{0.8max}$) tend to decrease with the increase of the pre-compression stress level.

Shear strength (τ) is a key mechanical parameter for evaluation of the stress states in masonry walls. By using the test data, the variation of the shear capacity with respect to the pre-compression stress level (σ) can be visualized as shown in Figure 10. An analogy with the Coulomb criterion points to a global friction coefficient of 0.3 and adhesion strength of 0.09 MPa as seen in Equation 1. It should be

noted that the obtained global shear coefficient is smaller than the 0.4 and 0.5 values provided by the Eurocode 6 (CEN (2005)) and Turkish Seismic Design Code (2007) documents, respectively.

$$\tau = 0.09 + 0.3\sigma \quad (1)$$

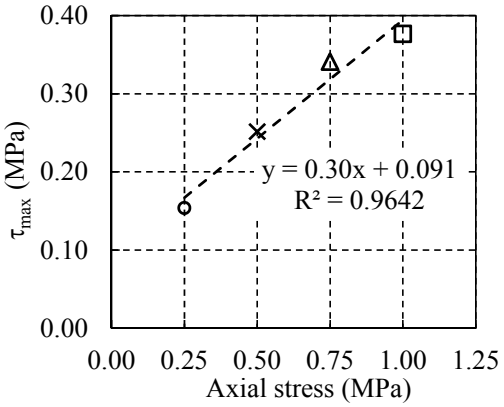

Figure 10 Variation of shear strength with pre-compression stress level

In Figure 11, variation of secant stiffness (K) with respect to displacement at peak values of each cycle (d_i) is presented for pushing direction of the M-25-C, M-50-C, M-75-C and M-100-C walls, for which the sole test parameter is the level of the pre-compression level. As it can be observed from this diagram, an increase in the axial stress level leads to remarkably higher secant stiffness values. However, the difference in stiffness parameter diminishes remarkably, as soon as the first significant cracks occur in the walls (before reaching drift ratio of 5%). Moreover, stiffness values of all investigated walls tend to approximate to very small values especially after formation of the diagonal cracks.

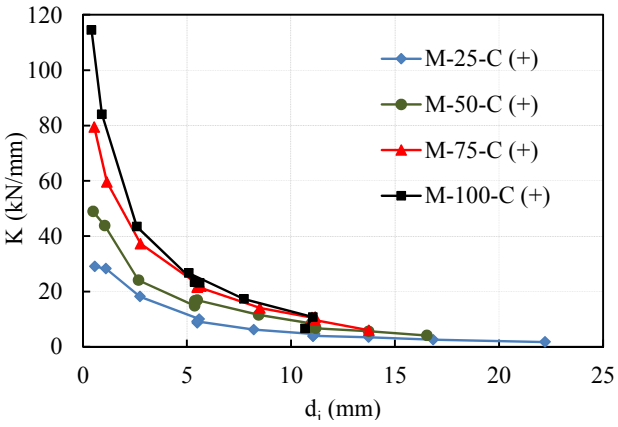

Figure 11 Variation of secant stiffness

4. CONCLUSIONS

An experimental study is carried out for investigating the in-plane seismic behavior of multi-leaf stone masonry walls observed in the Ottoman period structures. For this purpose, four multi-leaf masonry walls with ashlar external leaves and rubble masonry core were constructed and tested. The following conclusions can be drawn from the cyclic shear compression tests performed for four different normal stress levels:

- Although all shear compression test specimens clearly exhibited a shear-dominated behavior, bending effects were also observed particularly for walls with relatively lower axial stress levels.
- Due to the existence of the cramps, that were transferring tension forces from one unit to adjacent one, diagonal cracks were wide spread across the wall faces.
- The obtained hysteresis loops showed that the walls exhibited a highly nonlinear response with significant residual displacements after each load reversal.
- Shear strengths of the walls were directly proportional with the pre-compression stress level while the displacement capacities were inversely proportional.
- Increase in the axial stress level led to higher initial secant stiffness values.
- Stiffness values of tested walls approximated to each other particularly after formation of the diagonal cracks.

Abstract: Seismic retrofitting of unreinforced masonry structures in earthquake prone areas using cost effective and high performance materials is one of recent challenges which have attracted the attentions of many researchers worldwide. In this study, stress strain characteristics of FRP and FRP+PP-band retrofitted masonry wallets are studied under diagonal compression test. This study helps to quantify the amount of strain transferred from brick surface to the FRP. FRP can increase initial shear strength but exhibits a brittle failure. In spite of high cost and brittle failure, high tensile strength of FRP has made it a popular material. While PP-band retrofitted method do not affect initial shear strength but significantly increases the deformation and energy dissipation capacities of masonry structure at rate of very low cost. Whereas the FRP+PP-band composite, increases not only the initial strength but also deformation and energy dissipation capacities of masonry wall system. Diagonal compression test is carried out on a non-retrofitted, PP-band retrofitted, FRP retrofitted and one FRP+PP-band retrofitted masonry wallet. 45^{o} strain rosettes are applied on FRP and FRP+PP-band retrofitted masonry wallet on brick and FRP surface in order to evaluate the complete state of normal and shear strains and stresses.

1. INTRODUCTION

Masonry is worldwide famous material because of its local availability and minimum cost of construction. Masonry contributes a biggest number of houses in world building inventory. In the past, masonry structures were rarely designed for seismic loadings. Some of the recent earthquakes in Bam Iran, 2003, Kashmir Pakistan, 2005 and Wenchuan China, 2008 have exposed the vulnerability of masonry structures against earthquakes. In earthquake prone regions of developing countries, most of the existing masonry structures are still at high level of risks. Many different researchers have proposed different retrofitting and strengthening methods each method has its own advantages and disadvantages. Adding steel or concrete frames, applying thick and strong pilasters, shotcreting and applying ferrocement to the wall surface are some of the retrofitting methods. Most of these methods are time consuming, add mass and reduces clear spacing [J.M. Gilstrap et al., 1998]. FRP retrofitting has also become popular in the last two decades. Initially, FRP was used for concrete and later on its application was further increased on masonry structures. Figure 1 shows some of the experiments conducted by different researchers in order to determine the in plane behavior of FRP for different FRP retrofitting procedures. FRP application was easy; fast and also do not require skilled labor. Different researchers tried different application procedures and found that FRP can significantly increase the initial shear strength but the final failure of masonry was highly brittle. FRP has overcome the problem of difficult application procedures with less retrofitting time but at the rate of very high retrofitting cost. In this regard Kimiro Meguro and Paola Mayorca have developed a new PP-band retrofitting method [Meguro and Mayorca, 2003]. PP-band retrofitting method uses polypropylene band. It is very cheap and locally available material. Because of its local applicability, easy applicability and social acceptability, PP-band retrofitting method is one of the cheapest retrofitting techniques. PP-band retrofitting technique has been used for retrofitting of masonry and non-engineered houses in Indonesia, Nepal and in some parts of Pakistan. Figure 2 shows the application of PP-band over a masonry house in Kashmir, Pakistan after 2005 Kashmir Earthquake. FRP can increase the initial strength but it is a brittle and costly material. But, PP- band cannot increase the strength but can hold the wall system for a much bigger ground motion without collapse. PP-band hold the masonry wall system and give deformation capacity and energy

dissipation capacity to the masonry wall system [Meguro et al., 2008].

2. RESEARCH OBJECTIVES

In current research, stress strain characteristics of a new proposed composite retrofitting material are assessed. This composite material consists of Glass Fiber Reinforced polymer and PP-band. For efficient utilization of FRP and PP-band, both of these materials are applied in a specific way to the masonry structure. For most of the researchers, it is always the point of concern to transfer the maximum amount of strain from the brick to the FRP for better utilization of FRP strength. In this study, four types of masonry wallets are tested. Out of four types, one is non-retrofitted (URM), one is PP-band retrofitted and one is FRP+PP-band retrofitted masonry wallet. In case of FRP and FRP+PP-band retrofitted masonry wallet, a 45^{o} degree strain rosette is used to measure the strains on FRP and brick surface. In order to plot the stress strain curves of all types of masonry wallets a diagonal compression test is carried on all type of masonry wallets.

3. EXPERIMENTAL PROGRAM

3.1 Materials

Masonry materials are selected based upon the masonry construction in most of the developing countries. In order to construct the wallets at 1-4 scale, specially made clay burnt bricks of 75mm x 50mm x 38mm bricks are used. Bricks were soaked in water before construction of masonry wallet. Bricks were laid in cement lime mortar with weight mixed proportion (140g: 1110g: 2800g) of cement, lime and sand respectively. Mortar mixed is selected to replicate the decayed mortar conditions used in most parts of developing countries. Compression test is carried out on bricks and 50mm x50mm x 50mm mortar cubes according to ASTM C-67 and ASTM C-109. Bricks have shown an average compressive strength of 26.10 MPa. Whereas average compressive strength of mortar cubes is 1.16 MPa. Shear test, bond test and compression test is also carried out on masonry prisms. These masonry prisms were made using 5mm mortar thickness between the bricks. Brick triplets were made to measure the shear strength of mortar. The average shear strength of brick triplets was found to be 0.20 MPa. Biaxial type of GFRP is used with a fabric thickness of 0.5mm. Dimensions of PP-band are 6mm x 0.3mm. In order to determine the properties or GFRP and PP-band, tension test are carried out on one GFRP and 3 PP-band samples. Figure 3 shows the stress strain curve of PP-band and GFRP. GFRP has shown a very high tensile strength of 490 MPa with a failure strain of 2.7%. On the other hand, PP-band has shown relatively low tensile strength with an average value of 245 MPa but PP-band has shown a fairly long deformation capacity and has reached to a failure strain of 12.3%. E-250 epoxy bond is used to apply the GFRP over the surface of masonry wallet. Whereas PP-band is applied with the help of out of plane connectors provided at certain locations.

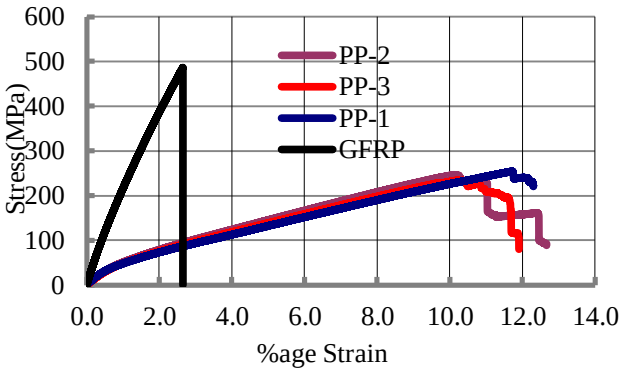

Figure 3 Stress strain curves of Glass Fiber Reinforced Polymers FRP and Polypropylene band

3.2 Experimental Setup

In current research, four types of masonry wallets are tested, one is non-retrofitted (URM), one is PP-band retrofitted, one is GFRP retrofitted and one GFRP+PP-band retrofitted wallet. All wallets were constructed using same constituent material and cured for 28 days before testing under same environmental conditions. Figure 4 shows the details of GFRP+PP-band retrofitted masonry wallet. All wallets have dimensions of 290mm x 280mm x 50mm.

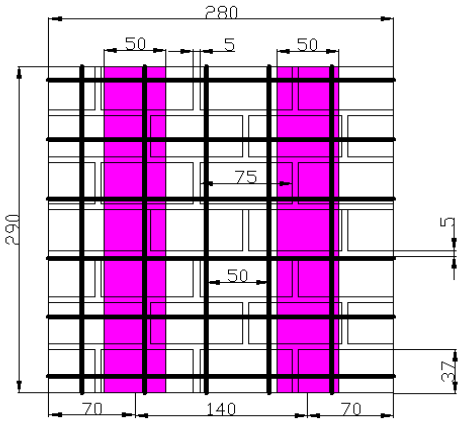

Figure 4 Details of GFRP+PP-band retrofitted masonry wallet

Wallet is tested under a static displacement control system. Response of wallet is measured in term of load and vertical displacement (ΔV) and horizontal displacement (ΔH). For displacement response measurement, two different type of test setup are used. High power lasers are used to measure the in plane horizontal deformation for URM and PP-band retrofitted masonry wallets. In case of FRP and FRP+PP-band retrofitted masonry wallet case two LDTV displacement transducers with 500×10-6/mm sensitivity are used. Six strain gauges are also used on each GFRP and GFRP+PP-band retrofitted wallet. Strain gauges at an angle of 45^{o} from each other are pasted using CN bond after application of PS bond over the brick surface whereas 3 strain gauges are directly applied over the GFRP surface using CN bond after rubbing the GFRP surface using a sand paper. In all masonry wallets, initial loading rate is kept equal to 0.15KN/mm up to the initial failure. In case of PP-band retrofitted and GFRP+PP-band retrofitted masonry wallets a loading rate of 1.00mm/min is used. PP-band is connected at 40mm from each corner of wallet. PP-band and FRP is applied on both faces of masonry wallet.

Shear stress and shear strain developed can be computed by the following equation (1) and (2).

$$v = \frac{P\cos\alpha}{((L+W)/2)t} \quad (1)$$

$$\gamma = \frac{(\Delta H+\Delta V)}{\sqrt{L^2+W^2}} \quad (2)$$

Where P = load applied, α = angle between the load and wallet top surface, L = length of wallet, W = height of wall, t = thickness of wall, ΔV = vertical deformation and ΔH = horizontal deformation.

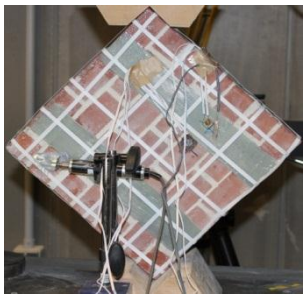

Figure 5 Experimental setup of a GFRP+PP-band retrofitted masonry wallet.

4. RESULTS AND DISCUSSION

4.1 Stress Strain Curve of Non-Retrofitted Masonry Wallet

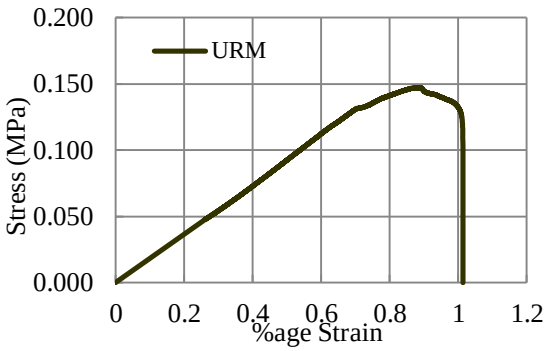

Figure 6 Stress strain curves of non-retrofitted masonry wallet

Figure 6 shows the stress strain curve of URM masonry wallet. Wallet has shown a peak stress of 0.144 MPa at a failure strain of almost 1%. URM wallet has shown a fairly linear behavior up to 0.6% strain. Failure of masonry wallet is shown in Figure 7.

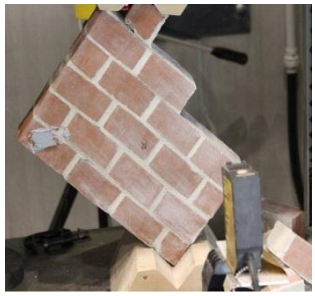

Figure 7 Failure Pattern of non-retrofitted masonry wallet

4.2 Stress Strain Curve of PP-band Retrofitted Masonry Wallet

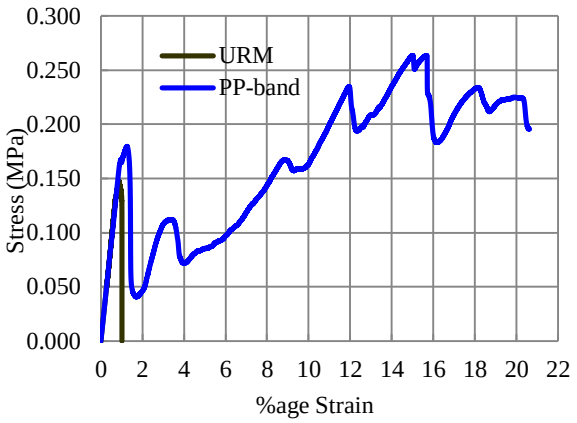

Figure 8 Stress strain curves of non-retrofitted and PP-band masonry wallet

Stress strain curve of URM and PP-band retrofitted masonry wallets are shown in Figure 8. URM and PP-band retrofitted masonry wallet has shown similar initial stiffness and peak load. In case of PP-band retrofitted masonry wallet, after the initial peak wallet again start taking load due to holding and confining effect provided by the PP-band. After the %age strain of 10, the wallet has shown a stress value which is greater than the initial peak strength of URM. PP-band retrofitted has shown a very high %age strain which indicates a very high ductility and deformation capacity of masonry wallet. Failure pattern of masonry wallet is shown in Figure 9.

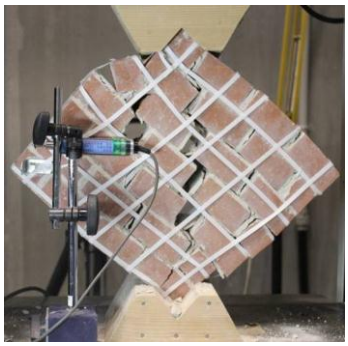

Figure 9 Failure Pattern of PP-band retrofitted masonry wallet

4.3 Stress Strain Curve of GFRP Retrofitted Masonry Wallet

Figure 10 shows the stress strain curve of URM, PP-band retrofitted and GFRP retrofitted masonry wallet. GFRP has increase the initial shear strength of URM and PP-band retrofitted masonry wallet from 0.17 MPa to 0.81MPa. But, failure strain of GFRP retrofitted masonry wallet was found to be only 4%. Final failure of GFRP retrofitted wallet was also brittle and failure was initiated due to debonding of GFRP from the wallet surface. Figure 11 shows the failure of masonry wallet due to detachment of GFRP from the wallet surface.

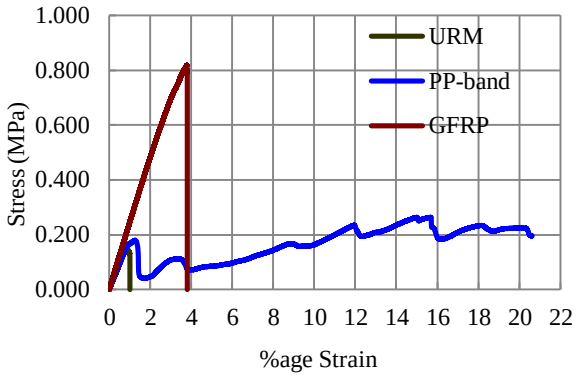

Figure 10 Stress strain curves of non-retrofitted, PP-band retrofitted and GFRP retrofitted masonry wallet

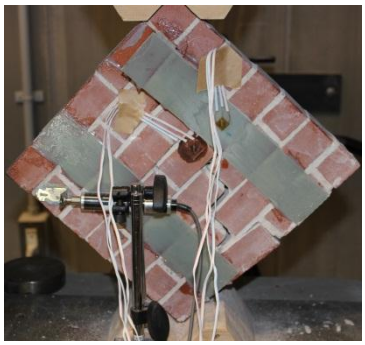

Figure 11 Failure Pattern of GFRP retrofitted masonry wallet

4.4 Stress Strain Curve of GFRP+PP-band Retrofitted Masonry Wallet

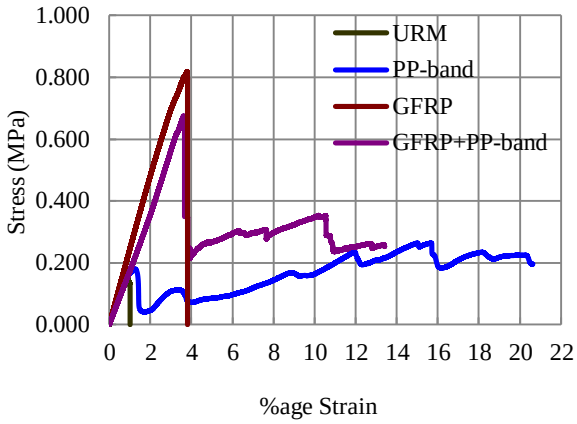

Figure 12 Stress strain curves of non-retrofitted, PP-band retrofitted, GFRP and GFRP+PP-band retrofitted masonry wallet

Stress strain curve of URM, PP-band retrofitted, GFRP retrofitted and GFRP+PP-band retrofitted masonry wallets are shown in Figure 12. GFRP+PP-band retrofitted masonry wallet has not only increased the initial strength as that of GFRP retrofitted masonry wallet but also the ductility and %age strain as that of PP-band retrofitted masonry wallet. Final failure of masonry wallet has also become gradual and ductile. In addition to, application of GFRP+PP-band has also increased the residual strength of masonry wallet. Figure 13 shows the failure mechanism of GFRP+PP-band retrofitted masonry wallet.

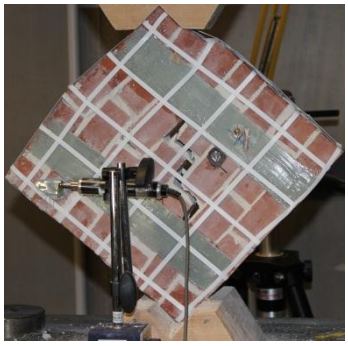

Figure 13 Failure Pattern of GFRP+PP-band retrofitted masonry wallet

5. CONCLUSIONS

Current study provides a very simple and clear stress strain analysis of different retrofitting methods. Each method has its strong points and weak points but proposed GFRP+PP-band composite retrofitting techniques is one the cost efficient and high performance composite retrofitting method which can be used for seismic retrofitting of masonry structures. GFRP is a cheapest type of FRP as compared to Carbon Fiber reinforced polymer and Aramid Fiber Reinforced Polymer. On the other hand PP-band is also one of the cheapest retrofitting materials. As a result, GFRP+PP-band composite is cost effective material which can increase the initial strength, ductility, deformation capacity and energy dissipation capacity. Failure of GFRP and GFRP+PP-band of wallets was started due to debonding of GFRP from the brick surface which motivates to use a strong epoxy agent rather than a strong FRP.

Abstract: Near-fault earthquake motion usually contains early arriving, large velocity pulses when forward directivity is present. These velocity pulses may greatly increase the strength demand on structures. To include the effect of near-fault motion the New Zealand design standard NZS 1170.5 introduce a spectral amplification factor for structures with periods longer than 1.5 s, but neglect this effect on short period structures. Previous research has shown that structural uplift can reduce the development of plastic hinges in structures. However, very few experimental studies of structural uplift including near-fault effects are contained in the literature; nearly all studies are numerical analyses. In this paper shake table tests of a multi-story building are presented and discussed. Two support conditions, i.e. fixed at the base and with uplift permitted on a rigid platform, are considered. To simulate possible damage to the moment-resistant frames artificial plastic hinges are constructed. Pulse motions were chosen from the recent series of Christchurch earthquakes. Structural response under a selected motion and a simulated motion from NZS 1170.5 is compared to reveal the effect of near-fault forward directivity related pulses. The influence of a velocity pulse on plastic hinge development, the maximum displacements of floors and maximum bending moments of columns are discussed.

1. INTRODUCTION

Urban areas have developed rapidly in seismically active zones worldwide since last century. Only in recent decades it has been noticed that the characteristics of ground motions in the vicinity of a fault are different from those of far-fault motions (Chopra and Chintanapakdee, 2001). Near-fault ground motion sometimes contains long-duration, low acceleration pulses. Forward directivity effects that occur in the near-fault region can be particularly damaging at sites lying in the direction of advancement of fault rupture from the hypocenter. The propagation of rupture towards a site, at a large shear wave velocity, causes most of the seismic energy from the rupture to arrive in a single large pulse of motion at the beginning of the record. To numerically describe these pulses the term incremental velocity has been used. This is defined as the area under the acceleration pulse (Anderson and Bertero, 1987). The long duration pulses that induce intensive incremental velocity can lead to unfavorable seismic performance of structures (Hall et al., 1995, Anderson and Bertero, 1987).

The study of near-fault ground motions has been difficult to carry out due to only a small number of near-fault ground motions being recorded. The damaging characteristics of near-fault ground motions are only apparent in moderate to large earthquakes, and these events occur relatively infrequently. The sparse spatial coverage of recording stations has also been a reason for the limited number of ground motions recorded close to fault rupture. After the 1994 Northridge and 1995 Kobe earthquakes, which occurred near large centers of population with more dense station coverage, more near-fault strong motions have been recorded. Somerville (1997) identified the characteristics of near-fault ground motions with forward directivity, especially the large spectral displacements in the strike-normal direction at long periods. Somerville et al. (1997) also suggested a simple model for near-fault design spectra to accommodate the effects of near-fault ground motions. This model has been adopted to derivate the near-fault spectral amplification factor in the New Zealand design standard NZS1170.5 (2004). However, the design standard NZS1170.5 applies no spectral modification factor to structures with a period less than 1.5 s. Somerville et al. (1997) also highlighted that the near-fault pulse could have significant effects on non-linear systems. To investigate this further a short-period structure with possible plastic hinge development during response has been utilized in this experimental study.

In the 2011 Christchurch earthquakes, a series of ground motions were recorded near a blind fault lying within 6 km of the city center. The characteristics of near-fault ground motion are able to be observed in some of these records. A very large amount of structural damage was reported. The performance of a 36 m high industrial

chimney at the Air New Zealand Engineering Base at the Christchurch airport (18 km away from the epicenter) during the February 17 main event is worthy of investigation. This chimney is one of the early structures that was designed to uplift under strong earthquake motion (Sharpe and Skinner, 1983). The design was carried out to avoid the difficulty of detailing the ductile region and the potential permanent deformation after shaking. Although the chimney was subjected to strong ground motions, no structural damage has been observed (Chouw and McCue, 2012). The superstructure was protected from seismic moment and shear by the redistribution of loads caused by lift-off.

The benefit of structural uplift was first recognized by Housner (1963) where the good performance of several elevated water tanks in the 1960 Chile earthquake was reported. He also initiated the study of structural uplift using a rectangular rigid and free standing block. This work established that earthquake energy can be dissipated via rocking. Huckelbridge and Clough (1978) were the pioneers of physical investigations of structural uplift when they tested a nine story steel frame with uplift using a shake table. They found that significant uplift to the structure would occur during a moderate, credible earthquake. The results also confirmed that a design including a planned uplift capability would provide a structure with a higher possibility of surviving a strong earthquake. About the same time Priestly et al. (1978) carried out shake table tests on a single degree of freedom model. Based on the results they suggested the first design approach to rocking structures. This design approach has been adopted by the FEMA 356 Guidelines (FEMA356, 2000). Recently, Hung et al. (2011) performed pseudo-dynamic and cyclic loading tests on bridge piers with and without plastic hinge. The uplift benefit of reducing ductility demand was confirmed.

However, research of structural uplift so far has infrequently considered the difference of response induced by near-fault and far-fault earthquakes. In Housner's work on rocking in 1963 it was stated that overturning of a block also depends on the incremental velocity and not merely on the peak ground acceleration, but this important concept received little attention. A procedure to estimate the level of a pulse-type ground motion that is needed to overturn a rectangular rigid block was provided by Makris and Roussos (2000). Hung et al. (2011) described experiments that focused on rocking and compared the effect of artificial earthquake accelerations generated from a design code with real ground motion records from a near-fault site. Results showed that the near-fault earthquake with high velocity impulses produced higher displacement demand at the deck level of a rocking pier.

In this paper the effect of near-fault pulse ground motions on structural displacements, bending moment and plastic hinge development is discussed. Shake table tests of a scaled six story building with a fundamental period less than 1 s are presented. Artificial plastic hinges were constructed to simulate the possible structural damage during the earthquake. The response of structure is compared for two different support conditions, 1) fixed at the base and 2) on a rigid base but with uplift permitted. In order to highlight the effect of near-fault ground motion, the model was subjected to a ground motion selected from the February 2011 Christchurch earthquake and a simulated motion shaped according to NZS 1170.5.

2. EXPERIMENTAL INVESTIGATION

2.1 Model design

A six-story office building was considered as the prototype structure. The building has a 3 m floor height, 48 m^2 floor areas and a 6 m × 6 m spread footing. The columns of the top three levels were 310UC118 and the columns of the bottom three levels were 310UC158. The size of the beams was 410UB53.7 throughout the entire structure. The beam and column arrangement is explained in Figure 1(a). A 170 mm thick reinforced concrete slab was placed on each floor. In Figure 1(b) the general view of the prototype and the coordinate system is shown. Excitations were applied in the x direction. The lateral stiffness in the direction of excitation for the top and bottom three levels was 3.21E7 N/m and 4.44E7 N/m, respectively. According to the NZS 1170.5 (2004) for earthquake actions, the seismic masses were 24 tones for the roof and 29 tones for each floor. The natural periods of the 1st to 6th modes are 0.680, 0.245, 0.151, 0.116, 0.101 and 0.087 s, respectively.

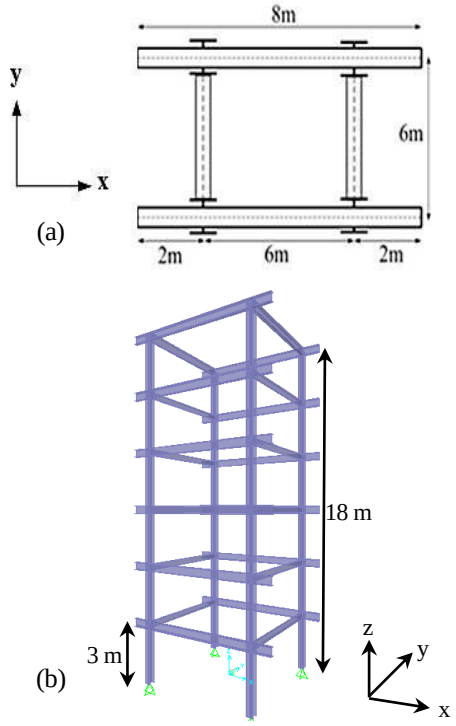

Figure 1 Prototype structure: (a) Beam and column arrangement and (b) general view

The experimental model was scaled to fit the capacity of the shake table. The scaling is based on the model and the prototype obeying the law of similitude. To achieve this similarity, dimensional analysis based on Buckingham π theorem (Buckingham, 1914) was performed. The three

basic dimensions: mass *M*, length *L* and time *T* in the dynamics of scale model were considered. All other dimensions of the selected physical parameters were then derived based on these three basic dimensions as displayed in Table 1. In numerous shake table tests with scaled structures the Cauchy number and Froude number are usually considered. The Cauchy number is the ratio between inertial and elastic restoring forces, and the Froude number is the ratio between inertial and gravitational forces. In Qin et al. (2012) experiments using a modified Cauchy number were adopted. The following dimensionless groups based on the new modified Cauchy Number are given in equation 1.

$$\pi_1 = t * \sqrt{\frac{a}{l}} \text{ and } \pi_2 = \frac{E*l^2}{m*a} \quad (1)$$

where *t, a, l, m, k* and *E* are defined in Table 1.

By equating these dimensionless groups when applied to the prototype and the model, the scale factors of all physical quantities considered were determined (Table 1). The model was scaled down 15 times. PVC was used to construct the columns (E_{PVC} = 2.5 GPa and E_{steel} = 200 GPa), and aluminium angle sections were selected to simulate the rigid beams. The lateral stiffness of the prototype was scaled in the excitation direction only. A scale factor of two was used for time. After applying the scale factor for time the fundamental period of the model is 0.340 s.

Table 1 Scale factors of parameters

Parameters	Symbols	Dimensions	Scale Factors
Length	*l*	L	15
Mass	*m*	M	4800
Time	*t*	T	2
Acceleration	*a*	LT^{-2}	3.75
Stiffness	*k*	MT^{-2}	1200
Young's Modulus	E	$ML^{-1}T^{-2}$	80

2.2 Artificial plastic hinges

Because of the difficulty of scaling the yielding moment of structural members in small-scale laboratory tests, artificial plastic hinges were constructed (Figure 2). These hinges are located at the supports and beam-column joints. The moment capacity of each artificial hinge was set using a torque wrench. A torque of 5 Nm was applied to all the hinges. Analysis of experimental test results for overturning moment showed that initiation of plastic rotational slippage occurred when the overturning moment was 140 Nm. A torque of 20 Nm was found to be sufficient to prevent any plastic hinge developing when the objective was to perform elastic analyses.

Once the bending moment reaches the capacity of a hinge, rotational sliding will occur. Thus, the structure becomes nonlinear and structural damage is able to be simulated. To ensure the repeatability of the artificial hinge performance, Teflon washers were placed as shown in Figure 2. Since the moment capacity of the artificial plastic hinge along the height of the building was the same, a beam-sway mechanism was represented.

2.3 Test setup

Two support conditions were considered in this project. The structure was fixed at the base to replicate the support assumption in most conventional design. To reveal the effect of structural uplift, the same structure was placed free standing on a rigid platform. Sand paper was attached to the top of the rigid base and the bottom of the foundation to increase the friction between the footing and base surfaces. Thus, sliding during uplift could be minimized. The other quantities measured include the acceleration and lateral displacement on each floor, the vertical displacements during uplift and the bending moment at the base of each column.

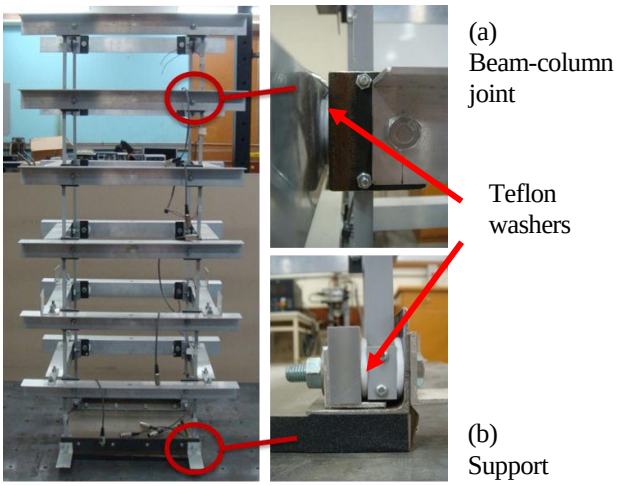

Figure 2 Model artificial plastic hinges

3. GROUND MOTIONS

The near-fault pulse ground motions were selected from records of 45 stations recorded in the February 2011 Christchurch earthquake. In order to identify the near-fault characteristics of the ground motions, a classification scheme modified from the work of Hayden et al. (2012) has been applied. The near-fault ground motions utilized were recorded within 30 km of the epicenter, with the largest peak to peak velocity (PPV) occurring over less than 2.5 significant cycles which have amplitudes larger than 25% of the PPV. These ground motions were than scaled to a very severe level using the highest hazard factor of NZS1170.5 (0.6) and a return period of 1000 years. In this paper, the structural response using the S88E component recorded in Christchurch Resthaven (denoted as REHS), scaled in the manner described, is presented. This station is 8 km from the source and on a site with a classification of class D (deep or soft soil site). The scaled time history is displayed in Figure 3(a).

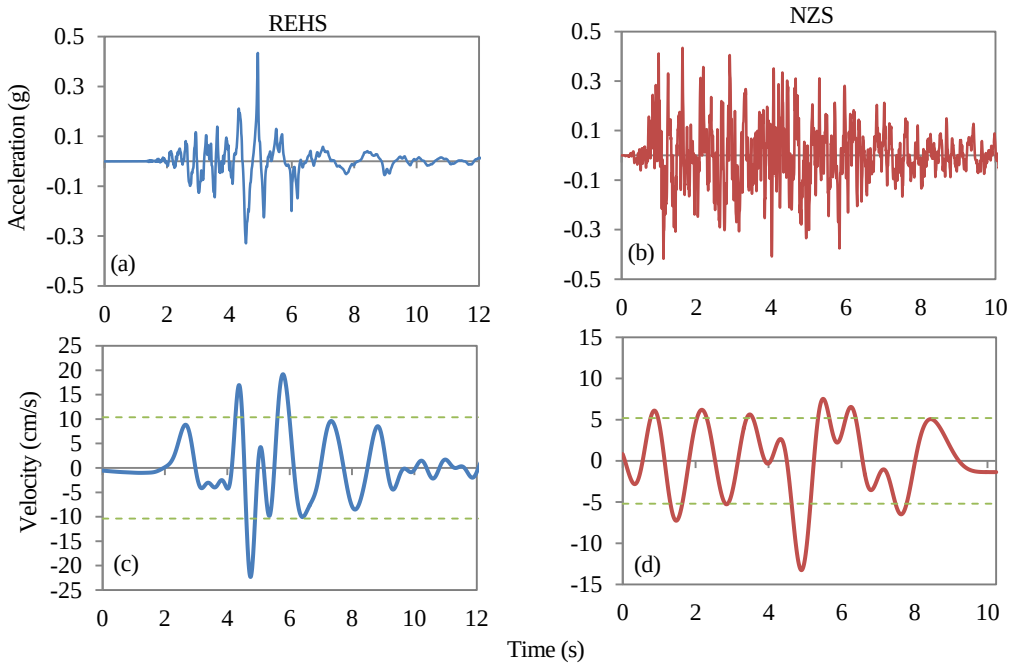

Figure 3 Scaled acceleration and velocity time histories of REHS ((a), (c)) and NZS ((b), (d)) ground motions

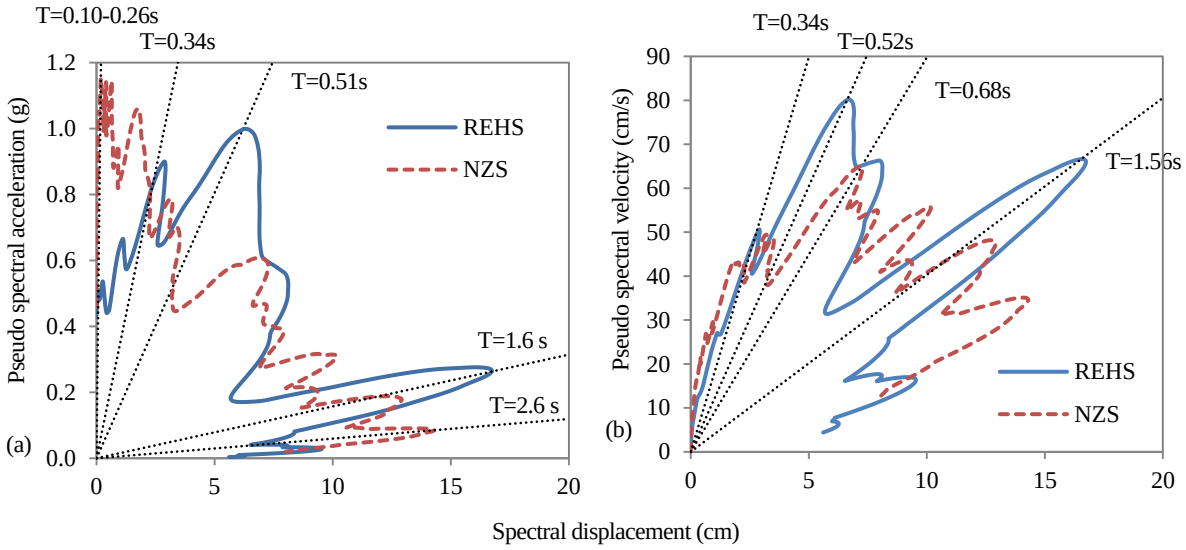

Figure 4 Scaled elastic spectral displacement, pseudo spectral acceleration and pseudo spectral velocity of REHS and NZS ground motions

A simulated ground motion based on NZS1170.5 (2004) design spectra for a class D site was used as a comparison to reveal the effect of velocity pulses. The simulated ground motion has the characteristic of far-field ground motion which is not affected by forward directivity. To simulate this ground motion, base rock excitations were filtered from white noise and the site effect was computed based on wave propagation theory (Bi and Hao, 2011). Since in conventional seismic design, peak ground acceleration is generally considered to be the main governing parameter, the simulated ground motion (denoted as NZS) was scaled to yield a peak ground acceleration (PGA) of 0.43 g, the same as the modified recorded REHS ground motion (Figure 3(b)).

The spectral displacement, pseudo spectral velocity and pseudo spectral acceleration (5% damping) of the two scaled ground motions are shown in Figure 4. The predominant period of the NZS motion lies between 0.1 to 0.26 s (0.05 to 0.28 s, scaled from NZS1170.5), while that of the REHS motion is 0.51 s (Figure 4(a)). The response of long period structures are more pronounced when they are subjected to a near-fault earthquake. The peak spectral acceleration of NZS motion (1.15 g) is 15% larger than that of the REHS motion. The spectral values for both ground motion at the fundamental period (T = 0.34 s) of the model are coincidentally the same.

The greatest spectral displacement of 16.7 cm is observed at a period of 1.6 s in the REHS ground motion, while peak spectral displacement of 14.3 cm is shown at a period of 2.6 s in the NZS motion. The periods 1.6 s and 2.6 s are the periods of the velocity pulses of the REHS and NZS ground motions, respectively. A corner period that is equal to one third of the pulse period was used to filter the velocity time history for each ground motion with a low-pass Butterworth filter. The filtered velocities of two ground motions are shown in Figure 3(c) and (d). PPVs of 41.5 cm/s and 20.8 cm/s are shown in the REHS and NZS ground motion, respectively. The stronger velocity effects of REHS ground motion can also be seen in the pseudo spectral velocity-spectral displacement plot (Figure 4(b)). Indicators of 25% of PPVs are illustrated using dash lines in Figure 3(c) and (d). There are one and an half significant velocity cycles of REHS motion, while the NZS motion contains four cycles. In near-fault motions with forward directivity effects, seismic energy is concentrated in one or two strong velocity cycles (Hayden et al., 2012).

4. RESULTS AND DISCUSSION

4.1 Plastic hinge development

In order to reveal the effect of velocity pulses on the plastic hinge development in structures, the bending moments at the base of the column near the support is plotted against the flexural displacement of the first floor in Figure 5. The values of residual deformation are shown on the top right corners of all the plots in Figure 5. The response of the structure fixed at the base is illustrated in Figures 5 (a) and (b). A larger maximum flexural displacement (8.5 mm) is measured when the structure is subjected to REHS ground motion. This deformation is 52% larger than the response under the NZS motion.

As displayed in the velocity time history of the REHS motion (Figure 3(c)), the first strong velocity pulse arrives at 4.4 s, followed by another pulse in the opposite direction and the last strong pulse is evident at 5.8 s. In Figure 5 (a), the first strong velocity pulse induces a dislocation of 7.9 mm in the positive direction. The first floor is almost pulled back to the origin due to the following pulse in the opposite direction. As a result of the third pulse, the first floor has an offset of 7.6 mm. A residual deformation of 5.3 mm was ascertained after the shaking. However, there is no obvious pulse dependent deformation of the structure under the NZS ground motion (Figure 5(b)). In the case of NZS ground motion, a residual deformation of 1.6 mm is resulted from the accumulation of small increments.

Severe damage of the plastic hinge, perhaps even structural collapse, is likely to occur under near-fault ground motion at the moment a strong velocity pulse strikes. Since a large amount of energy is stored in this pulse, to achieve the same ductility factor a higher strength of column plastic hinge would be required when the near-fault pulse ground motion is considered.

The responses of the structure with freedom to uplift and plastic hinge development are shown in Figures 5(c) and 5(d). The maximum flexural displacement of the structure with uplift (8.8 mm) is slightly less than that of structure

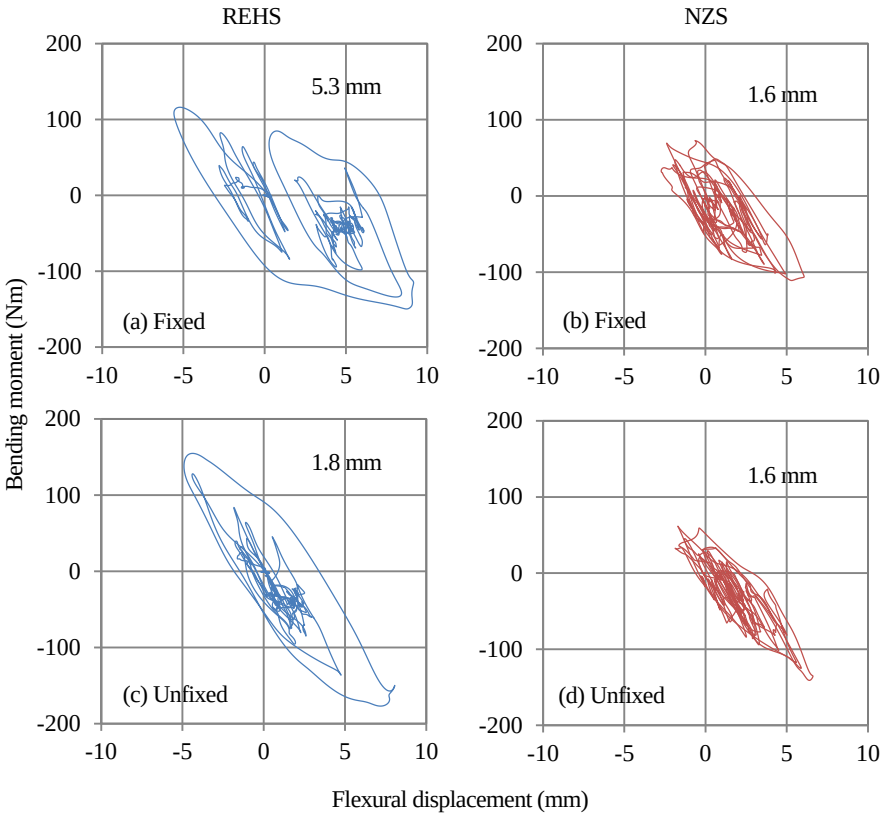

Figure 5 Bending moment at the base of column near the support and flexural displacement of first floor of the model (a) (b) fixed at the base and (c) (d) with uplift under both ground motions

fixed at the base (9.2 mm) in the case of REHS ground motion. However, the maximum flexural displacement of the structure free at the base is 0.5 mm larger than that of structure fixed at the base under NZS motion.

It is illustrated in Figure 5(c) that structural uplift has a large influence on the residual displacement in the case of near-fault ground motion containing large velocity pulses (i.e. the REHS case). The first velocity pulse leads to a similar deformation in both the free to uplift and the fixed base case. The subsequent pulse in the opposite direction lifts the structure and shifts the center of gravity in the negative direction. Thus a displacement of -5 mm is recorded. The last velocity pulse pushes the structure back to its original position. At the end of the excitation the residual displacement is 1.8 mm which is only one third of the fixed base case using the REHS motion containing velocity pulses. However, the effect of uplift on the structural response under the NZS ground motion is not significant, because no strong velocity pulse occurs when using this motion. The result confirms that the structure is more likely to uplift when it is subjected to near-fault motion containing velocity pulses.

4.2 Predominant periods

The predominant periods of the structures, of different cases, are summarized in Figure 6. The predominant period is where the maximum Fourier amplitude, calculated from recorded accelerations on the top of the structure, takes place. Using the motion REHS when the structure remains elastic a large predominant period of 0.75 s is obtained. This predominant period is the same as the rocking period of the structure with a foundation rotation of approximately 0.04 rad. Thus most of the lateral displacement arises from the base rotation rather than the flexural displacement.

In the case of the fixed base structures the predominant period of the structure does not change when nonlinearity is included under REHS ground motion. This predominant period is the same as the fundamental period of the elastic and fixed-base structure (0.34 s). When the structure is subjected to near-fault pulse motion, damage occurs at the moment the intense velocity pulse takes place.

However, the periods are lengthened from 0.34 s to 0.39 s in the case of NZS ground motion. Small increments of plastic deformation as a result of the artificial plastic hinges not being an ideal elasto-plastic system occur throughout the whole simulated excitation, since there is no intense velocity pulse.

4.3 Maximum lateral displacements of floors

The change of lateral displacements along the height of the building is displayed in Figure 7. Comparing the response of the linear structure under REHS and NZS ground motion, the lateral displacement of each floor is greater in case of the pulse ground excitation. Since the response to NZS ground motion is more pronounced for periods shorter than the structural fundamental period (0.34 s), as indicated in Figure 4(a), the higher modes of the structure are more readily excited. The contribution of the higher modes can reduce the maximum displacement of each floor.

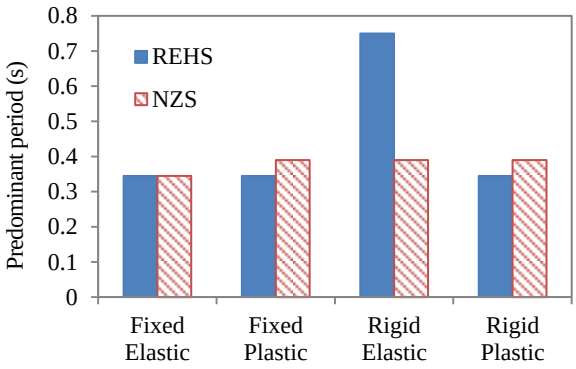

Figure 6 The predominant periods of the structures under different conditions

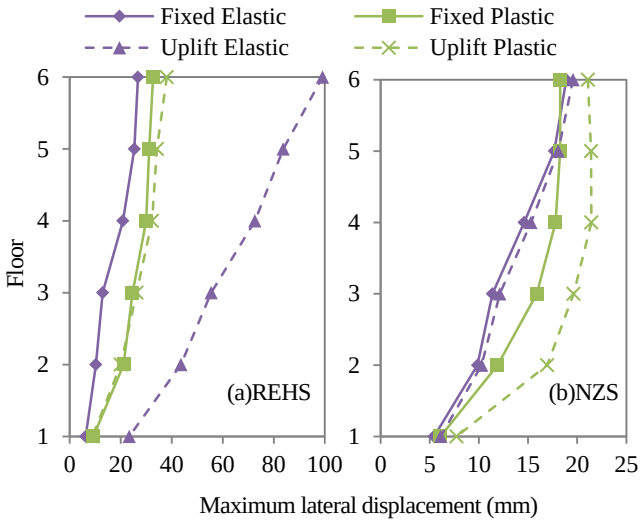

Figure 7 The maximum lateral displacement of each floor

The lateral displacements of structures with uplift are larger than those of structures fixed at the base as shown in Figure 7. When the structure without plastic hinge development is subjected to REHS ground motion, the maximum displacement at the top of the structure with uplift (99.1 mm) is 3.7 times that of the fixed base case (26.8 mm). However, the increase of displacement (3.7%) due to uplift is small in the case of NZS ground motion. The lateral displacement from footing uplift is substantially greater in the REHS case, as the overturning of a structure is related to the incremental velocity. This increase of displacement under REHS motion is greatly reduced to 16.3% when the structure deforms plastically. The coupling effect of plastic hinge development and structural uplift depends on both the yielding capacity of the plastic hinges and the resistance moment of overturning due to structural self-weight. Further investigation is required to understand the interaction of structural nonlinear behavior and footing uplift in near-source earthquakes.

4.4 Maximum bending moment of columns

The bending moment at the end of each column was evaluated using strain gauges. Figure 8 shows the maximum

bending moment developed by the structure under different conditions. Except for the case when large foundation rotation is present, both structural uplift and plastic hinge development can reduce the strength demand of columns. Comparing the response of structure under REHS and NZS ground motions, greater bending moments are developed during near-fault pulse excitation. Generally speaking, the effects of near-fault ground motion with forward directivity are significantly stronger at the base of building than at the top. For example, the bending moment of column on the fifth floor of structure with plastic hinges developed and footing uplift under REHS motion is 59% larger than that of structure under NZS motion. However, the value of bending moment near the supports is 1.1 times larger.

When plastic hinges are developed, the bending moment at the end of column on the second floor could be less than that on the third floor. Although same torque has been applied on each hinge, the yielding capacities of beam-column joint hinge and support hinge are different due to the variation of friction between different fabrication materials. As indicated in Figure 2, the beam-column joint hinge involves frictional contact between the Teflon and metal, while the support hinge has Teflon-PVC contact on one side and Teflon-metal on the other. Therefore, the effect of plasticization of the second floor beam-column hinge on bending moment is more obvious comparing to the other locations.

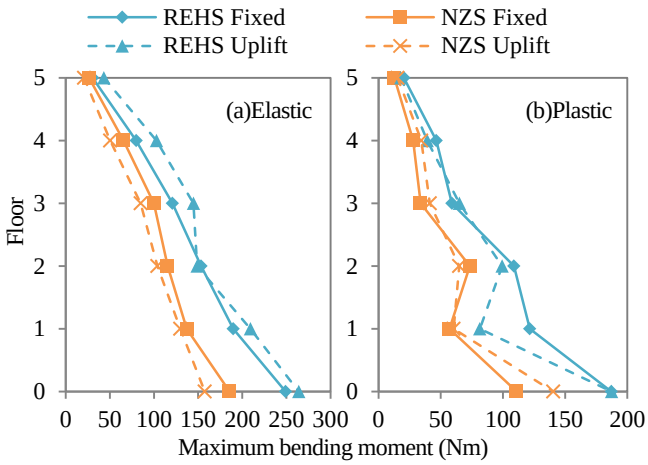

Figure 8 The maximum bending moment of column on each floor

5. CONCLUSIONS

In this work, shake table tests on a small scale six story building with a fundamental period of 0.68 s were performed to investigate the effect of near-fault pulse motion on the performance of structures with foundation uplift and plastic hinge development. The artificial plastic hinges are able to control the moment capacities of bean-column joints as well as the supports and were constructed to simulate the damage to the structure under strong seismic motions. Scaled near-fault ground motions recorded in the 2011 Christchurch earthquake containing intense velocity pulses were utilized. A simulated ground motion based on the site class D spectrum from NZS 1170.5 (scaled to the same PGA as the Christchurch motion) was also applied to reveal the effects of the characteristics of near-fault ground motion.

The responses of structures with and without plastic hinge development incorporating different support conditions, i.e. fixed at the base and with uplift on a rigid base, were studied. The study reveals that:

- The velocity pulses of near-fault ground motion can induce large rotations of plastic hinges almost instantaneously and may lead to large residual deformation.
- Structural uplift reduces the residual deformation of a structure subjected to near-fault ground motion with forward directivity effect.
- Near-fault pulse ground motion can induce larger lateral displacements compared to simulated ground motion broadly shaped to agree with a design code ground motion (far-field motion). The strength demand on plastic hinges of the structure will be underestimated when following conventional design procedures.
- Larger bending moments of the structural members will be induced by near-fault pulse ground motion compared with far-field motion.
- The effect of near-fault ground motion with forward directivity characteristics on a structure with a short period is likely to be significant. This effect is currently neglected in the design standard NZS1170.5 (2004). Where possible time history analyses with consideration of pulse type ground motion is recommended for important short period structures to avoid poor performance during near-fault forward directivity seismic motions.

Abstract: A new viewpoint to buildings with open ground storey is roposed. The potential benefits of soft storey mechanisms in existing buildings are numerically investigated. Response parameters from different case studies with and without soft-storey mechanisms are compared. The study initially considered two different infill configurations: the first with full masonry infill and the second with an open ground storey with full masonry infill above the first floor. Results of incremental dynamic analyses indicate that structures with uniform infill are less likely to collapse. However, the responses in isolated floors above the first floor are considerably improved for soft storey cases, provided that the large displacement demands at the soft storey are controlled properly. Then it is recognized that the need to retrofit structures with partial infill depends on the seismic hazard and acceptable risk. Loss estimation also demonstrates that the expected reduction of cost to non-structural components in isolated floors is a great advantage of buildings with soft-first storey.

1. INTRODUCTION

Earthquake surveys have shown that soft storey buildings, also called pilotis structures, are one the most vulnerable structures and their behaviour has been recognized as one of the most undesirable mechanisms among the structural and earthquake engineering society. For example, serious damages or collapse of first floor structural elements are reported in the 1971 San Fernando (M_w=6.6) and 1978 Miyagi-ken Oki (M_s=7.7) earthquakes. As a result, soft story structures were thoroughly studied and design procedures and recommendations were developed to prevent column side-sway mechanisms . Most of these studies emphasized that the column elements at the soft floor reach their ultimate capacity at considerably lower levels of intensity than mechanisms that involve distributed deformation demands over the height of the buildings.

2. CLASSIFICATION OF SOFT STOREY BUILDINGS

Based on current code definition, buildings are classified as having a "soft storey" if that level is less than 70% as stiff as the floor immediately above it, or less than 80% as stiff as the average stiffness of the three floors above it. In the other hand, general classification is to say that a soft-storey building is one in which deformations are expected to concentrate in a single “soft” storey. The most common types of existing building based on soft storey behaviour are called as: a) Discontinuous structural walls or infills, b) Strong beam- Weak column in frame type, c) Discontinuous load path, d)Walls in large openings at base.

Structures with discontinuous walls or infills are the most common type of existing soft storey buildings. Typical damage to buildings with this type of soft storey is shown in Figure 1.a, where a two-storey building is suffered significant lateral displacement at the ground floor level during the 1972 Managua Earthquake. In Figure 1.b. a five-storey residential reinforced concrete building is shown, which had been collapsed in Izmit, Turkey earthquake in 1999. Figure 1.c shows partial collapse due to Northridge earthquake occurred in Kaiser Permanente health institution in the form of pancaking of a weak second story, which was possible due to the weak column- strong beam mechanism. Finally, a well-known example of discontinuous structural wall is the Olive View Hospital, which had been badly damaged in the 1972 San Fernando earthquake, as shown in Figure 1.d.

Even though current design practice aims to avoid the occurrence of soft-storey mechanisms, there are a large number of older existing buildings that are expected to develop soft-storeys. Engineers must therefore decide when retrofit is required for such structures and what the best retrofit strategy is. This paper examines the effect of different structural characteristics on the seismic response of structures with soft storey mechanisms. Some initial case study structures are taken as benchmark buildings and incremental non-linear time history analyses are repeated by varying some key parameters including P-Delta effects of the first storey columns. Then, the effect of some key characteristics on the strength and deformation capacity of

the columns is investigated. The last part of the paper compares the losses in an open ground storey building to the full infill building, and consequently, the potential benefits of the soft storey scenario in loss estimation is explored. Finally, in light of all the results obtained, a potentially advantageous retrofit strategy for soft-storey structures is introduced.

2. DESCRIPTION OF CASE STUDIES

The six storey three bay concrete frame structure shown in Figure 2 is studied in this paper for two different distributions of masonry infills. In the first scenario, it is assumed that masonry infills are distributed over all storeys uniformly, while in the next step and for considering soft storey effects, it is assumed that masonry infills are omitted at the ground storey. The frame configurations are taken from . These frames are representative of typical buildings designed during the 1950s to the 1970s. Accordingly, structural elements were designed only for gravity loads without following any capacity design rules for seismic protection.

Time history analyses are carried out using ten recorded horizontal accelerograms selected as part of the DISTEEL project . The record set consists of 10 records that are scaled to be compatible with Eurocode 8 spectrum for soil type C and a corner period T_d = 8s. The acceleration and displacement response spectra of the selected records are shown in Figure 3. As it can be seen from this figure, the records show a good fit with the EC8 design displacement spectrum (shown for a peak ground acceleration (PGA) on rock of 0.4g) but they drop below the design acceleration spectrum in the low period range (T< 1s).

2.1 Modeling Approach

A two-dimensional non-linear Giberson beam element (refer Carr, 2006) is used for modelling the beams and columns. To this end, a plastic hinge is concentrated at the two ends of each element. RUAUMOKO contains several types of moment-curvature hysteretic rules for definition of plastic hinges in the elements and joints. Among them, the Takeda hysteresis rule is selected, where unloading and reloading stiffness reduces as a function of ductility. The model is used in order to obtain the unloading stiffness. Due to the fact that the structure is designed for gravity loads only, the hysteretic shape should be defined so that relatively low levels of energy dissipation occur, assuming relatively high axial load ratios and therefore relatively pinched hysteretic response.

(Variant1) (Variant2) (Variant 3)

Figure 2. Six-storey concrete frame, variant 1) full infill uniform distribution, variant 2) Partial infill disconnected in the first floor, 3)Bare Frame

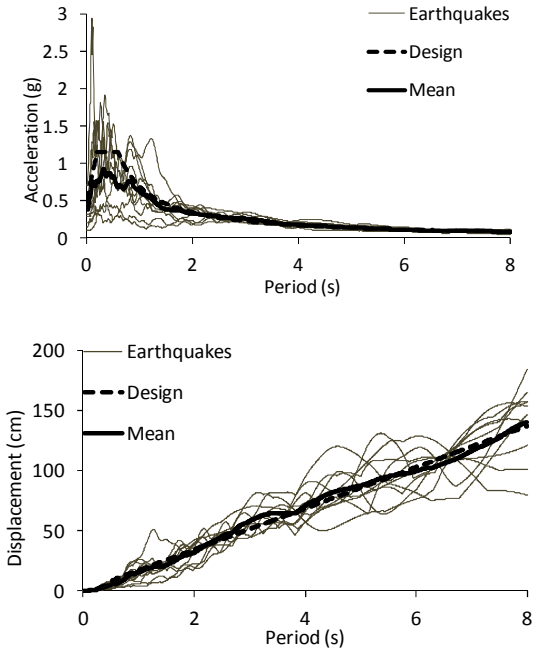

Figure 3. Acceleration and displacement Response Spectra for the selected records sets

A widely used approach is adopted for the modelling of masonry infills, based on the use of axial springs acting as equivalent compression diagonal struts. The stiffness of the equivalent diagonal strut is evaluated according to the model modified as proposed by . Moreover, four modes of failure are considered in order to evaluate the strength of the masonry infills: compression at the centre of the panel, compression of corners, sliding shear failures, and diagonal tension. cyclic behaviour of infill panels is modelled using the hysteresis rule proposed by Crisafulli (1997). This model takes into account the non-linear response of masonry in compression, including contact effects in the cracked material (pinching) and small cycle hysteresis. Based on this model, stiffness degradation due to shortening of the contact length between the frame and the panel is also considered. It should be noted that the dispersion of mechanical properties of masonry with respect to the mean values increases uncertainty of the infills characteristics and affects the global response of the structure.

In order to model joint behaviour, springs are inserted at beam-column locations using the approach proposed by Trowland (2003). The cyclic behaviour of the joint rotational springs has been defined using a hysteretic rule available in the RUAUMOKO program and specifically proposed to describe the characteristics of the joint response. In particular, the adopted hysteretic loop is able to describe the typical "pinching" effect due to the slippage of plain round reinforcing bars through the joint panel zone and to the opening and closing of diagonal shear cracks in the joint region.

2.1. Analytical Results

Response parameters of interest such as peak inter storey drift, peak acceleration and residual drift will be plotted versus the intensity of the ground motions. In order to estimate the mean response of all ground motions the geometric mean value (defined as per) as per Equation 3.1 is adopted.

Figure 4 shows the responses obtained from the nonlinear Incremental Dynamic Analysis (IDA) for the full infill and partial infill variants. In Figure 4.a the maximum of peak inter-storey drift in the full infill case, the maximum of peak inter-storey drift in the partial infill case, and the maximum of peak inter-storey drift above the first floors of the partial infill case (called isolated floors) are plotted separately.

The maximum of peak inter-storey drift in the partial infill case occurs in the open ground floor, and thus is indicated as the first floor in this figure. It can be seen that the inter-storey drift of the isolated floors is reduced significantly. However, as the intensity level is increased, the level of isolation is increased. The maximum drift ratio in the first floor of the partial infill case at the intensity level of 0.6g is double what it is for the full infill case, while the average drift in the upper floors are less than 0.3.

The peak floor acceleration of the full and partial infill variants are plotted in Figure 4.b. The peak floor accelerations are close to each other at the lower intensity level. This is explained by examining the acceleration response spectra that are shown in Figure 3. The elastic period of the full and partial infill frames is 0.78 and 0.32 sec respectively, and it can be seen that both these periods correspond to the short period spectral plateau. However, for high intensity levels, the period elongation of the soft storey case (partial infill) is higher than that of the full infill case, which results in lower acceleration demands for the whole structure. The reduction in peak floor accelerations in the soft storey frame could have a significant effect on the damage sustained by non-structural components and building contents.

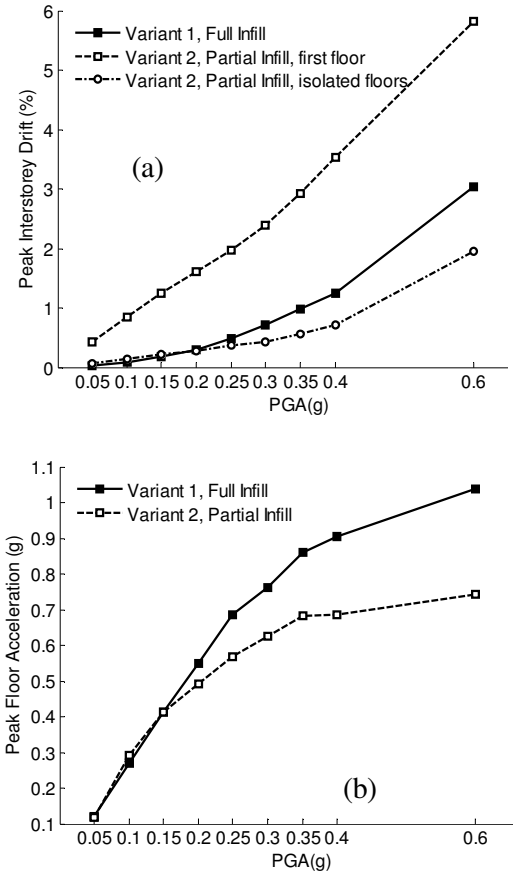

Figure 4. Comparison of peak inter-storey drift and floor acceleration obtained from IDA for two variants of full and partial infill

3 INFLUENCE OF P-DELTA EFFECTS ON SOFT STOREY RESPONSE

This section presents the results of numerical analyses of the six-storey frame with and without the inclusion of P-Δ effects. To this end, incremental time-history analyses of the structure with full and partial infills are carried out when large displacements are considered in the nonlinear deformation capacity of the structure. These results are

compared with the results obtained using small displacement analyses. Figure 5 shows the structural responses with and without considering P-Δ.

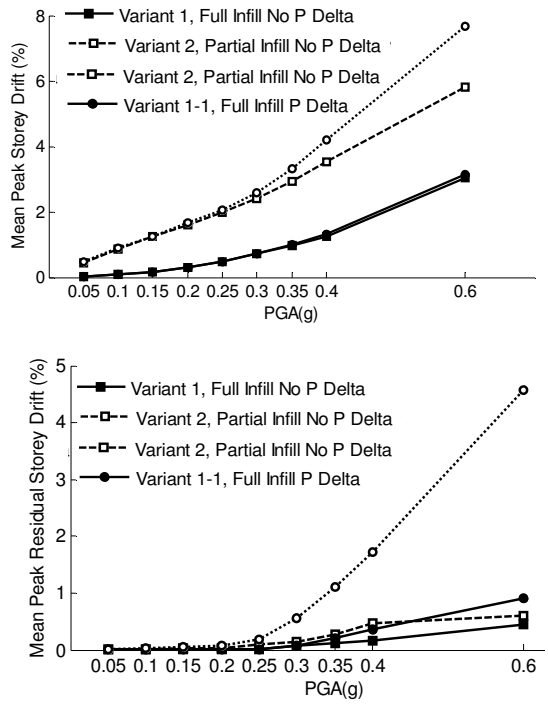

Figure 5. Influence of P-Delta effects on peak and residual drift variants

For the structure with full infill, considering P-Δ effects does not cause any difference in responses. On the other hand, the impact of P-Δ effects is more obvious for the soft storey case, where infills are not present in the ground floor. However, the difference between system response with and without P-Δ effects are not significant at low levels of intensity, and this is probably a reflection of the low stability indices for this structure. The drift ratios for the partial infill case at the hazard level of 0.6g are, respectively, 7.5% and 5.9% with and without P-Δ effects. On the other hand, the effect of P-Δ on residual drift is much more sensitive to the increasing level of intensity. It can be seen that the residual drift at a PGA of 0.6g is less than 1% without P-Δ effects, while P-Δ effects amplify this value by a factor of approximately 5.

4. INFLUENCE OF COLUMN CHARACTERISTICS ON SOFT-STOREY CAPACITY

Another aspect that to consider in this study is the impact of different column response characteristics on the frame capacity. To this end, cyclic analyses are conducted for the columns, considering different section depths, different axial load ratios and different reinforcement ratios in order to identify the likely strength and deformation capacity of the columns. Parameters γ, ρ and CF are axial force ratio, longitudinal reinforcement ratio, and confinement factor, respectively, defined as:

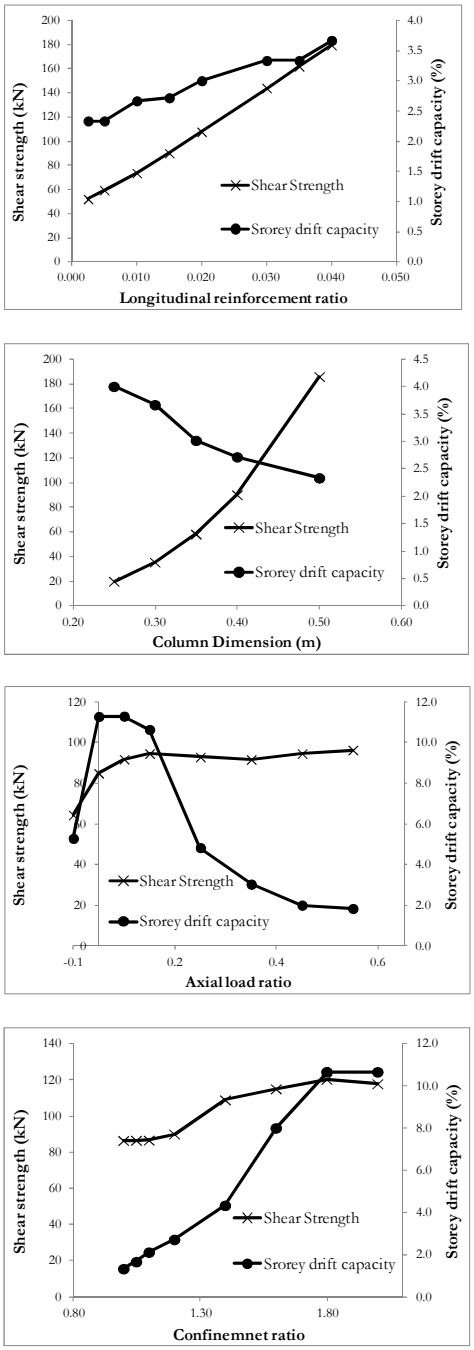

Figure 6. Comparison of key characteristics on column hysteresis response

$$\gamma = \frac{N}{A_g f_{cc}}, \quad , \quad \rho = \frac{A_{st}}{A_g} \quad , \quad \mathrm{CF} = \frac{f_c'}{f_{cc}}, \tag{1}$$

Where, N is the axial load, A_{st} is the total area of longitudinal reinforcement, Ag is gross section area, and f'_c and f'_{cc} are respectively the unconfined and confined

concrete compressive strength. For this study, wherever one parameter is changed, other parameters are kept constant.

Numerical models were developed and analyzed in Seismo-Struct for all geometrical and loading characteristics. The model is adopted in order to define constitutive relations for the concrete in compression. All piers are modelled by a single force-based element along the column height. The model of is applied for the longitudinal reinforcement. Additionally, a co-rotational formulation is used to account for geometrical nonlinear effects. Cyclic loading is implemented through lateral displacement control of the top end of the each column.

5. DISCUSSION OF RESULTS

This work began by comparing the behaviour of two RC frame buildings (variant 1 and variant 2 of Figure 2) that differed only by the fact that one had masonry infill from the first floor upwards whereas the other had masonry infill over its full height. Results of incremental dynamic analyses tend to indicate that the full masonry infill case could sustain much larger ground motion intensities when considering the collapse limit state. This might encourage structural engineers faced with the task of retrofitting the partial infill building to consider adding infills to the ground storey to render the structure similar to variant 1. While this option may help in reducing the probability of collapse, it would not necessarily reduce the damage and losses expected in the building for low to moderate earthquake intensities. This is partly because the floor accelerations for the infill case are likely to be higher than in the partial infill case but in addition, it is well known that damage to infill masonry occurs at much lower levels of drift than traditional RC frame structures. In addition, the open ground storey scenario would have a lower probability of reaching a partial-collapse limit state associated with masonry failure out-of-plane.

In addition to the points made above, it is recognised that the decision to retrofit a structure or not should be made within a risk assessment framework in which the probability of different levels of seismic intensity is considered along with the probable losses for each intensity level. With this in mind, it was decided that the effect of different structural characteristics on the seismic vulnerability of RC frame structures with soft storey mechanisms should be examined in more detail. As such, sections 3 has examined the influence of P-delta effects on the drift and acceleration demands of the open-ground-storey structure, whereas Section 4 examined how column dimensions, reinforcement contents and axial loads could affect deformation capacity.

The results in Figure 5 indicate that if the gravity load system could be de-coupled from the lateral load resisting system this could help reduce the likely deformation demands, which tend to be amplified by P-delta effects. In addition, it was demonstrated in Figure 6 that if the axial load ratios on column sections could be reduced their deformation capacities could be significantly increased. One potentially effective and innovative means of retrofitting a structure with an open-ground storey could therefore be to introduce a series of gravity columns at the ground level, as shown in Figure 7 that slide with the first storey. By doing this, P-delta effects would be minimised. In addition, by jacking the gravity column system into position, the axial loads on existing columns could also be reduced, thus greatly increasing their deformation capacity, without significantly affecting their lateral strength and potential for energy dissipation. Given the potential benefits of this retrofit scheme, this possibility is currently exploring as part of an undergoing research project. Detailing of the proposed system is not presented here as it is out of the scope of this paper.

It should be noted that with this retrofit strategy, the first floor deformations can be significantly increased, and thus damage is considerable in this floor, which is different from the traditional goals of base isolation where damage is avoided in most structural elements. In the next section, the expected repair cost to the existing open ground storey and the full infill case are compared together, and then the effect of the proposed retrofit strategy on the expected loss of the soft storey case is investigated.

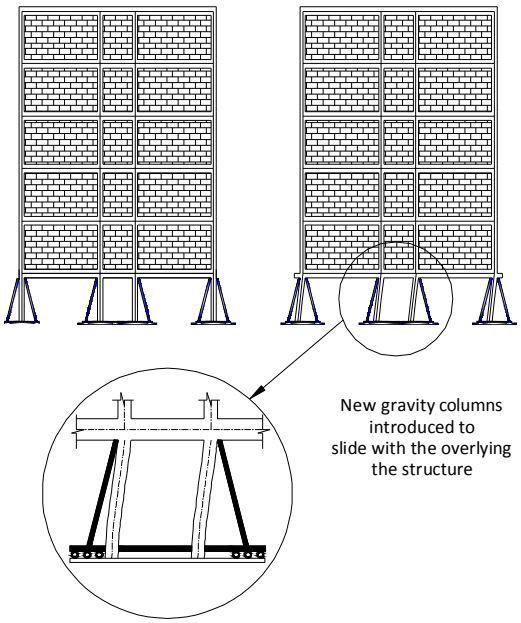

Figure 7. Possible means of de-coupling gravidity loads from lateral loads in a soft storey building

6. DAMAGE ANALYSIS AND LOSS ESTIMATION

Economic issues play an important role in the performance based design and assessment of buildings. It is stipulated that, provided that collapse does not occur and retrofit is possible, the total losses in buildings in which damage is concentrated in the first floor would be less than the case where it is distributed over all floors. However, this

could be sensitive to the performance level of the building and hazard intensities. For conventional buildings, where damage is distributed almost uniformly in all of the floors, non-structural components in the upper floors could be damaged even for low or moderate intensities. As non-structural costs are usually much higher than structural costs, this can result in high repair costs.

On the other hand, and for the case of soft storeys, the isolated floor can reduce the response in the storeys above, by sacrificing itself with higher levels of damage. In this case, even if the damage to the structural components in the first floor is significantly greater, as they cost less than non-structural elements, one can infer that the total damage will be decreased (provided that repair is possible) when compared to conventional methods to retrofit. The advantages of this response would be more beneficial as the number of storeys increases. This is studied quantitatively in this section by comparing the expected losses for the different variants.

It should be noted that the storey loss is obtained for the uniform pattern of component distribution over the building height. However, if the non-structural elements are distributed differently along the height, which is the case for soft storey buildings, their portion in the first floor is considerably changed. For the case of open ground storeys, where parking or stores are located at the first floor, the portion of the non-structural components in the first level may be considerably less than the other typical floors.

Figure 8 illustrates how the ratio of non-structural components in the first floor can affect the total cost of the building. As such, the total expected loss conditional on no collapse of the building is obtained by the summation of the components through the height of the building. To this end, different weights are assigned for the ratio of non-structural to structural elements in the first level, starting from zero (meaning that there is no structural component in the first level) to 1.6 (means that the value of the NS components at the first level are expensive, being 60% more than the typical levels). It should be noted that the total amount through the building height is kept constant, e.g. If the ratio in the first level is halved, it is increased by 10% in the rest of the five stories. The results obtained for the whole range of NS component ratios at the first level are compared to the full infill case in Figure 16a. From this graph, it can be seen that the NS distribution in the first level can highly change the total cost.

As a result, the main conclusion is that soft storey buildings could perform better than "no soft-storey" buildings depending on the intensity level and the contribution of non-structural elements to the total losses. For this case study, one can infer that for moderate intensity levels (0.25g-0.3g), and for a NS ratio of 0.5-0.6, the existing soft storey building (without any retrofit since the maximum expected drift in the first floor is 2.2% and the residual drift is around 0.5%) would perform better than the "no soft-storey" case. For very low intensity levels, the soft storey case has greater losses, since the first floor does not isolate the upper storeys for the very low intensity levels. To explain this, one can refer to the acceleration spectra in Figure 3. The elastic period of the partial infill case is T= 0.78 sand this period has higher acceleration demands than the full infill case with T= 0.32s, for the accelerograms used. However, for higher intensity levels, the period elongation in addition to inherent hysteretic damping of the soft storey is quicker, which decreases the acceleration demands at higher intensity levels. The acceleration demand can also be seen in Figure 4 where the peak floor acceleration for the soft storey case is higher than the full infill case for intensity values of 0.05 to 0.1g.

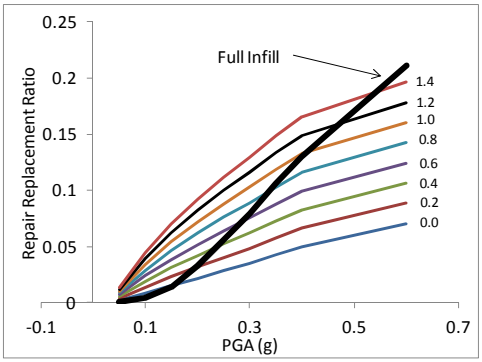

Figure 8. Effect of non-structural component distribution through the height of the building on the expected loss conditioned of open ground storey

Figure 9 shows the total cost for the three variants of full infill, partial infill, and the case where the proposed retrofit strategy is applied. It should be noted that it his plot, the collapse condition is considered in the loss estimation and in the event of collapse, a full replacement cost factor of 1.0 is assumed. However, it is assumed that by applying the conceptual retrofit strategy, the collapse is always prevented. It can be seen that the loss for the traditional soft storey case the costs increase rapidly compared to the full infill case. On the other hand, the effect of applying the proposed retrofit strategy on the soft storey case is significant. As a result, it can be argued that if the collapse of the soft storey case by applying P-delta mitigation strategy is prevented, the loss for the open ground storey case is significantly reduced. Furthermore, and as it can be seen from the figure, the total expected loss in the rerofitted soft storey building is less than the full infill case for a high range of the intensity levels.

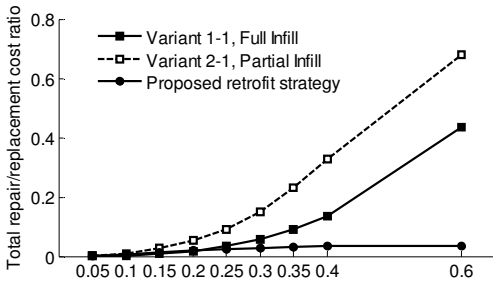

Figure 9. Total expected repair cost ratio for variants partial

infill, full infill, and the partial infill with collapse mitigation

7. CONCLUSIONS

The potential advantages of buildings with open ground storeys were discussed. It was observed that higher mode effects are less important in the global dynamic behaviour of the partial infill case. The incremental non-linear time history analysis results illustrated that peak floor accelerations in partial infill case are less than the full infill case, which can reduce damage to non-structural elements. In addition, the peak and residual inter storey drift at storeys above the open ground floor is highly decreased. However, the potential of collapse of the partial infill case is increased as the intensity level is increased, reflecting the observations made in past earthquakes.

The implications of the analysis findings were discussed in relation to potential retrofit schemes. A novel retrofit scheme was proposed in which sliding gravity columns are introduced to reduce the impact of P-delta effects on displacement demands and to increase the deformation capacity of existing columns. Based on that, an axial ratio, which has the largest improvement on the deformation capacity, is found, and applied to the case study. A comparison of the response parameters for each floor shows that if the first floor can be designed to respond in a stable manner, the upper floors can be isolated to remain without or with low levels of damage.

Damage analysis and loss estimation of the two variants with and without soft first storeys indicate that repair costs for the isolated floors is considerably reduced for the soft storey variant. It was shown that the distribution of the value of non-structural elements on the total loss of the open ground storey buildings is significant. For soft storey buildings where non-structural elements at the ground storey have low value, the expected loss is low and can be less than the full infill case. This conclusion is based on the condition that the structure does not collapse, which is attained by the proposed conceptual retrofit strategy. Based on these results, the main conclusion is that permitting a building to behave as a soft first storey, could be more efficient than preventing it. However, parameters like architecture, downtime, and performance should be considered in the final retrofit decisions.

Abstract: When seismic response analyses of buildings are conducted, habitually it is not considered the case that the buildings do not have well-regulated plane shapes, of which principal elastic axis is not perpendicular to the yield surface. And also, habitually it is not considered that seismic motions are input in two directions of principal elastic axes. The objective of this study is to examine the validity of seismic response evaluation by current equivalent linearizing method and the possibility that the seismic response through two directional input exceeds the one through one directional input. We conducted time history response analyses inputting in one direction and in two directions using one mass bidirectional vibration model. It is concluded that seismic responses appear in the direction differs from input direction of principal elastic axis by yielding when the principal elastic axis is not perpendicular to the yield surface, and that the maximum response displacement which is obtained through two directional input often exceeds the one which is obtained through one directional input.

1. INTRODUCTION

Considering seismic response of buildings, it is habitually premised that plastic deformation occurs in direction in which seismic motion is input. That means it's regarded that buildings have well-regulated plane shapes, and principal elastic axes are perpendicular to yield surface. For instance, equivalent linearizing method used for seismic response evaluation also considers only a principal elastic axis. However, buildings do not always have well-regulated plane shapes, and the principal elastic axis and the yield surface often do not cross at right angles. The problem is whether seismic response can be evaluated by current equivalent linearizing method when the principal elastic axes are not perpendicular to the yield surface. Meanwhile, seismic motion input is two directional in fact, but going seismic response evaluation considers only a direction of principal elastic axes. It is required to investigate whether the seismic response through two directional input exceeds the response through one directional input. In this paper, we examine the validity of seismic response evaluation by current equivalent linearizing method and possibility that the seismic response through two directional input exceeds the one through one directional input, using one mass bidirectional vibration model.

2. OUTLINE OF ANALYSIS

2.1 Establishment of Vibration Model

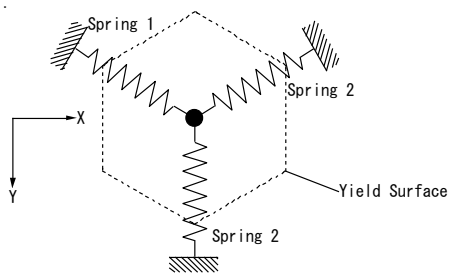

Figure 1 Vibration Model

Figure 1 shows the vibration model. It is composed of one mass point and three springs which have bilinear-type elasto-plastic restoring force characteristics. The yield surface is considered the boundary where two springs yield, and is shown as dashed line in Figure 1. The yield resistances of three springs are set to be equivalent, and the shape of the yield surface is hexagon as shown. The ratio of yield resistance of a spring to the mass is set to 0.32.

Stiffness matrix of this vibration model is given by following equation.

$$[K] = \begin{bmatrix} \frac{3}{4}(k_1 + k_2) & \frac{\sqrt{3}}{4}(k_1 - k_2) \\ \frac{\sqrt{3}}{4}(k_1 - k_2) & \frac{1}{4}(k_1 + k_2 + 4k_3) \end{bmatrix} \quad (1)$$

Where k_1, k_2 and k_3 indicate the stiffness of springs 1, 2 and 3 shown in Figure 1. We solved the generalized eigenvalue problem. The determinant to be solved is given

by following equation.

$$|[K] - \omega^2[M]| = 0 \tag{2}$$

The fundamental circular frequencies are obtained from Eq. (2), and Ax and Ay which provide the eigenvector are calculated. Ax and Ay give the directions of principal elastic axes in X-Y coordinate system. We defined *a* and *b* as shown in the following equation.

$$a = k_1/k_3 \tag{3}$$

$$b = k_2/k_3 \tag{4}$$

The following equation gives the ratio of Ay to Ax.

$$\frac{A_y}{A_x} = \frac{-(a+b-2) \pm 2\sqrt{a^2+b^2+1-ab-b-a}}{\sqrt{3}(a-b)} \tag{5}$$

T_1 and T_2, which indicate the primary natural period and the secondary natural period, are calculated from the fundamental circular frequencies. The ratio of primary natural period to secondary natural period is shown in the following equation.

$$\frac{T_1}{T_2} = \sqrt{\frac{(a+b+1)-\sqrt{a^2+b^2+1-ab-b-a}}{(a+b+1)+\sqrt{a^2+b^2+1-ab-b-a}}} \tag{6}$$

Equations (1) and (2) indicate that it is possible to vary the principal elastic axes and the ratio of natural periods by coordinate the stiffness of three springs. When the ratio of natural periods is equal to 1.0, the stiffness of the three springs is equivalent.

2.2 Behavior of Vibration Model

Time history response analyses are conducted by seismic motion of Kobe. The north-south motion and east-west motion of Kobe were reconstituted to two seismic motions. One of them is in direction in which maximum acceleration from the origin appears, and the other one is in direction which is at right angles to the other. And they were multiply by coefficients so as to provide appropriate ductility factors. The time histories of acceleration of seismic motion of Kobe and acceleration response spectrum are shown in Figure 2.

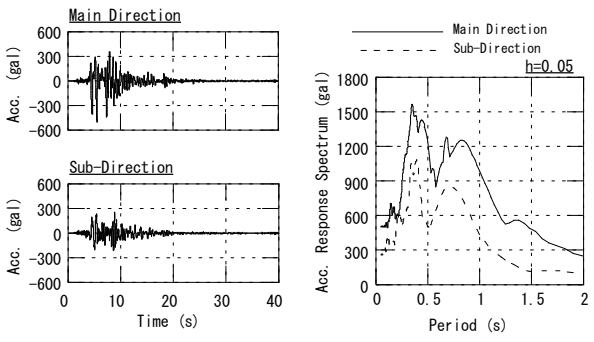

Figure 2 Seismic Motion of Kobe

Newmark-β method made use of numerical integration for dynamic response analysis of equation of motion. The β is equal to one-fourth.

We defined the direction which is input the seismic motion having maximum acceleration as "main direction" and the direction which is input the other seismic motion as "sub-direction". We also defined the ratio of the natural period in main direction to the natural period in sub-direction as "T_x", and set the natural period in main direction 0.5 seconds uniformly. The angle between the direction which is perpendicular to the main direction and yield surface is defined as "crossing angle". Figure 3 illustrates the results when T_x is set to 1.0, the crossing angle is zero degree, and seismic motion is input only in main direction. It contains graphs of time history response of restoring force and displacement in main direction, relation between restoring force and displacement in main direction, and orbits of restoring force and displacement in plane system. It is indicated that behavior doesn't appear in the direction other than the main direction. Figure 4 gives the relation between restoring force and displacement of springs 1 and 2. The behavior does not appear in spring 3 because the main direction is set in the direction which is at right angles to the direction of spring 3. Naturally, the behavior of springs 1 and 2 is symmetrical about a point.

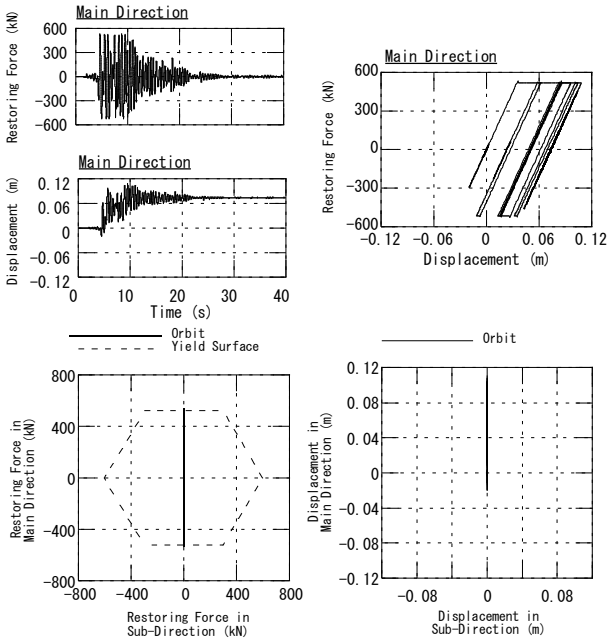

Figure 3 Behavior of Vibration Model When The Crossing Angle Is Zero Degree Inputting in One Direction

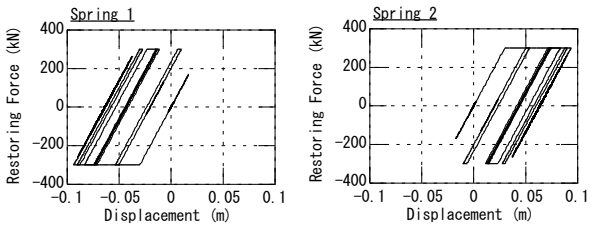

Figure 4 Relation between Restoring Force and Displacement of Spring 1 and 2

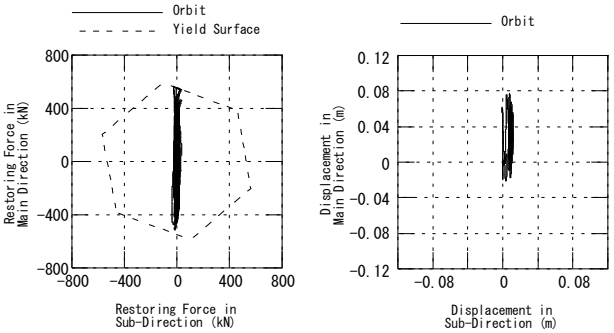

Figure 5 Orbits of Restoring Force and Displacement When The Crossing Angle Is 20 Degrees Inputting in One Direction

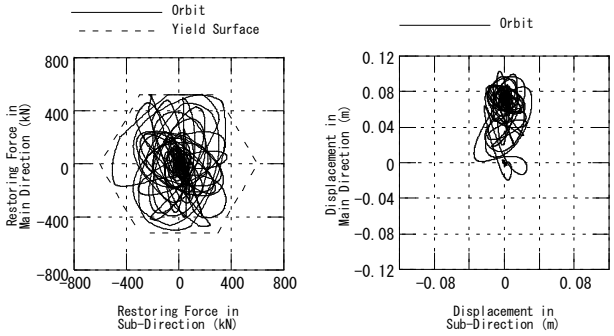

Figure 6 Orbits of Restoring Force and Displacement When The Crossing Angle Is Zero Degree Inputting in Two Directions

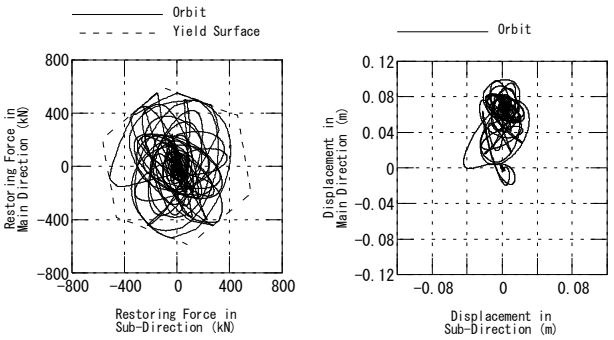

Figure 7 Orbits of Restoring Force and Displacement When The Crossing Angle Is 20 Degrees Inputting in Two Directions

Figure 5 gives the orbits of restoring force and displacement in plane system when the crossing angle is 20 degrees and seismic motion is input only in main direction. In spite of being input only in one direction of principal elastic axes, restoring force and displacement appear in the other direction by yielding.

Figure 6 gives the orbits of restoring force and displacement when the crossing angle is zero degree and seismic motion is input in main direction and sub-direction, and Figure 7 gives the orbits when the crossing angle is 20 degrees and seismic motion is input in two directions. When the crossing angle is zero degree, it is shown that the maximum response displacement in the main direction through which seismic motion is input only in main direction doesn't much differ from the one in the main direction through which seismic motion is input in two directions in Figures 3 and 6. In contrast, when the crossing angle is 20 degrees, the maximum response displacement in the main direction through which seismic motion is input only in main direction is smaller than the one when seismic motion is input in two directions, as illustrated in Figures 5 and 7.

3. PARAMETRIC EXAMINATION

3.1 Parameters

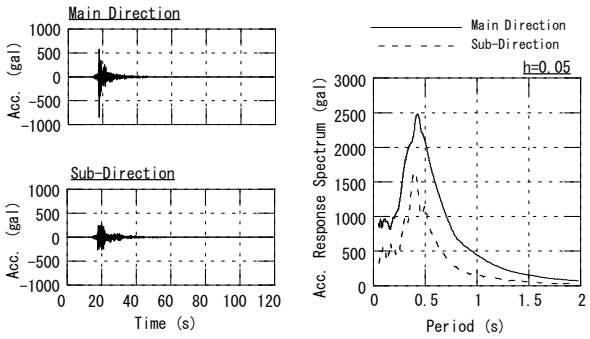

Figure 8 Seismic Motion of Ojiya

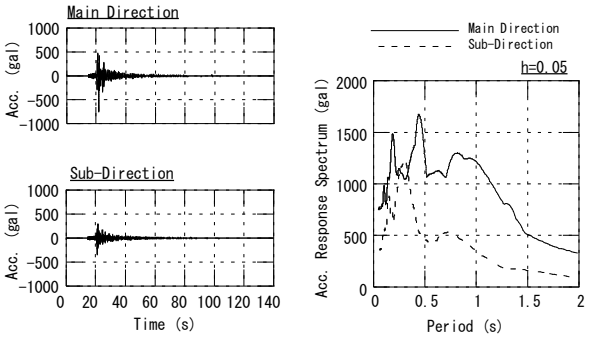

Figure 9 Seismic Motion of Yokaichiba

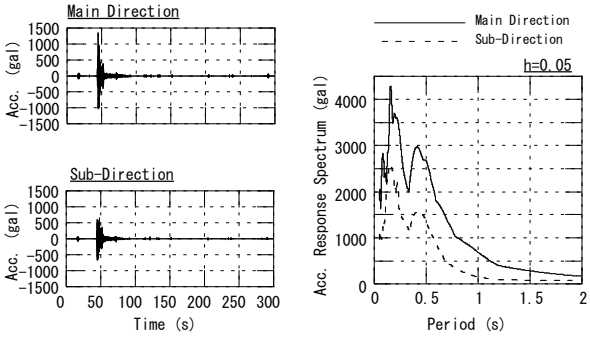

Figure 10 Seismic Motion of Takahagi

We used another three seismic motions for analysis. Seismic motions of Ojiya, Yokaichiba and Takahagi were quoted from K-net (Japanese strong-motion seismograph network). Their north-south motion and east-west motion

were reconstituted to two seismic motions to be input in the main direction and the sub-direction, and they were multiply by coefficients so as to provide appropriate ductility factors in the same way as Kobe. The time histories of acceleration and the acceleration response spectrum of the seismic motions of Ojiya, Yokaichiba and Takahagi are shown in Figures 8, 9 and 10.

The time history response analyses were conducted with four seismic motions. The natural period in main direction was set to 0.5 seconds uniformly. We set T_x 0.8, 1.0 and 1.2, and the crossing angles at intervals of five degrees from zero to 30 degrees. The vibration model was input only in the main direction and in two directions of the main and sub-direction.

3.2 Results and Discussion

Figure 11 shows the maximum of response displacements when the seismic motions are input in one direction and in two directions. The graphs are arranged by the seismic motions and the ratio of natural periods. Vertical axis gives displacement, and horizontal axis gives crossing angle.

The maximum response displacements for SDOF model which has restoring force characteristics of vibration model in the main direction are also shown in Figure 11, as the case the principal elastic axis of the analytical model is perpendicular to yield surface. Additionally, estimated values by equivalent linearizing method are shown in Figure 11. These values by equivalent linearizing method are supposed to be estimated low in some degree. The absorbed energy through one cycle of hysteresis loop which is used for calculation of equivalent linearizing method needs to be reduced because the vibration model does not always perform steady motion, but the absorbed energy is not reduced in these analyses.

Comparing the maximum response displacements by one directional input and the one from the analytical model, some difference can be identified, but it is not so large. The difference appears when the main direction is not at right angles to the yield surface. The difference does not appear when the crossing angle is 30 degrees because there is a singular point where the three springs yield on the principal elastic axis input. It seems whether the difference appears or not depends on the seismic motions and the ratio of natural periods, but what causes the difference was not able to be clarified.

The maximum response displacements by two directional input and the one from the analytical model are compared. The values by two directional input greatly exceed the values from the analytical model when the

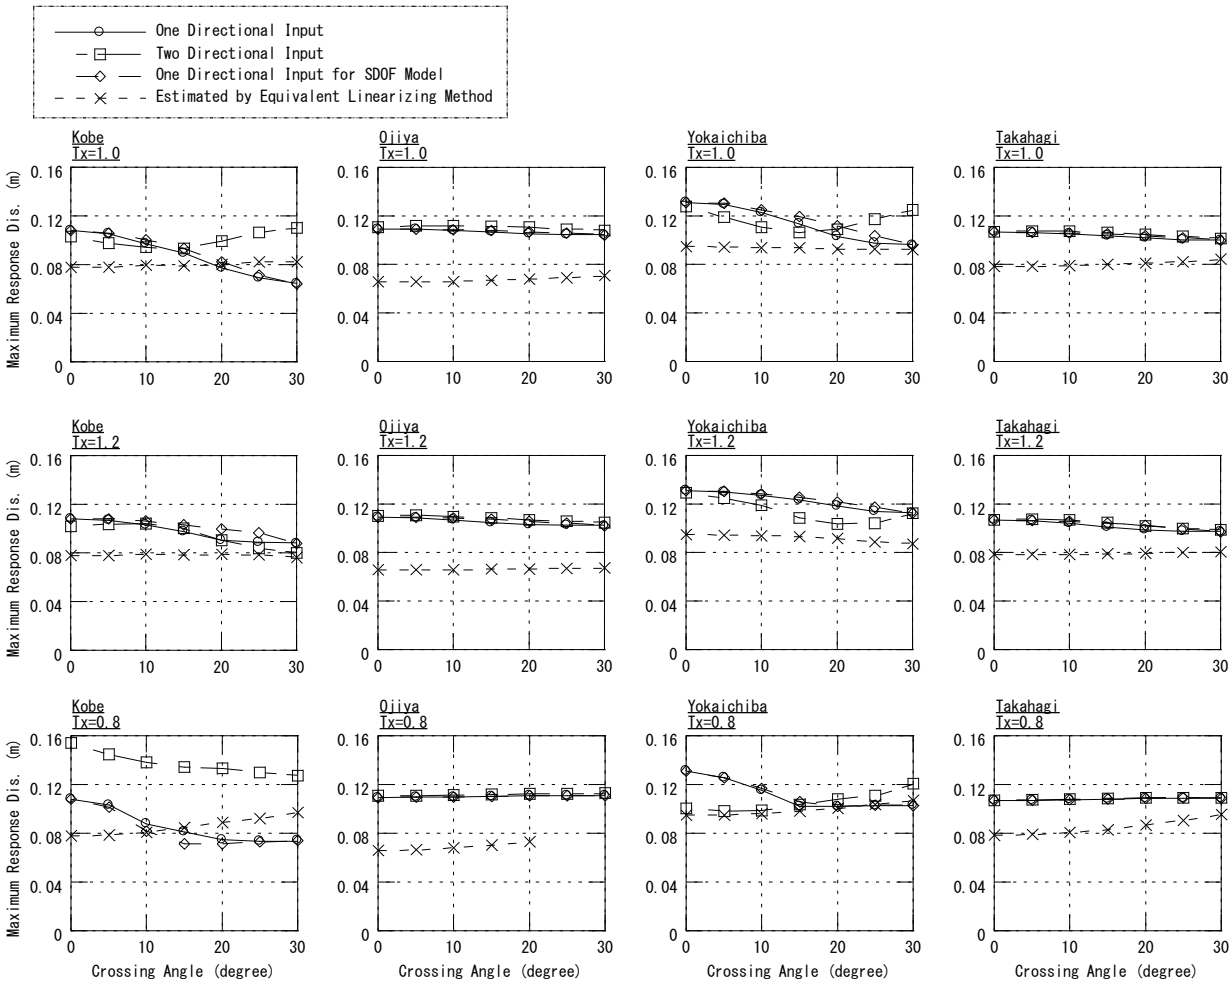

Figure 11 Comparison of Analytic Values

inputting seismic motion is Kobe or Yokaichiba and T_x is 1.0 and 0.8. We found it often happens that the seismic response displacements through two directional input greatly exceed the values through one directional input.

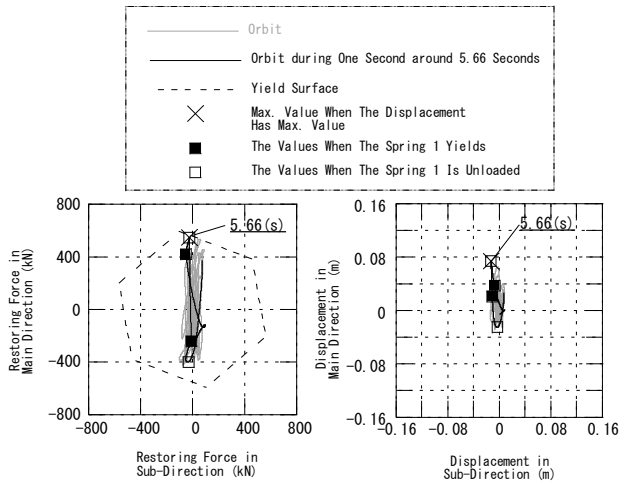

Figure 12 Detailed Analysis Results through One Directional Input

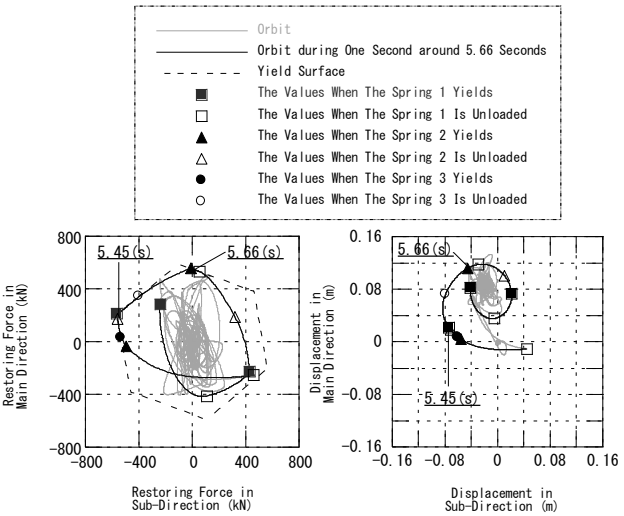

Figure 13 Detailed Analysis Results through Two Directional Input

The case of which input seismic motion is that of Kobe, crossing angle is 20 degrees, and T_x is 0.8 was investigated in more detail, as shown in Figures 12 and 13, in order to clarify differences of events when the response displacements through two directional input greatly exceed the values through one directional input. Figure 12 gives orbits of restoring force and displacement in plane system through one directional input, and Figure 13 illustrates the orbits through two directional input. The maximum response displacement through one directional input appears at 5.66 seconds as shown in Figure 12. The orbits during one second around 5.66 seconds (i.e. from 5.16 seconds to 6.16 seconds) and points which illustrate yielding and unloading of springs are also given in Figures 12 and 13.

In the case of one directional input, it is found that yielding and unloading of springs occur almost on the principal elastic axis of main direction as given in Figure 12. Meanwhile, as shown in Figure 13, some yielding and unloading occur around 5.45 seconds on the part of yield surface which does not cross the principal elastic axis of main direction, and it can be seen that that yielding is a reason of the differences of response displacements.

4. CONCLUSION

Time history response analyses were carried out inputting seismic motions in one direction of principal elastic axis and in two directions of principal elastic axes, varying crossing angles. The following results were obtained:

(1) When the principal elastic axis is not perpendicular to the yield surface and seismic motions are input in one direction of the principal elastic axes, restoring force and displacement appear in the direction which differs from inputting direction by yielding.
(2) There were some difference between the maximum response displacements when the principal elastic axis is not perpendicular to the yield surface and the ones when the principal elastic axis is at right angles to the yield surface.
(3) The maximum response displacements which is obtained through two directional input often exceed greatly the ones which are obtained through one directional input. Considering elastic-plastic seismic response of buildings, two directional input should be taken into account.

It is future issue to find the cause for which the maximum response displacements through two directional input exceeds the ones through one directional input.

Abstract: Shield tunneling has become one of the main approaches of large length tunnel construction in recent decades. However, the analysis technique of shield tunnel widely used among consulting engineers by now is still based on 2-D beam-spring model, which is hardly to be able to describe the contact mechanism of the interfaces between segments and rings. 3-D FEM analysis was always considered to be time consuming, therefore, was only adopted in local analysis, e.g. tunnel joints or connections to underground stations. With the demand of complicated underground environment analysis for shield tunnel, full-length 3-D FEM analysis is required more than ever. This paper presents a full-length shield tunnel 3-D FEM model with solid elements. In this model, both spring connection and interface contact between segments and rings are considered; the edge of each segment is treated as a strengthen part on elastic property; the nodes on the outer surface are connected with ground springs as boundary conditions. To keep computation accuracy, displacement under the same load is compared with another shell element model, and good agreement is reached. As an application, the rebound effect after earth remove due to the construction above an existing tunnel has been estimated.

1. INTRODUCTION

With the vast demand of city underground transportation system and expressway system covering large area, a lot of shield tunnels have been constructed, as one of the main approaches to construct large length tunnels in urban areas. Through decades' practice, large amount of techniques and field experiences have been accumulated, however, conventional 2-Dimensional beam-spring model is still mainly utilized to design the shield tunnels in Japan. The beam-spring model is convenient and has been contributed to obtain comparatively good results corresponding to the cross-sectional behavior of shield tunnels, but, it is hardly to be able to describe the contact mechanism of the interfaces between segments and rings, which may affect their longitudinal behavior. Therefore, it is necessary to develop the analysis method with 3-Dimensional FEM to investigate the long-term behavior of shield tunnels. However, 3-Dimensional FEM analysis was always considered to be time consuming, therefore, was only adopted in local analysis, e.g. tunnel joints or connections to underground stations (Lee 2009).

The development of computation technology has pushed the analysis technique forward. Several novel 3-Dimensional FEM models of shield tunnel have been proposed, among them, the full-length shell model developed by (Tsuno et al. 2012) is an effective tool for shield tunnel design and has been applied in engineering analysis. But due to the property of shell element it uses, this model cannot describe the surface connection between segments well. Another model (Tajima et al. 2004) tried to describe the interface connection using solid elements, but not yet been implemented to the full-length tunnel. Although the longitudinal behavior of shield tunnels was investigated with a full-length 3-Dimensional FEM model with solid elements (Wang et al. 2012), it can be said that analytical method with 3-Dimensional FEM in consideration of the connections between segments has not been established.

In this study, a full-length 3-Dimensional FEM model of shield tunnel with solid elements is presented, in which all the connections between segments will be considered, including the surface contact and spring connection. Through this model, a new full-length analyze approach for shield tunnel can be proposed.

2. 3-D SOLID FEM MODEL

2.1 Objective

The complication of shield tunnel engineering requires a numerical analysis method that can describe the tunnel components, including segments, joints, bolts, etc. and their connections as much close to the real engineering situation. However, due to the limitation of computation capability, the previous numerical analyze approaches are mostly based on

2-Dimensional method. 3-Dimensional FEM analysis was always considered to be time consuming. This limitation is about to be changed, at least moderated through the development of computation technology in recent years. The PC with multi-CPU and the parallel computing FEM technique can be easily afforded and applied by consulting company and institution now, which is an elementary platform for 3-Dimensional FEM analysis of shield tunnel. Under this background, 3-Dimensional FEM analysis is gradually applied in the simulation of shield tunnel, especially on the mechanism research of joints between segments and rings (Teachavorasinskun and Chub 2010), whereas the 3-Dimensional full-length shield tunnel simulation considering all the connection conditions is still rare to be seen.

In order to give a precise and trustable numerical analyze approach for shield tunnel engineering, e.g. design, construction, maintenance, monitoring, a full-length 3-Dimensional solid FEM model has been proposed in this study. In this model, both spring connection and interface contact between segments and rings are considered; the edge of each segment is treated as a strengthen part on elastic property; the nodes on the outer surface are connected with ground springs as boundary conditions. A 3D 8-node linear isoparametric element is used to simulate the concrete segment; nonlinear spring element is used to simulate the bolt connection between segments and rings, and the ground support; hard surface contact is considered for the interface contact between segments and rings. Abaqus v6.11 has been utilized as the FEM solver.

2.2 Details of The Model

A completed shield tunnel consists of thousands of segments, which are made of concrete or steel. In annular, several pieces of segments combine each other as a ring. In axial, two rings of segments connect together with a certain angle difference, then these two rings form a unit, repeatedly installed along the tunnel route. The connection mechanism of those segments is extremely important to analyze the whole tunnel structure, however, not yet to be understood so well.

In practical, in annular, between each two segments, there will be 2 joints of tension bolt as connection, and in axial, between each two rings, there will be numbers of joints of tension bolt evenly distributed on the circle. Usually attentions can be easily drawn by those joint-type connections, especially for the segmental joints, numbers of experimental studies have been conducted, to understand the mechanical performance of those segmental tension bolts (Koyama et al. 1994). In simulation, those joint-type tension bolt connections can be substituted by spring elements in FEM analysis, whose elastic constant can be partial-nonlinear, fitting the experimental data as much as possible. The longitudinal tension bolt connection performance is not clearly known due to the difficulty in ring-ring loading test. Another connection, which is hard to quantify and easily to be neglected, is the surface contact on each interface between two segments or two rings. Because of the existence of tooth-like concrete concave-convex on the edge of the segments, the friction on the interfaces may affect the mechanical behavior of shied tunnels. The effect of this surface-type connection also needs to be considered in this model.

Figure 1 shows the detail of connection simulation in this model. Figure 1 (a) and (b) are the surface contact between segments and rings respectively. The contact type is called “Hard contact”, which implies that only when the surfaces are in contact, namely, the clearance between them is zero, the contact pressure can be transmitted, otherwise, if the surfaces separate, then no pressure can be delivered. This “Hard contact” can be well applied in both static and dynamic analysis. Friction can also be considered on the interface. In this model, the element faces on the edges of the segments are set to be pairs of surface contact, including 7 pairs on each ring and 1 circle-shape pair between two rings, with “Hard contact” as normal behavior for pressure transmission and friction coefficient 0.6 as tangential behavior for concave-convex grip.

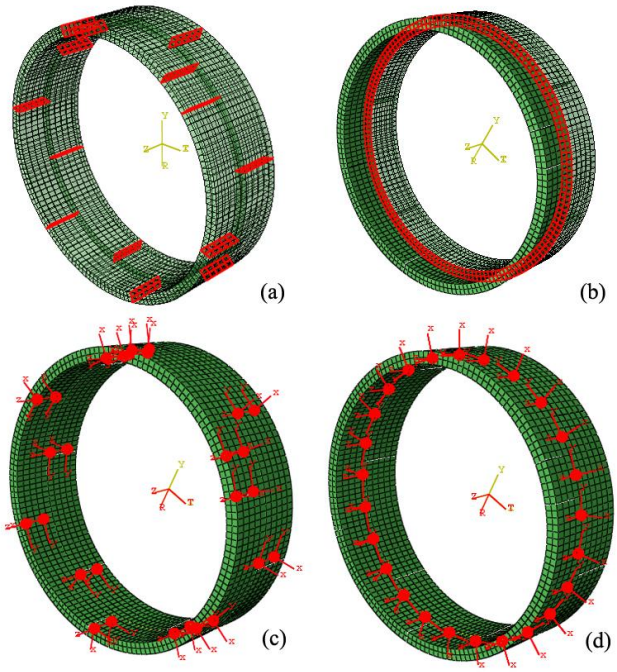

Figure 1 Surface Contact and Springs between Segments and Rings: (a) Surface Contact between Segments, (b) Surface Contact between Rings, (c) Springs between Segments, (d) Springs between Rings.

Figure 1 (c) and (d) are the spring connections between segments and rings respectively. Those springs are approximation of tension bolt on the interfaces. According to the knowledge about the tension bolt from experiments, 4 types of springs are set between segments: namely, radial, annular, axial, and rotational springs, while 3 types of springs are set between rings: namely, radial, annular, and axial springs. Springs’ amount and position setting is based on the design example (Railway Technical Research Institute, 2001).

Besides of the springs on the interfaces, 2 types (radial and axial) of ground springs will be set on each node on the outer surface of the tunnel, and the spring constant is evenly distributed.

For the 2-ring unit, which will be utilized in validity confirmation later, the number of elements is 10535. For the 50-ring full-length model, which will be utilized in rebound estimation, the number of elements is 293783.

3. VALIDITY AND MODEL MODIFICATION

Before this model being applied in any engineering computation, it needs to be examined with its validity. As the compared model, a 3-Dimensional FEM model with shell elements has been checked on validity by comparing the results obtained by beam-spring model (Tsuno et al. 2012). Then, the results of model with solid elements will be compared with those of shell elements model, which adds spring elements as the connections between segments, without considering surface contact on the interfaces.

The validity work will be carried out simultaneously with the process of parameter modification. The spring constants and friction coefficients on the interface are the parameters under modified. Another important factor is the material elastic property on the edge part of every segment. A special edge part is designed in this model, as Figure 2 shows. For these edge part elements, the Young's modules can be higher than the inner part, which is a simplification of the high strength design in practical treatment. In the process of parameter modification, those edge part elements' elastic property will be adjusted.

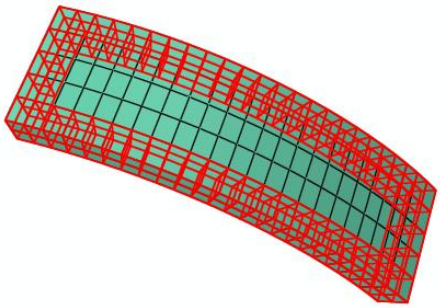

Figure 2 Edge Part Element with Different Parameter

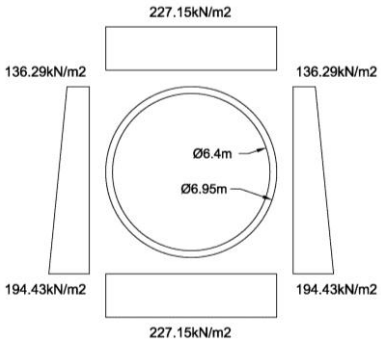

Figure 3 Earth Pressure Load on 2-ring Model

An earth pressure load (Figure 3), is applied on both solid and shell model. Figure 4 shows the result of u_2 component. After model parameter modification, the two FEM models get a good agreement on u_2 component, with a difference of 2.6%. Besides of the displacement, the solid model gives more information on edges and joints, which shows a capability of local detail analysis.

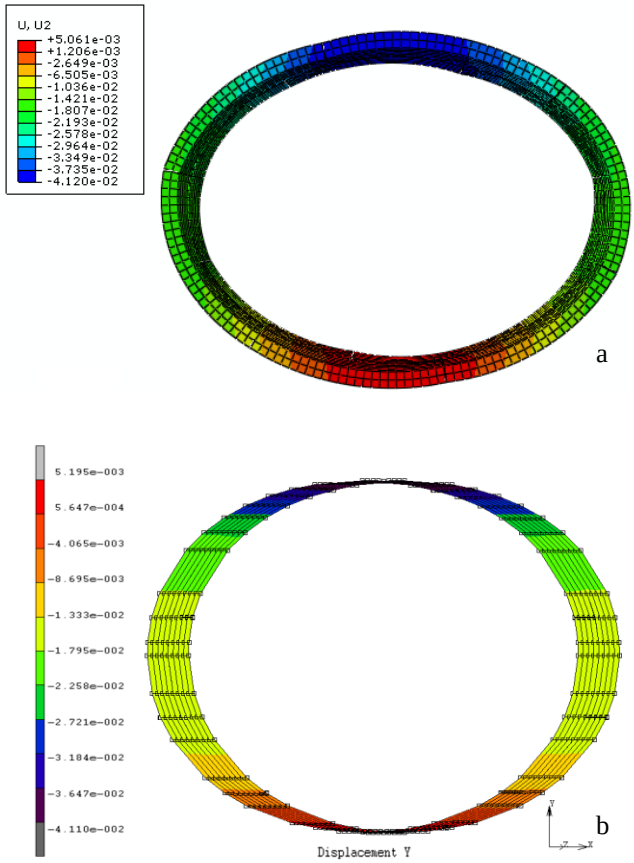

Figure 4 Displacement Comparison between Solid Model and Shell Model: (a) u_2 Solid Model, (b) u_2 Shell Model

4. SIMULATION OF CONNECTION

To look into the performance of those connections, including the surface contact and springs between segments and rings, and to find out how they work properly and how much they can affect the results, several cases of different damaged conditions (remove surface contact or spring somewhere) will be analyzed.

4.1 Effect of Surface Contact

Table 1 Damaged Cases when Surface Contact is Removed

Connect Type	with all contact (health)	without all contact	without ring contact	without segmental contact
Lateral Extension (mm)	5.90	11.6	5.91	10.8
Vertical Contraction (mm)	5.22	14.5	5.22	13.5
Damage Coeff. 1	1.00	1.97	1.00	1.83
Damage Coeff. 2	1.00	2.77	1.00	2.59

The first damaged condition is that surface contact in somewhere is removed, while all the spring connections are kept. 4 cases are considered: 1) with all surface contact, namely, health; 2) all the surface contact has been removed; 3) only the surface contact between rings is removed; 4) only the surface contact between segments is removed.

Two deformation value, lateral extension and vertical contraction, are used here as damage index. All cases are under the same earth pressure load. The results are shown in Table 1, where the Damage Coeff. 1&2 are the ratio of each case's lateral extension/vertical contraction compared to those of first case (health case) respectively. A larger value the Damge Coeff. 1&2 is, a severer damaged condition it represents. From Table 1 we can see that removing all the surface contact will bring a serious damaged condition. It will amplify the lateral extension for 2 times and vertical contraction for nearly 3 times as before. However, only removing the surface contact between rings seems will not affect too much. But if no segmental contact is considered, then the damaged level is almost the same with the one when they all gone.

From this table, we find that the surface contact between segments (annular) plays a much more important role compared to those between rings (longitudinal), under a symmetric and axial-even loading. The surface contact on the interfaces of every two segments supports the tunnel structure to withstand the vertical and lateral (in-plane) earth pressure with large percentage. Without it, the tunnel will deform more. On the other hand, the surface contact between rings cannot contribute too much even though the friction has been considered.

4.2 Effect of Segmental Spring

When the surface contact between segments is considered, most of the earth pressure load will be resisted by the surface contact, not the segmental springs. Only if all the contact is removed, left the spring type connection only, the function of those spring elements shows.

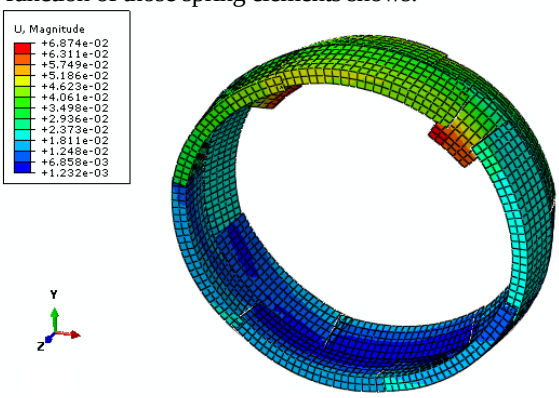

Figure 5 Deformation when Surface Contact and Segmental Spring are both removed

Figure 5 is the deformed shape of a 2-ring unit when both the surface contact and segmental springs have been removed. Without segmental springs, more local damage occurs, correspondingly with more rotational deformation, compared to the case with only no surface contact, which is generally a global deformation. Through analyzing more cases, among the 4 types of segmental springs, the annular and radial direction springs give most contribution to resist the earth pressure load, compared to the annular and rotational type.

4.3 Connection between Rings

In order to see the connection effect between rings, an offset loading needs to be applied. In this loading type, only one ring is loaded, lacking loading on another ring. Then, large shear force will occur on the interface between two rings, which will be resisted by the connection (surface contact and spring) between them.

Figure 6 shows the deformation of the 2-ring unit under this offset loading, without springs between them but with surface contact between them. Apparently, one ring keeps almost undeformed, while another deforms a lot. The connection between them almost failed when springs been removed, though the surface contact still there. This case has confirmed again that on the interface between two rings, the dominant connection is the spring element, not the surface contact. The surface contact may resist the axial load, but to the in-plane load, it cannot help much.

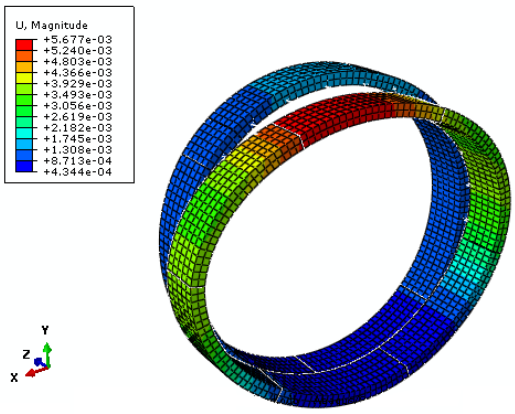

Figure 6 Deformation under Offset Loading without Springs between Rings but with Surface Contact between Rings

5. REBOUND ESTIMATION

This full-length 3-Dimensional solid FEM shield tunnel model can be applied in various engineering analyses. This chapter shows the application of this model in rebound effect estimation of shield tunnel.

5.1 Problem Statement

The rebound effect is the secondary upward deflection of shield tunnel caused by the removal of the covering earth above the tunnel, as shown in Figure 7. Usually this situation occurs when some new construction is developed above an existing tunnel. The removal of the earth pressure above will bring an unbalance in local area on the tunnel. The uplifting force below will cause a notable deflection on a short length of the tunnel. If the volume of the removed earth is large, some serious situation may happen.

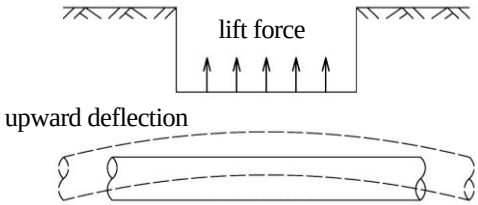

Figure 7 Rebound Effect due to Earth Removal

Since the impact of the rebound effect poses problem, it is necessary to estimate this effect according to soil properties, and the amount and depth of removed soil. Some empirical equations have been deduced based on monitoring or measurement after rebound (Okada et al. 2004).

With a field earth property assumption, the full-length model can soundly simulate the process of rebound, and give an estimation of final rebound value. In the following example, various cases of earth removal and the respective rebound effect will be calculated.

5.2 Results

The length of shield tunnel under consideration is 50m. In the middle 10m part, some volume of earth is removed. The condition of calculation is determined based on the site information (Railway Technical Research Institute 2007). The whole length of shield tunnel is assumed been built under 30m depth's earth, from which the elastic constant of ground spring can be set. Figure 8 shows one case of the rebound deformations. The inner-diameter of the tunnel is 6.4m, and the maximum rebound value in the center top is approximately 0.1m.

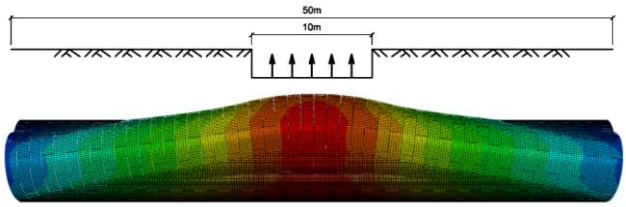

Figure 8 Simulation of Rebound Effect

After calculate 8 cases of different removed earth pressure from 57kN/m^2 to 413kN/m^2, the relationship between rebound values and removed earth pressure can be described by polynomial fitting.

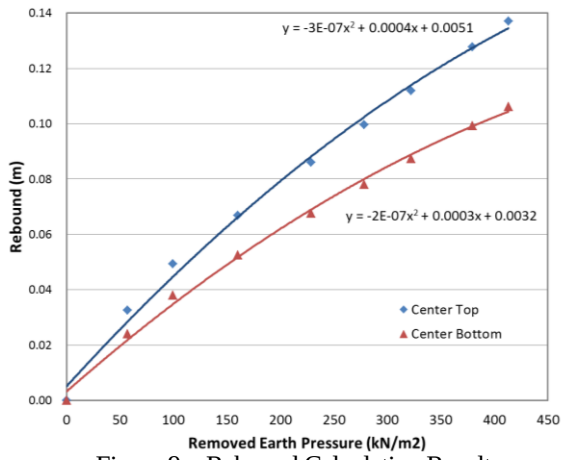

Figure 9 Rebound Calculation Results

Figure 9 shows the rebound value on center top and center bottom of the tunnel and their polynomial fitting. An approximate linear relation can be found between rebound and removed earth pressure, but small nonlinear also shows. More earth been removed, more rebound occurs, and more difference between top and bottom shows, which is due to the increasing vertical extension. Here we can see that the full-length solid model can successfully calculate the rebound effect with an earth environment assumption. In actual situation, this assumption can be substituted by soil investigation data and construction information. With this full-length FEM model, the estimation of rebound effect is feasible, and it is more accurate then empirical approach.

6. CONCLUSIONS

A 3-Dimensional full-length solid FEM model of shield tunnel has been developed. Different connection types between segments and rings have been considered. Through damage simulation, the performance of each connection type has been found, that is, on interface between segments in the circular direction, the surface contact will resist the in-plane load mostly; on interface between rings in the longitudinal direction, the spring element is much more effective than surface contact. Although the results are obtained by the calculation under some assumptions, they may be able to give advice to design and analysis work of shield tunnel. In the end, an application of this model has been shown, and a method of rebound estimation has been proposed.

Abstract: Aluminum alloy BRBs could be preferable in new buildings or bridges where severe corrosion effects are expected. BRBs can also be used in existing steel or reinforced concrete frames for seismic retrofit purposes to achieve the required strength, stiffness, and ductility. To the best knowledge of the authors, aluminum alloy core and outer tube BRBs having specific details developed in this study are designed, produced, and cyclically tested for the first time in this area. Two aluminum alloy, almost full-scale BRB specimens (TURKBRACE BRB-AC1 and TURKBRACE BRB-AC3) use rectangular plates as the core material made of A5083-H111. The core is surrounded by an aluminum square tube infilled with a high strength grout as the buckling restraining system. Both bolted (weld-free) and welded end connections are used. Experimental results show that, cumulative energy dissipation can be significantly increased when weld-free BRBs are tested. The fabricated BRBs achieved the desired behavior while no global buckling occurred under inelastic displacement cycles. Compared to steel core BRBs, relatively symmetrical hysteretic curves are obtained in aluminum alloy core BRBs. As a result, aluminum alloy core BRBs with special details developed herein showed promise for use in new buildings/bridges or as a retrofitting technique in buildings/bridges that lack strength, stiffness, and ductility.

1. INTRODUCTION

Since steel moment frames did not show the expected performance during the 1994 Northridge and the 1995 Kobe earthquakes, new effective solutions which could reduce the destructive effects of earthquakes have been sought. Structural dampers of various types which dissipate seismic energy have beneficial results in this sense. Buckling Restrained Braces (BRBs), being a sort of mechanical damper, display a balanced hysteretic behavior by axial yielding under reversed cyclic tension and compression forces during major earthquakes. BRBs can be used in existing steel or reinforced concrete (RC) frames for seismic retrofit purposes to achieve the required strength, stiffness, and ductility. Implementation of BRBs in new building and bridge projects is increasing.

Experimental and numerical studies have been conducted to promote the application different types of BRBs. For example, Sabelli et al. (2003) analytically investigated the seismic response of BRB frames (BRBFs) considering a number of important parameters, such as ground motion characteristics and the structural configuration. Fahnestock et al. (2003) addressed global ductility demands of BRBFs and local ductility demands of BRBs by nonlinear time-history analyses, which were compared with BRBF Recommended Provisions. Later, numerical and experimental simulations of a large-scale BRBF were given by Fahnestock et al. (2007a, 2007b). Besides, a series of pseudodynamic tests of a full-scale, three-story, three-bay BRBFs using concrete-filled tube columns was performed by Tsai et al (2008a, 2008b). Takeuchi et al. (2008, 2012) proposed a simple method for predicting the cumulative deformation capacity and energy absorption capacities of BRBs under random amplitudes. Three real substructures (parts of an existing RC building upgraded by means of several metal-based innovative techniques including BRBs) are tested to calibrate numerical models by Mazzolani (2008). Usami et al. (2008) studied buckling prevention condition with a series of well-controlled experiments. Vargas and Bruneau (2009a, 2009b) proposed an alternative design approach for systems with metallic fuses. An experimental work was also conducted on a three-story frame designed with BRBs to verify the proposed design procedure. A series of performance tests and analyses are carried out by Usami et al. (2009) to clarify the requirements of high-performance BRBs for the damage controlled seismic design of steel bridges. Celik and Bruneau (2009, 2011) analytically investigated the best geometrical layout to maximize the dissipated hysteretic energy in ductile diaphragms with BRBs end diaphragms in straight and skewed steel bridges. Component tests were conducted by Zhao et al. (2012) to address the effect of brace end rotation on the global buckling behavior of pin-connected BRBs with end collars. To increase the efficiency of BRBFs, a novel connection where the gusset is only connected to the beam and is offset

from the column face is proposed and tested in a three-story frame under quasi-static loading by Berman and Bruneau (2009). Palazzo et al. (2009) and Tsai et al. (2012) proposed new types and configurations for steel BRBs. All of these researches have sped up the application of steel BRBs in building and bridge engineering. Mostly, the concepts of BRBs published or applied for patents are essentially similar and the BRB's core brace member is mostly manufactured of steel owing to its great hysteretic performance.

Aluminum is being used increasingly in a variety of structural engineering applications due to its superior characteristics such as low density, high strength-to-weight ratio, good corrosion-resistant, durability, recyclability properties, high strength similar to steel and excellent formability (e.g., extrusion). These characteristics are of particular significance in the design of lightweight and transportable BRBs, for which ease and speed of construction, low maintenance, and long service life are important considerations. When compared to steel core BRBs, aluminum alloy core BRBs are expected to dissipate seismic energy through stable, relatively symmetrical compression-tension inelastic cycles. These considerations motivated the research presented in this paper that was addressed to study a special and unique aluminum alloy BRB, to be used for the aim of improving traditional steel BRB durability in corrosive environments.

Aluminum alloy core BRB is a relatively recent development in the field of BRB technology. Limited studies are present for the development of aluminum alloy core BRBs. For example, a series of low-cycle fatigue tests were conducted by Usami et al. (2012) to address the performance of the all-aluminum alloy BRB which has an aluminum core is separated by the restraining member by a small gap without mortar. Several experiments on welded and bolt-assembled aluminum alloy BRBs are performed. Extruded aluminum alloy BRBs were produced and tested to address their low-cycle fatigue performance and to evaluate the effect of stoppers which were used to prevent the slip-off movement of the restraining members (Wang et al. 2013).

To the best knowledge of the authors, two aluminum alloy core and outer tube BRBs (TURKBRACE BRB-AC1 and TURKBRACE BRB-AC3) having the same yield strength and simple end connection details developed in this study are designed, produced, and cyclically tested for the first time in this area as an alternative to commercially available BRB types in the U.S.A. and Japan (Karatas and Celik 2011, 2012, Karatas 2012). Examining the possible superiority of aluminum alloy BRBs that are developed herein is considered to be of importance in terms of earthquake engineering research and design applications. Reversed cyclic quasi-static loading tests were carried out in the Structural and Earthquake Engineering Laboratory (STEEL) at the Technical University of Istanbul. An unique strain-gauge placement configuration is also suggested and tested in order to measure strains and yield strength of the aluminum alloy core as precisely as possible. A displacement loading protocol proposed by the Seismic Provisions for Structural Steel Buildings, AISC-341 (2010) was used for all BRB tests. Details of the test set-up, details of specimens, cyclic testing of specimens, experimental observations, and conclusions are summarized.

2. EXPERIMENTAL PROGRAM

2.1 Test Set-up

A versatile test set-up composed of a steel L frame was previously constructed for cyclic testing of classical braces and was designed to accommodate different bracing sizes and lengths (Fig. 1, Haydaroglu at al. 2011). Using high safety factors, the test set-up was designed to remain elastic under the maximum actuator force. The steel grade used for testing set-up was S275JR. Loads were applied by a computer-controlled MTS hydraulic actuator, capable of producing up to 250kN horizontal loading. Displacement capacity of the actuator is ±300mm. Displacement-controlled testing was carried out via LVDTs mounted on the column face at the same height with the actuator. All specimens were designed well less than the capacity of the actuator. The specimens were tested a 38-degree diagonal bracing configuration with the steel foundation beam.

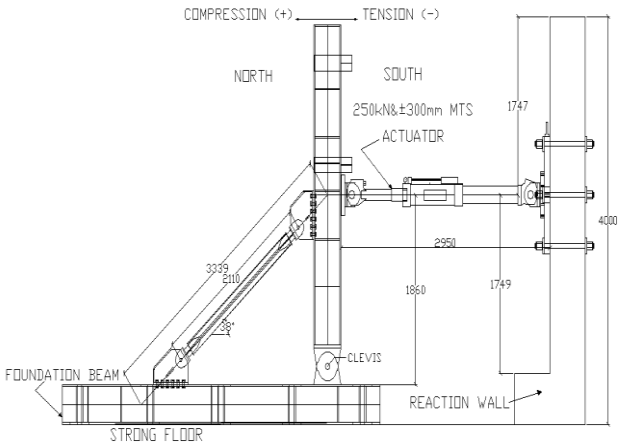

Figure 1 Test Set-up for specimens

2.2 Material Characteristics

In order to exactly determine the mechanical properties of aluminum alloy core materials from which the BRBs were produced, numerous tensile test specimens (coupons) were prepared in prototype samples according to the recommended standard (ASTM-E8/E8M-09, 2009). There are two types of aluminum alloys, A5083-H111 (nonheat-treated) and A6061-T6 (heat-treated and then artificially aged), used to manufacture the BRB's specimens considered in this work. 5xxx series aluminum alloy (namely A5083-H111 and is produced by adding magnesium, resulting in strong, corrosion resistant, and high welding strength alloy) is used one of the two BRBs. The second BRB was a 6xxx series aluminum alloy (namely A6061-T6 and contains magnesium and silicon and has a

good corrosion resistance and strength). Silicon provides excellent fluidity, so these alloys are well suited to intricate castings (Kissell and Ferry 2002).

Stress-strain relations of two tensile coupon test specimens, used in production of aluminum alloy core BRBs, are shown in Figure 2. Post-yield strain-gauges (namely TML-YFLA-10-3L with a gauge factor of 2.1) were used to determine the exact values of the yielding points, ultimate strength and strains as well as and the modulus of elasticity of the material.

The average coupon test results of the specimens are listed in Table 1. The yield strength of the BRB core coupons was calculated using a 0.2% yield strain offset, since aluminum alloy had no definite yield plateau. $F_{ysc}^{0.2}$ is the 0.2% yield strength/stress, ε_0 is the strain equal to $0.8\varepsilon_y^{0.2}$ for A5083-H111 and $0.9\varepsilon_y^{0.2}$ for A6061-T6, F_{ysc}^{0} is the strength/stress corresponding to the strain ε_0, F_u is the ultimate tensile strength, ε_u is the total tensile strain at fracture. The Poisson's ratio was obtained as ν=0.32~0.33. Prior to testing, these material data were used in static pushover analyses of the specimens conducted using SAP2000 v14 (CSI 2009) to predict the load-displacement curves of the specimens.

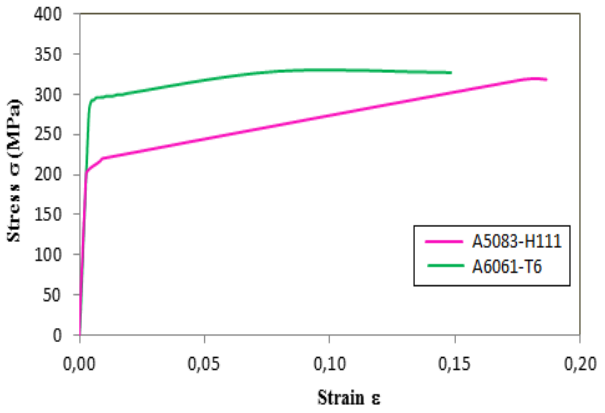

Figure 2 Stress-strain curves from the coupon tests

As per the results to be obtained from coupon test, the production was initiated by revising the structural calculations. Material test results contain valuable information on choosing the material classes to be used in designing the aluminum alloy BRBs. Failure mode of the welded aluminum alloy BRB (the core material is made of A6061-T6) is obviously affected by the ribs' welding under variable strain amplitudes. Although A6061-T6 aluminum alloy has notably higher yield stress than A5083-H111, another type of aluminum alloy core BRB (the core material is made of A5083-H111) was developed and tested.

Welding significantly reduces the strength of artificially aged aluminum alloys like A6061-T6 which has a tensile strength about 40% less than portions of the material not affected by welding. Aluminum alloy tubes of specimens are made of A6060-T66 hollow structural section.

Compression tests of the infill material revealed that the specified 7-day and 28-day mortar strength were 52.34MPa and 64.06MPa, respectively.

Steel bolts used are fully-tensioned, high-strength A490grade (10.9) in gussets-to-BRB and gussets-to-L frame connections. A manuel torque wrench was used to assure the minimum AISC specified slip-critical connection bolt pretension.

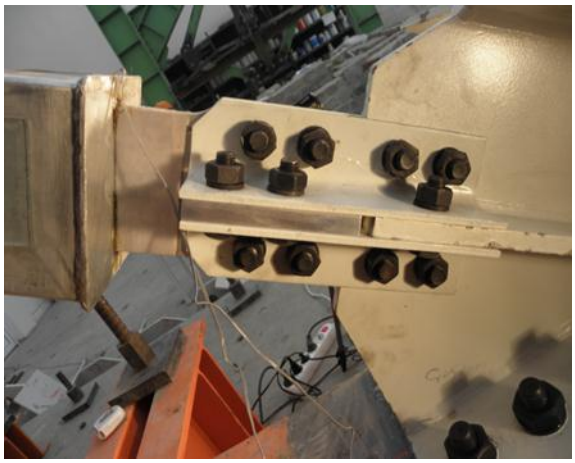
Table 1 Average material properties of aluminum alloys

Aluminum Alloy Series	E (GPa)	$F_{ysc}^{0.2}$ (MPa)	F_{ysc}^{0} (MPa)	$\varepsilon_y^{0.2}$ (%)	ε_0 (%)	F_u (MPa)	ε_u (%)
A5083-H111 (BRB-AC1)	73	182	145.6	0.27	0.22	314	17.5
5083-H111 (BRB-AC3)	73	177	141.6	0.27	0.22	318	20.0
A6061-T6	71	292	262.8	0.49	0.44	327	13.1

A5183 (ϕ=1.2mm) was used in all aluminum alloy welding process (AWSD1.2/D1.2M, 2008) as a special aluminum alloy solid MIG wire containing 5% Magnesium and 0.75% Manganese for improved weld strength and resistance to water.

Specially designed gusset-plates were used for the BRBs to avoid out-of-plane buckling. In order to have mobility for the replacement of BRBs, gusset-plates were designed as removable elements bolted to the test set-up. Rib stiffeners were added to gusset-plates to improve local and out-of-plane buckling capacity at the connection points. Higher safety factors were used in the design of gussets and all welds to achieve the desired ductile behavior of BRBs.

2.3 Details of Specimens



As an alternative to the existing BRBs, produced firstly under the patents of various firms in the U.S.A and Japan, two BRBs (TURKBRACE BRB-AC1 and TURKBRACE BRB-AC3) with aluminum alloy core and outer tube having the same yield strength, and simple edge details were designed, fabricated, and tested.

Aluminum alloy BRBs were designed to achieve the same yield strength for a better comparison of their cyclic performances. General views from the end connection of BRBs are given in Figure 3.

The geometrical parameters are summarized in Table 2. The length and width of the yielding portion of the brace are denoted by L_{ysc} and b_{ysc}, respectively. And likewise, L_{con} and b_{con}, are the length and width of the connection portion. The transition zone has a length of L_{tr} and a width of b_{tr}. The thickness of the cores is denoted by t.

(a)

(b)

Figure 3 General view from the end connection of BRBs (a)TURKBRACE BRB-AC1: Welded end connections, (b)TURKKBRACE BRB-AC3: Bolt-assembled (weld-free) cruciform end connections

Table 2 General geometrical parameters of the cores

Specimens	L_{ysc} (mm)	b_{ysc} (mm)	t (mm)	L_{con} (mm)	b_{con} (mm)	L_{tr} (mm)	b_{tr} (mm)
TURKBRACE BRB-AC1	1278	35	15	184	165	315	115
TURKBRACE BRB-AC3	1195	40		140	137	258	115

Two specimens have been produced according to the described details given below:

Almost full-scale BRBs specimens use rectangular plates (15mmx35mm for TURKBRACE BRB-AC1 and 15mmx40mm for TURKBRACE BRB-AC3) as the core material of A5083-H111 nonheat-treated aluminum alloy, which mostly expands at the ends to form a cruciform section. Both bolted (weld-free) and welded end connections are used to compare their performance under cyclic loading. Cross-sectional areas of the BRBs were selected based on the possible smallest core. For specimens, longer core yielding lengths were used (67% of the total braces length, $L_{ysc} \leq 1410$mm). The total lengths of BRBs are limited to 2275mm. Hole diameter for aluminum alloy connection plates is limited to no more than 0.7mm larger than the nominal steel bolt diameter.

The core is surrounded by an aluminum square tube infilled with a high strength non-shrink grout as the buckling restraining system. It is clear that the restraining member of the BRBs does not intend to withstand any axial force. For the cases when the yield load of the core exceeds the buckling load of the outer tube, brace fails in a global buckling mode. P_e/P_{ysc}, ratio of the Euler buckling load of the outer tube (P_e) to the yield load of the core (P_{ysc}), has to be checked as a criterion to guarantee the yielding of the core material. Watanabe et al. (1988) suggested that this ratio P_e/P_{ysc} should be over 1.5. Contributions of the mortar and the core to the buckling resistance of the brace have been neglected. Higher ratios of 12.7 and 14.2 were used in this work for TURKBRACE BRB-AC1 and TURKBRACE BRB-AC3, respectively.

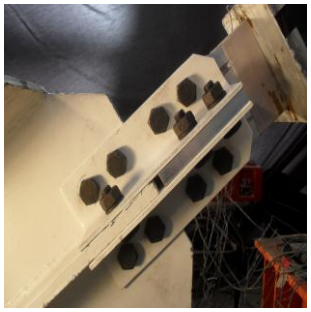
An unbonding material is adopted for the interface of aluminum alloy core and high strength mortar. It is required to prevent excessive shear stress transfer, since it would reduce the longitudinal stress in the core thus impairing the energy dissipation. Also, this interface involves some clearance between the core and the mortar to allow the Poisson expansion of the core during compression. When the unbonding material is too thin, the thickness does not tolerate the expansion in the plate thickness direction of the core caused by its axial deformation; on the other hand, when the unbonding material so thick, local buckling of the core is possible. The problems mentioned above are solved in this study by using the unbonding material having a thickness at least 0.5 to 10% of the core plate thickness and width.

A key issue of the design is to ensure a proper sliding between the core and mortar to avoid relevant shear stress transfer. In the proposed BRBs, the sliding is ensured by a three-layer interface: the aluminum alloy core coated with polytetrafluoroethylene, lubricated with rubber grease, and wrapped with air bubbles. The purpose of the air bubbles is to provide shear flexibility, to guarantee an even sliding surface and to allow the transversal expansion of the core when compressed.

Aiming at improving the out-of-plane stiffness of the core in the unrestrained segment, cruciform section at both ends of the core is expanded by welding the same thickness plates. However, cyclic performance of this type of aluminum alloy BRBs was not satisfactory mainly due to the adverse effect of welding. Therefore, another type of aluminum alloy BRB (TURKBRACE BRB-AC3) was developed with multi-bolted end connections (Figure 4). The difference between two kinds of aluminum alloy BRBs is

that four steel angle members are bolt-assembled around the core to prevent weak axis buckling of the core in the unrestrained region and avoid the cyclic fatigue performance degradation caused by welding of the rib stiffeners.

(a)



(b)

Figure 4 Bolted end connection (a) General view, (b) Side view

According to AISC-341 (2010), the axial yield strength of the BRBs, P_{ysc}, shall be determined as Eq. (1):

$$P_{ysc} = \beta\omega R_y F_{ysc} A_{sc} \quad (1)$$

where β and ω are the compression and strain-hardening adjustment factors, respectively, R_y is the ratio of the expected yield stress to the specified minimum yield stress, F_{ysc} is the specified actual yield stress of the core as determined from the coupon test, and A_{sc} is the net area of the core. The strain-hardening adjustment factor, ω, is calculated as the ratio of the maximum tension force (T_{max}) measured from the qualification tests to the yield force, P_{ysc}, of the test specimen. The compression strength adjustment factor, β, is calculated as ratio of the maximum compression force (P_{max}) to the maximum tension force of the test specimen. Value of β, at the point of maximum deformation, was obtained from previous studies (e.g., Meritt et al. 2003, and Lopez and Sabelli, 2004) as 1.15. Values of ω for TURKBRACE BRB-AC1 and TURKBRACE BRB-AC3 were determined, according to the strain-hardening properties of coupons, as 1.73 and 1.81, respectively. R_y was taken as 1.1 from Table I-6-1 from AISC-341 (2010).

Maximum displacement ductility of brace, μ_{max} was calculated as ratio of the maximum plastic displacement, Δ_u, to the yield displacement, Δ_{by}, and assumed as 7.5 for aluminum alloy BRBs.

Further details regarding the specimens can be found in Karatas and Celik (2012), and Karatas (2012).

2.4 Instrumentation

Instrumentation for the experimental part has been designed to measure global response of the steel test set-up and local performance of aluminum alloy BRBs. Seismic response of the column, foundation beam, and BRBs was obtained from strain gauges and LVTDs installed at critical points. In total, 21 strain-gauges were installed on TURKBRACE BRB-AC1, TURKBRACE BRB-AC3, and testing set-up. To monitor the internal forces and to verify that the loading frame remained elastic, a few gauges were used at the critical sections. Outer tubes were instrumented by 12 strain-gauges on the each side of the tube at the midpoint of the each side. The LVDT and strain-gauge layout was identical for both specimens (Figure 5). LVDT-T1E and LVDT-T1W were mounted to measure lateral drift of the frame. Several LVDTs were used to monitor accidental movement of the frame with respect to strong floor (e.g. at the mid-point of the column, on gusset plates, and on the foundation beam). The applied load was measured by a load cell installed in the actuator.

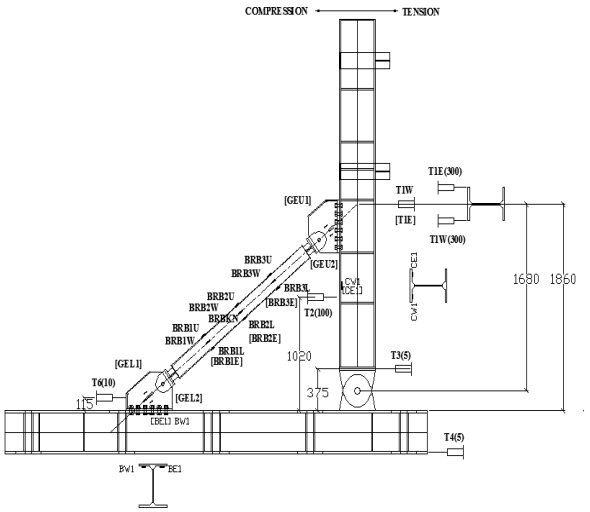


Figure 5 Instrumentation for TURKBRACE BRBs

2.5 Cyclic Testing

To characterize the hysteretic behavior of aluminum alloy BRBs and to develop bilinear analytical models, both BRBs were cyclically tested per the loading protocol proposed in AISC-341 (2010). The experiments are designed to reach the goals while accounting for the time, budget, and availability.

Quasi-static reversed cyclic testing in subassemblage configuration was carried out for each BRB based on the acceptance criteria given in AISC-341 (2010) loading protocol. Although additional cycles to satisfy the Office of Statewide Health Planning and Development (OSHPD) requirement for cumulative inelastic deformation are proposed, aluminum alloy BRBs did not arrive at the last cycles. Top horizontal displacement is related to the brace axial displacement and was taken as the displacement control parameter. Loading protocol used for the specimens and the vertical line normalized with respect to first axial yielding deformation of BRB, $\Delta_{by,}$ are depicted in Figure 6.

The calculation Δ_{by} was based on the deformation expected over the length L_1, which is the pin-to-pin distance of the core plate. Δ_{by} is estimated by Eq. (2).

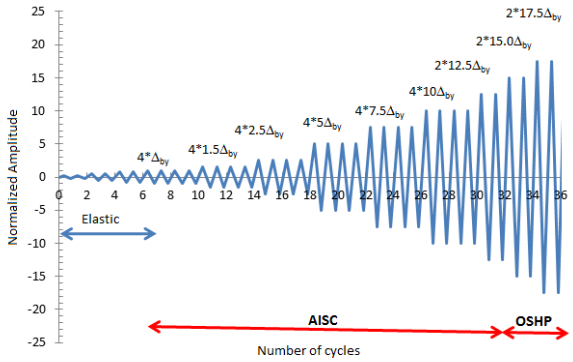

Figure 6 Test protocol normalized with respect to Δ_{by}

$$\Delta_{by} = \frac{P_{ysc} L_{ysc}}{EA_{sc}} + \frac{P_{ysc}\left[\dfrac{L_1 - L_{ysc}}{2}\right]}{EA_{tr}} \qquad (2)$$

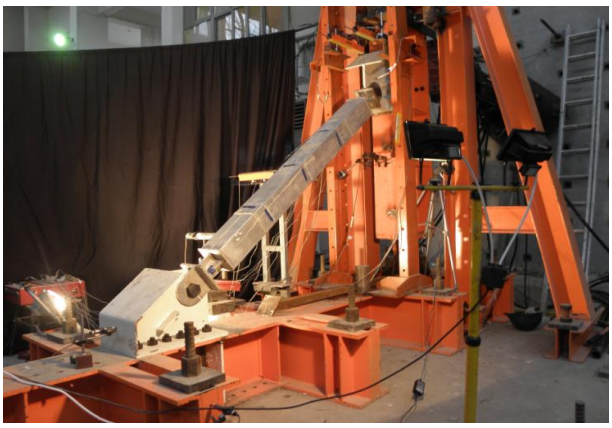
Here, A_{tr} and E are the area of transition zone and modulus of elasticity for aluminum alloy BRB, respectively. Also, elastic deformation of the aluminum alloy core plate outside the yielding length on the each end of the core is included. The brace deformation at the design story drift, Δ_{bm}, was taken as $5\Delta_{by}$ as proposed by AISC-341 (2010). Also, it was proposed that the design story drift shall not be taken as less than 0.01 times the story height ($\Delta_{bm}/h>0.01$).

In the present study, the following loading sequence for the elastic cycles was applied to the specimens, where the deformation is the axial deformation of the aluminum alloy core plate:

(1) 2 cycles of the loading at the elastic deformation corresponding to $1/4\Delta_{by}$,
(2) 2 cycles of the loading at the elastic deformation corresponding to $2/4\Delta_{by}$,
(3) 2 cycles of the loading at the elastic deformation corresponding to $3/4\Delta_{by}$

Table 3 presents the details of loading sequence for the inelastic range cycles according to the proposed provision. Shaded rows were not used for aluminum alloy BRBs.

Table 3 Loading protocol for the inelastic cycles



Cycles	Axial Displacement	η Cum. Inelastic Displacement	Estimated Axial Displacement (mm)	
			TURKBRACE BRB-AC1	TURKBRACE BRB-AC3
4	$1.0\Delta_{by}$	$0\Delta_{by}$	2.68	2.58
4	$1.5\Delta_{by}$	$4\Delta_{by}$	4.02	3.87
4	$2.5\Delta_{by}$	$16\Delta_{by}$	6.70	6.45
4	$5.0\Delta_{by}$	$48\Delta_{by}$	13.40	12.90
4	**$7.5\Delta_{by}$**	**$100\Delta_{by}$**	**20.10**	**19.35**
4	$10\Delta_{by}$	$172\Delta_{by}$	26.80	25.80
2	$12.5\Delta_{by}$	$218\Delta_{by}$	33.50	32.25
2	$15\Delta_{by}$	$274\Delta_{by}$	40.20	38.70

Testing was terminated at $7.5\Delta_{by}$ displacement level since the brace fractured. Yield values of forces and displacements were analytically estimated by static pushover analyses using SAP2000 (2009), and were used to initially control the tests. However, the experimentally obtained values were used as test control parameters beyond the elastic range. These were determined at the onset of visible nonlinearity in the force-displacement curve, or by using the strain-gauge data that were obtained in the mid-section of core.

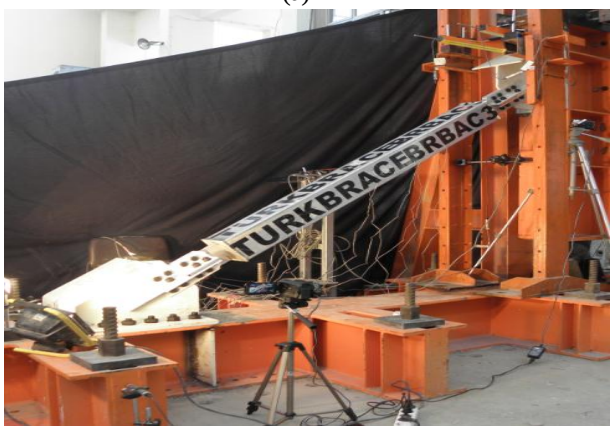


Figure 7 shows aluminum alloy BRBs installed in the test set-up and ready for testing. Two gusset-plates are placed at the both ends to ensure a proper anchoring to the test set-up.

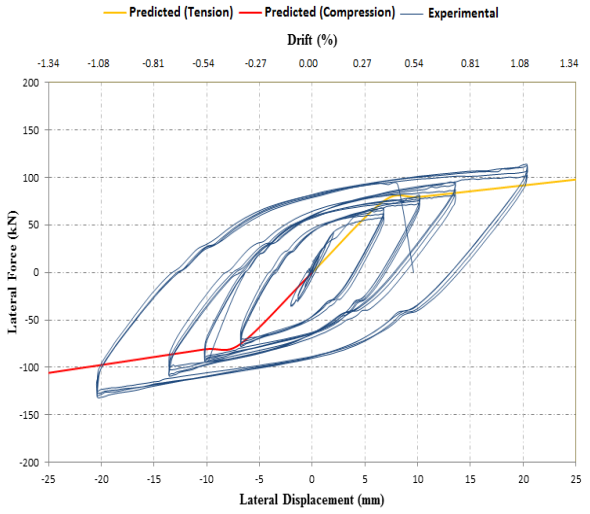
For both specimens, load was firstly applied to have a lateral load producing tension in the brace. Both tests were performed until the brace fractured. The loading sequence for the static test was performed by deformation-controlled. Loading was applied slowly due to the limited actuator speed and the need to closely monitor the behavior of specimens.

Using experimental hysteresis, some behavioral characteristics of specimens such as the maximum strength in tension and compression cycles, η cumulative inelastic deformation, E_h cumulative hysteretic energy dissipation, and ξ_{effb} hysteretic damping values are summarized and compared in the next section.

(a)



(b)

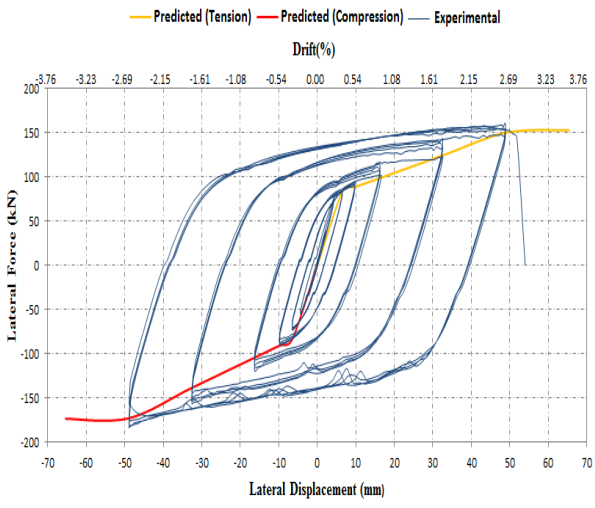


Figure 7 Overall view from the specimens prior to testing (a) TURKBRACE BRB-AC1 (b) TURKBRACE BRB-AC3

3. EXPERIMENTAL OBSERVATIONS

TURKBRACE BRB-AC3 performed well under the Standard Loading Protocol while a premature failure in TURKBRACE BRB-AC1 was experienced as the aluminum welds had an adverse effect on the failure mode. Up to core fracture, no fracture in welds, brace instability or no brace-to-end connection failures were observed in TURKBRACE BRB-AC3. Experimental horizontal force-horizontal displacement hysteretic curves representing the cyclic behavior and predicted pushover curves for specimens are given in Figure 8. Theoretical pushover curves are obtained using the axial plastic hinge properties proposed by FEMA 356 (2000). Plots showing the applied lateral load versus brace lateral displacement show stable, repeatable behavior with positive incremental stiffness. It was observed that elastic parts of hysteretic curves of the specimens obtained as a result of experimental study were similar and close to the curves obtained with coupon test results.

(a)

(b)

Figure 8 Experimental hysteretic curves and predicted pushover curves for specimens (a) TURKBRACE BRB-AC1, (b) TURKBRACE BRB-AC3.

The force amplitude decreases after first cycles at each displacement step but tends to stabilize quite fast. This is possibly due to a progressive detachment between the core and mortar. Estimation of experimental success ratio in terms of yield strength and initial stiffness were over 90%. Experimental force-displacement hysteretic loops for the BRBs reveal that no slip between the aluminum alloy BRBs and gusset-plates occurred. Obtained peak values of Δ_{by}, ω, β, maximum strength in tension (T_{max}), maximum strength in compression (P_{max}), and drifts are summarized and tabulated in Table 4 and Table 5 for TURKBRACE BRB-AC1 and for TURKBRACE BRB-AC3, respectively. Shaded rows show the yield displacement cycles.

Table 4 Peak response quantities and behavioral characteristics of TURKBRACE BRB-AC1

Δ_{by} (mm)	T_{max} (kN)	P_{max} (kN)	β	ω	Drift (%)
±1.69	24.60	-22.00	0.89	0.37	0.09
±3.40	44.00	-40.00	0.91	0.66	0.18
±5.10	59.50	-59.50	1.00	0.89	0.27
±6.80	**63.26**	**-74.51**	**1.18**	**1.00**	**0.37**
±10.19	77.51	-90.73	1.17	1.23	0.55
±13.59	89.31	-104.32	1.17	1.41	0.73
±20.39	108.97	-127.95	1.17	1.72	1.10

Table 5 Peak response quantities and behavioral characteristics of TURKBRACE BRB-AC3

Δ_{by} (mm)	T_{max} (kN)	P_{max} (kN)	β	ω	Drift (%)
±1.63	21.00	-20.00	0.95	0.25	0.09
±3.26	41.00	-32.00	0.78	0.49	0.18
±4.89	59.50	-54.50	0.92	0.70	0.26
±6.52	**84.50**	**-71.25**	**0.84**	**1.00**	**0.35**
±9.78	92.50	-87.50	0.95	1.09	0.53
±16.30	108.75	-113.75	1.05	1.29	0.88
±32.60	132.50	-149.25	1.13	1.57	1.75
±48.90	153.25	-174.00	1.14	1.81	2.63

Among the aluminum alloy BRBs, the highest tension adjustment factor at the maximum displacement level was obtained as ω=1.81 in TURKBRACE BRB-AC3. Also, the reached maximum tension and compression capacities are +153.25kN and -174.00kN, respectively. For TURKBRACE BRB-AC1, the reached maximum tension and compression capacities are +108.97kN and -127.95kN, respectively. Out-of-plane displacement of mid-span of TURKBRACE BRB-AC3's outer tube was measured between -2.82mm~+0.44mm. These values prove that out-of-plane

buckling was effectively prevented during the tests.

Out-of-plane displacement of mid-span of TURKBRACE BRB-AC1's outer tube was measured between -1.48mm~+1.24mm. For all inelastic cycles, in both specimens, the ratio of maximum compression force to the maximum tension force (i.e. β) did not exceed 1.3 for the specimens.

4. DISSIPATED HYSTERETIC ENERGY and EQUIVALENT DAMPING RATIOS

For any cycle, total area under the experimentally obtained hysteretic curve gives the dissipated energy through inelastic behavior. Since the cumulative energy dissipation is a useful measure of the seismic efficiency of a structural system, these values were calculated, and the variation of cumulative energy dissipation with cumulative number of cycles is plotted in Figure 9 as comparison for aluminum alloy BRBs having various end connection details.

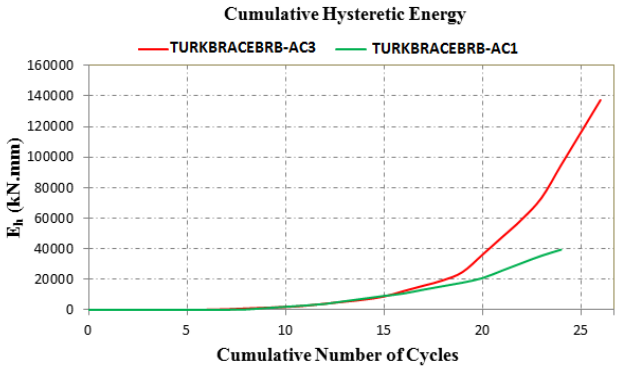

Figure 9 Comparison of cumulative energy dissipation

Numerical values of the cumulative hysteretic energy E_h and cumulative inelastic deformation η achieved by each specimen are summarized in Table 6.

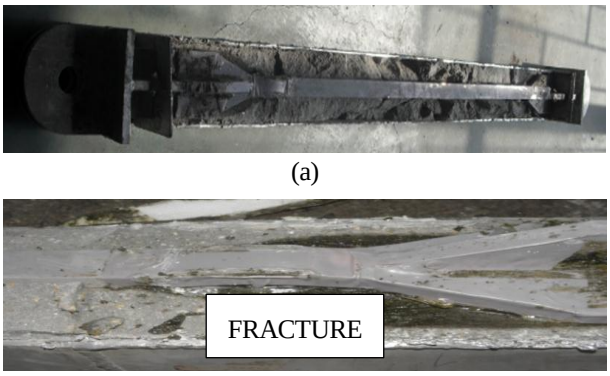

Table 6 Hysteretic energy and cumulative inelastic deformation

Specimens	Cumulative Inelastic Deformation η	Hysteretic Energy E_h (kN.mm)
TURKBRACE BRB-AC1	$48\Delta_{by}$	39,443.33
TURKBRACE BRB-AC3	$100\Delta_{by}$	137,301.40

Note that TURKBRACE BRB-AC1 core plate fractured at the transition zone from the yielding section to the cruciform section (elastic part) mainly due to the presence of heat affected zone (HAZ). η, maximum value of cumulative inelastic deformation was obtained to be $100\Delta_{by}$ in TURKBRACE BRB-AC3. Note that AISC-341 (2010) requires the braces to achieve a cumulative inelastic axial deformation of at least $200\Delta_{by}$ before failure during BRB component testing. However, for an experimental testing method as followed in this study, cumulative inelastic deformation of $200\Delta_{by}$ is not required. The most common method for defining equivalent damping ratio is to equate the energy dissipated in a cycle of the braces (Chopra, 2001). The computed values of equivalent damping ratios, ξ_{effb}, were obtained between 8.29%~32.56% for TURKBRACE BRB-AC1, and 8.10%~42.85% for TURKBRACE BRB-AC3. Maximum value of ξ_{effb} is taken as a representative value of equivalent damping. The maximum values were obtained at 0.55% and 2.63% drift ratios for BRB-AC1 and for BRB-AC3, respectively. Since ξ_{effb}, is greater than 15% for both specimens, the tested aluminum alloy BRBs can be classified as Energy Dissipating Devices (EDD) as per EN 15129 D.1 (2010).

5. DAMAGE DETECTION

Both specimens were disassembled by cutting them in half longitudinally and removing the fractured aluminum alloy core after failure. TURKBRACE BRB-AC3 fractured in the middle of yielding zone (Figure 10 and Figure 11).

(a)

(b)

Figure 10 Disassemble of TURKBRACE BRB-AC1 (a) General view (b) Fracture around the Heat-Effected-Zone (HAZ)

(a)

(b)

Figure 11 Disassemble of TURKBRACE BRB-AC3 (a) General view (b) Visible residual plastic deformation and typical buckling waves

The elastic transition zones at both ends of the aluminum alloy cores showed no damage or impairment; therefore it was safe to conclude that these parts remained elastic during the tests. No cracks or damage was apparent on the surface of the mortar that shall be separated from aluminum alloy core by the air gap. This leads to the conclusion that the mortar casing was not carrying axial loads, thus it was effectively decoupled from aluminum alloy cores. Typical buckling waves are shown in Figure 11a,b.

6. CONCLUSIONS

Two energy dissipative aluminum alloy BRBs having the same yield strength and simple edge details have been designed fabricated and cyclically tested. All experiments were conducted to failure of BRBs.

Based on the test results presented herein, the following conclusions and observations can be drawn from this work:

- TURKBRACE BRB-AC3 with bolted end connection details, performed well under the Standard Loading Protocol, and no premature fracture, brace instability or brace end connection failures were observed. However, TURKBRACE BRB-AC1 with welded end connection details experienced a lower fracture life mainly due to the heat affected zone (HAZ).
- Both tests showed that, in general, the devices performed properly, without relevant shear stress transfer to the casing and with stable hysteretic behavior.
- Plots showing the applied load versus lateral displacement revealed stable, repeatable behavior with positive incremental stiffness.
- For all displacement cycles greater than the yield deformation, Δ_{by}, the maximum tension and compression force were not less than the nominal brace yield force, P_{ysc}.
- For all inelastic displacement cycles, the ratio of the maximum compression force to the maximum tension force did not exceed 1.3 in aluminum braces (i.e. $\beta<1.3$).
- Experimental results show that, cumulative energy dissipation of aluminum alloy core BRBs can be significantly increased when weld-free BRBs are used in design.
- BRBs with high corrosion resistance requested by the industry were manufactured with aluminum alloy BRBs within the scope of this study.
- Compared to steel core BRBs, relatively symmetrical hysteretic curves are obtained in aluminum alloy core BRBs.

As a result, aluminum alloy core BRBs showed promise for use in new buildings/bridges or as a retrofitting technique in buildings/bridges that lack strength, stiffness, and ductility.

Acknowledgments:

This research was supported in part by the Scientific and Technological Research Council of Turkey (TUBITAK) and the Istanbul Technical University Research Projects Unit (ITU-BAP). Steel gusset plates and bolts were produced by CIMTAS. Aluminum alloy outer tubes were provided by FENIS. Teflon bands were provided by FIBERFLON. Technical assistance from the staff at Istanbul Technical University, Structural and Earthquake Engineering Laboratory (ITU-STEEL) and Bogazici University, Civil Engineering Department, Structures Laboratory are gratefully acknowledged and appreciated. However, any opinions, findings, conclusions, and recommendations presented in this paper are those of the authors and do not necessarily reflect the views of the supports.

Abstract: In this study, without using any optimization method, two main structural models that are five-storey and ten-storey planar building models with 43 different damper distribution sub-models are firstly constructed; and later analyzed to understand the suitable damper designs in terms of some structural response parameters such as story displacements, inter-storey drifts and storey absolute accelerations. El Centro earthquake acceleration record is used for time history analyses. Total damper capacity that is the sum of damping coefficient of the added dampers is chosen for each one of the main structural models. Then, a damper whose damping coefficient presents total damper capacity is passed through each storey level. In other damper designs, the total damper capacity is divided by the damper number, and more than one damper is placed on each storey sequentially and is passed on the height of the structure. The results of analyses point out that proper damper distribution relatively changes in terms of different response parameters. Suitable damper designs determined according to any performance parameter from the time history analyses are verified by sensitivity analyses. Sensitivity information is analytically derived based on transfer functions. The effects of distribution of the added dampers on performance functions are investigated by using sensitivity analysis.

1. INTRODUCTION

Since the exact nature of the external forces such as earthquake, wind and impact excitations that affect structures is unknown, structural control systems such as passive, active and semi-active systems have been developed to protect the civil engineering structures from dynamic vibrations. Passive energy dissipation devices have been used to absorb dynamic external effects in new structures or for the rehabilitation of old structures. Passive energy devices are inserted in the bare structures to improve damping, stiffness and strength. All such control systems are commonly used in practical applications in addition to designs using classical structural design methods. In recent years, various studies have investigated the proper placement of different types of control devices in order to obtain the best distribution by minimization or maximization of the defined structural responses.

A fluid viscous damper is one of the commonly known passive dampers. Fluid viscous devices that use a cylindrical piston immersed in a viscous fluid are extensively used in aerospace and military applications and more recently have been adapted for building applications as shown in Figure 1 [1].

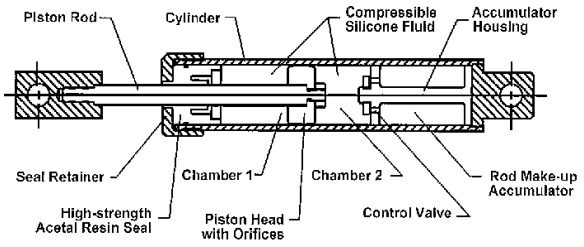

Figure 1. Taylor devices fluid damper [1]

The primary characteristics of these devices for structural applications are the linear viscous response achieved over a broad frequency range, insensitivity to temperature and compactness in comparison to the stroke and output force. The damper absorbs energy through movement of the piston in the highly viscous fluid. If the fluid is purely viscous, then the output force of the damper is directly proportional to the velocity of the piston. When this type of passive dampers began to be used in buildings, it was essential to ascertain the appropriate location

and number of dampers within the structure. However, there are a limited number of studies about damper allocation in structures.

The results of reducing the seismic response of multi-storey shear type buildings with first storey damping were presented by an optimization study [2]. The flexibility of the structure actually affects the optimal damping of the system and suitable objective functions were proposed for high buildings. Ashour and Hanson [3] conducted an interesting study on the optimal placement of visco-elastic dampers in relation to seismic excitation. An evaluation of the effect of added visco-elastic dampers on reducing the earthquake response of multi-storey steel frame structures was presented by Zhang and Soong [4].The seismic responses of simple building structures were examined in a study carried out by Hahn and Sathiavageeswaran [5] to assess the effects of different distributions and magnitudes of the damping derived from added visco-elastic dampers. A simple optimal design procedure was proposed by which the dimension and number of visco-elastic dampers could be determined and the results of the proposed method were also supported by experimental measurements [6]. An algorithm was introduced to find the optimum sets of storey stiffness coefficients and damping coefficients of dampers of an elastic planar shear building with viscous dampers [7]. Some of the optimal damper procedures based on active control theories were investigated to determine damper allocations [8], [9], [10], [11], [12] and [13]. Takewaki [14] devised an efficient method based on minimizing the sum of the amplitudes of the transfer functions of inter-storey drifts evaluated for the undamped fundamental natural frequency of a structural system together with a constraint on the sum of the damping coefficient of the dampers to obtain the optimal damper placement. A control strategy of seismic response of multi-storey building frames using optimally placed visco-elastic dampers was investigated using spectral analysis for narrow and broad band stationary random ground motions [15]. An efficient procedure, a steepest direction search algorithm, was devised to find the optimal damper distribution in a three dimensional shear building model [16]. A procedure for obtaining the optimal stiffness and damping distributions based upon the optimality criteria was presented by Takewaki [17]. An optimal damper placement method was proposed to minimize the dynamic compliance of a planar building frame [18]. An optimization approach based on a genetic algorithm was developed to find the optimal size and location of dissipation devices [19]. The proposed simplified sequential search algorithm (SSSA) for the optimization of damper configurations was simple and practical [20]. A simultaneous optimization procedure was presented to install both visco-elastic dampers and supporting braces in a structure [21]. Lavan and Levy [22] investigated a method for the optimal design of added viscous damping for an ensemble of realistic ground motion records and a constraint on an energy based global damage index for regular as well as irregular yielding shear frames. Cimellaro [23] defined top absolute acceleration as an objective function to find optimal damper placement and compared this with other methods. For planar building frames, a new objective function as base shear force based transfer functions was defined and the optimal damper location and size were determined [24].

To obtain an optimal solution of the damper distribution, we should define an objective function dependent on the structural response. An optimal solution upon damper placement relatively changes by the choice of objective function [23], [24]. There are some relevant investigations in the literature. To understand the effect of distribution of dampers, in the first step, it needs to be known which damper placement mitigates which response of the structures.

This study will help to understand the effects of viscous damper (VD) distribution in mitigating dynamic response of building structures due to seismic excitation. It needs to be pointed out how many and/or where the dampers should be supplemented. This study doesn't use any optimization method. In this study, without using any optimization method, two main structural models that are five stories and ten stories planar buildings, and 43 damper distribution sub-models are constructed and analyzed to understand the best suitable damper design in terms of some structural response parameters such as top displacement, inter-story drifts and top absolute acceleration. For each one of main structural model, a total damper capacity that is the sum of damping coefficient of the added dampers is chosen. Then, a damper whose damping coefficient presents total damper capacity is passed on each story level. In other damper designs, the total damper capacity is divided by the damper number and more than one damper is placed on each story sequentially and is passed on the height of the structure. In addition to time history analysis, the sensitivity analyses are performed for different damper placement according to the different structural response. The results of the time history analyses are compared with the sensitivity analyses for each model. The first order sensitivities are derived based on transfer functions for top displacement, inter-storey drifts and top absolute acceleration. It can be seen that the sensitivities of damper placement on structural response give us useful information for proper damper design among different damper placing options.

2. PLANAR BUILDING STRUCTURE WITH DAMPERS

The N-storey planar building frame as shown in Figure 2 is used to design the placement of the added dampers. In the case of no added dampers, the equation of motion for the model structure subjected to horizontal acceleration at fixed base is as follows:

$$\boldsymbol{M\ddot{u}(t) + C\dot{u}(t) + Ku(t) = -Mr\ddot{u}_g(t)} \quad (1)$$

where $\boldsymbol{u(t), \dot{u}(t), \ddot{u}(t)}$ represents displacement, velocity

and acceleration vector of the structural model, ***M***, ***C***, ***K*** represents the mass matrix, stiffness matrix and the structural damping matrix of the frame. ***r*** is the influence vector in terms of the direction of the base acceleration, $\ddot{u}_g(t)$ is the horizontal acceleration of ground motion. Let $\boldsymbol{U}(\omega)$ and $\ddot{U}_g(\omega)$ denote the Fourier Transform of $\boldsymbol{u}(t)$and $\ddot{u}_g(t)$, respectively. Eq. (1) is transformed to the following form using the Fourier transform:

$$(\boldsymbol{K} + i\omega\boldsymbol{C} - \omega^2\boldsymbol{M})\boldsymbol{U}(\omega) = -\boldsymbol{M}\boldsymbol{r}\ddot{U}_g(\omega) \tag{2}$$

Let ωdenote the circular frequency of excitation, i is $\sqrt{-1}$. If the added dampers are included in the equation of motion, the Fourier transform of the equation of motion converts to:

$$(\boldsymbol{K} + i\omega(\boldsymbol{C} + \boldsymbol{C}_{ad}) - \omega^2\boldsymbol{M})\boldsymbol{U}_{ad}(\omega) = -\boldsymbol{M}\boldsymbol{r}\ddot{U}_g(\omega) \tag{3}$$

where $\boldsymbol{C}_{ad}$is the added damping matrix which covers the design parameters, and $\boldsymbol{U}_{ad}(\omega)$ represents the Fourier transform of the displacement vector with added dampers. A new quantity defined by Takewaki [18] can be written as:

$$\hat{\boldsymbol{U}}(\omega) = \frac{\boldsymbol{U}_{ad}(\omega)}{\ddot{U}_g(\omega)} \tag{4}$$

If ω is taken as ω_1, the ground motion will have a harmonic excitation frequency which equals the fundamental natural frequency of the structure. Using Eq. (4), Eq. (3) can be rewritten as:

$$\boldsymbol{A}\hat{\boldsymbol{U}}(\omega_1) = -\boldsymbol{M}\boldsymbol{r} \tag{5}$$

Let $\hat{\boldsymbol{U}}(\omega_1)$ denote the transfer function vector of the displacements evaluated at the fundamental natural frequency of the structure and the matrix $\boldsymbol{A}$ which also includes the design variables ($c_1, c_2, \ldots, c_N$,), is presented as follows:

$$\boldsymbol{A} = \boldsymbol{K} + i\omega_1(\boldsymbol{C} + \boldsymbol{C}_{ad}) - \omega_1^2\boldsymbol{M} \tag{6}$$

where ***K***, ***M*** and ***C*** are prescribed. The construction of the added damping matrix ($\boldsymbol{C}_{ad}$) is the major objective of this study. Eq. (5) can be rewritten as:

$$\hat{\boldsymbol{U}}(\omega_1) = -\boldsymbol{A}^{-1}\boldsymbol{M}\boldsymbol{r} \tag{7}$$

The transfer function of the displacements has been derived by Takewaki [18]. The transfer function vector of the absolute acceleration at the fundamental natural frequency of the structure has been presented by Cimellaro [23] to find the placement of the optimal visco-elastic dampers as follows:

$$\hat{\ddot{\boldsymbol{U}}}(\omega_1) = -\boldsymbol{M}^{-1}(\boldsymbol{K} + i\omega_1\boldsymbol{C})\boldsymbol{U}(\omega_1) \tag{8}$$

The transfer function of inter-storey drifts at the first undamped natural frequency can be written as:

$$\boldsymbol{\delta}(\omega_1) = \boldsymbol{T}\hat{\boldsymbol{U}}(\omega_1) \tag{9}$$

where ***T*** is the transformation matrix that converts the displacements to the relative displacements [18].

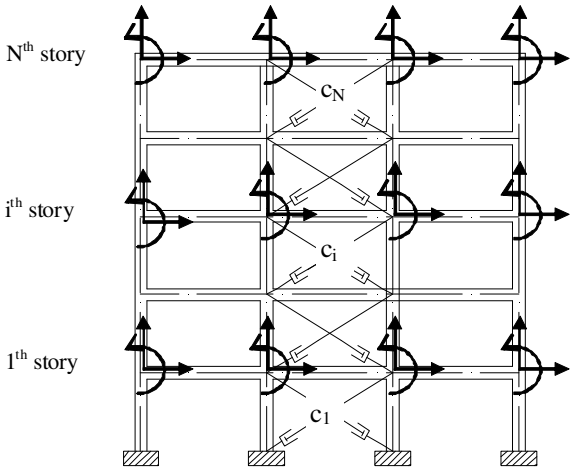

Figure 2. N-storey planar steel building with local coordinate systems

2.1 First Order Sensitivities of Structural Responses

If Eq. (5) is differentiated with respect to c_i as given below:

$$\frac{\partial \boldsymbol{A}}{\partial c_j}\hat{\boldsymbol{U}} + \boldsymbol{A}\frac{\partial \hat{\boldsymbol{U}}}{\partial c_j} = \boldsymbol{0} \qquad (j=1\ldots,N) \tag{10}$$

The first order sensitivity of $\hat{\boldsymbol{U}}$ is written as:

$$\frac{\partial \hat{\boldsymbol{U}}}{\partial c_j} = -\boldsymbol{A}^{-1}\frac{\partial \boldsymbol{A}}{\partial c_j}\hat{\boldsymbol{U}} \tag{11}$$

Eq. (10) and Eq. (11) have been derived by Takewaki [18]. The first order sensitivity of the transfer function vector of inter-storey drift multiplied by **T** is written as follows:

$$\frac{\partial \boldsymbol{\delta}}{\partial c_j} = -\boldsymbol{T}\boldsymbol{A}^{-1}\frac{\partial \boldsymbol{A}}{\partial c_j}\hat{\boldsymbol{U}} \tag{12}$$

The first order derivatives of the absolute accelerations

$\hat{\boldsymbol{U}}(\omega_1)$ at the first undamped natural circular frequency have been derived by a partial differential of Eq. (8) [23] as follows:

$$\frac{\partial \hat{U}}{\partial c_j} = -\boldsymbol{A}^{-1}\frac{\partial \boldsymbol{A}}{\partial c_j}\omega_1 \boldsymbol{U}(\omega_1) \tag{13}$$

The quantities of $\hat{U}_i$, δ_i and $\ddot{\hat{U}}_i$, which are given in Eqs. (7), (8) and (9) can be written as:

$$\hat{U}_i = Re[\hat{U}_i] + Im[\hat{U}_i] \tag{14}$$

$$\delta_i = Re[\delta_i] + Im[\delta_i] \tag{15}$$

$$\ddot{\hat{U}}_i = Re\left[\ddot{\hat{U}}_i\right] + Im\left[\ddot{\hat{U}}_i\right] \tag{16}$$

where $\hat{U}_i$, δ_i, and $\ddot{\hat{U}}_i$ are the transfer function values of the i^{th} storey displacement, i^{th} inter-storey drift and i^{th} storey absolute acceleration respectively in complex form. The first order sensitivities of the quantities $\hat{U}_i$, δ_i and $\ddot{\hat{U}}_i$, in Eqs. (11), (12) and (13) can be expressed as:

$$\frac{\partial \hat{U}_i}{\partial c_j} - Re\left[\frac{\partial \hat{U}_i}{\partial c_j}\right] + Im\left[\frac{\partial \hat{U}_i}{\partial c_j}\right] \tag{17}$$

$$\frac{\partial \delta_i}{\partial c_j} = Re\left[\frac{\partial \delta_i}{\partial c_j}\right] + Im\left[\frac{\partial \delta_i}{\partial c_j}\right] \tag{18}$$

$$\frac{\partial \ddot{\hat{U}}_i}{\partial c_j} = Re\left[\frac{\partial \ddot{\hat{U}}_i}{\partial c_j}\right] + Im\left[\frac{\partial \ddot{\hat{U}}_i}{\partial c_j}\right] \tag{19}$$

The absolute value of $\hat{U}_i$, δ_i and $\ddot{\hat{U}}_i$ can be written as:

$$\left|\hat{U}_i\right| = \sqrt{(Re[\hat{U}_i])^2 + (Im[\hat{U}_i])^2} \tag{20}$$

$$|\delta_i| = \sqrt{(Re[\delta_i])^2 + (Im[\delta_i])^2} \tag{21}$$

$$\left|\ddot{\hat{U}}_i\right| = \sqrt{(Re[\ddot{\hat{U}}_i])^2 + (Im[\ddot{\hat{U}}_i])^2} \tag{22}$$

If $\left|\hat{U}_i\right|$, $|\delta_i|$, and $\left|\ddot{\hat{U}}_i\right|$ are differentiated with respect to the j^{th} damping coefficient c_j, the first order sensitivity of the absolute value of transfer function amplitude of the i^{th} displacement [18], the i^{th} inter-storey drift [18] and the i^{th} absolute acceleration [23] are found as:

$$\frac{\partial\left|\hat{U}_i\right|}{\partial c_j} = \frac{1}{\left|\hat{U}_i\right|}\left\{Re\left[\hat{U}_i\right]\left(Re\left[\frac{\partial \hat{U}_i}{\partial c_j}\right]\right) + Im\left[\hat{U}_i\right]\left(Im\left[\frac{\partial \hat{U}_i}{\partial c_j}\right]\right)\right\} \tag{23}$$

$$\frac{\partial|\delta_i|}{\partial c_j} = \frac{1}{|\delta_i|}\left\{Re[\delta_i]\left(Re\left[\frac{\partial \delta_i}{\partial c_j}\right]\right) + Im[\delta_i]\left(Im\left[\frac{\partial \delta_i}{\partial c_j}\right]\right)\right\} \tag{24}$$

$$\frac{\partial\left|\ddot{\hat{U}}_i\right|}{\partial c_j} = \frac{1}{\left|\ddot{\hat{U}}_i\right|}\left\{Re\left[\ddot{\hat{U}}_i\right]\left(Re\left[\frac{\partial \ddot{\hat{U}}_i}{\partial c_j}\right]\right) + Im\left[\ddot{\hat{U}}_i\right]\left(Im\left[\frac{\partial \ddot{\hat{U}}_i}{\partial c_j}\right]\right)\right\} \tag{25}$$

2.2 Numerical Examples

To illustrate the effect of damper placement on planar steel building structures, two models which are 5-storey and 10-storey planar building structures are considered as shown Figure 3. The height of each storey is 4m, the span of each bay is 8m., Young modulus is $2.0*10^{11}$ N/m^2 in columns and beams. Shear deformation of members is neglected. Only bending deformation in beams, both bending and axial deformations in columns are considered. The critical damping ratio of steel structures is ξ=0.02 in the lowest undamped natural circular frequency. A lumped mass of 51'200 kg is placed on every interior node and a lumped mass of 25'600 kg is placed on every exterior node. Every interior node is assumed to possess a mass moment of inertia of $5.46*10^5$ kg.m^2, and every exterior node is assumed to possess a mass moment of inertia of $1.71*10^5$ kg.m^2. Structural member properties are shown in Table 1.

Table 1. Member properties of buildings

Models	Storey No	Beams		Columns	
		A(m^2) (10^{-4})	I(m^4) (10^{-5})	A(m^2) (10^{-4})	I(m^4) (10^{-5})
5-Storey	1st-2nd	756	383	756	383
	3rd-4th	683	353	683	353
	5th	365	205	365	305
10-Storey	1st-4th	756	383	756	383
	5th-7th	683	353	683	353
	8th-10th	365	205	365	305

The sums of damping coefficients of the dampers are chosen such as in Table 2. Total damping coefficients of the added dampers for each one of the models are equal to the values as shown in Table 2.

Table 2. Total damper capacity for the main models

Main Models	The sum of the damping coefficients of the added dampers (Ns/m)
5-Storey	$1.47*10^7$
10-Storey	$2.94*10^7$

It is possible to calculate the damping coefficient for a storey according to Eq. (26) given as below:

$$c = \frac{Total \quad Damper \quad Capacity}{Damper \quad Number} \tag{26}$$

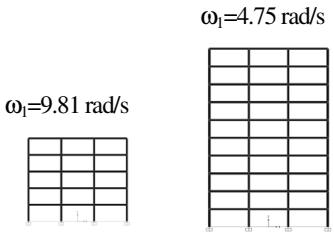

Figure 3. 5-storey and 10-storey model planar building frames

Initially, a damper is placed on the first storey. A damper whose damping coefficient presents the total damping capacity is moved on to the fifth storey level afterwards for the five storey building model. Then, multi damper placement models shown in Figure 4 are investigated. For 5-storey model structures as shown in Figure 4, time history analysis is performed by using El Centro (NS) ground motion record.

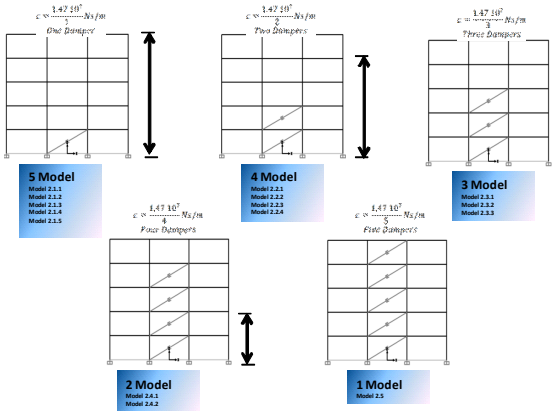

Figure 4. Sub models for 5-storey main planar building model

Figure 5 presents both the maximum story displacement profiles in top lines of the figures and the first order sensitivities of top displacement in the lower line. The sign of the sensitivities are changed by multiplying negative sign. It can be seen from these sensitivity figures that the sensitivities of top displacement according to the damping coefficients c_i of the 2nd and the 3rd stories are larger than the others in the case for without dampers. The best design in terms of both top displacement response and the sensitivities of the transfer function of top displacement is the model 2.2.2 (Dampers are uniformly placed to 2nd and 3rd storeys). It is observed that dampers should be distributed to the storeys where the inter-storey drifts are larger than in other storeys.

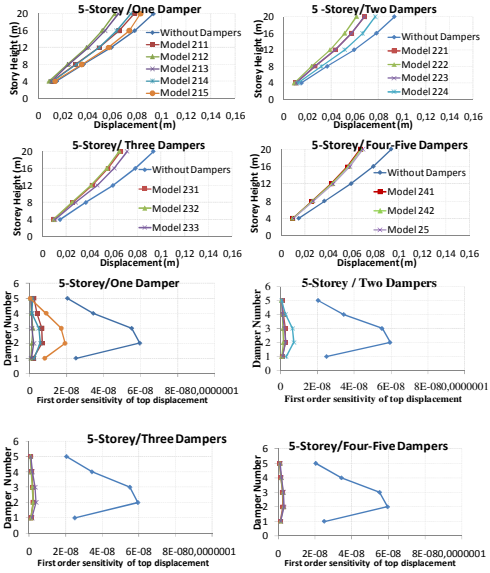

Figure 5. Storey displacement profiles and sensitivities of the top displacement according to the dampers for 5-storey planar building models

The best convergence among the damper designs also satisfy for the model 2.2.2 as shown in Figure 5. The maximum inter-story drift response and sensitivities of the first three inter-story drifts are plotted in Figures 6(a) and 6(b). For one damper case, the best design in terms of any inter-storey drift is either placement of a damper to that storey or placement of a damper to its neighboring storey.

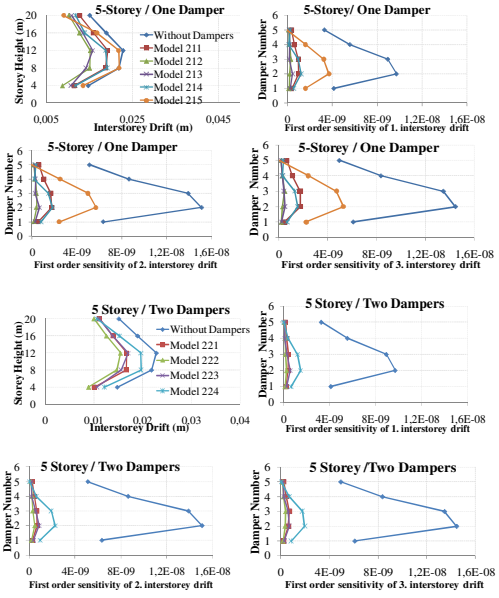

Figure 6(a). Interstorey drift profiles and sensitivities of the interstorey drifts according to the dampers for 5-storey planar building models

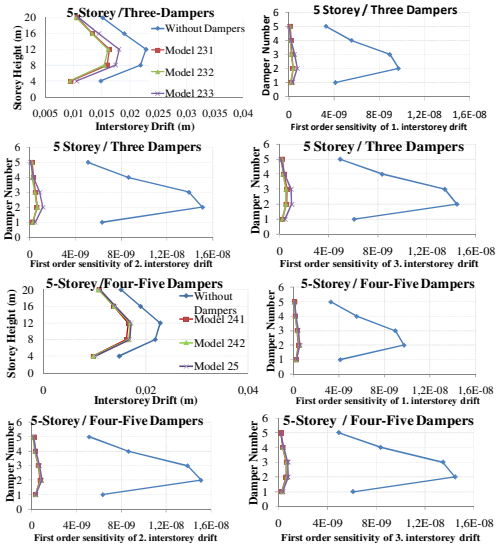

Figure 6(b). Interstorey drift profiles and sensitivities of the interstorey drifts according to the dampers for 5-storey planar building models

The best damper design in terms of top acceleration is the model 2.2.2 (Dampers are placed to 2nd and 3rd storeys). Figure 7 presents top absolute acceleration under El Centro earthquake ground motion and sensitivities of the acceleration. These sensitivity figures give us some information such that the 2nd and 3rd storeys are sensitive storeys in terms of damper placement.

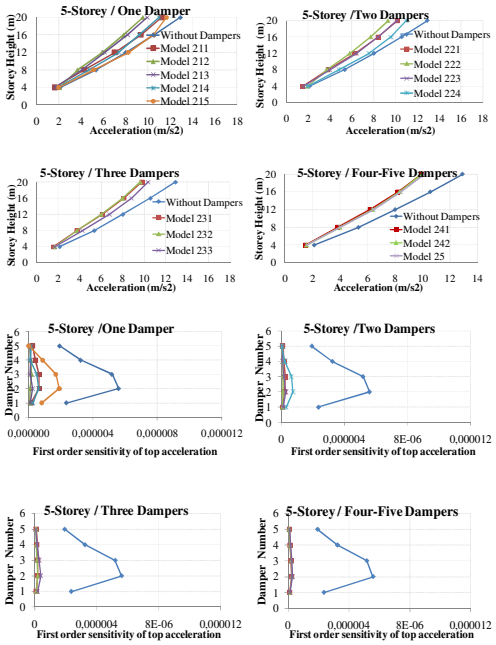

Figure 7. Storey absolute acceleration profiles and sensitivities of the top acceleration according to the dampers for 5-storey planar building models

The second main model is chosen as 10-storey planar building shown in Figure 3. The sub-damper placement models are constructed as given in Figure 8.

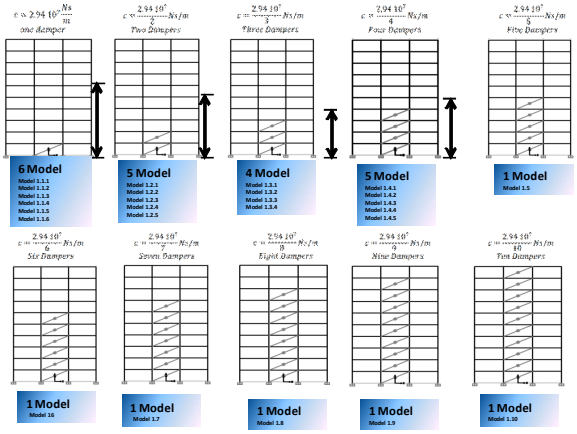

Figure 8. Sub models for 10-storey main planar building model

The results of earthquake analyses denote that the model 1.9 (Dampers are placed to the first nine storeys) and the model 2.2.1 (Dampers are placed to the 2nd and 3rd storeys) are better damper designs in terms of top displacement as shown in Figure 9.

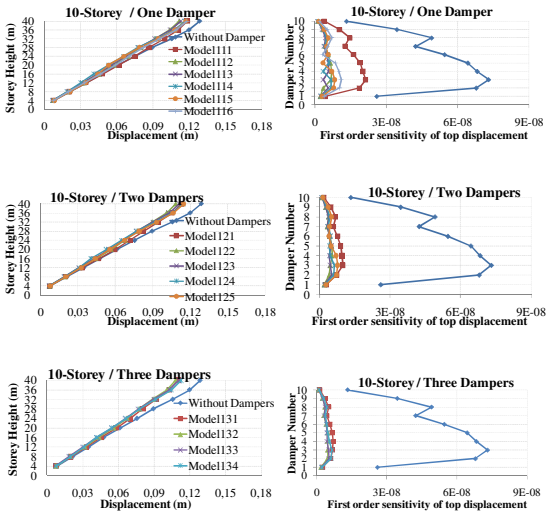

Figure 9. Storey displacement profiles and sensitivities of the top displacement according to the dampers for 10-storey planar building models

Dampers must be distributed to either the first nine storeys or to 2nd and 3rd storeys where the inter-storey drifts are large. If the dampers are placed to only 2nd and 3rd storeys, this damper design is preferred in terms of both good response and economical respect. As can be shown in Figures 9 and 10, the second and third storeys are sensitive storeys for placement of dampers.

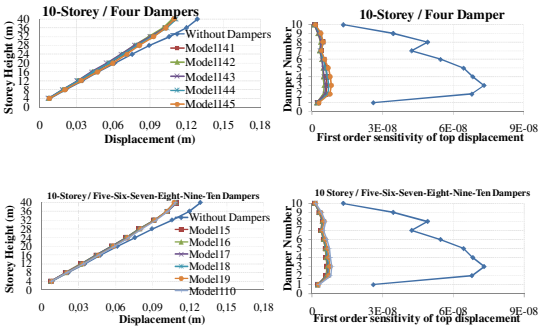

Figure 10. Storey displacement profiles and sensitivities of the top displacement according to the dampers for 10-storey planar building models

Figures 11(a) and 11(b) present the inter-storey drifts under El Centro earthquake and the inter-storey sensitivities for the first three inter-storey drifts. If a damper is placed on a storey, this damper design doesn't give us a good performance. This situation reveals the discontinuity in between sequential interstorey drifts, so it is not desirable. The second, third and fourth storeys are also sensitive storeys for placement of dampers. The amplitudes of sensitivities are also large in these storeys.

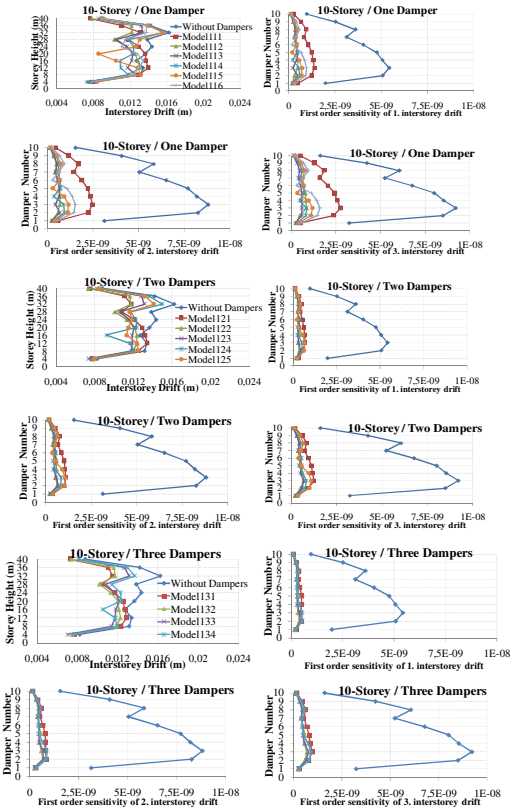

Figure 11(a). Interstorey drift profiles and sensitivities of the interstorey drifts according to the dampers for 10-storey planar building models

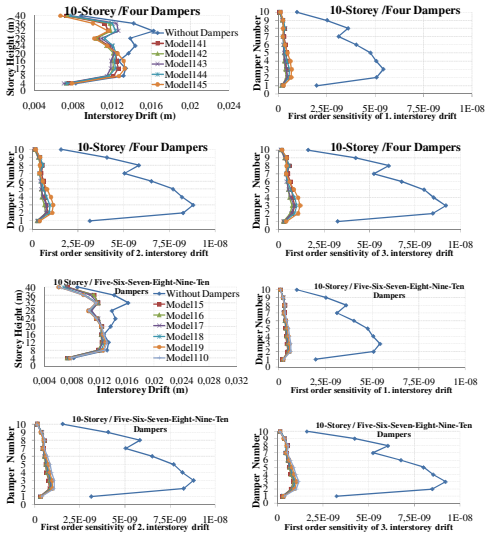

Figure 11(b). Interstorey drift profiles and sensitivities of the interstorey drifts according to the dampers for 10-storey planar building models

The absolute acceleration obtained from earthquake analyses and the top absolute sensitivities are plotted in Figures 12(a) and 12(b), respectively. The best design in terms of top acceleration is the model 1.10 (Dampers are placed to all storeys).

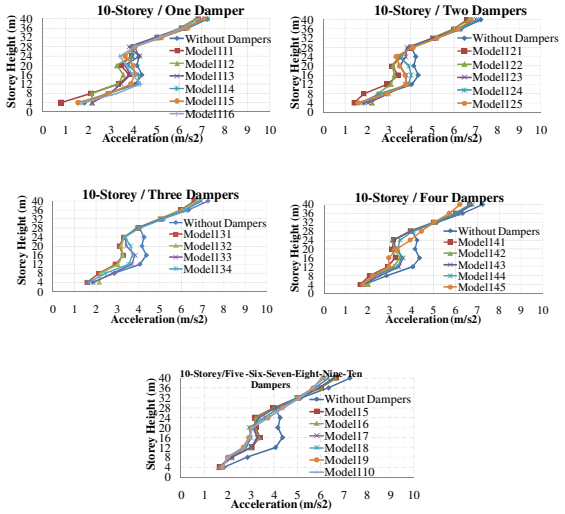

Figure 12(a). Storey absolute acceleration profiles according to the dampers for 10-storey planar building models

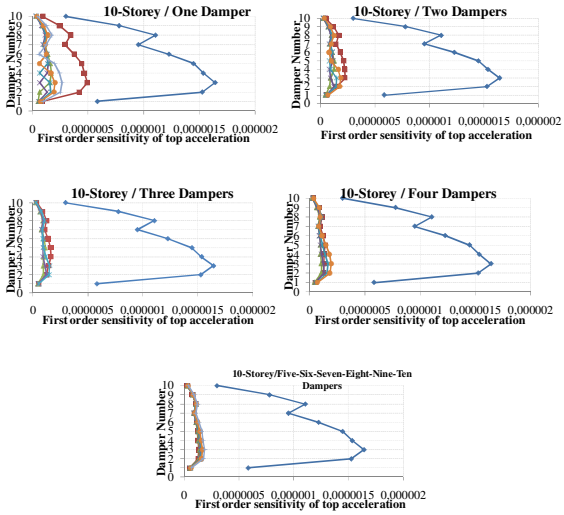

Figure 12(b). First order sensitivities of the top acceleration according to the dampers for 10-storey planar building models

For 5-storey building, the best design is the same both in terms of top displacement, top absolute acceleration and inter-storey drift values. For both of the two main models, the best design for top displacement occurs upon placement of dampers at storeys with high levels of inter-story drift. In the 5-storey building, the best design in terms of top displacement is the model 2.2.2 (Dampers are placed to 2nd and 3rd storeys). It is observed that dampers should be distributed to the storeys where the inter-storey drifts are larger compared to other storeys (The best damper design reduces the top displacement by 35 %.).

The best design in terms of any inter-storey drift is either placement of a damper to that storey or placement of a damper to its neighboring storey (Damper design reduces the inter-storey drifts by 33% to 40%). The best design in terms of top acceleration is the model 2.2.2 as in the case of top displacement (Dampers are placed to 2nd and 3rd storeys and top acceleration reduces by 28%).

In the 10 storey building, the best design in terms of top displacement is the model 1.9 (Dampers are placed to the first nine storeys and reduce the top displacement response by 20%). The model 2.2.1 (Dampers are placed to 2nd and 3rd storeys.) gives close solution to the solution of the best design. Dampers must be distributed to either the first nine storeys or to 2nd and 3rd storeys where the inter-storey drifts are large. The best design in terms of inter-storey drift is either placement of a damper to that storey or placement of a damper to its neighbor storey (Inter-storey drift response reduces by 15% to 28%). The best design in terms of top acceleration is the model 1.10 (Dampers are placed to all storeys and top acceleration is reduced by 17%)

3. CONCLUSIONS

This study investigates the effects of different damper placements on the different structural response parameters. In addition to time history analyses, sensitivity analyses are also performed to understand the effects of different damper distributions. The numerical results give us some information about damper placement as follows: 1) The potential locations for damper placements are some sensitive storeys where the inter-storey drifts are large. 2) One damper placement is not effective; even though it reduces the inter-storey drift of the storey it is located. 3) In the 5-storey building model, the best damper design brings on the best decrease in both top displacement and top absolute acceleration. 4) The increase in the building height causes the change on the damper designs for different response parameters. 5) If there are different damper distribution designs to select, the sensitivity analyses give beneficial information for proper damper allocation.

Abstract: This paper proposes a simple approach to the generalized optimal locations of linear viscous dampers in elastic two-way asymmetrical buildings under bi-directional ground excitations. The control target used in this optimization process is to maximize the average dissipation rate of the overall strain energy of the two-way asymmetrical building under the ground excitation of two bi-directional unit impulses. The proposed control target, referred to as the smeared damping ratio, is an intrinsic property of the building system. Two advantages of the proposed approach are appealing to engineering practice. First, the proposed approach does not require a complicated optimization algorithm. Second, due to the employment of an intrinsic property rather than a certain response parameter as the target performance index, the optimal damper locations resulting from the proposed approach are generalized, which are independent on the characteristics of input ground motions.

1. INTRODUCTION

Finding an effective method of placing viscous dampers in a building is a common issue in earthquake engineering practice. This issue may be considered from the viewpoint of optimal damper placement, with the constraint of either a given number of added dampers or a specified structural peak response. While investigating this issue, research into the literature found many published works that significantly contributed to this topic (Zhang and Soong 1992, Wu et al. 1997, Takewaki 1997, Agrawal and Yang 1999, Chen and Wu 2001, Lopez-Garcia 2001, Lopez-Garcia and Soong 2002, Singh and Moreschi 2002, Wongprasert and Symans 2004, Liu et al. 2005, Lavan and Levy 2006a, Lavan and Levy 2006b, Levy and Lavan 2006, Garcia et al. 2007, Levy and Lavan 2009, Aguirre et al. 2012). In much of these literatures, researchers usually first constructed the optimization problem in a formal mathematical format, and subsequently proposed suitable optimization procedures, *e.g.*, a sequential optimization procedure, heuristic search, a gradient-based approach or a genetic algorithm, to solve it. Liu et al. (2005) classified the previous studies into four categories, *i.e.*, parametric studies, analytical optimization, evolutionary approaches, and heuristic approaches, and carried out extensive literature reviews of these four categories. The efficiency and effectiveness of these powerful optimization procedures were validated by adopting different performance indices and considering various ground excitations. The performance indices were usually structural response parameters, such as inter-story drifts, absolute floor accelerations, *etc*. Liu et al. (2005) pointed out that the optimal damper configuration might be different if the performance index is selected differently.

Originating from the sequential search algorithm (Zhang and Soong 1992), Lopez-Garcia and Soong (Lopez-Garcia 2001, Lopez-Garcia and Soong 2002) proposed the simplified sequential search algorithm (SSSA), which appears to be the simplest way of optimizing the damper locations developed thus far. In the SSSA, the designer sequentially adds one damper at the location with the greatest engineering demand, which is determined by performing a response history analysis of the building with the previously added dampers. Obviously, the optimal placement of dampers resulting from the SSSA depends on the applied seismic ground motions. Takewaki (1997) proposed optimizing the damper placement by minimizing the sum of the amplitudes of the transfer functions of the inter-story drifts evaluated at the undamped fundamental natural frequency. Because the transfer functions are structural dynamic properties irrespective of the characteristics of input ground motions, the optimal damper placement resulting from Takewaki's approach (1997) was independent of the input ground motions. These works highlight the fact that an approach optimizing the damper locations without using complicated optimization theories and without depending on the seismic ground motion is attractive to engineering practice.

Due to architectural and commercial constraints, asymmetric-plan buildings are common among building

structures. Compared with symmetrical buildings, optimizing the damper placement in two-way asymmetrical buildings is more difficult, not only because of their complicated seismic responses, but also because of their various control targets and bi-directional ground excitations. The possible control targets for two-way asymmetrical buildings could be the response parameters at the four edges of the floor planes, or one rotational and two translational types of response parameters at the center of mass (CM). The response parameters may be inter-story drift, inter-story velocity, absolute floor acceleration, roof displacement, base shear, *etc*. As Liu et al. (2005) pointed out, even under the exertion of an ensemble of seismic ground accelerations or a white-noise ground motion, selecting a different response parameter as the control target is very likely to lead to a different optimal damper placement. Although response parameters are direct measures of the seismic performances of structures, differing optimal damper placements are usually an undesired engineering solution for building owners.

The aim of this research is to provide a simple approach to the generalized optimal locations of viscous dampers in two-way asymmetrical buildings. No complicated optimization algorithms or mathematical models will be adopted in this approach. For generalized optimal damper locations, an intrinsic property of the overall building system will be selected as the control target. Thus, the outcome of optimizing the damper locations will be independent of the response states of the building systems subjected to varied seismic ground motion inputs.

2. THE ENERGY-BASED APPROACH

2.1 The control target used in the proposed approach

It is useful to consider that there are some elastic oscillators with springs and dashpots. The only difference between these oscillators is the arrangement of their dashpots. The task is to find out which dashpot arrangement is the most effective at reducing the oscillators' vibrations. A very intuitive and simple way to do this is to excite these oscillators and then find out which oscillator reaches a stationary state first. This implies that the dissipation rate of the elastic strain energy is the generalized criterion for judging the effectiveness of the dashpot arrangement. Furthermore, to be shown later in this section, the dissipation rate of the elastic strain energy is correlated with the damping ratio, which is an intrinsic property of the building system. Thus, this study proposes to use the dissipation rate of the elastic strain energy, rather than a certain response parameter, as the control target for achieving the generalized optimal damper placement. In addition, due to the employment of an intrinsic property of the building system as the control target, the generalized optimal damper locations resulting from the proposed approach do not depend on the characteristics of input ground motions. Figure 1a shows the strain energy history of an elastic multistory two-way asymmetrical building subjected to a pair of unit impulses applied in the *x*- and *z*-horizontal directions, respectively. Figure 1a indicates that the dissipation rate of the elastic strain energy reflects the decrease of the peaks of the strain energy history.

When a single-degree-of-freedom (SDOF) oscillator is subjected to a unit impulse, its displacement response is the well-known unit impulse response function, denoted by $h(t)$:

$$h(t) = \frac{1}{m\omega_D} e^{-\xi\omega t} \sin(\omega_D t) \tag{1}$$

where m, ω, and ξ are the mass, vibration frequency, and damping ratio of the SDOF oscillator, respectively, and $\omega_D = \omega\sqrt{1-\xi^2}$. The unit impulse response function is the inverse Fourier transform of the frequency response function, which is a general dynamic property of the oscillator independent of the characteristics of the input excitations. The strain energy of the SDOF oscillator, denoted by E_S, is:

$$E_S(t) = \frac{1}{2} k h(t)^2 = \frac{1}{2m\left(1-\xi^2\right)} e^{-2\xi\omega t} \sin^2(\omega_D t) \tag{2}$$

where k is the stiffness of the SDOF oscillator. Thus, the damping ratio ξ of the SDOF oscillator can be approximated from Eq. 2 as:

$$\xi \approx \frac{\xi}{\sqrt{1-\xi^2}} = \frac{1}{4\pi} \ln\left(\frac{E_S(t)}{E_S\left(t + \frac{2\pi}{\omega_D}\right)} \right) \tag{3}$$

For a multi-degree-of-freedom (MDOF) building, the input seismic energy is the sum of the kinetic energy, the damping energy, and the absorbed energy. The absorbed energy, computed as the integration of the restoring force with respect to the displacement, is the sum of the energy dissipated by yielding and the elastic strain energy of the system (Chopra 2007). It is clear that the absorbed energy of an elastic MDOF building is only the elastic strain energy, E_S, and can be computed as $(\mathbf{Ku})^T \mathbf{u}/2$, where $\mathbf{K}$ and $\mathbf{u}$ are the stiffness matrix and the displacement vector of the MDOF building, respectively. Nevertheless, the damping ratio of a multi-degree-of-freedom oscillator computed from Eq. 3 depends on which cycle of the strain energy history is considered. This is because the higher modes' vibration, usually accompanied by larger modal damping ratios, diminishes faster than the lower vibration modes. It is clear that the influence of an impulse on the structural responses decreases with elapsed time. Thus, for a multistory asymmetrical building, the first and third peak values of the elastic strain energy history (marked in Fig. 1a), which represent the two peaks that occurred in the same direction during the first cycle of vibration, are used in Eq. 3. In addition, in order to consider the two-way asymmetrical buildings under the excitation of bi-directional ground motions, the two loading cases shown in Fig. 1b are used to excite the multistory buildings. The first case is a pair of in-phase impulses applied as the ground accelerations in the two horizontal directions, respectively. The second case is a pair of 180°-out-of-phase impulses applied as the ground

accelerations in the two horizontal directions, respectively. It is assumed that the probabilities of occurrence of in-phase and 180°-out-of-phase impulses in the two orthogonal components of historical seismic ground motion records are equal. Thus, the index of the dissipation rate of the elastic strain energy, denoted by I_E, for an asymmetrical building is defined as follows:

$$I_E = \frac{1}{2}\left(\frac{\xi_1}{\sqrt{1-\xi_1^2}} + \frac{\xi_2}{\sqrt{1-\xi_2^2}} \right) \approx \frac{\xi_1 + \xi_2}{2} \qquad (4)$$

where ξ_1 and ξ_2 are the damping ratios computed from Eq. 3 for the building under the exertion of the first and second loading cases, respectively. Furthermore, for each loading case, $E_s(t)$ and $E_s(t+2\pi/\omega_D)$ shown in Eq. 3 represent the first and third peak values of the strain energy history of the building. As the I_E value increases, the damping system becomes more effective at dissipating energy. Thus, the control target used in the proposed approach for the generalized optimal damper placement in the asymmetrical buildings is to maximize the value of I_E. It is worth noting that the I_E index can be considered as the smeared damping ratio of an asymmetrical building with supplemental damping. The smeared damping ratio reflects the combined effects of the overall supplemental damping parameters on the suppression of the vibration of two-way asymmetrical buildings under bi-directional ground excitations.

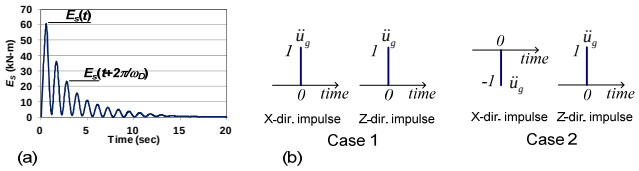

Figure 1 (a) The strain energy history of an elastic multistory two-way asymmetrical building subjected to a bi-directional unit impulse, and (b) the two applied loading cases.

2.2 Design procedures of the proposed approach

In engineering practice, the number and capacity of added dampers are usually limited by budgetary and commercial manufacturing constraints. Therefore, this study assumed that the number of added viscous dampers, denoted by *ND*, and the damping coefficient of each damper are known. The design procedures using the proposed control target are as follows:

Step 1: Confirm the possible damper locations in the multistory two-way asymmetrical building. The number of these locations is denoted by *NL*.

Step 2: Set $j = 1$.

Step 3: Place the jth damper at the ith possible location in the multistory asymmetrical building with $j - 1$ previously added dampers. Because there are *NL* possible locations for placing the jth damper, *i.e.*, $i = 1$ to *NL*, this results in *NL* buildings with different locations of the jth damper. Perform the elastic response history analyses to each of these *NL* buildings using the two loading cases shown in Fig. 1b as the ground excitations.

Step 4: Compute the *NL* values of the index I_E, denoted by $I_{E,ij}$, where $i = 1$ to *NL*. The subscript ij indicates that the index value corresponds to the jth damper at the ith location.

Step 5: Find the jth damper's optimal location, in which the corresponding index value is the maximum among $I_{E,ij}$, where $i = 1$ to *NL*. Add the jth damper to the building at this obtained optimal location.

Step 6: Set $j = j + 1$. If j is larger than *ND*, then stop the design procedure. Otherwise, repeat Steps 3 to 6.

Note that if only one added damper is permitted for each possible location, then the number of remaining possible locations is $NL - j + 1$ rather than *NL*, after $j - 1$ dampers have already been added. In such a case, the *NL* shown in Steps 3 to 5 should be replaced with $NL - j + 1$. Obviously, the design procedures of the proposed approach are very similar to those of the SSSA (Lopez-Garcia 2001, Lopez-Garcia and Soong 2002), which is straightforward and practical. It is worth noting that if a white noise input, a harmonic input of desired frequency, or an impulsive input is desired, then the SSSA can also easily adopt these as inputs. Thus, the key difference between the SSSA and the proposed approach is the control target. In this study, the proposed control target, which is an intrinsic property of the building system irrespective of the building's response states and the characteristics of the input ground motions, leads to the generalized optimal damper placement. The generalized optimal damper placement maximizes the efficiency of the supplemental damping system, *i.e.*, the building with this damper configuration can rapidly dissipate the strain energy and return to the stationary state.

3. NUMERICAL VALIDATIONS

Figure 2 shows the floor plan and the elevation of the two nine-story example buildings, which is a variation of the symmetrical building located in Los Angeles used in the SAC steel research project (Krawinkler 2000). Each floor was simulated as a rigid diaphragm with a lumped mass located at the CM. The center of rigidity (CR) was the geometric center. Details of the member sizes, materials, masses, and so forth can be found in the associated report (Krawinkler 2000). The z-directional span length of the original symmetrical building was reduced from 9144 mm to 6096 mm. In addition, the CM is intentionally located away from the geometric center, resulting in the 20% and 15% eccentricity ratios in the x- and z-directions, respectively. Figure 2 indicates that the flexible side (FS) and the stiff side (SS) in the x-direction are Frame 6 and Frame 1, respectively. The FS and the SS in the z-direction are Frame F and Frame A, respectively. The only difference between these two example buildings is the mass moment of inertia of each story, which is equal to 1 and 2.5 times the values of the original symmetrical building. The x- and z-directional frequency ratios of the example buildings, denoted by $\Omega_{\theta x}$ and $\Omega_{\theta z}$, are defined as the ratios of the rotational frequency

to the *x*- and *z*-translational frequencies of the corresponding symmetrical building, respectively. The building with the same mass moment of inertia as the original symmetrical building is designated Building TS, whose values of $\Omega_{\theta x}$ and $\Omega_{\theta z}$ are equal to 1.55 and 1.43, respectively. Another example building is designated Building TF, whose values of $\Omega_{\theta x}$ and $\Omega_{\theta z}$ are equal to 0.98 and 0.90, respectively. Thus, it is obvious that Building TS was torsionally-stiff in the *x*- and *z*-directions. Building TF was approximately torsionally-similarly-stiff and torsionally-flexible in the *x*- and *z*-directions, respectively. Rayleigh damping with a 2% damping ratio for the first and the second vibration modes was assumed to represent the inherent damping.

In order to validate the effectiveness of the proposed approach, elastic response history analyses using historical ground motion records were carried out on the example buildings with added dampers. Five pairs of historical ground motion records were selected for these analyses. The selected ground motion records were designated as LA21 to LA30 in the SAC steel research project for the buildings located in Los Angeles (Krawinkler 2000). Each pair of selected ground motion records has two orthogonal components. The two orthogonal components were interchanged for application along the *x*- and *z*-directions, respectively. In addition, the *x*-directional component was varied by multiplying plus and minus one. Therefore, this study applied a total of 20 pairs of ground motion records to each example building.

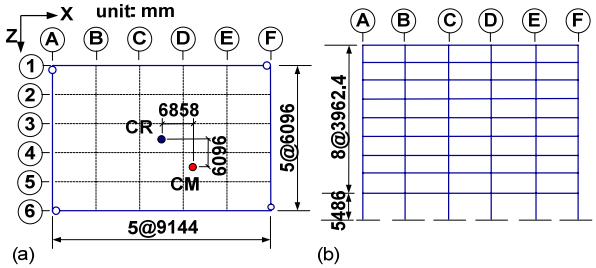

Figure 2 (a) The floor plan and (b) the elevation of Buildings TS and TF.

There were ten linear viscous dampers with a damping coefficient equal to 5×10^4 kN×sec/m to be diagonally installed in each example building. Because each floor was simulated as a rigid diaphragm, there were 36 possible locations for adding dampers. In the numerical validations, it was assumed that the optimal damper location could not be repeated, *i.e.*, there was only one damper at each optimal damper location.

For the purpose of comparison, the optimal damper locations were also designed based on the SSSA approach. The control target used in the SSSA approach was the peak inter-story velocity, which is the same as that used by Lopez-Garcia (2001). Based on the literature (Lopez-Garcia 2001), to decide the *n*th damper's optimal location, perform the elastic response history analysis to the building with the *n-1* previously added dampers using a selected pair of ground motions. Then, the *n*th damper was added to the building at the location where the peak inter-story velocity was the maximum among those in the *x*- and *z*-directions. Nevertheless, all of the aforementioned 20 pairs of ground motions should be considered in these numerical examples. It is clear that under different ground excitations, the peak inter-story velocities are likely to vary, *i.e.*, the optimal damper locations under different applied ground motions may be changed (Lopez-Garcia and Soong 2002, Aguirre *et al*. 2012). Thus, in order to decide the *n*th damper's optimal location, 20 elastic response history analyses using these 20 pairs of ground motions were carried out to the building with the *n-1* previously added dampers. Under the excitation of each pair of ground motion, the priority sequence for the *n*th damper's location is based on the peak inter-story velocities in descending order, that is, the location where the peak inter-story velocity was the highest in the x- and z-directions would be assigned the first priority location. With these 20 elastic response history analyses, the *n*th damper's optimal location is where the maximum first priority occurrences were observed. In case the maximum first priority occurrences were observed at more than one location, the number of second priority occurrences at these specific locations was further compared to decide the optimal damper location, and so forth. For example, when placing the *n*th damper, the highest number of first priority occurrences for the building under the 20 applied pairs of ground motions is six, which occurred at only one location, A. Unquestionably, location A is the *n*th damper's optimal location. Nevertheless, when placing the *n*th damper, the highest number of first priority occurrences for the building under the 20 applied pairs of ground motions is four, which occurred at two locations, A and B. That is, four first priority events occurred each at locations A and B. The remaining 12 first priority events occurred at other locations. The number of second priority occurrences at locations A and B under the 20 pairs of applied ground motions were one and three, respectively. In this case, location B was chosen as the optimal location for the *n*th damper because there was a higher occurrence of second priority events at this location when compared with location A. The approach discussed above allows a set of applied ground motions to be considered and is herein named the modified SSSA approach.

Figures 3a and 3b show the optimal damper locations of the ten viscous dampers in Building TS resulting from the proposed approach, denoted as GOLD, and the modified SSSA approach, respectively. The designation GOLD of the proposed approach stands for the generalized optimal locations of dampers. Figures 4a and 4b show the optimal damper locations of the ten viscous dampers in Building TF resulting from the GOLD and the modified SSSA approach, respectively. Figures 3 and 4 show that most of the dampers were located in the lower half of the buildings by using the GOLD. On the contrary, most of the dampers were located in the upper half of the buildings when using the modified SSSA approach. Furthermore, most of the dampers were located on the FS in both directions for Building TS

regardless of the adopted approaches (Fig. 3). Nevertheless, Fig. 4 shows that the dampers were more uniformly placed on the four sides of the floor plan for Building TF when compared with Building TS. The observations made from Figs. 3 and 4 indicate that the peak inter-story velocity and the strain energy demands on the FS of Building TS were significantly larger than on the SS of this torsionally-stiff building. Nevertheless, for the torsionally-flexible Building TF, the peak inter-story velocity and the strain energy demands were somewhat evenly distributed on the SS and the FS.

Table 1 shows the values of the index I_E when different numbers of dampers were added to the two buildings by using the GOLD. As a reminder, the index I_E represents the smeared damping ratio (including the inherent damping). Thus, Table 3 indicates that the smeared damping ratios were 0.210 and 0.155 for Buildings TS and TF, respectively, when all the ten dampers were added by using the GOLD. This indicates that adding the ten dampers benefitted the torsionally-stiff Building TS more than the torsionally-flexible Building TF.

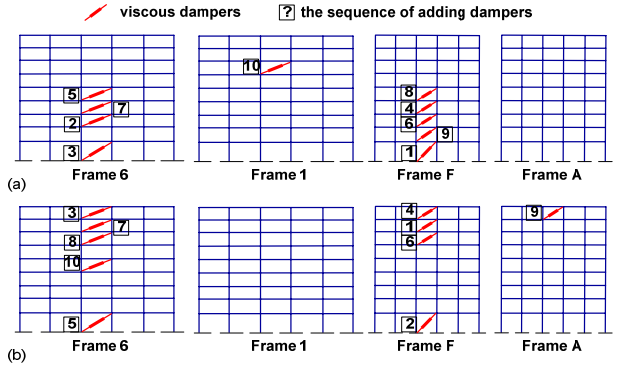

Figure 3 The optimal damper locations of the ten viscous dampers in Building TS resulting from (a) the GOLD and (b) the modified SSSA approach.

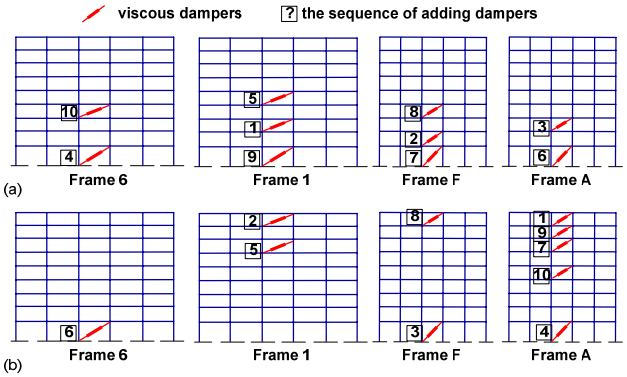

Figure 4 The optimal damper locations of the ten viscous dampers in Building TF resulting from (a) the GOLD and (b) the modified SSSA approach.

Table 1 The values of the index I_E (%) for different numbers of added dampers placed by using the GOLD.

bldg	The accumulative number of the added dampers									
	1	2	3	4	5	6	7	8	9	10
TS	4.3	6.3	7.8	9.7	11.3	13.2	14.9	17.9	19.2	21.0
TF	5.5	6.2	7.2	8.1	9.2	10.1	11.6	12.8	13.7	15.5

Figures 5 to 8 compare the seismic responses of Buildings TS and TF with the ten dampers resulting from the GOLD with those resulting from the modified SSSA approach. For the purpose of convenience, the modified SSSA approach is simply denoted as SSSA in these figures. Figure 5 shows the strain energy history of Buildings TS and TF with and without the ten dampers under the exertion of the two cases of ground unit impulses (Fig. 1b). It is apparent in Fig. 5 that Buildings TS and TF with the ten dampers located using the GOLD reached a stationary state faster than the two buildings with the dampers placed using the modified SSSA approach. In other words, the arrangements of the ten dampers in Buildings TS and TF obtained by using the GOLD were more effective at dissipating the strain energy than those obtained by using the modified SSSA approach.

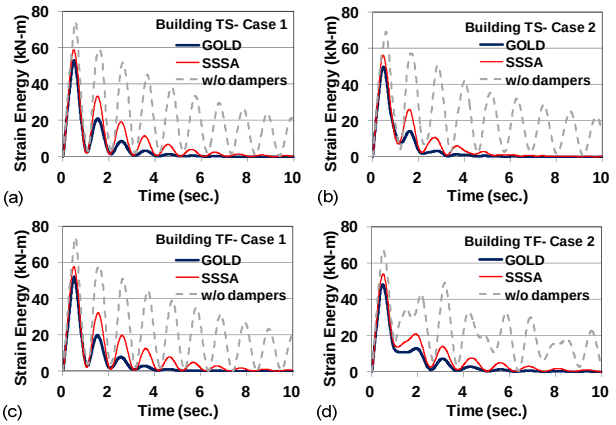

Figure 5 The strain energy histories of Building TS under loading (a) case 1 and (b) case 2, and of Building TF under loading (c) case 1 and (d) case 2.

Figures 6 to 8 show the peak story displacements at the CM, the peak story displacements and the peak story drifts on the four floor sides, respectively. Note that the abscissa values shown in Figs. 6 to 8 are the average of the 20 peak values obtained by applying the 20 pairs of ground motions to the buildings. Almost all of the average peak story displacements at the CM, including the two translations and one rotation, obtained using the GOLD were less than those obtained using the modified SSSA approach (Fig. 6). Almost all of the average peak story displacements on the sides of the floor plan obtained using the GOLD were significantly less than those obtained using the modified SSSA approach, with the exception of the *z*-directional SS (Fig. 7). Figure 8 shows that the average peak story drifts on the four floor sides obtained using the GOLD were more uniformly distributed along the building height than those obtained using the modified SSSA approach. Furthermore, the average peak story drifts from the first to the sixth stories were more significantly reduced using the GOLD than the

modified SSSA approach, except in the *z*-directional SS (Fig. 8). On the contrary, the average peak story drifts from the seventh to the ninth stories resulting from the modified SSSA approach were less than those resulting from the GOLD. This is reasonable because the layout of the added dampers using the modified SSSA approach concentrated on the upper stories (Figs. 3b and 4b). After all, Figs. 5 to 8 clearly indicate that the ten damper locations in the two example buildings obtained from the GOLD were more effective than those obtained from the modified SSSA approach.

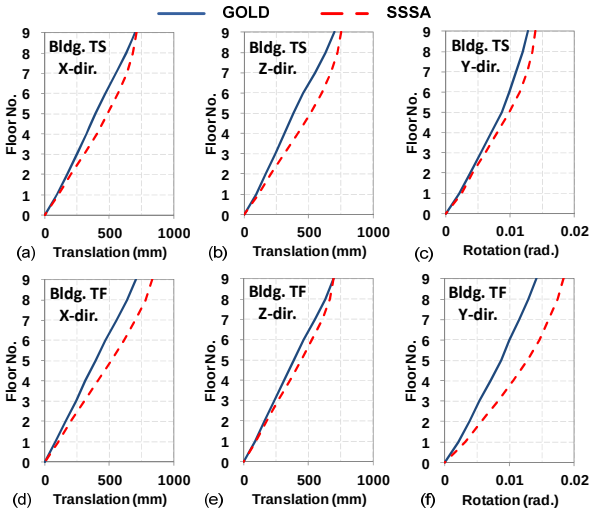

Figure 6 The average peak story translations in (a) the *x*-direction and (b) the *z*-direction, and (c) the average peak story rotation at the CM of Building TS. The average peak story translations in (d) the *x*-direction and (e) the *z*-direction, and (f) the average peak story rotation at the CM of Building TF.

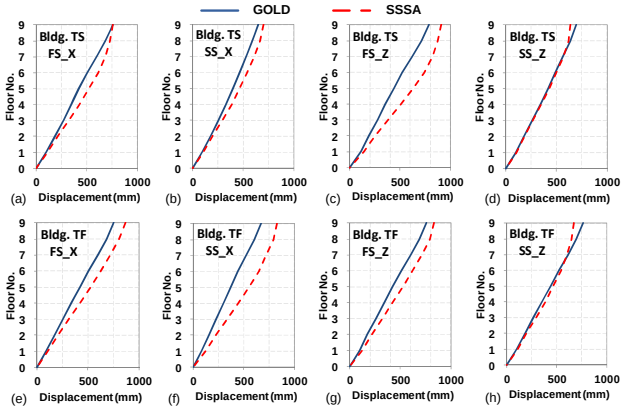

Figure 7 The average peak story displacements on (a) the FS and (b) the SS in the *x*-direction, and on (c) the FS and (d) the SS in the *z*-direction of Building TS. The average peak story displacements on (e) the FS and (f) the SS in the *x*-direction, and on (g) the FS and (h) the SS in the *z*-direction of Building TF.

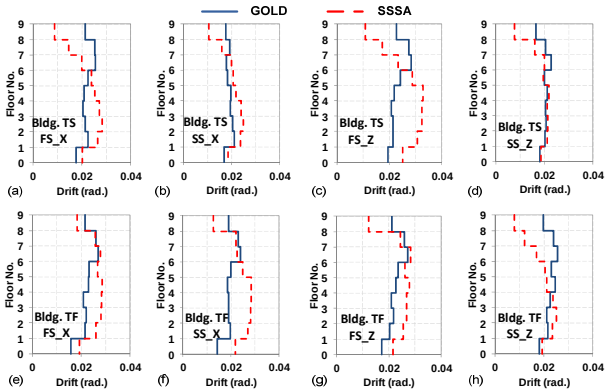

Figure 8 The average peak story drifts on (a) the FS and (b) the SS in the *x*-direction, and on (c) the FS and (d) the SS in the *z*-direction of Building TS. The average peak story drifts on (e) the FS and (f) the SS in the *x*-direction, and on (g) the FS and (h) the SS in the *z*-direction of Building TF.

4. CONCLUSIONS

This study demonstrated a satisfactory approach to the generalized optimal locations of viscous dampers by maximizing the dissipation rate of the overall strain energy of two-way asymmetrical buildings under the excitation of the two pairs of unit impulses. The defined dissipation rate of the overall strain energy used in this study is referred to as the smeared damping ratio, which is an intrinsic characteristic of the building system rather than any seismic response of the building system. In the numerical validations, the proposed approach ensured that the strain energy of the two example buildings was dissipated as fast as possible, which simultaneously resulted in several satisfactory seismic performances. These seismic performances included the displacements at the CM, the story drifts, and displacements at the four edges of the floor planes. In addition, the optimized damper configuration obtained by using the proposed approach is generalized, *i.e.*, not aimed at any specific set of seismic ground motions. This proposed approach is straightforward and suitable for engineering practice.

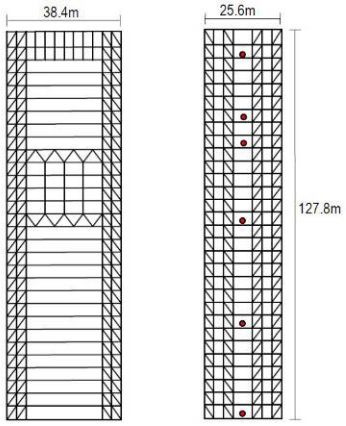
Abstract: A 29-story steel frame building in Kogakuin University was strongly shaken during the Great East Japan Earthquake, March 11, 2011. To study the feasible retrofitting schemes for the building in the future, Buckling-Restrained Braces (BRBs), Viscoelastic Dampers (VEDs) and Viscous Dampers (VDs), which are increasingly popular in Japan and China, are selected to study the energy dissipation effect of various dampers. About half of the steel braces in the building are replaced by BRBs, VEDs and VDs, respectively, and the location of those three types of dampers are identical. Nonlinear time history analysis is performed under the valuable base excitation recorded during the earthquake. The seismic performance of this building without dampers, with BRBs, VEDs and VDs are investigated respectively. It is concluded that the seismic effect of two velocity-dependent dampers, i.e. VEDs and VDs, behave better than BRBs. Further research will be performed on the optimization of the number and location of the dampers.

1. INTRODUCTION

This study is part of the Strategic China-Japan Cooperative Program on "Science and Technology (S&T) for Environmental Conservation and Construction of a Society with Less Environmental Burden". The research field of the program is "Evaluation and Mitigation of Environment Impacts of Earthquake and Typhoon Disaster on Urban Area and Infrastructures". The principal investigators of the China and Japan teams are Xilin Lu, (Tongji University) and Kazuhiko Kasai (Tokyo Institute of Technology).

This paper focuses on the application of energy dissipation devices on a tall steel building experienced the Great East Japan Earthquake, March 11, 2011. About half of existing building bracings are replaced by three kinds of dampers, including Buckling-Restrained Braces (BRBs), Viscoelastic Dampers (VEDs) and Viscous Dampers (VDs). The seismic performance of this building without dampers, with BRBs, VEDs and VDs are investigated.

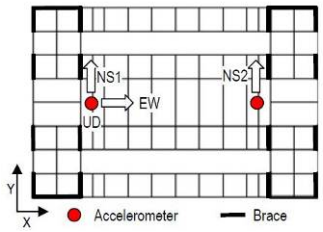
The companion paper (Kasai *et al*., 2013) discusses an alternative design, where existing bracings are retained and dampers placed at half number of building stories, aiming at minimum alterations with good seismic performance.



2. DESCRIPTION OF THE 29-STORY STEEL BUILDING

The building is a 29-story steel braced frame constructed in 1989. It is a school building of Kogakuin University, located in Shinjuku ward of central Tokyo. Figure 1 shows the elevation and plan layout of the building as well as locations of sensors instrumented.

At 14:46 on March 11, 2011, a 9-magnitude earthquake occurred off Sanriku coast of Japan and the 29-story steel building was strongly shaken. The sensors instrumented in the building recorded the valuable data of accelerations.



According to the report of the recorded data (Kasai *et al*., 2012), the peak accelerations in *X* and *Y* directions were 92 and 97 cm/s^2 at the first floor, and 235 and 316 cm/s^2 at the top floor, respectively. The average drift angle (i.e., top floor displacement divided by the height) is 1/350. The vibration periods for the first three modes are 2.96s, 1.00s, and 0.52s for *X* direction, and 3.10s, 0.94s, and 0.47s for *Y* direction, respectively. The corresponding damping ratios are 1.7%, 1.8%, and 3.4% for *X* direction, and 2.1%, 1.6%, and 3.4% for *Y* direction.

Figure 2 shows the time history curves of acceleration recorded at the first floor, which are used as actual ground input in the following analysis of the paper.

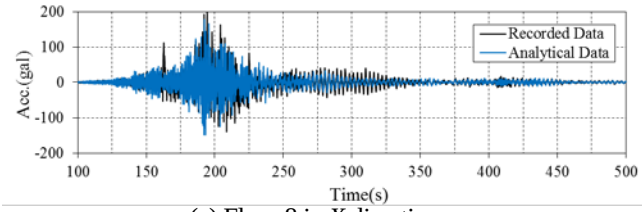
3. VERIFICATION OF THE STRUCTURAL MODEL

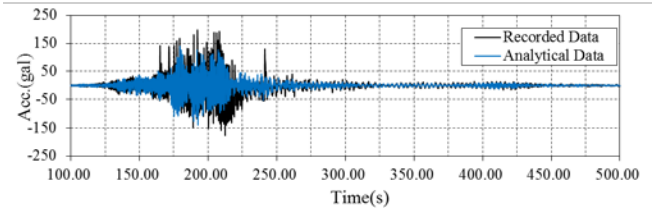
The finite element modeling is carried out using ETABS software. The dynamic properties and floor accelerations are firstly compared between analytical model and actual structure to verify the analytical model used in the paper.

3.1 Comparison of Dynamic Properties



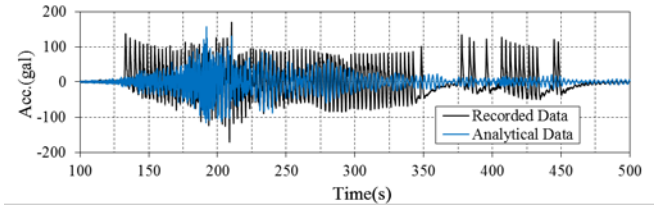
The dynamic property of the analytical model is obtained by performing modal analysis, and the actual structure's dynamic property has been obtained through small-amplitude vibration test (Hisada *et al.*, 2011). The comparison of dynamic property is shown in Table 1, which shows that the structural periods are very close.

Table1 Comparison of dynamic property between the analytical model and actual structure



Mode	Period (sec)		Error
	Analytical Model	Actual Structure	
1	3.076 (*Y*)	3.10 (*Y*)	-0.8%
2	3.032 (*X*)	2.96 (*X*)	2.4%
3	2.358 (*Torsion*)	-	-
4	1.039 (*X*)	1.00 (*X*)	3.9%
5	0.978 (*Y*)	0.94 (*Y*)	4.0%
6	0.788 (*Torsion*)	-	-
7	0.558 (*X*)	0.52 (*X*)	7.3%
8	0.504 (*Y*)	0.47 (*Y*)	7.2%
9	0.446 (*Torsion*)	-	-

3.2 Comparison of Floor Accelerations



The sensors were instrumented on Floor 1, 8, 16, 22, 24 and 29, and they recorded the accelerations of those floors. The accelerations recorded on Floor 1 are input into the structural model and the analytical accelerations are thus obtained and compared as shown in Figure 3. It can be seen that the accelerations agree quite well except the one in *X* direction on 16th Floor, which would be considered as fault record.

Fig. 3 Comparisons of time-history accelerations between the analytical model and actual structure

4. DAMPER DESIGN AND SEISMIC ANALYSIS

As described above, the original structural model without damper (ND) is established and bi-directional time history analysis is performed. Three other structural models are established too, they are structures with BRBs, VEDs and VDs replacing some braces of original structure respectively.

4.1 Location and Parameters of Dampers

The original structure has 240 braces in *X* direction and 460 braces in *Y* direction. About half of the steel braces are replaced by BRBs, VEDs and VDs, respectively, at the location shown in Figure 4. So the number and location of those three types of dampers are identical. In each structure with dampers, there are 120 dampers employed in *X* direction and 224 dampers employed in *Y* direction.

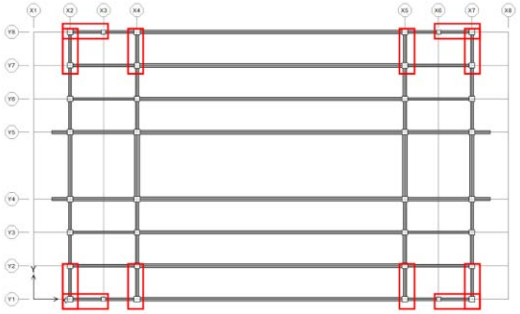

Fig. 4 Location of the dampers

The parameters of the BRBs are designed according to the axial stiffness of the replaced steel braces. As listed in Table 2, the designed damping forces are from 400kN to 800kN, and the average damping force is about 500kN. Wen model (Wen, 1976) is used for the simulation of the BRBs in ETABS program. The yield displacement of the BRBs is supposed to be 1.5mm, and the other parameters of the BRBs are listed in the Table 3, where K is the initial stiffness, F is the yield force, r is post yield stiffness ratio, exp is the yielding exponent.

The parameters of the VEDs are designed for a yield force of 500kN. The hysteretic behavior of viscoelastic damper is simulated by parallel connection of Wen and Maxwell models (Wen, 1976; Malvern, 1969) in ETABS program. Nonlinear parameters of Wen and Maxwell models are listed in Table 4. The physical meaning of the parametric symbols of Wen model is the same as Table 3, while in the Maxwell model K_d is stiffness, C is damping coefficient, and α is damping exponent. And the effective stiffness K_e of a VED is 60kN/mm.

Table 2 Distribution of the BRBs

Floor	BRBs		
	X-direction (axis Y1,Y8)	Y-direction (axis X2,X7)	Y-direction (axis X4,X5)
30	4×400 kN	-	-
29	4×400 kN	-	-
28	4×400 kN	4×400 kN	4×400 kN
27	4×400 kN	4×400 kN	4×400 kN
26	4×400 kN	4×400 kN	4×400 kN

25	4×400 kN	4×400 kN	4×400 kN
24	4×400 kN	4×400 kN	4×400 kN
23	4×400 kN	4×400 kN	4×400 kN
22	4×400 kN	4×400 kN	4×400 kN
21	4×400 kN	4×400 kN	4×400 kN
20	4×500 kN	4×400 kN	4×400 kN
19	4×500 kN	4×400 kN	4×400 kN
18	4×500 kN	4×400 kN	4×400 kN
17	4×500 kN	4×400 kN	4×400 kN
16	4×600 kN	4×400 kN	4×400 kN
15	4×600 kN	4×400 kN	4×500 kN
14	4×600 kN	4×400 kN	4×500 kN
13	4×700 kN	4×400 kN	4×500 kN
12	4×700 kN	4×400 kN	4×500 kN
11	4×700 kN	4×400 kN	4×500 kN
10	4×700 kN	4×400 kN	4×500 kN
9	4×700 kN	4×500 kN	4×600 kN
8	4×700 kN	4×500 kN	4×600 kN
7	4×700 kN	4×500 kN	4×600 kN
6	4×700 kN	4×500 kN	4×600 kN
5	4×700 kN	4×500 kN	4×600 kN
4	4×800 kN	4×500 kN	4×600 kN
3	4×800 kN	4×500 kN	4×600 kN
2	4×800 kN	4×600 kN	4×600 kN
1	4×800 kN	4×600 kN	4×600 kN

Table 3 Parameters of BRBs

Designed Damping Force(kN)	BRB			
	K(kN/mm)	*F*(kN)	*r*	*exp*
400	267	400	0.01	10
500	333	500	0.01	10
600	400	600	0.01	10
700	467	700	0.01	10
800	533	800	0.01	10

The parameters of the VDs are designed according to an actual maximum damping force of 500kN. The Maxwell model (Malvern, 1969; Lu *et al*., 2011; Lu *et al*., 2012) is used for the simulation of the viscous dampers in ETABS program. Because of the low velocity of the structure, the value of damping exponent should be low. When the structure is in low velocity, the dampers can rapidly generate force. Nonlinear parameters of viscous dampers are listed in the Table 5, where the physical meaning of the parametric symbols of Maxwell model is the same with Table 4. And the effective stiffness K_e of a VD is 20kN/mm.

Table 4 Parameters of VEDs

Model	Parameters			
Wen	*K*(kN/mm)	*F*(kN)	*r*	*exp*
	420	500	0.09	0.5

Maxwell	K_d(kN/mm)	C(kN/(mm/s)$^\alpha$)	α	
	30	0.2	0.2	

Table 5 Parameters of VDs

Model	Parameters		
Maxwell	K_d(kN/mm)	C(kN/(mm/s)$^\alpha$)	α
	280	500	0.1

4.2 Dynamic Properties of the Structures

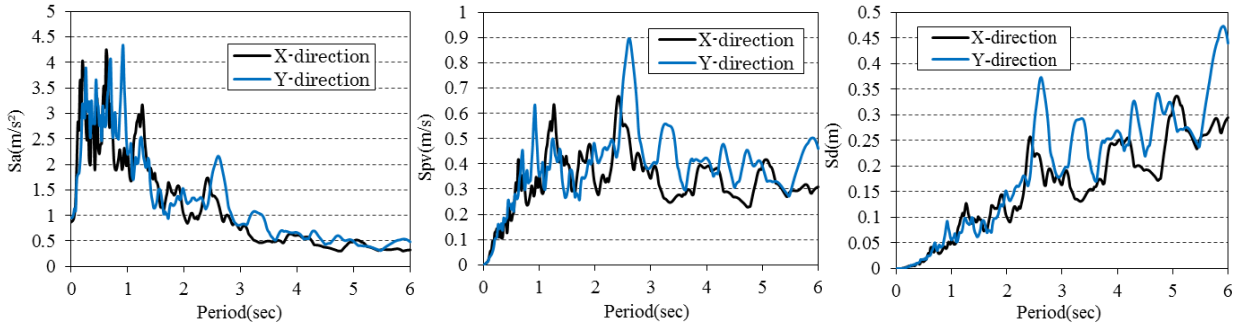
The comparison of the first nine periods of the original structure and the structure with BRBs, VEDs and VDs are shown in Table 6. All periods of the structures with dampers are longer than that of the original structure, because the stiffness provided by dampers is lower than the replaced steel braces. The periods of structure with BRBs is the shortest and that of structure with VDs is the longest, because the BRBs provide the biggest stiffness and the VDs provide the smallest stiffness.

Table 6 Dynamic properties of the structures

Mode	Period(sec)(Mode shapes)			
	ND	BRB	VED	VD
1	3.076(*Y*)	3.096(*Y*)	3.310(*X*)	3.375(*X*)
2	3.032(*X*)	3.057(*X*)	3.239(*Y*)	3.294(*Y*)
3	2.358(*T*)	2.383(*T*)	2.564(*T*)	2.626(*T*)
4	1.039(*X*)	1.048(*X*)	1.101(*X*)	1.117(*X*)
5	0.978(*Y*)	0.988(*Y*)	1.053(*Y*)	1.075(*Y*)
6	0.788(*T*)	0.799(*T*)	0.864(*T*)	0.885(*T*)
7	0.558(*X*)	0.565(*X*)	0.619(*X*)	0.631(*X*)
8	0.504(*Y*)	0.511(*Y*)	0.550(*Y*)	0.564(*Y*)
9	0.446(*T*)	0.454(*T*)	0.501(*T*)	0.514(*T*)

4.3 Input Time-history Records

The accelerations recorded by sensors instrumented on the first floor (Figure 2) are input into the structural models with dampers. Figure 5 shows corresponding response spectra in *X* and *Y* directions with 2% damping ratio.



4.4 Seismic Responses of the Structures

The comparison of maximum seismic responses of structures is shown in Table 7 and pictured in Figure 6~8.

From Table 7, it can be seen that all three kinds of dampers have good energy dissipation effect under the recorded base excitations. The two velocity-dependent dampers (VEDs and VDs) have similar energy-dissipating effect and both are better than the displacement-dependent dampers (BRBs).

The comparison of the inter-story drifts is shown in Figure 6. After half of the steel braces being replaced by BRBs, VEDs and VDs, the maximum inter-story drift of the structure decrease from 1/328 to 1/374 (BRB), 1/508 (VED) and 1/539 (VD) in *X* direction and from 1/241 to 1/276 (BRB), 1/320 (VED) and 1/346 (VD) in *Y* direction.

The distribution of the story displacement along the height is shown in Figure 7. It can be seen that the reduction of global displacement is more efficient in *X* direction that *Y* direction.

(a) Acceleration spectra (b) Pseudo-velocity spectra (c) Displacement spectra

Fig. 5 Response spectra of the input time-history records in *X* and *Y* directions

Table 7 Comparison of maximum responses of structures

Parameter	Direction	No Damper	With BRBs (Reduction percentage)	With VEDs (Reduction percentage)	With VDs (Reduction percentage)
Inter-story Drift	*X*	1/328	1/374 (-12%)	1/508 (-35%)	1/539 (-39%)
	Y	1/241	1/276 (-13%)	1/320 (-25%)	1/346 (-30%)
Story Displacement(mm)	*X*	256	226 (-12%)	160 (-37%)	182 (-29%)
	Y	314	301 (-4%)	287 (-9%)	282 (-10%)
Story Shear Force(kN)	*X*	1.76×10^4	1.38×10^4 (-22%)	1.21×10^4 (-31%)	1.10×10^4 (-37%)
	Y	2.16×10^4	1.70×10^4 (-22%)	1.61×10^4 (-25%)	1.53×10^4 (-29%)

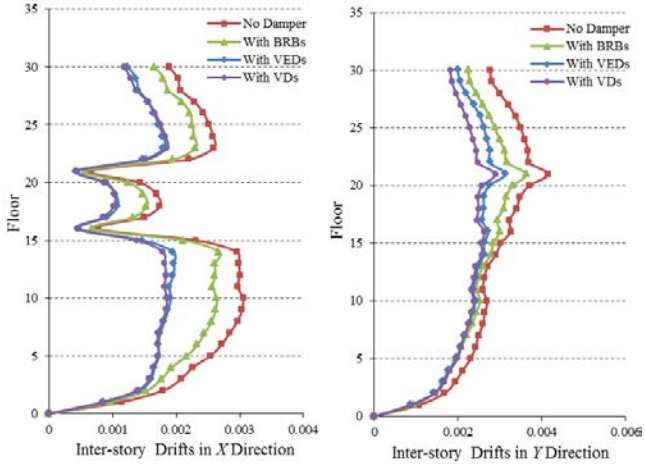


Fig. 6 Comparison of the inter-story drifts

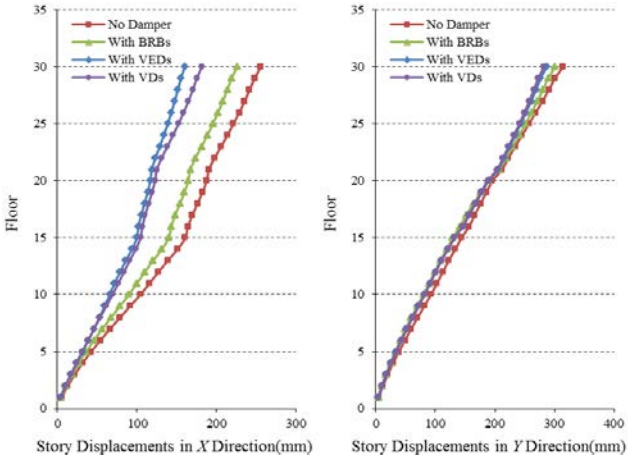

Fig. 7 Comparison of the story displacements

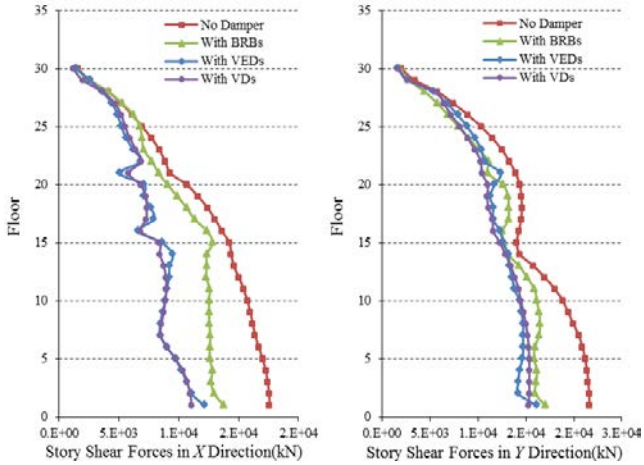

Fig. 8 Comparison of the story shear forces

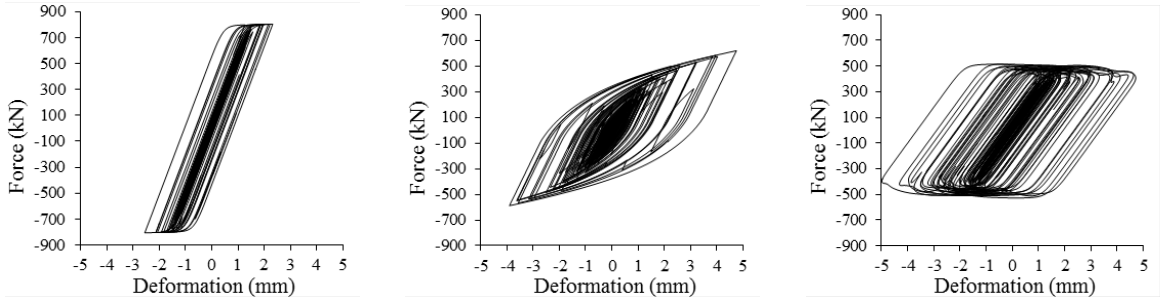
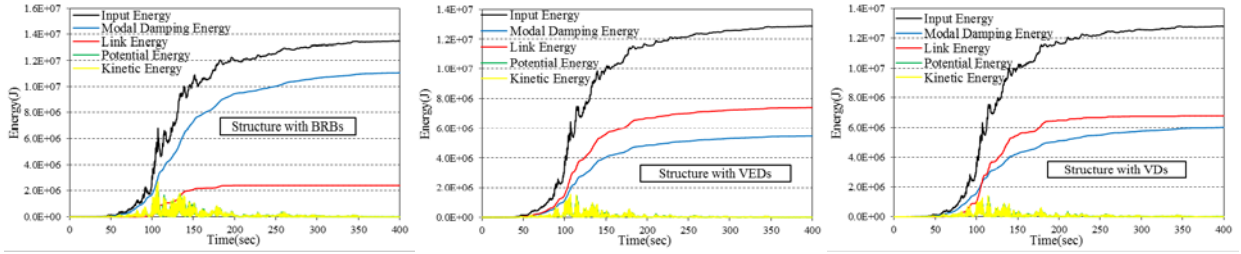
The comparison of the story shear forces is shown in Figure 8. All dampers have similar effect on shear forces in *Y* direction, while in *X* direction VED and VD has better energy dissipation than BRB.



From the comparisons above, we can see that structure with VEDs and structure with VDs have similar control effect, and structures with VDs is slightly better than that with VEDs from the perspective of the maximum seismic responses. They have excellent structural performances and remarkable energy-dissipation capacity which is much better than structure with BRBs. In addition to the difference of energy-dissipation capacity, the earthquake energy input to the structure is not exactly the same due to the different stiffness of the structures which should be taken into account.

4.5 Hysteretic Curves and Energy Time-history Curves

The force-deformation hysteretic curves of a BRB, VED, and VD damper are shown in Figure 9, which has a maximum force of 806kN, 619kN and 515kN, respectively. The maximum deformation of three types of dampers is 2.55mm, 4.75mm and 4.98mm. The full shapes of the hysteretic curves indicate that a large amount of energy input by the earthquake is dissipated by dampers.



The control effect in *Y* direction is not as good as that in *X* direction, the most likely cause is that the earthquake load will increase along with the extension of period as described in Figure 5.

As shown in Figure 10, the energy curves express the variation of the earthquake input energy, the energy dissipated by dampers, model damping energy, kinetic energy and potential energy with the times. About 18.3%, 56.5% and 53.1% input energy is dissipated by BRBs, VEDs, and VDs, respectively. This result indicates the energy dissipation capacity of those three types of dampers, structures with VEDs dissipate most seismic energy, followed by structures with VDs and BRBs, and this can explain why structures with VEDs and VDs have better control effect than structure with BRBs.

(a) BRB (b) VED (c) VD

Fig. 9 Force-deformation hysteretic curves of three types of dampers

(a) Structure with BRBs (b) Structure with VEDs (c) Structure with VDs

Fig. 10 Energy time-history curves of structures with dampers

5. FURTHER ANALYSIS UNDER INCREASED PEAK GROUND ACCELERATIONS

In order to investigate the energy dissipation effect of those three kinds of dampers under various peak ground accelerations (PGA), the PGA of the original recorded accelerations are scaled to 0.2g and 0.4g respectively and are input into those four models for nonlinear time history analyses.

5.1 Under a PGA of 0.2g

When the PGA of the input accelerations is 0.2g, the comparison of the inter-story drifts and story shear forces of the structures are shown in Figure 11 and 12, and the maximum seismic responses of structures are compared in Table 8.

From the comparisons above, we can see that the control effect of structure with VDs is obviously better than that of structure with VEDs and BRBs on inter-story drifts, and structures with VEDs is better than structures with

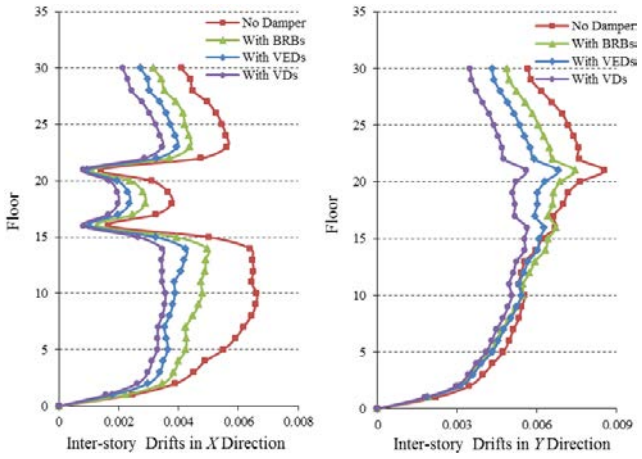


Fig. 11 Comparison of the inter-story drifts (0.2g)

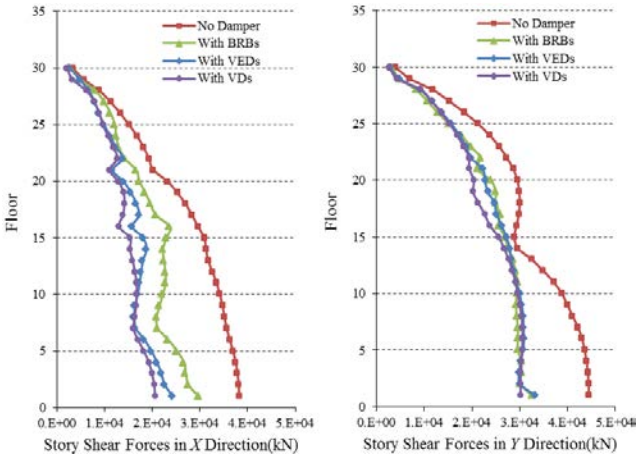

Fig. 12 Comparison of the story shear forces (0.2g)

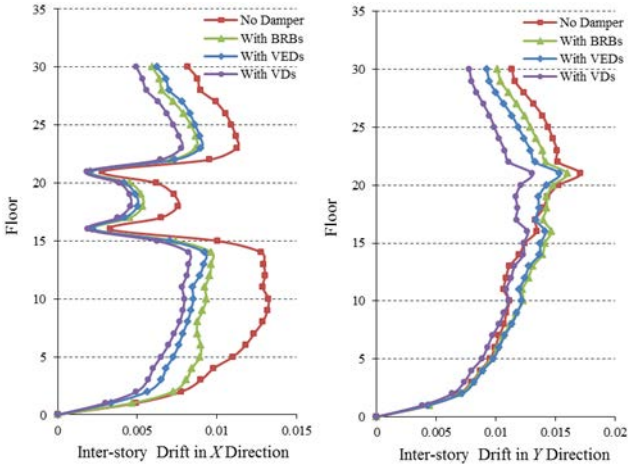

Fig. 13 Comparison of the inter-story drifts (0.4g)

BRBs. All dampers have similar effect on shear forces in *Y* direction, while in *X* direction VED and VD has better control effect than BRB.

In this case, about 30.3%, 55.7% and 65.0% input energy is dissipated by BRBs, VEDs, and VDs, respectively. This indicates the energy dissipation capacity of BRB and VD will improve under increased peak ground accelerations, and the increase of BRB is more obvious.

5.2 Under a PGA of 0.4g

When the PGA of the input accelerations is 0.4g, similar comparison is made in Figure 13~14 and Table 9. It can be seen that the distinction of the control effect of those three kinds of dampers reduces with the increase in PGA, and the control effect on inter-story drifts decreases while that on shear forces increases. The structure with VDs also shows better control effect than structures with VEDs and BRBs.

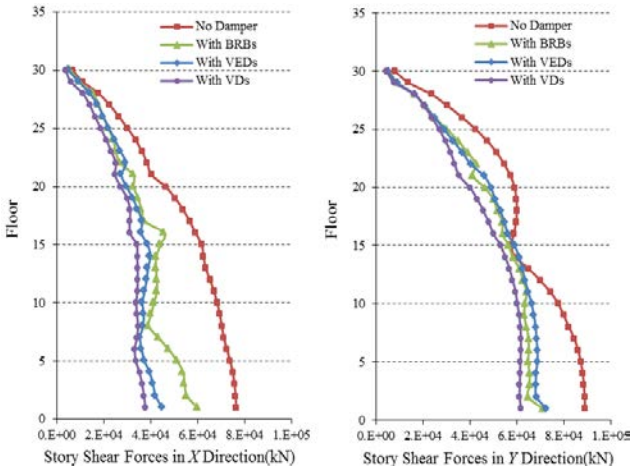

Fig. 14 Comparison of the story shear forces (0.4g)

In this case, about 30.6%, 49.7% and 65.0% input energy is dissipated by BRBs, VEDs, and VDs, respectively. The result indicates that the energy dissipation capacity of VED will decrease with the increase in PGA.

Table 8 Comparison of maximum responses of structures when the PGA is 0.2g

Parameter	Direction	No Damper	With BRBs (Reduction percentage)	With VEDs (Reduction percentage)	With VDs (Reduction percentage)
Inter-story Drift	X	1/151	1/201 (-25%)	1/236 (-36%)	1/281 (-46%)
	Y	1/117	1/134 (-13%)	1/147 (-20%)	1/178 (-34%)
Story Shear Force(kN)	X	3.82×10^4	2.97×10^4 (-22%)	2.43×10^4 (-36%)	2.05×10^4 (-46%)
	Y	4.45×10^4	3.26×10^4 (-27%)	3.32×10^4 (-25%)	3.02×10^4 (-32%)

Table 9 Comparison of maximum responses of structures when the PGA is 0.4g

Parameter	Direction	No Damper	With BRBs (Reduction percentage)	With VEDs (Reduction percentage)	With VDs (Reduction percentage)
Inter-story Drift	X	1/76	1/103 (-26%)	1/108 (-30%)	1/121 (-37%)
	Y	1/59	1/63 (-6%)	1/65 (-9%)	1/77 (-23%)
Story Shear Force(kN)	X	7.64×104	5.99×10^4 (-22%)	4.49×10^4 (-41%)	3.76×10^4 (-50%)
	Y	8.90×104	7.09×10^4 (-20%)	7.25×10^4 (-19%)	6.18×10^4 (-31%)

6. CONCLUSIONS

A 29-story steel building which has been strongly shaken during the Great East Japan Earthquake was introduced, and the structural model was established and verified by the valuable acceleration recorded during the quake. Three other structural models are also established, in which about half of the steel braces are replaced by buckling-restrained braces, viscoelastic dampers and viscous dampers, respectively. Modal analyses and dynamic time-history analyses of four structural models were conducted. Comparisons of dynamic properties, inter-story drifts, story displacements, and story shear forces of those four structures are carried out.

Through the comparison, we can come to the conclusion that structure with VEDs and structure with VDs have similar control effect, and structure with VDs is slightly better than that with VEDs from the perspective of the maximum seismic responses. They have excellent structural performances and remarkable energy-dissipation capacity which is much better than structure with BRBs.

The control effect of all structures with dampers in *Y* direction is not as good as that in *X* direction, the most likely cause is that the earthquake load will increase along with the extension of period as described by the seismic response spectra of the input time-history records.

In the further study, the PGA of the original recorded accelerations are scaled to 0.2g and 0.4g respectively and are input into those four structural models for nonlinear dynamic time-history analyses. The results indicate that the energy dissipation capacity of BRB and VD will improve while that of VED will reduce under increased peak ground accelerations. The structure with VDs continued to show better control effect than structures with VEDs and BRBs.

Although there are some differences in energy dissipation principle and mechanical properties and the control effects are dissimilar, all the three types of dampers show good damping effect and evidently can be used to achieve the expected energy-dissipation objectives if designed and distributed properly. Further research will be performed on the optimization of the number and location of dampers.

Abstract: A monitored 29-story steel frame building in Tokyo was strongly shaken during the Great East Japan Earthquake, March 11, 2011. By using its base acceleration records, the companion paper Part 1 explored effectiveness of seismic retrofit, hypothetically replacing about half of the existing steel braces with dampers at almost every story. Three cases using the buckling-restrained braces, viscoelastic dampers, and nonlinear viscous dampers were studied. The present paper as Part 2 considers an alternative retrofit scheme by adding oil dampers to half number of stories without removing the existing steel braces, in an attempt to minimize alterations of the building. A method to select appropriate locations to attach dampers to maximize control effect is proposed. It considers a special shear beam model to characterize the building with considerably reduced degrees of freedom. Excellent control performance of the building using the method is demonstrated. The accuracy of the shear beam model, in spite of complex deformation mode of the building, is also shown by comparing its global and local responses to those of a 3D member-to-member model.

1. INTRODUCTION

1.1 Strategic China-Japan Cooperative Program

This study is part of the Strategic China-Japan Cooperative Program on "Science and Technology (S&T) for Environmental Conservation and Construction of a Society with Less Environmental Burden". The research field of the program is "Evaluation and Mitigation of Environment Impacts of Earthquake and Typhoon Disaster on Urban Area and Infrastructures". The principal investigators of the China and Japan teams are Xilin Lu, (Tongji University) and Kazuhiko Kasai (Tokyo Institute of Technology), respectively.

1.2 First Phase - RC Building Repair with Dampers

In the first phase of this study, key issues related to repair of RC buildings using dampers were discussed (Lu *et al.* 2011, Kasai *et al.* 2011), by considering existing Chinese 7-story RC building damaged due to the 2008 Wenchuan Earthquake. Actual repair work performed, detailed full-scale damper tests, and hypothetical repair and analysis using the damper test results were discussed (Lu *et al.* 2011). A comprehensive design method was also proposed to determine the required capacity of viscous damper and its story-by-story distribution for RC building structure whose hysteresis is of a stiffness-degrading type. The design method was used for the existing 7-story RC building, and its accuracy demonstrated by time history analyses (Kasai et al. 2011).

1.3 Second Phase - Tall Building Retrofit with Dampers

As the second phase, key issues related to seismic retrofit of a tall building by using dampers are being discussed. The companion paper (Part 1) focused on a Japanese tall steel building that experienced the 2011 Great East Japan Earthquake (Lu *et al*., 2013). The building is instrumented and response records during the earthquake are also considered in the study. About half of existing building bracings are replaced by three kinds of dampers, buckling-restrained braces, viscoelastic dampers and viscous dampers. Seismic performance of the building with or without dampers were investigated (Lu *et al*., 2013).

This paper (Part 2) discusses an alternative design, where existing bracings are retained and dampers placed at

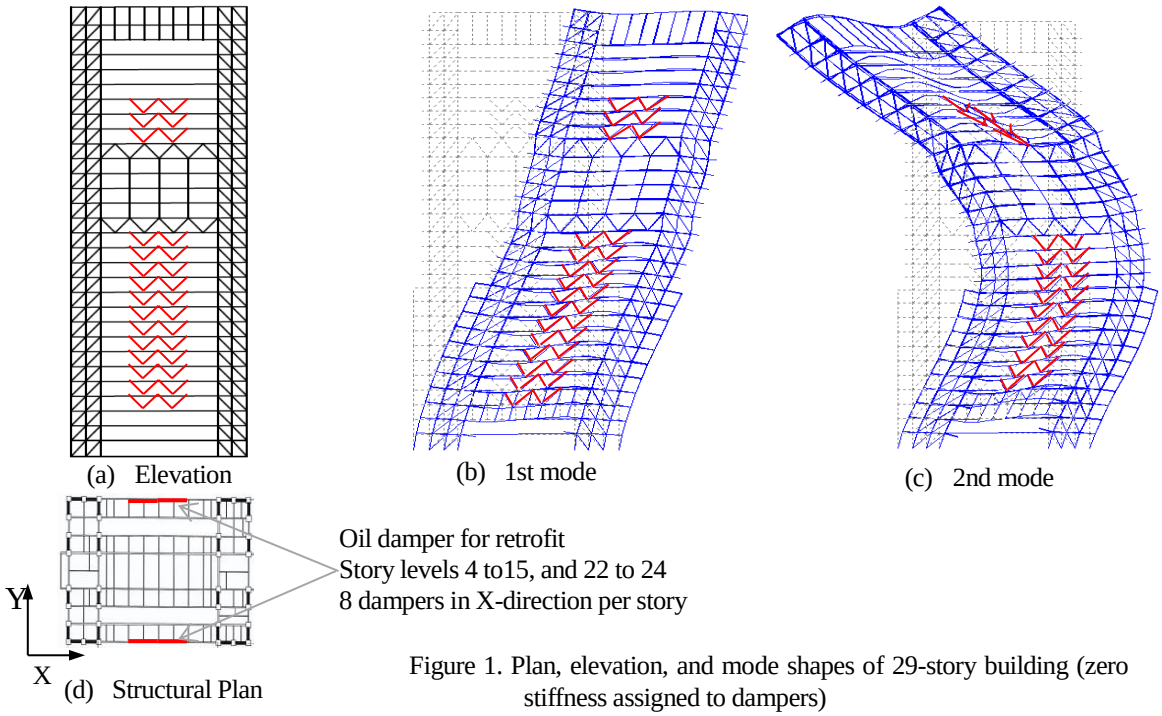

Figure 1. Plan, elevation, and mode shapes of 29-story building (zero stiffness assigned to dampers)

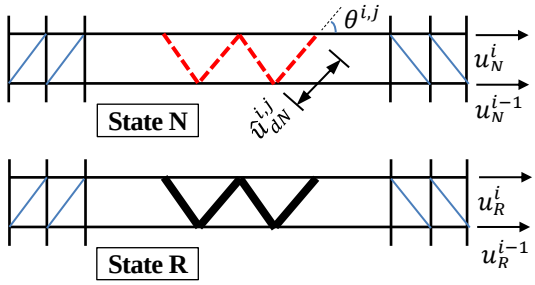

half number of building stories, aiming at minimum alterations with good seismic performance. A method to select appropriate locations to attach dampers to maximize control effect is proposed. It considers a special shear beam model to characterize the building with considerably reduced degrees of freedom. Excellent control performance of the building using the method is demonstrated. The accuracy of the shear beam model, in spite of complex deformation mode of the building, is also shown by comparing its global and local responses to those of a 3D member-to-member model.

2. SELECTION OF LOCATIONS FOR DAMPER INSTALLATION

Passive control effectiveness depends on properties of both damper and frame. In this study, the effects of frame properties are discussed by isolating those of dampers, and the contents in this section are applicable to any dampers. Effects of oil damper properties will be considered in the next section.

2.1 Initial Selections of Damper Locations

Fig. 1 shows the elevation and plan of the 29-story building (Hisada *et al.* 2012, 2013, Kasai *et al.* 2012, Lu *et al.* 2013). The dampers are assumed to be at story levels 1 to 15, and 22 to 24, respectively. The story levels as well as plan locations were selected by examining vibration modes of the 3D frame (member-to-member) model without dampers: by drawing dampers at the hypothetical locations in the undamped building (Figs. 1a to 1c), the locations assuring large axial deformations of the dampers are selected. This initial selection is checked and improved by the writers' method explained below:

$$K_N^i = \frac{Q^i}{u_N^i - u_N^{i-1}} \qquad K_R^i = \frac{Q^i}{u_R^i - u_R^{i-1}}$$

$$\alpha_N^{i,j} = \frac{\hat{u}_{dN}^{i,j}}{\cos\theta^{i,j}(u_N^i - u_N^{i-1})} \qquad \alpha_N^i = \frac{1}{8}\sum_{j=1}^{8}\alpha_N^{i,j}$$

Figure 2. Frame parameters K_N^i, K_R^i, and α_N^i, indicating control effectiveness

2.2 Frame Parameters Indicating Control Effectiveness

As shown in Fig. 2, inclined brace-type dampers are considered for the frame model. Each inclined member includes not only the damper but also brace and connections, and will be called as an "added component" that is oriented to directly connect the lower and upper beams in Fig. 2.

We define State *N* (no damper) and State *R* (rigid damper) where the added component has no stiffness and infinite stiffness in its stroke direction, respectively. Elastic static analyses are conducted for the two states of the frame model by applying lateral forces. From State *N* and *R* displacements u_N^i, u_N^{i-1} and u_R^i, u_R^{i-1}, and shear force Q_i at story levels *i* and *i*-1, story stiffnesses K_N^i and K_R^i are estimated as follows:

$$K_N^i = Q^i / (u_N^i - u_N^{i-1}) \quad , K_R^i = Q^i / (u_R^i - u_R^{i-1}) \quad \text{(1a,b)}$$

where K_R^i should be larger than K_N^i. Larger K_R^i means

Notes: Each span for damper L^{ij}=3200mm is common for all story level and dampers. Brace cosine angle $\cos\theta^{i,j}$ is common for j=1 to 8. Viscosity coefficient $\hat{C}_d^{i,j}$=37.5 kN·s/mm, post-relief viscosity ratio p=0.03, relief load $\hat{F}_d^{i,j}$=1200 kN, damper internal oil stiffness $\hat{K}_d^{i,j}$=430 kN/mm, and they are common for j=1 to 8. Brace cross section = circular tube 318.5x17.4 (=16459 mm^2), and typically $\hat{K}_b^{i,j}$ was estimated as diagonal length $\sqrt{(L^{ij})^2+(h^i)^2}$ minus rigid end zone length 800 mm and damper length 1480 mm.

more possibility for the added component to attract forces and make the control more effective.

For State *N*, axial deformation of the added component located at story level i and location j is defined as $\hat{u}_{aN}^{i,j}$. In order to indicate horizontal component of maximum possible deformation of the added component, we define deformability ratio $\alpha_N^{i,j}$ as follows:

$$\alpha_N^{i,j}=(\hat{u}_{aN}^{i,j}/\cos\theta^{i,j})/(u_N^i-u_N^{i-1}) \quad (2)$$

where $\cos\theta^{i,j}$ coverts axial deformation of each added component to horizontal direction. Larger $\alpha_N^{i,j}$ suggests good possibility of larger deformation and energy dissipation of the added component.

2.3 Control Effectiveness for 29-Story Building

For the 29-story building, the magnitudes of the three key parameters K_N^i, K_R^i, and $\alpha_N^{i,j}$ are indicated in Table 1. The K_R^i indicates maximum possible value of increased stiffness, and should be much larger than K_N^i for an ideal structure. For the 29-story frame, the K_R^i at the story with the added components is much lower, varying from 1.6 to 2.2 times K_N^i, as Fig. 3 shows. This is because, in spite of the rigid added component, the frame displaces due to flexural deformations of the girder connected to the added components, column flexural deformations, and column axial deformations causing overall chord drift. These deformations will reduce damper deformations and are detrimental to control.

However, it can be shown from the design theory of various dampers that $K_R^i \approx 2K_N^i$ is still acceptable for good passive control (e.g., Kasai, Ito, and Ogura 2008). Moreover, the value is found to be still much larger than when selecting other story levels or locations.

Noted also that $\alpha_N^{i,j}$ values at the selected locations are very large and well exceeding 1.0 as understood from Fig. 1b. In a typical diagonal brace-type damper, the value is usually close to but less than 1.0, and in a typical knee-brace type, it is usually less than 0.3. The present location took advantage of the double curvature deformation mode of the main girder to amplify $\alpha_N^{i,j}$, after confirming adequacy of

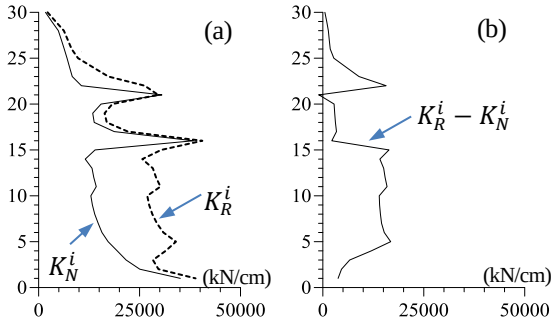

Figure 3. Plots of (a) K_N^i, K_R^i and (b) $K_R^i - K_N^i$

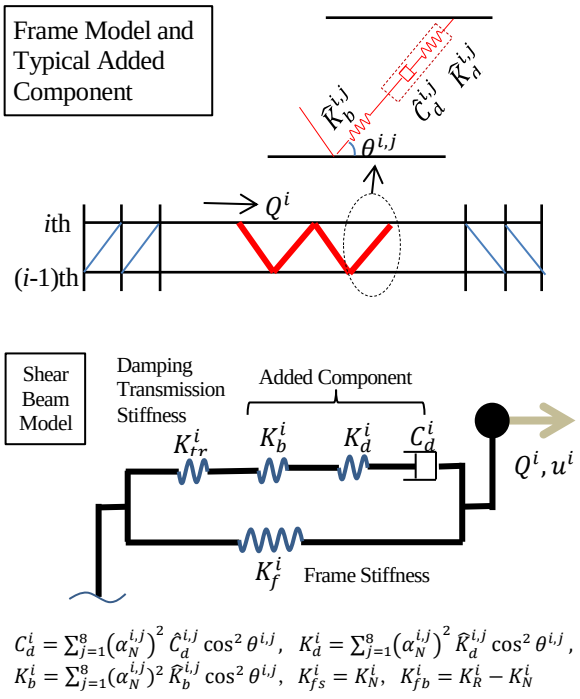
bending stiffness and strength of the girder, good control effectiveness was expected.

After the appropriate story levels and locations for the damper are determined, damper properties must be carefully chosen by maintaining good balance of stiffness with the frames. But due to time limitation, the present study crudely set damper sizes equally at every location, and did not necessarily assured the best performance. Nevertheless, significant improvement of building behavior will be noted later.

3. SHEAR BEAM MODEL

Based the frame model discussed above, a simple analytical model can be developed for time consuming dynamic analysis. The shear beam model is also suitable to understanding of passive control effect, by clearly expressing roles of damper, its support members, and frame, respectively.

3.1 Shear Beam Modeling for Frame Portion



Based on States *N* and *R* analyses of the frame model (Eq. 1), a shear beam model is created. The method is shown in Fig. 4. The K^i_N obtained from the frame (Eq. 1a) is equal to the frame stiffness K^i_f. In order to express the aforementioned deformations detrimental to control, the maximum possible added stiffness discussed earlier will be named now as "damping transmission stiffness" K^i_{tr}, and is included in the shear beam model *i.e.*,

$$K^i_f = K^i_N, \quad K^i_{tr} = K^i_R - K^i_N \qquad (3a,b)$$

where larger K^i_{tr} will transmit and distribute the localized damping of the added component to the overall structure.

3.2 Shear Beam Modeling for Added Components

Each added component of the frame model consists of three elements, bilinear viscous element of viscosity coefficients $\hat{C}_d^{i,j}$ and $p\hat{C}_d^{i,j}$ one of which is selected according to the damper force relative to the relief load $\hat{F}_{dy}^{i,j}$ (Fig. 5 right); damper internal elastic element $\hat{K}_d^{i,j}$ and; brace-connection element of stiffness $\hat{K}_b^{i,j}$ in axial

$C_d^i = \sum_{j=1}^{8} (\alpha_N^{i,j})^2 \hat{C}_d^{i,j} \cos^2\theta^{i,j}$, $K_d^i = \sum_{j=1}^{8} (\alpha_N^{i,j})^2 \hat{K}_d^{i,j} \cos^2\theta^{i,j}$,
$K_b^i = \sum_{j=1}^{8} (\alpha_N^{i,j})^2 \hat{K}_b^{i,j} \cos^2\theta^{i,j}$, $K_{fs}^i = K_N^i$, $K_{fb}^i = K_R^i - K_N^i$

Figure 4. Conversions Form 3D Frame Model to Shear Beam Model

direction, respecively (Fig. 5). For the shear beam model, the properties are converted to C_d^i, K_d^i, K_b^i, and F_{dy}^i as follows (Kasai and Iwasaki 2006) :

$$C_d^i = \sum_{j=1}^{8} (\alpha_N^{i,j})^2 \hat{C}_d^{i,j} \cos^2\theta^{i,j}$$

$$K_d^i = \sum_{j=1}^{8} (\alpha_N^{i,j})^2 \hat{K}_d^{i,j} \cos^2\theta^{i,j}$$

$$K_b^i = \sum_{j=1}^{8} (\alpha_N^{i,j})^2 \hat{K}_b^{i,j} \cos^2\theta^{i,j}$$

$$F_{dy}^i = \sum_{j=1}^{8} \alpha_N^{i,j} \hat{F}_{dy}^{i,j} \cos\theta^{i,j} \qquad (4a\text{-}d)$$

where $\cos\theta^{i,j}$ converts the axial property into that of horizontal direction, and $\alpha_N^{i,j}$ converts the frame model property to the shear beam property (Kasai and Iwasaki 2006, Ishii and Kasai 2010).

Eqs. 4 are based on the theoretical and exact relationship between the frame model and shear beam of a single story building (Kasai and Iwasaki 2006). They also provide good approximation for multistory models (Ishii and Kasai 2010).

3.3 Response Conversion between Shear Beam Model and Frame Model

Note also that the responses of thus-formulated shear beam model can be converted to represent responses of the frame model. First, the global displacements, velocities, and accelerations of the former are equal to those of the latter. Second, the local deformation and velocity of the damper

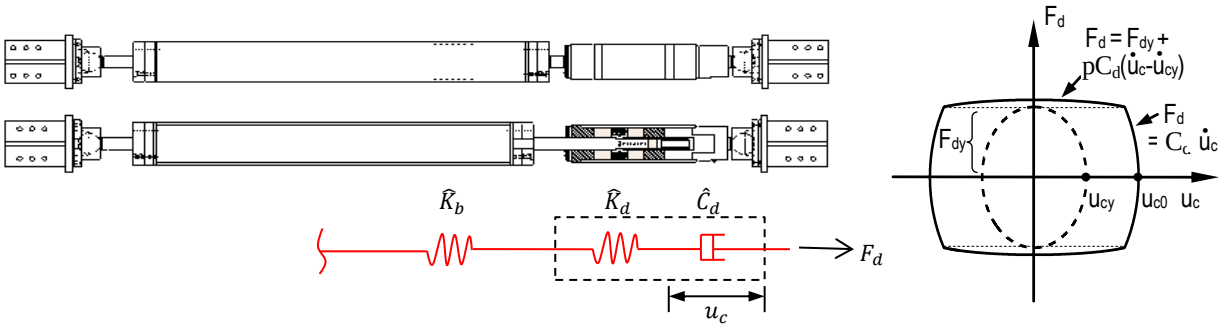


Figure 5. Bilinear oil damper and Maxwell model

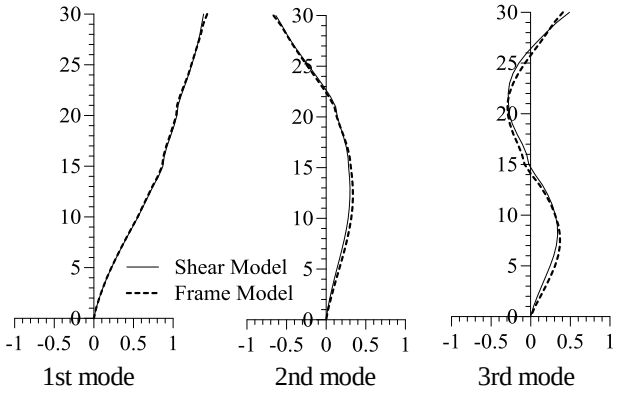

Figure 6. Comparison of modes between 3D Frame Model and Shear Beam Model

Table 2. Comparison of vibration periods and damping ratios between 3D Frame Model and Shear Beam Model

Model	T_1(s)	T_2(s)	T_3(s)	h_1	h_2	h_3
3D Frame	2.958	1.031	0.547	0.0147	0.0151	0.0235
Shear Beam	2.958	1.112	0.678	0.0147	0.0146	0.0198

Note: Rayleigh damping is used, of which 1st mode of X-dir. and 3rd mode of Y-dir. are set to be 0.015 and 0.025, respectively.

and other elements of the shear beam model are converted to those of the frame model by multiplying them with $\alpha_N^{i,j}\cos\theta^{i,j}$, respectively. Third, their local forces are converted similarly using $1/(\alpha_N^{i,j}\cos\theta^{i,j})$.

3.4 Shear Beam Model of 29-Story Building

For the 29-story building, the magnitudes of the shear beam parameters K_f^i, K_{tr}^i, C_d^i, K_d^i, K_b^i, and F_{dy}^i are indicated in Table 1. Note also that K_{tr}^i is small but not necessarily zero at the story without added components. This is because the deformation pattern there at Sate R is somewhat altered from that in Sate N. After some numerical experiments of validations, it was decided to use the value of K_R^i instead of K_f^i where added component is absent.

For simplicity, the stiffnesses K_{tr}^i, K_d^i, and K_b^i are reduced to an "equivalent brace stiffness" $K_{b,eq}^i$ as follows:

$$\frac{1}{K_{b,eq}^i} = \frac{1}{K_{tr}^i} + \frac{1}{K_b^i} + \frac{1}{K_d^i} \qquad (5)$$

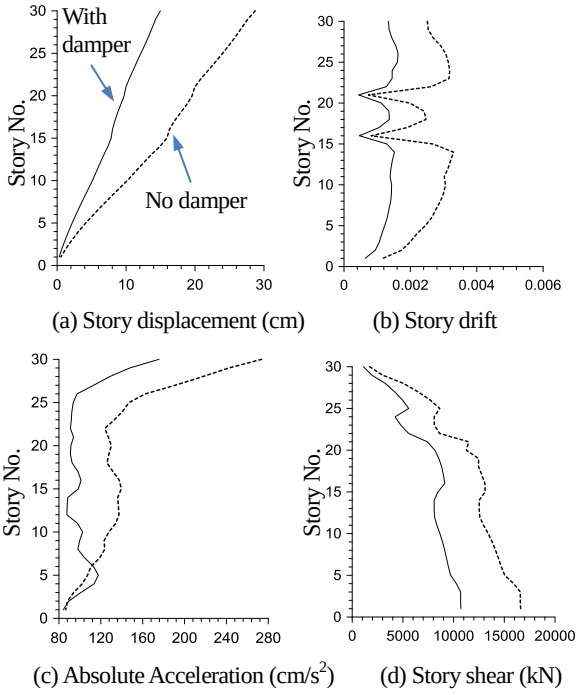

Figure 7. Comparison of maximum response of structures with and without dampers (PGA=92cm/s^2)

4. ANALYSES WITH OR WITHOUT DAMPERS

4.1 Frame Model Analysis and Retrofit Validations

Fig. 6 shows the 3D frame model mode shapes, and Table 2 indicates vibration periods and damping ratios for the 1st to the 3rd modes in X-direction. Rayleigh damping is used and set to satisfy damping ratio of 0.015 for the 1st mode of X-direction and 0.025 for the 3rd mode in Y-direction, respectively. Because of belt trusses in some stories, some abrupt change in the mode shapes occurs over the height (see also Fig. 3). For retrofit of the building with the oil dampers in X-direction, the damper properties (Figs. 4 and 5) are summarized at the footnote of Table 1.

The frame model is subjected to the recorded X-direction motion of PGA 92 cm/s^2. As will be shown, this level of shaking did not activate the relief valve, and the damper behaved linearly. Fig. 7 contrasts the responses between damped and undamped cases, where the response reduction by dampers is apparent, the maximum drift angles

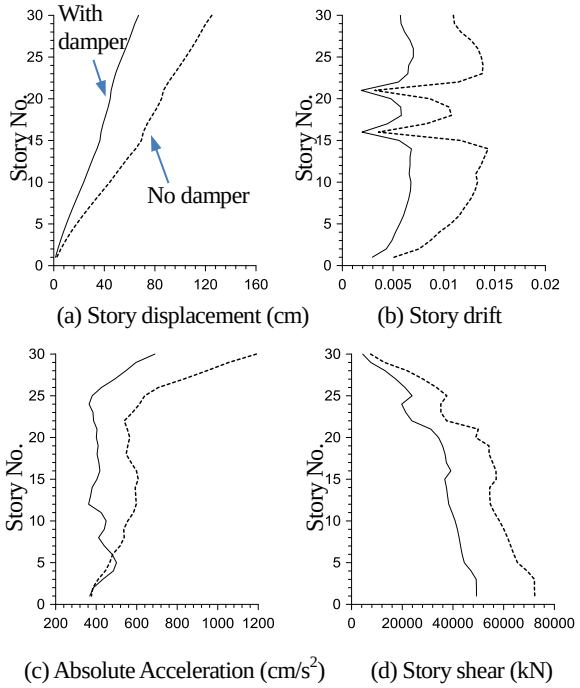

Figure 8. Comparison of maximum response of structures with and without dampers (PGA=400cm/s^2)

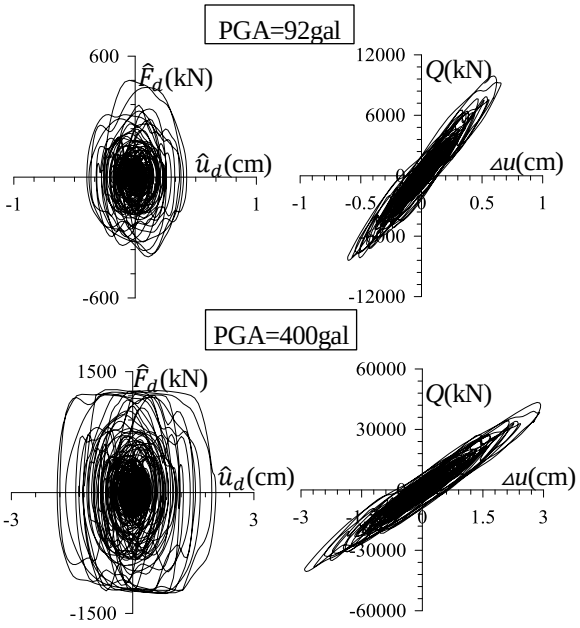

Figure 9. Hysteresis of damper subjected to different PGA

of the damped case and undamped case are 0.0015 and 0.0032 rad, accelerations are 180 and 270 cm/s^2, and base shear forces are 10715 kN and 16608 kN, respectively, indicating drift, accelerations, and base shear are reduced to 0.47, 0.67, and 0.64 times, respectively, by using the oil dampers.

Note also the reduction is more profound than the retrofit scheme in Part 1 where the most significant reduction of

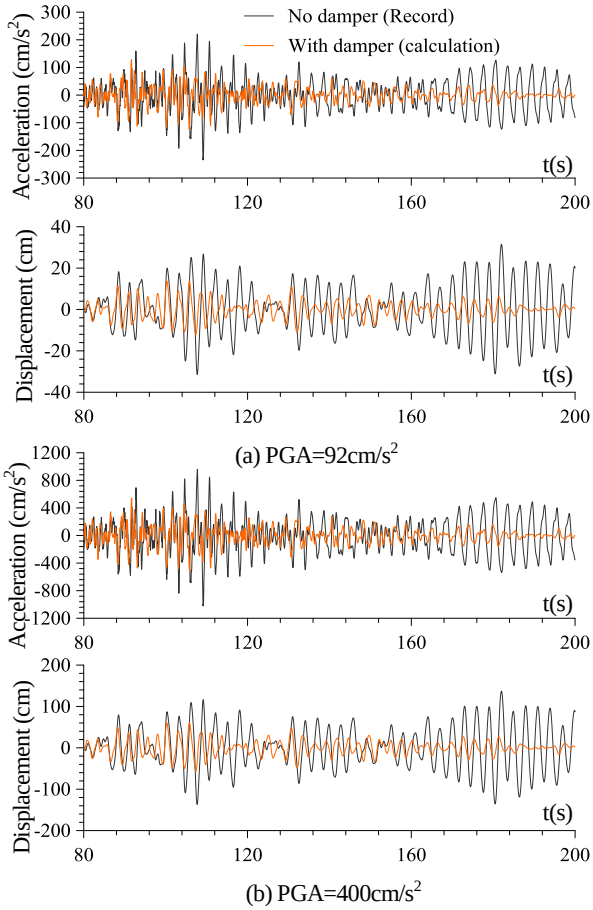

Figure 10. Comparison of response history between structures with and without dampers

drift angle and base shears were 0.61 and 0.63 times, over the three different kinds of dampers used.

The earthquake is amplified to PGA 400cm/s^2. The relief valve was active, and the damper behaved bi-linearly. Fig. 8 contrasts the responses between damped and undamped cases, where the latter is only 4.35 times scaled response from analysis using PGA 92 cm/s^2, since linear behavior is assumed for the undamped case. The maximum drift angles of the damped case and undamped case are 0.0069 and 0.0144 rad, accelerations are 689 and 1,190 cm/s^2, and base shear forces are 49276 kN and 72280 kN, respectively, indicating drift, accelerations, and base shear are reduced to 0.48, 0.58, and 0.68 times, respectively, by using the oil dampers.

Note also the reduction is more profound than the retrofit scheme in Part 1 where the most significant reduction of drift angle and base shears were 0.63 and 0.50 times, over the three different kinds of dampers used.

Fig. 9 shows the difference in hysteresis of the dampers with or without relief mechanism between the two distinct PGA values. Fig. 10 shows the response histories between the damped and undamped cases. The damped case does not only reduce the peak responses but also significantly reduces

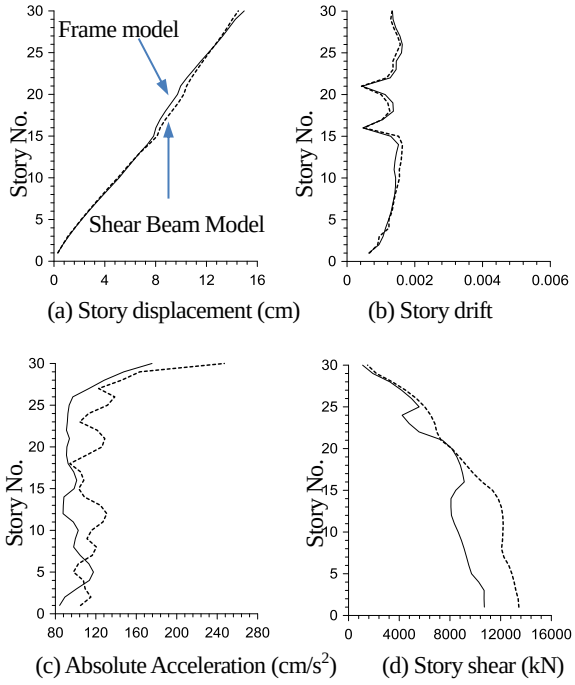

Figure 11. Comparison of maximum response between shear beam model and frame model (PGA=92cm/s^2)

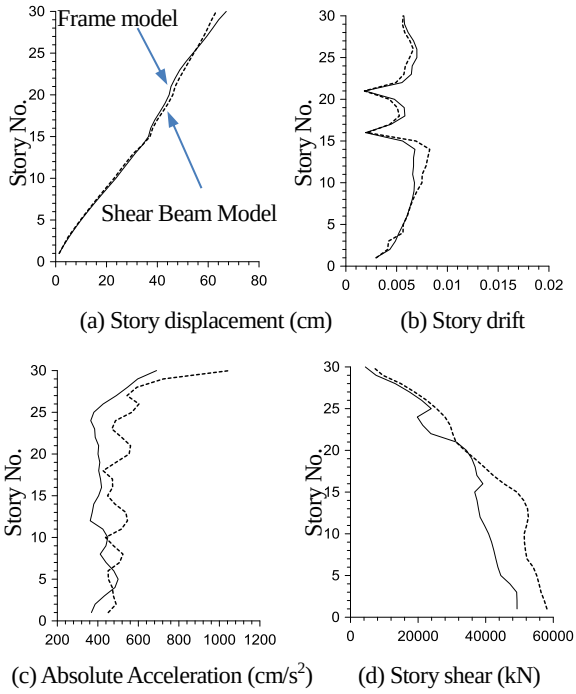

Figure 12. Comparison of maximum response between shear beam model and frame model (PGA=400cm/s^2)

the number of strong cycles as well as root mean square response of the building, which should be beneficial to reduce fatigue of building elements as well as fear of human-being.

4.2 Shear Beam Model Analysis

Fig. 11 shows the comparison of maximum story displacement, story drift, acceleration and story shear between shear beam model and 3D frame model. The displacement and story drift of two models agrees very well. However, the accuracy of acceleration and consequently the story shear are not as good as that of story drift. Figure 12 shows the same 4 kinds of maximum responses for 3D frame model and shear beam model with amplified PGA of 400 cm/s^2. They show the similar comparison results as in Fig.11, and good agreement of story drift is obtained. These results indicate that shear beam model obtained based on the previously described conversion rules is very useful to simulate the structures with added dampers. Through the proposed method, the damper quantity can be theoretically and effectively determined. The shear beam model produce good accuracy with frame model, it can be used to substitute frame model in earthquake response analysis, especially in preliminary design. On the other hand, there is still a little large difference in acceleration response, so further studies such as contribution of modes are also required to improve its accuracy.

5. CONCLUSIONS

The present paper (Part 2) together with the companion paper (Part 1) discussed seismic retrofit methodology using dampers for tall buildings, by considering an example Japanese 29-story steel building that experienced the 2011 Great East Japan Earthquake. The building is instrumented and its acceleration responses during the earthquake were recorded.

The companion paper considered replacement of half number of existing bracings by dampers, and three damper types are considered (Lu et al., 2013). The present paper discusses an alternative design, where existing bracings are retained, and dampers placed elsewhere at half number of building stories, aiming at minimum alterations with good seismic performance. Summary and conclusions are as follows:

(1) The present paper has identified parameters that can indicate effectiveness of passive control based on the frame static stiffness and orientation of dampers therein.

(2) The parameters were used to find suitable story levels and locations for the dampers, after which bilinear oil dampers are selected as an example.

(3) Time history analyses of the 3D frame model with oil dampers are conducted, and considerable improvement of seismic performance is demonstrated in comparison with the analysis and records of the original undamped building.

(4) The parameters identified to characterize the frame and evaluate control effectiveness can also be used to formulate a shear beam model that considerably reduces the degrees of freedom of the frame mode. Reasonable accuracy of the shear model is demonstrated by time history analyses.

Abstract: A building in the town of Augusta in eastern Sicily has recently been constructed using a hybrid base isolation system composed of 16 High Damping Rubber Bearings and 20 Low Friction Sliding Bearings. The building has three stories above the isolation plane and one story beneath it. Laboratory tests on the bearings have been performed by the manufacturers and the results have been used for the definition of a suitable model for the prediction of the behavior of the building under dynamic excitations. In order to make sure that the performance of the installed bearings will reflect the behavior exhibited during the laboratory tests, full scale dynamic tests are planned to be performed on the building by statically imposing a displacement and then suddenly releasing it. The purpose of these experiments, which pose several challenges, is to ascertain several characteristics of the isolation system of the building. The basic challenge is represented by the fact that the building is finished and that therefore no sort of damage can be accepted. The main objective of the simulation is to determine the maximum imposed displacement which causes no non-structural damage to the building. Other objectives include the prediction of the residual displacement after each test, the simulation of the re-centering process after each test, and the prediction of the real and of the apparent static friction force during each test. The blind simulations will serve as guidance in the preparation of the tests.

1. INTRODUCTION

A base isolated building has been recently designed and constructed in the Sicilian town of Augusta using the new Italian technical regulations, D.M. 14/01/2008 (NTC08). It is a reinforced concrete building composed of a story below the ground level, two stories above the ground level and a penthouse on the top, Figure 1.

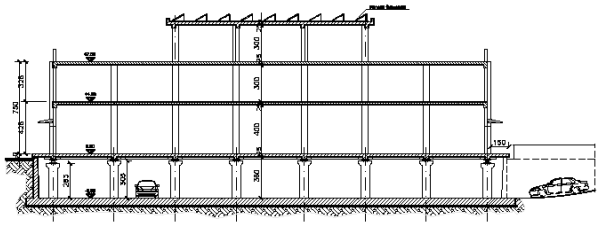

Figure 1 Longitudinal Cross-Section of the Building

The isolation plane runs along the top of the pillars of the basement story slightly above the ground level. The new Italian technical regulations, issued at the beginning of 2008, conclude a phase of evolution of the Italian construction code during which two intermediate documents have been issued in the same decade, O.P.C.M 3274 (2003) and D.M. 14/09/2005. The innovations introduced by the new code essentially consist of a point by point definition of the seismic input, a first attempt to a performance based engineering design and the inclusion of specific chapters dedicated to seismic isolation and supplemental energy dissipation. One of the aims of the present work is to illustrate through a case study the implications of the new code on the structural design of base-isolated buildings. In the Italian tradition all buildings need an independent certification before they are accepted for use. In the present code the certification authority is in charge of deciding whether special tests are needed on a building for the dynamic characterization of the isolation system. The main purpose of the present paper is to carry out a blind simulation of free vibration tests to be performed on the building considered. The simulations of the tests are meant to predict the dynamic behavior of the building so that the tests can be performed effectively and safely.

2. THE AUGUSTA BUILDING

The Augusta building considered was planned and constructed for commercial use. It has a rectangular shape with a length of 35.70 m, a width of 16.00 m and a maximum height above the ground of 10.50 m. The basement story has a free height of 3.60 m. A picture of the part of the building above the ground is shown in Figure 2.

The hybrid seismic isolation system consists of 16 High Damping Rubber Bearings (HDRB) and 20 Low Friction Sliding Bearings (LFSB). The design characteristics of the isolators are specified in Table 1, while the plan distribution is shown in Figure 3.

Figure 2 Picture of the Augusta Building above the Isolation Surface

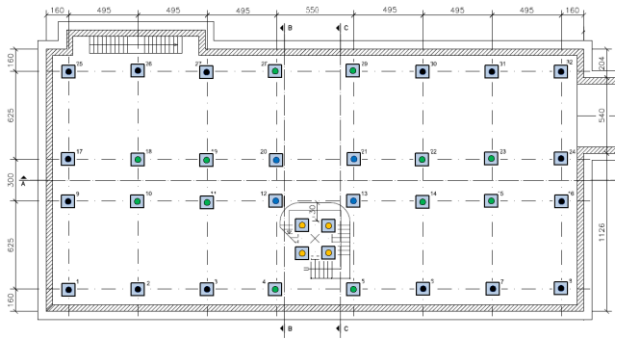

Figure 3 Plan Distribution of the Isolators

Table 1 Technical Requirements for Seismic Isolators

	HDRB : High Damping Rubber Bearings Vertical load in seismic condition 1000 KN Damping ratio at γ=1 ξ=15% Secant horizontal stiffness at γ=1 K_e = 1.00 *kN/mm* Vertical stiffness K_v>800 K_e Horizontal displacement at γ=2 d_c = 300 *mm*

	LFSB : Low Friction Sliding Bearings	
	Load (*kN*)	Displacement (*mm*)
	2000	300
	1500	300
	250	300

3. THE ITALIAN SEISMIC CODE

3.1 Seismic Input

According to NTC08 the seismic input is defined in terms of the geographical coordinates at the building site. For the Augusta building these are Longitude 15.2135° E and Latitude 37.2508° N. The seismic input at the site also depends on the limit state considered for the building. The Italian technical regulations consider two serviceability and two ultimate limit states. The two serviceability limit states are denoted respectively as Operational (SLO) and Damage (SLD) limit states. The two ultimate limit states are the Life safety (SLV) and the Collapse prevention (SLC) limit states. For each limit state and a reference life of the building, a probability for the seismic action to be exceeded is provided, as shown in Table 2.

Table 2 Probability P_{Vr} for the Seismic Action to be exceeded during the reference life V_R

Limit states		P_{Vr}
Service limit states	SLO	81%
	SLD	63%
Ultimate limit states	SLV	10%
	SLC	5%

The reference life V_R of the building is obtained by multiplying the nominal life V_N by a usage coefficient C_U depending on the class of importance of the building. The Italian technical regulations consider four usage classes shown in Table 3.

Table 3 Values of the Usage Coefficient C_U

Usage Class	I	II	III	IV
C_U	0.7	1.0	1.5	2.0

The owner of the building at hand chose the usage class III. This class includes buildings whose seismic resistance is important in view of the consequences associated with a collapse. Among these are schools, assembly halls, cultural institutions etc. The nominal life V_N of various types of constructions is specified by Italian technical regulations as shown in Table 4.

Table 4 Nominal Life for Various Construction Types

	Construction type	Nominal life V_N (years)
1	Provisional structures, temporary structures, structures in the construction phase.	≤ 10
2	Standard structures, bridges, infrastructures and dams of normal importance	≥ 50
3	Large structures, bridges, infrastructures and dams of large size and strategic importance	≥ 100

The building considered belongs to the second construction type of the classification above and its nominal life was chosen to be V_N=50 years. The reference life for the Augusta building is therefore $V_R = C_U \cdot V_N = 1.5 \cdot 50$ years =75years. The building reference life V_R is used for the calculation of the return period T_R, for each of the limit states specified in Table 2, through the following formula:

$$T_R = -\frac{V_R}{\ln(1 - P_{V_R})} \qquad (1)$$

For the four limit states specified in Table 2 the return periods are given in Table 5.

Table 5 Return Periods for the Augusta building

	SLO	SLD	SLV	SLC
T_R(years)	45	75	712	1462

In the Italian technical regulations the response spectrum as a function of the return period is given in terms of three parameters that for the case considered take the values provided in Table 6. The three parameters specified in Table 6 for the building considered and for each of the limit states are the maximum ground acceleration a_g, the maximum amplification of the horizontal spectral acceleration F_o and the separation period T_c^* between the acceleration and velocity sensitive regions of the response spectrum for firm soil.

Table 6 Response Spectrum Parameters for the Augusta Building (V_R=75 years, Long. 15.2135° E, Lat. 37.2508° N)

	SLO	SLD	SLV	SLC
a_g/g	0.057	0.076	0.286	0.408
F_o	2.512	2.493	2.314	2.348
T_c^* (s)	0.267	0.289	0.447	0.499

The characteristic periods of the response spectrum are defined in terms of the period T_c^* and of an additional parameter C_c depending on the soil properties as follows:

$$T_C = C_C \cdot T_C^*; \quad T_B = \frac{T_C}{3}; \quad T_D = \frac{4a_g}{g} + 1.6 \tag{2}$$

The soil classification of the Italian technical regulations complies with the Eurocode 8 standards and defines subsoil classes A, B, C, D and E. The building considered is on a site of class B and the parameter C_C takes the expression $C_C = 1.10 \cdot (T_c^*)^{-0.20}$. In order to be able to define the spectral acceleration an additional parameter is required in the characterization of the soil and topographical conditions. This parameter is given by the expression $S=S_S \cdot S_T$. For a soil of class B the subsoil coefficient S_S is provided by the formula:

$$1.00 \le S_S = 1.40 - 0.40 F_0 \frac{4a_g}{g} \le 1.20 \tag{3}$$

The topographical coefficient S_T for the site at hand is equal to 1.0 (flat topography). The elastic design spectrum is finally given in terms of pseudo spectral acceleration as follows:

$$\begin{aligned}
&S_e(T) = a_g \cdot S \cdot \eta \cdot F_o \cdot \left[\frac{T}{T_B} + \frac{1}{\eta \cdot F_o} \left(1 - \frac{T}{T_B} \right) \right], && 0 \le T \le T_B \\
&S_e(T) = a_g \cdot S \cdot \eta \cdot F_o, && T_B \le T \le T_C \\
&S_e(T) = a_g \cdot S \cdot \eta \cdot F_o \cdot \left(\frac{T_C}{T} \right), && T_C \le T \le T_D \\
&S_e(T) = a_g \cdot S \cdot \eta \cdot F_o \cdot \left(\frac{T_C T_D}{T^2} \right), && T_D \le T
\end{aligned} \tag{4}$$

The parameter η in Equations (4) accounts for damping and is defined by the following formula:

$$\eta = \sqrt{10/(5+\xi)} \tag{5}$$

where ξ is given in percentage and depends on the type of materials, soil, and structure.

3.2 Design Spectrum for Base Isolated Buildings

For ordinary structures the design spectrum is obtained from the elastic spectrum provided by Equations (4) by replacing the damping parameter η with the reciprocal of the strength reduction factor q, that is $\eta=q^{-1}$. This factor depends on materials and construction types and is specified in a particular section of the code. For base-isolated structures the code states that the substructure and the superstructure must be designed to behave elastically. For reinforced concrete structures this implies a strength reduction factor $q=1.5$.

This spectrum is further modified in the period range $T \ge 0.80 T_{is}$, T_{is} being the fundamental period of the base-isolated building. In this range the parameter η takes the value corresponding to the damping ratio of the isolation system, Equation (5). The parameters required for the full definition of the response spectra of the various limit states are given in Table 7, calculated according to the formulae previously specified.

Table 7 Spectral Parameters for the Augusta Building

Limit State	S	T_C (s)	T_B (s)	T_D (s)
SLO	1.200	0.382	0.127	1.828
SLD	1.200	0.407	0.136	1.904
SLV	1.135	0.578	0.193	2.744
SLC	1.017	0.631	0.210	3.232

As shown in the following section 3.3, the fundamental period of the Augusta building is T_{is}= 2.38*s*. The design spectra for the building are shown in Figure 4. The evident jump in spectral values in Figure 4 is needed to account for the different response behavior between the isolation and the structural modes.

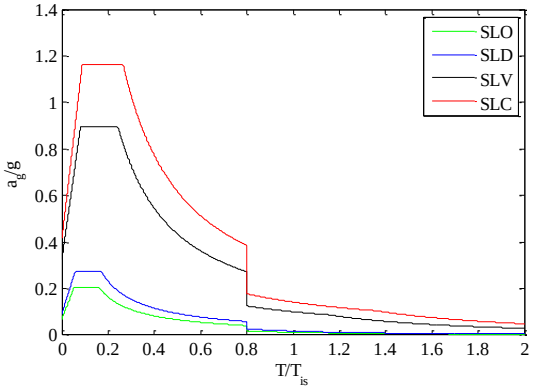

Figure 4 Elastic Spectra for the Augusta Building

3.3 Preliminary Design

The Italian seismic code for base isolated buildings requires that the isolation period (fundamental period of the base isolated building) be in the range $3T_{bf} \leq T_{is} \leq 3s$, T_{bf} being the period of the same structure on fixed base. This period may be calculated using the empirical formula $T_{bf}=C \cdot H^{0.75}$, where C is a coefficient depending on the type of construction and H is the height of the building expressed in meters, provided that it is less than 40*m*. For reinforced concrete framed buildings C=0.075 and so for the Augusta building it follows that

$$T_{bf}=0.075 \cdot (10.5)^{0.75}=0.44\ s$$

Therefore the seismic code suggests that the isolation period for the Augusta building be in the range $1.32s \leq T_{is} \leq 3s$. The actual isolation period is then a compromise between the value selected by the designer and the availability of commercial isolation bearings with the required stiffness. In the case at hand a reasonable period was T_{is}=2.40*s*. The required horizontal stiffness for the isolation system is therefore provided by the formula

$$K_{esi} = \frac{4\pi^2 \mathrm{M}}{\mathrm{T}_{is}^2} \qquad (6)$$

where M is the mass of the building above the isolation plane. For the case at hand, where M=2400 *tons*, the required overall stiffness is 16.45 *kN/mm*. The designer, in view of the plan presented in Figure 3, decided for the distribution of elastomeric bearings shown in Figure 5.

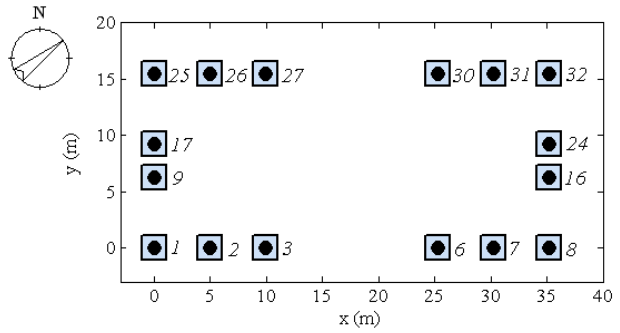

Figure 5 Distribution of High Damping Rubber Bearings for the Augusta Building.

The Italian manufactures of High Damping Rubber Bearings (HDRB) provide catalogs of bearings for maximum displacements in the range of 100 *mm* to 400 *mm*, assuring damping ratios of 0.10 or 0.15 at a shear strain of γ=1, FIP Industriale SpA (2006). The damping ratio decreases of about 12% the nominal value when the shear strain reaches γ=2.

The displacement at the collapse prevention limit state can be calculated by the following formula:

$$d_{dc} = \left(\frac{\mathrm{T}_{is}}{2\pi} \right)^2 S_e^{SLC} \left(\mathrm{T}_{is}, \xi_{esi} \right) \qquad (7)$$

If a damping ratio ξ_{esi} = 0.15 is used and large strains are assumed at the collapse prevention limit state, then introducing the reduced damping ratio $\xi_{esi,min}$ = 0.132 in Equation (7) leads to the following value for the displacement:

$$d_{dc}(2.40,0.132)=272mm$$

For economic reasons related to device testing, the HDRB where chosen of the same size. Therefore the required horizontal stiffness for the HDRB is 16.45/16 *kN/mm* = 1.03*kN/mm*. In the catalog provided by the manufacturer the isolator with the nearest horizontal stiffness is the type SI-N500/150 which has the geometrical and mechanical characteristics shown in Table 8.

Table 8 Characteristics of Isolator SI-N500/150

Characteristic	*Value*	*Units*
External diameter of isolator	500	*mm*
Diameter of internal steel shims	480	*mm*
Thickness of steel shims	3	*mm*
Number of rubber layers	25	
Thickness of a single rubber layer	6	*mm*
Total thickness of the rubber	150	*mm*
Primary shape factor S_1	20	
Secondary shape factor S_2	3.2	
Total height with cover plates	312	*mm*
Seismic vertical load capacity	1200	*kN*
Maximum horizontal displacement	300	*mm*
Vertical stiffness K_V	1016	*kN/mm*
Horizontal stiffness K_e	1.05	*kN/mm*
Equivalent viscous damping ξ_e at shear deformation γ=1	15	%

The total horizontal stiffness of the isolation system is therefore K_{esi} =16.8 *kN/mm* and the isolation period turns out to be T_{is}=2.38*s*. The displacement evaluated according to Equation (7) is

$$d_{dc}(2.38,0.132) = 269\ mm$$

3.4 Modeling Base Isolated Structures

The superstructure and the substructure are modeled as linear elastic systems. The isolation system can be modeled, according to its mechanical characteristics, as a linear viscous-elastic system or as a system with non-linear constitutive behavior. The vertical deformability of the isolators must be accounted for when the ratio of the vertical stiffness of the isolation system K_v to the equivalent horizontal stiffness K_{esi} is less than 800. If a linear model is adopted, then the equivalent stiffness must be referred to the total design displacement at the considered limit state, for each isolation device belonging to the isolation system. The energy dissipated by the isolation system must be expressed in terms of a viscous equivalent damping ratio ξ_{esi} evaluated with reference to vibration cycles within the interval of the natural frequencies of the isolation modes. For

the higher structural modes the damping ratios of the complete model must be those of the superstructure on fixed base. When the equivalent stiffness and/or damping ratio depend significantly on the design displacement, an iterative procedure must be applied.

The behavior of the isolation system can be modeled as linear equivalent if the following conditions are satisfied:

a) The equivalent stiffness of the isolation system is at least equal to 50% of the secant stiffness for cycles with displacement amplitude equal to 20% of the reference displacement.
b) The equivalent linear damping ratio of the isolation system must be less than 30%.
c) The load-displacement characteristics of the isolation system do not vary more than 10% due to variations in the strain velocity in a range of $\pm 30\%$ about the design value, and to the vertical loads in the design variability range.
d) The increase of the restoring force in the isolation system, for displacements between $0.5d_{dc}$ and d_{dc}, is not less than 2.5% of the total gravity load above the isolation system.

If a non-linear model is adopted, the constitutive law for the individual isolation devices must adequately describe their behavior in the strain and velocity ranges that occur during seismic action. The model considered must also provide a correct estimate of the energy dissipated during the earthquake motion.

3.5 Linear Static Analysis

The linear static analysis can be applied to base-isolated structures if some basic requirements are satisfied. The most important are the following:

a) The isolation system can be modeled as an equivalent linear viscous system.
b) The period of the isolated structure is in the range $3T_{bf} \le T_{is} \le 3\ s$.
c) The vertical stiffness K_V of the isolation system is not smaller than 800 times the equivalent horizontal stiffness of the isolation system K_{esi}.
d) The period of the isolation system in the vertical direction must be smaller than 0.1 *s*.
e) No isolator must be in tension under the combined seismic and gravity action.
f) The structural configuration must be regular in plan.
g) The height of the building must be less than 20 *m* and the number of stories less than 6.
h) The period of the substructure must not be larger than 0.05 *s*.
i) The maximum plan dimension of the structure cannot be larger than 50 *m*.
j) In each principal direction, the eccentricity of the center of mass with respect to the center of rigidity of the isolation system cannot be larger than 3% the size of the structure in the direction transversal to the considered one.

If the above conditions are satisfied, the total force to be applied to the isolation system is given by the formula

$$F = M \cdot S_e(T_{is}, \xi_{esi}) \tag{8}$$

where $S_e\ T_{is}, \xi_{esi}$ is the spectral acceleration specified by Equation (4).

The displacement of the center of rigidity due to the seismic action d_{dc} must be calculated through the formula

$$d_{dc} = \frac{M \cdot S_e(T_{is}, \xi_{esi})}{K_{esi,\min}} \tag{9}$$

where $K_{esi,min}$ is the minimum equivalent stiffness considering variability of the mechanical properties of the isolation system due to various factors such as strain amplitude, manufacturing and material uncertainties, maximum strain velocity, amplitude of gravity forces acting simultaneously to the seismic action, temperature, aging, etc.

The horizontal forces to be applied at each story of the superstructure must be calculated for each horizontal direction by using the following expression:

$$f_j = m_j \cdot S_e(T_{is}, \xi_{esi}) \tag{10}$$

where m_j is the mass of story *j*.

Torsional effects of the superstructure on individual isolation devices may be accounted for by amplifying in each direction the displacements and forces given above by the following factors δ_{xi} and δ_{yi}:

$$\delta_{xi} = 1 + \frac{e_{tot,y}}{r_y^2} y_i; \quad \delta_{yi} = 1 + \frac{e_{tot,x}}{r_x^2} x_i \tag{11}$$

where (x_i, y_i) are the coordinates of the isolation device considered with respect to the center of rigidity; $e_{tot,x}$ and $e_{tot,y}$ are the total eccentricities (permanent + accidental) in the direction *x* and *y* respectively; r_x and r_y are the components in the *x* and *y* directions of the radius of gyration of the isolation system:

$$r_x^2 = \frac{\sum_i \left(x_i^2 K_{yi} + y_i^2 K_{xi} \right)}{\sum_i K_{yi}}; \quad r_y^2 = \frac{\sum_i \left(x_i^2 K_{yi} + y_i^2 K_{xi} \right)}{\sum_i K_{xi}} \tag{12}$$

In Equations (12) K_{xi} and K_{yi} are the stiffness of the isolation device "*i*" in the directions *x* and *y* respectively.

3.6 Linear Dynamic Analysis

Linear dynamic analysis is admitted for base-isolated structures when the behavior of the isolation system can be modeled as elastic. For the complete system composed of the substructure, the isolation system and the superstructure a linear elastic behavior is assumed. The model must include the substructure any time the isolation system is not right above the foundation. Modal decomposition and response

spectrum analysis can be performed or step-by-step integration of` the equations of motion, possibly after modal decoupling. When the substructure is included in the model, a sufficient number of modes must be considered in the analysis to account for a significant part of its mass.

The two horizontal components of the seismic action must be considered as acting simultaneously, using prescribed combination rules. The vertical component of the ground motion must be accounted for any time the ratio of the vertical to the horizontal stiffness of the isolation system is $K_v/K_{esi} < 800$. In such cases a number of vertical modes have to be considered in the analysis to excite vertically a significant part of the system mass.

When the step-by-step integration of the equations of motion is performed, the correct value of the equivalent viscous damping ratio can be introduced directly in the modal equations, if modal decoupling is used, or by providing the appropriate damping matrix if integration is performed on the coupled system.

NTC08 totally ignores the fact that the equations of motion for base-isolated structures are not classically damped and that modal decoupling is only possible if complex modes are used. No information is provided on whether to use complex modes or to neglect modal coupling. However it is reasonable to assume that approximate modal uncoupling is suggested by neglecting the coupling terms.

3.7 Safety Checks

Serviceability Limit States. Safety checks are prescribed with reference to both the serviceability limit states and the ultimate limit states. Of the two serviceability limit states, only the Damage Limit State (SLD) is considered. For the superstructure it is required that the story drifts be less than 2/3 of the bound prescribed for fixed base structures in the SLD limit state. For reinforced concrete structures such bound is 0.005 for in-fills rigidly connected to the structural members and 0.01 for in-fills designed in such a way that they are not damaged by structural drifts.

The isolation devices must not undergo damage that compromises their correct functioning under service conditions. These conditions are considered to be satisfied and the checks omitted if the requirements for the Life Safety Limit State (SLV) are satisfied. In the case of systems with non-linear behavior, residual displacements at the end of an SLD earthquake must be compatible with the functionality of the construction. Under an SLD earthquake, all connections, whether between the isolated structure and the ground or between isolated and non-isolated parts of the structure, must be able to absorb relative displacements with no damage or usage limitations.

Ultimate Limit States

Life Safety Limit State. For the Life Safety Limit State (SLV) the substructure and the superstructure must be verified with the same material safety factors γ_m used for non-isolated structures. If the substructure is included in the analysis, the structural elements of the substructure must be verified with respect to the stress resultants obtained directly from the analysis. If not they must be verified with respect to the forces transmitted by the isolation system combined with the stress resultants due to the accelerations directly applied by the ground motion to the substructure. When the substructure can be considered as rigid (natural period less than 0.05*s*) the inertia forces applied to the substructure may be taken equal to the mass multiplied by the ground acceleration. The combination of the stress resultants can be carried out using the SRSS rule.

The strength of the structural members of the superstructure can be verified by considering the effects of the seismic action divided by q=1.5 combined with the other actions using the combination rules specified for non-isolated structures.

In the conditions of maximum stress, the parts of any device that are not directly involved in the dissipation of energy must remain elastic in conformity with the standards for the constituent materials and a safety factor of at least 1.5.

For constructions of usage class IV (maximum seismic protection) structural and non-structural connections between the isolated structure and the ground or non-isolated parts of the structure, particularly those concerning equipment, must absorb the relative displacements deriving from the analysis with no damage.

Collapse Prevention Limit State. The isolation devices must be able to avoid ruptures when undergoing the displacements d_2 evaluated for an earthquake having a probability of being exceeded equal to that expected for the Limit State of Collapse Prevention (SLC). In the case of systems with non-linear behavior the maximum displacement must be calculated by adding that due to the considered seismic action and the largest between the residual displacement at the SLD and the displacement corresponding to the vanishing of the restoring force along the unloading branch starting from the maximum displacement at SLD.

In all constructions, the gas connections and the connections of any dangerous equipment crossing the separation joints must be designed to allow the relative displacement of the isolated superstructure with the same safety factor adopted for the isolation system.

3.8 Acceptance Tests for Elastomeric Bearings

NTC08 prescribe qualification and acceptance tests for elastomeric bearings. The qualification tests are more detailed and severe than acceptance tests and shall not be considered herein. The requirements of the acceptance tests will be briefly described because the results of these tests will be used in the following.

The acceptance tests on the isolation devices are performed with the same methodology used for the qualification tests. The devices are considered acceptable whenever they satisfy the requirements specified below and the static shear modulus G does not differ more than $\pm 10\%$ from the value obtained from the qualification tests.

a) The external geometry must satisfy the prescriptions of the standards on bearing devices. For isolators taller than 100 *mm* the height

tolerance is 6 *mm*.

b) Evaluation of the static vertical stiffness between 30% and 100% of the vertical load V.

c) Evaluation of the static shear modulus G, or alternatively, of the dynamic shear modulus G_{din}, by the same methodology adopted for the qualification tests. Whenever possible, it is preferable to evaluate the dynamic shear modulus G_{din} because it reduces uncertainties on the control of the real dynamic behavior of the device.

d) Evaluation of the effectiveness of the steel-rubber adhesion by the same methodology used for the qualification tests but adopting the value corresponding to the displacement d_2 for the strain γ.

The acceptance tests must be performed on at least 20% of the devices and in any case on not less than 4 and not more than the total number of the devices to be used on site.

4. MODELING LABORATORY TESTS

Two series of acceptance tests were performed by the manufacturer on the isolators used in the Augusta building, one for the rubber bearings and another for the sliding bearings.

4.1 Rubber Bearings

Vertical Stiffness. In conformity with the acceptance tests specified by NTC08, four elastomeric bearings were tested for the evaluation of the vertical stiffness. The values of the vertical stiffness obtained were (1167, 1316, 1566, 1299) *kN/mm*, FIP Industriale SpA (2009-a). Since the design requirements were $K_v > 800K_e$ = 840 *kN/mm*, the acceptance tests for the vertical stiffness are amply satisfied.

Static Horizontal Stiffness. Again four elastomeric bearings were tested for the evaluation of the static shear modulus G. The testing facility allows for the testing of two isolators in parallel and therefore the results are the average properties of the couple of isolators considered. The cyclic tests were performed at a peak shear strain $\gamma = 1$ providing at the third cycle the stress-strain curve shown in Figure 6.

The static shear modulus was evaluated by the manufacturer from the curve in Figure 6 according to EN 1337-3 (2005) and resulted equal to 0.48*MPa*. Such value is in fact a tangent shear modulus but the manufacturer also calculated a secant shear modulus at $\gamma = 1$ equal to 0.65*MPa*. A bilinear identification of the stress-strain curve shown in Figure 6 led to the parameters k_o, k_1, Q for the device, (Naeim and Kelly 1999).

For the second couple of isolators (IT752E, IT753E) the measured static shear modulus was 0.51*MPa*, the secant static shear modulus at $\gamma = 1$ was 0.69*MPa*, while the identified parameters for the bearings were k_o = 3521 *N/mm*, k_1 = 708 *N/mm*, Q = 28 *kN*.

Dynamic Horizontal Stiffness. Four elastomeric bearings were tested for the evaluation of the dynamic shear modulus G_{din}. For each couple of isolators five sinusoidal cycles with peak strain $\gamma = 1$ were applied at a frequency of

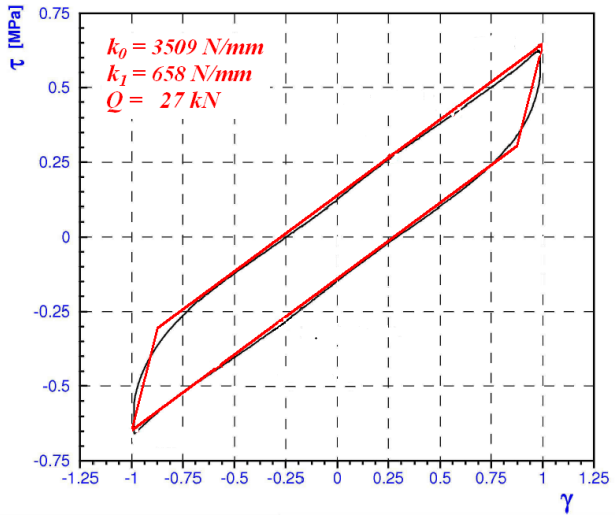

Figure 6 Third Cycle Static Stress-Strain Curve for Isolators IT421E and IT404E

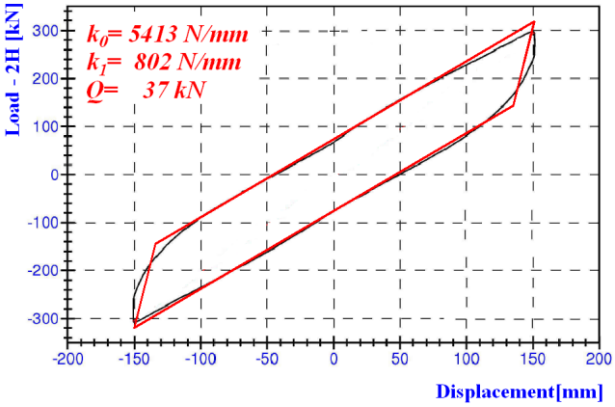

Figure 7 Third Cycle Load-Displacements Curve for Isolators IT421E and IT404E

0.5 *Hz*. The load-displacement curve obtained for the third cycle is shown in Figure 7. From the load-displacement curve in Figure 7 the manufacturer evaluated the secant stiffness K_e = 1.0 *kN/mm* at $\gamma = 1$ and the energy dissipated in the cycle W_d = 21097 *J*. From the above values the dynamic shear modulus G_{din}=0.77 *MPa* and the damping ratio ξ_e = 14.8% were derived. From the test performed on the second couple of isolators (IT752E, IT753E) the following parameters were evaluated: K_e =1.05 *kN/mm*, W_d = 22588 *J*, G_{din} = 0.81 *MPa*, ξ_e = 15%.

The bilinear identification of the isolation bearings led to the following sets of parameters: (k_o = 5413 *N/mm*, k_1= 802 *N/mm*, Q= 37 *kN*) for isolators IT421E and IT404E and (k_o=6199 *N/mm*, k_1= 847 *N/mm*, Q = 40 *kN*) for isolators IT752E and IT753E.

Adhesion Tests. The adhesion acceptance tests mentioned at point d) of section 3.8 were performed in couples on all isolators. A typical test result is shown in Figure 8.

In principle the adhesion test on only four isolators would have been sufficient for the acceptance of the total supply of sixteen SI-N500/150 elastomeric isolators.

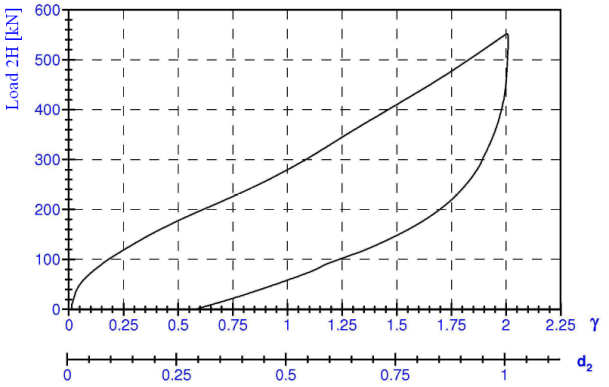

Figure 8 Load-Displacement Curve for Isolators IT421-404 during Adhesion Test at displacement d_2=300*mm*

However, the adhesion acceptance test on a previous batch of isolators failed and therefore every isolator of the new batch was tested for adhesion by autonomous decision of the manufacturer.

4.2 Sliding Bearings

One couple of each of the three types of sliding bearings used in the Augusta building has been tested simultaneously for the evaluation of the friction coefficient, FIP Industriale SpA (2009-b). The tests were performed at a velocity of 4 *mm/s* and at 0.5 V_{max}, 0.75 V_{max} and V_{max}, where V_{max} is the maximum vertical load. The results are shown in Figure 9.

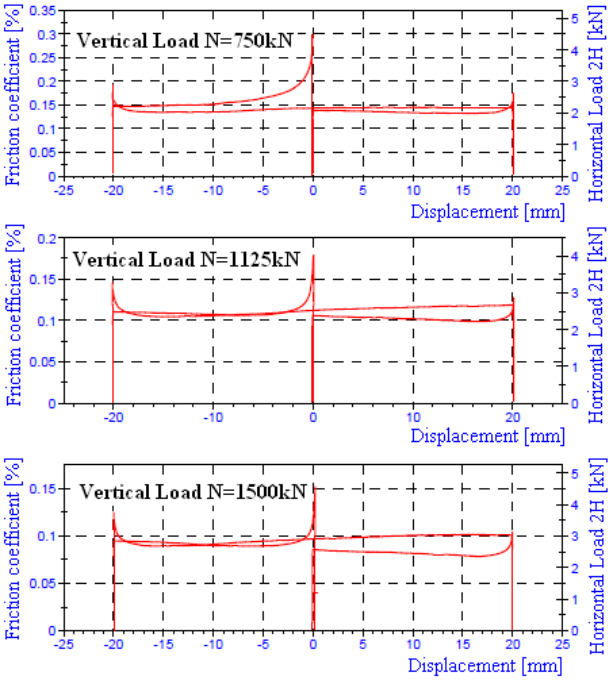

Figure 9 Friction Coefficient for the Sliding Isolators VM 150/600/600 at 0.5 V_{max}, 0.75 V_{max} and V_{max} maximum vertical load

The start-up friction coefficient for the isolators considered varies from a maximum of 0.3% when the vertical load is 0.5 V_{max} to a minimum of 0.15% under V_{max}. The dynamic friction coefficient ranges from a maximum of 0.15% to a minimum 0.09%. Such exceptionally low values of the friction coefficient are due to the lubrication of the PTFE and, in the case of the dynamic friction coefficient, to the very low testing velocity.

5. DISPLACEMENTS ESTIMATES

NTC08 prescribes the evaluation of displacements by means of an iterative procedure when the stiffness and/or the damping ratio of the isolation system depend significantly on the design displacement. By using the two bilinear models derived from the laboratory tests, the suggested iterative procedure leads to the results shown in Table 9. The corresponding displacements, calculated using the linear equivalent model suggested by NTC08, are shown in Table 10.

Table 9 Displacements of the Center of Rigidity of the Isolation System for Four Different Earthquake Levels based on two Bilinear Models

Model 1	*Q (kN)*	*k_0 (N/mm)*	*k_1 (N/mm)*	*D_y (mm)*
	37	5413	802	8.02
	SLO	SLD	SLV	SLC
T(s)	1.29	1.47	2.46	2.56
ξ (%)	20	26	11	7
D (mm)	13	19	209	354
γ (%)	9	13	140	236
Model 2	*Q (kN)*	*k_0 (N/mm)*	*k_1 (N/mm)*	*D_y (mm)*
	40	6199	847	7.47
	SLO	*SLD*	*SLV*	*SLC*
T(s)	1.21	1.39	2.38	2.48
ξ (%)	20	27	12	8
D (mm)	12	18	198	336
γ (%)	8	12	132	224

Table 10 Displacements of the Center of Rigidity of the Isolation System calculated using an Equivalent Linear Model suggested by NTC08

NTC 08	*SLO*	*SLD*	*SLV*	*SLC*
T(s)	2.38	2.38	2.38	2.38
ξ (%)	15	15	15	15
D (mm)	21	31	181	257
γ (%)	14	21	121	171

The linear equivalent model suggested by the Italian code NTC08 underestimates the displacements at the limit states SLV and SLC, while it overestimates the displacements at the limit states SLO and SLD. The discrepancies are due to the fact that the damping ratio and the stiffness of the isolation system are considered constant and equal to the values established at the shear strain amplitude $\gamma = 1$. Better results are obtained if the equivalent secant stiffness K_e and the equivalent damping ratio ξ_e are

Table 11 Modified Linear Equivalent Model for the calculation of the System Displacements at various Limit States

NTC 08	SLO	SLD	SLV	SLC
T(s)	2.38	2.38	2.38	2.38
ξ (%)	12	12	12	12
D (mm)	23	34	197	279
γ (%)	15	22	131	186

calibrated at the displacement of the system under the SLV earthquake. In this case the results shown in Table 11 are obtained.

By comparing the results of Table 9 with those of Table 11 it may be seen that the displacements under the SLV earthquake are very close to each other. As it may have been expected the displacement under the SLC earthquake is still underestimated and those under the SLO and SLD earthquakes are overestimated. However, the underestimation under the SLC earthquake might not be a serious matter because the bilinear model may be unreliable under such an earthquake. In fact the tangent stiffness is expected to increase under large shear strains and this is not accounted for by the bilinear model. The overestimation of the SLD displacement is balanced in part by the underestimation of the stiffness and in part by a code prescription which requires the drift at the SLD to be less than two thirds of the value accepted for fixed base structures. No verification is required by the code for the SLO earthquake.

6. SIMULATION OF FREE VIBRATION TESTS

For the simulation of the free vibration tests to be performed on the Augusta building in the near future, the formulation presented by (Oliveto et al. 2012) is being used. The main parameters required for the analysis are the three parameters defining the behavior of the HDRB Q, k_0, k_1, and the friction coefficient for the characterization of the sliding bearings. Ideally, the parameters for the characterization of the HDRB could be specified for each isolator and the same applies for the friction coefficient of the sliding isolators. However, as shown in Table 9, only average data are available for two couples of HDRB. If the average values from the two sets were to be taken, the properties would be the average taken over four samples out of sixteen. Since no other data is available, the average properties chosen from Table 9 are used for simulation purposes, that is Q= *38.5 kN*, k_0= *5806 N/mm*, k_1= *824.5 N/mm*. The friction coefficients provided by the manufacturer for the LFSB were evaluated at very low testing velocities and appear to be too low for working conditions applications. For this reason the information obtained by identification of the Solarino Buildings isolation system is used, (Oliveto et al. 2010). The average friction coefficient from those tests was μ *=0.8 %*. The values of the vertical load for the evaluation of the friction force in the expected test conditions were taken as follows: 750 *kN*, 900 *kN*, 25 *kN* in the order of load bearing capacity of each type of sliding isolator.

6.1 Choice of Initial Test Displacements

The Augusta building shown in Figure 2 is architecturally finished and therefore no structural or non-structural damage must be produced by the tests planned. The internal and external partition walls have been designed and constructed with a fixed connection to the structural members. The Italian code NTC08 prescribes a drift limit of 0.5% to ensure that no non-structural damage can occur when the in-fills are rigidly connected to the structure. The purpose of the present analysis is to evaluate the maximum initial displacement that can be imposed to the building so that the drift limit is not exceeded during the phase of free vibration following the sudden release of the force used to impose the displacement. For safety reasons several tests will be performed under increasing initial displacement. Apart from the need to avoid damage, two other factors limit the maximum displacement that can be applied. One is related to the capacity of the available equipment in terms of force, stroke and strength of the contrast wall. The other is connected to the validity of the bilinear model which is expected to fail at large strain amplitudes. Therefore a suitable test protocol is given in Table 12.

Table12 Initial Strain and Displacement for Planned Tests

Strain amplitude γ(%)	Initial Displacement (mm)
20	30
50	75
80	120
100	150
120	*180*
140	*210*

6.2 Effects of the Friction Coefficient on Test Response

The friction coefficient is a main uncertainty in the evaluation of the test response because of the discrepancies between the results of the available laboratory tests, obtained under very low testing velocities and displacement amplitude, and the results deriving from full scale dynamic identification tests. For this reason a test has been simulated using different friction coefficients ranging from 0.2% to 1%. The results of the simulation are shown in Figure 10 in terms of displacement and in Figure 11 in terms of velocity.

The main effects of an increasing friction coefficient appear to be a reduction of the duration of motion and an increase of the residual displacement. When the largest friction coefficient is considered the system comes to rest after only 2 cycles, while when the lowest friction coefficient is used the motion of the system stops after 6 cycles. However, it should be noticed that only two cycles of motion involve energy dissipation in the HDRB. In the remaining cycles, according to the bilinear model, the behavior is purely elastic. The full scale dynamic tests to be performed on the Augusta building in the near future should provide a realistic value of the friction coefficient under seismic conditions.

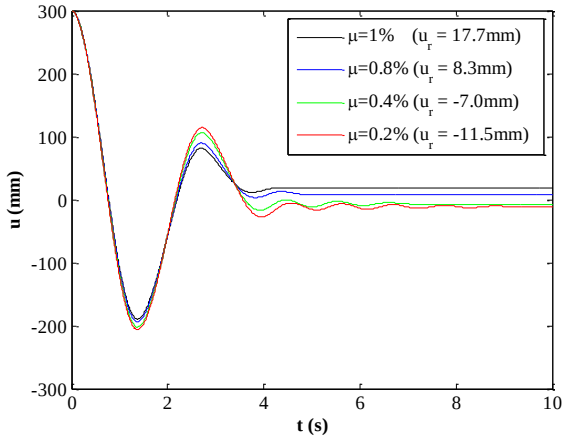

Figure 10 Displacement Response as a function of the Friction Coefficient

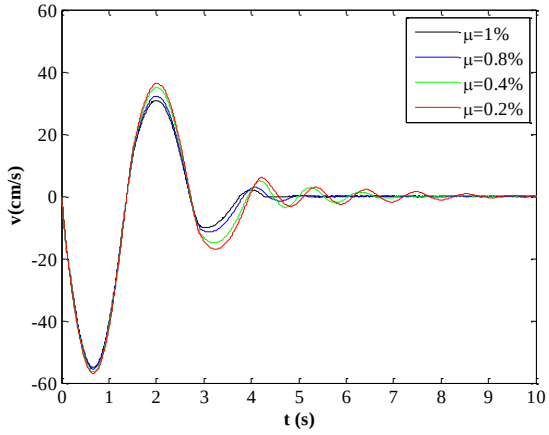

Figure 11 Velocity Response as a function of the Friction Coefficient

6.3 Application of Initial Displacement

The planning of free vibration tests under imposed initial displacements requires the evaluation of the static load needed to apply the considered displacement. The load-displacement curve for the Augusta building shown in Figure 12 has been evaluated using a bilinear model for the HDRB with the properties derived by the static laboratory tests described in section 4.1, namely k_0= 3515 *N/mm*, k_1= 683 *N/mm*, *Q*=28*kN*. For the friction coefficient the value μ=0.8% has been used.

The value of the friction force which must be overcome for the building to start moving has been evaluated as 111 *kN*, using the friction coefficient μ = 0.8%. Whether this value is realistic or not will be assessed when the tests are performed. The experience gained with the tests on the Solarino building shows that the considered value of the friction coefficient may be underestimated in static conditions. However, as the building starts to move the friction coefficient is expected to shift from the static value to the dynamic one. Therefore the use of the dynamic coefficient will underestimate the static friction force but might provide a good estimate of the force required to apply the considered displacement. The table in Figure 12 provides the force

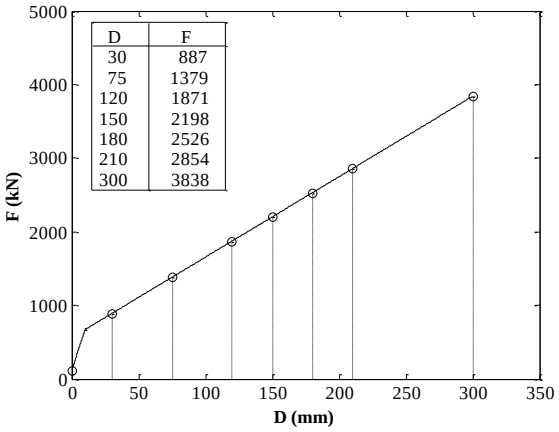

Figure 12 Static Load Displacement Curve for the Augusta Base Isolation System

required to apply a given displacement and is essential for the planning of the tests. The same push and quick release device used in the Solarino tests will be used for the Augusta building. A description of the device and of the preliminary results of the tests on the Solarino building has been given by Oliveto et al. (2004).

6.4 Effect of Initial Displacement on System Response

The amplitude of the initial displacement can considerably affect the response of the system as the results of Figure 13 show for the case when no mass eccentricity is considered. Response histories can be easily obtained also in terms of velocity, acceleration and of any other response parameter. Some typical response parameters are shown in Table 13.

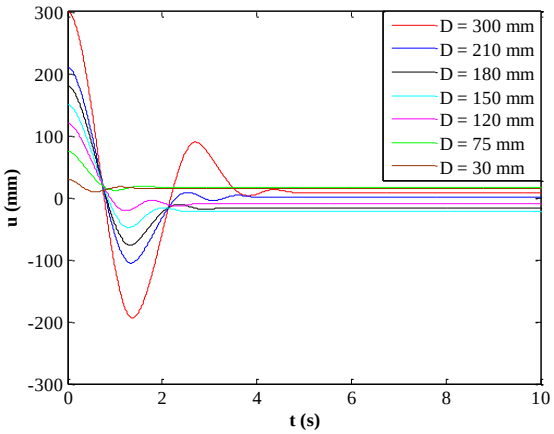

Figure 13 Free Vibration Response of the Isolation System as a function of the Imposed Initial Displacement

As expected the peak values of velocity and acceleration increase as the initial displacement increases. The initial period (T_1) and the time required for the motion to stop (t_r) are also increasing functions of the initial displacement. The residual displacement (u_r) does not show a characteristic pattern. The largest value (u_r = 21.2 *mm*) is obtained with an initial displacement *D* = 150 *mm* and the

Table13 Variation of System Response Parameters with Displacement Amplitude in the Absence of Mass Eccentricity

D (*mm*)	*peak v* (*cm/s*)	*peak a* (*gal*)	T_1 (*s*)	u_r (*mm*)	t_r (*s*)
30	5.7	33.8	1.115	14.6	1.650
75	9.6	56.3	1.550	16.6	2.080
120	16.9	78.7	1.780	-9.1	2.850
150	22.9	93.7	2.035	-21.2	3.090
180	29.3	108.7	2.355	-16.0	3.420
210	35.7	123.7	2.540	0.3	4.130
300	55.5	168.6	2.710	8.3	4.950

smallest (u_r = 0.3 *mm*) is obtained for an initial displacement of D = 210 *mm*.

When the accidental eccentricity is considered as prescribed in D.M. 14/01/2008, the displacement response of the corner isolator 32 in the longitudinal and transverse directions are those of Figure 14 and Figure 15. If the scale used in Figure 14 were to be used in Figure 15 the transverse displacement would be barely noticeable. Therefore the response of the system to the experiments is expected mainly in the longitudinal direction.

Peak velocities and accelerations at corner isolators are given in Table 14 for different levels of imposed initial displacement. The increase in peak velocity due to considering the accidental mass eccentricity is barely noticeable, while the increase in peak acceleration is on average about 6%. The fundamental period seems to be little affected by the presence of the accidental eccentricity, the maximum amplification being less than 1%. The residual displacement appears to increase everywhere because of the effect of the mass eccentricity. The variation of the time required for the motion to stop seems to occur randomly.

Table14 Variation of System Response Parameters with Displacement Amplitude in the Presence of Mass Eccentricity

D (*mm*)	*peak v* (*cm/s*)	*peak a* (*gal*)	T_1 (*s*)	u_r (*mm*)	t_r (*s*)
30	5.7	35.9	1.120	14.8	1.685

300	55.7	179.0	2.720	9.3	4.915

6.5 Story Drifts

It is recognized in the international literature that structural and nonstructural damage in a building is related to story drifts. The Italian code NTC08 prescribes that for RC structures with in-fills rigidly connected to the structural members, story drifts at the damage limit state should not

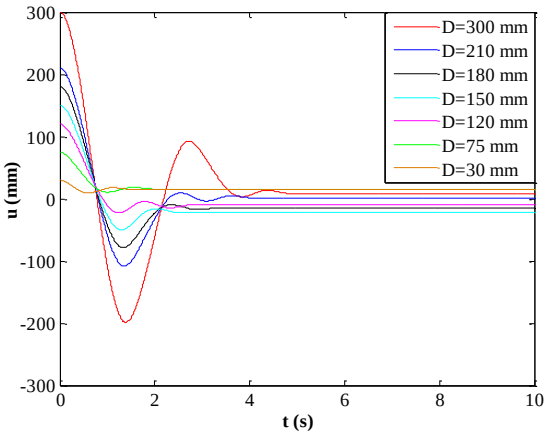

Figure 14 Free Vibration Displacement Response of Isolator 32 in the Longitudinal Direction as a function of the Imposed Initial Displacement

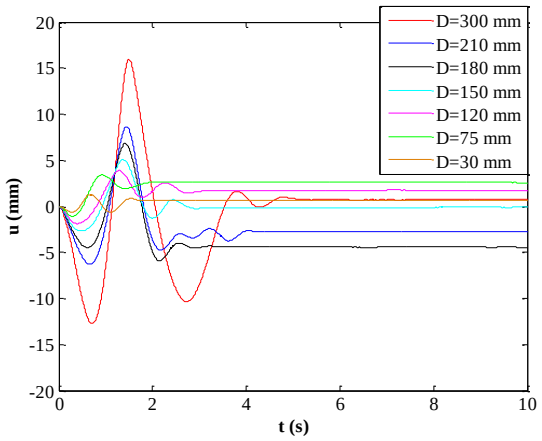

Figure 15 Free Vibration Displacement Response of Isolator 32 in the Transverse Direction as a function of the Imposed Initial Displacement

exceed 5‰. During the tests planned for the Augusta building the story drift should be comfortably smaller than the damage limit. The aim of this subsection is to evaluate the story drifts arising from the test conditions and to check that they do not exceed the stated limit. The procedure used for this evaluation starts from the following equation of motion for the base-isolated structure.

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} + \mathbf{F} = \mathbf{0} \tag{13}$$

where

$$\mathbf{u} = \begin{bmatrix} \mathbf{u}_S \\ \mathbf{u}_B \end{bmatrix}, \mathbf{M} = \begin{bmatrix} \mathbf{M}_{SS} & \mathbf{0} \\ \mathbf{0} & \mathbf{M}_{BB} \end{bmatrix}, \mathbf{C} = \begin{bmatrix} \mathbf{C}_{SS} & \mathbf{C}_{SB} \\ \mathbf{C}_{BS} & \mathbf{C}_{BB} \end{bmatrix},$$

$$\mathbf{K} = \begin{bmatrix} \mathbf{K}_{SS} & \mathbf{K}_{SB} \\ \mathbf{K}_{BS} & \mathbf{K}_{BB} \end{bmatrix}, \mathbf{F} = \begin{bmatrix} \mathbf{0} \\ \mathbf{F}_B \end{bmatrix}$$

The matrices **M, C** and **K** in Equation (13) refer to the superstructure, while $\mathbf{F_B}$ is the vector of the restoring forces provided by the isolators. The partitioned form of the above matrices is used to separate the degrees of freedom of the superstructure from those shared with the base isolation system. Therefore vector **F** is a known function of time evaluated by considering the superstructure as rigid (Oliveto et al. 2012). The results shown in subsection 6.4 were obtained by such a method and the sub-vector $\mathbf{F_B}$ is a bi-product of that analysis. The damping matrix has been calculated by assuming a 2% modal damping ratio for all the superstructure modes. The response of the superstructure is shown in Figures 16, 17 and 18 in terms of displacements, velocities and accelerations. From Figure 16 it may be seen that displacements at the various floors are barely distinguishable. The high frequency components, which provide a significant contribution to velocity and acceleration, determine significant variations of these response parameters from floor to floor. The peak acceleration on the top floor appears to be significantly larger than that at lower floors.

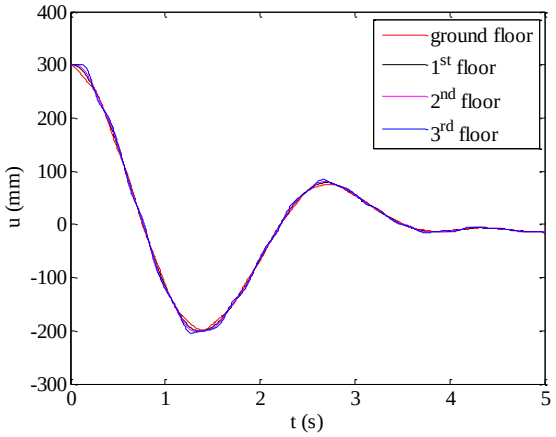

Figure 16 Predicted Floor Displacement Response for the Augusta Building under D = 300 *mm*

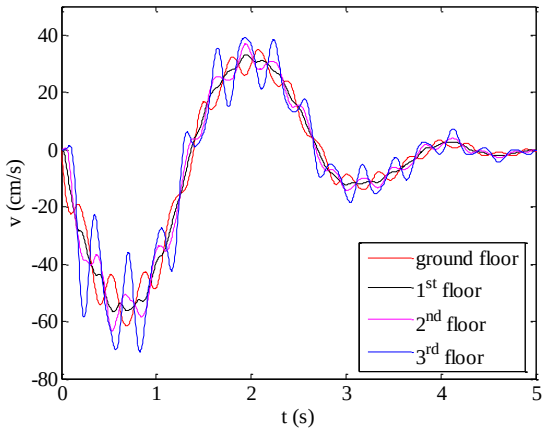

Figure 17 Predicted Floor Velocity Response for the Augusta Building under D = 300 *mm*

The story drifts are shown in Figure 19 and, although the displacement imposed to the isolation system reaches the

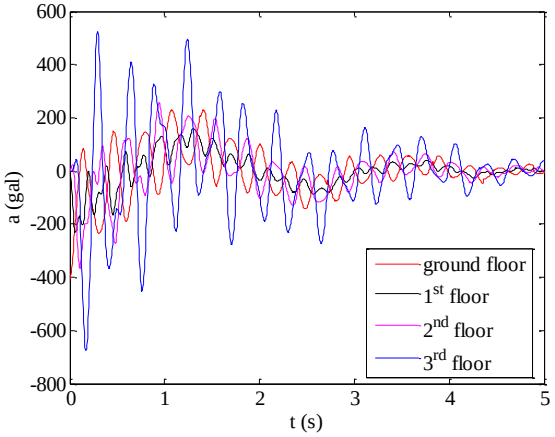

Figure 18 Predicted Floor Acceleration Response for the Augusta Building under D = 300 *mm*

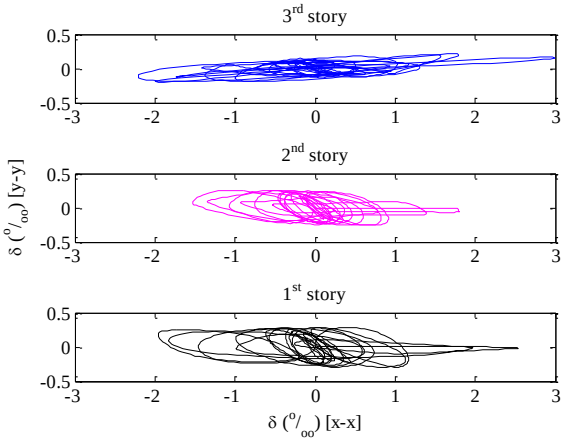

Figure 19 Predicted Story Drifts for the Augusta Building under D = 300 *mm*

maximum guaranteed by the manufacturer for the Collapse Limit State (SLC), the maximum drift does not exceed the limit value for the Damage Limit State (SLD). The variation of peak velocity and peak acceleration at the various floors, as a function of the amplitude of the imposed initial displacement, is shown in Table 15.

Table15 Variation of System Response Parameters with Displacement Amplitude in the Absence of Mass Eccentricity

D (mm)	*peak v (cm/s)*			*peak a (gal)*		
	Floor			*Floor*		
	1	*2*	*3*	*1*	*2*	*3*
30	6.2	7.7	11.8	46.6	73.2	135.7
75	10.4	12.7	19.6	77.5	121.8	225.8
120	18.4	22.2	27.4	108.5	170.5	316.0
150	24.7	29.1	33.1	129.2	202.9	376.1
180	31.0	36.0	40.2	149.8	235.4	436.2
210	37.4	42.8	47.5	170.4	267.8	496.3
300	56.7	63.4	70.6	232.4	365.1	676.8

Table16 Variation of the Maximum Story Drifts [‰] with Displacement Amplitude

D (mm)	*Mass eccentricity neglected*			*Mass eccentricity considered*		
	Story			*Story*		
	1	*2*	*3*	*1*	*2*	*3*
30	0.51	0.36	0.66	0.52	0.37	0.66
75	0.85	0.60	1.10	0.86	0.61	1.09
120	1.19	0.85	1.54	1.20	0.86	1.53
150	1.41	1.01	1.83	1.43	1.02	1.82
180	1.64	1.17	2.13	1.65	1.18	2.12
210	1.87	1.33	2.42	1.88	1.34	2.41
300	2.54	1.81	3.30	2.57	1.83	3.28

As expected peak velocity and acceleration increase as the amplitude of the imposed displacement increases and they are generally higher at the top floor. The maximum story drift is shown in Table 16 as a function of the imposed initial displacement for the case when accidental mass eccentricity is neglected and for the case when it is considered. Again the story drifts increase as the amplitude of the imposed initial displacement increases. The effect of the accidental eccentricity is that of increasing the maximum drift at the first and second stories and decreasing it at the top story. It is important to notice that the maximum story drift is always well within the limit of the SLD. Therefore the story drifts will not be a limiting factor in the definition of the maximum imposed displacement during the tests on the building.

7. CONCLUSIONS

This work has considered the Italian construction code NTC08 with reference to seismically isolated buildings through a case study. The code prescribes the seismic actions by providing response spectra for four different limit states on a point by point basis. The spectral ordinates have different characteristics for isolation modes and for structural modes. Provided that some specific conditions are satisfied, linear static analysis and/or linear dynamic analysis can be used for design purposes. Linear analysis, either static or dynamic, seems to be based on viscous equivalent properties of the base isolation system obtained from tests at a shear strain $\gamma = 1$. The behavior of the base isolation system at the ultimate limit states SLV and SLC involves values of the shear strain well above $\gamma = 1$ and the Italian manufacturers of elastomeric bearings guarantee the integrity of the elastomeric isolators up to a maximum shear strain $\gamma = 2$. The analysis of the seismic response at the ultimate limit states SLV and SLC should therefore converge to results where the corresponding shear strain should be $\gamma \leq 2$. This can be easily achieved if the base isolation system is treated as an equivalent linear system with the properties calibrated at a shear strain $\gamma = 1$. However it would seem more appropriate to calibrate the equivalent linear system at the shear strain competing to each of the limit states considered. In order to do this the designer should have at his disposal not only the results of the acceptance tests, but also the results of the qualification tests on the isolation bearings. In fact these are performed at different levels of shear strain up to the maximum value for which the isolation device is guaranteed. At the present time it does not appear that such tests are available to the designer.

The code seems to imply that if the stated conditions for linear analysis, whether static or dynamic, are not fulfilled by the isolation system, the designer should opt for a non-linear analysis. However, as far as models are concerned, no guidance is offered and these are left to the responsibility of the designer.

Typical results of acceptance tests performed on samples of the batch of isolators used for the Augusta building have been discussed in this paper. Based on these results a bilinear model has been developed for the elastomeric bearings and a Coulomb friction model has been calibrated for the sliding isolators. The two models have been combined and used for the simulation of free vibration tests to be performed on the building under imposed initial displacements. Some basic facts necessary for the planning of the tests have been established. Among these are the evaluation of the forces needed to apply each initial displacement, the duration of the successive phase of free motion, the residual displacements at the end of the motion, periods and number of cycles of free vibration. Other response parameters that have been evaluated are peak floor velocities and accelerations in test conditions.

One particularly relevant issue involved in performing a dynamic test on a finished building is that of avoiding structural and non-structural damage. International building codes define the limit state that separates undamaged and damaged states of a building in terms of the value of the story drift. For this reason the story drifts have been evaluated for various imposed initial displacements in the absence and in the presence of accidental mass eccentricity.

Even for the largest displacement considered, corresponding to the integrity limit for the isolators, the story drifts remain well below the value stated by NTC08 for the SLD. Therefore it is believed that the maximum applicable displacement depends more on the available equipment in terms of maximum force and/or stroke rather than on the necessity of avoiding damage.

The results of the tests planned for the near future will provide a means of assessing the reliability of the predictions presented. Anyway, this study allows the performance of the tests with a sufficient degree of reliance.

Abstract: Base isolated buildings subjected to extreme earthquakes can exceed their design displacements and impact against the surrounding moat wall. To better understand the consequences of impact on the superstructure, experimental simulations of a base isolated structure with simulated moat walls were conducted on a shaking table. Based on experimental observations and impact theory, an impact element considering moat wall compliance was proposed and shown to accurately capture impact forces. In this paper, the impact model is extended to 3-D structures and the response of 3-story moment and braced frame prototype models is examined considering impact to a surrounding moat wall at the base level by implementing the proposed impact element to finite element models of the buildings. The effect of pounding to moat wall in both prototype buildings were investigated by comparing the superstructure response with and without the presence of the moat wall. These studies provide critical information for the design of base isolated buildings, particularly the moat wall clearance and its potential effect on the superstructure response.

1. INTRODUCTION

A typical base isolated basement design requires a space in which the building is free to move sideways without contacting the surrounding structure. This space is commonly referred to as the "moat". Structural design codes such as ASCE 7-05 (ASCE 2005) specify the minimum moat wall distance equal to the expected displacement of the isolation system under the maximum considered earthquake (MCE) while the superstructure is designed for design basis earthquake (DBE). Despite the cautious regulation for moat wall gap distance, pounding of base isolated building to moat wall has been reported in previous earthquakes. Current design specifications may not adequately account for the large forces generated during impact in base isolated buildings.

The base-isolated Fire Command and Control (FCC) building in Los Angeles experienced pounding to its moat wall during the 1994 Northridge earthquake (EERI 1995). Post-earthquake evaluations showed that the base isolated FCC building performed well, except for impact, which increased structural shear, and drift demands (Nagarajaiah and Sun 2001). In the more recent 2011 Christchurch earthquake, post-earthquake investigations revealed pounding of the only base isolated building in that region to moat wall resulting in damage to sacrificial non-structural components at the seismic gaps (Gavin and Nigbor 2012).

Komodromos et al. (2007) conducted a series of parametric studies to investigate the influence of potential poundings of seismically isolated buildings with adjacent structures on the effectiveness of seismic isolation. The numerical simulations demonstrated that poundings may substantially increase floor accelerations, especially at the base floor where impacts occur. The effects of seismic pounding on the structural performance of a base-isolated reinforced concrete (RC) building are investigated by Pant and Wijeyewickrema (2012). In particular, seismic pounding of a typical four-story base-isolated RC building with retaining walls at the base and with a four-story fixed-base RC building is examined. Three-dimensional finite element analyses are carried out considering material and geometric nonlinearities. It is found that the performance of the base-isolated building is substantially influenced by the pounding.

Masroor and Mosqueda (2012a) investigated experimentally the behavior of base isolated buildings during contact with different types of moat wall. The test setup consists of a quarter scale three-story frame isolated at the base with friction pendulum bearings and various moat wall models. The moat wall was modeled as either a rigid steel stopper or concrete walls of various thicknesses with soil backfill. Test results indicate that the contact forces are largely dependent on the gap distance, impact velocity and wall flexibility and, in extreme cases, pounding can induce yielding in the superstructure. They proposed a simplified impact element considering moat wall flexibility based on impact theory and observations during experimental simulations (Masroor and Mosqueda 2012b). It was demonstrated that numerical simulations using the proposed impact element can capture the dominant characteristics of the contact force observed in experiments of base isolated buildings impacting various moat wall configurations.

In this paper, the impact model proposed by authors (Masroor and Mosqueda 2012b) is extended to 3-D structures for improved modeling of limit states in base isolated structures. Two moment frame and two braced frame base isolated structures designed by professional engineers are examined. The effects of pounding to moat wall in these prototype buildings were investigated by comparing the superstructure response with and without the presence of the moat wall.

2. PROTOTYPE BUILDINGS

As part of the NEES TIPS project (Ryan et al. 2008), a series of conventional and base-isolated buildings were professionally designed by Forell/Elsesser Engineers Inc. and adapted here for use in the experimental and numerical studies on structural pounding. The 3-story base isolated building models include a base isolated Intermediate Moment Resistant Frame (IMRF), and a base isolated Ordinary Concentric Braced Frame (OCBF). These buildings were designed for occupancy category II and importance factor I = 1.0 according to ASCE 7-05. These office buildings were designed by the Equivalent Lateral Force Method to meet the requirements of 2006 International Building Code, ASCE 7-05, and AISC 341-05. The buildings were designed for a Los Angeles, California, location (34.50 N, 118.2 W) on stiff soil (site class D with reference shear wave velocity of 180 to 360 m/s). The mapped spectral accelerations for this location are S_S = 2.2 g for short periods and S_1 = 0.74 g for a 1-s period.

The model layout is 6 by 4 bays with 30 ft. width in both directions for both frames. The height of each story is equal to 15 ft. Lateral resistance is provided by two 5-bay perimeter moment frames in the X-direction and two 3-bay perimeter and two 2-bay interior moment frames in the Y-direction in the IMRF model. The exterior brace system shown in Figure 1 was used for the OCBF model. Both base isolated IMRF and OCBF models were designed for the same hazard level and location although the IMRF model was designed for response modification factor of R=1.67 and the OCBF model was designed for R=1. A higher R for IMRF model resulted in a more flexible superstructure in comparison with the OCBF. The superstructure first mode period for the IMRF and OCBF models are 1.4 and 0.4 sec.

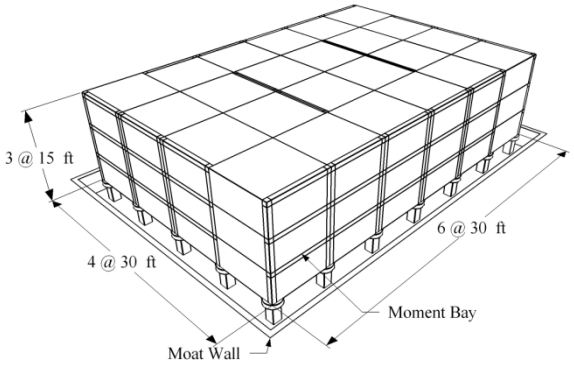

Table 1 summarizes the design parameters for the isolation system. These parameters are comparable for both the IMRF and OCBF since the total weight of the two systems are very close (~7200 kips). In this table, T_D and T_M are effective isolation periods at DBE and MCE level, D_M and D_{TM} are the maximum displacement and total maximum displacement of the isolation system calculated from Equations 17.5-3 and 17.5-6 in ASCE7-10:

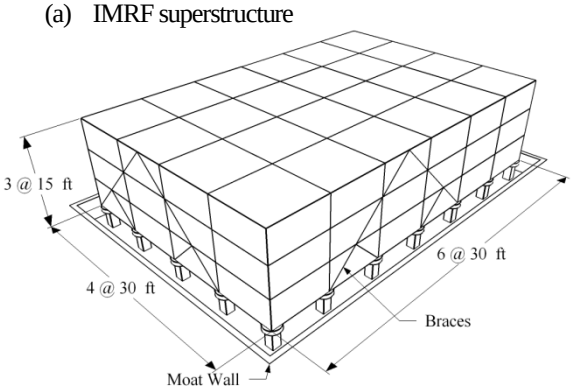
$$D_M = \frac{gS_{M1}T_M}{4\pi^2 B_M},\ D_{TM} = D_M\left[1 + y\frac{12e}{b^2+d^2}\right] \qquad (1)$$



where B_M is a coefficient that modifies from 5% damping spectrum to a desired damping (Table 17.5-1 in ASCE7-10), S_{M1} is 1-s spectral acceleration for MCE events, e is the actual eccentricity plus accidental eccentricity taken as 5 percent of the longest plan dimension of the structure perpendicular to the direction of force under consideration, and b and d are the shortest and longest plan dimension of the structure, respectively. The minimum moat wall gap distance required by ASCE 7-10 equals to D_{TM} (approximately 760 mm or 30 in. for these models).

Table 1 Design parameters for isolation systems

Isolator Properties	DBE Event	MCE Event
Effective period (s)	$T_D = 2.77$	$T_M = 3.1$
Effective Damping (%)	$\beta_D = 24.2$	$\beta_M = 15.8$
Isolator Displacement (in)	$D_D = 12.7$	$D_M = 24.3$
Total Displacement (in)	$D_{TD} = 15.3$	$D_{TM} = 29.4$

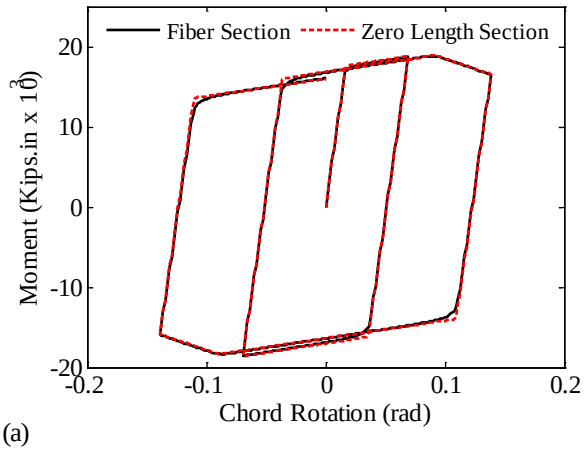
3. ISOLATED BUILDINGS WITH MOAT WALL

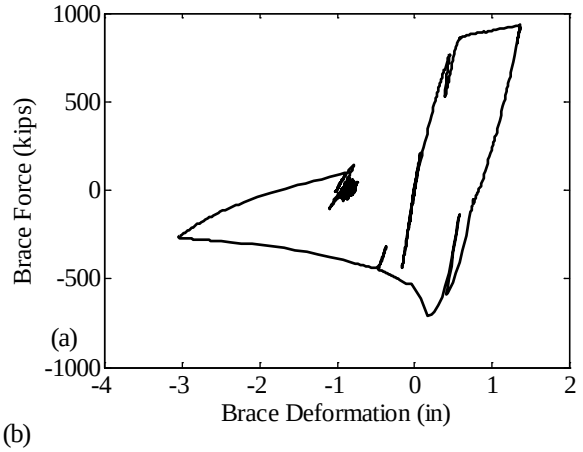
3.1 Superstructure and Isolator Model

Detailed 3D numerical models of the IMRF and OCBF buildings were developed in OpenSees (Erduran et al. 2011; Sayani et al. 2011). Equivalent mass and rotational inertia were lumped at the center of mass (master node) at each level which is shifted by 5% of the longest plan dimension in both directions to account for accidental torsion. Slab action was accounted for through a rigid diaphragm constraint. Energy dissipation was added to the superstructure using



tangent stiffness proportional damping calibrated to give 2.5% damping at its respective first mode frequencies.

All columns and moment-resisting beams were modeled using force-based nonlinear beam-column elements that combine finite length "plastic hinge" regions at the element ends with an interior elastic region. Modeling structural behavior through collapse requires, to the extent possible, numerical models that directly simulate all significant deterioration modes contributing to collapse behavior such as stiffness, strength, and inelastic deformation simulation in structural component models. For this purpose, the steel stress-strain and moment-curvature relationships for all the elements were modified to include strength and stiffness degradation using Modified Ibarra Krawinkler (MIK) deterioration model (Lignos and Krawinkler 2011). Lignos and Krawinkler (2011) tested a large number of beam section under cyclic loading and proposed equations to calculate the degradation parameters for different beam section. They proposed these parameters for moment-chord rotation behavior for each section. Assigning moment-curvature relationships for beam elements in which axial force plays insignificant role is adequately reasonable. Unlike beam elements, column section experienced a large axial force especially under large deformations. For this reason, fiber sections were selected to property account for the effects of axial load on moment strength of the columns.



In order to consider the effects of strength degradation for column sections, the following procedure was conducted to modify the MIK model proposed by Lignos and Krawinkler (2011) for stress-strain relationship. First, moment-rotation response of each column section was developed using parameters proposed by Lignos and Krawinkler (2011) and assigning these values to a zero length section for a cyclic pushover. Then, a fiber section for the same column geometry was generated with the MIK model assigned to each fiber element as stress-strain behavior. The required parameters for the fiber section using MIK model was calibrated based on comparing these two responses for a given displacement history. Figure 2(a) compares the zero length section response with fiber section element for moment frame column section in the first floor of the IMRF model.

In the OCBF model, multiple nonlinear beam–column elements were strung together to physically simulate the inelastic buckling behavior in braces (Uriz et al. 2008). A single brace using two force-based nonlinear beam–column elements with fiber sections and three numerical integration points along the length of the element was selected. An initial camber of 0.1% of the brace length was applied at the brace midpoint to initiate buckling. The resultant simulated cyclic force–deformation of a representative brace is shown in Figure 2(b).

In both models, isolators were modeled independently, one beneath each column, using a combination of elements to realize a composite force deformation in each direction that could represent either elastomeric or friction pendulum devices. An elastic column element and an elastic-perfectly plastic spring were assembled in parallel to obtain the composite bilinear lateral force-deformation behavior. The compressive stiffness of the isolators was computed assuming a vertical frequency of 10 Hz. Since typical bearings have no or low resistance to tension, the tensile stiffness was assumed to be 1% of the value of the compressive stiffness.

3.2 Moat Wall Model and Experimental Verification

In order to consider the potential and effects of pounding in a time history analysis of base isolated buildings under ground motion, a comprehensive study was conducted by Masroor and Mosqueda (2012b) leading to propose an impact element based on impact theory and verifications with experimental simulations. It is demonstrated that numerical simulations using the proposed impact element can capture the dominant characteristics of the contact force observed in experiments. The experimental program consisted of shake table testing of a quarter-scale model representative of the IMRF model using the NEES equipment site at the University at Buffalo. The principal objective of these experiments was to generate experimental data for base isolated building pounding against a moat wall, specifically the impact force and the superstructure response. Figure 3(a) shows the shake table test setup. In this

(a)

(b)

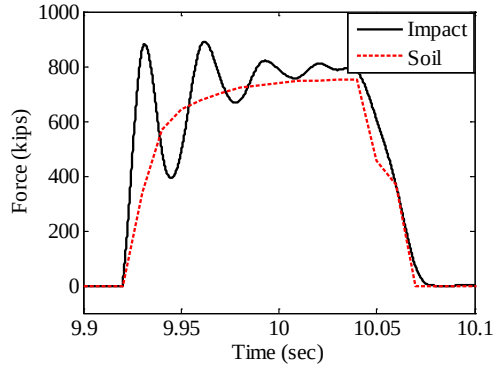
Figure 3 (a) Shake table test setup, (b) Proposed impact element implemented at base level of the prototype model.

experiment, different types of moat walls were installed at various gap distances relative to base level of isolated model and different ground motions were applied to capture the variation in response with moat wall stiffness and impact velocity.

Based on nonlinear dynamic response of moat walls with soil back fill and verification with experimental results, an impact element for moat walls was proposed. This element is implemented in finite element modeling of the base isolated buildings at the base level (Figure 3(b)). The contact force is dependent on impact velocity, geometry and material properties at the contact surface, as well as the global dynamic flexibility characteristic of the moat wall. This moat wall model includes both local deformation and global vibration aspects of structural impact. The local aspect of impact consist of local material deformation or indentation and can be implemented using a Hertz damped element (Muthukumar and DesRoches 2006) at the contact location. The global vibration aspects of impact results from deformations of the moat wall and soil backfill excited by a dynamic impact force. To simulate nonlinearity in the concrete moat wall and soil back fill due to the pushing impact force, a single beam element is combined with a nonlinear spring in series. The single beam element simulates vibration response of the moat wall representing a certain wall width. The height of the beam element can be set to the height of the wall and a rotational spring is assumed at the base of the beam to capture the post-elastic behavior due to the formation of a plastic hinge.

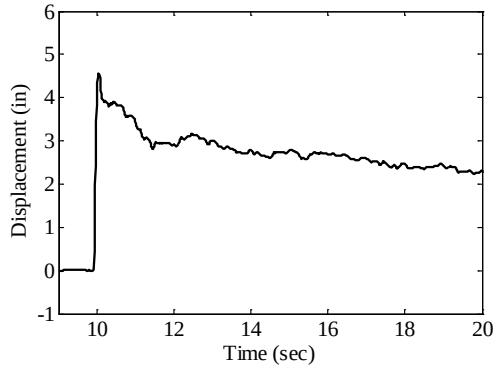
A hyperbolic force-displacement (HFD) relationship was developed by Shamsabadi et al. (2007) to simulate the mobilized passive pressure behind the abutment back wall in bridges. The HFD tool is found to be a good fit with many experimental test data and all curves calculated by the log-spiral hyperbolic (LSH) model. This model was used here to simulate the response of soil back fill by assuming a nonlinear spring connected to top of the moat wall beam element.

The proposed moat wall model consists of moat wall nonlinear beam element, a Hertz damped local spring in front and HFD soil spring behind to capture the impact forces between a point at the base level of the superstructure and a point on the moat wall with specific length and fixed boundary condition at the bottom. This element can be replicated at a given distance to represent continuous walls along the base level of the superstructure. Figure 3(b) shows the simulated moat wall model using this element. The spacing between these moat wall elements could be set to the bay span of the superstructure to align the end of column elements with moat wall elements. These single moat wall elements should be connected using interactional elements to represent continues moat wall behavior. The behavior of these internal elements was defined here based on finite element analysis.



The shape of the impact force generated due to pounding to the base level at one corner impact element and also displacement in this moat wall node is shown in Figure 4 The total impact force is a combination of dynamic oscillation in the moat wall element and force generated in soil backfill. Residual deformation shown in this figure verifies plastic deformation in the moat wall and soil backfill, which is a source of damping for the impact force.

4. EFFECT OF POUNDING ON RESPONSE OF BASE ISOLATED MODELS



The performance of the two prototype base isolated models was examined under 20 ground motions from the NEES TIPS project with and without moat walls. All the ground motions were scaled to MCE level for the period range of 0 to 3 sec. Two horizontal components of each ground motion were applied on the frame simultaneously. The moat wall gap distance was set to 30 in, which is approximately equal to D_{TM} specified by ASCE (2005) based on a static design procedure.

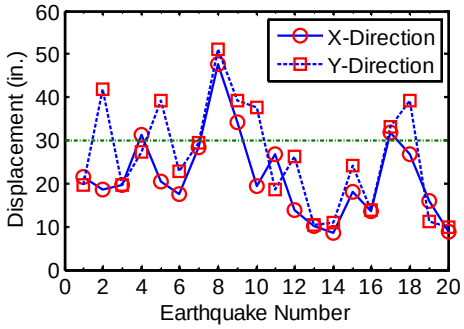
Figure 5 shows the maximum base level corner node displacement in X and Y directions for each ground motion for both frames for the case that there is no moat wall. The reference gap distance from ASCE 7-05 is shown by the dashed line (30 in.). It can be seen that only 8 ground motions induce corner node displacements larger than 30 in. in the IMRF model while 11 ground motions induce corner displacement more than the specified gap distance in the OCBF frame. Higher participation of the first mode of the IMRF model resulted in reducing maximum base level

displacement demand in comparison with equivalent single degree analysis. Stiff behavior of the OCBF model leads to larger displacement at base level resulting in stronger pounding to moat walls.

(a)

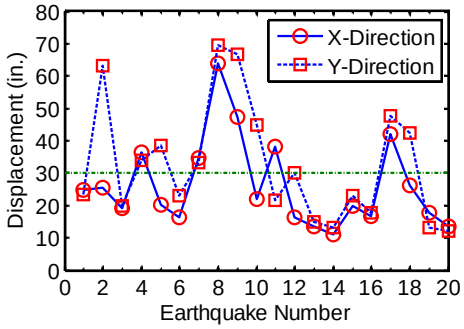
(b)

Figure 4 Corner impact element (a)force and (b)displacement



Installing the moat wall at 30 in. gap distance (equal to D_{TM} for both models) resulted in pounding of base level to moat walls in 8 and 11 ground motion for IMRF and OCBF models. The average impact force generated is equal to 2000 and 3300 kips for ground motions inducing pounding in IMRF and OCBF, respectively.

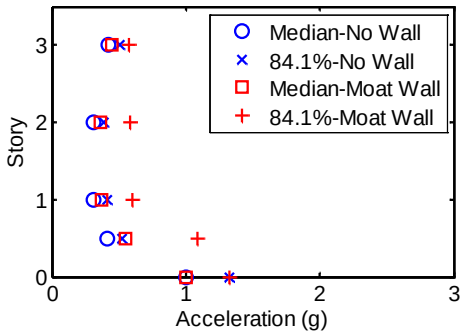
Seismic response, when sampled over many motions, are widely accepted to follow a lognormal statistical distribution. As such, the median and dispersion of the lognormal data, defined as



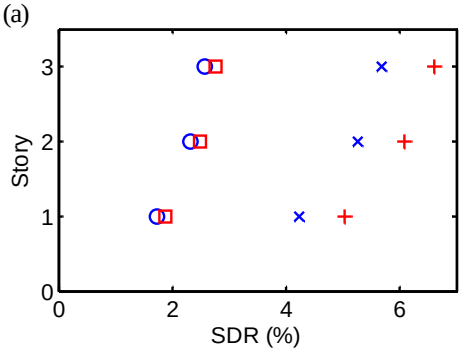
$$\mu = exp\left[\frac{\sum_{i=1}^{n} \ln x_i}{n}\right], \quad \zeta = \left[\frac{\sum_{i=1}^{n} (\ln x_i - \ln \mu)^2}{n-1}\right]^{1/2} \qquad (2)$$

are generally used to describe the central tendencies and variability of the response quantities for different ground motion sets. The median plus one standard deviation, or 84 percentile values, were computed as $\mu.\exp(\zeta)$.

Median and 84% of story drift ratio (SDR) and acceleration for both IMRF and OCBF models are shown in Figure 6 and Figure 7. Story drift ratio was evaluated as the maximum drift among the four corners of the building while the maximum vector summation acceleration for the master node in each floor was used. These parameters are compared for the two cases with and without moat wall to show the effect of pounding.



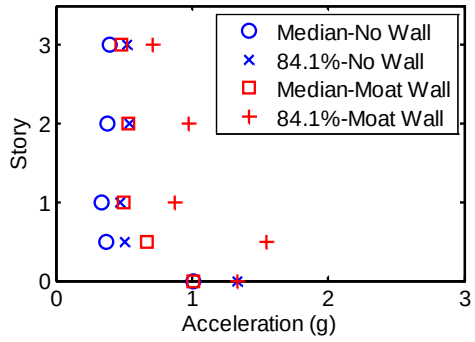
(a)



(b)

Figure 5 Base level corner node displacement for (a) IMRF model and (b) OCBF model without moat wall

(a)



(b)

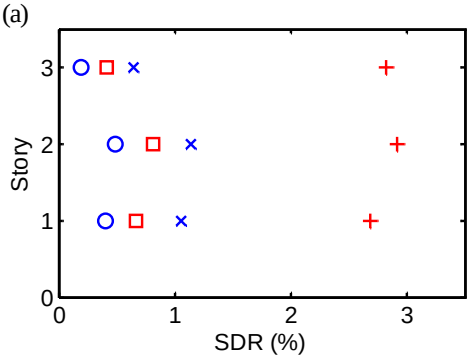


Figure 6 Median and 84% of (a) Acceleration (b) SDR for IMRF

Both frames show that the median floor accelerations are held within about 0.5g without moat walls although median PGA is on the order of 1g. Pounding to moat walls increases the acceleration in all levels especially in lower levels. The median floor acceleration does not show

significant increase although 84% value shows 200% increase in base level and approximately 80% increase in floor levels. The average value remains the same because of the fact that in many ground motions no pounding occurs but the 84% value increases substantially since the ground motions pounding to moat wall contribute a significant deviation from the average.

(a)

(b)

Figure 7 Median and 84% of (a) Acceleration (b) SDR for OCBF.

Large median and 84% SDR in IMRF model for the case without moat wall verifies the effects of the flexible superstructure. Unlike the IMRF model, OCBF model shows very stiff behavior. The median SDR value is on the order of 0.5 to 0.9% with smaller dispersion. Pounding to moat walls increases SDR in all levels especially in upper floors. The effect of pounding on median SDR is more clear for OCBF model because of the fact that 11 out of 20 ground motions induce pounding to moat walls in OCBF model while 8 out of 20 ground motions pound in the IMRF model. The flexible superstructure of the IMRF model leads to large SDR even in cases without moat walls. When the moat walls are added, the SDR increases only slightly, but as a percentage it is less significant compared to the OCBF. A larger increase in SDR response for the OCBF frame is obtained that is likely due to the larger number of ground motions inducing pounding, stiffer and non-ductile superstructure frame. Stiff superstructure in OCBF frame also results in larger displacement demand at the base level inducing stronger pounding to moat walls in comparison to the IMRF model.

As expected, larger dispersions are obtained in both acceleration and SDR for the cases with pounding in comparison with the case without moat walls. This shows that the response of the models worsens for the case of pounding to moat walls, inducing sudden increased accelerations and drifts.

5. CONCLUSIONS

The response of 3-story IMRF and OCBF prototype models were examined considering impact to a surrounding moat wall at the base level by implementing the proposed impact element to finite element models of the buildings. The effect of pounding to moat wall in both prototype buildings were investigated by comparing the superstructure response with and without the presence of the moat wall under 20 ground motions from the NEES TIPS project scaled to MCE ground motions. Response of the minimally code-compliant IMRF based isolated structure without considering pounding to moat walls does not perform satisfactorily at for MCE events. Large story drift ratio and yielding occurs in the building at this level of shaking. Pounding to moat walls worsen this situation for the IMRF model. A more robust design is necessary for this model to improve its performance in a rare earthquake. One suggestion in this regard could be designing a stiffer superstructure which leads to larger period shifting by considering the base isolation system or decreasing R factor to design for higher base shear. Although the response of the isolated OCBF is better compared with the IMRF for the case without moat walls, wherein the median demands for story drifts are substantially lower than those of the IMRF, pounding to moat walls makes a significant change in this behavior resulting in large median SDR with huge dispersions. Brace buckling and significant inelastic response were observed in all the motions inducing pounding to moat walls. It can be concluded that pounding to moat walls worsens the response of both frames in terms of both acceleration and SDR, although this effect is worse for stiff OCBF frame.

Abstract: The effects of modeling viscous damping on the response of seismically isolated reinforced concrete buildings subjected to earthquake ground motions, are investigated. The test results of a reduced-scale three-story building previously tested on a shaking table are compared with three-dimensional finite element simulation results. The study is focused on nonlinear direct-integration time-history analysis, where many different approaches of modeling viscous damping, developed within the framework of Rayleigh damping are considered. It is found that the damping ratio as well as the approach used to model damping has significant effects on the response. It is shown that stiffness-proportional damping, where the coefficient multiplying the stiffness matrix is calculated from the frequency of the base-isolated building with the post-elastic stiffness of the isolation system, provides reasonable estimates of the peak response indicators, in addition to being able to capture the frequency content of the response very well.

1. INTRODUCTION

Modeling energy dissipation in structures is a challenging task, adding complexity to nonlinear time-history analysis of structures. The major source of energy dissipation due to inelastic material behavior can be modeled with reasonable accuracy using material models based on experiments. Other sources of energy dissipation such as (a) foundation damping due to soil nonlinearity and radiation of seismic waves and (b) damping in the structure including non-structural elements, are usually modeled using linear viscous damping. In base-isolated buildings, it is logical to prescribe viscous damping separately for the isolation system and the superstructure, where the use of viscous damping in the isolation system can be avoided by using hysteretic models of bearings to account for all the energy dissipation. On the other hand, the application of viscous damping to the superstructure alone can be done using various approaches within the Rayleigh damping framework, where damping matrix $\mathbf{c}$ is given as,

$$\mathbf{c} = a_0\mathbf{m} + a_1\mathbf{k}, \tag{1}$$

where $\mathbf{m}$ is the mass matrix, $\mathbf{k}$ is the stiffness matrix, and a_0 and a_1 are the damping coefficients. The damping ratio for the n^{th} mode of a structure ξ_n is defined as,

$$\xi_n = \frac{a_o}{2\omega_n} + \frac{a_1\omega_n}{2}, \tag{2}$$

where ω_n is the frequency of the n^{th} mode. The coefficients a_0 and a_1 are determined assuming the same damping ratio ξ for two selected modes as,

$$a_0 = \xi\frac{2\omega_i\omega_j}{\omega_i + \omega_j}, \qquad a_1 = \xi\frac{2}{\omega_i + \omega_j}, \tag{3}$$

where ω_i and ω_j are the frequencies of mode *i* and mode *j*, respectively. The two modes *i* and *j* are chosen to ensure nearly the same amount of damping for all the modes significantly contributing to the response of the structure. Typically, ω_i is selected to be the frequency of the first mode and ω_j corresponds to a higher mode. Mass-proportional damping where $\mathbf{c} = a_0\mathbf{m}$ and $a_0 = 2\xi\omega_i$; and stiffness-proportional damping where $\mathbf{c} = a_1\mathbf{k}$ and $a_1 = 2\xi/\omega_i$, can be viewed as special cases of Rayleigh damping.

Because of the potential problems associated with the use of Rayleigh-type damping, several studies have been carried out concerning the analysis of *fixed-base buildings* (Priestley and Grant 2005, Hall 2006, Smyrou et al. 2011, and Erduran 2012). These studies highlight the undesirable effects of improper use of Rayleigh-type damping in time-history analysis of inelastic structures. Various suggestions have been proposed to avoid problems, which include the use of the tangent inelastic properties of the system instead of the initial elastic properties and imposing bounds on the damping forces. Nonetheless, there is no consensus among researchers regarding the best approach to

model viscous damping, due to uncertainties associated with quantification of energy dissipation. While the issue of modelling viscous damping has been explored extensively for fixed-base buildings, it is only recently that the base-isolated buildings have been considered (see Hall 2006 and Ryan and Polanco 2008). Hall (2006) studied the effects of mass-proportional damping and stiffness-proportional damping using a rigid superstructure model. Ryan and Polanco (2008) recommended the application of stiffness-proportional damping instead of Rayleigh damping to the superstructure of the building but their study was based on two-dimensional models of the buildings assuming linear elastic behavior of the superstructure. Stiffness-proportional damping was also used by Pant and Wijeyewickrema (2012) to evaluate the performance of a base-isolated reinforced concrete (RC) building subjected to seismic pounding using three-dimensional nonlinear finite element (FE) models. However, the effects of modeling viscous damping on the structural response of the building were not discussed in that study. Therefore, a systematic study investigating the effects of modeling viscous damping on the important response indicators of base-isolated buildings such as floor displacements, floor accelerations and story shear forces, using rigorous three-dimensional FE models, is needed. In addition, none of these previous studies have compared numerical analysis results with the results from experiments or instrumented buildings.

In the present study, the consequences of modeling viscous damping in time-history analysis of base-isolated RC buildings by using various approaches based on the Rayleigh damping framework, are investigated. Existing shaking table test results of a three-story base-isolated building, where the superstructure was shaken strongly but did not undergo significant inelastic excursions, are compared with the numerical analysis results to arrive at the appropriate technique for modeling viscous damping. In these numerical simulations, energy dissipation due to inelastic material behavior of the superstructure was simulated using well-established material models, while the viscous damping was applied to the superstructure using many different approaches. All the energy dissipation in the isolation system was explicitly modeled using bilinear hysteretic models of bearings.

2. BENCHMARK BUILDING AND MODELING

2.1 Benchmark Building and Shaking Table Tests

The base-isolated benchmark building used to compare numerical simulation results is a 0.4 scale model of a three-story two-bay by one-bay RC structure built in Japan (Fig. 1) and reported by Clark et al. (1997). To maintain proper scaling, packets of lead billets were tied down to each slab and the total weight of the model was 400 kN. Three phases of shaking table tests were carried out following initial system identification tests including the static pull-back tests. However, due to improper calibration of loadcells during the first static pull-back test, localized cracking was observed especially in first-floor beam-column joints (Clark et al. 1997). Despite this shortcoming, this test was chosen as a benchmark for the present study; because this represents the only experiment conducted on a code-compliant multi-story base-isolated RC framed-building with a fairly well-documented report. In the first phase of the shaking table tests, the structure was braced in the transverse direction as well as the longitudinal direction to enable comparison of various isolation systems by avoiding damage to the superstructure. Design-level 1 and design-level 2 earthquake excitations, according to Japanese practice were used as input in this stage. In the second phase of the tests, the model was braced only in the transverse direction and the two design-level earthquakes were run again, followed by very high-intensity motions intended to cause damage to the structure. In the final phase, the model was repaired and moderate-intensity motions were applied. It is noted that in all the tests, the earthquake excitation was only in the longitudinal direction. This study focuses on the second phase of the tests where design-level earthquakes were used. In this phase, identical 176 mm diameter high damping rubber bearings with twenty 2.2 mm thick rubber layers alternating with 1 mm thick steel shims were used under each of the six column bases.

Design-level 2 tests are considered in the present study. In these tests, recordings of the 1940 El Centro, 1968 Tokachi-oki, and 1979 Miyagiken-oki earthquakes were run at an intensity corresponding to the full-scale peak velocity of 50 cm/sec (corresponding to the design-level 2 earthquake) and are referred to as ELC-50, HACH-50, and MIYA-50, respectively. One additional excitation that represented the design forces typically specified by the US codes was also used in these tests. The excitation referred to as ELC-S1, is a synthetic record generated from the 1940 El Centro earthquake recording. The sequence of excitation was in the following order: ELC-S1, ELC-50, HACH-50, and MIYA-50.

2.2 Modeling of Structural Elements

A three-dimensional FE model of the building was developed in OpenSees (2012). Beams and columns were modeled using force-based, Euler-Bernoulli fiber beam-column elements that account for the spread of inelasticity along the length of the element. For concrete the modified Kent and Park model (Park et al. 1982) was used in compression and an initial linear elastic branch together with a linear softening branch up to zero stress was used in tension. The model proposed by Yassin (1994) was used to account for concrete damage and hysteresis. For reinforcing steel, the constitutive model of Menegotto and Pinto (1973), which includes strain hardening and the Bauschinger effect, was used. In this study, the strain-hardening ratio is taken as 1%. Bearings were modeled using elastomeric bearing elements with a bilinear hysteretic model used to represent the lateral force-deformation relationship of each element and to simulate all the energy dissipation in the isolation system. The parameters of the bilinear hysteretic model for each

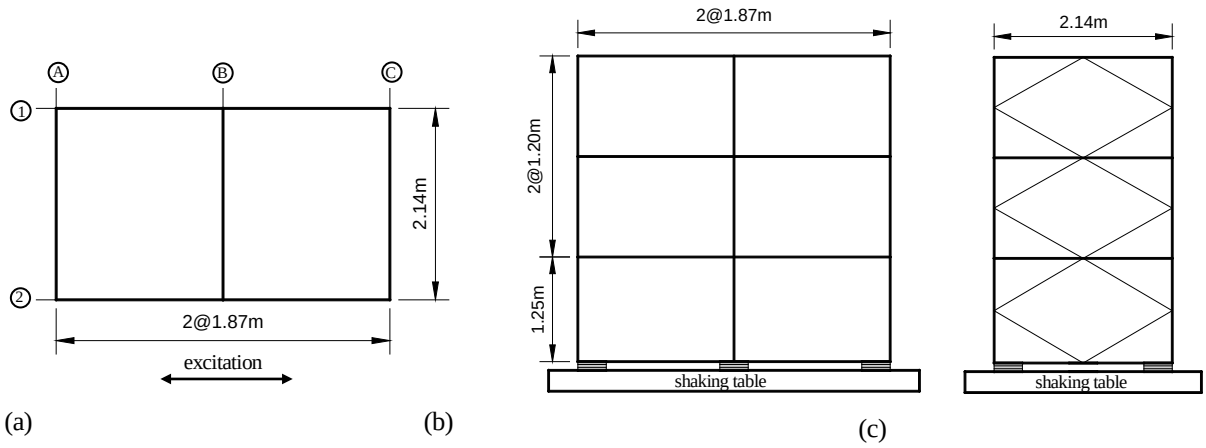

Fig. 1. Geometry of the three-story building tested on shaking table: (a) plan; (b) elevation along longitudinal direction; and (c) elevation along transverse direction (note that no braces were used along grid line B).

element as determined from the component test results of a bearing that was similar to the ones used in the building, are initial stiffness $K_1 = 1{,}167.5$ kN/m, post-elastic stiffness $K_2 = 300$ kN/m, and yield force $F_y = 3.94$ kN. The vertical force-deformation relationship of each element was simulated using a linear elastic compression-only spring with a stiffness $K_v = 338{,}000$ kN/m. The standard horizontal characteristic test of the bearing at 100% shear strain level and an axial load of 78.5 kN was reproduced quite well using these properties as shown in Fig. 2.

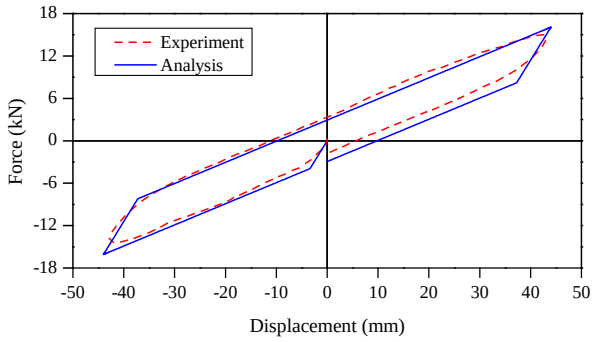

Fig. 2. Hysteretic loop of the bearing for one cycle of displacement at 100% shear strain level. Experimental curve is reproduced after Clark et al. (1997).

2.3 Modeling of Viscous Damping

Viscous damping was applied only to the superstructure of the building using many different approaches of computing the damping matrix $\mathbf{c}$ that cover a wide range of options available in many existing FE programs (Table 1). The relevant frequencies as obtained from modal analyses are also shown in Table 1. Since the modal damping values could not be estimated reasonably well during the test (Clark et al. 1997), numerical simulations were performed using damping ratio $\xi = 1\%$, 2%, 3%, 4%, and 5%. This also enables the investigation of the effects of damping ratio on the analysis results. The approaches considered here depend on:

(1) Damping type: Rayleigh, mass-proportional or stiffness-proportional damping.
(2) Damping coefficients a_0, a_1: The damping coefficients a_0 and a_1 are constant throughout the analysis (based on the initial stiffness) or updated in each analysis step (based on the tangent stiffness).
(3) Basis for computing a_0, a_1: Modes of deformation chosen and the structural model considered for modal analysis to calculate frequencies necessary for the evaluation of damping coefficients.
(4) Stiffness matrix: Initial or tangent stiffness matrix used in Eq. (1).

The approaches are categorized in 7 groups as shown in Table 1.

3. COMPARISON OF SHAKING TABLE TEST AND NUMERICAL ANALYSIS RESULTS

Nonlinear direct-integration time-history analysis of the building was carried out using OpenSees (2012) for a single continuous sequence of concatenated records ELC-S1, ELC-50, HACH-50, and MIYA-50 using the 28 approaches of modeling viscous damping. The $P-\Delta$ effect for the superstructure as well as the isolation system was included in the analysis to consider geometric nonlinearity effects. Numerical analysis results only for the strongest (i.e., MIYA-50) excitation are discussed in this paper, for brevity. The selected response indicators are relative floor displacements, absolute floor accelerations, and story shear forces. To enable the comparison of various approaches of modeling damping, the error E_n of the peak value of the response indicator representing displacement, acceleration or shear force at n^{th} story was calculated as,

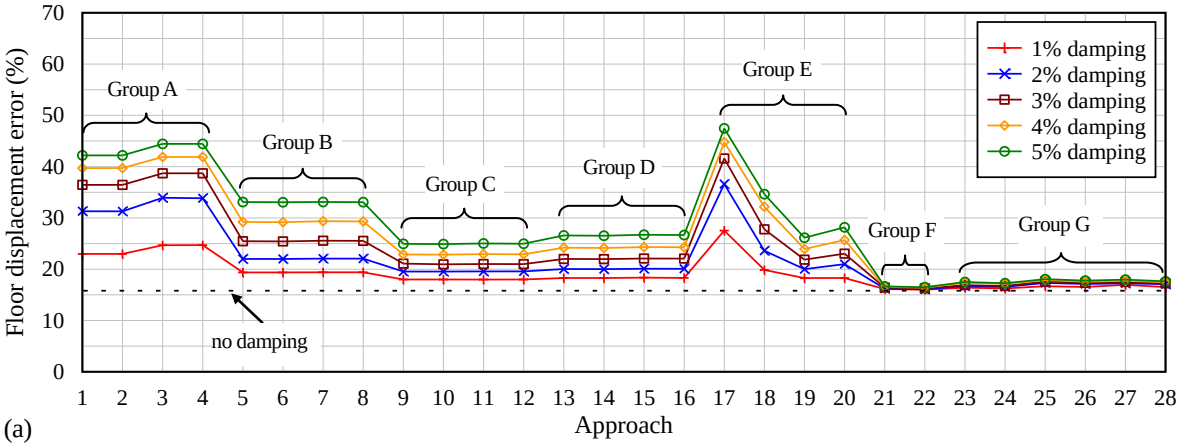

Table 1. Different approaches of modeling viscous damping considered in this study.

Approach	Group	Damping	Damping coefficients a_0, a_1	Basis for computing a_0, a_1		Stiffness matrix	ω_i (rad/s)	ω_j (rad/s)

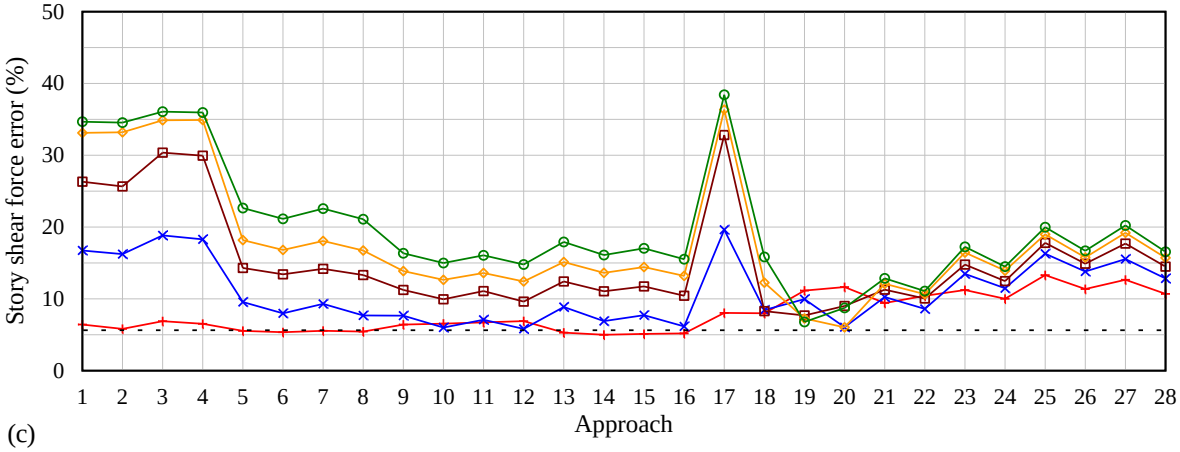
$$E_n = \left| \frac{N_n - T_n}{T_n} \right|, \qquad n = 0 \text{ (base)}, 1, 2, 3 \text{ (roof)}, \quad (4)$$

where N_n and T_n are the peak values of numerical analysis and test results, respectively of the response indicator at n^{th} story. Maximum of E_n values at all the stories for various damping ratios and approaches of modeling viscous damping are shown in Fig. 3 for the MIYA-50 excitation. Maximum errors when the viscous damping was not considered in the analysis are also shown for comparison purposes.



It is clearly seen from Fig. 3 that errors for a particular damping ratio using various approaches within any group other than Group E, do not show significant differences for all the response indicators. This implies that the choice of (a) higher mode (mode 3 or mode 4) frequency and (b) stiffness matrix (initial or tangent), in the application of viscous damping has negligible influence on the response indicators. The choice of stiffness matrix does not have a significant influence because stiffness-proportional damping constitutes a very small fraction of viscous damping, compared with mass-proportional damping. In addition, the fact that the stiffness of the superstructure is not changed significantly during the excitations also implies that the choice of stiffness matrix in the application of damping has negligible influence. This is different from fixed-base or base-isolated structures subjected to strong ground motions which result in significant stiffness degradation. The errors

(b)

(c)

Fig. 3. Maximum errors in peak values of response indicators for all the stories for the MIYA-50 excitation: (a) relative floor displacement; (b) absolute floor acceleration; and (c) story shear force. The dashed line indicates the maximum error when viscous damping was not considered.

for a particular damping ratio using the approaches within Group E are significantly different. In addition, the error trends with respect to damping ratio are changed for Approaches 18–20 compared with other approaches. Although the related results are not shown here for brevity, it was found from the numerical analysis results that Approaches 18–20 underestimate the floor displacement response but overestimate the floor acceleration and story shear force responses for almost all the damping ratios. The floor displacement response using Approaches 18–20 were found to be slightly smaller than the corresponding Rayleigh damping counterparts, while the floor accelerations and story shear forces were significantly larger for all the damping ratios. This is because mass-proportional damping, which can be visualized as dampers connecting each mass to an external support, does not correspond to a realistic physical phenomenon. Therefore, the application of only mass-proportional damping is not desirable. Here it is noted that although the mass-proportional damping dominates, the errors obtained using only the mass-proportional damping part of Approaches 1–16, are not the same errors when only mass-proportional damping is considered in Approaches 17–20, as the damping coefficient a_0 is computed using different equations. For example, for $\omega_1 = 37.14$ rad/s and $\omega_3 = 66.62$ rad/s ($\omega_4 = 130.62$ rad/s), $a_0 = 47.7\xi$ ($a_0 = 57.8\xi$) for the mass-proportional part of Rayleigh damping and $a_0 = 74.3\xi$ for only mass-proportional damping. Therefore, the damping coefficient for only mass-proportional damping is larger than that for the mass-proportional part of Rayleigh damping, which essentially results in higher degree of damping. Similar results were observed by Erduran (2012) for fixed-base steel buildings.

Another important observation from the results is that for the floor displacements, smallest errors occur when viscous damping was neglected in the model (Fig. 3(a)). However, Fig. 3(b) and (c) suggests that neglecting such damping may lead to higher errors in terms of the floor accelerations and story shear forces. In certain scenarios, viscous damping is also desirable by analysis programs for purposes of numerical stability. In addition, the higher error due to a particular approach of modeling damping, results mainly because of the inclusion of higher degree of damping.

It is observed that the errors using the updated damping coefficients a_0 and a_1 are smaller compared with using constant a_0 and a_1, and the differences are more obvious for higher damping ratios. For example, consider the errors using approaches in Group B (constant a_0 and a_1) and Group D (updated a_0 and a_1), where in the latter group the errors are smaller (Fig. 3). It is interesting to consider the results obtained using the approaches in Group C, where damping coefficients were computed based on the modal analysis of the base-isolated building with post-elastic stiffness of the isolation system. The errors using the approaches in Group C are either smaller than or comparable with the errors in Group D for all the damping ratios (Fig. 3). In addition, the analysis time with the approaches in Group C was found to be about one fourth of the analysis time using approaches in Group D, where damping coefficients were updated in each analysis step. Therefore, approaches in Group C are more attractive from the view point of computational cost than approaches in Group D.

The analysis results in terms of peak response indicators clearly indicate that it is preferable to use 1% damping. Although there is no unique best approach suitable for all situations, the following two methods yield the least errors:

Method 1: Group C type damping, i.e., Rayleigh damping, with the damping coefficients a_0 and a_1 computed from the frequencies of the base-isolated building with the post-elastic stiffness of the isolation system. However, with this type of damping, the errors depend greatly on the selected damping ratio ξ (Fig. 3).

Method 2: Group F or Group G type damping, i.e., stiffness-proportional damping. With this type of damping, the errors do not vary significantly with the selected damping ratio ξ, compared with Group C type damping, indicating less uncertainty in the predicated response with the choice of ξ (Fig. 3).

To further understand the differences in response indicators using various approaches, and to investigate the ability of an approach in capturing the frequency content of the response, *acceleration time histories* and *response spectra* for all floors corresponding to MIYA-50 excitation were examined for the approaches in all the groups. Here, only roof acceleration time histories and roof response spectra for approaches in Groups C, F, and G, which lead to least simulation errors in terms of peak response indicators, are discussed in detail. Similar results were obtained for the other floors. The absolute roof acceleration time histories for the MIYA-50 excitation are shown in Fig. 4, while the roof response spectra evaluated for secondary systems with damping ratio $\xi_{sub} = 1\%$ attached to the roof are plotted in Fig. 5. Figure 4(a) shows that when viscous damping is not considered in the analysis, the acceleration response is characterized by spurious high-frequency content, which is also manifested as an unrealistic peak appearing at about 8 Hz in the response spectra shown in Fig. 5. Approach 9 (Group C) and Approach 21 (Group F) with 1% damping, which resulted in relatively smaller errors in the peak response indicators (Fig. 3), do not capture the frequency content of the response well as seen in Fig. 4(b) and (c), which is also indicated in Fig. 5(a) by a peak at about 8 Hz in the response spectrum that is not present in the test results. It was found that the use of 5% damping with Approach 9 suppresses the presence of unrealistic high-frequency content as seen in Figs. 4(f) and 5(b) but was shown to be resulting in higher errors in the peak response indicators (Fig. 3). Although the corresponding time history is not shown here for brevity, similar observations were also made for the Approach 21 with 5% damping. Furthermore, it was noted that Approach 9 (Approach 21) at a particular damping ratio produces the results nearly identical to those produced by Approaches 10–12 (Approach 22). Roof accelerations using Approaches 23 and 25 (Group G) with 1% damping match with the test results in terms of frequency content reasonably well as shown in Figs.

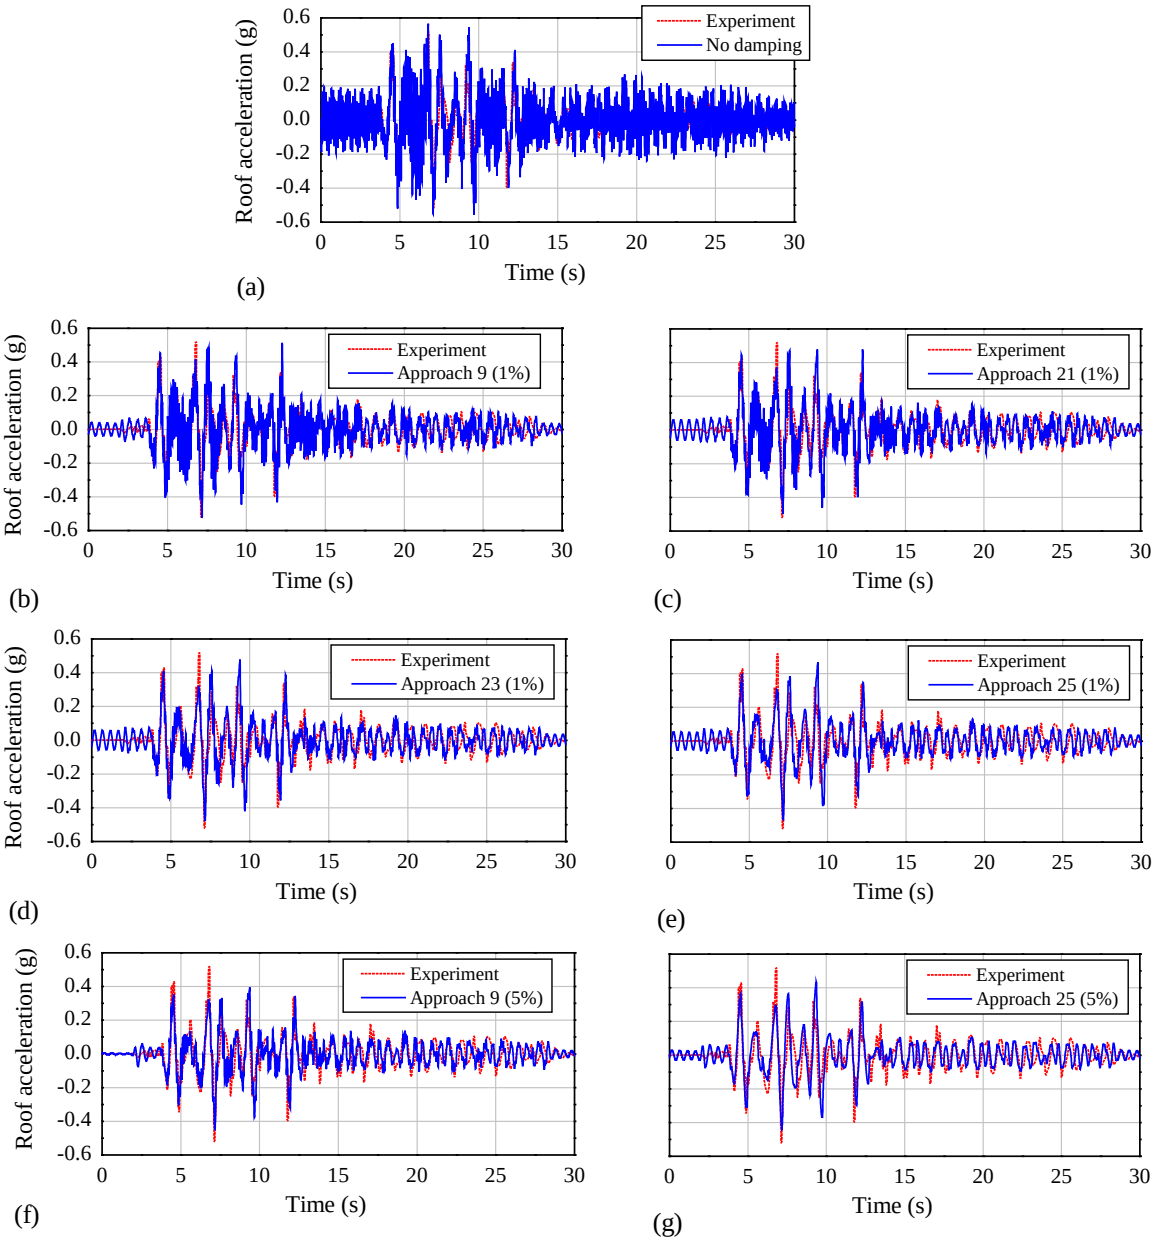

Fig. 4. Absolute roof acceleration time histories for MIYA-50 excitation: (a) no damping; (b)–(e) 1% damping; and (f)–(g) 5% damping. Experimental curve is reproduced after Clark et al. (1997).

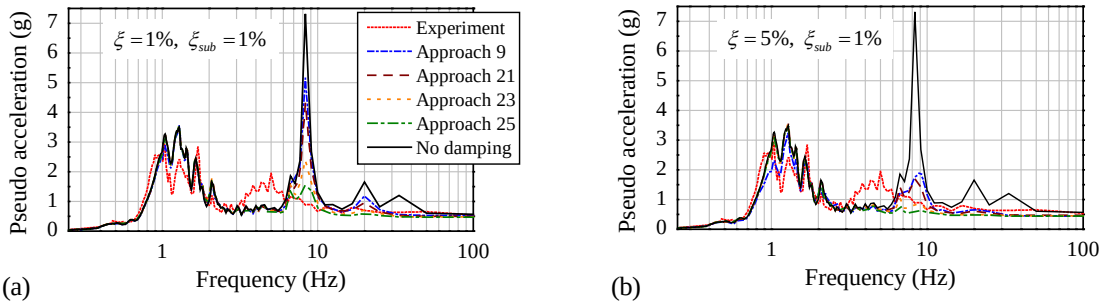

Fig. 5. Roof acceleration response spectra for the MIYA-50 excitation for different damping ratios of the structure: (a) $\xi = 1\%$ and (b) $\xi = 5\%$. The damping ratio for the secondary systems $\xi_{sub} = 1\%$. Experimental curve is reproduced after Clark et al. (1997).

4(d), 4(e), and 5(a). In the high-frequency range, results of Approach 25 are closer to the test results. It is noted that the errors in peak response indicators using Approaches 23 and 25 are not necessarily the smallest but are still smaller than the errors using many of the other approaches (Fig. 3). Since the errors in peak response indicators were not found to be much different between Approaches 23 and 25, it is preferable to use Approach 25. Figure 4(e) and (g) shows that there is a slight difference between the results for $\xi = 1\%$ and $\xi = 5\%$ with Approach 25 but close examination of Fig. 5 suggests the use of 1% damping, because 5% damping causes excessive suppression of the high-frequency response, particularly in the frequency range of 7–9 Hz. Although the corresponding results are not shown, the response histories obtained using Approach 23 (Approach 25) at a particular damping ratio were identical to those obtained using Approach 24 (Approaches 26–28).

In summary, it can be said that Approaches 25–28 with 1% damping provide reasonable estimates of the peak response indicators in addition to being able to capture the frequency content of the response very well. Furthermore, considering the higher computational cost associated with Approaches 27 and 28, it is preferable to use either Approach 25 or Approach 26. It is also important to note that the stiffness-proportional damping in contrast to the Rayleigh damping is effective in suppressing the spurious high-frequency content of the response without affecting its low-frequency content (Fig. 5). However, a large amount of stiffness-proportional damping may lead to undesirable suppression of the high-frequency content of the response.

4. CONCLUDING REMARKS

The consequences of modeling viscous damping in base-isolated RC buildings using different approaches were investigated, by evaluating the response of a three-story building previously tested on a shaking table. The results of nonlinear direct-integration time-history analysis, where Rayleigh-type damping is used, have led to the following conclusions and recommendations:

(1) Application of Rayleigh damping where the damping coefficients a_0 and a_1 are calculated from the frequencies of the superstructure for a fixed-base condition (Group A) and mass-proportional damping (Group E) should be avoided, as these approaches could produce large errors in response predictions.

(2) Rayleigh damping where damping coefficients a_0 and a_1 are calculated from the frequencies of the base-isolated building with the post-elastic stiffness of the isolation system (Group C), at $\xi = 1\%$ results in relatively lower simulation errors in peak response indicators but does not capture the frequency content of the response well. Stiffness-proportional damping where the damping coefficient a_1 is computed from the frequency of the base-isolated building with the post-elastic stiffness of the isolation system (Group G), at $\xi = 1\%$ is found to be better compared with the other approaches investigated in this study, as it provides reasonable estimates of the peak response indicators, in addition to being able to capture the frequency content of the response very well.

(3) Updating damping coefficients in each analysis step is computationally demanding and does not provide substantially improved results compared with the results when damping coefficients computed based on the post-elastic stiffness of the isolation system are considered.

Abstract: Elastomeric bearings are typically used for seismic isolation of buildings, bridges and structures. Assessment of individual bearing stability is an important consideration for the design of seismic isolation systems composed of elastomeric bearings. In this study, critical load behavior of one elastomeric bearing was simulated using both a detailed three-dimensional (3D) finite element (FE) modeling and using an existing two-spring based analytical model. From a comparison of result, the simple analytical model showed similar simulation capability to the detailed 3D FE model. A global variance-based sensitivity technique was applied to the analytical model whereby the sensitivity of the simulated critical displacements to variations in four independent model parameters was determined. The results of the sensitivity analysis demonstrate that the simulation of critical displacement is sensitive to the shear modulus and the rotational spring parameter for large vertical load that are 0.6 to 0.9 times the critical load at zero lateral displacement. For small vertical loads, those less than 0.6 times the critical load at zero lateral displacement, the critical displacement is most sensitive to values of the rotational spring parameter.

1. INTRODUCTION

Elastomeric bearings are widely used for the seismic isolation of buildings, bridges and other important structures. A typical elastomeric seismic isolation bearing consists of a number of rubber layers (natural or synthetic) bonded to intermediate steel shim plates. The total thickness of rubber provides the low horizontal stiffness required to shift the structure's fundamental period into the long period range (e.g. 2.5s to 4s) whereas the spacing of the intermediate steel shim plates directly affects the vertical stiffness and critical load capacity of the bearing for a given bonded rubber area and shear modulus. An important consideration for the design of isolation systems composed of elastomeric bearings is stability of the isolation system and the individual bearings under service (laterally undeformed configuration) and seismic loading (laterally deformed configuration).

When an elastomeric bearing is subjected to simultaneous vertical compressive load, P, and increasing lateral displacement, u, the shear force might pass through a maximum value at which point the tangential stiffness is zero. This point is the point of neutral equilibrium that is considered the stability limit of the bearing and characterized by the critical lateral displacement, u_{cr}, and corresponding vertical load referred to herein as the critical load, P_{cr}.

In practice, the critical load capacity of the bearing in the laterally undeformed configuration, P_{cro}, is estimated based upon theoretical work of Haringx (1948, 1949a, 1949b) for rubber rods that accounts for shear deformations assuming geometric and material linearity. The critical load in the laterally undeformed configuration is calculated according to:

$$P_{cro} = \frac{\sqrt{(GA_s)^2 + 4P_E GA_s} - GA_s}{2} \quad (1)$$

where GA_s = effective shear rigidity and P_E = Euler buckling load (Kelly 1997).Though not codified, the reduced area (RA) method (Buckle and Liu 1994) is the generally accepted procedure for estimating critical loads in the lateral deformed configuration. Using this RA method, the critical load at a given lateral displacement is estimated by multiplying P_{cro} (Eq. 1) by a ratio of areas as:

$$P_{cr} = \left(\frac{A_r}{A_b}\right) P_{cro} \quad (2)$$

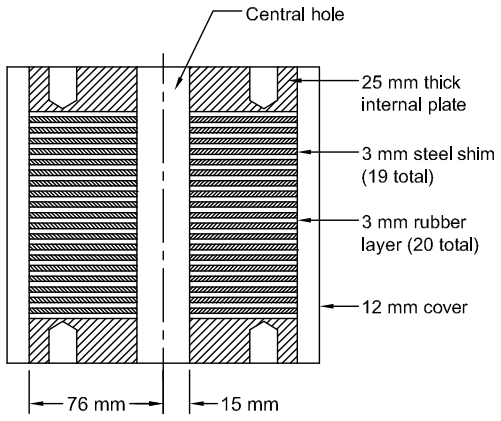
where A_r is the overlapping area between the top-bonded and bottom-bonded elastomer area at a given lateral displacement, u. Buckle et al. (2002) showed the RA method conservatively estimated critical loads for elastomeric bearings with shape factors ranging from 1.67 to 5 though the RA method did not capture well the general trends observed in the experimental data.

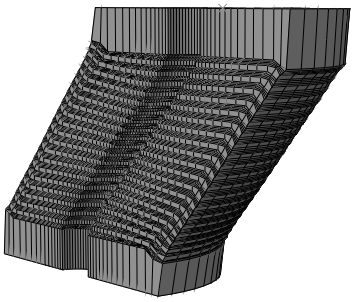
The primary objective of this study was to investigate the capability of a two-spring based analytical model (Iizuka 2000) for simulating the critical load behavior of elastomeric bearings. The specific objectives of the work presented in this paper were: (i) use the analytical model to simulate the critical load behavior of an elastomeric bearing and to compare the analytical results to those obtained from

detailed three-dimensional (3D) finite element (FE) modeling; and (ii) to perform a global variance-based sensitivity analysis on the output of the analytical model to identify the parameter(s) controlling the simulation of the critical displacement. Furthermore, the results of the global sensitivity analysis might identify model parameters to which the simulated critical displacement is insensitive, thus enabling model simplifications for practical implementation and simulation of critical loads for the analysis and design of elastomeric isolation systems.

2. FINITE ELEMENT MODEL

Past research (Warn and Whittaker 2006) suggests 3D Finite Element (FE) modeling is able to simulate the vertical force-displacement and vertical stiffness response of elastomeric bearings in both the laterally undeformed and laterally deformed configurations with reasonable accuracy. The bearing (details presented in Fig. 1) utilized by Warn and Whittaker (2006) is modeled in this study using 3D FE analysis. The general purpose finite element software package ABAQUS (DSSC 2010) is used to develop the FE model and to simulate the critical load behavior of the elastomeric bearing. A mesh sensitivity analysis was performed on different meshes of the bearing model to determine the converged mesh. Fig. 2a shows a rendering of the converged mesh for the FE model. In an effort to minimize the computation demand the symmetry of the bearings and loading is exploited so that only half of the bearing needed to be modeled However, nodes which are located on the "cut" surface of the bearings were constrained against lateral translation to prevent bulging of the rubber layers that would be restrained by the other half of the bearing(shown in Fig. 2a).Boundary conditions are used to simulate the restrain that would be provided by structural framing above and below the bearings in which the bottom end plate is fixed in all degrees of freedom and the top end plate is fixed against rotation yet allowed to translate freely in the horizontal and vertical directions.





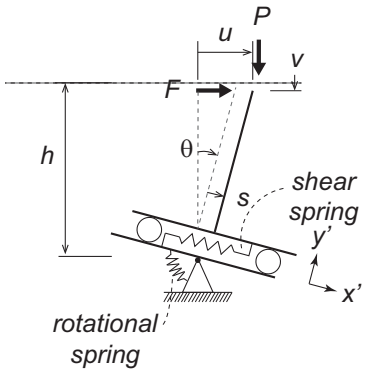


Figure 1 Details of elastomeric bearing specimen

(a) FE model

(b) Two-spring model

Figure 2 Models used for simulating critical loads of elastomeric bearings

The rubber components in the bearing, i.e. rubber layers and cover are modeled using 8-node solid elements (C3D8H) with first order hybrid formulation. The C3D8H element is able to specify the pressure and displacement fields independently to prevent volumetric locking due to the nearly incompressible material behavior of rubber (Poisson's ratio, $\nu \approx 0.5$). The steel shim plates and end plates were also modeled using C3D8H element also to prevent volumetric locking during plastic flow. The Neo-Hookean constitutive model is selected since both the model parameters have a direct relationship with the engineering properties, specifically, the shear modulus, G and bulk modulus, κ. The Neo-Hookean model assumes that the material is hyper elastic, isotropic, and incompressible or nearly incompressible if a value of the bulk modulus is specified. The strain energy potential for the Neo-Hookean model is defined as:

$$U = C_{10}(\bar{I}_1 - 3) + \frac{1}{D_1}(J^{el} - 1)^2 \tag{3}$$

where U is the volumetric strain energy; C_{10} is equal to $G/2$; D_1 is equal to $2/\kappa$; $\bar{I}_1$ is the first strain invariant of the Cauchy–Green deformation tensor; and J^{el} is the elastic volume ratio. The shear modulus G, used in the FE study is the effective shear modulus at 100% shear strain determined from characterization tests performed on the bearing (Warn an Whittaker 2006). The effective shear modulus G at 100% shear strain is reported to be 0.84 MPa (120psi) that results in a C_{10} value of 0.42 MPa. Although the exact value of bulk modulus was not determined from their tests, Warn and Whittaker (2006) showed that the FE solution is insensitive

to the bulk modulus over a range of 20% of the assumed 2,000 MPa (290,000 psi) value. Therefore the bulk modulus is assumed to be 2,000 MPa. The steel material is modeled as a plastic isotropic material with v = 0.3, elastic Young's modulus E = 200 GPa (29,000 ksi) and yield strength σ_y = 448 MPa (65 ksi).The strain hardening ratio was assumed to be 2% for the steel.

3. ANALYTICAL MODEL

The analytical models for simulating the critical load behavior of elastomeric bearings considered in this study is from Iizuka (2000) and based on the two-spring model (TSM) introduced by Koh and Kelly (1988).The two-spring model (see Fig. 2b) consists of a shear spring and a rotational spring that are connected through rigid elements and frictionless rollers. The height of the model from the applied load at the top of the rigid tee to the hinge is h. Under simultaneously vertical force, P, and shear force, F, the top of the model translates with a lateral displacement, u, and height reduction, v (see Fig. 2b). The global deformation (u and v) are the result of local deformations, s, and θ, in the shear and rotational springs, respectively, due to the internal shear spring force, Q_s, and internal rotational spring moment, M. Considering equilibrium and compatibility of the two-spring model in the deformed configuration (see Fig. 2b), the following equations are derived:

$$u = s\cos\theta + h\sin\theta \tag{4}$$

$$v = s\sin\theta + h(1-\cos\theta) \tag{5}$$

$$M = Pu + F(h-v) \tag{6}$$

$$Q_s = P\sin\theta + F\cos\theta \tag{7}$$

Specifying linear properties for the shear, K_s, and rotational, K_θ, springs, Koh and Kelly (1988) demonstrated the two-spring model was able to simulate the reduction in initial horizontal stiffness, increased mechanical damping, and reduction in height, v, with increasing vertical load, P. From the two-spring model, the initial shear spring stiffness, K_{so}, is calculated according to:

$$K_{so} = \frac{GA_b}{T_r} \tag{8}$$

where T_r= total rubber thickness; A_b and G as previously defined. The initial rotational spring stiffness, $K_{\theta o}$, calculated according to:

$$K_{\theta o} = \frac{\pi^2 E_b I}{T_r} \tag{9}$$

where E_b = bending modulus of an individual rubber layer; and I = moment of inertia of bonded rubber area.

Iizuka (2000) proposed a nonlinear model, based on the two-spring model, for the purpose of predicting the shear force response at large shear strains for a range of vertical loads. The model proposed by Iizuka uses semi-empirical nonlinear relationships for the shear and rotational springs. The relationship for the rotational spring is based, in part, on the yield moment, M_y, and ultimate moment, M_u, for an individual rubber layer. Details for the yield and ultimate moment calculations are provided in Iizuka (2000). The tangential rotational stiffness in the elastic range ($dM/d\theta$) is given as:

$$\frac{dM}{d\theta} = K_{\theta o} \quad \left(\theta \le \theta_y\right) \tag{10}$$

where $K_{\theta o}$ is calculated according to Eq. (9) and θ_y = yield rotational angle calculated according to:

$$\theta_y = \frac{M_y}{K_{\theta o}} = \frac{2Z\left(\sigma - \sigma_y\right)}{K_{\theta o}} \tag{11}$$

where Z = elastic section modulus of bonded rubber area; σ = nominal stress ($\sigma = P/A$); and σ_y = tensile yield stress of rubber (assumed to be equal to $3G$ (Gent 2001)). For rotations beyond yield, i.e. $\theta \ge \theta_y$, $dM/d\theta$ is assumed to be:

$$\frac{dM}{d\theta} = \frac{K_{\theta o}}{\left[1 + \frac{r}{3}\left(\frac{\theta}{\theta_y} - 1\right)\right]^{\frac{1+r}{r}}} \quad \left(\theta > \theta_y\right) \tag{12}$$

where r = a dimensionless parameter. Iizuka reported values for r ranging from 1.2 to 3.5 determined empirically from characterization tests performed on elastomeric bearings.

Iizuka proposed the following relationship for the tangential stiffness of the shear spring:

$$\frac{dQ_s}{ds} = \left[1 + s_1\left(1 + s_2\right)\left(\frac{s}{T_r}\right)^{s_2}\right] K_{so} \tag{13}$$

where s_1 and s_2 = dimensionless parameters. Similar to r, s_1 and s_2 are empirical parameters determined from the results of characterization testing. Iizuka specified values for s_1 ranging from 0.0068 to 0.01 and a value of 3 for s_2.

Iizuka's model requires an incremental form of the two-spring equilibrium and compatibility equations presented in Eqs. (4) through (7) be solved using a stepwise procedure. The incremental equilibrium and compatibility equations are:

$$\begin{Bmatrix} {}_i(\Delta\theta) \\ {}_i(\Delta s) \\ {}_i(\Delta v) \\ {}_i(\Delta F) \end{Bmatrix} = \left[K\right]^{-1} \times \begin{Bmatrix} 0 \\ 1 \\ P \\ 0 \end{Bmatrix} \times \Delta u \tag{14}$$

where incremental force and deformation quantities ${}_i(\Delta\theta)$, ${}_i(\Delta s)$, ${}_i(\Delta v)$ and ${}_i(\Delta F)$are obtained for step i from Eq. (14) for a specified vertical force, P, incremental lateral displacement, Δu, and the matrix $[K]$ is defined by:

$$\left[K\right] = \begin{bmatrix} h\sin{}_i\theta + {}_i s\cos{}_i\theta & \sin{}_i\theta & -1 & 0 \\ h\cos{}_i\theta - {}_i s\sin{}_i\theta & \cos{}_i\theta & 0 & 0 \\ {}_i\left(\frac{dM}{d\theta}\right) & 0 & {}_i F & {}_i v - h \\ P\cos{}_i\theta - {}_i F\sin{}_i\theta & {}_i\left(\frac{dQ_s}{ds}\right) & 0 & \cos{}_i\theta \end{bmatrix} \tag{15}$$

The incremental response quantities obtained from the solution of Eq. (14) are added to those from the current step to obtain response values for the subsequent (i+1)th step. Linear spring properties are assumed for the first step and the initial response quantities determined using Eqs. (4)

through (7) to avoid an ill-conditioned matrix for solving Eq. (14) (Iizuka 2000).

The analysis is terminated when the height reduction v is larger than the total rubber thickness T_r. The shear force response, $F(u)$ is obtained from the solution for a specified vertical load P. The critical displacement u_{cr} is determined by numerically differentiating the shear force- lateral displacement response from which the displacement where the tangential stiffness equals zero is determined, i.e. $dF/du = 0$. The stepwise solution procedure is repeated for several values of P to obtain a series of critical points (i.e. P_{cr} and u_{cr}) used to develop a "stability" curve.

4. GLOBAL SENSITIVITY ANALYSIS

Sensitivity analysis quantifies how variability in a given model output, $y = f(x_1, x_2 \ldots x_k)$, can be attributed to variability in model factors $x_1, x_2, \ldots, x_k$ (Saltelli et al.2004). Sobol' method (Sobol'1993), a global, variance-based, sensitivity analysis technique is used in this study to identify model factor (e.g. parameters, variables, and initial conditions) to which the model output (i.e. u_{cr}) is most sensitive.

Sobol' sensitivity analysis method (Saltelli et al.2008) is unique among the sensitivity methods in that it decomposes a models output variance $V(y)$ into the relative contributions from individual factors and factor interactions through numerical integration in a Monte Carlo framework. The term factor is used as an umbrella term including model parameters (those that do not vary with time) and variables. Assuming the factors are statistically independent, the model's output variance can be expressed as:

$$V(y) = \sum_i V_i + \sum_i \sum_{j>i} V_{ij} + \ldots + V_{12\ldots k} \tag{16}$$

where k = number of factors (e.g. parameters); y = distribution of model output; $V(y)$ = total model output variance; V_i = output variance due to the ith parameter; V_{ij} = output variance due to interaction of factors x_i and x_j; $V_{12\ldots k}$ = output variance due to higher order interactions. A given parameter's sensitivity is quantified by a ratio of variance contributing to the total (i.e. due to all parameters) output variance, resulting in an index value ranging from 0 to 1. The "First order" Sobol' sensitivity index used in this study reflects the effect of the ith parameter alone and is defined as:

$$S_i = \frac{V_i}{V(y)} \tag{17}$$

The "total" Sobol' sensitivity index, also used in this study, reflects the effect of the ith parameter alone plus interactions of the ith parameter with all other parameters and is defined as:

$$S_{Ti} = 1 - \frac{V_{\sim i}}{V(y)} \tag{18}$$

where $V_{\sim i}$ =the average variance from all factors but f_i. The total order index S_{Ti} is the sum of the interactions index and the first order index S_i.

5. RESULT AND DISCUSSION

5.1 FE model validation

Prior to the critical load simulation of elastomeric bearing (shown in Fig. 1), a comparison between the experimentally obtained vertical force displacement response and that from the FE analysis is performed to partially validate the capability of the FE model to simulate bearing behavior. Figure 3 shows the comparison between experimental and FE force-displacement response. From the comparison, the FE model captures well the vertical stiffness behavior of elastomeric bearings. The relative error between the vertical stiffness from the FE simulation and experimental data is within 10% where the vertical stiffness was calculated as the secant slope between minimum and maximum force values. Based on the comparison of the vertical force-displacement response, it was judged that the FE model is sufficiently able to capture the mechanic behavior of elastomeric bearings. The FE model was then used to simulate the critical load behavior of elastomeric bearings.

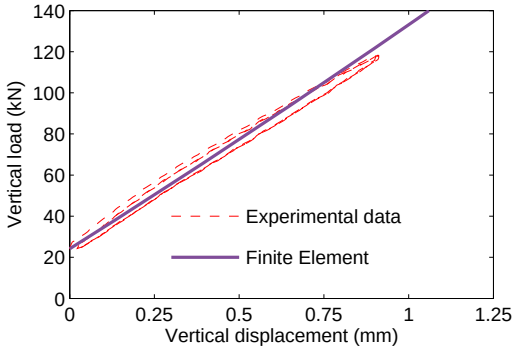

Figure 3 Vertical stiffness comparison between experimental data and FE analysis

5.2 Critical load simulation

Both the detailed FE model and Iizuka analytical model were used to simulate the critical load behavior of the elastomeric bearing shown in Fig. 1. The purpose is to assess the capability of the simple analytical model (Iizuka model) to simulate critical load behavior by comparison to the more detailed and computationally intensive FE model.

A series of FE analyses were performed whereby the model was subjected to vertical compressive load P ranging then sheared to a target lateral displacement. This analysis was repeated for vertical compressive loads ranging from 0 to 356 kN. The results of these FE analyses are presented in Fig. 4. The plots presented in Fig. 4 show the effect of axial load on the force–displacement response: specifically, as the axial load increases, the initial stiffness, maximum shear force attained and critical displacements decrease. The critical displacements (i.e. point of zero horizontal stiffness) and corresponding vertical load from the force-displacement results taken as the critical points and are plotted in Fig. 5.

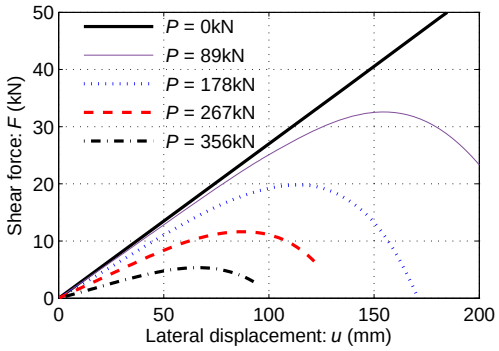

Figure 4 Shear force-lateral displacement relationship for elastomeric bearing

Critical loads simulation results (u_{cr}, P_{cr}) obtained using Iizuka model are also shown in Fig. 5 along with those obtained from the analyses of the detailed FE model. However, values for parameters r, s_1 and s_2 had to be assumed in lieu of characterization data for each of these bearings. Based on values provided in Iizuka (2000), s_1 ands_2 were assumed to be $s_1 = 0.01$ and $s_2 = 3$, respectively. Values of the parameter r reported in Iizuka (2000) ranged from 1.2, 1.5 and 3.5. With no guidance provided by Iizuka for determination of the value of the r parameter, an average value of 2 was used for the analytical simulations.

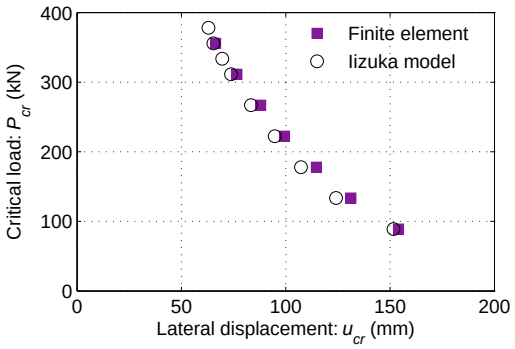

Figure 5 Critical load simulation comparison between FE model and Iizuka model

Critical loads simulated from the FE model and Iizuka model presented in Fig. 5 show a similar trend of reducing critical load values with increasing lateral displacement, which was also found in previous experimental testing (Buckle and Liu 1993, 1994). From the result presented in Fig. 5, the simulation capability of Iizuka's simple analytical model agrees well with the more detailed and computationally demanding 3D FE model over a wide range of lateral displacement. The relative difference between the analytical and FE critical load values at particular lateral displacement range between 2 and 8% with the FE values assumed as the true value in the relative error calculation. Based on these results, Iizuka model is capable to simulate the critical load behavior of this elastomeric bearing.

5.3 Global sensitivity analysis

Sobol' method was used to compute sensitivity indices for the four independent Iizuka model parameters, specifically G, r, s_1 and s_2, to identify the relative importance of the individual parameters in the simulation of the critical displacement, u_{cr}. The sensitivity analysis was performed on an ensemble of u_{cr} values generated for various levels of vertical load, P. Table 1 presents the range of values considered in the sensitivity analysis for the four model parameters (i.e. G, r, s_1 and s_2). Each parameter was assumed to be uniformly distributed over the ranges presented in Table 1. The range of values for parameters r, s_1 and s_2 were kept as broad as possible while avoiding non-physical combinations leading to nonrealistic predictions, noting $s_1 = 0$ was considered in the parameter range.

Table 1 Varied parameter and parameter ranges used for global sensitivity analysis

Type	Symbol	Unit	Range
Material	G	MPa	0.77-0.87
Model	r	n.a.	0.5–6
	s_1	n.a.	0–0.01
	s_2	n.a.	0–5

Total indices (individual contribution plus interactions) and first order indices (individual) computed using the properties of the bearing shown in Fig. 1 are presented in Figs. 6. Figure 6 includes four bar graphs, one for each parameter, with total and first order sensitivity indices plotted for vertical load values P normalized by the corresponding P_{cro} (calculated by Eq. 1) ranging from 0.3 to 0.9. The total and first order indices for parameters s_1 and s_2 are near zero, indicating variability in these parameters has no impact on the critical displacement value simulated by the Iizuka model over the range of vertical load values considered. By considering $s_1 = 0$ and $s_2 = 0$ in the parameter range, these results demonstrate the relationship assumed for the shear spring (i.e. linear vs. nonlinear) has no effect on the predicted critical displacement Therefore, the Iizuka model could be simplified by assuming linear spring properties.

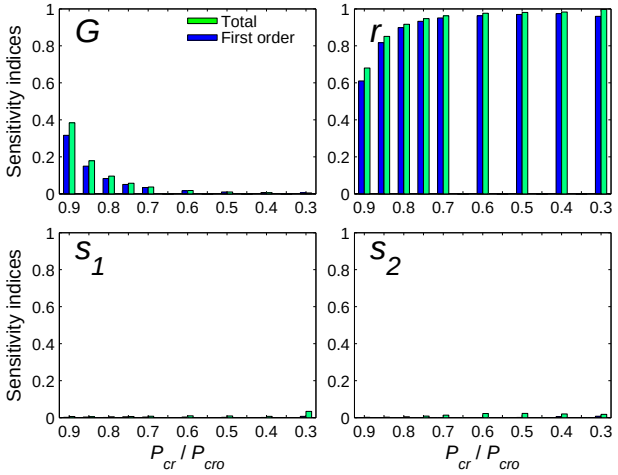

Figure 6 Sensitivity indices for elastomeric bearings

The results presented in Figs. 6 show that both total and

first order indices for the shear modulus, G, decrease as P_{cr}/P_{cro} decreases. This result suggests variation in the shear modulus only has an appreciable impact on the u_{cr} value when P_{cr} is a significant percentage (70 to 90%) of P_{cro}. There is a difference between the total and first order indices for G when P_{cr}/P_{cro} is large. This suggests there is interaction between G and r for large P_{cr}/P_{cro}. Sensitivity indices for parameter r show that as P_{cr}/P_{cro} decreases, both first and total order indices increase approaching a value of nearly 1 for P_{cr}/P_{cro} equal to or less than 0.6.

6. CONCLUSION

The critical load behavior of one bearing (see Fig. 1) was simulated using FE analysis of a detailed 3D model and an existing analytical model. A comparison of the simulated critical displacement values showed the values obtained from the simple Iizuka model compare well with those from the significantly more detailed and computationally demanding finite element model. This result suggests the Iizuka model could be an efficient and accurate method of simulating the critical load behavior of elastomeric bearings.

A global variance-based sensitivity analysis was performed on the Iizuka model output whereby the sensitivity of the u_{cr} simulation to variability in four independent model parameters, specifically, G, r, s_1 and s_2 was determined. The results of the sensitivity analysis demonstrated that the simulated u_{cr} value is sensitive to the shear modulus G and the rotational spring parameter r for vertical loads that are a large percentage (e.g. 60 to 90%) of P_{cro}. As the vertical load decreases, the sensitivity of the u_{cr} value to the G diminishes and the rotational parameter r becomes the controlling parameter. Additionally, the results of sensitivity analysis demonstrated that the u_{cr} prediction is insensitive to the value of the shear spring parameters (i.e. s_1 and s_2) even when values of zero are considered. It can be concluded then that the form of the shear spring (linear versus nonlinear) has no appreciable impact on the critical load values simulated using the Iizuka model.

Abstract: The design of structures, systems and components of nuclear power plants (NPPs) in the United States is moving toward a risk-informed performance-based approach. Seismic risk is an important concern for NPPs due to the extremely rare levels of shaking that must be considered in design. In response to events at Fukushima Dai-ichi following the Great Eastern Japan Earthquake, renewed attention has been focused on the mitigation of seismic risk to NPPs. The goal of this paper is the introduction of a practical strategy for the design of seismic isolation systems for standardized NPPs who's structural and non-structural components have been certified to a particular level of seismic demand. Such a design may be considered a template of a standard NPP to be deployed in multiple geographic regions, all having varying levels of seismic hazard, fault mechanisms, soil types, etc. Whereas a conventionally-built standard NPP would be expected to have varying seismic reliability for each seismic hazard environment in which it is built, the introduction of a properly-tuned seismic isolation layer can modify the seismic effects such that the target performance objectives are met regardless of the original design basis. This paper presents a practical method to target bilinear isolation system properties (strength and stiffness) given a standard NPP design and a set of seismic hazard curves for a specific site and soil type. This method has the potential to simplify the design of new NPPs located worldwide, while providing the high level of reliability against failure that is required of such crucial facilities.

1. INTRODUCTION

The goal of this paper is the development of a practical strategy for the design of seismic isolation systems for standardized nuclear power plants (NPPs.) In this context, "standardized" refers to an NPP who's structural and non-structural components have been certified to a particular level of seismic demand. Such a design may be considered a template of a standard NPP to be deployed in multiple geographic regions, all having varying levels of seismic hazard, fault mechanisms, soil types, etc. Whereas a conventionally-built standard NPP would be expected to have varying seismic reliability for each seismic hazard environment in which it is built, the introduction of a properly-tuned seismic isolation layer can modify the seismic effects such that the target performance objectives are met regardless of the original design basis of the superstructure and associated components. This idea has been investigated for small modular reactors by Blandford et al [2009.] The deployment of numerous small-scale, standard NPPs throughout the US is an attractive way to increase and distribute nuclear energy output with higher safety and less expense [The Economist, 2009.]

In this study, the standard NPP has been designed as a conventional structure at a site with very low seismicity, representing a practical minimum for seismic certification of the plants structures, systems, and components (SSCs.) Such an NPP could be constructed in any region with very low exposure to seismic hazard, and the structural system and non-structural components and contents could be identical for each NPP. The structural system, once designed to the original very low seismic criteria, has quantifiable force-deformation characteristics which may be adopted from the pushover curve and transformed into fragility curves for performance states applicable to NPPs. The non-structural systems, including electrical, mechanical, and plumbing equipment, and the associated distribution systems, would also be subjected to some floor response spectrum based on the initial design criteria. Once the structural and non-structural systems have been certified to the level of seismic demand, this design basis is used in the optimization of isolation systems considering a broad classification of seismic hazard, from the lowest to the most severe found in the US. The isolation systems considered in this study are assumed to be bilinear with supplemental dampers, and are applicable to either spherical sliding bearings or lead rubber bearings. However, the conceptual framework is easily extensible to other devices should they be considered.

Unless otherwise indicated, design of NPP structures,

systems, and contents (SSCs) in this paper is based on the provisions and underlying philosophy described in ASCE 43-05 [2005.]

2. SEISMIC RESISTANCE OF STRUCTURAL SYSTEMS

The standard design of an NPP in this study is based on one constructed in a region of very low seismicity. The site is arbitrarily chosen as Houston, TX, since it is among the least active seismic regions in the US. Applying the provisions of ASCE 43-05 [2005], the design base shear for a structure at this site would be 0.21 *g*, assuming a rock site and stiff containment structure with a natural period around 0.25 sec. This base shear corresponds to an annual return period of 10,000 years, plus a modification to achieve uniform risk of failure. ASCE 43-05 also provides estimates of structural system over-strength based on the random strength having a 98% exceedance probability relative to the design strength, and an assumed dispersion of 0.35. This leads to an over-strength factor of 2.05. Assuming the NPP structure is reinforced concrete, a reasonable estimate of the pushover curve for our standard NPP is shown below in Figure 1. This pushover curve may be thought of as the seismic certification of the structure, since it is a measure of seismic resistance, and depends only on the structural geometry and detailing, and not on the assumed hazard environment.

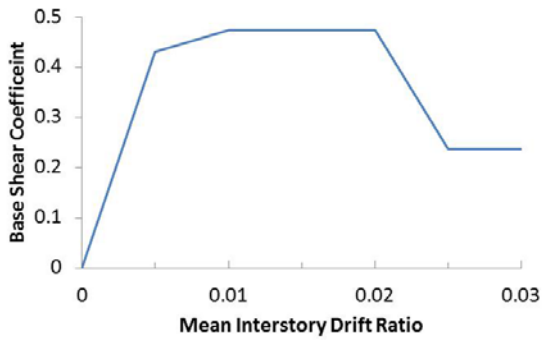

Figure 1. Assumed pushover curve for the standard NPP structure

3. SEISMIC CERTIFICATION OF EQUIPMENT

The seismic certification of an equipment unit establishes the ability of that unit to withstand a particular intensity of seismic shaking and perform its function immediately following that shaking. Recognizing that earthquake shaking produces a broadband excitation, the intensity is generally represented not by a single parameter or even acceleration history, but by an acceleration response spectrum (ARS). This ARS is a demand imposed on an equipment unit by an earthquake, and is a function of many parameters: structural system supporting the equipment, earthquake magnitude, site-to-source distance, soil type, etc. The resistance of an equipment unit must also be described in terms of a spectrum, since harmonic shaking at a fixed frequency may not cause a failure, whereas the same or lower amplitude shaking at a different frequency may cause a failure due to the dynamic response of the internal components of the unit. To address this, equipment manufacturers develop what is known as the Required Response Spectrum (RRS) to describe the maximum amplitude of shaking across a range of frequencies the unit may experience while remaining functional. The ability of the equipment to function is established by testing, and if the tested response spectrum envelopes the RRS for the frequency range of interest, the equipment units are considered to be seismically certified for that RRS. Further information about the seismic certification of electrical equipment can be found in Wilkie et al [2009.]

Given the standard NPP structure, the in-structure floor spectra may be computed for a specific level of seismic hazard. To generate a spectrum, a set of spectrum-compatible ground motions was selected and scaled to the original Houston, TX site. The mean in-structure floor spectrum was then computed at the roof level based on response history analysis (RHA.) The roof is the location with highest acceleration demand. A generic spectrum was then generated based on the assumed peak roof acceleration from static analysis, and an amplification factor of 5 for peak roof spectral acceleration. The peak of the spectrum is based on the natural period of the standard NPP structure = 0.25 sec. The generic spectrum is compared with that obtained from RHA in Figure 2. The generic spectrum is denoted the required response spectrum (RRS) since this spectrum forms the basis of seismic certification testing for all nonstructural systems and components.

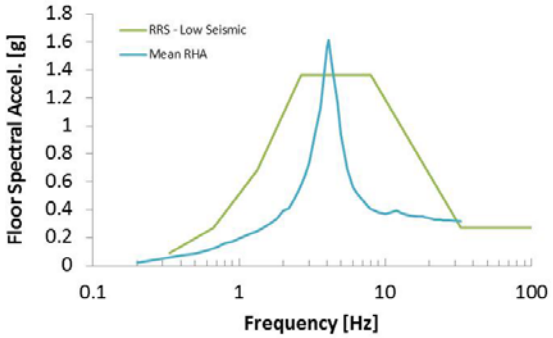

Figure 2. Comparison of mean floor spectrum from RHA with generic RRS for the standard NPP.

4. APPLICATION OF SEISMIC ISOLATION TO STANDARD NPP DESIGN

With the seismic resistance of the standard NPP structural and non-structural components defined, we apply seismic isolation technology to this standard design and enhance its performance capabilities so it may be

constructed in any part of the US, regardless of the seismic hazard environment. To motive this study, three sites have been selected to represent large, moderate, and low levels of seismic hazard. These sites are located, respectively, in Los Angeles CA, St. Louis MO, and Boston MA, each with firm soil site conditions (shear wave velocity between 200 m/s and 400 m/s). The seismic hazard curves for each of these sites, assuming rock sites, are shown in Figure 3, where the intensity measure is taken to be the spectral acceleration at a period of 1-sec (commonly denoted S_{a1}.) This is an appropriate measure for isolated structures, where the period range is generally in the constant-velocity region.

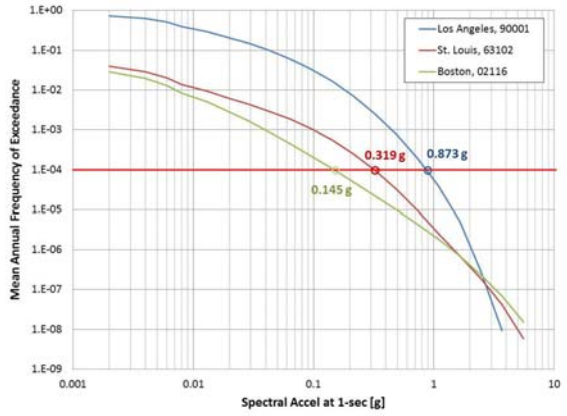

Figure 3. Comparison of seismic hazard curves for S_{a1} used in this study, including demand at MAFE = $1x10^{-4}$.

In selecting the basic properties of the target isolation system, the adequate performance of the structure and non-structural components must be targeted. First considering the structure, the primary design parameter is the base shear demand. By limiting the design base shear of the isolated NPP to that of the standard NPP described in Section 2, elastic behavior of both structures with the equivalent level of confidence is achieved. The basic procedure for this is to develop the constant velocity region of the design spectrum based on the 10,000 yr return period earthquake as

$$S_a = \frac{S_{a1}}{T_I B} \quad (1)$$

Where S_{a1} is the spectral acceleration at 1-sec with an MAFE = 1 x 10^{-4}, T_I is the isolation period, and B is a damping-based spectral reduction factor which can be taken as $B = 2.4\zeta^{0.3}$ (ζ is the critical damping ratio of the isolation system.) By setting Eq. (1) equal to the design base shear coefficient 0.21 g for the standard NPP above, some combination of isolation period and damping can be determined. In the protection of nonstructural components, it is generally advised to use lower-damping isolators (Yang et al, 2010.)

To facilitate comparison of in-structure floor spectra with the RRS for equipment, some generic in-structure spectrum must be developed based on the intensity of shaking at the floor levels of the isolated NPP. Since isolated structures may be treated as a single-degree-of-freedom system, this study considers a single representation of demand for all locations above the isolation layer. This assumption is valid for stiff superstructures having an isolation system with a substantial period separation (say fixed-to-isolated period ratio = 4.) The estimated in-structure ARS is based on the peak floor acceleration and an amplification factor to reach the peak spectral acceleration. This amplification factor depends on the hysteretic properties of the bearings, but can be as large as 4.5 (Yang et al, 2009.) For simplicity, a conservative amplification factor of 4.0 was adopted here, and nonlinear RHA supports its use over a range of isolator types.

The isolator properties are selected so that Eq. (1) is satisfied (for structural performance) and such that the in-structure demand ARS exceeds the RRS for all frequencies between 1 Hz and 35 Hz. A comparison of the ARS for the three sites with the RRS for the standard NPP is shown in Figure 4. A summary of isolator properties which provides the standard NPP with suitable performance for each of the three sites is given in Table 1. These properties are easily achievable in practice with either elastomeric or spherical sliding bearings.

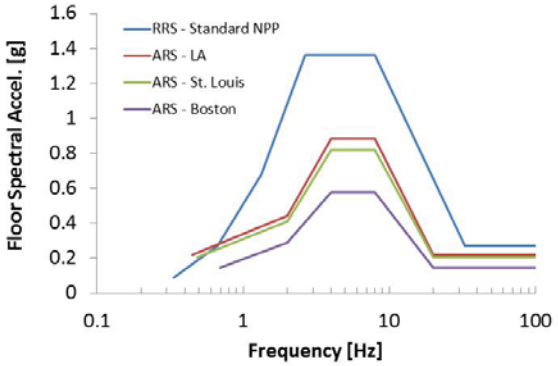

Figure 4. Comparison of floor acceleration response spectra (ARS) for three sites with the required response spectrum (RRS) for the standard NPP.

Table 1. Isolation system period, damping, and displacement demand for each of the three selected sites.

Site	T_b	ζ_b	Δ_b
LA	4.0 s	20%	34.6"
St. Louis	2.0 s	15%	8.04"
Boston	1.5 s	10%	3.19"

5. CONCLUSIONS

This paper concludes with practical method to target bilinear isolation system properties (stiffness and damping) given a standard NPP design and a set of seismic hazard curves for a specific site and soil type. The standard NPP was designed as a conventional structure assuming a site with very low seismicity. A procedure for developing optimal strength and stiffness of the isolators was presented starting with the seismic hazard environment and soil type, certified design strength of standard NPP, and required response spectra (RRS) for nonstructural components. This method therefore incorporates the performance both structural- and non-structural systems, and uses nonlinear response history analysis to validate the procedure presented. This design approach has the potential to simplify the design of new NPPs located in all parts of the US and around the world, while providing the high level of reliability required for such crucial facilities.

IDENTIFICATION OF MASS ECCENTRICITIES FROM SEISMIC RESPONSE OF THREE DIMENSIONAL BUILDINGS

Roshanak Omrani[1], Ralph E. Hudson[2], and Ertugrul Taciroglu[3]

Abstract: We propose an algorithm for identification of mass-eccentricities in a one-story framed building from its nonlinear response to moderate seismic excitations. Most time-domain system identification techniques assume the mass of the structure to be a known parameter, which can be determined from the structural and architectural drawings with reasonable accuracy. However, in the presence of torsional motion, mass eccentricities are needed in addition to the lateral mass of the structure in order to characterize the mass matrix. Often, high uncertainties associated with the spatial distribution of mass complicate the determination of mass eccentricities. The proposed algorithm adopts the well-known Bouc-Wen model to represent the nonlinear force-displacement relationships in the lateral load resisting elements of the structure. Subsequently, Unscented Kalman Filtering is employed to carry out a sequential state and parameter estimation by using the lateral and torsional accelerations of the structure as the observed response quantities. The identified state/parameter vector includes the deformation and the internal force of individual lateral load resisting elements, Bouc-Wen parameters, and mass eccentricities.

1. INTRODUCTION

System identification techniques have become conventional tools for assessing the state of health of civil structures either on a permanent basis during the service life of a structure, or after extreme events. In addition to structural health monitoring purposes, these methods can be utilized to identify the actual—versus the expected—behavior of structural systems during seismic events so that predictive response models can be validated or calibrated. Enhanced understanding of the inelastic response of structural systems and characterization of their deformation and energy dissipation capacities can be utilized towards the improvement of performance-based seismic assessment methodologies.

Most methods concentrate on response characteristics that exhibit variations within different regimes of response (e.g., restoring forces), or structural properties whose values are altered from a baseline value, typically due to extreme damage scenarios (e.g., stiffness). Consequently, identification of mass properties, which are generally presumed to remain constant over the service life of a structure and throughout damaging events, has received less attention. Nonetheless, model updating and most of the time-domain identification methods require reasonable estimates of structural mass and its distribution.

The most common approach encountered in the current literature for identification of structural mass properties is the calibration of these properties via model updating techniques, such that the output of the model matches the measured response of the structure (Yu et al., 2006; Ventura et al., 2001). Another conventional approach employs the definition of impulse response function to identify lumped masses associated with discrete degrees of freedom. This is achieved by using the vibration history induced by impulsive forces applied at the location of the lumped masses (Masri 1982). A publication by Ruge (1992) describes a state-space technique, which extracts the stiffness matrix of the system from the eigenvalue problem associated with the state-space representation of the system. This is done by imposing conditions that correspond to a static response. Having the stiffness matrix, the mass matrix is deduced from the eigenvalue problem under the dynamic conditions. Angeles-Cervantes and Alvarez-Icaza (2011) propose a least-squares-based method for identifying the products of the inverse of mass matrix with both stiffness and damping matrices and approximating the center of torsion of shear-type buildings. If the mass of the structure is given, then the stiffness and damping matrices can be extracted from the identified matrix products. Zhou et al. (2012) propose a method, which utilizes the forced vibration testing results of a continuous structure, before and after addition of a known mass, to identify the unknown mass of the structure.

The present paper elaborates on extending the previous work (Omrani et al. 2012) in developing an algorithm for identifying nonlinear response of torsionally coupled buildings from their seismic response. The new extension identifies the floor's mass eccentricities and moment of

inertia—which were previously considered as given—along with the nonlinear force-deformation history of the lateral-load-resisting elements of the building. The identification of the aforementioned quantities allows the characterization of the distribution of the mass, which usually cannot be decided accurately from the structural drawings. The current approach does not estimate the value of lateral mass. However, the lateral mass can be evaluated with reasonable accuracy from the structural and architectural drawings. Furthermore, it is possible to identify the *extent* of nonlinearity and the *shape* of the hysteretic force-deformation loop of each lateral-load-resisting element, even without a precise knowledge of the lateral mass, by assuming a unit value.

2. METHODOLOGY

2.1 State-Space Formulation

The general form of the second order differential equation which governs the response of a system to support excitation is given in Equation (1),

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{f}\left(\mathbf{U}, \dot{\mathbf{U}}\right) = -\mathbf{M}\ddot{\mathbf{U}}_{\mathbf{g}} \tag{1}$$

Matrix **M** is the global mass matrix and **U** is the (relative to support) displacement vector, where $\dot{\mathbf{U}}$ and $\ddot{\mathbf{U}}$ denote the first and second derivatives of **U** with respect to time, respectively. Vector **f** contains the nonlinear restoring (resisting) forces. In case of a viscously damped linear system, **f** reduces to a linear combination of relative displacement and velocity terms. Vector $\ddot{\mathbf{U}}_g$ contains the support accelerations.

Assuming that the total mass can be lumped at the roof level in a one-story shear-type building with a rigid roof slab, three degrees of freedom (two translational and one torsional) would suffice for characterizing the motion of the building, i.e.,

$$\mathbf{U} = \begin{bmatrix} u_x & u_y & u_q \end{bmatrix}^{\mathrm{T}} \tag{2}$$

Under the aforementioned assumptions the mass matrix will assume the following form,

$$\mathbf{M} = \begin{bmatrix} m & 0 & -me_y \\ 0 & m & me_x \\ -me_y & me_x & I_O \end{bmatrix} \tag{3}$$

where m is the lateral mass of the building, e_x and e_y are the orthogonal distances between the center of mass and the origin of the Cartesian coordinate system with respect to which the equations of motion are defined, and I_o is the mass moment of inertia with respect to the same origin.

The elements of the resisting force vector, **f**, are the resultants of the resisting forces which are developed in all lateral-load-resisting elements of the structure. It can be reasonably assumed that the contribution of the gravity load bearing elements—such as beams or columns that are not integrated into a moment resisting frame or a shear wall—to the overall lateral-load-bearing capacity of the structure is negligible compared to the capacity provided by moment resisting frames and/or shear walls, henceforth referred to as Lateral Load Resisting Systems (LLRSs). Hence, if the structural system consists of a total of r LLRSs, q of which are aligned with the x and the rest with the y directions, **f**, will acquire the following form,

$$f = \begin{bmatrix} \sum_{j=1}^{q} z_j & \sum_{j=q+1}^{r} z_j & -\sum_{j=1}^{q} z_j y_j + \sum_{j=q+1}^{r} z_j x_j \end{bmatrix}^{\mathrm{T}} \tag{4}$$

in which ζ_j denotes the restoring force in the j^{th} LLRS, and y_j's and x_j's correspond to the normal distance from the origin, to the vertical planes where the LLRS is aligned.

The well-known Bouc-Wen model (Bouc 1971, Wen 1976) has been adopted for parameterizing the nonlinear force-deformation relationship in the LLRSs, i.e., the restoring force in each LLRS is related to the deformation, u, and velocity, $\dot{u}$, at the top of the system relative to its base through a first-order differential equation,

$$\dot{z}_j = k_j \dot{u}_j - b_j \left|\dot{u}_j\right| \left|z_j\right|^{n-1} z_j - g_j \dot{u}_j \left|z_j\right|^{n} + c_j \ddot{u}_j \tag{5}$$

The relationship defined by Equation (5) is a semi-physical constitutive law, as the coefficients of the first and the last terms (i.e., k and c) correspond to the initial stiffness and the viscous damping coefficient. However, the rest of the parameters that appear in the formula do not have any physical attributes.

The aforementioned parameterization of the restoring forces is used to develop the state-space representation of the equation of motion by assigning the restoring forces and the displacements of LLRSs, and roof velocity relative to the base as the state variables. The state vector is further extended to include the unknown parameters of the system, as well as the mass eccentricities and moment of inertia. As such,

$$\mathbf{X} = \begin{bmatrix} k_1 & \cdots & k_r & b_1 & \cdots & b_r & g_1 & \cdots & g_r \\ a_1 & \cdots & a_r & c_1 & \cdots & c_r & \dot{u}_x & \dot{u}_y & \dot{u}_q \\ u_1 & \cdots & u_2 & z_1 & \cdots & z_r & e_x & e_y & \bar{I} \end{bmatrix}^{\mathrm{T}} \tag{6}$$

where $\bar{I}$ is the moment of inertia normalized by the lateral mass, i.e.,

$$\bar{I} = \frac{I_o}{m} \tag{7}$$

The state-space equation would follow as,

$$\dot{\mathbf{X}} = \left[\begin{array}{cccccccccc} 0_{1\times 5r} & \ddot{u}_x & \ddot{u}_y & \ddot{u}_q & & & & & & \\ & & & & \dot{u}_1 & \cdots & \dot{u}_r & \dot{z}_1 & \cdots & \dot{z}_r \end{array} \quad 0_{1\times 3} \right]^{\mathrm{T}}. \tag{8}$$

The state variables including model parameters need to be tied to the observed response of the system through an observation equation in order to be able to utilize an extended state estimation filter for their identification. Accelerometers are the most common type of measurement instruments that are used for the vibration monitoring of building structures. Therefore, an appropriate formulation for the observation equation should devise a relationship between the state variables/parameters and the recorded acceleration of the building. This can be achieved through the reconfiguration of Equation (1) as follows,

$$-\left(\ddot{\mathbf{U}}_{\mathbf{g}} + \ddot{\mathbf{U}}\right) = \mathbf{M}^{-1}\mathbf{f}\left(\mathbf{U}, \dot{\mathbf{U}}\right) \tag{9}$$

The vector on the left-hand-side of Equation (9) corresponds to the total acceleration of roof and consists of two lateral, (a_x and a_y) and one torsional (a_θ) components of acceleration. The product on the right-hand-side can be fully characterized in terms of the unknown state variables and parameters. Thus,

$$-\begin{bmatrix} a_x \\ a_y \\ a_q \end{bmatrix} = \frac{1}{m\left(\bar{I} - e_x^2 - e_y^2\right)} \begin{bmatrix} \bar{I} - e_x^2 & -e_x e_y & e_y \\ -e_x e_y & \bar{I} - e_y^2 & e_x \\ e_y & e_x & 1 \end{bmatrix} \times \begin{bmatrix} \sum_{j=1}^{q} z_j & \sum_{j=q+1}^{r} z_j & -\sum_{j=1}^{q} z_j y_j + \sum_{j=q+1}^{r} z_j x_j \end{bmatrix}^{\mathrm{T}} \tag{10}$$

Subsequently, the elements of the state vector can be approximated recursively through a pair of prediction and correction steps as the dynamic system evolves in time. The values of the elements of the state vector are predicted due to the adopted model of the system (Equations 5 and 8). The predicted quantities are then corrected based on the measured response of the system, which, as mentioned earlier, is related to the state variables through the observation equation (Equation 10). Unscented Kalman filtering algorithm (Julier and Uhlmann, 1997; Cao, 2008), which is an extension of the well-established Kalman filtering for the state-estimation of nonlinear dynamic systems, has been employed in the present study. Details of the Kalman filtering algorithm and the formulation of predictor-corrector equations are omitted here for brevity, and may be found, for example, in Speyer and Chung (2008).

Although the lateral mass of the structure, m, is appearing in the right-hand-side of the observation equation, it was not included in the state vector (Equation (6)). Theoretically, Equation (10) implies that m can also be estimated along with the eccentricities and moment of inertia. However, as discussed in the authors' previous work on an earlier version of the algorithm (Omrani et al. 2012), the scales of the physical and non-physical parameters of the Bouc-Wen model are significantly different. The scale difference leads to singularity problems in the matrices that are involved in the correction step. In order to circumvent the numerical issues due to the parameters' scales, the restoring forces are normalized by the lateral mass. This does not affect the estimates of the story velocities and the deformations of the LLRSs. However, the identified restoring forces needs to be scaled by the lateral mass, m, after the filtering is complete, if the actual magnitudes of the restoring forces are desired in addition to the shape of the hysteretic force-deformation response. This would exclude the lateral mass from the identification process. The revised form of the observation equation would follow as,

$$-\begin{bmatrix} a_x \\ a_y \\ a_q \end{bmatrix} = \frac{1}{\bar{I} - e_x^2 - e_y^2} \begin{bmatrix} \bar{I} - e_x^2 & -e_x e_y & e_y \\ -e_x e_y & \bar{I} - e_y^2 & e_x \\ e_y & e_x & 1 \end{bmatrix} \times \begin{bmatrix} \sum_{j=1}^{q} \tilde{z}_j & \sum_{j=q+1}^{r} \tilde{z}_j & -\sum_{j=1}^{q} \tilde{z}_j y_j + \sum_{j=q+1}^{r} \tilde{z}_j x_j \end{bmatrix}^{\mathrm{T}} \tag{11}$$

in which $\tilde{\zeta}_j$ is the restoring force, ζ_j, normalized by the lateral mass, m. The mass-normalization procedure alters the scale of the model parameters as follows,

$$\tilde{k} = \frac{k}{m} \quad , \quad \tilde{c} = \frac{c}{m} \quad , \quad \tilde{b} = m^{n-1} b \quad , \quad \tilde{g} = m^{n-1} g \tag{12}$$

3. NUMERICAL EXAMPLE

The simulated response of a one-story building to the 1989 Loma Prieta earthquake (PEER 2012) has been used to investigate the performance of the proposed method. The dimension of the building is 40 m in the east-west and 20 m in the north-south direction. Two LLRSs are aligned with the east-west direction and are located 10 m to the north and 6 m to the south of the floor's center of geometry. Two other LLRSs are aligned with the north-south direction, 15 m to the east and 20 m to the west of the center of geometry.

The robustness of the algorithm is assessed through a Monte Carlo analysis. For that purpose lateral mass, m, and Bouc-Wen parameters—except for the exponent n, which was fixed at 2 for all simulations—were drawn from random number generators with uniform distributions between -10% and +10% of the nominal values listed in Table 1. The normalized nominal values are shown in Table 2 to better

clarify the effect of normalization on the scaling properties of the model parameters. The coordinates of the center of mass was also perturbed about the geometric center of the floor by selecting the eccentricities, e_x and e_y, randomly from uniform distributions over -l/4 and l/4, where l is the dimension of the floor in each direction. Subsequently half of the mass of the structure was modeled as uniformly distributed over the ceiling slab. The other half was modeled as a concentrated mass at the (e_x, e_y) coordinates. In addition to the structural properties, the incident angle of the ground motion was extracted from a uniform distribution between 0° and 90° (with respect to the east-west direction). Acceleration records from 25 simulations were polluted with realizations of a 5×10^{-4} g root-mean-square Gaussian white-noise process in order to account for instrument (measurement) noise. The same realizations were used to model the measurement noise in all 25 simulations. Table 3 contains the a priori mean (μ_0) and variance (σ_0^2) values, which were adopted to initialize the filter. The initial values for parameters β and γ are set to zero. This is analogous to presuming the system to be linear. In order to incorporate the high level of uncertainty associated with the abovementioned a priori values for β and γ, arbitrarily large a priori variances have been assigned to them. No a prior information is assumed regarding the mass distribution, i.e., the eccentricities are initialized as zero and the moment of inertia is taken as $1/12\,(l_x^{\,2}+l_x^{\,2})$, which corresponds to a uniform mass distribution.

Table 1 Nominal Values of Model Parameters

m (kg)	k (N/m)	c (N/m/s)	β	γ
6×10^6	8×10^7	3.5×10^5	3.5×10^{-5}	7.0×10^{-5}

Table 2 Normalized Values of Model Parameters

m	k	c	β	γ
1	133.33	0.5833	21	50

Table 3 A Priori Mean and Variance Values

	k	c	β	γ	n	e_x, e_y	$\bar{I}$
μ_0	10^3	10	0	0	4	0	1.66×10^2
σ_0^2	10^6	10^2	10^3	10^3	1	4×10^2, 10^2	2.77×10^4

Except for 2 cases out of the 25 simulations, the identified and simulated force-displacement loops show fair agreement. Figures 1 and 2 illustrate representative best- and worst-case scenarios.

The distribution of relative estimation errors for the normalized physical and nonphysical parameters (100 samples per each), as well as eccentricities and normalized mass moment of inertia (25 samples per each) are demonstrated in Figures 3 through 5. The samples corresponding to the two worst-case scenarios (8 samples per each model parameter and 2 samples per each mass property) are marked with asterisks in the figures.

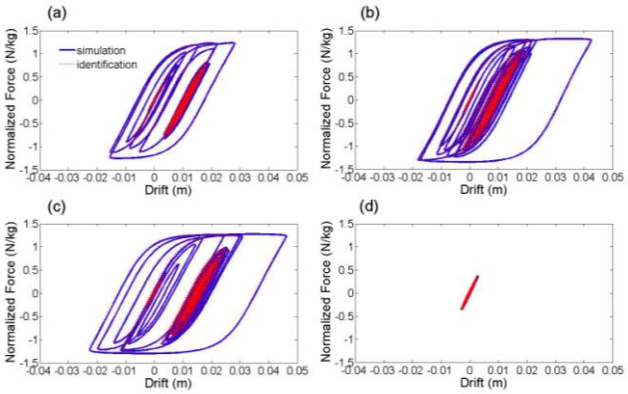

Figure 1 Representative Best-Case Scenario (a) North LLRS, (b) East LLRS, (c) South LLRS, and (d) West LLRS

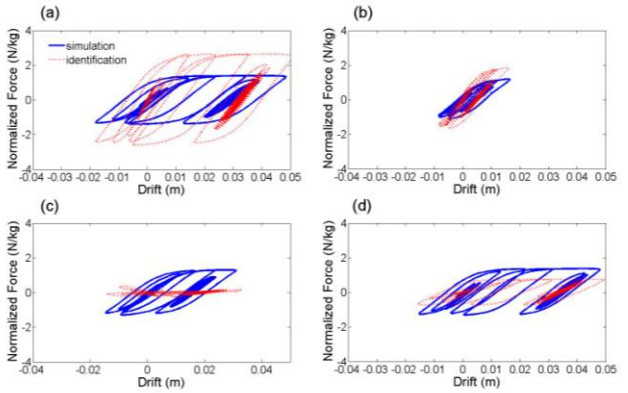

Figure 2 Representative Worst-Case Scenario (a) North LLRS, (b) East LLRS, (c) South LLRS, and (d) West LLRS

It is evident from the error distributions that large errors associate with the non-physical Bouc-Wen parameters (i.e., β, γ, and n) alone do not necessarily lead to the divergence of the identified hysteretic loops from the actual ones. On the other hand, large deviations in the estimated values of physical parameters k and c from the actual values always lead to inferior identification results for the force-deformation loops.

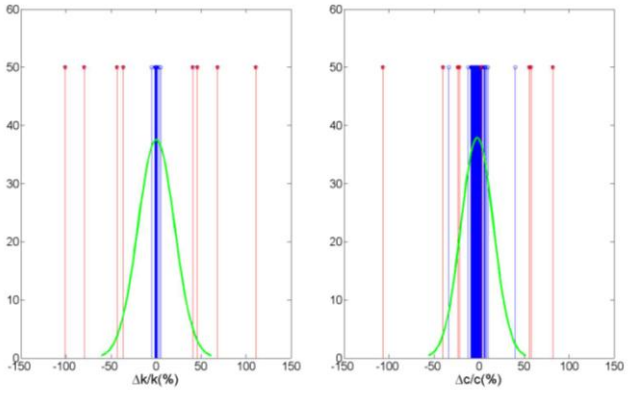

Figure 3 Distribution of Estimation Error for Parameters k and c

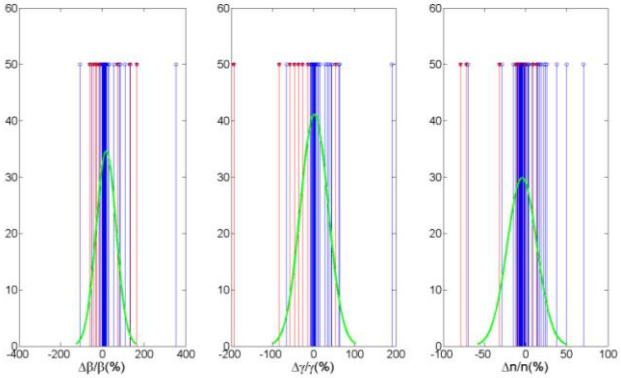

Figure 4 Distribution of Estimation Error for Parameters β, γ, and n

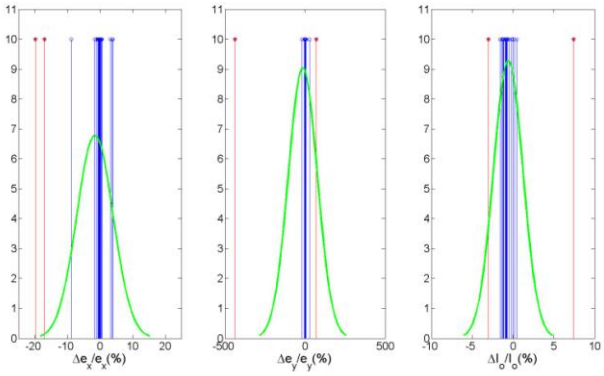

Figure 5 Distribution of Estimation Error for Mass Eccentricities and Moment of Inertia

Figures 6 and 7 display plots of the estimated versus the actual values of model parameters, eccentricities, and moment of inertia. These plots can be used to study the dispersion of the abovementioned parameters about the line of unit slope. Except for a few outliers, the data points are well aligned with the unit-slope line. However, the estimated values for parameter β seem to be biased.

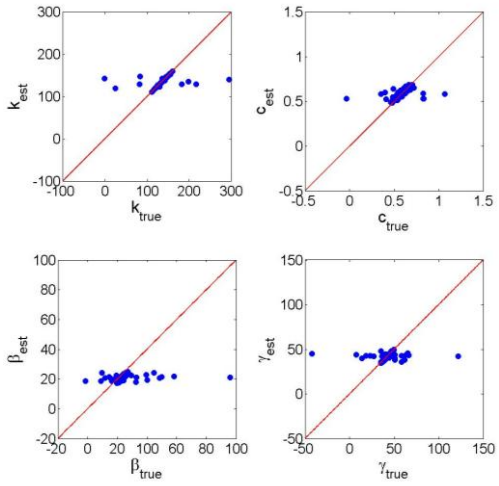

Figure 6 Dispersion of Identified Bouc-Wen Parameters

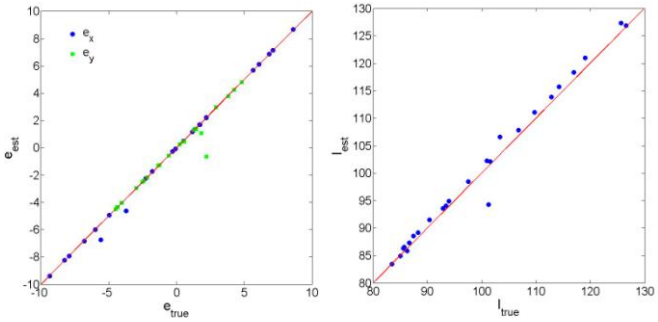

Figure 7 Dispersion of Identified Eccentricities and Moment of Inertia

The importance of including the unknown mass eccentricities and moment of inertia in the identification process was investigated by running the filter while the eccentricities and moment of inertia were frozen to their initial values. This is achieved by assigning very small initial variances to those parameters. Figure 8 implies that parallel identification of the distribution of mass of the structures is inevitable in order to achieve reasonable estimates of the hysteretic force-deformation loops.

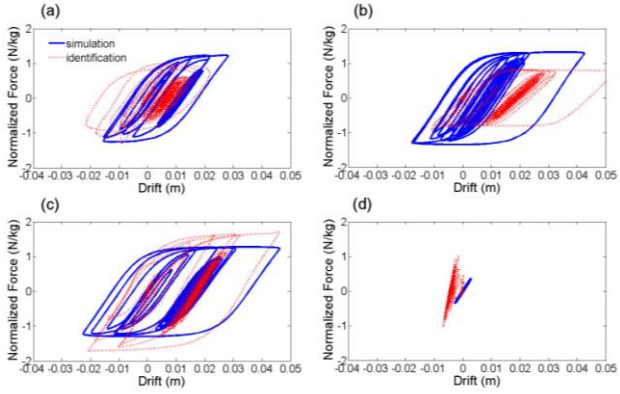

Figure 8 Effect of Excluding Unknown Eccentricities and Moment of Inertia from the Identification Scheme

3. CONCLUSIONS

An algorithm for identifying mass eccentricities and normalized moment of inertia is developed. The algorithm is an extension of a previous method, which identifies the nonlinear response of individual moment resisting frames and/or shear walls that contribute to the overall resistance of a one-story shear building against lateral loads. The capability and robustness of the algorithm is demonstrated through Monte Carlo analysis of the simulated responses of a one-story torsionally-coupled shear-type building. The identified force-displacement loops exhibit very good agreement with the simulation response in most cases. It is observed that large estimation errors in the parameters that have physical attributes lead to poor estimation of the hysteretic loops. An investigation of the specific

combinations of mass eccentricities and incident angle of ground motion that have resulted in poor performance of the method can be a topic of future studies. Numerical convergence issues are prohibitive of identifying the value of lateral mass. Improvement of this aspect of the algorithm can also be an area for further investigations.

Abstract: The development of new structural systems which suffer no or minor damage following a severe event was a key interest of researchers during the past few decades. Self-centering walls with alternative dissipation mechanisms were among the next generation candidates for a damage avoidance design of structures while being cost effective. However, the applications of such rocking wall systems are limited in practice due to the lack of experimental and analytical evidences. Therefore, in this study the dynamic characteristics of a four-story RC rocking wall-frame was evaluated under near-fault pulse-like and far-field ground motions considering both design and risk-targeted maximum considered earthquake levels. For that purpose, a three dimensional finite element model of the prototype structure was developed using OpenSees. The rocking wall system was designed as a retrofitting solution for existing RC frame structures, but equally suitable for use in new buildings. The wall was designed to confirm to the requirements in ACI ITG-5.2-2009. The energy dissipation of walls has been introduced through unbonded mild steel bars located at the base. The rocking wall-frame system undergoes only moderate damage. Moreover, negligible residual drifts proved the superiority of the systems with self-centering ability. Hence, repairs are more likely to be feasible following a severe event.

1. INTRODUCTION

The rocking motion of structures to mitigate earthquake induced damage to buildings was first investigate by Housner (1963). Rocking response of massive concrete blocks studied by Aslam et al. (1980) identified that rocking can be further improved against overturning by anchoring to the ground by prestress tendons or allow it to slide by reducing the coefficient of friction. However, the energy dissipation capacities of such systems were negligible. Stone et al. (1995) tested hybrid systems which combines the mild steel bars to dissipate energy and unbonded post-tensioned bars to provide sufficient flexural resistance. Kurama et al. (1998) introduce a seismic design methodology for unbonded post-tensioned precast walls and subsequently developed a numerical modeling procedure to simulate the lateral load behavior of rocking walls (Kurama 1999).

While earlier studies were focused only on the wall behavior, many recent studies have been conducted on the interaction between wall and frame system (Lu 2005, Marriott et al. 2008 and Nagae et al. 2011). Lu (2005) showed the benefits of incorporating the three dimensional effect in the analysis of wall-frame structures allowed to rock on their foundation. However, the rocking walls used by Lu (2005) did not possess the self-centering ability. Marriott et al. (2008) tested precast, post-tensioned walls with alternative dissipation solutions for existing frame structures. Nagae et al. (2011) simultaneously tested a four-story RC wall-frame building and RC precast rocking wall-frame building on the E-Defense shaking table in Japan under three dimensional ground motions. However, the results of the shaking table test are still subject to further investigations. On the other hand, no previous numerical studies have been focused on RC rocking wall-frame buildings designed according to contemporary design guidelines. Since, only hand full of evidence for RC rocking wall-frames are available, further investigations are required to build the confidence among Engineers prior to implement such rocking wall-frame structures in practice.

In this study, a rocking wall system was designed as a retrofitting solution to the existing four-story RC frame structure, but equally suitable for use in new buildings. The rocking wall was designed using ASCE 7 (2010), ACI 318 (2011) and ACI ITG-5.2 (2009). A three dimensional finite element model created using OpenSees (2011) was analyzed under two sets of ground motions namely, near-fault pulse-like and far-field considering both design earthquake (DE) and risk-targeted maximum considered earthquake (MCE_R) levels. The performance of the rocking wall-frame system was evaluated by comparing the building drift demands with the performance levels specified in the documents such as ASCE 41 (2006) and Elnashai and Sarno (2008).

2. BUILDING DESCRIPTION

The plan view of the prototype structure is shown in Fig. 1. The typical story height is 3.6 m. The lateral load resistance of the building in the X- direction is provided by the two rocking walls and Y- direction is provided by the special moment resistance frame system. The design short period and 1.0 s spectral accelerations were $S_{DS} = 0.921g$ and $S_{D1} = 0.488g$ respectively. When designing the rocking DE and MCE_R levels were considered. The design strength of the concrete was 28 N/mm^2 chosen to satisfy the minimum requirements given in ACI ITG-5.2 (2009). The unit weight of concrete was 22.76 kN/m^3. The yield strengths of the main steel reinforcement and tie bars were taken as 420 and 280 MPa respectively (ASTM A 615-2003). The floor live load and roof live load are 4.79 kN/m^2 and 0.96 kN/m^2 respectively. The typical column size is 400 mm × 400 mm. The typical floor beam size is 550 mm × 300 mm and roof beam size is 350 mm × 300 mm. The wall size is 5000 × 300 mm in plan. The slab thickness is 200 mm.

The performance objective for the rocking wall-frame was set to be 1.0% transient drift under DE level which is corresponding to a moderate joint damage. The joints are likely to suffer some strength degradation but repair should be possible. Furthermore, a transient drift of 1.5% was established under MCE_R level which would result in an extensive damage to the exterior joints while maintaining the gravity load carrying capacity of the joints, and hence the frame (Marriott et al. 2008).

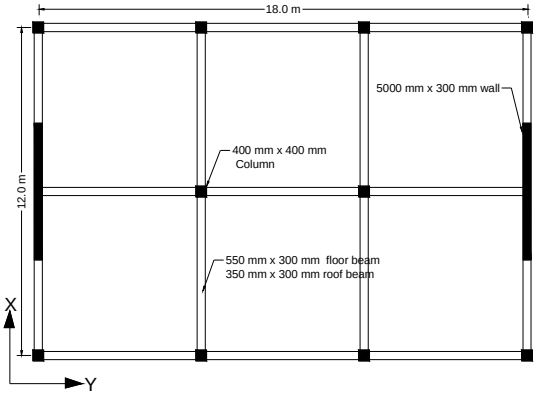

Fig. 1. Plan view of the prototype building.

3. ROCKING WALL DESIGN

The design loads for the rocking walls were calculated using ASCE 7 (2010). The walls were conservatively analyzed as an isolated lateral load bearing system. The lateral load capacity of the existing frame system is not considered. When designing, the ACI ITG-5.2 (2009), specific guidelines for the design of special unbonded post-tensioned precast shear walls and ACI 318 (2011) were followed. A more details about the calculation procedure can be found in Smith and Kurama (2012). The wall height (h_w) and length (l_w) was 14.4 m and 5.0 m respectively (resulting in an aspect ratio of 2.88). The wall design was carried under two different drift limits: (1) Design drift limit (Δ_{wd}) according to ASCE 7 (2010) considering as a fixed base wall (2) Validation drift limit (Δ_{wm}) from Equation 1 according to ACI ITG-5.2 (2009). The linear elastic drift was calculated by assuming a cracked flexural stiffness of $I_{cr} = 0.5I_{gross}$ and a shear area of $A_{sh} = 0.8A_{gross}$. When calculating design level drift a displacement amplification factor of $C_d = 5.0$ was used. The calculated drift limits were $\Delta_{wd} = 0.362\%$ and $\Delta_{wm} = 2.84\%$.

$$0.90 \le 0.8\left[h_w / l_w\right] + 0.5 \le 3.0 \qquad (1)$$

The proportioning of the amount of mild steel bars and post-tensioned bars were done in order dissipate sufficient amount of energy at the base of rocking wall while ensuring the re-centering of the system. The unbonded mild steel bars were designed to resist about 38% of the total base moment of the wall. The details of the rocking wall near the base are shown in Fig. 2.

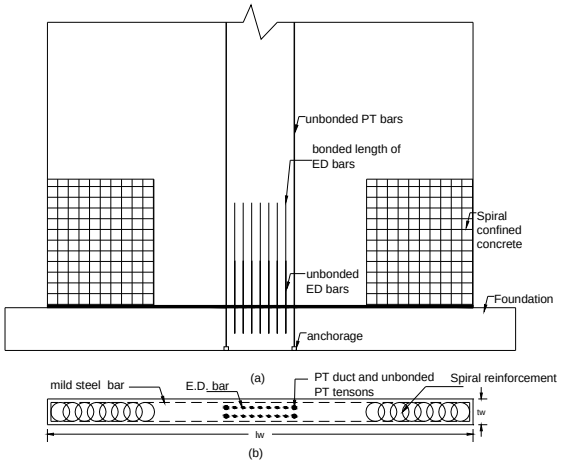

Fig. 2. Details of the rocking wall near the base: (a) Elevation (b) Plan view.

3.1 Modeling of the Post-Tensioned Rocking Wall

The analytical modeling procedure described in this paper is developed based on the DRAIN – 2DX model proposed by Brian et al. (2011). More details of the modeling procedure can be found Kurama et al. (1999). In this study OpenSees (2011) was used to simulate the rocking wall behavior with some minor modifications to the original model. In OpenSees model, a large numbers of displacement-based beam column elements were used at the base of the wall. The rest of the wall was modeled with force-based beam column elements. The gap opening of the rocking wall was simulated by setting a zero tensile strength and zero stiffness of the wall concrete over a critical height (H_{cr}) of the wall. The H_{cr} was taken as the confined concrete thickness of the wall as specified by Brian and

Kurama (2012). Confinement reinforcement details were not modeled along the region of H_{cr}. The unbonded mild steel bars were modeled using truss elements on the outside of the wall to have a uniform strain along the length of the element (Brian et al. 2011). The truss elements were considered to be fixed at the foundation level and kinetically constrained to the corresponding fiber element nodes of the wall at the top. The post-tensioned bars were modeled with co-rotational truss elements with initial strain material models available in OpenSees. The use of co-rotational truss elements with initial strain material model did not consider the secondary effect as the real system behavior. At the top of the rocking wall, the wall degree of freedoms (both translation and rotation) and tendon degree of freedoms were make equal by kinetic constrains. At other floor levels, only the lateral movements (vertical and rotational movement are free) of the post-tension tendons were kinetically constrained to the corresponding fiber element node of the wall to simulate the unbonded behavior of tendons.

4. MODELING OF THE ROCKING WALL-FRAME BUILDING.

A three dimensional model of the rocking wall-frame structure was developed with OpenSees (2011) by considering both material and geometric nonlinearities. The Nonlinear Beam Column elements were used to model the beams and columns. The concrete and steel material models are chosen to be Concrete02 and Steel02, respectively. The constitutive behavior of concrete modeled using the modified Kent and Park model (Kent 1971). For reinforcing steel, the constitutive model of Menegotto and Pinto (1973) is used.

The modeling of rocking walls was done as explained in Section 3.1. The initial post-tension stress was 60% of the yield stress limit (F_y .= 1686 MPa). A frame element with high flexural and axial rigidity was used at each floor level to represent the width of the wall (Fig. 3). The restraining effect of the slab was modeled with the truss elements with higher axial rigidity instead of rigidDiaphragm command available in OpenSees (Vesna 2011). The plastic mechanism of the structure is shown in Fig. 4.

Nonlinear time history analyses of the structure were carried out where the system of equations are solved using Newmark method with β = 0.5 and γ = 0.25 along with modified Newton-Raphson technique. Stiffness proportional damping was used with coefficients calculated based on 1st fundamental frequency with a 5% damping ratio. The fundamental period of the building was T= 0.626 s .

5. GROUND MOTION SELECTION AND MATCHING

Response of the rocking wall-frame structure were evaluated under two sets of ground motions (10 per each) namely, near-fault pulse-like and far-field (Table 1). The ground motion records were obtained from PEER NGA Ground Motion data base (PEER 2012). The wavelet analysis algorithm developed by Baker (2007) was used to identify the pulse-like characteristics of ground motion records. The seed ground motions were linearly scaled in such a way that the average value of the 5% damped response spectra for the suite of ground motions is not less than the design response spectrum (Figs. 5 and 6) in the period range of $0.2T$ to $1.5T$. The scaling factors for DE level were in the range of $0.7-1.7$ and MCE_R level were in the range of $1.0-2.6$. The DE level was taken as 2/3 MCE_R.

6. RESULTS AND DISCUSSIONS

The maximum inter-story drifts results for the near-fault ground motion suite under MCE_R level is shown in Fig. 7. The inter-story drifts showed a uniform variation over the height of the building. Hence, prove the advantage of having such wall elements to eliminate the soft-story mechanism in frame structures to enhance the seismic resistance. It is important to highlight that a minimum damage to the rocking wall was ensured during the design phase by providing spiral reinforcement at base of the wall (Fig. 2). Due to the gap opening behavior at the base of the rocking wall, the damage to the rocking wall-frame structure is mainly concentrated at monolithically cast joints (Fig. 4). Therefore, the inter-story drifts indicate the degree of damage to the beams, columns and their connections only.

The maximum residual drift observed was 0.4% (Fig. 8) which is well below the 1.0% residual drift limit required for life safety according to ASCE 41 (2006). In all other cases the residual deformations were negligible. This proves the superior performance of systems with self-centering walls. The maximum 1st story drifts results found during the analysis are shown in Figs. 9 and 10 respectively.

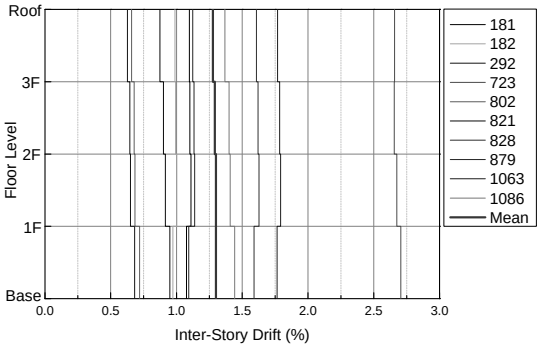

Fig. 7. Typical inter-story drift variation of the rocking wall-frame building under near-fault MCE_R level.

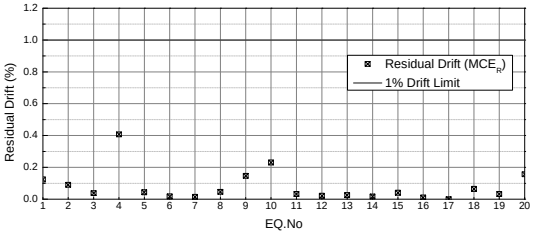

Fig. 8. The resulting residual drifts for MCE_R level ground motions.

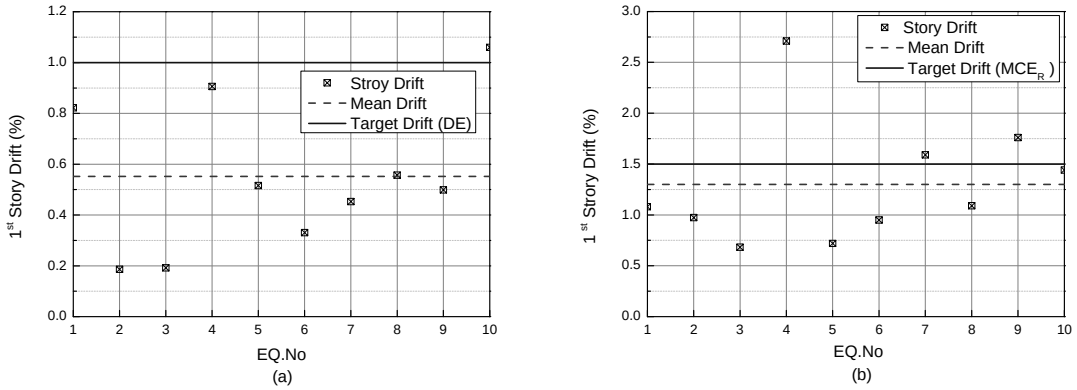

Fig. 9. Comparison of 1st story drift results for near-fault pulse-like ground motion set: (a) DE Level (b) MCE_R Level.

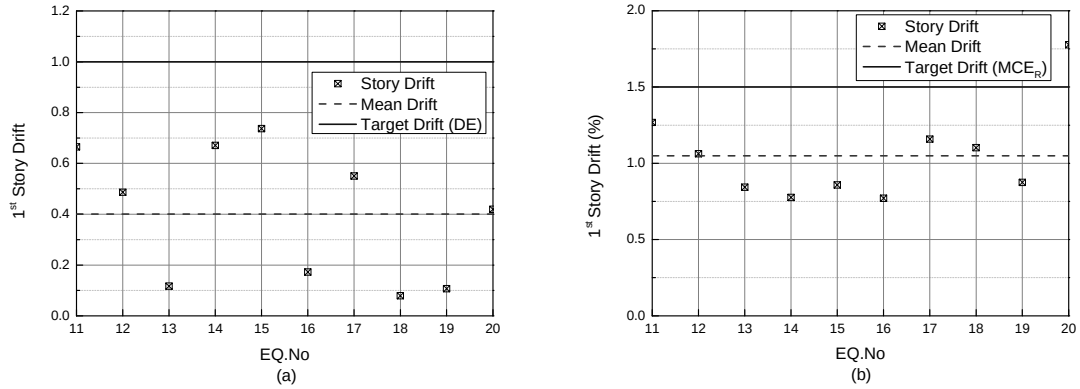

Fig. 10. Comparison of 1st story drift results for far-field ground motion set: (a) DE Level (b) MCE_R Level.

For DE level, the mean 1st story drifts for near-fault (Fig. 11a) and far-field (Fig. 12a) ground motions were 0.55% and 0.40% respectively. The story drift of 0.55% is corresponding to moderate type of damage to the building (Elnashai and Sarno 2008). However, the expected damage is unlikely to be considerable. Under far-field ground motions only a non-structural type damages to the building was expected. The resulting mean drifts were well below the limiting inter-story drift requirement of 1.0% **.**

Under MCE_R level, the resulting mean 1st story drifts were 1.29% and 1.04% for near-fault (Fig. 11b) and far-field (Fig. 12b) ground motions respectively. Both the drift limits are corresponding to moderate type of damage to the building. Hence, the load carrying capacity of the exterior joints can be maintained to prevent local collapse. Therefore, the structure is more likely to undergo repair together with negligible residual deformation of the building. In other words, the rocking wall-frame structure developed in this study showed superior performance against both near-fault pulse-like and far-field ground motions.

In order to have a better understanding about the performance of the rocking wall itself, the roof drift results obtained during the analysis was compared with the design drift limits for the rocking wall. The roof drift results for near-fault and far-field ground motions are shown in Figs. 11 and 12 respectively.

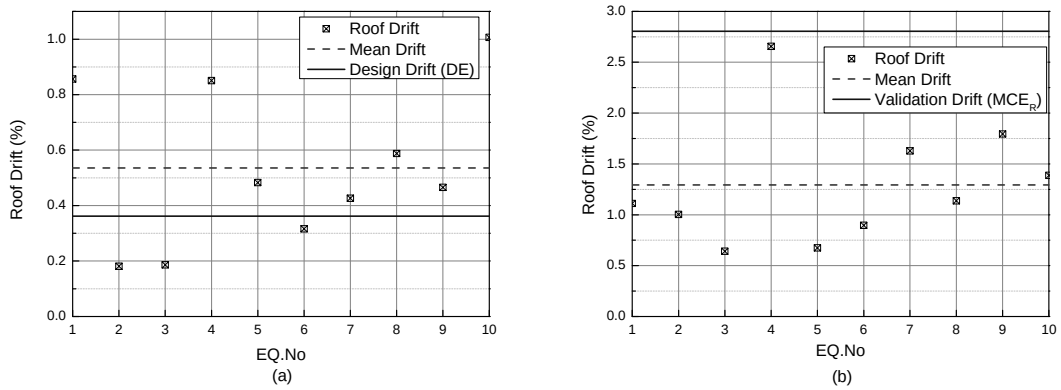

Fig. 11. Comparison of roof drift results for near-fault pulse-like ground motion set: (a) DE Level (b) MCE_R Level.

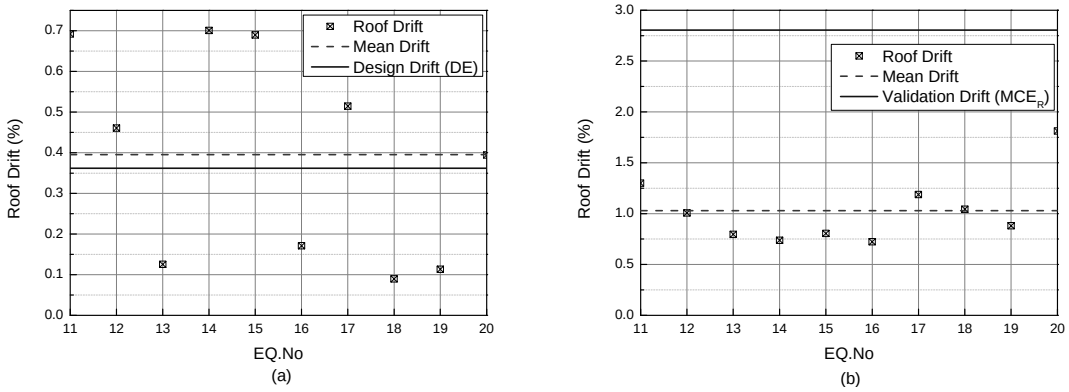

Fig. 12. Comparison of roof drift results for far-field ground motion set: (a) DE Level (b) MCE_R Level.

Under DE level, for near-fault ground motion set the mean roof drift was found to be approximately 150% of the design drift level (Fig. 11a). Such variations can be as a result of gap opening behavior due to the large seismic demand induced by the pulse-like characteristics of ground motions (which did not considered while calculating the DE level drift). For far-field ground motions the variation was only about 9% (Fig. 12a). However, a large variation of the roof drift response was found.

For MCE_R level, the mean drift was found to be less than 50% of the validation drift limit for both near-fault and far-field ground motions. Hence, the post-tension tendons were remained essentially elastic while no fractures in unbonded mild steel bars.

7. SUMMARY AND CONCLUSIONS

A RC rocking wall-frame system was successfully developed as a retrofitting solution to an existing four-story frame structure, but equally suitable for use in new buildings. Moreover, a fiber based model to simulate the lateral load behavior of rocking walls under both static and dynamic loading conditions were developed with OpenSees (2011).

The rocking walls were designed according to the according to ACI ITG-5.2 (2009). A three dimensional finite element model developed with OpenSees (2011) was analyzed under two sets of ground motions namely, near-fault pulse-like and far-field (under both DE and MCE_R levels). The results obtained were compared with limiting drifts to investigate the performance of the structural system. The findings of this study can be summarized as bellow.

The introduction of rocking walls resulted in a uniform inter-story drift variation over the height of the building. As a result of that, no soft-story mechanism was observed. In general near-fault pulse-like ground motions resulted in a larger drift response of the building compared to far-field set (37.5% for DE level and 24% for MCE_R level). Other than that, large scattering of the data was observed.

Under DE level near-fault pulse-like ground motions, moderate damage to the frame systems was expected. However, the expected damage is likely to be minor. In contrast, under DE level far-field ground motions, only non-structural damage was expected. However, the mean story drifts results were well below the 1.0% target performance drift level of the building under DE level.

Under MCE_R, moderate damage to the building under both near-fault and far-field ground motions were expected. However, the mean story drifts were under the 1.5% target performance drift level of the building. Moreover, the residual deformation was negligible. Therefore, the load carrying capacity of the exterior joints can be maintained to prevent local collapse.

The DE level roof drifts were found to be under estimate by the current design procedure for pulse-like ground motions. Therefore, it is highly recommended to carry out dynamic analysis of rocking walls under specific ground motion suites to estimate the design drift limits due to the uncertainties of results observed during the present study.

In general, the rocking wall-frame structure investigated in this study showed superior performance against the both near-fault pulse-like and far-field ground motions. Therefore, such structural systems with self-centering rocking walls can be utilized as a cost effective solution to retrofit existing frame structures or to design new structures.

Abstract: In this paper, five output-only modal identification techniques are systematically investigated, which can be categorized as frequency domain, time domain, and time-frequency domain approaches. A numerical three-story frame model is firstly utilized for the application of the five techniques to show the identification performance of these techniques under different situations, such as seismic excitation, closely spaced modes, noise effect, and local damage. Secondly, these modal identification approaches have been applied to identify the modal information of a high-rise building in Shanghai with measurements under microtremors. The accuracy and efficiency of these techniques are then investigated. Finally, an integrated algorithm is proposed to improve the in situ modal identification of the output-only structures under microtremors.

1. INTRODUCTION

Performance of a civil engineering structure subjected to seismic, wind and other dynamic loads depends upon its modal properties such as natural frequencies, damping ratios and mode shapes. A good knowledge of the dynamic properties would pave the way to dynamic analysis, structural health monitoring, updating finite-element models, detecting structural modification, and so on. The modal parameter information is usually obtained by means of artificial excitation or ambient vibration tests using modal identification techniques. For civil engineering structures, cases exist where it is rather difficult to apply an artificial force. Thus, ambient vibration test is the better candidate, insofar as it constitutes an efficient, easy and inexpensive way to understand the dynamic behavior without causing any harm to the structure. The excitation of ambient vibration test is natural form (i.e., wind, traffic, or waves) which cannot be controlled or measured, hence the name "unknown input" and the need for special processing to obtain the modal parameters.

Recently the extension of modal identification methods to ambient vibration cases, in which an input cannot be measured, has received considerable attention in civil engineering community. The operational modal identification methods including frequency domain, time domain, and time-frequency domain approaches. Individual output-only modal analysis methods are discussed in many papers (Clough and Penzien 1995; Brincker et al. 2001a; Ibrahim 1977b; Shi et al. 2012); unfortunately, hardly any studies have pursued an overview or comparison of the state-of-the-art modal identification algorithms. In response of this, five output-only modal identification methods are investigated and compared in this study including Peak-Picking with Half-Power Bandwidth (PP-HPBW), Enhanced Frequency Domain Decomposition (EFDD) method in the frequency-domain; Single Station Time Domain (SSTD) technique, Covariance driven Stochastic Subspace Identification (SSI-COV) in the time-domain; Hilbert-Huang Transform (HHT) in frequency-time domain.

The performance of the five modal identification techniques under different situations (i.e., white noise or seismic excitation, closely spaced modes, noise effect, and local damage) was firstly presented by applying to a numerical three-story frame model in this paper. Then, the acceleration time series recorded during the ambient vibration test of a high-rise building in Shanghai were processed with these algorithms. Finally, it proposed an integrated algorithm to improve the in situ modal identification of the output-only structures under microtremors.

2. MODAL IDENTIFICATION ALGORITHMS

2.1 Peak-Picking method with Half-Power Bandwidth method (PP-HPBW)

The Peak-Picking (PP) method is a traditional frequency domain method using output-only data and already applied to the modal identification of engineering structures. It stems from the fact that the frequency response function (FRF) of a given system will peak at the modal frequencies of the system. For instance (Andersen et al. 1999; Peeters and Roeck 2001), the method is described in details. With the broadband white noise assumption, the Fourier power spectrum of the response data can be considered as

equal to the FRF of the structure at that sensor location. The modal frequencies are identified through the power spectrums from every experimental measurement. The corresponding damping ratios can be estimated with half-power bandwidth method, defined as:

$$\xi_i = \frac{B_i}{2 f_i} \tag{1}$$

where B_i is the half-power bandwidth of the spectral peak corresponding to ith-order modal frequency f_i.

2.2 Enhanced Frequency Domain Decomposition (EFDD) method

The enhanced frequency domain decomposition (EFDD) technique which was developed by Brincker et al. (2001c) is an extension of the Peak-Picking (PP) method and keeps the important features of user-friendliness. With the assumption that the input is a white noise, the structure is slightly damped, and the modal forms of the coupled modes are orthogonal, the results of the EFDD are exact.

In the EFDD identification, the first step is to estimate the power spectral density (PSD) matrix. The estimate of the output PSD $\hat{G}_{yy}(j\omega)$ known at discrete frequencies $\omega = \omega_i$ is then decomposed by taking the SVD of the matrix

$$\hat{G}_{yy}(j\omega) = U_i S_i U_i^H \tag{2}$$

where the matrix $U_i = [u_{i1}, u_{i2}, ..., u_{im}]$ is a unitary matrix of singular vectors u_{ij}; and S_i is a diagonal matrix of scalar singular value s_{ij}. Near a peak in the PSD function corresponding to a given mode in the spectrum, this mode or a possible close mode will be dominating. From the piece of the SDOF density function obtained around the peak of the PSD, the natural frequency and the damping ratio can be obtained.

2.3 Single Station Time Domain (SSTD) method

The SSTD method is a variant of the Ibrahim Time Domain (ITD) technique. In the standard ITD method (Ibrahim and Mikulcik 1973; Ibrahim and Mikulcik 1976; Ibrahim and Mikulcik 1977a), at least 2N response locations need to be measured to identify a model of order N. In the SSTD method (Zaghlool 1980), the identification can be conducted based on the response at a unique location, considered for different time intervals. The correlation functions between measured responses to random excitation can be written as

$$x(k\Delta t) = x_k = \sum_{r=1}^{2N} a_r e^{s_r k\Delta t} \tag{3}$$

where x_k is the discrete correlation function at kth discrete time, a_r is a constant associated with rth mode and s_r is the rth complex frequency defined as

$$s_r = -\xi_r \omega_r + i\omega_r \sqrt{1-\xi_r^2} \tag{4}$$

Writing Eq. (3) for different shifted starting time samples, gives

$$\begin{bmatrix} x_1 & x_2 & \cdots & x_L \\ x_2 & x_3 & \cdots & x_{L+1} \\ \vdots & \vdots & \ddots & \vdots \\ x_{2N} & x_{2N+1} & \cdots & x_{L+2N-1} \end{bmatrix} = \begin{bmatrix} a_1 & a_2 & \cdots & a_{2N} \\ a_1 e^{s_1 \Delta t} & a_2 e^{s_2 \Delta t} & \cdots & a_{2N} e^{s_{2N} \Delta t} \\ \vdots & \vdots & \ddots & \vdots \\ a_1 e^{s_1 (2N-1)\Delta t} & a_2 e^{s_2 (2N-1)\Delta t} & \cdots & a_{2N} e^{s_{2N} (2N-1)\Delta t} \end{bmatrix} \cdot \begin{bmatrix} e^{s_1 t_1} & e^{s_1 t_2} & \cdots & e^{s_1 t_L} \\ e^{s_2 t_1} & e^{s_2 t_2} & \cdots & e^{s_2 t_L} \\ \vdots & \vdots & \ddots & \vdots \\ e^{s_{2N} t_1} & e^{s_{2N} t_2} & \cdots & e^{s_{2N} t_L} \end{bmatrix} \tag{5}$$

where $t_k = k\Delta t$, N is the total number of modes considered for the identification and L is the number of correlation values per row. The modal order N is usually not known a priori but it is a general practice to compute poles at different modal orders and at last correct poles and number of modes are chosen from convergence of poles in the stabilization diagram.

In symbolic form, Eq. (5) can be written as

$$\underset{(2N\times L)}{\mathbf{X}} = \underset{(2N\times 2N)}{\mathbf{A}} \underset{(2N\times L)}{\mathbf{\Lambda}} \tag{6}$$

A similar equation can be written by shifting all the discrete response values by as Δt follows

$$\begin{bmatrix} x_2 & x_3 & \cdots & x_{L+1} \\ x_3 & x_4 & \cdots & x_{L+2} \\ \vdots & \vdots & \ddots & \vdots \\ x_{2N+1} & x_{2N+2} & \cdots & x_{L+2N} \end{bmatrix} = \begin{bmatrix} a_1 e^{s_1 \Delta t} & a_2 e^{s_2 \Delta t} & \cdots & a_{2N} e^{s_{2N} \Delta t} \\ a_1 e^{s_1 2\Delta t} & a_2 e^{s_2 2\Delta t} & \cdots & a_{2N} e^{s_{2N} 2\Delta t} \\ \vdots & \vdots & \ddots & \vdots \\ a_1 e^{s_1 2N\Delta t} & a_2 e^{s_2 2N\Delta t} & \cdots & a_{2N} e^{s_{2N} 2N\Delta t} \end{bmatrix} \cdot \begin{bmatrix} e^{s_1 t_1} & e^{s_1 t_2} & \cdots & e^{s_1 t_L} \\ e^{s_2 t_1} & e^{s_2 t_2} & \cdots & e^{s_2 t_L} \\ \vdots & \vdots & \ddots & \vdots \\ e^{s_{2N} t_1} & e^{s_{2N} t_2} & \cdots & e^{s_{2N} t_L} \end{bmatrix} \tag{7}$$

$$\underset{(2N\times L)}{\widehat{\mathbf{X}}} = \underset{(2N\times 2N)}{\widehat{\mathbf{A}}}\,\underset{(2N\times L)}{\mathbf{\Lambda}} \tag{8}$$

Now let us define a system **matrix S** so that

$$\underset{(2N\times 2N)}{\mathbf{S}}\,\underset{(2N\times 2N)}{\mathbf{A}} = \underset{(2N\times 2N)}{\hat{\mathbf{A}}} \tag{9}$$

Pre-multiplying Eq. (6) by **S and** taking account of Eq. (9)

$$\underset{(2N\times 2N)}{\mathbf{S}}\,\underset{(2N\times L)}{\mathbf{X}} = \underset{(2N\times 2N)}{\mathbf{S}}\,\underset{(2N\times 2N)}{\mathbf{A}}\,\underset{(2N\times L)}{\mathbf{\Lambda}} = \underset{(2N\times 2N)}{\widehat{\mathbf{A}}}\,\underset{(2N\times L)}{\mathbf{\Lambda}} \tag{10}$$

Taking account of Eq. (8)

$$\underset{(2N\times 2N)}{\mathbf{S}}\,\underset{(2N\times L)}{\mathbf{X}} = \underset{(2N\times L)}{\widehat{\mathbf{X}}} \tag{11}$$

The system matrix **S** can thus be computed as a least square solution of Eq. (11) (taking $L > 2N$).

Finally the eigenvalues are deduced from S be observing that Eq. (9) can be decomposed as

$$\mathbf{S}\begin{Bmatrix} a_r e^{s_r 0\Delta t} \\ \vdots \\ a_r e^{s_r (2N-1)\Delta t} \end{Bmatrix} = \begin{Bmatrix} a_r e^{s_r 0\Delta t} \\ \vdots \\ a_r e^{s_r (2N-1)\Delta t} \end{Bmatrix} e^{s_r \Delta t}, r = 1, 2, \cdots, 2N \tag{12}$$

and therefore

$$\left\{\mathbf{S} - e^{s_r \Delta t}\right\}\begin{Bmatrix} a_r e^{s_r 0\Delta t} \\ \vdots \\ a_r e^{s_r (2N-1)\Delta t} \end{Bmatrix} = \mathbf{0} \tag{13}$$

Eq. (13) is a standard eigenvalue problem, from which s_r can be found. Modal frequencies and damping ratios can be computed from the values of s_r.

2.4 Covariance driven Stochastic Subspace Identification (SSI-COV) method

It is well known that the stochastic subspace model of a linear time-invariant structure at the *k*th time step with the white noise assumption is defined as

$$\begin{aligned} x_{k+1} &= Ax_k + w_k \\ y_k &= Cx_k + v_k \end{aligned} \tag{14}$$

where x is the state vector, A is the state matrix, C is the real output influence matrix, w_k,v_k are white noise terms representing process noise and measurement noise together with the unknown inputs, and y is the output vector.

The Covariance driven Stochastic Subspace identification technique is a two-step data-analysis method. The first step involves making projection of certain subspaces generated from the input/output observations to estimate the state vector (x) of the system by linear algebra tools such as QR decomposition and singular value decomposition (SVD). The second step retrieves the system matrices A and C from the estimated states based on a linear least-squares solution. It is proven that the output covariances Λ_i can be decomposed as

$$\Lambda_i = CA^{i-1}G \tag{15}$$

where G is the next state-output covariance matrix and is defined as

$$G = E\left[x_{k+1} y_k^T\right] \tag{16}$$

Hereto, a block Toeplitz matrix $T_{i,i}$ is formed that consists of covariances

$$\begin{aligned} T_{i,i} &= \begin{pmatrix} \Lambda_i & \Lambda_{i-1} & \cdots & \Lambda_1 \\ \Lambda_{i+1} & \Lambda_i & \cdots & \Lambda_2 \\ \vdots & \vdots & \ddots & \vdots \\ \Lambda_{2i-1} & \Lambda_{2i-2} & \cdots & \Lambda_i \end{pmatrix} \\ &= \begin{pmatrix} C \\ CA \\ \vdots \\ CA^{i-1} \end{pmatrix}\begin{pmatrix} A^{i-1}G & \cdots & AG & G \end{pmatrix} = O_i \Gamma_i \end{aligned} \tag{17}$$

where matrix O_i is the extended observability matrix and Γ_i is the reversed extended stochastic controllability matrix. By computing the SVD of $T_{i,i}$ and splitting the SVD in two parts, A, C, G is finally estimated. The complex eigenvalues (λ) and eigenvectors (Ψ) of the damped system can be calculated from the system matrix A, according to

$$A = \Psi \Lambda \Psi^{-1} \tag{18}$$

It is then straightforward to determine the modal parameters (natural frequencies, damping ratios and mode shapes) as (Alvin and Park 1994; Safak 1991)

$$f_i = \frac{|\lambda_i|}{2\pi} \tag{19}$$

$$\xi_i = \frac{\mathrm{Re}(\lambda_i)}{2\pi f_i} \tag{20}$$

$$\phi_i = \left|C\Psi_i\right| \cdot sign\left[\mathrm{Re}\left(C\Psi_i\right)\right] \tag{21}$$

for the *i*th mode where $\mathrm{Re}(\cdot)$ and $sign[\cdot]$ denote the real part and the algebraic sign of $\cdot$.

In order to obtain a good model for modal analysis applications, a construction of the stabilization diagram, by identifying a whole set of models with different orders, is an efficient idea (Bodeux and Golinval 2001).

2.5 Hilbert-Huang transform (HHT) method

The HHT method is a two-step data-analysis method (Huang et al. 1998). The first step is the empirical mode decomposition (EMD) by which a complicated time history can be turned into a series of intrinsic mode functions (IMFs) that admit well-behaved Hilbert transforms. The second step of the HHT method is implemented by performing the Hilbert transform (HT) to each IMF component (Xu et al. 2003). With Hilbert transform, an analytic signal $z(t)$ for a real-valued function $y(t)$ can be defined as

$$z(t) = y(t) + i\tilde{y}(t) = A(t)\cdot e^{-i\theta(t)} \tag{22}$$

$$\tilde{y}(t) = H\left[y(t)\right] = \int_{-\infty}^{\infty} \frac{y(u)}{\pi(t-u)} du \tag{23}$$

where $\tilde{y}(t)$ is the Hilbert transform of $y(t)$, i is the imaginary unit, $A(t)$ and $\theta(t)$ are the amplitude and instantaneous phase angle of $y(t)$, respectively. The instantaneous frequency $\omega(t)$ is thus the time derivative of $\theta(t)$. The definition equations of $A(t)$, $\theta(t)$, $\omega(t)$ and are shown as follow

$$A(t) = \left[y^2(t) + \tilde{y}^2(t)\right]^{(1/2)} \tag{24}$$

$$\theta(t) = \tan^{-1}\left[\frac{\tilde{y}(t)}{y(t)}\right] \tag{25}$$

$$\omega(t) = \frac{d\theta(t)}{dt} \tag{26}$$

For a linear Single-Degree-of-Freedom (SDOF) system under impulsive loading, the free vibration response function of the system is

$$v(t) = A_0 \sin\left(\omega_d t\right) e^{-\xi\omega_0 t}, t \geq 0 \tag{27}$$

where ω_0 is the natural circular frequency, ξ is the damping ratio, ω_d is the damped natural circular frequency and A_0 is a constant depending on the intensity of impulsive loading and the mass and frequency of the system. By applying the Hilbert transform method, the signal $z(t)$ for $v(t)$ can thus be obtained using Eq. (22)

$$z(t) = v(t) + i\tilde{v}(t) = A(t)\cdot e^{-i\theta(t)} \tag{28}$$

For a special case in which ξ is small and ω_0 is large, the amplitude $A(t)$ and the phase angle $\theta(t)$ for the SDOF system can be obtained as follow (Yang and Lei 1999)

$$A(t) = A_0 e^{-\xi\omega_0 t} \tag{29}$$

$$\theta(t) = \omega_d t - \frac{\pi}{2} \tag{30}$$

By introducing the logarithmic and differential operators to Eqs. (29) and (30), respectively, one obtains

$$\ln A(t) = -\xi\omega_0 t + \ln A_0 \tag{31}$$

$$\omega(t) = \frac{d\theta(t)}{dt} = \omega_d \tag{32}$$

Therefore, the damped natural circular frequency ω_d can be identified from instantaneous frequency $\omega(t)$ by Eq. (32). With the identified ω_d and the slope $-\xi\omega_0$ of the straight line of the decaying amplitude $A(t)$ in a semi-logarithmic scale, the damping ratio can be identified from the function $\omega_d = \omega_0 (1 - \xi^2)^{1/2}$. It should be noted that the Random Decrement technique (RDT) is performed on the target IMF to derive the free vibration response $v(t)$ before the Hilbert transform.

3. COMPARISONS UNDER DIFFERENT SITUATIONS

3.1 Numerical Model

In this section, a three-story concrete frame finite element model (FEM) with damping ratio of 4% is established using ANSYS (see Figure 1) to investigate the identification performance of the aforementioned modal identification approaches. The FEM is excited by white noise or seismic excitation in two translational directions, and then the acceleration responses at the centre of the third floor are recorded in both directions with an acquisition frequency of 50 Hz in order to identify the natural frequencies and damping ratios of the structure.

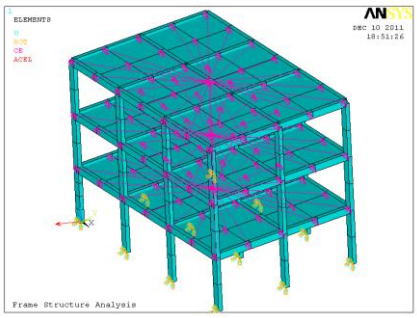

Figure 1 The finite element model.

3.2 White Noise Input

Ambient vibrations commonly have a multiple input

nature and wide band frequency content, and it is assumed to be a stationary zero-mean Gaussian white noise in the application of the output-only modal identification techniques. Thus, the FEM is firstly calculated under stationary white noise input which last for 12 minutes and the acceleration responses at the centre of the third floor are recorded for data processing like that in the field test. The estimates of the first four modes obtained by the five methods are characterized in Figure 2 and quantified in Table 1. It shows that the estimated modal frequencies and damping ratios are approximately identical with the theoretical values calculated directly from the FEM, especially for the first two modes. And the identified damping ratios do not show the same agreement as the modal frequencies. A satisfactory correspondence can be seen to be better for the method in time-frequency domain and in time domain than for that in frequency domain in the evaluation of damping ratios. There is a general accepted opinion that the spectral damping is generally overestimated and can have significant uncertainty in light of variance errors. There must be at least four spectral lines in the half-power bandwidth of each mode for limit bias errors (Bendat and Piersal 1993). Since it is recommended that the length of FFT should be 1024×2^{n} if the interested modal frequency is in the range of ($f_{nst}/2^{n+1}$~ $f_{nst}/2^{n}$, where f_{nst} is the Nyquist frequency of the test), the segment length utilizes 2048 in the PP method. It presents that the accuracy of PP-HPBW method and EFDD technique are similar with each other. Employing the stabilization diagram in SSI method, the structural modes can be distinguished from superfluous modes which improve its identification performance. The Random Decrement technique (RDT) plays an important role in ensuring the accuracy of the HHT method by providing the free vibration modal response. The applied modal identification methods need more or less user interaction to try to improve the estimate results, and they sensitize to the selection of the parameter in data processing.

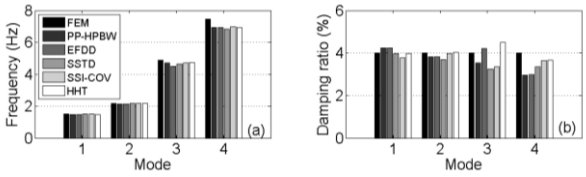

Figure 2 Comparison of the identified modal information under white noise input: (a) modal frequency; (b) damping ratio.

Table 1 The frequencies and damping ratios of the FE model under white noise input.

Method	f_1(Hz)	f_2(Hz)	f_3(Hz)	f_4(Hz)	ξ_1(%)	ξ_2(%)	ξ_3(%)	ξ_4(%)
FEM	1.50	2.16	4.88	7.45	4.00	4.00	4.00	4.00
PP-HPBW	1.49	2.15	4.71	6.93	4.25	3.81	3.54	2.97
EFDD	1.49	2.15	4.51	6.93	4.25	3.81	4.22	2.98
SSTD	1.50	2.16	4.65	6.85	3.99	3.68	3.24	3.34
SSI-COV	1.50	2.16	4.73	6.98	3.77	3.98	3.34	3.63
HHT	1.49	2.17	4.76	6.93	3.97	4.03	4.51	3.66

3.3 Noise Effect

In real field test, noise caused by environment or experimental instruments is inevitable which may affect the identified result. Signal-to-noise ratio (SNR) is a measure used in science and engineering that compares the level of a desired signal to the level of background noise. It is defined as

$$SNR_{dB} = 10\log_{10}\left(\frac{P_{signal}}{P_{noise}}\right) = 20\log_{10}\left(\frac{A_{signal}}{A_{noise}}\right) \qquad (33)$$

where P_{signal} is the signal power, P_{noise} is the noise power, A_{signal} is the signal amplitude and A_{noise} is the noise amplitude.

In this section, acceleration series with SNR equal to 0.1 are utilized by adding a white noise to the acceleration records in Section 3.2. The estimates are essentially the same as that in Section 3.2. Since the adding noise is white noise of which the energy is well-distributed, it is not difficult to identify the real mode. However, the noise would be more complicated in practice.

3.4 Local Damage

It is demonstrated that natural frequencies are sensitive indicators of structural integrity which can be used as a diagnostic parameter in structural assessment (Salawu 1997). This offers the possibility of using data from dynamic testing to detect damage. The stiffness of the three side columns at the first floor in the modified FEM is 40% lower than that in the FEM in Section 3.2. The stiffness reduction can be regarded as local damage in the primary structure. The first four modal frequencies of the modified FEM are estimated from the white noise induced responses at the same location with that in Section 3.2 by using the five algorithms. The identified frequencies are listed in Table 2 and the rates of frequency reduction based on the primary model in Section 3.2 are reported in the same table as well. The rate of frequency reduction is defined as

$$\delta f_i = \frac{f_{i,p} - f_{i,d}}{f_{i,p}} \times 100\% \qquad (34)$$

where $f_{i,p}$ is the ith modal frequency of the primary FE model, $f_{i,d}$ is the ith modal frequency of the model with local damage. The damage is well-estimated in the first two modes for all the adapted methods. Generally, the identification techniques in time domain are better performed than these in frequency domain.

Table 2 The frequencies of the FE model with local damage and the rates of frequency reduction.

Method	f_1(Hz)	f_2(Hz)	f_3(Hz)	f_4(Hz)	δf_1(%)	δf_2(%)	δf_3(%)	δf_4(%)
FEM	1.47	2.13	4.80	6.95	2.00	1.39	1.64	6.71
PP-HPBW	1.46	2.12	4.54	6.79	2.01	1.40	3.61	2.02

SSI-COV	2.32	2.38	7.80	7.92	4.44	3.64	3.65	3.32
HHT	2.35	2.39	7.92	7.93	4.15	3.79	3.52	1.83

3.5 Closely Spaced Modes

The finite element model is then modified to possess the characteristic of closely spaced modes and calculated to obtain the theoretical modal frequencies (see Table 3). The same stationary white noise is used as the input to the finite element model for the acquisition of acceleration responses as well. The identification procedure furnished the values of the dynamic properties reported in Table 3 and Figure 3. The PP-HPBW method, EFDD method, SSI method and HHT method reveal a good performance in close modes identification. However, a modal missing appears in the result of ITD technique.

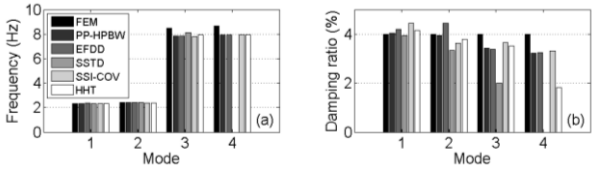

Figure 3 Comparison of the performance in closely spaced modes identification: (a) modal frequency; (b) damping ratio.

3.6 Seismic Excitation

The assumption of stationary white noise input may be a little tough for practical use. This section introduces a non-stationary excitation – El Centro earthquake motion records as an input to explore the evaluation of structural parameters. The FE model utilized here is the same as the one in Section 3.2. The identification procedure furnished the values of the parameters reported in Table 4 and Figure 4. Limited modal parameters (only the first two modes) are obtained because of the narrow band characteristic of seismic excitation. It is observed that the estimated frequencies are similar with that under white noise input, showing a very good fitting with the calculated values. However, the damping ratios are not well-estimated except the HHT method. Since the EMD is based on the local characteristic time scale of the data, the HHT algorithm is applicable to non-stationary processes.

Table 4 the frequencies and damping ratios for the FEM under El Centro seismic excitation.

Method	f_1(Hz)	f_2(Hz)	ξ_1(%)	ξ_2(%)
FEM	1.50	2.16	4.00	4.00

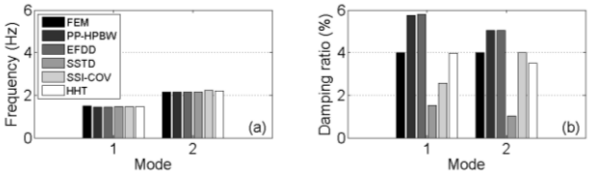

Figure 4 Comparison of the identified modal information under El Centro seismic excitation: (a) modal frequency; (b) damping ratio.

4. AMBIENT VIBRATION TEST AND DATA PROCESSING

4.1 Field Test

A field test of Tongji United Plaza Block B was took place. It is an office high-rise building located in Shanghai, China. The height of 23-storey building (one basement floor and 22 ground floors) is 99 m above ground (see Figure 5). The lateral force resistant system of the structure is a combined system of concrete core wall – steel frame.

Figure 5 General view of Tongji United Plaza Block B.

The field test was performed on the 22th floor (22F) of the building to record the acceleration responses in two translational directions. In order to record the accurate low frequency behaviors of the structure, the acceleration responses were sampled at a rate of 10 Hz. The acquisition time of the measurement was about 30 minutes. A dynamic response range of piezoelectric accelerometers used in this test is from 0.05 Hz to 500 Hz, the measurement capacity range is 0.1 g, and the sensibility is 10^{-5} g.

4.2 Data Processing

The acceleration records passed the augmented Dickey-Fuller unit root test after detrending, which confirm the stationary property of the *in situ* measurements. The density of probability of the ambient vibration responses is hypothesized as a Gaussian distribution, indicating that the structure is subjected to a broadband white noise excitation. To perform a Gaussian distribution test, the dynamic records were first normalized by their mean and standard deviation values, and then the K-S test was used for determining whether the records contained the hypothesized cumulative distribution function. It was verified that the records passed the test.

The data are then processed by the five modal identification approaches, respectively. The results are listed in Table 5 and presented in Figure 6 as well. The PP-HPBW method and HHT technique, as shown in Table 5, miss to identify the second mode which can be regarded as a closely spaced mode. A very good agreement can be observed in frequency evaluation that increase the confidence on the obtain results. The damping ratios extracted using the frequency domain methods are larger than that obtained by the other methods for the probability of overestimate.

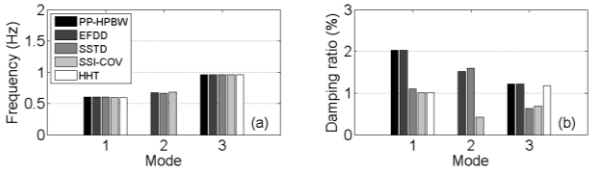

Figure 6 Identified modal information of Tongji United Plaza Block B: (a) modal frequency; (b) damping ratio.

Table 5 The identified frequencies and damping ratios of Tongji United Plaza Block B.

Method	f_1 (Hz)	f_2 (Hz)	f_3 (Hz)	ξ_1 (%)	ξ_2 (%)	ξ_3 (%)
PP-HPBW	0.6055	/	0.9651	2.03	/	1.22
EFDD	0.6055	0.6738	0.9647	2.03	1.52	1.22
SSTD	0.6003	0.6676	0.9613	1.10	1.60	0.63
SSI-COV	0.5990	0.6811	0.9610	1.01	0.42	0.68
HHT	0.5986	/	0.9588	1.01	/	1.18

5. DISCUSSION

Based on the performance of the five state-of-the-art modal identification approaches both in numerical model and full-scale building, there is not any perfect method in application. Therefore, an integrated method is proposed to improve the data processing by taking the advantages of all the techniques. It is firstly to have a quick estimation of frequency and damping ratio by using PP-HPBW method and EFDD method which ensure to identify the closely spaced modes. Then, the empirical mode decomposition (EMD) is applied to turn a complicated time history into a series of intrinsic mode functions (IMFs) and the selection of IMFs is based on the information obtained by the frequency domain approaches. Finally, except performing the Hilbert transform to each IMF component, it can be processed by SSI-COV technique or SSTD technique which abandon the superfluous modes by using stabilization diagram. In addition, the traditional SSTD method, SSI-COV method and HHT method can be used as references. Nonetheless, this integrated method is very time-consuming. It is revealed

that the frequency domain approaches are more suitable for real-time modal identification.

6. CONCLUSION

This paper reviewed five different output-only modal identification methods and the performance of these methods have been compared and discussed both in numerical simulated test and full-scale field test. The five algorithms can be categorized as frequency domain (PP-HPBW method and EFDD method), time domain (SSTD method and SSI-COV method), and time-frequency domain (HHT method) approaches.

The comparison reveals that all the techniques give reasonable estimates of the natural frequencies. The time domain and frequency-time domain approaches return more stable estimates of the damping ratios, while the frequency domain approaches seem to be overestimate. However, the frequency domain algorithms are simpler and faster. Therefore, there is not a perfect method with both advantages of accuracy and efficiency. The integrated method proposed in this paper can be applied to improve the modal identification of a structure under ambient vibration.

Abstract: The present paper discusses the active vibration control of arch structures. In previous paper discussing the active vibration control tests, it is successful to reduce the seismic response. However, this control by displacement feedback is impractical in point of the sensors. Therefore, this paper deals with the active vibration control on the Optimal control theory with Kalman filter so that the acceleration feedback control using accelerometers as a sensor should be possible. First, we explain the control algorithm with Kalman filter. Next, for demonstration, the active vibration control tests of the arch structures are carried out. As a result, the response to sine waves reduces by up to 70 % and that to seismic wave reduces by up to 20 %.

1. INTRODUCTION

In recent year, the number of building structures equipped with response control mechanisms increases for the sake of its safety. Especially in spatial structures, the safety demands are higher, for these are the places to attract customers and for disaster refuge. But we suffered some damage such as the fall of roof members also from the 2011 Great East Japan Earthquake. Thus the provision for earthquake disasters is not sufficient and the response control is the prime task. It is considered that an active response control is applied to the spatial structures as one method of response control. In high-rise buildings, a large number of studies are made on the active vibration control, for example the studies by Tsuji et al. (1995), Nishitani et al. (1996), and Haramoto et al. (2000). But only a few studies have so far been made at the active response control of spatial structures, for example the study by Shingu et al. (1990), in comparison with the studies of the passive response control by Xue et al. (2001), and Yoshinaka et al. (2010). In comparison with the passive vibration control, the active vibration control is able to reduce the responses more and characterized by the vibration control in no relations at the period of ground motion.

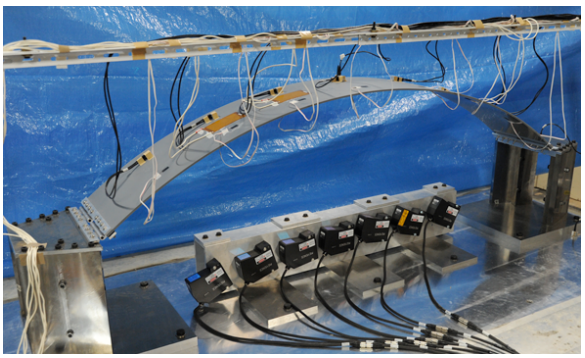

Figure 1 Picture of Vibration Control Test of Arch Structures

Because of this, we have studied the active vibration control of arch structures in previous works by Minowa et al. (2010, 2011, and 2012). In references by Minowa et al. (2011 and 2012), the active vibration control tests of arch structure models with piezoelectric films and a digital signal processor (DSP) are carried out (Fig.1). As a result, the control by displacement feedback was effective but the control by acceleration feedback was ineffective. However, the control by displacement feedback is impractical in point of the sensors. Therefore, this study deals with the acceleration feedback control with Kalman filter in order to improve the effects of acceleration feedback control. In this study, the demonstration tests of active vibration control of arch structures using accelerometers are carried out.

2. ACTIVE VIBRATION CONTROL TESTS OF ARCH STRUCTURES

2.1 Experimental Outline

For actual proof of the active vibration control with the modal control, we carry out the active vibration control tests. Specimens are the same arch structures as references by Minowa (2011 and 2012) (Fig.1). The shape properties are

Table 1 Shape Properties

Arch Structure	
Span L_x [mm]	1500
Width L_y [mm]	250
Rise H [mm]	236
Curvature Radius R [mm]	1308
Subtended Half-angle θ [deg.]	35

Table 2 Material Properties

Material	Acrylic Resin
Thickness t [mm]	5.18
Young's Modulus E [N/mm^2]	3.10×10^3
Tensile Strength σ_b [N/mm^2]	61.8
Fracture Strain ε_b [%]	3.8

shown in Table 1 and the material properties are shown in Table 2. The thicknesses t is about 5 mm so that the 1st natural periods T_1 is about 0.2 s.

Figure 2 shows experimental mechanism. The responses of arch structure are measured with laser displacement sensors, accelerometers and strain gages. An input direction of earthquake motion is the horizontal direction. Input waves are sine waves with 1st natural period T_1 and BCJ-L1 (artificial earthquake motion of the Building Center of Japan). The maximum accelerations A_g of sine waves are 20 cm/s^2 and those of seismic waves are normalized to 100 cm/s^2. In case of Ra0.2 model's tests, the time bases of seismic waves are halved as the natural period of arch structure becomes relatively long against the seismic waves.

For control, a digital signal processor (DSP), piezoelectric films, and accelerometers are used. The piezoelectric films generate force in direct proportion voltage. In this paper, the voltage amplifier limits the voltage for control force to plus or minus 600 V.

Here, names of control models are defined as Ra (1st natural period) - (control type) - (kind of weighting coefficient matrix **Q**). Where, the control type expresses the control positions as shown in Table 3.

2.2 Vibration Characteristics of Arch Structure

The vibration characteristics of arch structure are grasped by inputting sweep waves. Table 4 shows measured vibration characteristics. The 1st natural period T_1 of Ra0.2 model is 0.175 s. Antisymmetrical 2 waves mode and antisymmetrical 4 waves mode are observed and called 1st mode and 3rd mode. Every damping ration is about 10 %.

3. CONTROL SYSTEM AND ALGORITHM

Figure 3 shows detail of control system on this study. First, the accelerometers at the points 3 and 7 measure the accelerations. Then, DPS calculates control input **u**. In DSP, a band-pass filter eliminates noise from the observation data.

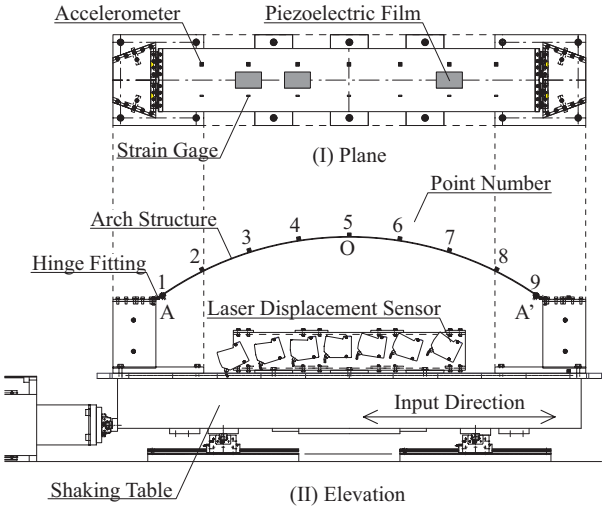

Figure 2 Experimental Mechanism

Table 3 Control Positions

Control Type	Point Number		
	3	4	7
1M1	O	-	-
1M3	-	O	-
2M1	O	-	O

Table 4 Vibration Characteristics

Ra0.2 Model	1st Mode	3rd Mode
Natural Period T [s]	0.175	0.0372
Damping Ratio h [%]	8.1	11.5
Effective Mass Ratio [%]	31.5	5.1

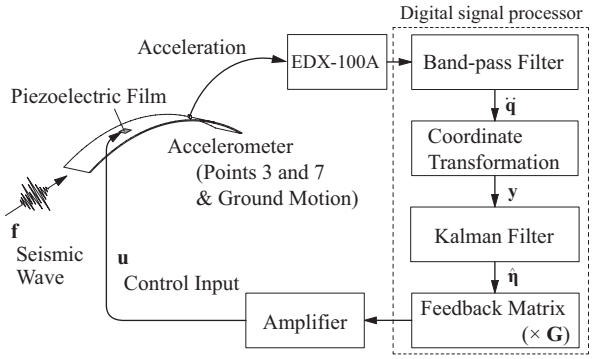

Figure 3 Detail of Control System

And a coordinate transformation of the observation date is carried out. Moreover, Kalman filter is used. Then, the feedback matrix **G** determines the control input **u**. Also, detailed accounts of these theories are given below. Finally, the piezoelectric film generates the control force.

MATLAB 7.10.0 and Simulink ver.7.5 are used for the design for the control system.

3.1 Reduction of Degree-of-Freedom of Model

In this study, a reduction of the degree-of-freedom of controlled model is carried out in order to easy the hardship of control system design and decrease the delay time. First, the equation of motion expresses controlled structures, as follow:

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{F}\mathbf{f} + \mathbf{U}\mathbf{u} \tag{1}$$

Where **M** is a mass matrix, **C** is a damping matrix and **K** is a stiffness matrix. **q** is a relative displacement vector, **f** is a disturbance vector and **u** is a control input vector. And **U** and **F** are coefficient matrices expressing positions where the forces are added.

Next, the overall coordinate is transformed into the modal coordinate by the modal matrix **Φ**, as follow:

$$\mathbf{M}_m\ddot{\boldsymbol{\xi}} + \mathbf{C}_m\dot{\boldsymbol{\xi}} + \mathbf{K}_m\boldsymbol{\xi} = \mathbf{F}_m\mathbf{f} + \mathbf{U}_m\mathbf{u} \tag{2}$$

$$\mathbf{M}_m = \boldsymbol{\Phi}^T\mathbf{M}\boldsymbol{\Phi} \quad \mathbf{C}_m = \boldsymbol{\Phi}^T\mathbf{C}\boldsymbol{\Phi} \quad \mathbf{K}_m = \boldsymbol{\Phi}^T\mathbf{K}\boldsymbol{\Phi}$$
$$\mathbf{F}_m = \boldsymbol{\Phi}^T\mathbf{F} \quad \mathbf{U}_m = \boldsymbol{\Phi}^T\mathbf{U} \tag{3}$$

Where ξ is a displacement vector on the modal coordinate. Index *m* expresses the modal coordinate.

Then, some modes are truncated based on the generalized orthogonality of eigenmodes. As a result, it is important to reduce measure points for the feedback control.

In this study, for the reduction of degree-of-freedom, the models approximate 1st ~ 4th modes those are the dominant modes and these periphery modes. The measure points are the points 3 and 7 those are in the vicinity of antinode of 1st mode.

3.2 Application of Optimal Control Theory

A controller to compute control forces is designed on the Optimum control theory. In order to use the Optimal control theory, the equation of motion, Eq.(2), is transformed into the state equation, as follow:

$$\dot{\boldsymbol{\eta}} = \mathbf{A}\boldsymbol{\eta} + \mathbf{B}\mathbf{u} + \mathbf{E}\mathbf{f} \tag{4}$$

$$\boldsymbol{\eta} = \begin{Bmatrix} \dot{\boldsymbol{\xi}} \\ \boldsymbol{\xi} \end{Bmatrix} \quad \mathbf{A} = \begin{bmatrix} -\mathbf{M}_m^{-1}\mathbf{C}_m & -\mathbf{M}_m^{-1}\mathbf{K}_m \\ \mathbf{I} & \mathbf{O} \end{bmatrix}$$
$$\mathbf{B} = \begin{bmatrix} \mathbf{M}_m^{-1}\mathbf{U}_m \\ \mathbf{O} \end{bmatrix} \quad \mathbf{E} = \begin{bmatrix} \mathbf{M}_m^{-1}\mathbf{F}_m \\ \mathbf{O} \end{bmatrix} \tag{5}$$

The control input vector **u**, the amount of feedback, is calculated from the feedback matrix **G**. The feedback matrix **G** is determined so that a linear quadratic evaluation function *J* is minimized, as follows:

$$J = \int_0^\infty \left\{ \boldsymbol{\eta}^T\mathbf{Q}\boldsymbol{\eta} + \mathbf{u}^T\mathbf{R}\mathbf{u} \right\} dt \tag{6}$$

Where **η** is a state vector in the modal coordinate. **Q** and **R** are weighting coefficient matrices those keep a balance between reduction effects of the responses and the quantity of control input. The weighting coefficient matrix **R** is calculated so that the responses with control become *r* times compared with those without control as shown in previous work by Minowa et al. (2010).

In this study, the weighting coefficient matrix $\mathbf{Q}_1$ is the unit matrix. In the case of $\mathbf{Q}_2$, the weighting is put on the only 1st mode and improvement in stability is attempted.

3.3 Application of Kalman Filter

This study tries the vibration control using accelerometer. In reference by Minowa et al. (2012), the suboptimal theory is used for the realization of acceleration feedback control. However, that control method is ineffective. The reason is thought that a phase of control force is not considered on the suboptimal theory. Therefore, this study uses Kalman filter as an observer as shown in the work by Kalman (1960). The observer is a mechanism that estimates all states from the observed variable when it is difficult to observe all the states.

Kalman filter is a method to estimate state vector $\hat{\boldsymbol{\eta}}$ form output vector **y** in case system noise **f** (i.e. the disturbance vector) and measurement noise **v** are a white noise. The above is expressed to the equation, as follow:

$$\dot{\hat{\boldsymbol{\eta}}} = \mathbf{A}\hat{\boldsymbol{\eta}} + \mathbf{B}\mathbf{u} + \mathbf{K}_\mathbf{f}\left(\mathbf{y} - \mathbf{H}\hat{\boldsymbol{\eta}}\right) \tag{7}$$

Where $\mathbf{K}_\mathbf{f}$ is Kalman gain and **H** is a matrix shown the relation between the output vector **y** and the state vector $\hat{\boldsymbol{\eta}}$, as follow:

$$\mathbf{y} = \mathbf{H}\hat{\boldsymbol{\eta}} + \mathbf{v} \tag{8}$$

Then, the Kalman gain $\mathbf{K}_\mathbf{f}$ is expressed, as follow:

$$\mathbf{K}_\mathbf{f} = \mathbf{X}\mathbf{H}^T\mathbf{V}^{-1} \tag{9}$$

Where **V** is a covariance matrix of measurement noise **v**. And **X** is obtained as the solution of Riccati matrix equation, as follow:

$$\mathbf{A}\mathbf{X} + \mathbf{X}\mathbf{A}^T - \mathbf{X}\mathbf{H}^T\mathbf{V}^{-1}\mathbf{H}\mathbf{X} + \mathbf{E}\mathbf{W}\mathbf{E}^T = \mathbf{O} \tag{10}$$

Where **W** is a covariance matrix of system noise **f**.

As seem above, the covariance matrices **V** and **W** are set for the design of Kalman filter. In this study, the covariance matrix of system noise **W** is calculated from BCJ-L1 normalized to 100 cm/s^2. And the covariance matrix of measurement noise **V** is calculated form the observation data, the output vector **y**, in the absence of the disturbance vector **f**.

Also, in this study, the output vector **y** and the matrix **H** are expressed on the relationship between Eq.(2) and Eq.(8), as follow:

$$\mathbf{y} = \ddot{\boldsymbol{\xi}} - \mathbf{M}_m^{-1}\mathbf{F}_m\mathbf{f} \tag{11}$$

$$\mathbf{H} = -\mathbf{M}_m^{-1}\left(\begin{bmatrix} \mathbf{C}_m & \mathbf{K}_m \end{bmatrix} + \mathbf{U}_m\mathbf{G}\right) \tag{12}$$

3.4 Control Properties

The band-pass filter (BPF) is used to eliminate noise from the observation data. The BPF consists of a low-pass filter and a high-pass filter as shown in the work by Minowa et al. (2011). Figure 4 shows the property of BPF. In this study, cutoff frequencies ω_{lc} and ω_{hc} are 162.5 rad/s and 31.13 rad/s, respectively.

Table 5 shows the delay time. The ratios of delay time to 1st natural period d/T_1 are 11.5 %. In comparison with reference by Minowa et al. (2012), the delay time d/T_1 increases because of the calculation on Kalman filter. However, we showed that the response reduction is possible when the delay time d/T_1 is less than 12 % in reference by Minowa et al. (2012). Thus it is possible to suppress the delay time d/T_1 of the control using Kalman filter within 12 %.

4. RESULTS OF ACTIVE VIBRATION CONTROL TESTS

In the following results, the responses are shown in the relative coordinate to the shaking table. The maximum response displacement and acceleration are normalized with the maximum input displacement D_g and acceleration A_g. The maximum member force is normalized with N_b or M_b. Where, N_b is the axial force with the fracture strength and M_b is the moment with the edge stress reaching the tensile strength σ_b. Moreover, r = 1.0 shows the condition that control does not exist.

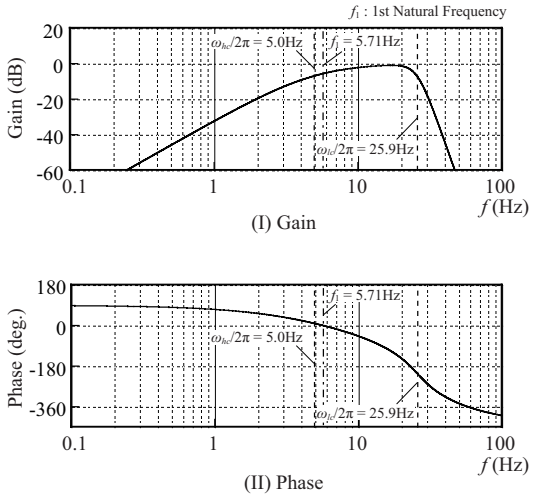

Figure 4 Property of Band-pass Filter

4.1 Comparison with Past study about Control Effect

Figure 5 shows the results of the active vibration control tests. Where, ratio of response displacement d_n^c/d_n^{uc}, on the left axis, is defined as the value of the maximum displacement with control d_n^c divided by that without control d_n^{uc} at the points 3 and 7. The point 3 and 7 are in the vicinity of antinode of the dominant mode, which is the first antisymmetrical mode. The response reduces on every

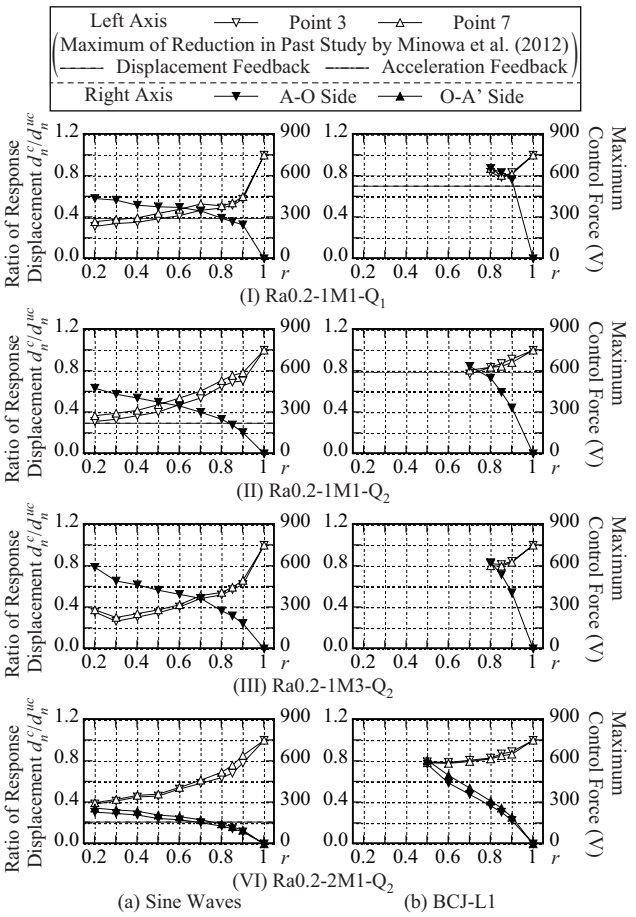

Figure 5 Results of Active Vibration Control Tests of Arch Structure

Table 5 Delay Time

Ra0.2 Model	1M	2M
Data Processing Time at EDX-100A d_1 [ms]	2.9	2.9

model. The response to sine waves reduces by up to 70 % and that to seismic wave reduces by up to 20 %. In reference by Minowa et al. (2012), in the case of displacement feedback control, the response to sine waves reduces by up to 80 % and that to seismic wave reduces by up to 40 %. And, in the case of acceleration feedback control, the response to sine waves reduces by up to 40 % and that to seismic wave reduces by up to 20 %. The latest results are better than the results of acceleration feedback control in reference by Minowa et al. (2012) but worse than the results of displacement feedback control in the reference above. Although it is difficult to get the higher effects than the displacement feedback control because of the use of observer, it is thought to be possible to acquire an effect equivalent to it. This means there is still room for improvement in the acceleration feedback control.

4.2 Analyses of Control Results

In this section, we analyze the results of Ra0.2-2M1-Q_2 model. This control model is characterized by the large response reduction.

Figure 6 shows the distributions of maximum response displacement. Although the response of the center point 5 increases, the responses of the other points decrease. The distribution shapes do not vary regardless of presence of control force. As mentioned in references by Minowa et al. (2010 and 2012), the response reduction to BCJ-L1 is smaller than that to sine waves in the case of same r.

Figure 7 shows the distributions of maximum response acceleration. In reference by Minowa et al. (2012), the reduction of response acceleration is smaller than that of response displacement. However, in this study, the reduction of response acceleration is large and approaches that of response displacement. The reason is that the BPF eliminates the high frequency area of the control force through narrowing its range. In this way, the setting of BPF affects the control results. How decisions on the setting of BPF are made will be an issue to be addressed in the future.

Figure 8 shows the distributions of maximum member force and the maximum control force. The axial force reduces except for the control positions, the points 3 and 7. The bending moment reduces at all the points. For the sake of control, the required control force is about equal to the member force without control.

Figure 9 shows the time history responses to sine waves. In the response displacement, the response reduction is shown. The period of vibration does not vary despite the control. The phase of bending moment with control progresses by a half of the vibration period compared with that without control, as r is small. The phase of axial force is the same as that of control force.

Figure 10 shows the Fourier amplitude spectra of response displacement at the point 3. In the vicinity of 1st natural period T_1, the Fourier amplitude spectrum to BCJ-L1 reduces like the Fourier amplitude spectrum to sine waves. However, the Fourier amplitude spectrum to BCJ-L1 increases in the vicinity of about 0.147 s. Figure 11 shows the ratio of Fourier amplitude spectrum of response displacement at these periods. Where, F_s^{uc} is a value of Fourier amplitude spectrum without control and F_s^c is a value of Fourier amplitude spectrum with control. At the 1st natural period T_1, the reduction of Fourier amplitude spectrum to BCJ-L1 is the same as that to sine waves. When r is 0.5, the Fourier amplitude spectrum at T_1 decreases by about 50 %. However, at 0.147 s, the Fourier amplitude

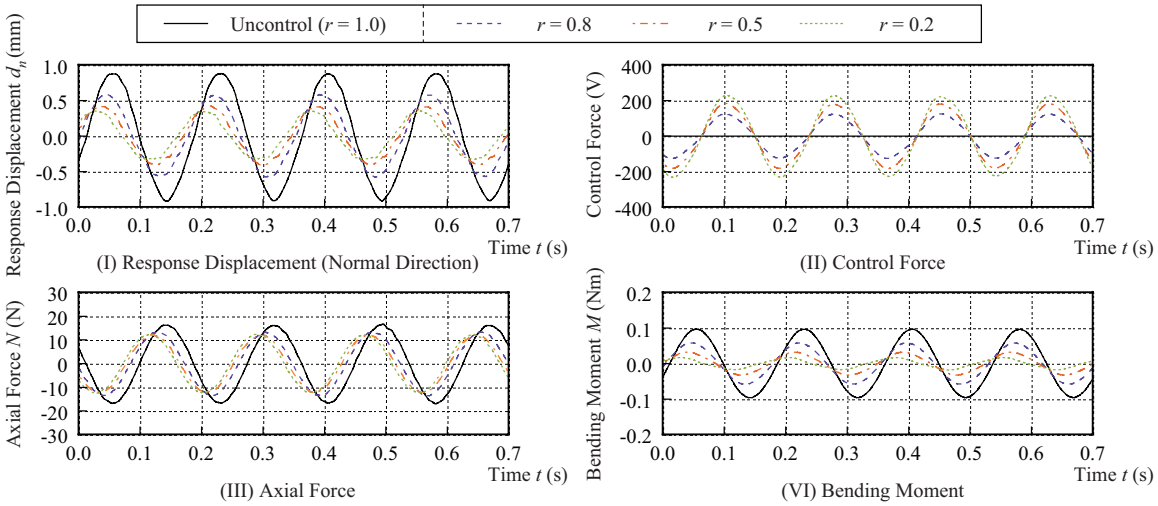

Figure 9 Time History Responses (Ra0.2-2M1-Q_2, Point 3, Sine Waves)

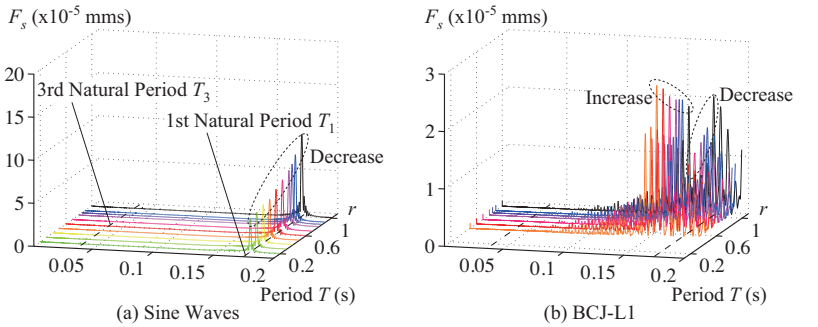

Figure 10 Fourier Amplitude Spectra of Response Displacement (Ra0.2-2M1-Q_2, Point 3)

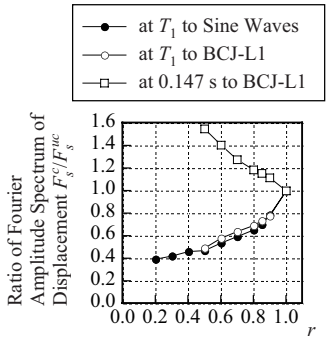

Figure 11 Ratio of Fourier Amplitude Spectrum of Response Displacement (Ra0.2-2M1-Q_2, Point 3)

spectrum to BCJ-L1 increases by about 60 %, when r is 0.5. Also, at the reference by Minowa et al. (2012), such an increase is not seen. In other words, this increase is the main reason that the response reduction to earthquake motion is smaller. The reason for this increase is that the control phase on this period deviates from the phase of response velocity because the setting of BPF is narrow, in addition to the long delay time. As mentioned above, how decisions on the setting of BPF are made will be an issue to be addressed in the future.

5. CONCLUSIONS

This study discussed the active vibration control on the Optimal control theory with Kalman filter for the acceleration feedback control. The vibration control tests of arch structure model are carried out. It is concluded as follows, from the above results.

1) In the experiment, the response to sine waves reduces by up to 70 % and that to seismic wave reduces by up to 20 %.
2) The response reductions are larger than the results of acceleration feedback control in reference by Minowa et al. (2012). However, the response reductions are smaller than the results of displacement feedback control in the reference above.

SEISMIC RESPONSE AND PERFORMANCE OF FIXED BASE AND BASE ISOLATED STRUCTURES CONSIDERING CONTINUED FUNCTIONALITY DAMAGE STATE

Sarun Chimamphant[1)], Kazuhiko Kasai[2)]

1) Graduate Student, Tokyo Institute of Technology, Japan
2) Professor, Structural Engineering Research Center, Tokyo Institute of Technology, Japan

Abstract: In this paper, the seismic performance of fixed base and base isolated structures are investigated. MDOF linear response history analysis is utilized to investigate the seismic responses of these fixed base and base isolated structures. Fixed base structures with different superstructure damping ratios and damping mechanisms are investigated. Also base isolated structures with several combinations of isolation period and superstructure period are examined and compared with the response of the fixed base structures. How well the isolation system added to the fixed base structure improves the overall structural responses of drift ratios and floor accelerations is observed. Floor response spectrum analysis is conducted on these structures to examine the influences of the superstructure damping ratio, superstructure damping mechanism, and the isolation period of the isolated structure on the floor spectrum. Furthermore, to study the performance of these structures considering continued functionality, the PEER Performance Based Earthquake Engineering (PBEE) methodology is adopted. A continued functionality *CF* performance state is obtained from the fragility functions for nonstructural components. In this study, the *CF* performance state of nonstructural partition walls and suspended ceilings are adopted to determine the seismic performance of the structures. The performance of these structures, in term of return period *TR*, is observed and compared.

1. INTRODUCTION

Base isolation of structures is usually characterized by a low frequency of the fundamental mode which corresponds to low pseudo-acceleration spectral values for the possible earthquake excitations. This leads to a significant reduction of the forces experienced by the superstructure. However, this reduction of forces is achieved on the expense of displacement being concentrated at the isolation level. To reduce the base displacement, isolation damping is usually added by inserting devices with energy dissipation capacity. Additional isolation damping results in the significant reduction of the base displacement. However, it could cause higher forces and accelerations attributed to high damping and also render the drift distribution along the superstructure.

Nevertheless, base isolation system has gained large attention by researchers from around the world and also popularity among practice engineers. Therefore, in order to properly observe how well the added isolation improves the overall performance of the structure, several fixed base structures are investigated in comparison with those isolated structures. In addition, the performance of these fixed base and base isolated structures are also investigated following the PEER Performance Based Earthquake Engineering.

2. ANALYTICAL MODEL

The analytical model for a generic MDOF system is represented in this study by a shear model. An example model representing a 3-story fixed base and base isolated structures are shown in Figures 1(a) and 2(a). The superstructure is assumed to have an inverted triangular mode shape as shown in Figures 1(b) and 2(b). The mass in each floor is assumed to be equal, $m_b = m_1 = m_2 = \ldots = m_n$.

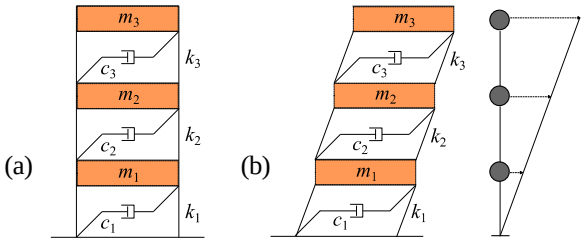

Figure 1 Fixed Base Structure Model:
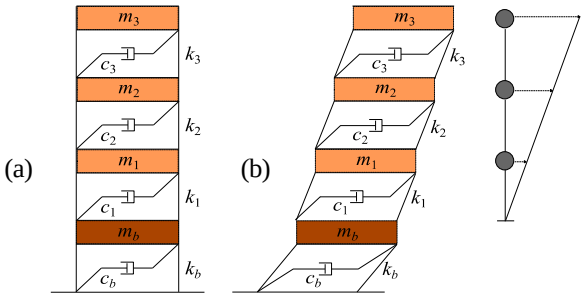
(a) Shear Model (b) Mode Shape



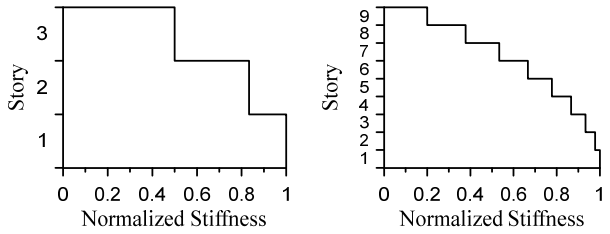


Figure 2 Base Isolated Structure Model:
(a) Shear Model (b) Mode Shape

For the fixed base structures, superstructure period T_s is assumed to be $0.1N_s$ where N_s is the number of stories. In order to control the superstructures to have the periods T_s, the stiffnesses, k_1, k_2, …, k_n distribution along the superstructure is obtained by solving simultaneous equations in Equation 1, where ϕ is the mode shape vector of the superstructure that is $\{1 \;\; 2 \;\; \ldots \;\; N_s\}^T$. The normalized stiffness distribution is shown in Figure 3(a) and 3(b) for 3- and 9-story structures. The superstructure is assumed to behave linearly throughout the excitation of the ground acceleration.

$$\left(\underset{N_s \times N_s}{\tilde{k}} - \frac{4\pi^2}{T_s^2} \underset{N_s \times N_s}{\tilde{m}} \right) \underset{N_s \times 1}{\tilde{\phi}} = \underset{N_s \times 1}{\tilde{0}} \qquad (1)$$

(a) (b)

Figure 3 Normalized Stiffness Distribution: (a) 3-story and (b) 9-story structures

Two types of superstructure damping of the fixed base structures are studied which are (1) stiffness proportional damping matrix $(\underset{\sim}{c} = \beta \underset{\sim}{k})$ and (2) Rayleigh damping matrix $(\underset{\sim}{c} = \alpha \underset{\sim}{m} + \beta \underset{\sim}{k})$

For the base isolated structures, an additional flexible floor is added at the bottom of the fixed base structure. The isolation period T_b and isolation damping ratio ζ_b are defined with the assumption that the superstructure is infinitely rigid. A linear viscous base isolation system is considered. Therefore, the isolation stiffness k_b and the isolation dashpot c_b can be obtained from Equation 2. Due to high demand concentration at the isolation level, the demands induced on the superstructure are reduced largely. Therefore, the superstructure damping for the base isolated structure is considered only 2% and is proportional to the stiffness matrix of the superstructure $(\underset{\sim}{c} = \beta \underset{\sim}{k})$.

$$k_b = \frac{4\pi^2}{T_b^2}\left(m_b + \sum_{j=1}^{N_s} m_j \right), \;\; c_b = \frac{4\pi\zeta_b}{T_b}\left(m_b + \sum_{j=1}^{N_s} m_j \right) \qquad (2)$$

Masses in all floors are assumed equal to one, story heights are equal in all stories and are assumed to be equal to 350 cm. Twenty ground accelerations from Los Angeles SAC suite of ground accelerations for a 2% in 50 years seismic hazard (LA21–LA40) are used in this study. Figure 4 shows the response spectra plots with 5% damping ratio for these ground accelerations.

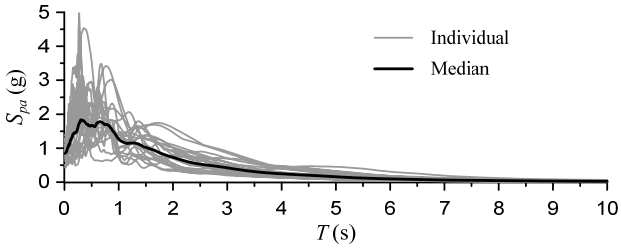

Figure 4 Pseudo Spectral Acceleration of LA21 – LA40 Ground Accelerations

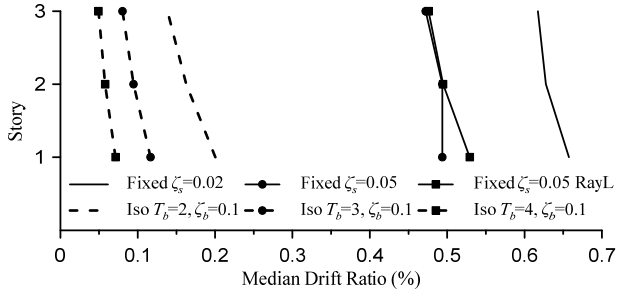
3. CASE STUDIES

By using the previously defined analytical model, a parametric study is conducted. For the fixed base structures, several combinations of (1) superstructure damping ratio ζ_s and (2) number of stories N_s are investigated as listed below.

(1) ζ_s = { $0.2(\beta \underset{\sim}{k})$, $0.5(\beta \underset{\sim}{k})$, $0.5(\alpha \underset{\sim}{m} + \beta \underset{\sim}{k})$ }
(2) N_s = { 3, 9, 20 } stories

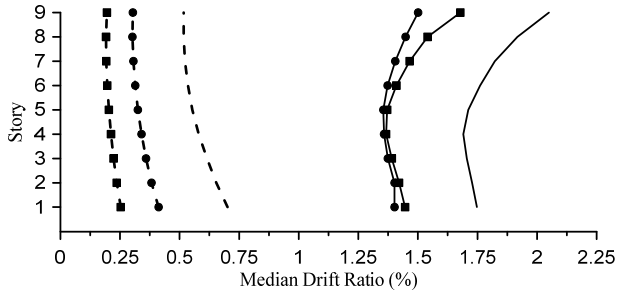
Although such small damping ratio ζ_s of $2\%(\beta \underset{\sim}{k})$ is not realistic, it is also investigated in order to compare the responses with the base isolated structures which have ζ_s of 2%, and also to compare, among the fixed base structures as well, the effects of damping ratio and damping mechanism on the response demand and distribution along the height of the superstructure. For Rayleigh damping mechanism, the first two modes are specified with the selected damping ratio.

For the base isolated structures, a variety of (1) base isolation period T_b and (2) number of stories N_s (above the isolation, excluding the isolation floor) with isolation damping ratio ζ_b of 10% are investigated as listed below.



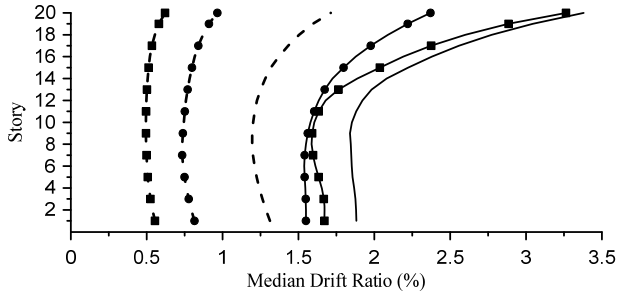
(1) T_b = { 2.0, 3.0, 4.0 } seconds
(2) N_s = { 3, 9, 20 } stories

These fixed base and base isolated structures are subjected to the 20 ground motions previously defined. The responses are described as median values with an assumption that these responses are lognormally distributed. Therefore, the medians and dispersions are calculated for each structure by Equations 3 and 4 respectively,



$$x_m = \exp\left(\frac{1}{M} \sum_{i=1}^{M} \ln r_i \right) \qquad (3)$$

$$\beta = \sqrt{\frac{1}{M-1} \sum_{i=1}^{M} \ln\left(r_i / x_m \right)^2} \qquad (4)$$



where x_m is median, β is dispersion, M is number of ground accelerations, and r_i is unique response for each ground motion.

4. ANALYSIS RESULTS

It is necessary to study the natural behaviors of these fixed base and base isolated structures. Hence, these structures are subjected to the real unscaled ground accelerations (LA21–LA40). Median drift ratios and median peak absolute accelerations are used to describe the response. Median drift ratios for 3-, 9-, and 20-story structures are shown in Figure 5(a), 5(b), and 5(c), respectively. Median absolute peak floor accelerations for 3-, 9-, and 20-story structures are shown in Figures 6(a), 6(b), and 6(c), respectively. The comparisons of these structures are described in subsequent sections.

4.1 Comparison among the Fixed Base Structures

Since all fixed base structures have linear elastic behavior, there is no other source of damping, such as hysteretic damping, involved. Only the influence of the inherent structure damping is considered. From Figures 5 and 6, solid lines, for less superstructure damping cases, ζ_s = 2%, the responses are observed to be always higher, while cases of ζ_s = 5% (stiffness proportional) and 5% (Rayleigh), the responses are slightly different. For 3-story structures, drift and peak acceleration demands show almost the same, this is due to short and stiff nature of the structure. However, for taller structures, 9- and 20-story structures, slightly larger difference start to appear. When the structure is very tall, 20-story structure, the responses of 5% Rayleigh damping structures, seem to get closer to the response of 2% superstructure damping structures. This is because when the structures are very tall, 2nd mode, 3rd mode or even higher mode response may become dominant. And higher mode damping ratios for the Rayleigh damping case seems to be much lower than the stiffness proportional damping case, ζ_s = 5%, but closer to the 2% case as clearly shown in Table 1.

Table 1 Modal Damping Ratios of 20-Story Fixed Base Structures

Mode	Modal Damping Ratio		
	Stiffness Proportional Case		Rayleigh Case
	ζ_s = 2%	ζ_s = 5%	ζ_s = 5%
1	0.020	0.050	0.050
2	0.049	0.122	0.050
3	0.077	0.194	0.065
4	0.106	0.265	0.083
5	0.134	0.335	0.103

4.2 Comparison among the Base Isolated Structures

From Figures 5 and 6, dashed lines, it can be clearly observed that an increase of base isolation period T_b reduces both the drift and acceleration demands in superstructures of both stiff and flexible buildings. This is unsurprising because an increase of the base isolation period T_b is a reduction in the isolation stiffness resulting in concentration of drift demand in the base isolation level. More details of the effects of other properties influencing the response of the base isolated structures are described in the previous work by the authors (Chimamphant et al. 2012)

4.3 Comparison between the Fixed Base and Base Isolated Structures

Figures 5 and 6 reveal that adding the isolation system to the fixed base structure reduces the demands significantly. Comparison of the drift demands between the fixed base (ζ_s = 5% Rayleigh) and base isolated (T_b = 2 sec, ζ_s = 10%) structures show that the drift demands are reduced to around 30-50% at the top story as shown in Figure 5. However, in tall buildings, 9- and 20-story structures, the drift demands become concentrated in the upper stories more severely than the base isolated structures.

Comparison of the peak floor accelerations between the fixed base and base isolated structures also exhibit the reduction of the acceleration demands on the superstructures as shown in Figure 6. The results show similarly with the drift demands that the accelerations get severely concentrated in the upper stories. The difference is that the acceleration demand is slightly more steadily increasing along the height of the superstructure, unlike the drift demands that they tend to jump to rapid concentration at the upper stories.

In short buildings, the response could be reduced even more if the isolation system is more flexible by increasing the isolation period T_b as shown clearly in both Figures 5 and 6. This indicates that adding isolation system could always reduce the drift and acceleration responses on the superstructure.

5. FLOOR RESPONSE SPECTRA

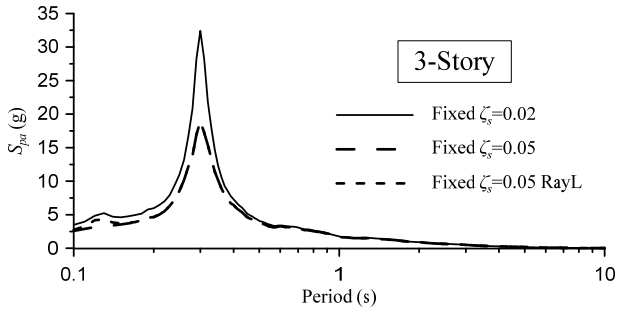
In order to observe how the floor response spectra (FRS) are influenced by the structures having a variety of properties, floor response spectra with 2% damping ratio are conducted by using the absolute floor acceleration at the top floor of the structures. Figures 7 and 8 show the floor response spectra of the fixed base and base isolated structures, respectively. These floor response spectra represent the median values of the floor response spectra from all the ground accelerations. Median value is used to represent the value at the 50 percentile. Also it is easier to observe the peak at the natural periods and the smooth plateau at the other periods.

5.1 FRS of the Fixed Base Structures

The effects of the superstructure damping ratio and damping mechanism on the floor response spectra can be observed shown in Figure 7. Increasing the superstructure damping ratio from 2%$(\beta\underset{\sim}{k})$ to 5%$(\beta\underset{\sim}{k})$ results in rather uniform reduction in the floor response spectra as shown consistently in Figure 7(a), 7(b), and 7(c). However, alteration of the damping mechanism from stiffness proportional to Rayleigh results in the differences shown in the same Figure. As previously shown in Table 1, the 1st mode damping ratio for the 5% Rayleigh damping case is the same as the 5%$(\beta\underset{\sim}{k})$ case, which results in rather same pseudo spectral accelerations at the 1st mode period. However, the 2nd mode damping ratio for the 5% Rayleigh damping case is very close to the 2nd mode damping ratio of the 2% $(\beta\underset{\sim}{k})$ case. Therefore, the pseudo spectral acceleration at the 2nd mode period is shifted upwards close to what is observed for the 2%$(\beta\underset{\sim}{k})$ case.

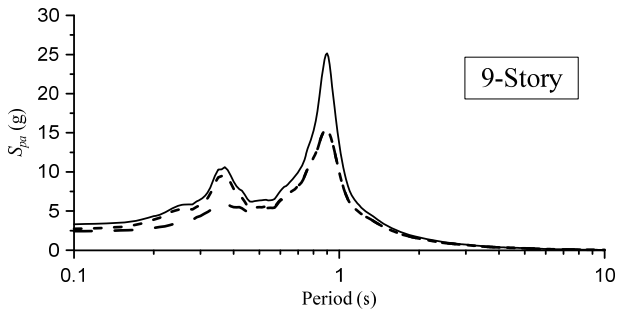
5.2 FRS of the Base Isolated Structures

The effects of the base isolation periods T_b are observed and shown in Figure 8. It is obvious that not only is the natural period shifted, but also the reduction of the pseudo acceleration is significant. This is clear why increasing the isolation period T_b always improves the performance or reduces the demands induced on the superstructure.



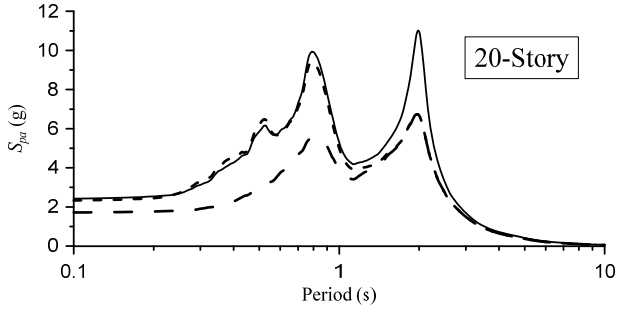
5.3 Comparison between the FRS of the Fixed Base and Base Isolated Structures

Examining the results described in Figures 7 and 8, comparison between the fixed base structures with ζ_s = 0.05 (Rayleigh) and the base isolated structures with T_b = 2 and ζ_b = 0.1 in both Figures show clearly that the maximum acceleration reduces almost around 10 times at the 1st mode natural period for the 3-story structures, and reduces smaller for 9- and 20-story structures shown in Figures 7 and 8. The reduction is smaller in taller structures because the isolation period T_b of 2 seconds is getting close to the superstructure T_s of 0.9 and 2 seconds for the 9- and 20-story fixed base structures, resulting in merely slight improvement. The improvement is usually higher since the isolation period T_b should always be much higher than the superstructure period T_s. Despite the slight improvement, this serves as a proof that adding a flexible isolated floor always improves the superstructure resting on it.



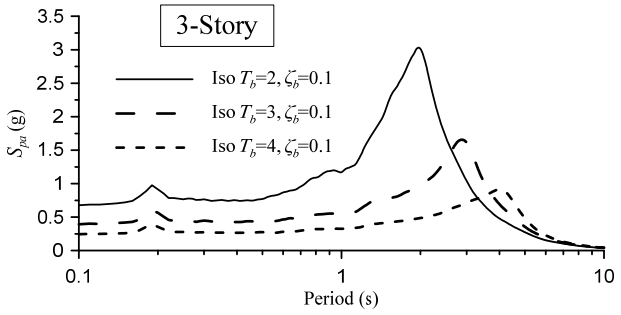
6. PERFORMANCE EVALUATION METHOD

6.1 Performance Based Earthquake Engineering

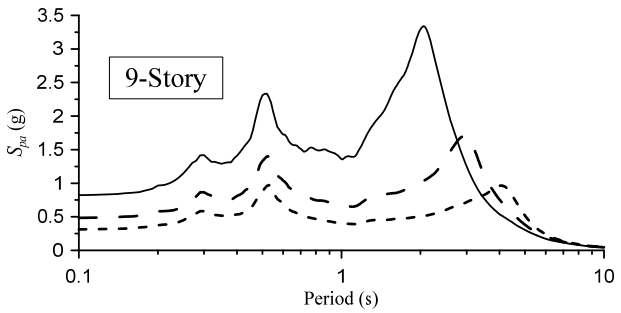


To determine the performance of the fixed base and base isolated structures considering the continued functionality (*CF*) damage state by using the drift ratios and the accelerations at the ceiling's period as the engineering demand parameters (*EDP*), the PEER Performance Based Earthquake Engineering (PBEE) methodology is adopted.

(a) 3-Story Fixed Base Structures (Top Floor)



(b) 9-Story Fixed Base Structures (Top Floor)



(c) 20-Story Fixed Base Structures (Top Floor)

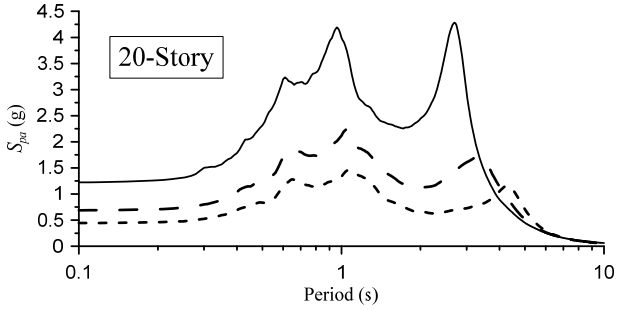


Figure 7 Top Floor Response Spectra for (a) 3-Story, (b) 9-Story, and (c) 20-Story Fixed Base Structures

(a) 3-Story Base Isolated Structures (Top Floor)

(b) 9-Story Base Isolated Structures (Top Floor)

(c) 20-Story Base Isolated Structures (Top Floor)

Figure 8 Top Floor Response Spectra for (a) 3-Story, (b) 9-Story, and (c) 20-Story Base Isolated Structures

In this framework, seismic hazard analysis, structural analysis, and damage analysis are used concurrently. The hazard analysis is used to define the seismic intensity at a specific location and mean annual exceedance frequency of interest. Structural analysis is conducted by linear response history analysis using a suite of scaled ground acceleration records to obtain story drifts at multiple levels of seismic intensity. Damage analysis, obtained from experimental data and damage observations of partition walls and suspended ceilings, describes the likelihood of exceeding continued functionality (*CF*) as a function of seismic demand.

The complete equation for calculating λ_{CF}, the annual probability that a fixed base or base isolated structure exceeds the continued functionality of partition walls (or other drift-sensitive components), is shown in Equation 5.

$$\lambda_{CF} = \sum_{k=1}^{n} \left\{ \begin{array}{l} P\left[dm > CF \,|\, \delta = \delta_k\right] \cdot \\ \sum_{j=1}^{m} \left\{ P\left[\delta = \delta_k \,|\, S_a = \overline{S}_{a,j}\right] P\left[S_a = \overline{S}_{a,j}\right] \right\} \end{array} \right\} \quad (5)$$

$P\left[dm > CF \,|\, \delta = \delta_k\right]$ is the probability of damage state exceeding continued functionality state for a specific drift ratio and is determined from the damage fragility curve.

$P\left[\delta = \delta_k \,|\, S_a = \overline{S}_{a,j}\right]$ is the probability that a specific drift occurs for a specific ground motion intensity level and is determined from drift distribution at each intensity level.

$P\left[S_a = \overline{S}_{a,j}\right]$ is the annual probability that a specific seismic intensity level is observed at a specific site and is obtained directly from hazard curve corresponding to a specific site location and natural period of interest.

6.2 Definition of Continued Functionality

Continued functionality is the performance state in which a building remains usable without interruption after

an earthquake. Hence, the damage that triggers this continued functionality state is very slight, corresponding to small values of drift ratio and floor acceleration.

7. FRAGILITY FUNCTIONS

In this study, the performance based on continued functionality (*CF*) damage state of partition walls and suspended ceilings, which serve as general representations of drift sensitive and acceleration sensitive components, respectively.

7.1 Fragility of Drift Sensitive Components

To represent drift sensitive components, fragility functions for partition walls are selected. Experiments on light gauge steel studded gypsum partition walls have been conducted recently at the University of Buffalo to assess their seismic fragility (Filiatrault et al. 2010). Fifty partition wall specimens, corresponding to 22 different wall configurations, were constructed following standard construction techniques. The fragility functions reported in their study is adopted here. The damage description corresponding to *CF* is "slight damage to partition walls." For this damage state, the median drift ratio and dispersion are 0.35% and 0.56, respectively.

7.2 Fragility of Acceleration Sensitive Components

To represent acceleration sensitive components, fragility functions for suspended ceilings are selected. From recent work by the authors (Motoyui et al. 2011), fragility of Japanese ceiling systems is obtained through Monte Carlo analysis using 2D finite element analysis and assumed statistical variation of the strength of connections from experimental testing. The period of the ceiling T_{ceiling} is 0.32 second. The fragility function describing "failure of ceiling" reported in their study is used. The median acceleration and dispersion are 0.505g and 0.046, respectively.

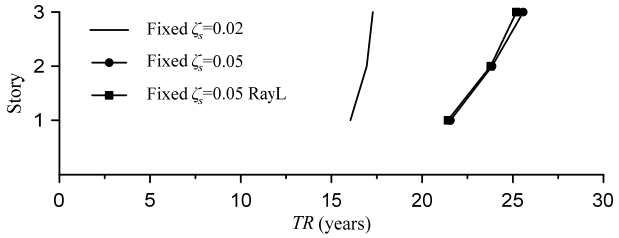
8. SEISMIC HAZARD CURVE

The last component needed in order to determine the performance is the seismic hazard curve for a site. This hazard curve can be obtained for a specific site location and a natural period of interest based on some attenuation model. In this study, the site is assumed to be located in downtown Los Angeles area, where the latitude and longitude used to specify the location are 34 and -118, respectively. The hazard curve is then obtained using the attenuation model by Campbell and Bozorgnia (2008) with V_{S30} = 760 m/s representing the boundary between B and C soil types, as defined in ASCE 7 (2005).

9. PERFORMANCE EVALUATION RESULTS

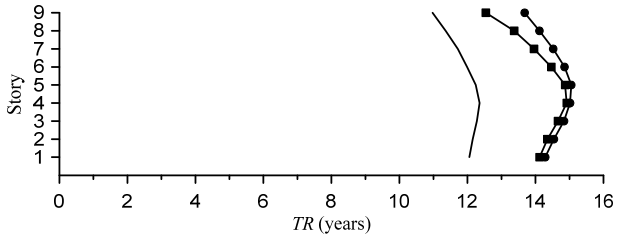
In order to obtain the performance, three components are needed as described previously which are (1) the probability of damage state exceeding continued functionality state, (2) the probability that a specific drift occurs for a specific ground motion intensity level, and (3) the annual probability that a specific seismic intensity level is observed at a specific site. These components are used concurrently as shown in Equation 5. The value obtained from this Equation is the mean annual frequency of exceeding the continued functionality damage state λ_{CF}. The expected return period *TR* can be calculated by taking the reciprocal of λ_{CF} ($TR = 1/\lambda_{CF}$). Figures 9 and 10 show the performances in terms of return periods *TR* for the fixed base structures based on the continued functionality damage state of partition walls and suspended ceilings, respectively. Figures 11 and 12 show the performances in terms of return periods *TR* for the base isolated structures based on the continued functionality damage state of partition walls and suspended ceilings, respectively. Note that TR_{drift} means the expected return period *TR* considering drift-sensitive components and TR_{acc} means the expected return period *TR* considering acceleration-sensitive components.

9.1 Performance of the Fixed Base Structures



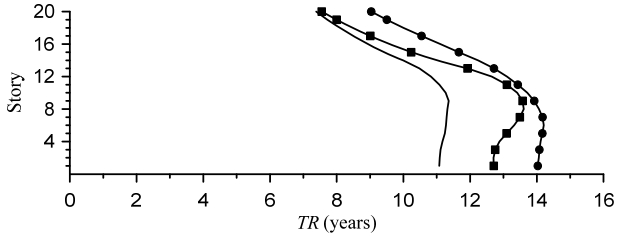
Examining the results described in Figure 9, the performance in terms of return period TR_{drift} (years) in each story corresponds well to the drift demands described previously in Figure 5. Higher drift demands result in poorer performance, whereas lower drift demands result in better performance. All results show that the expected return period TR_{drift}, Figure 9, are lower than 30 years. The TR_{drift} in the top story of the 20-story fixed base structure could be as low as 7 years, meaning that there is very high chance that the walls will need to be fixed or replaced during the expected return period of 7 years.

From Figure 10, the performances TR_{acc} in the 3-story cases are the same. This is because of the nature of short buildings; the accelerations induced on the structure are almost same in all cases when the ground accelerations are scaled to the same level. However, in taller buildings, the differences in the TR_{acc} start to appear, since damping ratio and damping mechanism start to take part more in the response.



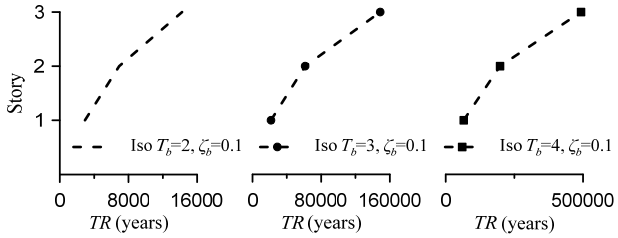
The fixed base structures are assumed to be linearly elastic and have no other supplemental dampers to absorb energy. Therefore, the performance observed here could be served as a generic performance observation where it could be improved and worsened if the structure implements additional control system or experiences severe nonlinearity.

9.2 Performance of the Base Isolated Structures

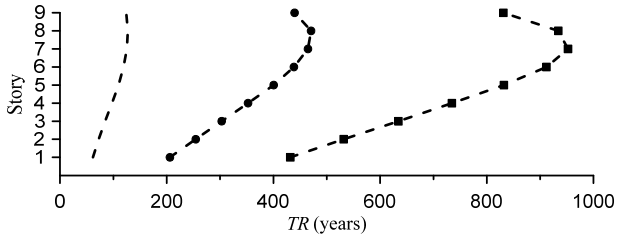


Similar to the performance observed in the fixed base structures, the results described in Figure 11 also correspond well to the drift demands described previously in Figure 5. Observing the expected return period TR_{drift} for 3-, 9-, and 20-story isolated structures, it is seen clearly that the return periods in short buildings are significantly higher than tall buildings. This indicates that, considering drift-sensitive components, isolation systems work well for short buildings.

(a) 3-Story Fixed Base Structures



(b) 9-Story Fixed Base Structures



(c) 20-Story Fixed Base Structures

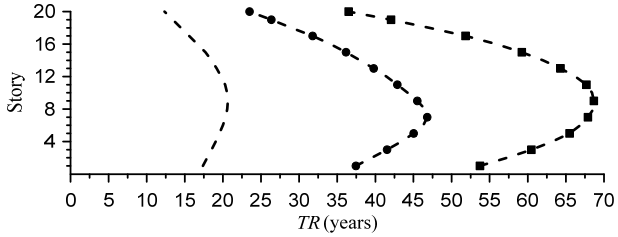


Figure 9 Performance in Return Period (years) Based on the Continued Functionality Damage State of Partition Walls

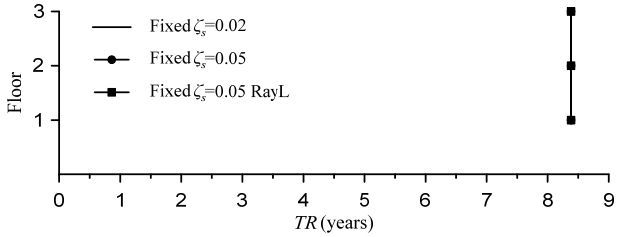
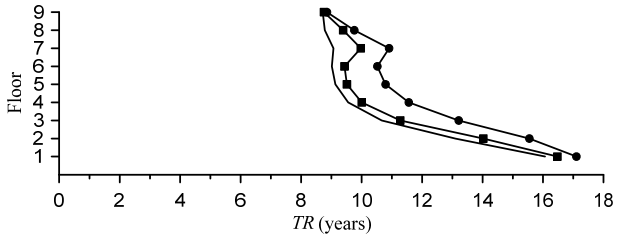
(a) 3-Story Base Isolated Structures



(b) 9-Story Base Isolated Structures



(c) 20-Story Base Isolated Structures

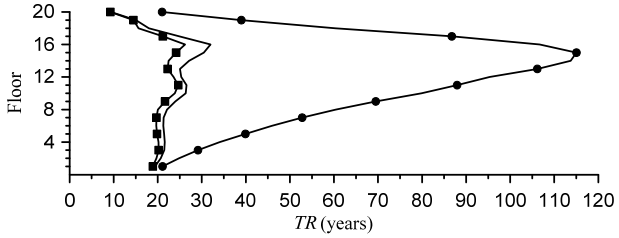


Figure 11 Performance in Return Period (years) Based on the Continued Functionality Damage State of Partition Walls

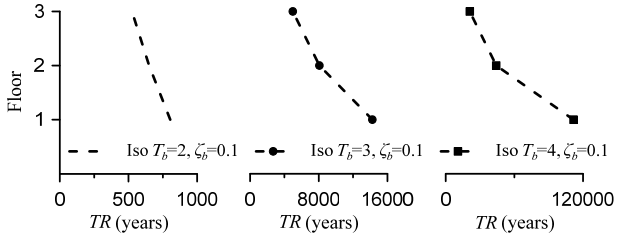
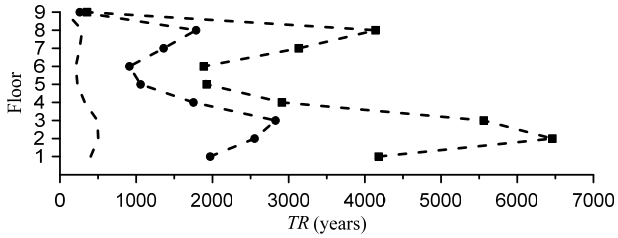
(a) 3-Story Fixed Base Structures



(b) 9-Story Fixed Base Structures



(c) 20-Story Fixed Base Structures

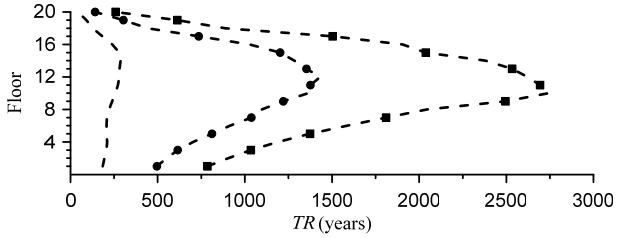


Figure 10 Performance in Return Period (years) Based on the Continued Functionality Damage State of Suspended Ceilings

(a) 3-Story Base Isolated Structures

(b) 9-Story Base Isolated Structures

(c) 20-Story Base Isolated Structures

Figure 12 Performance in Return Period (years) Based on the Continued Functionality Damage State of Suspended Ceilings

However, for tall buildings, the expected return period TR_{acc} could be as low as around 10 years at the top story of 20-story base isolated structures, meaning that there is a high chance that some partition walls need to be fixed or replaced over the life of the building, resulting in interruption of the usage of this story due to wall repair or replacement. The performance is always improved as well as the isolation period T_b increases.

Examining the results in Figures 12, the expected return period TR_{acc} in each floor does not correspond well to the acceleration demands described earlier in Figure 6. This is because the performance calculated is based on the peak acceleration at the period of the ceiling, T_{ceiling} = 0.32 sec as defined in Section 7.2, not the peak floor acceleration as shown in Figure 6. The improvement when increasing the isolation period T_b is more pronounced in short buildings, 3-story isolated structures. In tall buildings, the improvement can still be obviously observed. Also in tall buildings, higher mode response contribution could play an important role in the total response. Therefore, the expected return periods TR could become irregular as shown in the 9-story isolated structures, Figure 12(b), where in the middle floors, the return periods decrease significantly. This is because the 3rd mode period of this 9-story isolated structure, which is 0.296 second, falls in the proximity of the ceiling's period. More detail has been described by the authors (Chimamphant et al. 2012).

9.3 Comparison between the Performance of the Fixed Base and Base Isolated Structures

Examining the results described in Figures 9 to 12, the results confirm that the isolation system helps improve the fixed base structures significantly. The comparison between the 3-story fixed base structure with ζ_s = 5% Rayleigh damping and the 3-story isolated structure with T_b = 2 sec and ζ_b = 10%, shows that the expected return periods TR_{drift} increase from around a few ten years to several thousand years, which is around a thousand times as shown in Figures 9(a) and 11(a). The expected return periods TR_{acc} also show similarly that the improvement is around a hundred times as shown in Figures 10(a) and 12(a). It is obvious that the expected periods increase even more significantly, if the isolation period T_b increases.

For 9-story cases, the improvement still exists, however, less significantly as can be seen between Figures 9(b) and 11(b) for the TR_{drift} and Figures 10(b) and 12(b) for the TR_{acc}.

For 20-story cases, the improvement is rather small. It is interesting to see that adding an isolated floor with T_b = 2 seconds actually improves the expected return periods TR_{acc} only a few years. This might actually be expected since the isolation period T_b is equal to the superstructure period T_s. Therefore, by adding more flexibility to the isolation story, the performance can be gained as shown in Figure 11(c). On the other hand, the TR_{acc} always exhibits improvement as seen in Figures 10(c) and 12(c). This is again because the performance is considered at the ceiling's period. As long as none of the natural modes of the structure falls close to the ceiling's period, the performance should be improved.

10. CONCLUSIONS

This research focuses on the comparison of the responses and performances between fixed base structures and base isolated structures in order to clearly observe how well an isolation system can contribute to a fixed base structure in terms of the response demands, drift ratios and peak floor accelerations, and the performance, return periods. By adopting the PEER PBEE methodology, the mean annual frequency of exceeding the continued functionality damage state is obtained, leading to the expected return period *TR*.

In the fixed base structures, reducing the superstructure damping ζ_s increases the demands on the superstructure accordingly. However, when the mechanism changes from stiffness proportional damping to Rayleigh damping, the demands appear differently, due to different modal damping ratios in higher modes. This becomes obvious in tall buildings because in tall buildings higher mode responses start to contribute to the total response. These can be observed clearly in the FRS shown in Figure 7. For base isolated structures, the performance can always be improved by adding the flexibility to the isolation story as shown clearly in Figures 11 and 12

All the results described indicate that isolation system could always improve the overall performance of the superstructure resting on it, if the selection of the base isolation properties is properly made. In summary, it is possible to conclude that isolation system is significantly beneficial to short buildings, while also exhibiting moderate improvement on taller buildings

Abstract: Despite recent advances in active and semi-active control, the majority of civil engineering structures are still controlled via passive devices. A key limitation of this approach is that classical passive devices are typically only efficient over a narrow frequency band for which they are tuned, while earthquakes display complex frequency content. Therefore, we have developed an improved control system that overcomes this limitation. We proposed the use of the inerter, a device that was initially developed for the high-performance suspension systems of Formula 1 racing cars. This type of device is to be employed in vibration control of single and multiple storeys buildings subjected to earthquake loads. The inerter is designed to replace devices such as tuned mass dampers and its main advantage is that a better isolation level can be achieved with lower physical mass installation. Moreover, the device no longer sits on the building's floor, but is mounted on braces between adjacent storeys. Different configurations are studied in order to find the one offering best performance for a one-storey and a two-storeys building. We show results as the key parameters are varied to study the system performance under a range of operating conditions. Based on this parametric analysis, we propose a series of guidelines for inerter systems tuning.

1. INTRODUCTION

Research in the field of vibration isolation has been carried out since early 1900s. The complexity and dimensions of civil engineering structures make this problem particularly difficult to solve due to high control effort demand and many other associated limitations. Attempts are being made towards the use of active and semi-active control, but practical application of these techniques is still limited. Many state of the art reviews have been conducted in this respect (Soong and Spencer (2002), Soong and Cimellaro (2008), Wagg and Neild (2011)). Active control and its related problems regarding costs, stability and robustness have also been extensively studied (Preumont (2002), Wagg and Neild (2009)). Semi-active control devices seem to be closer to large scale application and they have already been installed on bridges (Dongting Lake Bridge, China – magneto-rheological dampers). Most of the civil structures are still controlled passively via base isolation systems, tuned mass dampers (TMDs) or viscous dampers (Soong and Dargush (1997)).

The aim of this paper is to introduce a new type of control system to be used for unwanted vibration mitigation in civil engineering applications. The systems presented in this paper are passive, but it is our intention to study semi-active systems of the same type. The proposed configurations are based on an inerter device mounted in series and/or parallel with spring and damper elements.

The inerter is a new device that has been proposed by M.C. Smith (2002). This device completes the force-current analogy between mechanical and electrical networks and it is equivalent to the capacitor. The inerter overcomes the limitations present in the mass-capacitor equivalence, its advantage being that it no longer needs to be grounded. Smith defines the ideal inerter as a two terminal device with the property that the force generated is proportional to the relative acceleration between the two nodes. Its constant of proportionality is intuitively named inertance and is measured in kilograms, suggesting its similarity to mass. The force produced by an inerter is given by:

$$F = b(\ddot{x}_i - \ddot{x}_j) \tag{1}$$

where b is the constant inertance and $\ddot{x}_i - \ddot{x}_j$ is the relative acceleration between its nodes.

Initially, the inerter has been used in Formula 1 racing cars suspension systems, under the name of "J-damper", as explained by Chen et al. (2009). Currently, several attempts are being made to widen its field of application. Experimental testing has been conducted for studying several types of inerters and many installation possibilities. Wang et al. (2010) propose the use of a hydraulic inerter. Chen et al. (2009) describe the rack and pinion inerter and the ball and screw inerter. Wang and Chan (2011) propose a vehicle suspension system employing a mechatronic network strut. Papagiorgiou et al. (2009a and 2009b) conduct a

series of experimental tests on several types of inerter devices. Kuznetsov et al. (2010) study the optimisation of inerter-based suspension systems.

Research is carried out towards the practical use of inerters in vehicle suspension systems. Several installation layouts have been studied in order to ensure optimal performance by Scheibe and Smith (2009), Smith and Wang (2004) and Wang and Su (2008a and 2008b). Train suspension systems have been studied by Wang et al. (2009a) and Wang and Liao (2010). Motorcycle steering compensator applications were proposed by Evangelou et al. (2007).

In the field of Civil Engineering, inerters have been proposed for use in buildings suspensions, namely in base isolation systems, by Wang et al. (2007, 2009b). They investigate several suspension layouts for both a one-degree of freedom (DOF) and a two-DOF model.

The novel aspect of this paper is that we intend to go one step further and model the inerters inside the building, ideally on braces situated between adjacent storeys. Therefore, the inerter is no longer used in a suspension system, but in a vibration suppression one.

As explained earlier, the inerter device employed in this paper is passive and therefore it has constant inertance. Depending on the other elements used in the system, this can remain passive (e.g. when springs and viscous dampers are used) or become semi-active (e.g. in the case when magneto-rheological (MR) dampers are present). Zhang et al. (2012) studied a semi-active suspension system employing a passive inerter.

The inerter chosen in this paper is of rack and pinion type and the inertance is a function of the moment of inertia of the flywheel and the flywheel rotation as detailed by Chen et al. (2009). Therefore, the inertance produced depends on the choice of gearing and can be much higher than the physical mass of the device.

Given its equivalence with mass, it is intuitive to compare the inerter-based systems performance with that of tuned mass dampers (TMD). TMDs were introduced by Den Hartog (1940). He proposed the use of a mass-spring system called undamped dynamic vibration absorber. Optionally, a damper can also be introduced. Den Hartog gave a series of guidelines for optimal tuning of TMDs. However, the TMD performance is limited by the amount of mass that needs to be mounted. Generally, this has to be in the range of 1%-10% of the mass on the targeted vibration mode. The inerter overcomes this limitation due to its small physical mass and proves to be very efficient in vibration suppression.

We will test six different layouts employing either an inerter or an additional mass and assess their performance. The systems' parameters will be varied and their influence discussed. We first investigate a one-DOF system and then a two-DOF system. Both types of structure are subjected to seismic excitation. We used an acceleration time history recorded during the Great East Japan Earthquake (Tohoku Earthquake) that took place on the 3rd of March, 2011.

If proved efficient in practice, an inerter-based vibration suppression system could solve the problems associated with TMD installation. Most important, there is no need for significant additional mass installation, the inertance being dependent on the choice of gearing only. Moreover, the overall dimensions of the control system will be much smaller, a fact that is advantageous from architectural point of view and space considerations.

2. ONE-DOF STRUCTURAL SYSTEM

Firstly, a one-DOF structure is proposed for analysis. The uncontrolled system is shown in Figure 1(a). The control is applied via the concentrated force F which depends on the configuration chosen (Figure 1(b)). Six configurations have been proposed, four of them being based on the inerter, Figure 2(a)-(d), and two on additional mass elements, Figure 2(e)-(f).

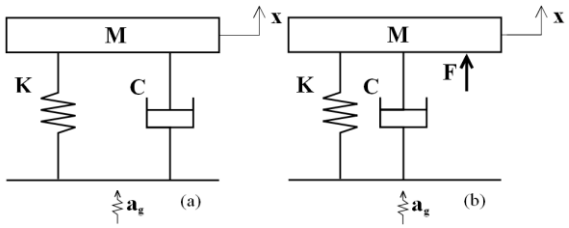

Figure 1 One-DOF structural system (a) uncontrolled and (b) with general control force – Parameters: M=1kNs^2/m; K=1000 kN/m; C= 3.16kNs/m.

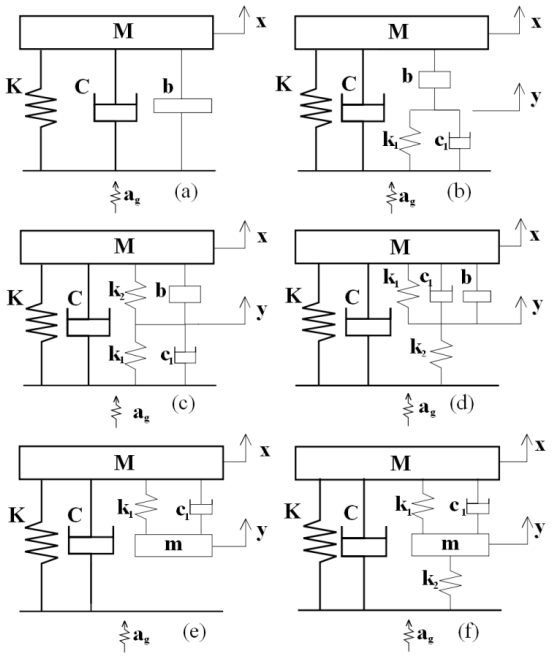

Figure 2 Controlled systems (a) Inerter 1; (b) Inerter 2; (c) Inerter 3; (d) Inerter 4; (e) TMD 1; (f) TMD 2;

The system in Figure 2(e) represents a classical TMD system. For all uncontrolled and controlled systems M, C and K represent the structural mass, damping and stiffness respectively. The structural parameters values have been chosen such that the natural frequency of the uncontrolled system is $\omega_n = 5.03Hz$. This is because the Fourier spectrum of the seismic input used has highest amplitudes at

low frequencies, situated mainly under $6Hz$. Therefore, the structure will be sensitive to the chosen ground-motion record.

The ground acceleration has been conventionally represented as vertical in Figure 2, but the equations of motion remain unchanged regardless its direction.

The equation of motion for the uncontrolled one-DOF system, expressed in physical coordinates is given in Eq. (2). Eq. (3) shows the equation of motion for the controlled systems.

$$M\ddot{x}(t) + C\dot{x}(t) + Kx(t) = -Ma_g(t) \quad (2)$$

$$M\ddot{x}(t) + C\dot{x}(t) + Kx(t) = -Ma_g(t) + F \quad (3)$$

Writing Eq. (2) in the Laplace domain, the displacement response is obtained as:

$$X(s) = \frac{-M}{Ms^2 + Cs + K} A(s) \quad (4)$$

where *X(s)* and *A(s)* are the Laplace transforms of the displacement and ground acceleration, respectively.

The control force can be written as:

$$F(s) = T_{XF} X(s) + T_{AF} A(s) \quad (5)$$

where T_{XF} and T_{AF} are the transfer functions from structural displacement and ground acceleration to the control force, respectively. Therefore, by writing Eq. (3) in the Laplace domain and replacing the control force expression from Eq. (5), the structural displacement is obtained as:

$$X(s) = \frac{-M + T_{AF}}{Ms^2 + Cs + K - T_{XF}} A(s) \quad (6)$$

The displacement response has been calculated by evaluating Eq. (6) for all layouts shown in Figure 2.

2.1 Parameters Tuning

The mass-based systems (Figure 2(e)-(f)) are tuned based on Den Hartog's guidelines for damped vibration absorbers. The expressions of the newly introduced components, *m*, *b*, c_1, k_1 and k_2 are shown in Eq. (7).

$$m = \mu_m M;\ \ b = \mu_b M;\ \ k_1 = k_2 = \frac{\mu}{(1+\mu)^2} K;$$
$$\xi = \sqrt{\frac{3\mu}{8(1+\mu)}};\ \ c_1 = 2\xi \frac{\omega_n}{1+\mu} \mu M;\ \ \mu \in \{\mu_m, \mu_b\} \quad (7)$$

where ξ represents the damping ratio and μ_m and μ_b are the mass ratios for the mass-based and inerter-based systems, respectively.

Given our intention to compare the inerters performance to that of a TMD we will start our analysis by using the same tuning rules. It must be mentioned that this may not be the optimal tuning philosophy. However, the tuning rules have been adapted to base-excited structures according to Soong and Dargush (1997). We have considered that $\mu_m = 0.1$. This is close to the maximum allowable mass ratio in case of regular TMDs. Since the inerters can produce much higher mass ratios compared to their actual mass, we chose $\mu_b = 0.7$. Smith (2002) shows that the ratio between the inertance and the actual inerter mass, can attain values as high as 300, much greater than the one considered in this paper, which is only 7.

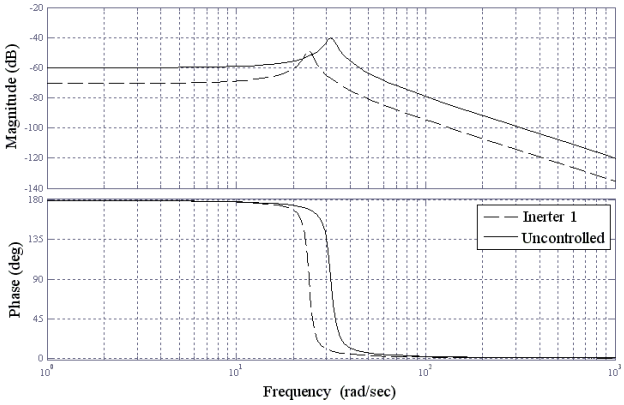

Figure 3 Comparison between Inerter 1 controlled system and the uncontrolled system

2.2 Frequency Domain Performance Analysis

Figures 3-7 show the frequency response of the systems shown in Figure 2, in the form of bode plots, based on the transfer functions described in Eq. (6), evaluated for each of the six layouts. All responses are shown in comparison to the uncontrolled system frequency response.

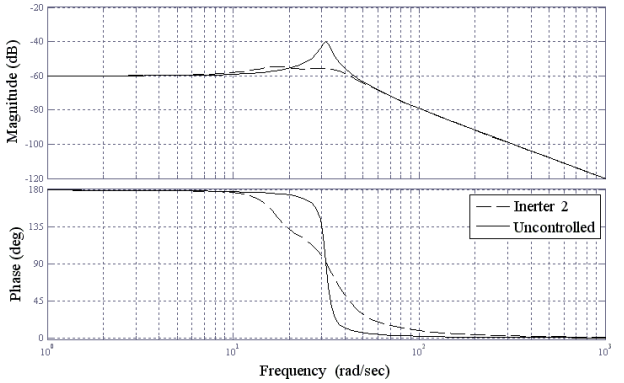

Figure 4 Comparison between Inerter 2 controlled system and the uncontrolled system

Figure 3 shows that the system represented by Inerter 1 shifts the natural frequency of the uncontrolled system to the left and improves its performance significantly for the entire frequency range. Inerter 2 shows promising results as well, the displacement amplitudes are reduced and it can be seen in Figure 4 that the resonant peak is split as in the case when TMDs are used. Inerter 3 creates a new resonant peak at lower frequency, but this is smaller in amplitude than the uncontrolled one.

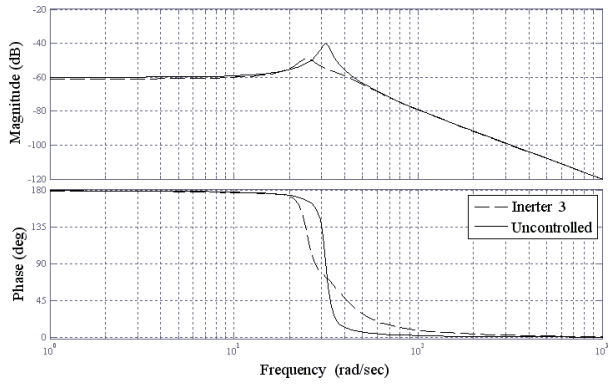

Figure 5 Comparison between Inerter 3 controlled system and the uncontrolled system

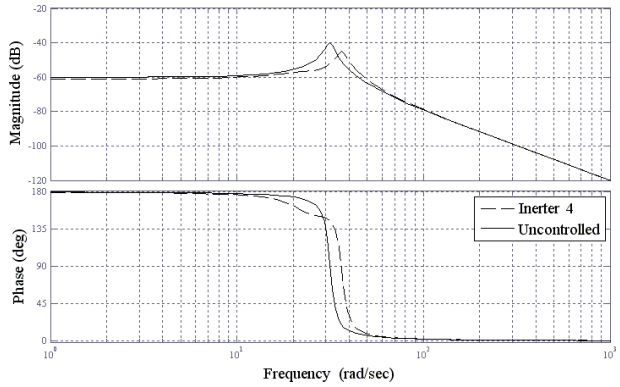

Figure 6 Comparison between Inerter 4 controlled system and the uncontrolled system

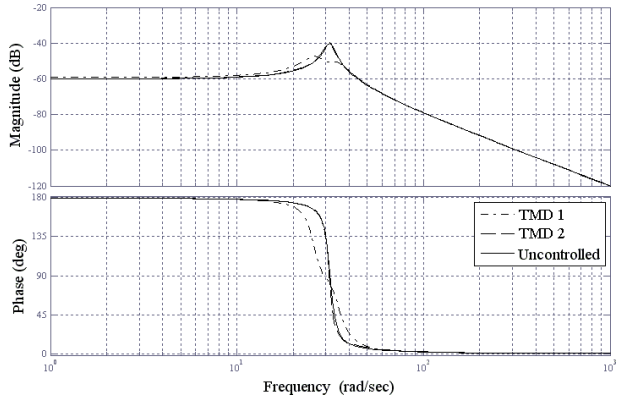

Figure 7 Comparison between TMD 1 and TMD 2 controlled systems and the uncontrolled system

Inerter 4 has a good performance as well, despite some slight overshooting present in the case of high frequency excitation. The same resonant peak split, specific to TMDs, is observed. However, the lower frequency peak has smaller amplitude, due to the presence of a heavily damped pole of the new system. The poles and zeros of all one-DOF systems are given in Tables 1 and 2. As seen from Figure 7, TMD 1 displays the behaviour of a classical TMD system, while TMD 2 proves to have a poor performance, very close to that of the uncontrolled system. Figure 8 shows a comparison between all the inerter based systems, Inerter 1-4.

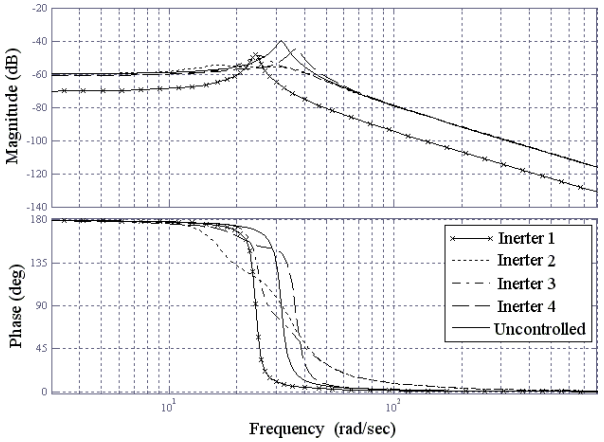

Figure 8 Comparison between the inerter-based systems and the uncontrolled system

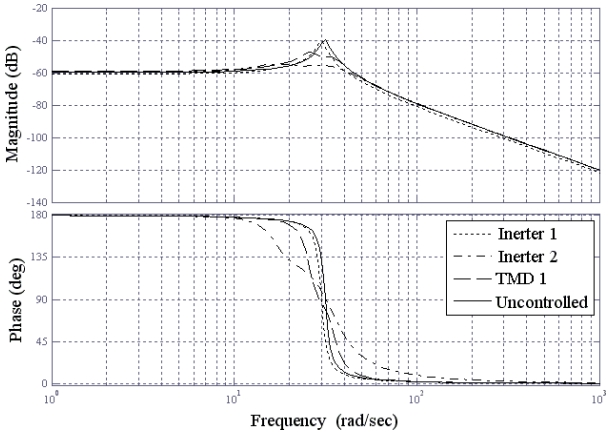

Figure 9 Comparison between Inerters 1, 2, TMD 1 and the uncontrolled system for $\mu_m = \mu_b = 0.1$

Table 1 Poles of the one-DOF systems, of the form x+yj

System	x	y
Uncontrolled	-1.58	±31.58
Inerter 1	-0.90	±24.23
Inerter 2	-9.77	±32.84
	-4.24	±16.64
Inerter 3	-9.42	±49.98
	-4.59	±35.72
Inerter 4	-2.29	±36.56
	-6.60	±23.13
TMD 1	-4.48	±34.39
	-2.94	±26.05
TMD 2	-6.02	±41.45
	-1.40	±31.29

The systems represented by Inerter 1 and Inerter 2 display the best frequency response. In order to underline once again the advantages of the inerter systems over systems implying additional mass installation, Figure 9 shows a comparison between Inerters 1, 2, TMD 1 and the uncontrolled system, for $\mu_m = \mu_b = 0.1$. This is done to show that even in the case of equal mass ratios, the inerter performance is similar

to that of the mass-based systems.

Table 2 Zeros of the one-DOF systems, of the form x+yj

System	x	y
Inerter 2	-7.31	± 17.105
Inerter 3	-7.31	± 25.271
Inerter 4	-7.31	± 25.271
TMD 1	-5.839	± 29.580
TMD 2	-5.839	± 41.249

However, we must keep in mind that much larger mass ratios can be achieved in the case of inerter-based systems. It can be seen that Inerter 2 system still performs better than the classical TMD 1. Inerter 1 system is not as efficient, but this is not a problem since much higher mass ratios can be selected. Given the results shown so far, it can be concluded that the inerter-based systems are a very feasible solution for replacing the classical TMDs.

2.3 Seismic Performance

For this analysis we have chosen an acceleration time history recorded during the Tohoku Earthquake at the Sendai station, on NS direction. The time history is shown in Figure 10.

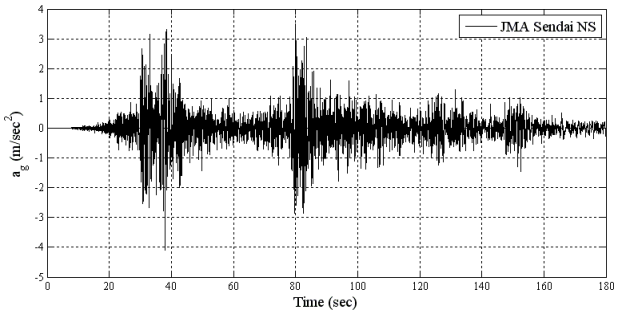

Figure 10 Acceleration time history – Tohoku Earthquake

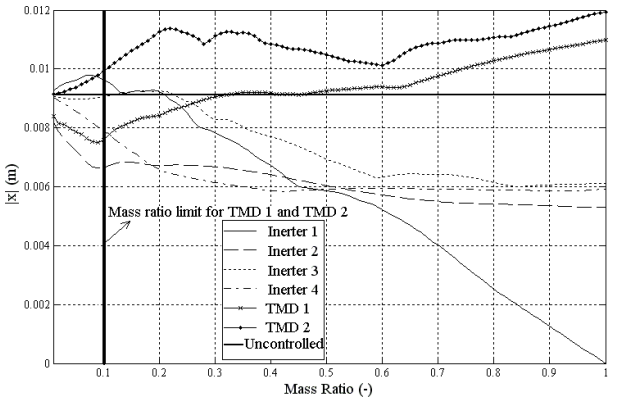

Figure 11 Maximum absolute response variation with mass ratio

Figure 11 shows the variation of the maximum absolute displacement of the structure with the mass ratio. We have chosen $\mu \in [0, 1]$. For $\mu = 0$ the structure is uncontrolled, while for $\mu = 1$ we add 100% more mass/inertance. Such a mass ratio is unrealistic for mass-based systems, but an inerter-based system can easily attain this value. As revealed by Figure 11, Inerter 1 has the best performance. The maximum displacement decreases continuously as the mass ratio becomes higher. As expected, the behaviour of Inerter 2 is similar to that of TMD 1 for mass ratios up to 10% of the total mass. Inerter 2 behaviour improves as the mass ratio is further increased. Inerter 3 becomes efficient for mass ratios $\mu_b > 0.6$. After passing this threshold, its performance is close to Inerter 2 and Inerter 4. TMD 2 has the same limitations regarding the mass ratio as TMD 1. However, its performance is poor.

Figures 12(a)-(c) show the displacement time histories obtained with Inerter 1, Inerter 2, TMD 1 and the uncontrolled system. It can be seen that the systems represented by Inerter 1 and Inerter 2 display improved behaviour, while the TMD 1 response is similar to the uncontrolled one. This proves that the inerter-based systems are more efficient than the classical TMD.

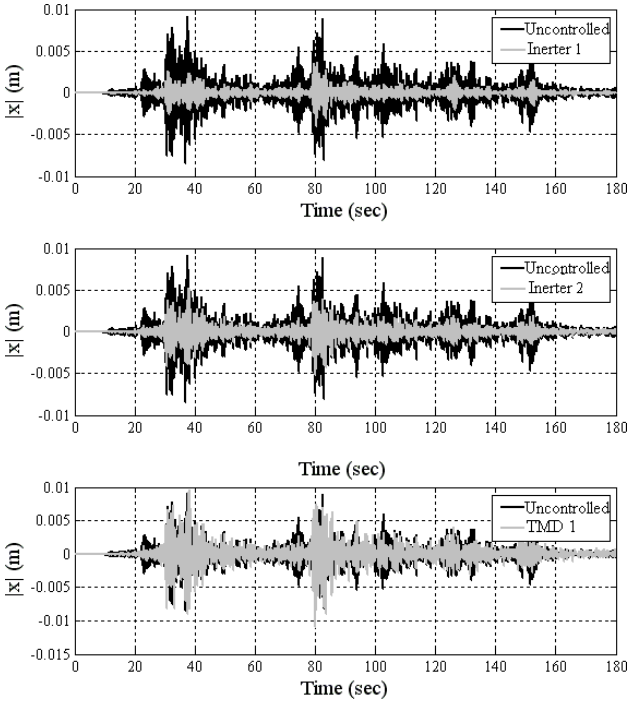

Figure 12 Displacement time histories for Inerter 1, Inerter 2 and TMD 1 compared to the uncontrolled response to the Tohoku Earthquake record ($\mu_b = 0.7$ and $\mu_m = 0.1$)

3. TWO-DOF STRUCTURAL SYSTEM

The two-DOF system chosen and the equivalent controlled system are shown in Figures 13(a) and (b) respectively. The analysis carried out on the one-DOF structure is extended for the system represented by Inerter 2. The classical TMD case (TMD 1) is also kept for reference. The new controlled systems are shown in Figures 14(a)-(b).

The control systems were placed alternatively at the upper and lower floor levels. However, only results pertinent to the upper location are presented in this paper as these systems proved to be more efficient. This result was

expected, since it is known that in order to control the first mode of vibration (the predominant one, with higher participation factor), the control force must act in the point of maximum displacement amplitude in the first vibration mode.

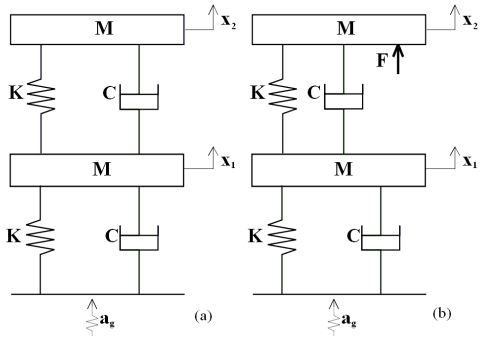

Figure 13 Two-DOF structural system (a) uncontrolled, and (b) with general control force

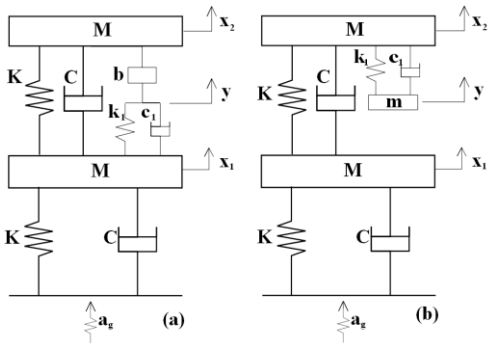

Figure 14 Controlled systems (a) Inerter 2' and (b) TMD 1'

The equations of motion of the uncontrolled and controlled systems can be expressed using Eq. (2) and (3). In this case, *M*, *K* and *C* are matrices, not scalars. They are given in Eq. (8).

$$M = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} kNs^2/m; \quad K = \begin{bmatrix} 5000 & -2500 \\ -2500 & 2500 \end{bmatrix} kN/m; \quad C = \begin{bmatrix} 6.708 & -2.236 \\ -2.236 & 4.472 \end{bmatrix} kNs/m \tag{8}$$

3.1 Parameters Tuning

The tuning is done following the same principles as in the case of the one-DOF system (Eq. (7)), keeping in mind that we are targeting the first mode of vibration. We have set the mass ratios to be $\mu_m = 0.05$ and $\mu_b = 0.7$.

3.2 Frequency Domain Performance Analysis

Figures 15 and 16 show the frequency response of all the two-DOF systems in the form of bode plots, for each displacement output. The behaviour of the two systems appears to be similar. However, the inerter-based system, Inerter 2', displays a heavily damped pole at low frequency, which isn't present in the case of the mass-based system. TMD 1' generates a split of the original resonant peak, but the resulting poles are similarly damped.

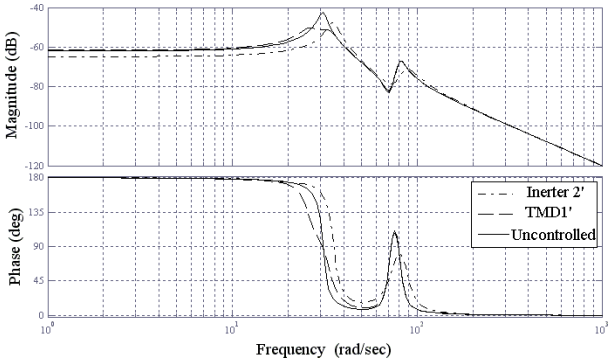

Figure 15 Bode plots for x_1 displacement output

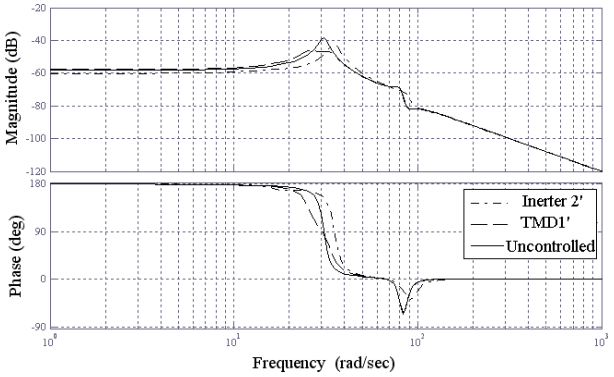

Figure 16 Bode plots for x_2 displacement output

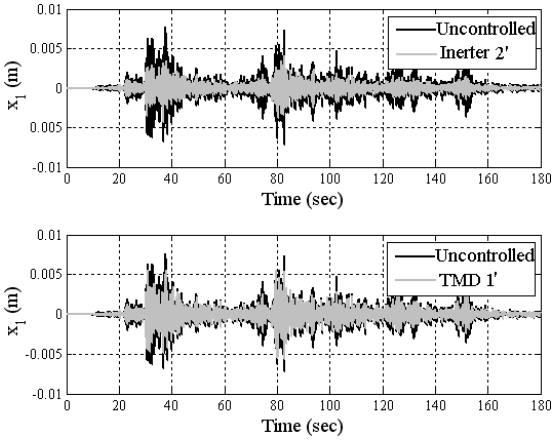

Figure 17 x_1 displacement time history

In both Figures 15 and 16 it can be seen that the inerter-based system displays better behaviour at low frequencies. Although on the upper DOF there appears some amplification in response in the region of the second fundamental frequency, this is not a problem because the response amplitudes are relatively small and it is unlikely for the ground excitation frequency content to be dominated by such high frequencies.

The frequency response of the structures can also be explained by analyzing the poles and zeros locations for each of the two considered outputs. These are not given explicitly.

3.3 Seismic Performance

The structures have been subjected to the same ground

motion as the one-DOF systems (Figure 10). The displacement time histories are shown on each DOF in Figures 17 and 18, respectively. It is visible that the inerter-based system has better results on both degrees of freedom. The structural response is reduced with respect to the uncontrolled system. The TMD 1' system does not bring a significant improvement of the uncontrolled response. Moreover, Figure 19 shows that the mass from system TMD 1' displaces more that the Inerter 2' system. Therefore, it is advantageous to use an inerter-based system which has lower displacement and is lighter, since in some cases the required additional mass may be very large.

4. CONCLUSIONS

This paper introduced a new type of control system to be used for the control of seismically excited structures. The proposed systems are based on a new device, called an inerter that has been successfully installed in high performance car suspension systems, mainly in the Formula 1 industry. We have chosen four design layouts comprising of inerters mounted in series and/or parallel with springs and dampers. The performance of the newly introduced device has been compared with that of two reference mass-based systems, a classical TMD and a TMD having an extra spring component. All systems have been subjected to a seismic record from the Tohoku Earthquake.

We have firstly considered a one-DOF structural system. Given the mass-capacitor equivalence and the obvious similarities between a mass element and an inerter, the tuning of the inerter-based systems was done using the well know TMD tuning rules, adapted for base-excited structures. We have evaluated the influence of each of the six layouts on the frequency response of the system. Since inerters can display very high mass ratios with respect to their actual mass, we have initially chosen $\mu_b = 0.7$, which is still a small mass ratio for an inerter device, and $\mu_m = 0.1$, the latter being considered the maximum TMD mass ratio. Results revealed that the best performing inerter-based systems are Inerter 1 and Inerter 2. A more in depth analysis has been carried out on these systems and their performance has been compared to that of the traditional TMD 1 system. We have shown that even for equal mass ratios $\mu_m = \mu_b = 0.1$, the inerter-based systems have better performance. Moreover, in the case when an earthquake load is applied, TMD 1 creates a dangerous new low resonant frequency, which is prone to being excited by the seismic action. Hence, the TMD controlled system doesn't change the performance of the uncontrolled system significantly. The inerter-based systems improve the uncontrolled system response.

We have also presented results for a two-DOF system. In this case we have only analyzed the behaviour of one of the best performing systems in the one-DOF case, Inerter 2'. This has been compared with the response obtained using a classical TMD located at the top of the structure (TMD 1'). It has been shown that the inerter-based system has better frequency response. Moreover, the structural displacements were improved when the structure was subjected to the Tohoku Earthquake record. The inerter-based control ensemble has smaller displacement than the TMD. Therefore the inerter-based system has a good performance in the case of two-DOF structures, superior to that of a classical TMD.

The inerter represents a promising feasible solution for the control of seismically excited structures. In future work, we will evaluate the performance of inerters that are mounted in series and/or parallel with semi-active devices, such as MR dampers. Another promising research direction is represented by the introduction of variable inertance devices (e.g. by using a clutch). Moreover, the inerter-based systems have smaller overall displacement and represent a good solution for problems related to installation, costs, space and aesthetics.

Abstract: The effects of seismic pounding on the response of a four-story base-isolated reinforced concrete (RC) building subjected to bidirectional excitation are investigated. Three-dimensional nonlinear finite element analyses are carried out, where a new contact element capable of simulating pounding including friction, is utilized. Performance of the building is evaluated separately for the subsets of far-fault non-pulse-like ground motions and near-fault pulse-like ground motions, which are scaled to represent two levels of shaking viz. the design earthquake (DE) level and the risk-targeted maximum considered earthquake (MCE_R) level. Nonlinear time-history analyses are carried out considering lower bound as well as upper bound properties of isolators. It is found that if pounding is avoided, performance of the building is satisfactory under DE-level motions and MCE_R-level far-fault motions, while unacceptably large demands are imposed by MCE_R-level near-fault motions. Seismic pounding under MCE_R-level near-fault motions is found to be detrimental, where the effect of pounding is mostly concentrated at the first story.

1. INTRODUCTION

Seismic pounding of base-isolated buildings with adjacent structures is likely under near-fault ground motions containing long-period pulses. Several previous studies have been carried out to investigate the effects of seismic pounding on base-isolated buildings. (Hall et al. 1995, FEMA 2009, Matsagar and Jangid 2010, Polycarpou and Komodromos 2010, Pant and Wijeyewickrema 2012, and Masroor and Mosqueda 2012). Previous studies indicate that the response of base-isolated buildings can be substantially influenced by seismic pounding. However, except the work by Matsagar and Jangid (2010), other studies on seismic pounding of base-isolated buildings have been carried out considering only one component of horizontal excitation. Matsagar and Jangid (2010) investigated seismic pounding of a single-story structure under bidirectional horizontal excitation by neglecting friction, using a shear-building idealization, and considering linear elastic behavior of the superstructure.

The effect of bidirectional horizontal excitation on base-isolated buildings is an important issue and has been mostly studied in the past without considering seismic pounding (see for example Jangid and Kelly 2001, Tena-Colunga and Pérez -Osornio 2006, Ozdemir and Constantinou 2010, and Erduran et al. 2011). While most of these previous studies focused on the response of the isolation system by adopting rigid or linear elastic models for the superstructure, the study by Erduran et al. (2011) focused on the multi-level seismic response of a *steel* superstructure through three-dimensional models considering nonlinear behavior of the superstructure as well as the isolation system. Multi-level seismic response evaluation is important in performance-based earthquake engineering. In addition, two levels of excitations are explicitly considered for the design of seismically isolated buildings, where the superstructure is designed for the forces associated with design earthquake (DE) and the isolation system is designed for the effects of risk-targeted maximum considered earthquake (MCE_R) (BSSC 2009 and ASCE 2010). None of the previous studies have investigated multi-level seismic performance of base-isolated *reinforced concrete (RC)* buildings under bidirectional horizontal excitation considering nonlinear behavior of the superstructure as well as the isolation system.

In the present study, the response of a typical four-story base-isolated RC building, under bidirectional excitation is evaluated with the objectives to investigate (i) multi-level seismic performance considering bounding values of isolator properties and (ii) influence of seismic pounding. A three-dimensional finite element (FE) model of the building is created considering material and geometric nonlinearities. A new contact element is developed and utilized to simulate seismic pounding of the building with the retaining wall at the base. A set of 40 pairs of ground motions containing far-fault non-pulse-like motions and near-fault pulse-like motions is considered. Scaled earthquakes are employed to represent both the DE and MCE_R.

2. METHODOLOGY OF SEISMIC POUNDING SIMULATION

In the present study, a previously developed modified Kelvin-Voigt model for pounding without friction (Pant et al. 2010 and Pant and Wijeyewickrema 2012) has been extended based on the models proposed by Zhu et al. (2002) and Guo et al. (2011) to simulate pounding with friction, specifically that of a base-isolated building with the retaining wall at the base. This new model has been used to develop a contact element, which is then implemented in OpenSees (2012). The underlying assumptions for the development of the new element are (i) base slab has in-plane rigidity and (ii) retaining wall behaves rigidly under earthquake ground motions. Due to these assumptions (i) the use of contact elements only at the corner nodes of the base slab becomes adequate and (ii) the contact condition depends only on base displacement. The contact element is used as a zero-length element between the slab corner node i and a fully-restrained fictitious node i'. The response of the element does not depend on the position of node i relative to node i' and the orientation vector of the element is set such that the local x- and y-directions of the element coincide with the normal and tangential directions to the target surface (i.e., the retaining wall), respectively. It is noted that though the focus of the present study is on symmetric structures, this contact element is capable of simulating pounding in asymmetric structures as well. Consider an instance where one corner of the base slab has a potential of pounding with the retaining wall along the positive X-direction as shown in Fig. 1. Note that the expressions presented herein are derived for one contact element, and in base-isolated buildings, a pair of such contact elements is necessary at each corner of the base slab to simulate pounding with the retaining wall in two orthogonal horizontal directions. The impact force in the direction normal to the target surface F_n is given by,

$$F_n = \begin{cases} F_{sn} + F_{dn} & u_X^i > d_g \text{ and } \dot{u}_X^i > 0 \\ F_{sn} & u_X^i > d_g \text{ and } \dot{u}_X^i \le 0 \\ 0 & u_X^i \le d_g \end{cases}, \qquad (1)$$

where F_{sn} and F_{dn} are forces analogous to the spring and dashpot forces, respectively in normal direction, where $|F_{sn}| = k_n |u_X^i - d_g|$ and $|F_{dn}| = c_n |\dot{u}_X^i|$, where k_n is element stiffness in normal direction, u_X^i and $\dot{u}_X^i$ are displacement and velocity, respectively of node i in X-direction, d_g is separation distance between the building and the retaining wall, and damping coefficient in normal direction c_n is expressed as,

$$c_n = \frac{3k_n(1-r_n^2)}{2|\dot{u}_{X0}^i| r_n^2} |u_X^i - d_g|, \qquad (2)$$

where r_n is coefficient of restitution in normal direction and $\dot{u}_{X0}^i$ is velocity of node i in X-direction at the instance of time immediately prior to impact. The impact force in tangential direction F_t is given by,

$$F_t = \begin{cases} F_{st} + F_{dt} & u_X^i > d_g,\ |F_t| \le \mu_s |F_n| \\ F_f & u_X^i > d_g,\ |F_t| > \mu_s |F_n| \\ 0 & u_X^i \le d_g \end{cases}, \qquad (3)$$

where F_{st}, F_{dt}, and F_f are forces analogous to the spring, dashpot, and frictional forces, respectively in tangential direction, where $|F_{st}| = k_t |u_Y^i - u_{Y0}^i|$, $|F_{dt}| = c_t |\dot{u}_Y^i|$, and $|F_f| = \mu_k |F_n|$, where k_t is element stiffness in tangential direction, u_Y^i and $\dot{u}_Y^i$ are displacement and velocity, respectively of node i in Y-direction, u_{Y0}^i is displacement of node i in Y-direction at the instance of time immediately prior to impact, μ_s and μ_k are coefficients of static and kinetic friction, respectively, and c_t is damping coefficient in tangential direction. It is customary to assume that the expression for c_t follows the same pattern as that of c_n (see Zhu et al. 2002 and Guo et al. 2011) and is given as,

$$c_t = \frac{3k_t(1-r_t^2)}{2|\dot{u}_{Y0}^i| r_t^2} |u_Y^i - u_{Y0}^i|, \qquad (4)$$

where r_t is coefficient of restitution in tangential direction and $\dot{u}_{Y0}^i$ is velocity of node i in Y-direction at the instance of time immediately prior to impact. Sign convention for the forces analogous to the spring, dashpot, and frictional forces (if applicable) is such that they are always negative (i.e., compressive forces) in the normal direction, while they could be positive or negative in the tangential direction depending on the orientation of the contact element in the tangential direction as well as the movement of the node i with respect to the point of first impact on the retaining wall.

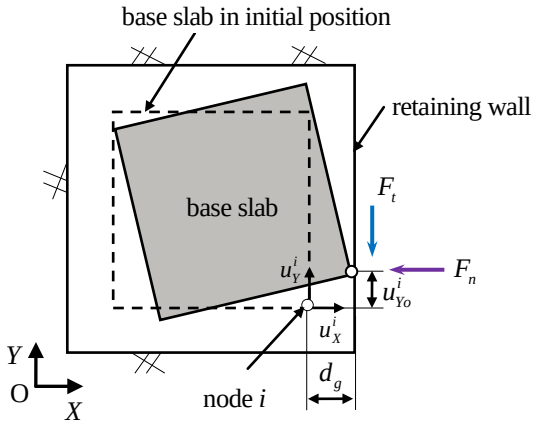

Fig. 1. Illustration of impact between base slab and retaining wall.

3. BUILDING DESCRIPTION AND DESIGN

A four-story, three-bay by three-bay base-isolated RC moment-frame building was chosen as a typical building (Fig. 2). The retaining wall extends from ground level up to the base level of the building. The bay width of the building in both directions is 6.0 m. The story height of the building is 4.0 m, except for the first story which is 4.5 m high. The building was designed by the ELF procedure, following the provisions of 2012 International Building Code (ICC 2012), ASCE 7-10 (ASCE 2010), and ACI 318-11 (ACI 2011). The building was assumed to be located on a stiff soil site (site class D) and was intended to be used as an office building (risk category II). The mapped MCE_R spectral response acceleration parameters are $S_s = 1.609g$ and $S_1 = 0.593g$ at short periods and 1 s period, respectively. The compressive strength of concrete is 28 MPa, and the yield strengths of main steel reinforcement bars and ties are 420 MPa and 300 MPa, respectively. Dead load consists of member self-weight, and 7.6 kN/m and 6.8 kN/m loads due to partitions and external cladding on base beams and upper floor beams, respectively. Live loads on floor and roof slabs were assumed to be 4.8 kPa and 1.0 kPa, respectively. Total seismic weight of the building $W = 21{,}809$ kN.

A lead rubber bearing (LRB) isolation system was designed for the building where typical bounding values of isolation system parameters shown in Table 1 were considered (Constantinou et al. 1999, Naeim and Kelly 1999, and Pavlou 2005). Identical 650 mm diameter circular bearings having a lead core of 113 mm diameter were provided under each of the sixteen column bases. Each bearing consists of forty seven 5 mm thick rubber layers alternating with 2 mm thick steel shims. Based on lower bound properties of isolators, for the isolation system at DE (MCE_R) effective period $T_D = 2.24$ s ($T_M = 2.53$ s), effective damping $\beta_D = 27.2\%$ ($\beta_M = 18.8\%$), isolator displacement $D_D = 201$ mm ($D_M = 383$ mm), and total displacement $D_{TD} = 231$ mm ($D_{TM} = 440$ mm).

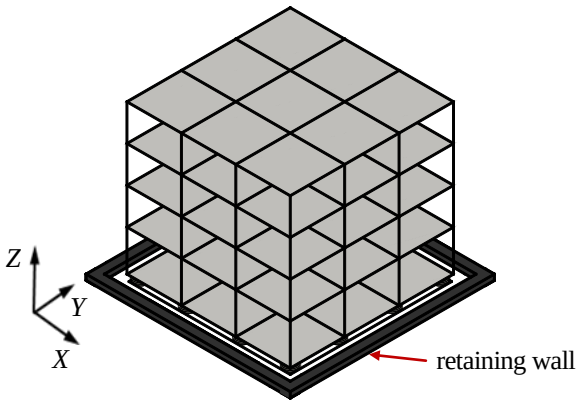

Fig. 2. The four-story building considered in the present study.

Table 1. Bounding values of the parameters for the isolation system.

	Lower bound	Upper bound
Rubber shear modulus G (MPa)	0.44	0.6
Lead stiffening factor f_L	0.95	1.05
Lead yield stress σ_{YL} (MPa)	10	12

4. NUMERICAL MODELING

Three-dimensional FE modeling was carried out using OpenSees (2012). Beams and columns were modeled using force-based, Euler-Bernoulli fiber beam-column elements that account for the spread of inelasticity along the length of the element. A section discretized into unconfined concrete, confined concrete, and steel fibers is located at each integration point in the element. In this study five Gauss-Lobatto integration points were taken per element. Uniaxial material models with nonlinear constitutive relationship were assigned to the fibers. The section response is derived through the integration of uniaxial responses of the fibers. For concrete, the modified Kent and Park model (Park et al. 1982) was used in compression and an initial linear elastic branch together with a linear softening branch up to zero stress was used in tension. The model of Yassin (1994) was used to account for concrete damage and hysteresis. For reinforcing steel, the constitutive model of Menegotto and Pinto (1973), with a strain-hardening ratio of 1% was used. In this study 2% stiffness-proportional damping, where the damping coefficient was calculated from the fixed-base frequency of the superstructure, was applied to the superstructure. In-plane stiffness of slabs was accounted for by using rigid truss elements connecting two ends of each beam element and opposite corners of each slab of every bay, while out-of-plane stiffness was neglected.

Lead rubber bearings were modeled using elastomeric bearing elements. A coupled plasticity model, with a circular yield surface is used for bidirectional lateral response of these elements (Huang 2002). Parameters of the coupled plasticity model are based on a bilinear force-deformation relationship. Here, for the lower bound properties (upper bound properties), initial stiffness $K_1 =$ 5,945.5 kN/m (8,858.7 kN/m), yield force $F_y =$ 111.4 kN (133.7 kN) and $\alpha = K_2/K_1 =$ 0.1, where K_2 is the post-elastic stiffness.

A pair of the new contact elements (see Section 2) was used at each corner of the base slab to simulate pounding with the retaining wall in two orthogonal horizontal directions. The parameters of each contact element computed based on previous studies (Zhu et al. 2002, Guo et al. 2011, and Pant and Wijeyewickrema 2012) are $k_n = k_t = 2{,}500$ MN/m, $r_n = r_t = 0.65$, $\mu_s = 0.5$, and $\mu_k = 0.4$.

5. SELECTION AND SCALING OF GROUND MOTIONS

Two subsets of earthquake ground motions were taken from the Pacific Earthquake Engineering Research Center database (PEER 2011) viz. subset 1 containing 20 pairs of far-fault non-pulse-like motions (Table 2) and subset 2 containing 20 pairs of near-fault pulse-like motions (Table 3). The ground motions had been rotated to fault-normal (FN) and fault-parallel (FP) components. Pulse-like nature of a ground motion was identified using the method proposed by Baker (2007).

Selection and scaling was accomplished using the interactive web interface of the PEER database (PEER 2011), where the ground motion pairs with geometric mean spectrum of two horizontal components that are most similar in shape to the target spectrum in the desired period range are selected and subsequently linear amplitude scaled. The ground motions were first selected and scaled to the MCE_R level such that the mean of the 5%-damped geometric mean spectrum of two components of ground motion pairs closely matches the 5%-damped target spectrum in the period range of 0.75 s to 5 s, which covers the recommended range of $0.5T_D$ to $1.25T_M$ by ASCE 7-10 (ASCE 2010). The acceleration time-histories of records scaled to represent MCE_R were then multiplied by $2/3$ to obtain the records representing DE.

6. ANALYSIS RESULTS

Nonlinear time-history analyses were carried out first by assuming that a sufficient separation distance d_g is available between the building and the retaining wall such that pounding does not occur, and then by setting the separation distance d_g equal to the total maximum displacement of the isolation system $D_{TM} = 440$ mm, to investigate the effects of seismic pounding. Fault-normal (FN) and fault-parallel (FP) components of ground motions correspond to X-direction and Y-direction, respectively. The numerical models with lower bound and upper bound properties of isolators are referred to as lower bound model and upper bound model, respectively.

Peak response indicators are presented as the mean values from time-history analysis for all the ground motions in each subset of ground motions. Superstructure response is discussed in terms of mean values of peak inter-story drift ratio, peak column curvature ductility, peak normalized story shear force, and peak absolute floor acceleration. The story shear force was normalized by the seismic weight W. Peak inter-story drift ratio is presented for both X- and Y-directions. Since mean values of X-direction response indicators were found to be larger than those of Y-direction, column curvature ductility and normalized story shear forces are presented only for the X-direction. Floor accelerations are presented as resultant of the demands in two orthogonal directions. In this study, peak inter-story drift ratios in the ranges of 0.2–0.5%, 0.5–1.5%, and 1.5–3% correspond to damage of drift-sensitive nonstructural components, moderate structural damage, and severe structural damage, respectively (Elnashai and Sarno 2008). Peak inter-story drift ratios greater than 3% can be assumed to correspond to a collapsed story.

6.1 Superstructure Response without Considering Pounding

When pounding was not considered in the analysis, under DE-level ground motions, as expected, the superstructure response is governed by the upper bound model, where larger forces are transmitted to the superstructure compared with the lower bound model (Fig. 3). Under DE-level far-fault motions, the peak inter-story drift ratio is very small and reaches a maximum value of 0.25% at the second story in X-direction, indicating no structural damage to the building (Fig. 3(a) and (b)). Column curvature ductilities are less than one indicating that yielding of columns does not occur in any story (Fig. 3(c)). Maximum superstructure base shear force is about $0.15W$, which is half of the base shear capacity of $0.3W$, predicted based on the pushover analysis (Fig. 3(d)). Maximum floor acceleration is $0.42g$ at the roof level (Fig. 3(e)), which is slightly higher than the limit of $0.35g$ often exercised in the design of seismically isolated buildings. Under DE-level near-fault motions maximum drift is 0.36% in X-direction and column curvature ductilities and superstructure base shear force remain small (Fig. 3(f)–(i)). Effect of near-fault motions is more pronounced in lower stories. Furthermore, peak roof-level acceleration under near-fault motions is nearly the same as that under far-fault motions (Fig. 3(j)).

Under MCE_R-level ground motions the superstructure response is also governed by the upper bound model, similar to the case of DE-level ground motions (Fig. 4). For MCE_R-level far-fault motions, the peak inter-story drift ratio is 0.57%, the maximum at the first story which then gradually reduces at upper stories (Fig. 4(a) and (b)). This indicates some moderate structural damage to the building at the first story. Compatible with the drift is the peak column curvature ductility which is 2.3 at the first story and remains less than one at upper stories (Fig. 4(c)). Superstructure base shear force is much less than the capacity (Fig. 4(d)). Maximum floor acceleration is $0.5g$ at the roof level (Fig. 4(e)). Peak inter-story drift ratio under MCE_R-level near-fault motions is 2.4% at the first story, 0.59% at the second story, and then gradually reduces at upper stories (Fig. 4(f) and (g)). The demand at the first story is unacceptably large and shows 321% larger drift compared with the drift under corresponding far-fault motions. Column curvature ductility also indicates extensive yielding of columns in the first story and some minor yielding in the second story, while upper story columns remain elastic (Fig. 4(h)). Superstructure base shear force reaches a value of $0.26W$ but is still less than the capacity (Fig. 4(i)). The maximum floor acceleration which is observed at the roof level is the same as that observed under far-fault motions (Fig. 4(j)).

6.2 Superstructure Response Considering Pounding

When the retaining wall is located at a separation distance $d_g = D_{TM}$, DE-level far-fault motions do not induce pounding, while only 2 of the DE-level near-fault motions induce pounding. Therefore, the effect of pounding on all the superstructure response indicators, except the floor accelerations was found to be negligible for DE-level motions. Under MCE_R-level far-fault motions, inter-story drift ratios using lower bound model are slightly increased due to pounding but are still less than the drifts using upper bound model which are negligibly influenced due to pounding (Fig. 5(a)). Drift response predictions

using lower and upper bound models have become very close compared with the no-pounding case (Fig. 5(a) and (b)). Similar is the case for column curvature ductilities and story shear forces (Fig. 5(c) and (d)). This also highlights the benefits of conducting a bounding analysis, where even neglecting the pounding could provide conservative estimates of drifts, ductilities, and shear forces. However, this is not true for floor accelerations, which show a maximum value of 2.3*g* at the base level using lower bound model, which is much larger than that obtained using upper bound model and marks a substantial increase due to pounding (Fig. 5(e)).

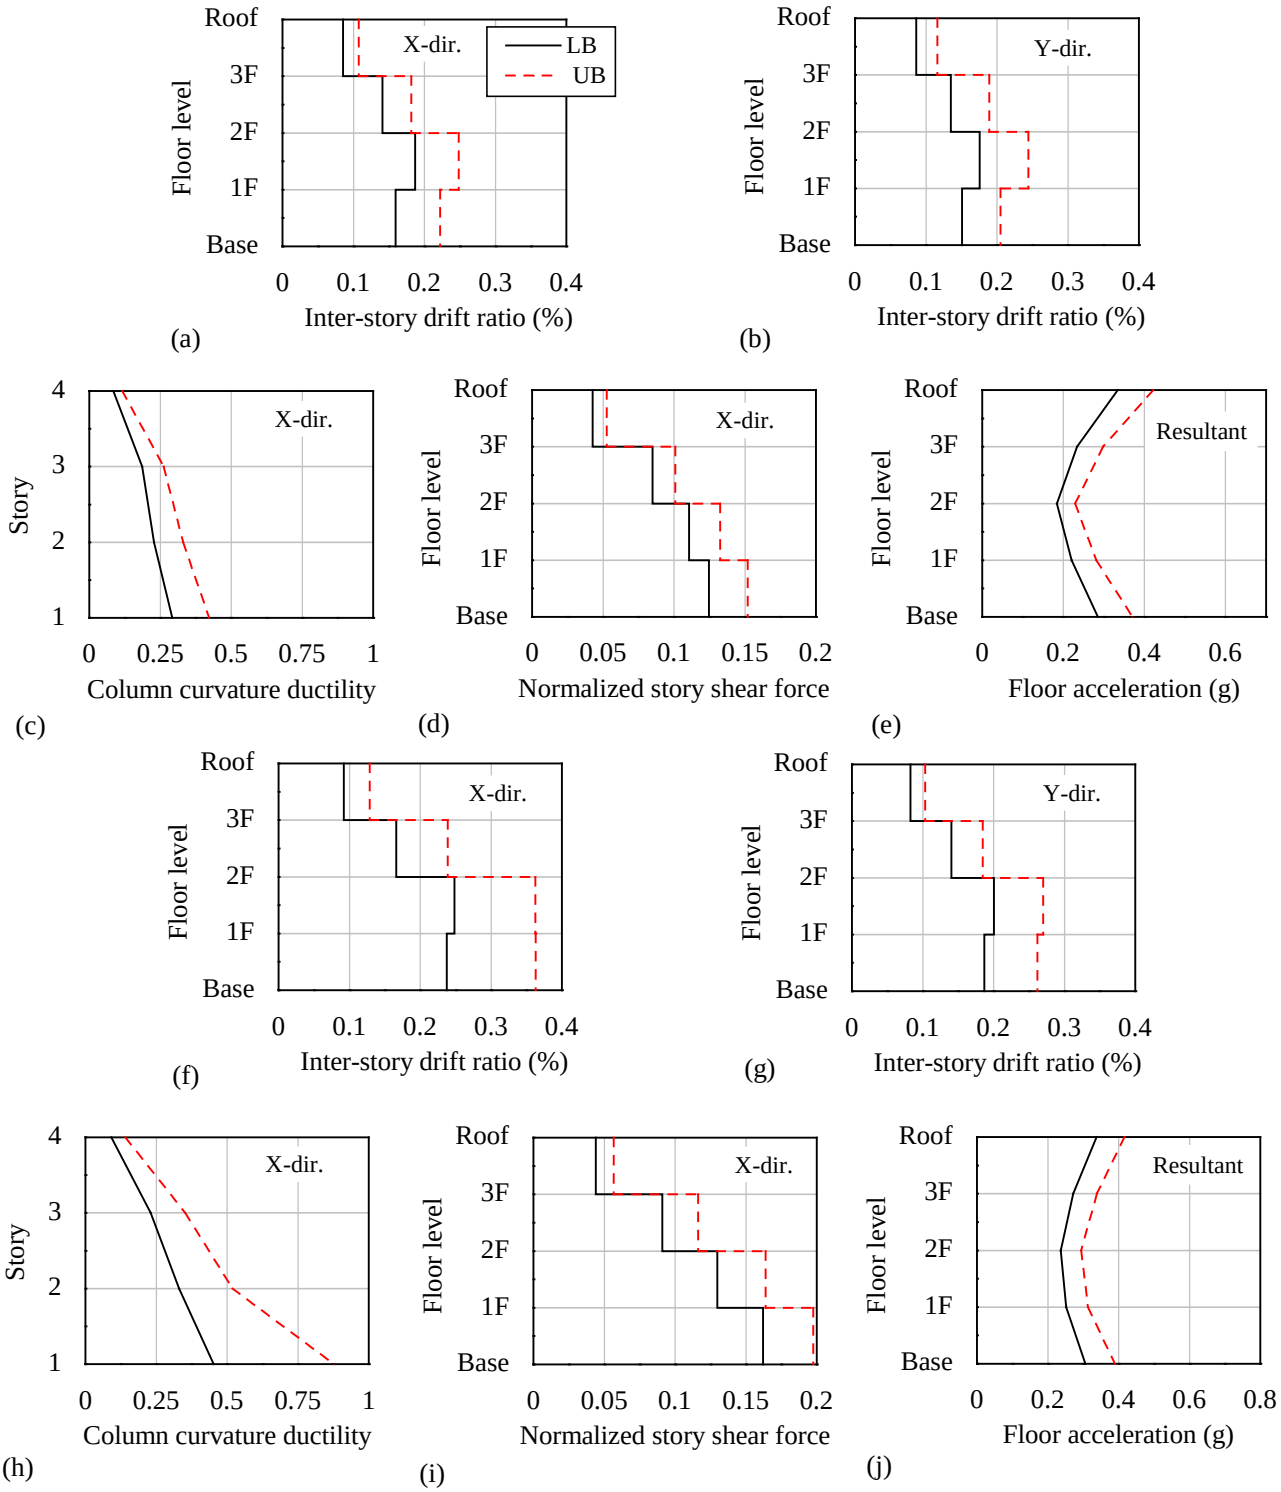

Fig. 3. Mean values of superstructure response indicators for DE-level ground motions without considering pounding: (a)–(e) far-fault and (f)–(j) near-fault.

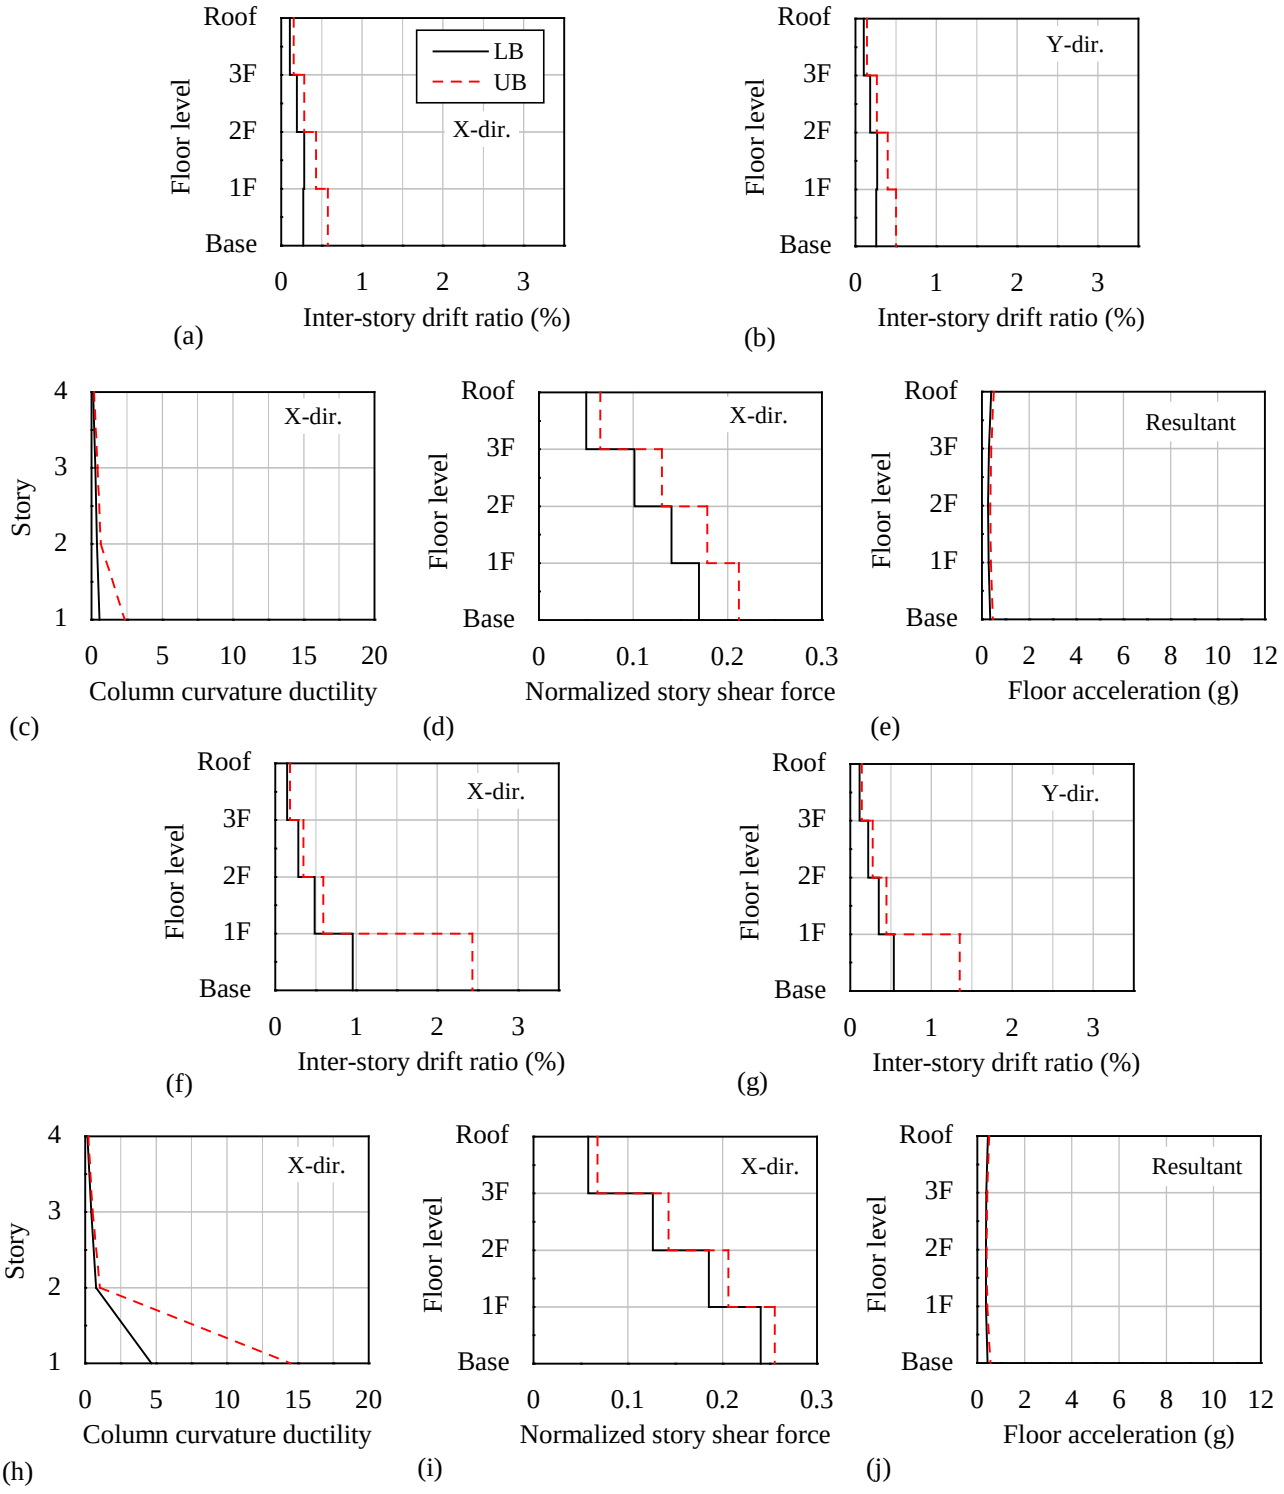

Fig. 4. Mean values of superstructure response indicators for MCE_R-level ground motions without considering pounding: (a)–(e) far-fault and (f)–(j) near-fault.

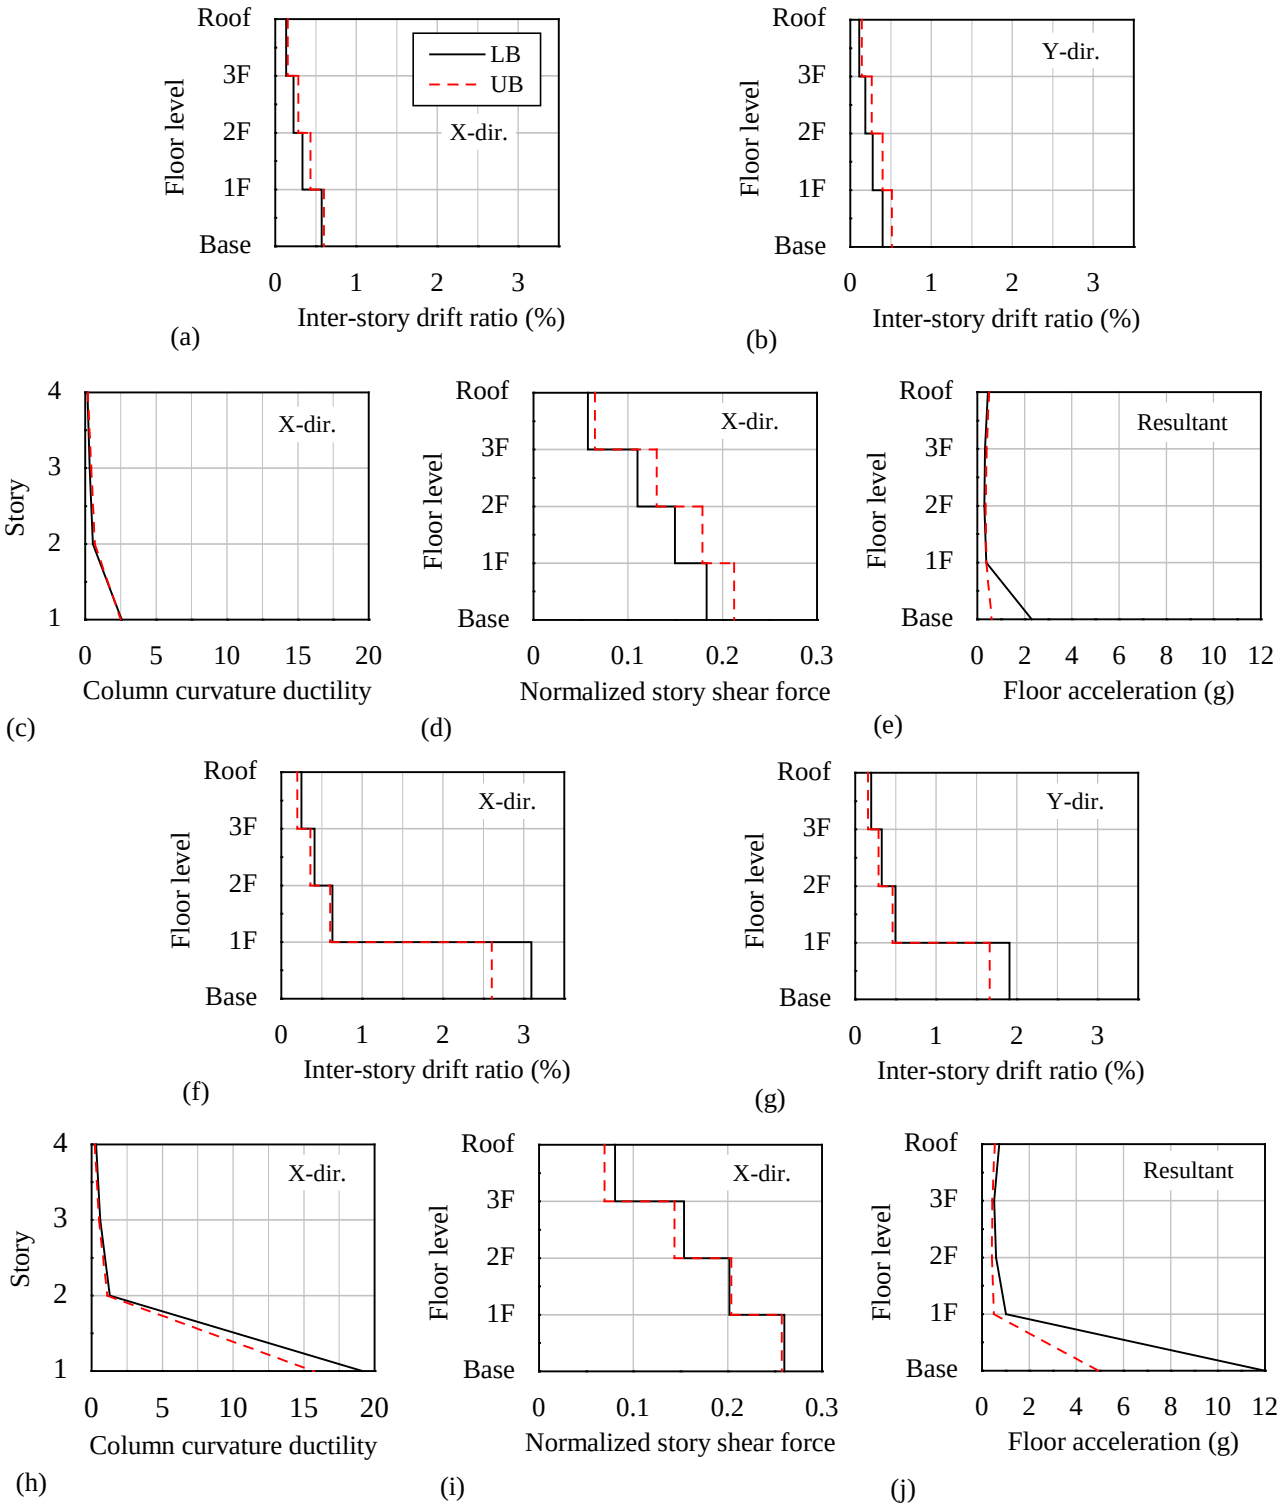

Fig. 5. Mean values of superstructure response indicators for MCE_R-level ground motions considering pounding at $d_g = D_{TM}$: (a)–(e) far-fault and (f)–(j) near-fault.

Significant influence of pounding is observed under MCE_R-level near-fault motions. Considering lower bound model, the inter-story drift ratio at the first story in X-direction has increased from 0.96% to 3.1% (Fig. 5(f)) due to pounding, indicating remarkable three-fold increase. As expected, the drift demands using upper bound model are not much influenced due to pounding and in contrast to all the previous cases, the lower bound model governs the drift response (Fig. 5(f) and (g)). While building suffered severe structural damage when pounding was not considered, the drift ratio greater than 3% indicates imminent collapse of the first story due to pounding. Furthermore, extremely large column curvature ductilities at the first story are also observed with a maximum value of 19 (Fig. 5(h)). Story shear forces are also increased due to pounding but the increase is not as severe as the increase in drifts, and the superstructure base shear force is below the capacity of $0.3\,W$ (Fig. 5(i)). This indicates that the predominant mode of failure due to pounding is flexural. Dramatic increase only in the base-level acceleration is observed due to pounding, where a maximum value of $12g$ is resulted (Fig. 5(j)).

7. CONCLUDING REMARKS

Seismic performance of a typical four-story base-isolated RC building was investigated under bidirectional far-fault and near-fault ground motions scaled to represent DE and MCE_R. Seismic pounding of the building with the retaining wall at the base was simulated using a newly developed special purpose contact element. Bounding values of isolator properties were considered in the nonlinear time-history analyses. The main conclusions based on the mean values of response indicators are as follows:

(1) Floor accelerations, which affect the building contents and nonstructural components, remain relatively low when pounding is not considered but may increase dramatically due to pounding.

(2) Regardless of whether pounding is considered or not, structural damage to the building does not occur under DE-level far-fault as well as near-fault motions, while some moderate structural damage is observed under MCE_R-level far-fault motions. This reveals the satisfactory performance of the base-isolated building, where superstructure remains essentially elastic under DE-level motions and some minor yielding occurs under MCE_R-level far-fault motions. However, the building experiences severe structural damage under MCE_R-level near-fault motions when pounding is not considered while pounding with the retaining wall at a separation distance equal to the total maximum displacement D_{TM} of the isolation system, initiates collapse. The predominant mode of structural failure when pounding is considered or not, is flexural and shear failure does not occur.

(3) The adverse effects of pounding are mostly concentrated in the immediate vicinity of impact i.e., at the first story.

(4) The superstructure response of the building is entirely governed by the upper bound properties of isolators when pounding is not considered. Considering pounding increases the dependence of the superstructure response on the lower bound properties of isolators, where in some instances the response is entirely governed by these properties.

Abstract: A smart base isolation system is composed of conventional low-damping isolators and controllable damping devices such as magnetorheological (MR) dampers. The controllable damping devices provide additional damping to the structure and reduce the base drift without the accompanying acceleration increases if appropriate control algorithms for the dampers are adopted. In this paper, real-time hybrid testing of a smart base isolation system has been conducted. It is a base-isolated where the superstructure and the low-damping base isolator are numerically simulated and the MR damper is physically tested. The control voltage is computed by using a linear-quadratic controller or a fuzzy-logic controller and converted to a corresponding current sent to the MR damper. Meanwhile, the target displacement obtained from the step-by-step integration of the numerical substructure is imposed on the MR damper in a real-time manner. An adaptive phase-lead compensator is implemented to compensate the actuator delay and increase the accuracy of the test. Experimental results demonstrate the effectiveness of the smart base isolation system as well as the accuracy of each test which is investigated by the root mean square error and the tracking indicator. .

1. INTRODUCTION

A smart base isolation system is composed of conventional low-damping elastomeric bearings and controllable damping devices such as magnetorheological (MR) dampers (Ramallo et al. 2002). Compared with the passive damping devices, a smart base isolation system can reduce base drifts without the accompanying acceleration. Several control methodologies have been studied and implemented for the smart base isolation system such as sliding-mode control, clipped-optimal control, and fuzzy control. (Yang et al. 1996; Symans and Kelly 1999; Spencer et al. 2000).

Real-time hybrid testing, combining numerical simulation with experimental testing, provides an efficient method to evaluate the dynamic responses of rate-dependent structural systems subjected to earthquake excitation. During a real-time hybrid test, the target displacement is obtained using a step-by-step integration scheme and applied on the test specimen through servo-hydraulic actuators. The restoring force is measured from the test specimen and fed back to the integration algorithm to calculate the target displacement for the next time step. Real-time hybrid testing provides an alternative way to evaluate the seismic responses of structures subjected to earthquake ground motions. However, it is very challenging because there is a small but significant enough time delay between the command and the achieved displacements due to the dynamics of the servo-hydraulic systems (Dyke et al. 1995; Zhao et al. 2003). This time delay is often referred as actuator delay, which produces a negative damping effect and adds energy into a hybrid test (Horiuchi et al. 1999).

Various compensation methods have been developed and proposed to minimize the effects of actuator delay for real-time testing. Horiuchi et al. proposed two compensation schemes based on polynomial extrapolation and linear acceleration assumptions. Nakashima and Masaoka made use of interpolation schemes to refine the time stepping. Zhao et al. used a first-order phase-lead compensator to improve the tracking performance of a real-time hybrid test. Chen and Ricles simplified the dynamics of the servo-hydraulic as a first-order discrete transfer function and then performed the inverse compensation. Phillips and Spencer developed a model-based feedforward feedback control framework to achieve more accurate real-time hybrid testing. Chen and Tsai proposed an adaptive phase-lead compensator (PLC) which is formulated by using weighted linear extrapolation and the inverse model principle. The stability of the PLC is guaranteed as long as the selected weightings locate in the derived stable regions. In addition, the gradient adaptive law with instantaneous cost function is adopted to estimate the actuator delay online.

In this paper, real-time hybrid testing of a smart base isolation system has been conducted. The numerical model contains the superstructure, low-damping base isolator, and MR damper control algorithm. The hysteresis response of

the MR damper is identified and verified first. Then a linear-quadratic (LQ) controller and a fuzzy-logic controller (FLC) are designed for computing the control voltage which is sent to the physically tested MR damper in a real-time manner. The adaptive PLC, proposed by Chen and Tsai, is adopted to compensate the actuator delay to increase the accuracy during the test. The efficacy and feasibility of the compensation strategy for servo-hydraulic system and the controller for the MR damper are examined through several analytical simulations. Finally, the overall task is validated by conducting real-time hybrid tests of a smart base isolation system using a dynamic servo-hydraulic actuator. The performance of a real-time hybrid testing is evaluated by introducing the root mean square (RMS) error and the tracking indicator (TI) proposed by Mercan and Ricles.

2. SYSTEM IDENTIFICATION

An online identification proposed by Chassiakos et al. is used to identify the hysteresis response of the MR damper. It introduces a linear parameterized estimator to represent the Bouc-Wen model and then separates the responses and model parameters. The restoring force $F_{MR}(t)$ of MR damper simulated by using the Bouc-Wen model can be expressed as:

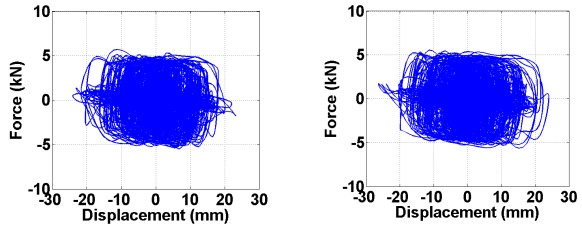
$$F_{MR}(t) = C(V)\dot{x}(t) + \upsilon(t)$$
$$\dot{\upsilon}(t) = A\dot{x}(t) + \beta\left|\dot{x}(t)\right|\left|\upsilon(t)\right|^{n-1}\upsilon(t) + \gamma\dot{x}(t)\left|\upsilon(t)\right|^{n} \quad (1)$$

where υ(t) is a hysteretic parameter that follows the differential equation in Eq. (1). A, β, γ and n are parameters that determine the scale, general shape, and smoothness of the hysteretic loop. The hysteretic model is parameterized linearly with respect to the coefficients A, β, and γ, but nonlinearly with respect to the power n. It is noted that most of the test facilities in the lab are running in digital form. The system identification experiments were conducted in discrete time with a sampling time Δt (50ms in the study). As a result, a discrete-time modified model considering the contribution of the power n to the response is adopted:

$$\upsilon[k+1] = \upsilon[k] + \Delta tA\dot{x}[k] + \Delta t\sum_{n=1}^{N}\kappa_n\left\{\beta\left|\dot{x}[k]\right|\left|\upsilon[k]\right|^{n-1}\upsilon[k] + \gamma\dot{x}[k]\left|\upsilon[k]\right|^{n}\right\} \quad (2)$$

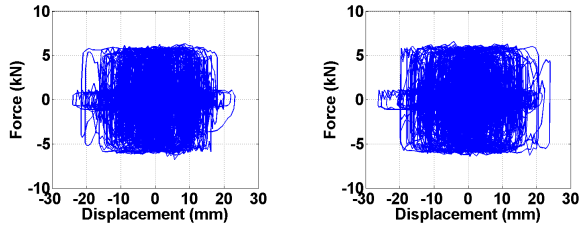
where κ_n is the coefficient corresponding to the power of n. By separating the unknown parameters from the known signals, the parametric model of the estimator is constructed:

$$\tilde{\upsilon}[k+1] = \upsilon[k] + \theta_0[k+1]\dot{x}[k] + \sum_{n=1}^{N}\left\{\theta_{2n-1}[k+1]\left|\dot{x}[k]\right|\left|\upsilon[k]\right|^{n-1}\upsilon[k] + \theta_{2n}[k+1]\dot{x}[k]\left|\upsilon[k]\right|^{n}\right\}$$
$$= \upsilon[k] + \Phi^{T}[k]\Theta[k+1] \quad (3)$$



where N is a large enough integer and the coefficients θi [k], i=0,…2N are estimates at time step k of the corresponding coefficients from Eq. (2). The vector Φ[k] contains the known signals measured from the identification tests, and Θ[k+1] is a vector of the parameters estimated at time step k+1. Based on Eq. (3), the parameters of the MR damper can be identified. The detail of the identification method and application can be referred to Lin et al.

The MR damper employed in this study is made at the National Center for Research on Earthquake Engineering (NCREE) in Taiwan in 2005. Its maximum generated force and stroke are ±7kN and ±150mm, respectively. Three different approaches of performance tests have been conducted: (a) Sinusoidal displacement excitation with constant voltage input. Different excitation frequencies, strokes, and command voltages are tested; (b) Random displacement and constant voltage input. Different stroke levels and frequency contents of random excitations are tested with different constant command voltages; and (c) Random displacement and random voltage input. Both the displacement and command voltage are random. Each performance test was conducted for 120 seconds. It is noted that one set of model parameters can only represent the MR damper response under a specific command voltage. As a result, the nonlinear regression is used to get the model function corresponding to different command voltages. The Matlab function lsqcurvefit is used to solve nonlinear curve-fitting problems in least-squares sense. Finally, the identified Bouc-Wen model takes the form:



$$\tilde{F}_{MR}[k] = C(V[k])\dot{x}[k] + \upsilon[k]$$
$$\upsilon[k+1] = \upsilon[k] + \sum_{n=1}^{N}\theta_n(V[k])\phi_n[k]\Delta t \quad (4)$$

where θ_n is the identified parameters with respect to the power of n. The parameter $\tilde{F}_{MR}[k]$ is the identified generated force of the MR damper at the time step k. It is a function of control voltage V at each time step. The signal ϕ_n can be measured from the identification tests.

Two more performance tests are conducted to validate the mathematical model. The two input excitations are generated with a series of random displacements and random control voltage inputs for the MR damper in 60 seconds. The peak stroke for each test is 22mm with a frequency contents from 0.1Hz to 5Hz. The control voltages vary from 0V to 1.2V. Figure 1(a) and 1(b) show the hysteresis loops of the MR damper in the two performance tests and the identified Bouc-Wen model for the MR damper, respectively. It demonstrates that the identified model can predict the damper force fairly well. In addition, this mathematical model is approved to be stable in the two cases of performance tests. Figure 2(a) and 2(b) illustrate the time histories of the MR damper force from the identified model and measured from the two identification tests from 50 to 60 seconds. It appears that the global behavior of the MR damper can be captured by the numerical model. However, the force computed form the MR damper model is larger than the measured force from the test. The peak force of the numerical model is 20% larger than that of the test. It indicates that the seismic response of a smart base isolation system may not be accurately evaluated through numerical simulation. As a result, real-time hybrid testing becomes a necessity for investigating the behavior of a smart base isolation system.

3. STRUCTURE MODEL

Consider a base-isolated building as shown in Figure 3, where the superstructure is modeled as a single degree-of-freedom (SDOF) system representing the one-story residential house. The mass, damping coefficient and the stiffness of the base isolation and the superstructure are mb, cb, kb and ms, cs, ks, respectively. The structural parameters of the SDOF fixed-base and 2DOF isolated structure models are given in Table 1. It is known that the linear behavior of low-damping rubber bearings can extend to shear strains above 100% and even 150%. Therefore, the isolation layer is modeled as a combination of linear stiffness and viscous damping with a fundamental period of 2.5 s period and a 2% of damping ratio. It is assumed that the nonlinear response of the superstructure can be neglected due to the moderate application of the base isolation system. In addition, the maximum generated force of the MR damper in the lab is 7kN. Therefore, the total mass of the base-isolated building is assumed to be 7000 N-s^2/m. In other words, the MR damper is assumed to be able to provide shear force up to 10% gravity force of the building.

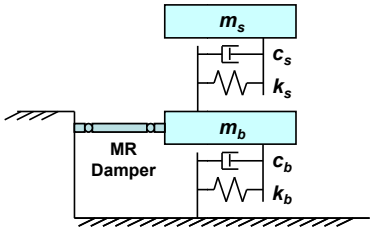

Figure 3 2DOF model of a smart structure adopted in the study

Table 1 Structural properties of the smart structure

Mass (N-s^2/m)	Damping Coefficient (N-s/m)	Stiffness (N/m)
Isolation Parameters		
3000	720	44600
Structure Parameters		
4000	3350	1754600

4. CONTROLLER FOR THE MR DAMPER

Various active control algorithms have been used to oppose earthquake excitations in numerical and experimental studies such as linear-quadratic regulator, modal control, and sliding mode control. In this paper, the state output-feedback linear-quadratic (LQ) control algorithm, and the fuzzy-logic control (FLC) algorithm are adopted.

4.1 Linear-quadratic Control

The equations of motion of the base-isolated system may be expressed as:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{\Lambda}F_{MR}(t) - \mathbf{M}\mathbf{l}\ddot{u}_g(t) \quad (5)$$

where $\mathbf{\Lambda}$ gives the position of the MR damper force; $\mathbf{l}$ is a vector whose elements are all unity; u_g is the ground displacement. The mass, damping, and stiffness matrices are represented as **M**, **C**, and **K**.

The state-space form of the equation of motion is given by:

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}F_{MR}(t) + \mathbf{E}\ddot{u}_g(t) \quad (6)$$

where the system matrix **A**, the control force distributed matrix **B**, and the disturbance location matrix **E** are:

$$\mathbf{A}=\begin{bmatrix}\mathbf{0} & \mathbf{I}\\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C}\end{bmatrix};\quad \mathbf{B}=\begin{bmatrix}\mathbf{0}\\ \mathbf{M}^{-1}\mathbf{\Lambda}\end{bmatrix};\quad \mathbf{E}=\begin{bmatrix}\mathbf{0}\\ -\mathbf{I}\end{bmatrix} \tag{7}$$

In this study, the MR damper is installed between the isolation layer and the ground as shown in Figure 3; therefore, $\mathbf{\Lambda}=[1\ \ 0]^T$. The system parameters of the superstructure are: m_s=3000 N-s^2/m, c_s=720 N-s/m, and k_s=44600 N/m. Also, the system parameters of the isolation layer are: m_b=4000 N-s^2/m, c_b=3350 N-s/m, and k_b=1754600 N/m. The associated structural period and the damping ratio of the superstructure and the isolation layer are: T_s=0.3 sec, ζ_s=2% , and T_b=2.5 sec , ζ_b=2%, respectively. The regulated output vector $\mathbf{y_r}$ used for designing the linear-quadratic controller takes the form:

$$\mathbf{y}_\mathbf{r}(t)=\mathbf{C}_\mathbf{r}\mathbf{x}(t)+\mathbf{D}_\mathbf{r}F_{MR}(t) \tag{8}$$

The vector $\mathbf{y_r}$ includes the inter-story drifts and absolute floor accelerations. The matrices $\mathbf{C_r}$ and $\mathbf{D_r}$ are:

$$\mathbf{C}_\mathbf{r}=\begin{bmatrix}1 & 0 & 0 & 0\\ -1 & 1 & 0 & 0\\ -\mathbf{M}^{-1}\mathbf{K} & & -\mathbf{M}^{-1}\mathbf{C} & \end{bmatrix};\quad \mathbf{D}_\mathbf{r}=\begin{bmatrix}\mathbf{0}\\ \mathbf{M}^{-1}\mathbf{\Lambda}\end{bmatrix} \tag{9}$$

The state-feedback control force is obtained by minimizing the quadratic cost function:

$$J=\int_0^\infty\left(\mathbf{y}_\mathbf{r}^T\mathbf{Q}\mathbf{y}_\mathbf{r}+F_C{}^T R F_C\right)dt \tag{10}$$

where $\mathbf{Q}$ and $\mathbf{R}$ are the state weighting matrix and the control cost, respectively. The parameter F_C is the state feedback control force of the MR damper. By solving the Ricatti equation and the state feedback gain $\mathbf{K_g}$ is obtained. Finally, the control force for the MR damper, F_C = - $\mathbf{K_g}$ $\mathbf{x}$ is obtained.

The idealized optimal control force, F_C = - $\mathbf{K_g}$ $\mathbf{x}$, is imposed on the base-isolated building by a semi-active MR damper. As a result, it is necessary to convert the optimal control force to equivalent control voltage (CV) for the MR damper. As the MR damper is a nonlinear device, the calculation of the inverse model (input: response and damper force/output: control voltage) is difficult. As a result, the clipped optimal control (Lin et al. 2005) is used to calculate the suitable control voltage at each time step. With the Bouc-Wen model of the MR damper, the damper force in each voltage level can be calculated. Thus, the closest damper force is obtained by comparing to the calculated optimal control force. Similarly, the control voltage at time each time step can also be found.

4.2 Fuzzy-logic Control

In addition to the linear-quadratic control algorithm, a fuzzy logic control (FLC) method is also studied in this paper. Fuzzy-logic theory, introduced by Zadeh in 1965, has been extensively applied on complex control problems. FLC is a type of intelligent language control and adopts manual control rules established by engineering intuition and experience. It provides a simple and robust nonlinear control strategy and can be accommodated to the uncertainties and un-modeled dynamics of the MR damper.

Fuzzy-logic operations consist of three steps: fuzzification, fuzzy inference and defuzzification. In the fuzzification module, crisp values are converted into fuzzy sets and degrees of membership. A membership function defines how each point in the input space is mapped to a membership value between 0 and 1. The fuzzy inference consists of the linguistic IF–THEN rules, which connect the mapping relationship between the input and output. The defuzzification, the opposite of fuzzification, converts the output of the inference rules back to a crisp control signal.

In this study, the control targets are: (1) to control the displacement of the isolation layer when it is under large deformation; (2) when the deformation of the isolator is small, do not apply any force on it; (3) to limit the control voltage up to 1.2V; and (4) to reduce the inter-story drift and absolute acceleration of the superstructure. It is noted that the fuzzy rule base in this study is proposed by engineering experience without optimization. Some optimal approaches for FLC such as genetic algorithm or neural network are not discussed.

The displacement and the velocity of the base isolation are used as the control inputs for the FLC. The output of the FLC is the control voltage for the MR damper. In this paper, the triangular membership functions are used for all variables. The membership functions are obtained through trial and error in numerical simulation. The parameter CV represents the control voltage for the MR damper. The fuzzy rule base is shown in Table 2 where NL, NM, NS, ZR, PS, PM, and PL represent negative large, negative medium, negative small, zero, positive small, positive medium, and positive large, respectively. Mamdani's method is used for fuzzy inference due to its simple structure of 'min-max' operations. For defuzzification, the center of area method is adopted. The surface of the fuzzy rule base is illustrated in Figure 4.

5. ADAPTIVE PHASE-LEAD COMPENSATOR

Various compensation methods have been developed and proposed to achieve more accurate strucutral responses of real-time hybrid testing. Most of the compensation methods require a prior knowledge of the servo-hydraulic system. Therefore, system identification of the servo-hydraulic system needs to be conducted to obtain the system dynamics before performing a real-time hybrid test. In addition, these compensation methods are mostly based on a fixed identified system parameter, for example, the actuator delay, to complete the design of the compensation. However, it has been shown that the actuator delay would vary during a hybrid test due to the nonlinear structural responses (Darby et al.). The transfer function of a servo-hydraulic system would also change due to the nonlinearity of the test component such as a MR damper (Phillips and Spencer 2012). It appears that the system parameters would not be fixed during a real-time hybrid test. As a result, a parameter estimator is necessary to detect the system parameters online to further improve the accuracy of the real-time hybrid testing.

Chen and Tsai have introduced the adaptive control theory to propose an adaptive phase-lead compensator (PLC) for the servo-hydraulic system. The discrete transfer function of the PLC is formulated by using weighted linear extrapolation and the inverse model principle. It has also been proved stable as long as the selected weightings locate in the derived stable regions. The only one parameter, delay constant, is obtained online by the delay estimator which adopts the gradient adaptive law formed in the format of parametric model. The stability and parameter convergence have been strongly supported by mathematics. The discrete PLC, C(z), takes the form:

$$C(z)=\frac{\left[W_1+(W_1+W_2+1)\alpha\right]z^2+\left[W_2-(W_1+W_2+1)\alpha\right]z+1}{W_1z^2+W_2z+1} \quad (11)$$

where z is a complex number in the z domain and α is the delay constant which is an integer greater than 0. The variables W_1 and W_2 are the weightings. The stable regions for the weightings are shown in Figure 5. By selecting different pairs of weightings, the PLC could be more accommodating to different compensation demands.

In order to evaluate the effects of different weightings for the PLC, frequency response analyses of four pairs of weightings located in the stable regions are carried out: (1)PLC1 with large W_1 and W_2 values ($W_1 = W_2 = 10000$); (2) PLC2 with large W_1 and small W_2 values($W_1 = 10000$ and $W_2 = 0.01$); (3) PLC3 with intermediate W_1 and W_2 values ($W_1 = 3$ and $W_2 = 2$); and (4) PLC4 with extremely small W_1 and W_2 values ($W_1 = 0.0001$ and $W_2 = 0.025$). Generally, the servo-hydraulic system is viewed as a first-order dominant system (Zhao et al. 2003). Magnitude reduction and response delay are expected for a first-order transfer function. Figure 6 shows the Bode diagram of the four PLCs applied on a servo-hydraulic system simulated as a first-order transfer function with a roll-off frequency of 11Hz. It is found that PLC4 under-compensates the magnitude but over-compensates the phase. On the other hand, PLC3 performs the best among the four PLCs because the magnitude is less amplified and the phase lag is close to zero. In addition, the weightings for PLC3 are more reasonable because they are close to each other. As a result, PLC3 is adopted for delay compensation in the study.

6. EXPERIMENTAL STUDIES

6.1 Test Setup

The schematic of the 2DOF smart structure shown in Figure 3 can be divided into two parts: (1) the experimental substructure, consisting of the semi-active MR damper, and (2) the numerical model, consisting of the stiffness, damping and mass terms of the superstructure and the isolation layer with a lightly-damped base isolator. The experimental test setup is shown in Figure 7. The MR damper is pin-connected to a 250kN dynamic servo-hydraulic actuator

at one end by a high strength bolt while the other end is connected to a reaction support fixed to a stiff frame.

The test facility can be divided into two major components: (1) the MTS GT digital controller, and (2) the dSPACE system. The dSPACE system is adopted in the test because it supports a large number of D/A and A/D input/output channels. It provides solutions for automotive engineering and industrial control throughout the integration of the control desk and Matlab/Simulink. The control desk is used to compute and collect the signals of a test system with a friendly graphical-user-interface. The layout of the test facilities is shown in Figure 8. The adaptive phase-lead compensator and control algorithms for the MR damper are programmed and compiled in a host computer with the Matlab/Simulink. With Real-Time Workshop and C complier, executable codes can be created and linked to the dSPACE which runs in real time. Signals generated by the dSPACE are passed to the GT controller (command displacement) and the MR damper (control voltage) in analog form through the cables. The measured signals including the displacement and force of the MR damper are sent back to the GT controller and conditioned. After that, the measured signals are sent from the GT controller to the dSPACE to compute the command displacement and control voltage in the next time step. By using these advanced experimental control facilities, complex hybrid simulation test could be conducted in real time. The GT controller is a well-tuned proportional-integral controller and forms a closed-loop system together with the servo-hydraulic system. All the tests are conducted with a sampling rate of 200Hz. The response of the MR damper is related to the velocity which is obtained by directly differentiating the measured displacement in the test. As a result, a second-order digital low-pass filter is used to cut off the measurement noise above 30Hz. The magnitude of the signal passed by the filter is 30% reduced at the frequency of 30Hz. The block diagram of the real-time hybrid testing is illustrated in Figure 9, where x_c and x_m are the command and measured displacements, respectively.

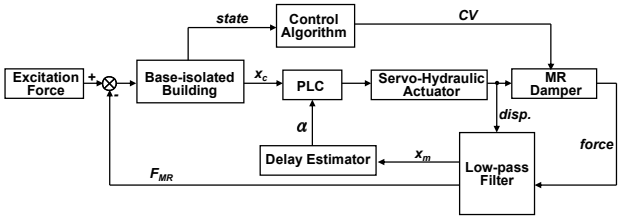

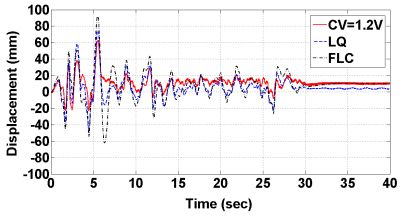

Figure 9 Block diagram of the real-time hybrid testing in this study

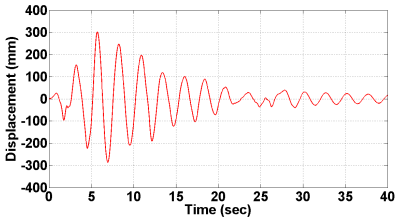
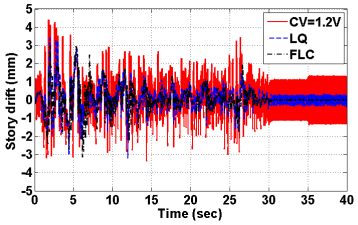
6.2 Experimental Results



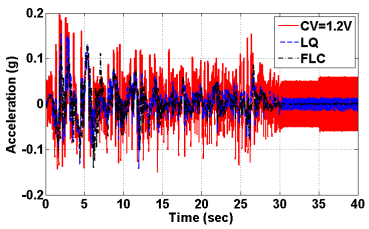
Three control algorithms are adopted for the MR damper: case (1) a constant voltage of 1.2V, which can be viewed as a passive damper; case (2) the MR damper is driven by using the linear-quadratic (LQ) control algorithm; and case (3) the MR damper is driven by using fuzzy logic control (FLC) algorithm. The feedback control gain vector $\mathbf{K_g}$= [368045 -307514 47750 -16262] is obtained by solving the Ricatti equation. The adaptive gain for the delay estimator is set 100 to prevent it from oscillation.

It is noted that the force capacity and peak stroke of the MR damper are 7kN and ±150mm, respectively. If the peak displacement of any test is larger than 150mm, the servo-hydraulic actuator could break the MR damper. Therefore, numerical simulation has been conducted to evaluate the potential peak displacement imposed on the MR damper under different levels of earthquake ground accelerations. From the analytical simulation results, two records of earthquakes are adopted: the 1940 El Centro Earthquake and the 1999 Chi-chi Earthquake and the peak ground accelerations (PGA) are normalized to 0.33g and 0.20g, respectively. It is worth noted that the record of the 1999 Chi-chi earthquake, TCU068EW, was measured at a near-source location. According to the previous research results, base-isolated buildings are vulnerable to strong near-fault impulsive ground motions (Hall et al. 1995). On the other hand, smart dampers have been shown to provide a superior base isolation system for near-source excitations. As a result, special concerns to the efficacy of base isolation system subjected to near-fault ground acceleration have been raised in this study.

For the smart base isolation system subjected to the 0.33g 1940 El Centro Earthquake, the displacement time histories of the isolation layer for each case are shown in Figure 10(a). It appears that case (1) performs the best among the three cases because the control voltage for case (1) is kept 1.2V, which is the maximum control voltage for the MR damper. The displacements of the isolation layer for all the three cases are significantly reduced due to the MR damper compared with the uncontrolled building as shown in Figure 10(b). Figure 11(a) and 11(b) show the time histories of the relative displacement and the absolute acceleration of the superstructure in each case. Both case (2) and (3) have smaller relative displacements and absolute accelerations compared with case (1). It demonstrates that the semi-active controlled damper can effectively reduce the relative displacement and absolute acceleration of the superstructure as well as the displacement of the isolation layer.



(a)



(b)

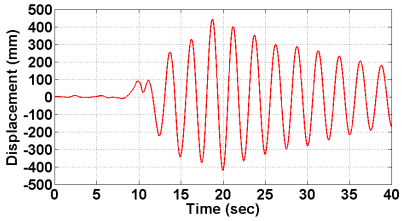
(a)



(b)

Figure 11 Time histories of the superstructure (0.33g El Centro): (a) story drift, (b) absolute acceleration

For the smart base isolation system subjected to the 0.20g near-fault Chi-chi Earthquake, The state feedback control gains and the fuzzy rule base remain unchanged. However, as mentioned in the system identification section, the force measured from the MR damper is smaller than that obtained from the numerical simulation. As a result, the displacement of the isolation layer in the validation test is larger than that in the simulation. If the peak displacement of any test is larger than 150mm, the servo-hydraulic actuator could break the MR damper. The peak displacement in case (3) is larger than 140mm, the limit of safety for the MR damper. Therefore, the PGA of the near-fault Chi-chi Earthquake is reduced to 0.15g for the experimental studies. The displacement time histories of the isolation layer in each case and the uncontrolled building are shown in Figure 12(a) and 12(b), respectively. Again, case (1) performs the best among the three cases. The time histories of the relative displacement and the absolute acceleration of the superstructure in each case are shown in Figure 13(a) and 13(b). It appears that case (2) and (3) have smaller relative displacements and absolute accelerations compared with case (1). Summarily, the advantages of a smart base isolation system (reducing base drifts without the accompanying acceleration increases) has been observed and demonstrated through real-time hybrid tests.

(a)

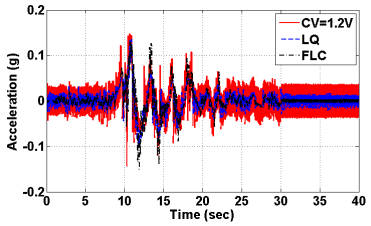
6.3 Tracking Performance

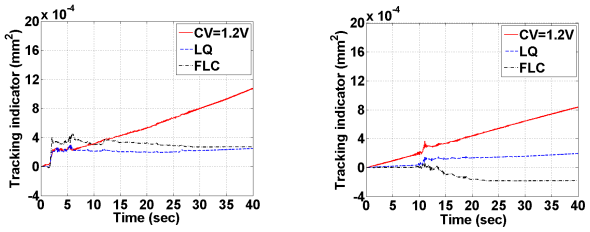


The tracking performance of a real-time hybrid test depends on the difference between the computed command and the measured displacements. For simplicity, the root mean square (RMS) error is mostly used as an index of the tracking performance. The RMS error is defined as:

$$RMS_{error}(\%) = \sqrt{\frac{\sum_{k=1}^{N}\left(x_c[k]-x_m[k]\right)^2}{\sum_{k=1}^{N}x_c[k]^2}} \times 100\% \quad (12)$$

where $x_c[k]$ and $x_m[k]$ are the command and measured displacements at the step k, respectively. Good tracking performance is indicated by a low RMS error between the command and measured displacements. Table 3 shows the RMS errors of each test. It appears that all the RMS errors are within 6% indicating that the adaptive PLC compensates the servo-hydraulic system fairly well. It is noted that the passive-on case has larger RMS error than the other two semi-active cases subjected to the two different earthquake ground accelerations. This is because in the passive-on case, little oscillation was observed when the response is small. Before the test was conducted, a small but significant enough restoring force (about 0.5kN) was measured from the MR damper under the maximum input voltage 1.2V. This small measured force was larger than the restoring force provided by the stiffness term. The equation of motion could not be in equilibrium; as a result, the structural system was oscillated until the earthquake ground acceleration became relatively significant. However, the oscillation was not observed in the two semi-active cases because the control voltage varied from time to time. Even though, the RMS error for the passive-on case is still good enough.

(a)



(b)

Figure 13 Time histories of the superstructure (0.15g near-fault Chi-chi): (a) story drift, (b) absolute acceleration

The tracking performance can be also evaluated by introducing the so-called tracking indicator (TI) proposed by Mercan and Ricles in 2007. The initial values for the enclosed and complementary areas are set as zero. A positive slope of TI corresponds to a lagged actuator response, meaning that negative damping is introduced into the real-time hybrid testing. On the other hand, a negative slope of TI represents a leading actuator response, indicating that artificial damping is added into the test. In addition, a zero slope of TI demonstrates a perfect tracking, i.e., the measured and command displacements are identical. Figure 14 shows the tracking indicators of the displacement for each test. It shows that the responses of the constant voltage case are mostly lagged, while the other two cases perform much better. It is also because the MR damper was oscillated when the displacements were small in the constant voltage case. The high-frequency oscillation leads to significant tracking errors during the test and result in worse TI values. Even though, all the TI values are considered acceptable because they are close to zero. A good tracking performance of the proposed PLC is then demonstrated.

Table 3 Tracking performance for each test in terms of RMS error

Earthquake Record	Controller for the MR damper	RMS_{error} (%)
El Centro (0.33g)	Passive-on	5.97
	LQ	4.84
	FLC	4.07
Chi-chi near-fault (0.15g)	Passive-on	4.55
	LQ	3.22
	FLC	2.36

7. CONCLUSIONS

The efficacy of a combination of low-damping elastomeric bearings and controllable MR dampers, namely smart base isolation system, has been evaluated using real-time hybrid testing methodology. The numerical model contains the superstructure, low-damping base isolator, and MR damper control algorithm. The control voltage computed by the control algorithm is sent to the MR damper which is physically tested in a real-time manner. An adaptive phase-lead compensator (PLC) is adopted to compensate the actuator delay to increase the accuracy during the test. The main observation and contribution of the study are summarized below:

(1) A series of identification tests of the MR damper have been performed to calibrate the nonlinear Bouc-Wen model of the MR damper. However, it is shown that the numerical model could not be perfectly represented the physical MR damper in terms of maximum generated force. The response of a smart base-isolation structure could not be clearly investigated through numerical

simulation. As a result, real-time hybrid testing is considered an alternative and necessary approach to evaluate the behavior of a smart base-isolation structure.

(2) The PLC is proved to successfully compensate the time delay and magnitude reduction due to the servo-hydraulic actuator and the low-pass filter. The frequency response analyses with different selected weightings provide the design flexibility of the PLC. Experimental studies demonstrate the delay estimate of the PLC converges to a constant within limited time duration. It indicates the adaptive PLC can be applied on a nonlinear test system as the servo-hydraulic actuator with the MR damper in the study.

(3) The MR damper is demonstrated to provide additional damping to the structure and reduce base drifts without the accompanying acceleration increases if appropriate control algorithms for the dampers are adopted. Experimental results indicate that the linear-quadratic control and the fuzzy logic control algorithms can be effectively reduce the relative displacement and absolute acceleration of the superstructure compared with the constant voltage case.

(4) The accuracy of the real-time hybrid test is evaluated by the tracking performance in terms of the root mean square error (RMS) and the tracking indicator (TI). The RMS error for each test is under 6%, showing that the test results are fairly enough to investigate the behavior of the smart base-isolation system. In addition, the TI time history for each test demonstrates the PLC can well-compensate the phase lag induced by the servo-hydraulic system as well as the low-pass filter.

Acknowledgements:

The tests were conducted at the National Center for Research of Earthquake Engineering (NCREE) in Taiwan. The authors would like to thank the technicians from NCREE for their assistance in test setup. In addition, the works carried out by Mr. Li-Hao Chen on the system identification tests of the MR damper was also acknowledged.

Abstract: This paper proposed the new system for building damage assessment using photos of damaged house taken by residents or volunteer fire corps in damaged area. Specialists outside the damaged confirm these photos on the website and assess their damage levels. All the data used for building damage assessment is managed with GIS database on the management server located outside the damaged area under cloud condition. This kind of digital management system can contribute to enhance the accuracy and efficiency of the procedures for issuing the Victim Certificates for residents. In this paper, the total system for supporting building damage assessment was designed and its prototype system was developed. The system for uploading the photos of damaged houses was developed as mobile communication service. The remote system for specialists to assess the damage level was developed as web service.

1. INTRODUCTION

In Japan, several big earthquakes are expected to occur in the near future. A lot of structural damages due to these earthquakes will cause enormous needs for building damage assessment. Building damage assessment is necessary for governments to issue the Victim Certificates for residents who suffered housing damages. However, current number of human recourses who are trained with the procedure of building damage assessment is not enough. It is necessary to develop the new system which can correspond to next large-scale earthquake disaster. The guidelines of general procedure for inspecting building damage and evaluating loss due to disasters were published by the Cabinet Office in 1968, 2001 and 2009. However, in past disasters, various problems of building damage assessment have been pointed out such as inaccurate inspection, difficulty in quick inspection and lack of human recourses with sufficient skill of assessment.

New remote system for building damage assessment using IT system was proposed and prototype system was developed. These systems have some features that can solve some problems pointed out by past building damage assessments and execute building damage assessment quickly after a large scale earthquake disaster. This proposed system has two sub-systems. First one is photo uploading system used in damaged area. Second one is assessment system for supporting experts such as registered architects and experienced workers outside the damaged area. But authors only develop the prototype system, and do not evaluate the effectiveness of developed system. In this research, authors conducted operation test for some local government staffs to evaluate the effectiveness of developed systems.

2. CONCEPT OF NEW REMOTE SYSTEM FOR BUILDING DAMAGE ASSESSMENT

As a new system for achieving all the solutions for the problems reported at the past building damage assessments, we proposed a new remote system for supporting building damage assessments during large-scale earthquake disaster. The concept of the system is illustrated in figure 1.

The total system consists of two sub-systems. The first one is photo upload system in damaged area. Photos of a damaged house are taken by residents or volunteer fire corps in damaged area and those data is uploaded to the server. The second one is remote assessment system for specialists. Specialists located outside the damaged area confirm these photos through the website, and assess their damage levels and area.

All the data used for building damage assessment is managed with GIS database on the management server located outside the damaged area under cloud condition. This kind of digital management system can contribute to enhance the accuracy and efficiency of the procedures for issuing the Victim Certificates for residents.

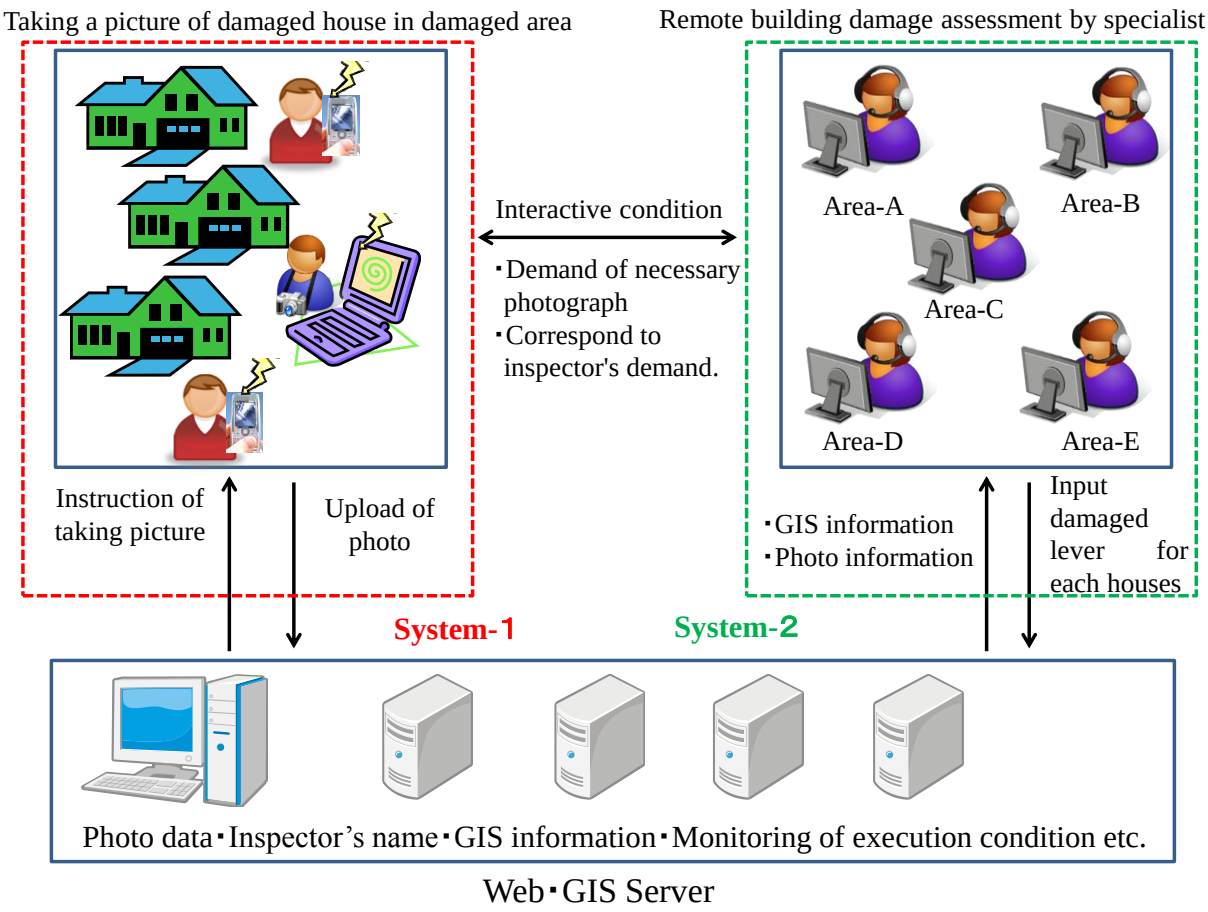

Figure 1: Concept of remote building damage assessment system

3. DEVELOPMENT OF REMOTE BUILDING DAMAGE ASSESSMENT SYSTEM

3.1 Development of photo upload system in damaged area

Here, prototype of "Photo upload system in damaged area" was developed. Photos of a damaged house are taken by residents or volunteer fire corps in damaged area and those data is uploaded to the server. This system was developed by Android as the mobile phone operating system which is installed in almost all the smart phones except iPhone. Photo upload application is installed to each Android smart phone by inspectors who are residents or volunteer fire corps in damaged area.

Flow of photo upload system is as follows. Firstly, residents or volunteer fire corps as inspectors input the basic information such as GPS information, address and owner name. Secondary, they upload some photos such as overview of damaged house, incline of damaged house and damaged point of roofs, walls and fundamentals. Finally, they confirm the input data and some photos.

Method of completing for photo upload in damaged area using upload application is as follows. Inspectors take some damaged house photos which are full views of a damaged house (north side, east side, south side and west side) and closeup views of damaged points. They select some photos for upload in each factors page, and fill in the comments about damage level and location of a house etc. Inspectors should take pictures of damaged house concerning three factors: externals, inclination and building element (roof, exterior wall and foundation). Furthermore, they have to relate closeup views of damaged points to full views using touch screen functions. The prototype system of photo upload system was developed based on the data of totally damaged houses due to the 2011 off the Pacific coast of Tohoku Earthquake.

After taking some pictures, inspectors need to upload them to an exclusive server in cloud condition using upload application. Using this application makes it easier to select and upload photos which are taken by inspector in damaged area. The reason is that smart phone has touch screen functions which are tap, drag, flick and pinch out/in operations.

3.2 Development of remote assessment system for specialists

Here, prototype of "remote assessment system of

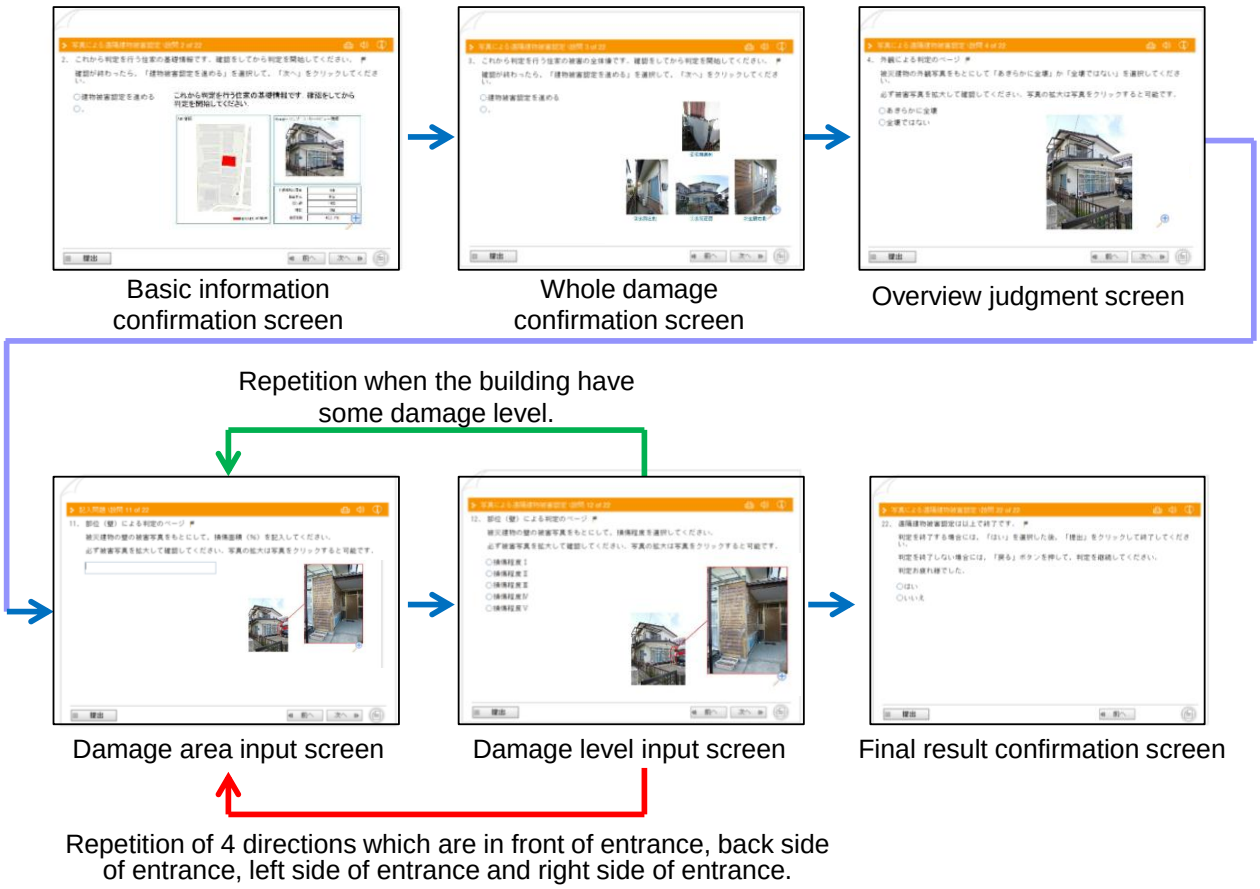

Figure 2: Remote building damage assessment system

photos of damaged houses was developed as shown in figure 2. Specialists outside the damaged area confirm these photos on the website and assess their damage levels. All the data used for building damage assessment is managed with GIS database on the management server located outside the damaged area under cloud condition.

Flow of remote assessment system is as follows. Firstly, specialists who are registered architects and experienced workers outside the damaged area confirm the basic information such as shape of damaged house, location and seismic level on the web system and overview all the photos of a damaged house. Secondary, they assess the damage level and area using some photos such as overview of damaged house, incline of damaged house and damaged point of roofs, walls and fundamentals. Finally, specialists confirm the input data and some photos. Then result of first assessment is passed to the next specialist to carry out double check.

Figure 2 shows the prototype system of the system for primary inspection. These systems were developed based on the data of moderate damaged houses due to the 2011 off the Pacific coast of Tohoku Earthquake. Total damage level of a house is decided based on damage levels of three factors: externals, inclination and building element. Assessment for one damaged house should be conducted by two or three specialists to double-check the result and keep accuracy, fairness and objectivity.

They can see close-up photos if necessary. They evaluate the photos and decide its damage level and damage area as shown in figures 2. Specialists select the damage level and area from pull down choice set in each factor page. In addition, they can request additional photos for accurate assessment to inspectors in damaged area through the each assessment page. In final page, fill in the special or caution comments of assessed damaged house and pass to the next specialist. When the assessment ends here, Victim Certificates for resident is issued from local government.

4. EVALUATION OF EFFECT OF REMOTE BUILDING DAMAGE ASSESSMENT SYSTEM

4.1 Condition of Operation test

Authors conducted operation test for twenty local government staffs which experienced building damage assessment due to the the 2011 off the Pacific coast of Tohoku Earthquake, and they belong to Yokohama city and Sendai city as shown in figure 3.

The date of operation test is 26 and 27 April in Yokohama city, and 15th May in Sendai city. Duration of operation time is about two hours. Contents of operation test are explanation of building damage assessment, developed

Figure 3: Operation test in Yokohama city

Table 2: Condition of operation test

Scenario	Damage Level	Test Conditions
1	Major damage	Easy to assess for all test persons
2	Major damage	Easy to assess for all test persons
3	Major–moderate damage	Difficult to assess for experienced person
4	Moderate damage	Easy to assess for all test persons
5	Moderate damage	Difficult to assess for experienced person
6	Minor damage	Easy to assess for all test persons
7	Minor damage	Difficult to assess for experienced person

Scenario 4

Scenario 5

Figure 4: Example of damage photo for remote assessment system

system and questionnaire survey for developed system. After the explanation of that, operation test was started by author using developed system. When the operation test finished, test staffs answer the questionnaire survey regarding usability and feasibility of developed system.

Table 1 shows condition of operation test. Operation test has four damage patterns and two cases respectively (except major-moderate damage). Totally seven scenarios of operation test are examined by operation test staffs. Damage patters of operation test are major damage, major-moderate damage, moderate damage and minor damage, and two scenarios are easy to assess and difficult to assess for experienced person. Operation test adopt local government staffs which have experienced to carry out the building damage assessment during the 2011 off the Pacific coast of Tohoku Earthquake. Figure 4 shows example of damage photo for remote assessment system due to the 2011 off the Pacific coast of Tohoku Earthquake which are moderate damaged houses. Scenario 4 is moderate damaged house which is easy to assess for all test persons, and scenario 5 is also moderate damaged house which is difficult to assess for experienced person.

4.2 Result of Operation test

Figure 5 shows result of final damage level using developed remote building damage assessment. As a result of operation test, scenario 1 and 2 are all operation staffs assess correct damage level. On the other hand, scenario 3,4,5,6 and 7 does not assess completely. East to assess for all test persons cases are high correct answer ratio which is about 80%. But, correct ratio of difficult to assess for experienced person cases is lower than another case.

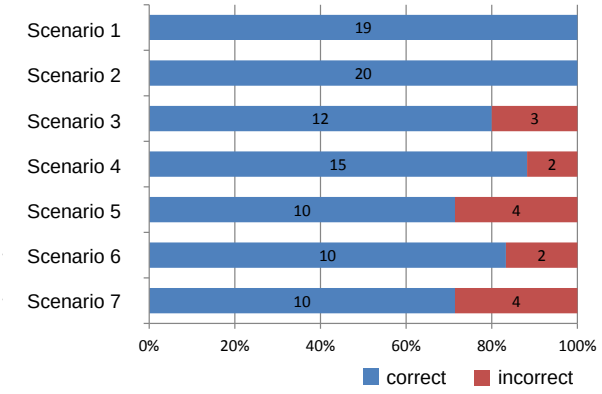

Figure 5: Result of final damage level

Figure 6 shows result of judgment of damage level which is scenario 7. Scenario 7 is difficult to assess for experienced person case. Scenario 7 has three walls which locate left side of entrance and back side of entrance. Red circle in the graph indicate correct judgment. As a result of operation test, about 70% of test staffs can assess correct damage level of wall. But, about 30% of test staffs do not assess the damage level correctly because of small cracks cannot find.

Figure 7 shows result of judgment of damage area which is scenario 7. Scenario 7 is difficult to assess for experienced person case. Scenario 7 has three walls which locate left side of entrance and back side of entrance. Red circle in the graph indicate correct judgment. As a result of operation test, wall 1 and wall 2 is assessed larger damaged area than correct damaged area, but wall 3 is assessed smaller than correct damaged area. The reason of that result as follows. Test staffs cannot evaluate correct damaged area because of small cracks. Damaged area is difficult to assess using photos for test persons. As a result of two reasons, it is necessary to install the easy calculation system using area mesh, and procedures which can assess the damage level using example of damage.

Figure 8 shows result of questionnaire survey regarding usability and feasibility. This system has many advantages than present procedures. Especially, "reducing inspection time" and "Result of inspection is managed by digital data." is high evaluated point by test staffs thorough the questionnaire survey. As a result of discussion as test staffs, developed system is very useful to carry out the primary inspection.

5. Conclusions

In Japan, several big earthquakes are expected to occur in the near future. It is necessary to develop the new system which can be corresponds to next large-scale earthquake disaster. In this research, new remote assessment system for building damage assessment was developed and conducted operation test.

The prototype system of remote building damage assessment system was developed based on the data of damaged houses due to the 2011 off the Pacific coast of Tohoku Earthquake, and conducted operation test for local government staffs which experienced building damage assessment. As a result of operation test and questionnaire survey, it become clear that building damage suffered from earthquake can assess using developed system and this system has many advantage point than present procedures.

In the future, we plan to conduct the operation simulation using developed system for Tokyo metropolitan inland earthquake, and examine its effectiveness and quickness.

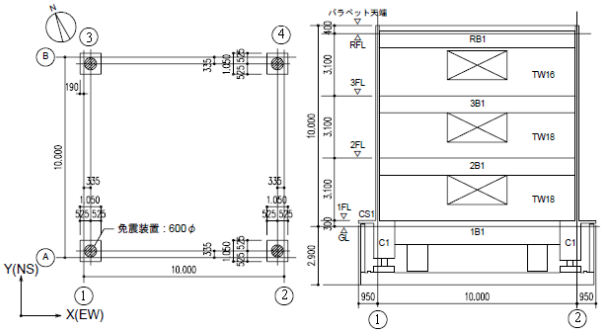
Abstract: This work is an attempt to the dynamic identification of base isolation systems from earthquake response records. A very simple base isolation system is considered, composed of only four lead rubber bearings at the four corners of a building in the city of Kushiro in northern Japan. The acceleration of the building, recorded during the 2003 Tokachi-oki earthquake, is used for the identification. The identification procedure is based on the minimization of the distance between the acceleration of the building measured during the earthquake and the simulated one obtained by using a model presented at CUEE-12. A state-of-the art optimization algorithm (CMA-ES), based on the adaptation of the covariance matrix of a multivariate Gaussian probability distribution, is used to guide the identification process. The model parameters, obtained by identification from three laboratory tests performed in 1996 and in 2004, are used as a reference for the definition of the search space where the system parameters are expected to be. The optimal solution is given in probabilistic terms, namely the average value, standard deviation and coefficient of variation of the system parameters. The work is completed with a critical analysis of the minimal system response required to obtain a realistic prediction of the system parameters for the model considered.

1. INTRODUCTION

The design of seismic isolation systems is usually based on static and/or dynamic laboratory tests performed on individual isolation devices and on suitable models derived from such tests. A model widely used for the simulation of the dynamic response of a wide class of isolation devices, including various types of elastomeric bearings, lead core elastomeric bearings and friction pendulum bearings is the so-called bi-linear spring model, (Naeim and Kelly 1999). Such a model, in parallel with a Coulomb type model for sliding bearings, has been used for the identification of hybrid base isolation systems composed of High Damping Rubber Bearings (HDRB) and Low Friction Sliding Bearings (LFSB) from full scale free vibration tests performed on a base-isolated building, (Oliveto et al. 2004), (Oliveto et al. 2010). The full scale tests are justified by the fact that laboratory tests are usually performed on a limited number of isolation devices, while a full scale test involves the whole isolation system and engages the isolators as they are installed in the construction with possible manufacturing and placing defects. Therefore full-scale tests allow for the assessment of the overall isolation system as it really is. If the test is performed soon after the construction is completed, it could play the role of a certification test that qualifies the isolation system and the building to which it belongs. If it is performed several years after the installation of the isolation system it may be used to assess the present state of the system and to gather some information on the aging process. Free vibration tests on base-isolated buildings have usually been performed by applying a static displacement to the part of the structure above the isolation system and then suddenly removing the force used to apply the initial displacement. The collaborative work by the designer, the constructor, the certifying authority and the owner is required to perform such tests and usually they result in well-conceived and executed experiments. In all known tests, the buildings and the isolation systems were symmetrical, with negligible mass eccentricity or none. This leads to a 1D motion of the superstructure relative to the substructure. For this reason the mechanical models for the identification of the isolation system were 1 Degree of Freedom (1DOF) systems. In spite of the high non-linearity of Hybrid Base Isolation Systems (HBIS) it was possible to provide an analytical solution for the response of such systems under free vibration conditions, (Oliveto et al. 2010), (Athanasiou and Oliveto 2011). The analytical solution made the simulation of the free vibration tests very simple and the identification of the HBIS from such tests very effective. The main ingredients that led to such effectiveness were the analytical solution and the limited number of system parameters to be identified. The least squares method was successfully used for the identification of the isolation system of the Solarino building, (Oliveto et al. 2010). In that case system parameters were identified along with the imposed initial displacement. Subsequent developments allowed for considerable improvements in the simulation of the response of HBIS and in their dynamic identification. A first improvement derived from the extension of the analytical solution from free vibration to forced vibration and earthquake motion,



(Athanasiou et al. 2011-a, Oliveto et al. 2012-a). A second improvement came from the application of state-of-the-art methods of system identification imported from computer science, (Athanasiou et al. 2011-b). The extension of the analytical solution to the case of earthquake excitation is a simple derivation based on the assumption that the ground acceleration is linear within a time step. The analytical solution is evaluated within each time step using the initial conditions at the beginning of the step and therefore assuring continuity for all the loading history. The interaction with researchers in the computer science field led to the testing of several evolutionary algorithms on a basic identification problem, denoted " The Toy Problem", specifically designed for base isolation systems. Of all the tested algorithms, the most effective one, by several orders of magnitude, was the CMA-ES, (Athanasiou et al. 2011-b). This algorithm has been successfully used thereafter in all of our subsequent identifications, (Athanasiou et al. 2013) and (Oliveto et al. 2012-b). The analytical solution, although effective, is limited to symmetrical systems under symmetrical excitation. For this reason a numerical solution based on a Mixed Lagrangian Formulation (MLF) was originally developed for 1DOF systems, (Athanasiou et al. 2011-c), and subsequently extended to 3DOF systems, (Oliveto et al. 2012-c). The original development was extremely useful as it allowed checking the numerical solution against the available analytical solution. The extension to the 3DOF systems allowed overcoming the limitations of the previous formulation by including 2D ground motion excitations and considering non-symmetrical systems with mass eccentricities. The mathematical formulation, along with some numerical applications may be found in the previously quoted work (Oliveto et al. 2012-c). The object of the present work is to use the numerical formulation for 3DOF base isolation systems in the identification of the mechanical properties of such systems, using their recorded response to actual earthquakes. The work is exploratory in nature and is meant to identify all the difficulties that may be involved in the pursuit of the stated goal. In principle each isolator can have different properties and it may be interesting to identify the properties of all isolators as independent quantities so that eventually defective or damaged isolators can be singled out. However, this goal may be overambitious because when many isolators are being used, the number of system parameters to be identified can easily become very large and the identification task can become prohibitive. The problem can be easily simplified, or reduced in size, if classes of isolators are assumed to have the same properties. This way the properties of classes of isolators are sought rather than those of individual isolators. However, even in a simplified form, the problem is still daunting because the inverse solution of a highly non-linear problem is being sought. Even for linear systems it is well known that inverse problems do not have a unique solution, meaning that several systems can produce the same record data on which the identification is being based. However, a good identification algorithm can produce several of the possible solutions and with suitable bounds and engineering judgment the real solution can often be found. In the present paper, the ideas that have been briefly exposed shall be illustrated by several trials of parameter identification on a simple base-isolated building with a simple base isolation system.

2. PREVIOUS STUDIES ON THE BUILDING CONSIDERED

The building considered, which belongs to the Manboku Construction Company, is an office building located in the city of Kushiro. It has three stories above the ground for a total height of 9.6 m. A view of the building is given in Figure 1 while a plan and a cross-section are shown in Figure 2 and Figure 3.

Figure 1 Photograph of the exterior of the building

Figures 2 and 3 Plan and cross-section of the building

The fundamental periods of the fixed base building are 0.095 s in the X direction and 0.105 s in the Y direction. The isolation system is composed of four identical Lead Rubber Bearings (LRB) centered at the corners of a 10mx10m square. The bearings have a diameter of 600 mm and the total thickness of the rubber is 200 mm with a secant shear modulus G=0.39 N/mm^2 at γ=1. The equivalent periods of the isolated building at γ=1 are 2.396 s in the X direction and 2.397 s in the Y direction. The building was erected in 1996 and was hit by the Tokachi-oki Earthquake in 2003. The response of the building to the earthquake has been studied by Suzuki et al. (2004), who have reported the motions recorded at the basement level below the isolation system, at the first floor and on the roof. These show a considerable reduction of the peak acceleration above the isolation plane; in the X direction the reduction factor is 0.8 for both the first

floor and the roof, while in the Y direction it is 0.47 for the first floor and 0.51 for the roof. An orbit tracer device installed at a certain location of the isolation plane of the building shows the trace of the relative horizontal displacement at that location with a maximum displacement of about 300 mm in the X direction. The authors also show a comparison between the 5% damping response spectrum for the horizontal ground motion recorded by a K-net station at a distance of 2.2 km from the building and that for the motion recorded in the basement of the building. As compared to the motion recorded by the K-net station, the motion recorded in the basement of the building shows a significant spectral amplification in the range of periods of interest for base-isolated buildings. The second part of the study, authored by Kaneko et al. (2004), concerns the simulation of the response of the building and the comparison between the simulated and the measured responses. The first comparison is in terms of the orbit of the relative motion. Although the amplitude and the general direction of motion are evaluated with sufficient accuracy, the simulated and recorded paths do not exactly match. The authors provide estimates of the peak acceleration at the first floor and on the roof that are somewhat lower than the measured ones. Of great interest to the mentioned work are three static cyclic tests performed on one of the isolation bearings. The bearing was originally tested in 1996, and in 2004 it was removed from the building and tested in the two perpendicular directions along which the earthquake acceleration had been measured, that is the two principal directions of the building. The authors note how the properties of the bearing changed in the eight years between the tests. The increase in secant stiffness k_d at γ=1 appears to be negligible in the Y direction and only about 2% in the X direction; this seems to point out that the small change in stiffness may be due more to strain hardening induced by the seismic action than to aging. The yield strength instead shows an increase of about 5% in the X direction and about 7% in the Y direction. By integration of the recorded acceleration the authors obtain the following peak velocity and displacement components: v_x=872mm/s, v_y=490mm/s, u_x=304mm, u_y=152mm. The orbit calculated by integration of the recorded acceleration is in good agreement with the recorded one. Of considerable interest are the graphs of the restoring force in the isolators versus the relative displacement. The graphs are given separately for the X and Y direction and a comparison between recorded and simulated responses is provided. The simulated response appears to be based on a bilinear model while for the experimental response the restoring force is most likely derived by equilibrium based on an estimated mass and the recorded acceleration. Moreover, the displacement is derived by double integration of the recorded acceleration. The matching between simulated and experimental responses appears to be reasonably good. The authors also provide an estimate of how the secant stiffness and the yield strength of the isolators vary with the shear strain amplitude. The stiffness and the strength at a shear strain γ=100% are taken as reference points and the variations at shear strains of γ=50% and γ=150% are provided. A 20% increase in the secant horizontal stiffness is shown at γ=50% and a decrease slightly larger than 10% is shown at γ=150%. In terms of yield strength the behavior is inverted; a slight decrease is seen at γ=50% while a slight increase seems to occur at γ=150%. Anyway, the decrease and the increase are significantly less than 10%. The authors finally present an estimate of the energy dissipated by the isolation system for the X and Y direction respectively. The experimental and simulated estimates are in good agreement for the Y direction while in the X direction the results from the simulation appear to underestimate the experimental ones. Finally a cross-section of the removed isolator shows no apparent damage caused by the earthquake.

3. IDENTIFICATION OBJECTIVES

The building described in the previous section is taken as a case study to investigate the level of information that can be gathered from the use of suitable models and structural identification techniques on base isolation systems, given the structural response to actual earthquakes. The building considered and its isolation system are a perfect fit in serving the purpose of this work since the isolation system is composed of only four identical isolators. This considerably simplifies the mechanical model and reduces to a bare minimum the number of parameters to be identified. In principle the four isolators that compose the isolation system are different entities with different properties depending on material characteristics, manufacturing process, installing tolerances, possible damage due to external agents, and so on. As it was shown in the previous section, the building is very stiff and, as far as the isolation system is concerned, it is quite reasonable to consider the superstructure as a rigid body. The negligible difference between the acceleration records at the first floor and on the roof appears to corroborate this hypothesis. Therefore a simple model for the description of the behavior of the isolation system may be one that considers the superstructure as a rigid body. Moreover if the substructure can also be considered as rigid, then the model only needs to include 6 degrees of freedom. However, the seismic isolators are very stiff in the vertical direction so that the relative vertical displacement between the substructure and the superstructure can be neglected and negligible are also the two rocking motions about any two perpendicular horizontal axes through the isolation plane. Therefore the mechanical model can be further simplified to include only 3 degrees of freedom, i.e. the two components of the horizontal displacement and the rotation about a vertical axis. Even though the number of degrees of freedom is reduced to a bare minimum, the problem can still be highly redundant due to a large number of isolation devices, which could also be of different types and sizes. Based on a Mixed Lagrangian Formulation, a robust algorithm for the numerical evaluation of the dynamic response of HBIS was proposed at 9th CUEE and 4th ACEE by Oliveto et al. (2012-c). This algorithm will be used, along with a state of

the art system identification strategy, in the attempt of identifying the properties of the isolation system of the considered building, from its response to the 2003 Tokachi-oki Earthquake. The system identification algorithm to be used is the Covariance Matrix Adaptation – Evolution Strategy and a tutorial can be found on-line, (Hansen 2011). The readers that are interested in a comparison between the considered algorithm and competing ones are referred to (Hansen 2006). To set the stage for the identification problem one should first have clear how the identification algorithm works. The algorithm considers a population of feasible systems, where the parameters of each system are generated by using a multivariate Gaussian distribution. Using our mechanical model, the response to the given earthquake is generated for each member of the population, i.e. for each system belonging to the population. The simulated response is then compared to the measured one and the distance between the two is evaluated. This distance is the identification error, which in computer science jargon is called fitness of the individual (i.e. system). All the λ members of the population are ranked according to their fitness and only the best $\mu<\lambda$ are retained. The covariance matrix of the Gaussian distribution is then updated by taking into account the retained μ members of the population and a new generation of λ individuals is created. These are ranked again according to their fitness and the worse $(\lambda-\mu)$ are discarded. The procedure is terminated either when the distance between simulated and experimental response becomes very small or when the number of iterations (generations) exceeds a given limit. Below is a brief description of the identification method introducing aspects of the problem that will motivate the numerical applications presented later. First a set of parameters is generated, defining one of the λ individuals of the population; with this set of parameters a model is constructed and the earthquake response is simulated. This simulation requires a computation time that depends on the size of the system considered. For the time being we can assume that the size of the system is a function of the number of isolators and therefore, the larger is the number of isolators, the larger is the computation time required to produce a system response. At each iteration of the identification procedure, λ of such system responses need to be generated, one for each member of the population. Therefore, since a large number of iterations could be performed before convergence is achieved, it seems clear that large computation times could be involved and that the procedure could benefit from parallel processing. For instance at each iteration, λ different processors could be used simultaneously to evaluate the λ system responses. The CMA-ES software already has parallel processing as an option but this feature has not been exploited within the present work. The size of the population λ depends on the number of parameters needed to be identified. Generally the larger the number of parameters to be identified and the larger is the size of the population required for an effective identification. Moreover, the larger the required size of the population and the larger is the computation time necessary for an identification run. Therefore, if we have good reasons to believe that each isolator in a set of isolators has the same properties as all the others, for that set we can reduce the number of parameters to be identified to those of a single member of the set. This results in a huge saving of computation time making the identification objective more achievable. If however there is evidence that the properties of one or more isolators in a given set may be different because of defective manufacture, installation or exposure, then it may be necessary to consider independent parameters for those isolators or for the whole set, according to whether they are recognizable or not. In that case the computational effort will be much larger but the identified parameters will in the end lead to a more reliable model. The number of parameters to be identified therefore depends on the objectives of the identification and is largely problem dependent. Another aspect of the identification problem that will also guide the applications is related to the fact that an inverse problem can admit more than one solution, i.e. different systems can produce the same response. In such cases any additional knowledge can guide the user to choose the physically consistent solution and to abandon those that are not physically significant. In a way, the more we know about a system, the higher is the probability that we can identify the true parameters. However, there is a minimum amount of information that is required for the true solution to be included among all the possible ones. We shall show, by means of an artificially constructed problem, how a better approximation to a known solution can be achieved, when a minimum amount of information is available, and how worse the approximation can be when the available information drops below that minimum.

4. MODEL PARAMETER IDENTIFICATION FROM LABORATORY TESTS

In order to define a search domain within which the system parameters are expected to be found, it is useful to estimate average values of the system parameters and typical scatters about these average values. To this purpose, static and/or dynamic laboratory tests performed on individual isolators belonging to the class used in the building may be particularly useful. For the building considered, three cyclic tests performed under static conditions at a strain amplitude γ=1 are available in the literature, Kaneko et al. (2004). A set of parameters for a bilinear model were evaluated from each of these tests using the CMA-ES evolution strategy and the fitness function (error function) defined below:

$$e^2 = \left(\frac{A-A^e}{A^e}\right)^2 + \left(\frac{I_{xx}-I^e_{xx}}{I^e_{xx}}\right)^2 + \left(\frac{I_{yy}-I^e_{yy}}{I^e_{yy}}\right)^2 + \left(\frac{I_{xy}-I^e_{xy}}{I^e_{xy}}\right)^2 \quad (1)$$

where $A^e, I^e_{xx}, I^e_{yy}, I^e_{xy}$ are the area and second moments of area of the experimental restoring force-displacement curve, and $A, I_{xx}, I_{yy}, I_{xy}$ are the corresponding quantities from the

model. The minimum value attained by Equation (1) provides an optimal set of parameters for each test. A comparison between experimental and identified curves for the test performed in 1996 is shown in Figure 4, while the three sets of identified parameters from the three available tests are shown in Table 1. A comparison between the results from the 1996 and 2004 tests shows that aging results in a 5% increase of the hardening stiffness k_1, a 10% increase of yield strength Q and a 13% reduction in the initial stiffness k_0. A comparison between the results from the two tests performed in 2004 provides hints of anisotropic behavior, possibly due to large strains induced by the 2003 earthquake.

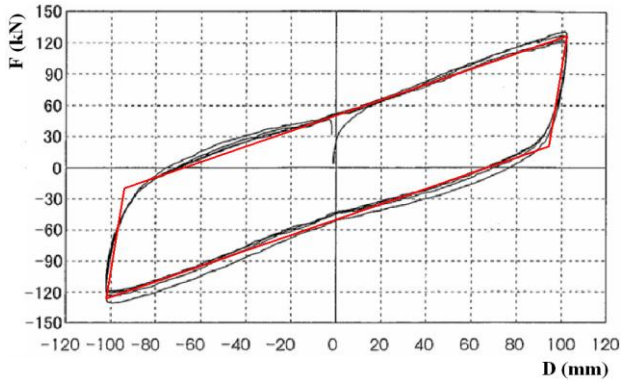


Figure 4 Experimental and identified curves for the test performed in 1996

Table 1 Identified bilinear curve parameters from the provided laboratory tests

Test	*Q (kN)*	k_0 *(N/mm)*	k_1 *(N/mm)*
1996	50	13569	755
2004 X	55	10443	788
2004 Y	55	13043	800

5. MODEL PARAMETER IDENTIFICATION FROM EARTHQUAKE RESPONSE RECORDS

When trying to identify the system parameters, it is useful to define a search space within which realistic values of the unknown parameters may be found. This can be achieved by defining lower and upper bounds for each system parameter. Starting point in this case are the results from the static laboratory tests performed in 1996 and 2004. The lower bounds for each parameter are tentatively set to 80% of their lowest value obtained from the laboratory tests, while the upper bounds are set to 140% of their largest value obtained from the same tests. For the system mass the same criterion is applied starting from a reference mass of 575 tons. The lower bound for the damping ratio is set to zero while the upper bound is set to 5%. The resulting search space is given in Table 2.

5.1 Isolators with identical properties

In this first identification application it is assumed that the four isolators all have the same properties. The identification of the system parameters is based on the

Table 2 Search space for the real problem

	Lower bound	*Upper bound*
m (ton)	460	716
k_0 *(N/mm)*	8354	18996
k_1*(N/mm)*	604	1119
Q (kN)	40	77
ζ *(%)*	0	5

minimization of the distance between the recorded and simulated responses of the building to the earthquake. Available are the horizontal input motion in terms of acceleration components measured at the basement of the building below the isolation surface, and the response of the roof and first floor of the building, just above the isolation system. Because the model used for the identification considers the superstructure as a rigid body, the simulated acceleration is compared to the average of the accelerations measured on the first floor and on the roof. The fitness of the solution, or error function, is defined as follows:

$$e^2 = \frac{\left[a_x - a_x^e, a_x - a_x^e\right]}{\left[a_y^e, a_y^e\right]} + \frac{\left[a_y - a_y^e, a_y - a_y^e\right]}{\left[a_y^e, a_y^e\right]} \quad (2)$$

where a_x, a_y, a_x^e, a_y^e are the acceleration components obtained from the numerical simulation and the earthquake response records. The inner product in Eq. (2) is defined as follows:

$$[a,b] = \sum_{i=1}^{N} a_i b_i = \sum_{i=1}^{N} a(t_i) b(t_i) \quad (3)$$

A first run of the CMA-ES led to a solution with an identification error e^2 = 0.0823 or 8.23%. However, two of the identified parameters were at their bounds. The mass, at 716 tons, was at the upper bound, while the initial stiffness k_0, at 8338 N/mm, was slightly below the lower bound. For this reason the search space was enlarged as shown in Table 3. This way the identified parameters are all well within the chosen bounds. It's worth observing that the initial stiffness k_0 is much lower than the values obtained from the identification of the static laboratory tests. This can be explained by the fact that the tests were performed at a much lower strain level than that experienced during the earthquake. On the other hand, the yielding stiffness k_1 is much larger than the one obtained from the static laboratory tests in 1996 and 2004. This can be explained by the fact that the tangent stiffness is generally larger in dynamic conditions than in static ones. The yield strength parameter Q was in all runs somewhat smaller than that obtained from the static laboratory tests; again this result can be attributed to the much larger strains experienced under the earthquake than in the laboratory. The identified mass was in all runs 16 to 36% greater than the reference value. Finally the

Table 3 Identified system in run 1 and new search space

	Identified	*Lower bound*	*Upper bound*
m (ton)	716.0	460	800
k_0 *(N/mm)*	8338.3	6000	18996
k_1*(N/mm)*	1102.3	604	1200
Q (kN)	44.4	40	77
ζ *(%)*	4.1	0	5

identified value of the structural damping resulted in a minimum value of 4.11% and a maximum value of 4.63%.

The quality of each solution is measured by the error function which, as shown in Table 4, is minimum in run 4 and maximum in run 1. Table 4 provides also information about the number of iterations in each run and also the iteration at which the minimum error was obtained. It should be noticed that 8 system response simulations are required at each iteration. The fittest 4 are then used to update the mean and the covariance matrix of the multivariate Gaussian distribution used to select the members of the next generation. Table 4 also includes the iteration at which the best fitness or least error was achieved.

Table 4 Performance of each identification run

	Run 1	*Run 2*	*Run 3*	*Run 4*
Iterations	86	122	100	72
Minimum error	0.0823 (iter.84)	0.0814 (iter.120)	0.0815 (iter.92)	0.0809 (iter.69)

The comparison between simulated and recorded accelerations is shown in Figures 5 and 6. Figure 5 (a) and 5 (b) show the NS and EW components of the first floor accelerations, while the NS and EW components of the roof accelerations are shown in Figure 6(a) 6 (b). Although the comparisons refer to the solution of best fitness, i.e. e^2 = 0.0809, almost the same plots are obtained for the other runs since the order of magnitude of the fitness is the same in all cases.

In order to appreciate the difference between the solutions produced in various runs some histories of selected response parameters are shown in the following. In Figure 7 the history of the yield force is shown in different colors for the four runs. It is obvious that the vertical lines between positive and negative yield loads correspond to phases of elastic behavior. The differences among the various solutions can be appreciated in terms of amplitude of the yield load. The histories of the restoring force in each isolator are shown in Figure 8 (a) and 8 (b) for the NS and EW directions respectively. The major differences among the solutions appear to be in terms of stiffness and peak force rather than of peak displacement. Finally the orbit of the relative motion of the isolation system is shown in Figure 9. It is worth noticing that the differences among the solutions barely emerge in the orbits. A statistical interpretation of the results may be worth considering, especially for cases in which the number of runs should assume a statistical significance. The solutions for each of the four runs are

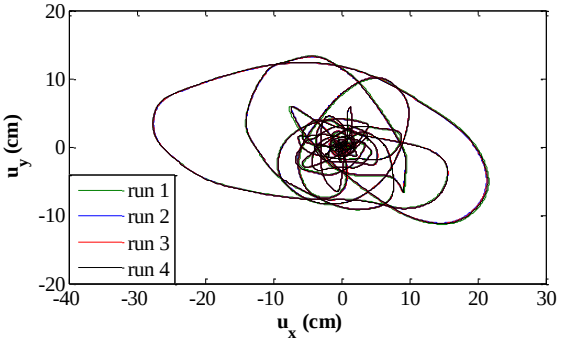

Figure 9 Orbit of the relative motion of the isolation system for all runs

shown in Table 5, while their average, standard deviation and coefficient of variation are shown in Table 6. For the initial stiffness only the coefficient of variation is almost 10%, while for all the other identified parameters it is in the range 5%-7%. It is reasonable to believe that for a large number of runs the coefficient of variation could become considerably smaller and the solution may be given a probabilistic structure.

5.2 Isolators with different properties

The manufacturing process of component materials and of the isolators themselves can hardly assure the identity of the mechanical properties of the isolators even when they are designed to be the same. Installing imperfections and damage during service can also contribute to the diversification of the mechanical properties from one unit to another. If each isolator has to be considered has having independent properties, the number of parameters to be identified can easily become quite large and the identification problem can become unmanageable. For the problem at hand, where there are three mechanical parameters to be identified for each isolator, the number of unknown parameters increases from 3 to 12. The computational time becomes exceedingly long and several computers may have to be committed to this single task. Preliminary runs have shown that a good match between simulated and recorded accelerations can be obtained by considering widely different values of the mechanical properties among the isolators. However the physical conditions did not point to such large diversification. This rose doubts about the well-posedness of the problem and whether the available data is sufficient to obtaining a realistic solution. In order to provide some insight in the problem a fictitious system with known properties was generated as follows. The isolators were numbered from 1 to 4, as shown in Figure 2, and given properties estimated from the 1994 test (isolator 1), the 2004 test in the X direction (isolator 2), the 2004 test in the Y direction (isolator 3) and the average value from the three previous estimates (isolator 4). The mass of the system was assumed as provided by the designer

and damping was set to 1%. The data specified above are shown in the second column of Table 7. In the third and fourth column of the same table the lower and upper bounds are shown, established on the base of a normal distribution with a 80% probability of the parameters being within the bounds. The bounds for the system mass were established by using a standard deviation equal to 10% of the mean, while the bounds for the damping ratio were arbitrarily chosen as 0 and 5%.

5.3 Minimum requirements for measured response

It has already been mentioned that dynamic identification is equivalent to the solution of an inverse problem whereby several systems can provide the same solution; therefore the solution of an inverse problem is generally not unique and only engineering judgment can help to select a physically acceptable solution among several ones that are mathematically feasible. Heuristically it may be thought that the more information is available, the closer one can get to the actual solution. However, one may enquire what is the minimal information required to obtain acceptable identification results. We argue that with a model like ours, characterized by three degrees of freedom, at least three independent acceleration components are required for the identification to converge to a physically acceptable solution. To verify this assumption a system simulation was run under the considered earthquake and the three independent acceleration components shown in Figure 10 (a) were calculated. These were assumed as the recorded system response under the earthquake and used for system identification. For comparison the two acceleration components at the center of mass, Figure 10 (b), were also calculated to be used as an alternative system identification. If our assumption is valid, the identification obtained by using the data of Figure 10 (a) should provide better results than the identification obtained by using the data acquired according to Figure 10 (b).

5.4 Results and comments

All together 7 runs were performed, 5 of which referring to the system response described in Figure 10 (a)

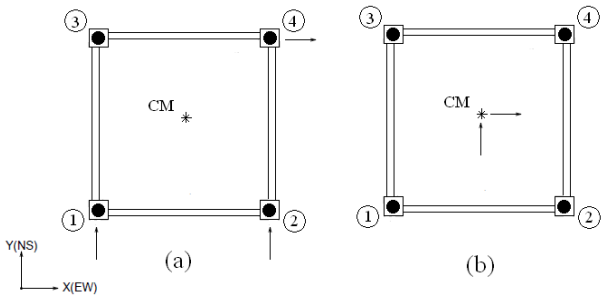

Figure 10 System identification using (a) 3, and (b) 2 acceleration components

and 2 concerned with the system response sketched in Figure 10 (b). The results of runs 1,2,3,4,6 are shown in Table 8 in terms of errors of the identified parameters. Before commenting on the errors it is worth mentioning some general features. On the first row of the table, besides the number characterizing the run, the total population λ is shown along with the number μ of the fittest members retained as parents for the next generation. It may be worth noticing how the results of section 5.1 were obtained with the couple (μ,λ)=(4,8), while in the present application two different settings have been used: (μ,λ)=(5,11) which is the default setting for CMA-ES and (μ,λ)=(11,22), used in an attempt to get closer to the real solution. The use of a larger population results in a much larger number of fitness (error) evaluations and in the exploration of a larger area of the search space. By looking at the last row of Table 8, where the best fitness obtained in each run is shown along with the iteration in which that fitness was obtained, it may be observed that the best fitness was obtained with the larger population. In general we may expect that the best results should be those in run 6, where the smallest fitness (error) is obtained, followed by those in run 3. However, a large population does not always lead to better results because the worst fitness is obtained in run 4, which is characterized by a large population. The next worst solution is obtained in run 2 where the default population was used. A very important point that needs to be emphasized is that the best fitness or minimum error results also in the least error for the system parameters, as may be seen from the row above the last where the average of the absolute value of the error on all the identified parameters is shown. It is true that the average of the absolute errors for run 3 is smaller than that for run 6, but the difference in fitness is very small in the two cases. Another point worth noticing is that the error on individual parameters can be positive or negative, that is the value of the parameter can be approached from above or from below. Although the best fitness value would indicate that run 6 provides the best solution, the error on each parameter and the average of the absolute value of the errors tells us that run 3 is the one providing the best approximation to the real solution. However, in a real situation we would know the best fitness but not the error on the individual parameters. The results of runs 5 and 7, obtained from only two acceleration components of the response, are shown in Table

Table 8 Error (%) on identified parameters when 3 components of acceleration are used in the identification

9. In these cases only the default population was used and the fitness obtained is comparable to the worse results of the previous case, i.e. in the order of 10^{-4}. The mean value of the absolute error on the individual parameters is also comparable to the worse results of the previous case. In general one would be tempted to conclude that better results are obtained by using three independent acceleration components of the response rather than just two. However, the comparison is unfair for two reasons. Only two runs are considered in the second case against five in the first, and a larger population is used in three out of five runs in the first case against none out of two runs in the second. At this point the results should be considered inconclusive until a fair comparison can be made by using the same number of runs and the same population size in both cases.

6. CONCLUSIONS

The dynamic identification of base isolation systems from earthquake response acceleration records has been considered. A mathematical model based on a Mixed Lagrangian Formulation presented at CUEE_12 has been used as the theoretical basis for the prediction of the dynamic response of the system. The model parameters are the basic unknowns of the identification procedure, which is based on the optimal match between the response recorded during the earthquake and the simulated response by means of the mechanical model. While it may be easy to simulate the response of a given system and to find a measure of the distance between recorded and simulated response, it may be difficult to guide the process of generating a new system that provides a better match than previous ones and eventually converge to the actual or optimal system. This task is performed by a state-of-the-art algorithm denoted "Covariance Matrix Adaptation – Evolution Strategy" or simply CMA-ES. Although the identification has been carried out for a very simple base isolation system composed of only four identical isolators, the exercise has given rise to a series of problems that need to be solved if the dynamic identification of such systems is to be of any use in practice. The first problem is in terms of computational time. The simulation of the response of a single isolation system to a given earthquake motion takes a given time depending on the complexity of the system. However, the identification process requires the simulation of the response of a large number of base isolation systems, and therefore the computational time can easily become very large, even for the simple system considered in this work. This problem can be handled by parallel computing by which a number of processors can be used at the same time to perform different tasks of the same problem. The CMA-ES algorithm is already predisposed for parallel applications but this capability was not exploited in the present study. A second problem concerns the possibility of solutions characterized by unrealistic system parameters but a very good match between recorded and simulated response. Understanding why these situations arise and how to handle them is an obvious and interesting problem. An answer lies in the very nature of the identification problem which, being an inverse problem, can admit multiple solutions. A possible barrier to unsuitable system parameters may be devised by defining suitable search spaces where physically admissible system parameters can be found. The barrier is obviously provided by the boundary of the search space. In the applications of the present work the construction of the search space was aided by the identification of laboratory tests performed on the isolators constituting the isolation system considered. Another problem is given by the possible incompleteness of the measured data. In order to define without ambiguity the

configuration of the system considered, which is modeled as a three degrees of freedom system, three independent kinematic response parameters (displacements, velocities or accelerations) are needed; if we only have two of them we do not have a unique configuration and a multiplicity of systems could produce the same response. An experiment has been carried out within this study to verify whether the assumption is correct or defective; the results are so far inconclusive but the direction to pursue in order to obtain a clear answer seems well defined. In conclusion it can be said that one identification run is not sufficient to provide reliable results, even when the problems outlined above have been handled with care. Several runs are generally necessary which at best can all provide the same results, but in general do not. The solution is therefore provided in probabilistic terms with a mean vector of system parameters, the standard deviation and the coefficient of variation. The smaller is the standard deviation and the associated coefficient of variation, the more accurate is the solution obtained. For the case considered, the elastic stiffness k_0 evaluated from system identification is considerably lower than the one obtained from laboratory tests. The yield strength parameter Q is also considerably smaller than the value obtained from laboratory tests. In both cases the discrepancy can be attributed to the considerably different strain level in the two cases (much larger under the earthquake than during the laboratory tests). The post yielding stiffness k_1 obtained from system identification is much larger than that identified from laboratory tests. The discrepancy is justified by the fact that dynamic tests always provide larger values of this parameter than static tests do.

Abstract: In the past few decades, the concept of "base-isolation" has been adopted as a practical strategy for earthquake-resistant design. Many base-isolated structures use 2 types of devices: one with high compressive strength and low lateral stiffness (e.g. rubber bearings) and the other with high energy dissipation capacity (e.g. U-dampers). U-shaped steel dampers are a relatively new system, therefore the previous research involves only the basic behavior under 1D dynamic loading test (Kishiki 2008) and 2D static loading test with circular and elliptical patterns (Takayama 2012). These studies proposed a fatigue evaluation curve using the cumulative damage index D_2 and the index for torsion-induced reduction of the cyclic deformation capacity J_f. The present study focuses on assessing the behavior under 2D random loading histories and establishing whether the results agree with the previously proposed relationship. This objective was achieved by conducting 2 sets of experimental tests: (1) 2D dynamic random loading test (UCSD) and (2) 2D static random loading test (Tokyo Tech). The results show the following: (1) all the specimens fracture after meeting the minimum requirements given by the D_2-J_f relationship; (2) Tokyo Tech test results agree with those from UCSD test, which proves that loading speed has negligible effect on the U-dampers' hysteresis curves.

1. INTRODUCTION

The present study focuses on the fatigue behavior of U-dampers as energy dissipating elements during a seismic event. The main goal of the present paper is to assess whether the fatigue evaluation curve D_2-J_f defined in (Takayama 2012) can be applied to estimate the damage induced by a two-dimensional seismic excitation. In order to do that, the first step was to establish a set of realistic loading histories (named "orbits") by conducting appropriate response analysis as described in (Ene 2012). Using these orbits, two sets of experimental tests were performed as summarized in **Table 3**. In the following, the obtained results are explained and compared to each other.

2. FATIGUE EVALUATION CURVE

The algorithm and formulae for computing the damage index D_2 and J_f index are described in (Takayama 2012) and summarized below.

The first step for the computation of D_2 induced by a 2D orbit is to compute the damage index of the dampers on X (**Eq. (1a)**) and the one of those on Y direction (**Eq. (1b)**) by using Miner's rule. This is done by summing up the damage at 0º and 90º for each direction. The total damage index D_2 will be the maximum value (**Eq. (2)**).

$$D_{2_X} = \sum_i \frac{1}{N^{0^\circ}_{fX,i}} + \sum_i \frac{1}{N^{90^\circ}_{fY,i}} \tag{1a}$$

$$D_{2_Y} = \sum_i \frac{1}{N^{0^\circ}_{fY,i}} + \sum_i \frac{1}{N^{90^\circ}_{fX,i}} \tag{1b}$$

$$D_2 = \max(D_{2_X}, D_{2_Y}) \tag{2}$$

where:
D_{2_X} – damage index for dampers parallel to X axis;
D_{2_Y} – damage index for dampers parallel to Y axis;
$N^{0^\circ}_{fX,i}$ – number of cycles to fracture for amplitude A_i selected when applying the displacement on X (for dampers parallel to X);
$N^{90^\circ}_{fY,i}$ – number of cycles to fracture for amplitude A_i selected when applying the displacement on Y (for dampers parallel to X);
D_2 – total damage index.

$$J_f = \sum_{i=1}^{n} \left(\gamma_i \cdot \gamma_{i+1} \cdot \frac{\gamma_i + \gamma_{i+1}}{2} \cdot \left| \Delta\varphi_i \right| \right) \qquad (3)$$

where:

$\gamma_i = \frac{R_i}{H}$ is the ratio between the radius at step "i" and the height of the damper element (**Figure 1**);

$\Delta\varphi_i$ infinitesimal angle between 2 consecutive steps

n total number of steps in the input orbit.

Using these 2 indices, the fatigue evaluation curve is defined as:

$$D_2 = \begin{cases} 1 & \text{if } J_f \le 15 \\ 1.6 - 0.04 \cdot J_f & \text{if } 15 < J_f \le 30 \\ 0.4 & \text{if } 30 < J_f \end{cases} \qquad (4)$$

3. SETUP

The basic concept of the setup is the same for both tests: specimen is loaded by inducing at its bottom part a given displacement history – dynamically for UCSD test, statically for Tokyo Tech test – while its upper part is kept fixed.

The setup for the static loading test is shown in **Figure 2**. The moving table is acted upon by two orthogonal horizontal jacks that control the input orbit. The reaction block keeps the upper part of the specimen fixed and prevents it from tilting.

3. PARAMETERS OF ANALYSIS AND ANALYTICAL RESULTS

The target parameter for both dynamic and static test is the input orbit. The set of orbits has been established by conducting 2D response analysis on a single mass system with 2 degrees of freedom and bilinear behavior (Figure **5**). The response of the system is determined by using Multiple Shear Spring model (MSS) (**Figure 4**). Using this analytical model and the fatigue evaluation curve, preliminary analysis was conducted for El Centro, Hachinohe, JMA Sendai and Kobe records. By looking at the results shown in **Figure 6**, one can easily notice that the damage produced by the original records is very small. That is why a maximum displacement limit of 400mm was set, in accordance to typical design criteria for base-isolated structures in Japan. Thus, each seismic record has been assessed a suitable amplification factor in order to reach this value. Moreover, since the limit capacity of the actuators in the UCSD facility is 8m of cumulative displacement, some of the records had to be trimmed or divided into two parts.

As input data, 21 seismic records were used and, function of the value of the damage index D_2 and of the shape of the orbit, 14 of them were selected to be conducted in the dynamic test (**Table 3**) (Ene 2012).

4. LOADING HISTORIES AND RESULTS OF THE DYNAMIC LOADING TEST

The specimens used in UCSD test consist of 4 units of 4 U50 and 2 units of 8 U50 (**Table 3**). The geometric characteristics of U40 and U50 elements are given in Table **1**.

According to Miner's rule, a specimen fractures when the damage index D_2 reaches 1.0. By looking at the values of the damage indices listed in **Table 2**, one can understand that it takes several earthquakes to reach the fracture of a specimen. Hence, a sequence of seismic events is required in order to load one specimen up to fracture. This will be called a "loading protocol".

The 14 orbits obtained by conducting response analysis are organized into 4 loading protocols. Theoretically, one loading protocol ends when it intersects the fatigue evaluation curve because that is considered to be the point where the specimen reaches fracture. However, in practice, the specimens proved to be able to take a larger number of cycles. The objectives of the loading protocols as well as the main observations during the test are listed in **Table 3**. The obtained results show that, with the exception of unit UD4 which was able to resist considerably longer than expected, all the data points are situated on the conservative side, relatively close to the fatigue evaluation curve. The latter represents, thus, the lower bound of the data set, therefore it can be stated that the proposed fatigue evaluation curve is suitable to estimate the amount of damage induced by seismic excitation.

5. LOADING HISTORIES AND RESULTS OF THE STATIC LOADING TEST

The specimens for the static loading test consist of 4 units of 4 U40 (**Table 3**). Since the size of the U-damper elements in this test (U40) is different from the one used in the dynamic loading test (U50), in order to be able to compare the two sets of results, the orbits were scaled down with factor r:

$$r = \frac{H_{U40}}{H_{U50}} \cdot d_{\max} \qquad (5)$$

where: H_{U40}, H_{U50} heights of U40, U50
$d_{\max}$ maximum displacement in UCSD test (400mm).

Because loading random orbits using Tokyo Tech's facilities is time-consuming and difficult to conduct, the number of data points for each input orbit has been reduced and part of the small amplitude cycles was disregarded. The orbits obtained after applying this and **Eq. (5)** are further on referred to as "simplified orbits". The loading protocols for the static loading test are summarized in **Table 3**, and are, generally, the same with the ones used in UCSD test.

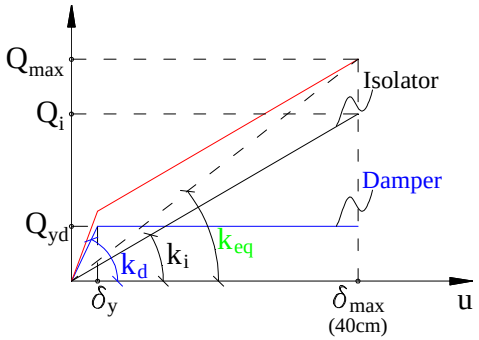

Figure 5 Behavior of the analytical model

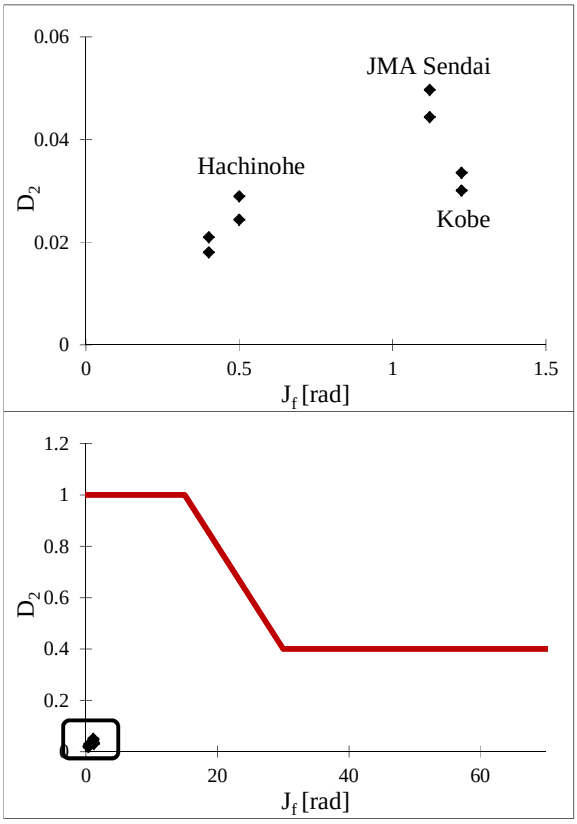

Figure 6 Results of the preliminary analysis

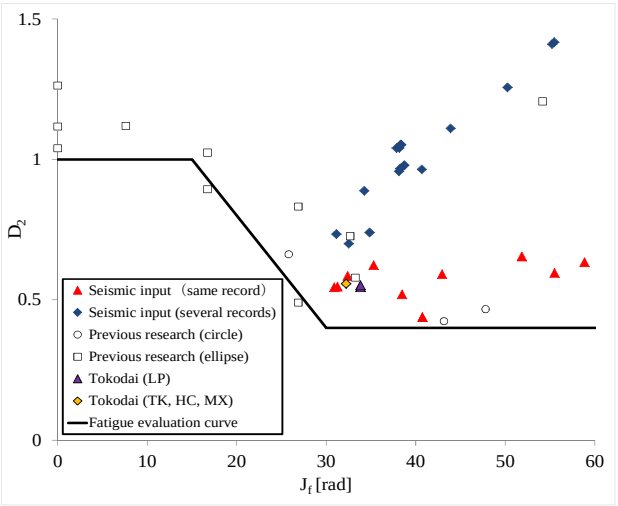

Figure 7 Fatigue evaluation curve and fracture points

5. COMPARISON BETWEEN THE TWO SETS OF RESULTS

As stated above, the main objective of the present study is to investigate the hysteresis behavior and the deformation capacity of U-dampers under 2D random loading histories. Hence, the most representative results are the force-deformation relationships for each specimen.

In order to be able to compare the hysteresis curves from the two sets of tests one needs to take into consideration the fact that different damper sizes have been used. This is done by calibrating the data in the static test as it follows:

a. Displacement is multiplied with scale factor s_{f1} :

$$s_{f1} = \frac{h_{U50}}{h_{U40}} = 1.450 \qquad (6)$$

b. Force is multiplied with scale factor s_{f2}:

$$s_{f2} = \frac{Q_{y_U50}}{Q_{y_U40}} = 2.030 \qquad (7)$$

where Q_{y_U50} is the yileding force of U50 damper size found in UCSD test

Q_{y_U40} is the yileding force of U40 damper size found in Tokyo Tech test

In Figure **8** are plotted the results obtained by applying **Eq. (6)** and **(7)** to the data in the static test against the original data in the dynamic test, both for the first set of (Takatori, Hachinohe, Mexico). In Figure **9** the same data types are plotted for the units loaded with Loma Prieta input orbit. Based on these graphics, one can state that the shape of the hysteresis curves in UCSD test agrees well with that in Tokyo Tech test. The slightly larger differences in Figure **9** are more noticeable because the simplified version of Loma Prieta orbit neglects a considerable part of the small amplitude cycles in the dynamic orbit in order to reduce the difficulty and the loading time during the test.

Overall, the results show that the loading speed has negligible effect on the force-deformation relationships for U-dampers.

5. CONCLUSIONS

The results of the two tests can be summarized in the following conclusions:

1) The relationship between the damage index D_2 and fracture index J_f (Takayama 2012) provides a conservative and sufficiently accurate estimation for the damage induced by earthquake excitation.
2) The force-deformation curves for the dynamic and static tests have almost the same shape which proves that the loading speed has negligible effect on the fatigue behavior of U-dampers.

Abstract: This paper presents component tests of two all-steel buckling-restrained braces (BRBs) to examine the effect of unbonding materials on their low-cycle fatigue performance. The axial loading history consisted of the variable strain amplitude and the constant strain amplitude. Test results showed that the BRB with the unbonding material has a better low-cycle fatigue capacity than the BRB without the unbonding material. Unbonding materials can reduce the friction coefficient between the core brace member (BM) and the restraining members (RMs). The gradually stripping of oxygen films of the BM and the RMs increases the friction coefficient and the unbonding material can also prevent the core brace from wear. The friction between the BM and the RMs causes the concentration and accumulation of negative plastic deformations in the middle region and positive plastic deformations in the end region. The accumulation of plastic deformations is significant, when the friction is large enough.

1. INTRODUCTION

Buckling-restrained braces (BRBs) are one of the structural components with excellent hysteretic behavior, which have found widespread applications in the US, Japan, Taiwan and elsewhere (Uang *et al.*, 2004; Tsai *et al.*, 2004). Wakabayashi *et al.* (1973) developed a pioneering system with a flat steel plate sandwiched between a pair of precast reinforced concrete panels, and a layer of epoxy resin and silicon resin was covered over the steel plate to reduce the friction between the steel plate and the concrete panels. Watanabe *et al.* (1988) conducted tests on BRBs with the core members coated with the concrete encased in a steel tube, using vinyl/mastic tape to permit the transverse expansion due to the effect of Poisson's ratio and to avoid the adhesion between the steel core and the restraining concrete. Until now, some possible unbonding materials (e.g. epoxy resin, silicon resin, vinyl tapes, etc.) have been widely employed (Black *et al.*, 2002; Tsai *et al.*, 2004). Especially, Tsai *et al.* (2004) tested ten BRBs with the different unbonding materials and found that a 2-mm thick silicon rubber sheet has the least axial load difference for the proposed BRB.

However, pouring and curing of the concrete rise the manufacturing costs of BRBs. As an alternative, all-steel BRBs have been developed (Tsai *et al.*, 2004; Trembly *et al.*, 2006; Usami *et al.*, 2008, Chou and Chen, 2010). Iwata (2004) studied all-steel BRBs without the unbonding materials and found they finally fractured as a result of the continued progress of the plastic deformation. Tremblay *et al.* (2006) compared the performance of the conventional BRBs with all-steel BRBs without the unbonding material. The results indicated that it is necessary to minimize the friction and satisfy the uniform strain demand in the brace core. Recently, in the experiment presented in the literature (Chou and Chen, 2010), a small air gap, replacing the unbonding material, was used between the brace member and the steel restraining tubes. Test results showed the small air gap does not affect the cyclic behavior of the proposed BRB.

It is obvious that additional experiments are needed to further investigate the necessity of the unbonding materials. In this paper, two BRB specimens with the same dimensions are employed to estimate the effect of the unbonding material on the low-cycle fatigue performance of the all-steel BRB. Their difference is one specimen with the unbonding material, a type of butyl rubber, and another without the unbonding material, instead of a small air gap.

2. TEST PROGRAM

2.1 Specimens

As shown in Figure 1, the employed BRB consists of a steel plate brace member (BM), a pair of steel restraining members (RMs) and a pair of steel fillers. The end ribs are welded on the steel plate to increase the out-of-plane stiffness of the end region. The stopper is set by enlarging the width of the brace member at the center. Specimen A-2.0, has a 1-mm thick air gap, and specimen U-2.0 employed the unbonding material, a 1-mm thick butyl rubber, on four sides of the BM.

Figure 2 gives the nominal geometric dimensions of the BM and Table 1 lists some corresponding measured geometric dimensions. As shown in Figure 3, the BM is inserted between a pair of RMs connected by the

high-strength bolts through two filler members. The out-of-plane and in-plane gaps d and d_0, respectively, are between the BM and the RMs or filler members. Table 2 provides the actual values of the gap widths.

Specimen	Actual gap width (mm)	
	Out-of-plane d	In-plane d_0
A-2.0	0.94	0.97
U-2.0	0.97	1.01

2.2 Test Setup and Loading Pattern

The specimen was vertically mounted on the Material Test System (MTS) by high-strength bolts. A hydraulic actuator with a loading capacity of 1000 kN and with a displacement capacity of +/-75mm was used for the cyclic loading, which was displacement-controlled via a linear variable displacement transducer mounted on the actuator.

As show in Figure 4, the test programs consisted of two phases, including the variable strain amplitude (VSA) loading and the constant strain amplitude (CSA) loading. At the beginning, four cycles with the strain amplitude of $0.75\varepsilon_y$ were adopted to measure the initial axial stiffness of the specimens within the elastic stage. Subsequently, the loading was imposed at the target brace strain amplitude (the yielding segment deformation δ divided by its length L_b) of 0.5, 1.0, 1.5, 2.0, 2.5 and 3.0% (two cycles at each strain level). The second phase was the CSA loading with the constant strain amplitude of 2.0%.

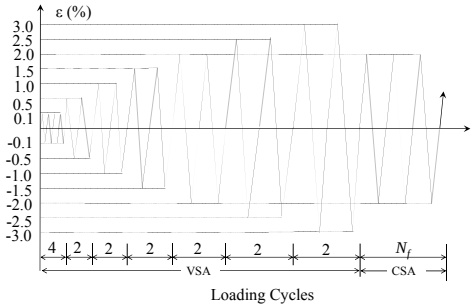

Figure 4. Strain-controlled loading pattern

3. TEST RESULTS

3.1 Hysteretic Curves

The stress-strain relations of the two specimens are presented in Figures 5 and 6. They exhibit stable behavior without any signs of degradation until the 45th and the 53rd cycles of the CSA loading, respectively. It can be concluded from the different failure cycle numbers that specimen U-2.0 has a better low-cycle fatigue properties due to the existence of the unbonding material.

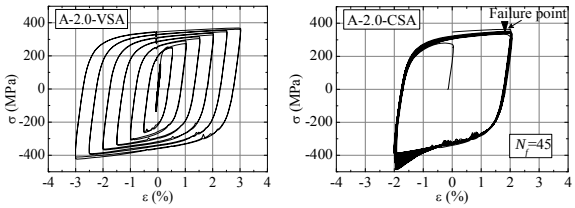

Figure 5 Stress-strain curve of A-2.0

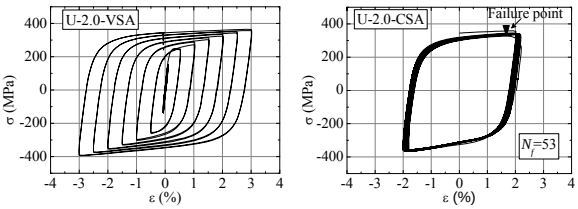

Figure 6 Stress-strain curve of U-2.0

It can be seen in Figure 5 that the tension behavior and compression behavior of specimen A-2.0 are severely asymmetry. The maximum compressive force of BRBs is generally greater than the tensile force, due to the friction and the Poisson's effect (Tsai *et al.*, 2004). The axial load difference Γ is defined as:

$$\Gamma = \frac{P_{\max} - T_{\max}}{T_{\max}} \quad (1)$$

where P_{max} and T_{max} are the maximum compressive and tensile brace forces at a same absolute axial deformation level.

Figure 7 provides the Γ values of the two specimens except for the first cycle of the two phases, which are significantly influenced by strain-hardening effect. During the VSA loading, the Γ values of the two specimens both increase as the strain becomes larger. It is because that the friction between the BM and the RMs increases as the normal contact force between the BM and the RMs enlarges. However, the Γ values of specimen A-2.0 increase more rapidly than those of specimen U-2.0. It can be concluded that the unbonding material can reduce the friction coefficient between the BM and the RMs. When it comes to the CSA, The Γ values of Specimen U-2.0 remain steady. However, the Γ values of Specimen A-2.0 increase much higher with the load imposing on it. The maximum Γ value of Specimen A-2.0 before fracture is 42.7%, which is exceeding the recommended value of 30% (AISC, 2010). The excessive Γ value could bring the unbalanced force to structures under earthquake.

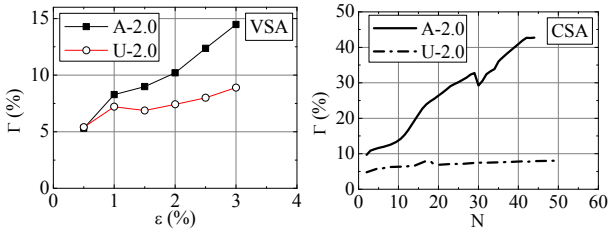

Figure 7 Axial loading difference under cyclic loading

It can be inferred that the friction between the BM and RMs of specimen A-2.0 gradually increases, even though the strain retains constant. As shown in Figure 8, the polishing of the surface and the absence of surface oxygen films were observed after the test in the BM of specimen A-2.0. The removal of the surface oxygen films from the brace member could amplify the coefficient of kinetic friction for several times, due to the greater molecular interaction and adhesion between the surface of the BM and the RMs, as discussed in the literature (Bowden amd Hunghes, 1939). The stripping of surface oxygen films in specimen A-2.0 was gradually happened due to the friction between the BM and the RMs, while this phenomenon was not found in specimen U-2.0 which is protected and lubricated by unbonding materials. So, without polishing and wear, the friction between the BM and RMs will not increase rapidly during the CSV loading. Unbonding materials can limit the Γ value of all-steel BRBs in an acceptable level. In addition, unbonding materials can prevent the BM from wear, which allows all-steel BRBs to suffer three strong earthquakes without severe damage and replacement (Usami *et al.*, 2007).

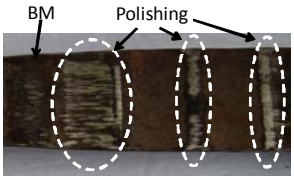

Figure 8 The absence of oxygen films after the test

3.2 Failure Mode

The failure modes of the two specimens are presented in Figures 9 and 10. These figures show that the brace's failure was induced by the crack initiating from the weld toes of the ribs. Reduction of the section area was found at the center of the brace member of specimen A-2.0 and there is not the same phenomenon in specimen U-2.0. Besides, a few subtle cracks were found near the stopper in specimen U-2.0.

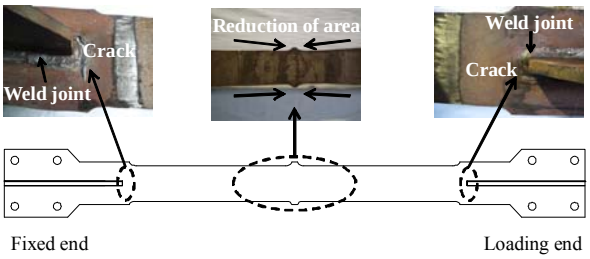

Figure 9 Failure mode of A-2.0

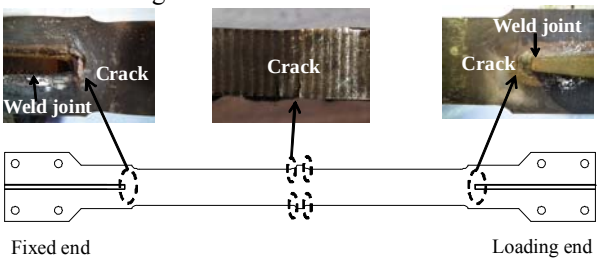

Figure 10 Failure mode of U-2.0

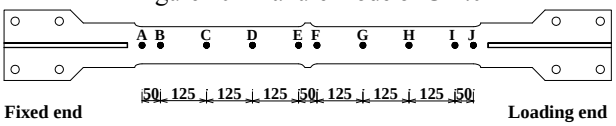

Figure 11 The locations of measured points in specific brace regions

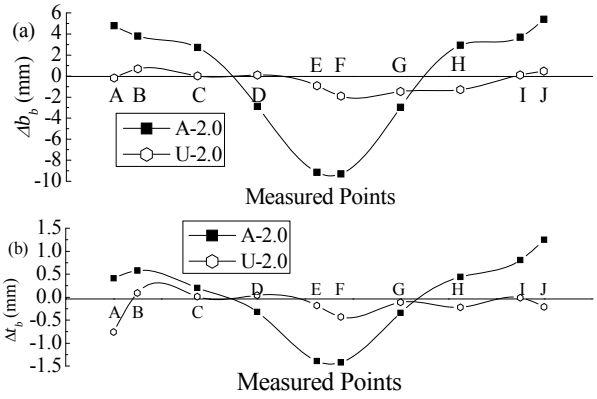

Figure 12 The brace residual transverse deformations of the two specimens (a) in the direction of the width; (b) in the direction of the thickness

After tests, the brace members were examined and residual transverse dimensions were measured along the brace yielding segment (points A-J in Figure 11). The fabrication errors of the brace member are controlled within 0.2mm for the width and 0.05mm for the thickness, so the initial average width (b_b) and thickness (t_b) of the brace member are used to calculate the brace residual transverse deformations. The brace residual transverse deformations are showed in Figure 12.

These observations indicate that, in specimen A-2.0, the middle region of the yielding segment shrunk and the end region of the yielding segment expanded obviously after the test, while the residual deformations of specimen U-2.0 are irregular and relatively small. The reason for the residual deformations in specimen A-2.0 could be the large friction between the BM and the RMs. Figure 13 shows the friction between the BM and the RMs under compression in the influence of the stopper. Then the axial force in the end region of the yielding segment F_e and the axial force at the middle region of the yielding segment F_m can be calculated as:

Under compression:

$$F_e=P \quad (2)$$

$$F_m=P-f_p \quad (3)$$

Where P is the axial force imposed on the specimen by the actuator under compression; f_p is the friction force between the BM and the RMs under compression.

Under compression, F_e is larger than F_m due to friction, so the section of the end region of the yielding segment expanded much more than that of the middle region of the yielding segment. And when it came to tension, the stress of the middle region of the yielding segment is higher than that of the end region due to the smaller section area. As a consequence, the middle region of the yielding segment developed more residual transverse deformation in tension.

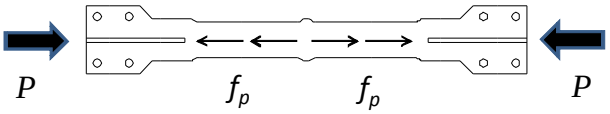

Figure 13 The friction between the BM and the RMs under compression

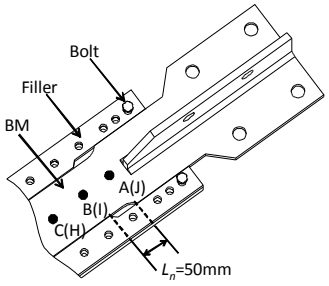

Figure 14 Details of the assemblage in the end region

What's more, in specimen A-2.0, the brace residual transverse deformations in the width direction of the measured points A, B, C, H, I and J exceeded the constrained dimension, which is twice the in plane gap width d_0 (0.97mm). As shown in Figure 14, points A and J lie in the in-plane unrestrained region (L_n), so the two sections can expand freely under compression. However, if the width of the restrained region (points B, C, H and I) expands more than twice the in plane gap width d_0, the BM would squeeze into the RMs. If the squeezing force is large enough, the filler will move aside slightly, allowing larger expansion of the section of points B, C, H and I. The squeezing force could intense the phenomenon that F_e is larger than F_m, encouraging more pronounced concentration and accumulation of negative and positive plastic deformations in specific brace regions. The concentration deformations in the end region of the yielding segment also enlarge the squeezing force, which forms a vicious circle. The squeezing force not only contributes to the residual deformation of all-steel BRBs, but also enlarges the axial load different. Lager in-plane width is needed to avoid the squeezing force. However, the comparable tests showed that unbonding materials can avoid the squeezing force and decrease the demands of the in-plane gap width.

4. CONCLUSIONS

Component tests of two BRB specimens was performed to examine the effect of unbonding materials on their low-cycle fatigue performance. The main results are summarized as follows:

(1) Test results showed that the BRB with the unbonding material has a better low-cycle fatigue capacity than the BRB without the unbonding material.

(2) Unbonding materials can reduce the friction coefficient between the BM and the RMs. The test of specimen A-2.0 show that the gradually stripping of oxygen films of the BM and the RMs increases the friction coefficient and the unbonding material can also prevent the BM from wear.

(3) The friction between BM and the RMs causes the concentration and accumulation of negative plastic deformations in the middle region and positive plastic deformations in the end region. The accumulation of plastic deformations is significant, when the friction is large enough.

(4) The in-plane squeezing force occurred between the BM and the fillers of the BRB without the unbonding material because of the excessive plastic deformation in the end region, which contributes to the large axial loading difference. The test of specimen U-2.0 showed that the unbonding material can avoid the squeezing force and decrease the in-plane gap width demand.

A NEW RESTRAINING SYSTEM FOR BUCKLING-RESTRAINED BRACES

Quan Chen Tao Li Chun-Lin Wang Shao-Ping Meng

Key Laboratory of Concrete and Prestressed Concrete Structures of the Ministry of Education, Southeast University, Nanjing China
quanchenseu@gmail.com; litaojinling@126.com; chunlin@seu.edu.cn; msp1960@vip.sina.com

Abstract: A new restraining system for Buckling-Restrained Brace (BRB) has been proposed in this paper. Its feature is that the steel plate core is partially sandwiched by the restraining system. The corresponding advantages include increasing the stiffness of the restraining system, enhancing the design flexibility and decreasing the self-weight of the brace. In order to investigate this new partial restraining mechanism, a relatively simple restraining system made of the multilayer steel plates, is presented. Component tests are conducted on three BRB specimens under the uniaxial quasi-static cyclic loading. Test results reveal that this type of BRB with proper details exhibits a stable cyclic behavior and cumulative inelastic ductility capacity, so it can serve as the effective hysteretic damper. Moreover, the failure mechanism is experimentally verified by investigating the ratio of the unrestrained width to the thickness of the core plate as an important design parameter. At last, some suggestions for the design of this BRB are summarized based on the experimental results and they are considered helpful to develop the similar BRBs.

1. INTRODUCTION

Buckling-restrained braces (BRBs), which exhibit stable and predictable hysteretic behavior both in tension and compression, are an attractive alternative to conventional steel braces. To ensure the performance of BRBs under earthquake loading, the AISC Seismic Provisions for Structural Steel Buildings (2010) recommend each tested brace to achieve ductility corresponding to 2.0 times the design story drift and a cumulative inelastic axial ductility capacity of 200 times the yield displacement. Component tests of BRBs have been conducted by numerous researchers (Black, *et al.*, 2002, Merritt, *et al.*, 2003, Wang, *et al.*, 2012). As shown in Table 1, the maximum and cumulative ductility requirements in these tests can be easily achieved, which are defined as (Fahnestock, *et al.*, 2007)

$$\mu_{max} = \frac{\Delta_{max}}{\Delta_{by}} = 2\frac{\Delta_{bm}}{\Delta_{by}} \approx 1.8C_d \tag{1}$$

$$\mu_c = \frac{\sum \Delta_i}{\Delta_{by}} \tag{2}$$

Where Δ_{max} is the brace maximum deformation, Δ_{by} is the brace yield deformation; Δ_{bm} is the brace deformation corresponding to design story drift; C_d is the displacement amplification factor; Δ_i is the brace inelastic deformation. What's more, previous large-scale tests of BRBFs developed failure modes that did not permit BRB ductility capacity to be fully utilized (Lin, *et al.*, 2011).

When BRBs are applied to bridge structures or large-span frame structures, the deflection dramatically grows and the construction becomes rather difficult. Therefore, the development of lightweight BRBs is essential. Moreover, lightweight BRBs have the potential to allow manual transport, lifting and connection of braces to the existing structures. In the past few years, several types of lightweight BRBs have been proposed to achieve weight savings against mortar-filled steel tubes. Tests of the BRB composed of an H-shaped core element and an external tube (Ju, *et al.*, 2009) show that global flexural buckling is the main failure mode. Another new type of aluminum alloy BRBs is proposed and its low-cycle fatigue performance has proved to be well in the experiment (Usami, *et al.*, 2012, Wang, *et al.*, 2013). What's more, Ultra-Lightweight BRBs (composed of BRBs, structural aluminum seismic dissipaters and FRP) is designed (Tinker and Dusicka 2012), reducing the weight by 59% to 76% of conventional BRBs.

Since conventional BRBs demonstrate much greater ductility capacity than needed, it is cost-efficient to develop lightweight BRBs by reducing the materials used in the restraining system with limited impact to the ductility capacity. Based on this idea, a new type of BRB as one example has been given in this paper, as shown in Figure 1. The new restraining system comprises four small steel tubes, a pair of steel fillers and a few connecting plates. The proposed restraining system can provide sufficient stiffness against the overall and local buckling of the BRBs with fewer materials.

In order to investigate this new partial restraining mechanism, this paper gives a relatively simple type of BRB made of the multilayer steel plates, which is convenient for manufacture. Tests of three BRB specimens with different

ratios of the unrestrained width to the thickness of the core plate are conducted to estimate the performance of the new restraining system.

2. TEST PROGRAM

2.1 Specimens

As shown in Figure 2, the employed all-steel BRB consists of a steel core plate, a pair of steel outer restraining plates, four steel inner restraining plates and a pair of steel fillers. End ribs are welded on the steel brace core to increase the out-of-plane stiffness of the end region. A stopper is set in the center by enlarging the width of the brace core.

The cross-section of the BRB is shown in Figure 3. The core plate is inserted between a pair of outer restraining plates and four steel inner restraining plates connected by the high-strength bolts through two filler plates. The unrestrained width of the core plate (b_u) is shown in Figure 3, which is an important factor for this type of BRB. Figure 4 gives the nominal geometric dimensions of the core plate and Table 2 lists some corresponding measured geometric dimensions. The three specimens have different values of b_u, which is illustrated in Table 2 along with the values of b_u/t.

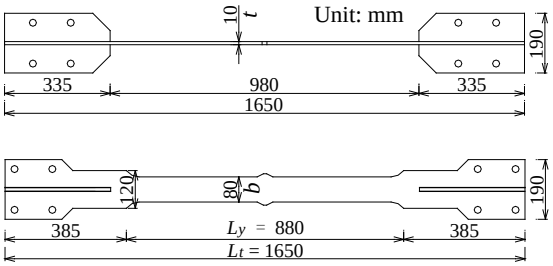

Figure 4 Dimensions of the Core Plate

Table 2 Geometric Dimensions of the Core Plate

Specimen	L_y (mm)	t (mm)	b (mm)	b_u (mm)	b_u/t
P1	879.5	9.68	79.81	0.00	0.00
P2	879.5	9.71	79.90	49.66	5.11
P3	879.5	9.72	79.80	69.94	7.19

Note: L_y is the length of yielding segment of the core plate; t and b are the thickness and the width of the core plate; b_u is the unrestrained width of the core plate.

2.2 Test Setup and Loading Pattern

The specimen is vertically mounted on the Material Test System (MTS) by high-strength bolts. A hydraulic actuator, with a loading capacity of 1000 kN and a displacement capacity of +/-75mm, is used for the cyclic loading, which is displacement-controlled via a linear variable displacement transducer mounted on the actuator.

As show in Figure 5, the test programs consisted of four main phases, including three identical variable strain amplitude (VSA) loadings and one constant strain amplitude (CSA) loading. Before the four main phases, four cycles with the strain amplitude (the yielding segment deformation δ divided by its length l_y) of $0.75\varepsilon_y$ are adopted to measure the initial axial stiffness of the specimens within the elastic

stage. Subsequently, the three VSA loadings are imposed at the target brace strain amplitude of 0.5%, 1.0%, 1.5%, 2.0%, 2.5% and 3.0% (three cycles at 0.5%, two cycles at the other strain levels). The fourth phase is the CSA loading with the constant strain amplitude of 2.0%. The three continuous VSA loadings are designated as VSA1, VSA2 and VSA3 hereinafter, respectively.

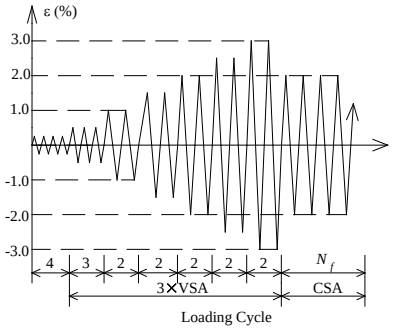

Figure 5 Strain-Controlled Loading Pattern

3. TEST RESULTS

3.1 Hysteretic Curves

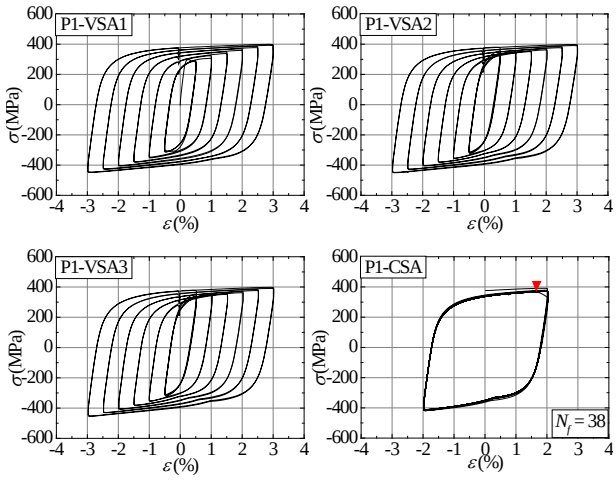

Figure 6 Stress-strain curve of Specimen P1

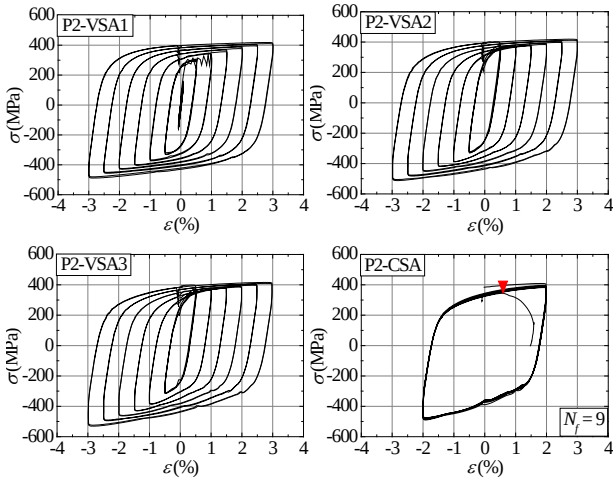

Figure 7 Stress-strain curve of Specimen P2

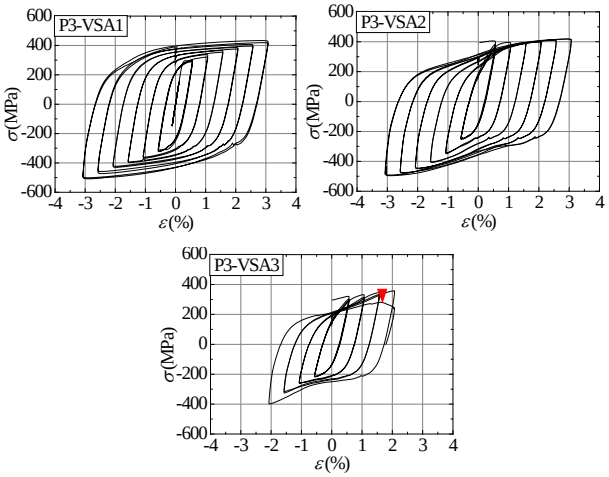

Figure 8 Stress-Strain Curve of Specimen P3

The stress-strain relationships of the three specimens are presented in Figures 6, 7 and 8. Specimen P1 and Specimen P2 exhibit stable behavior without any signs of degradation until the 39th and the 10th cycles of the CSA loading, respectively. Specimen P3 witnesses its failure at the second cycle of 2.0% during VSA3 loading.

3.2 Failure Mode

The failure modes of the three specimens are presented in Figures 9, 10 and 11. The fracture of specimen P1 is induced by the main crack initiating in the middle of the core plate besides the stopper. Other subtle cracks are also found in this region, where there is a stress concentration caused by the change of section and the great friction force applied by the restraining plates. Similarly, the main crack of specimen P2 is also in this region. What's different is that obvious out-of plane waves are found in the unrestrained region of specimen P2, especially in the end region of the core plate.

However, the out-of-plane waves of specimen P3 are so significant that the wave peak touches the outer restraining plates, as shown in Figure 11. Unlike the other two specimens, the main crack of specimen P3 initiates in the wave valley near both the loading end and the fixed end. The out-of-plane deformation will induce great bending strain in the wave valley, which contributes to the strain concentration in the core plate (Wang *et al.*, 2012). Therefore, specimen P3 fractured before the other two specimens. According to the test results, employing a b_u/t less than 5.1 can avoid excessive out-of-plane deformation and strain concentration in the core plate.

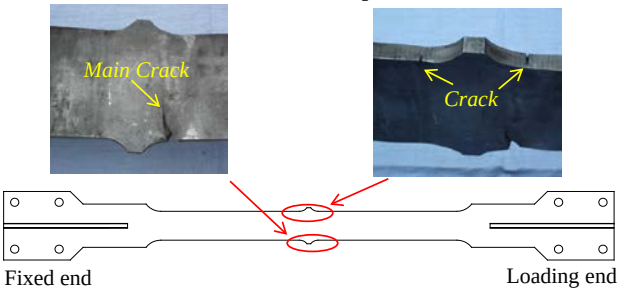

Figure 9 Failure Mode of Specimen P1

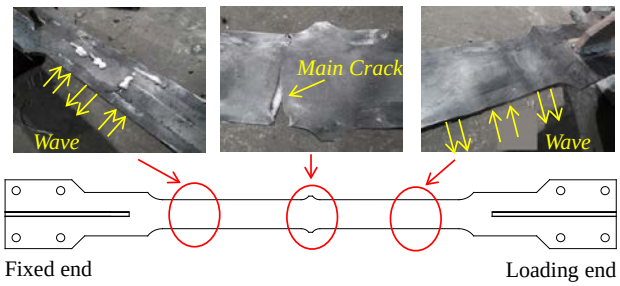

Figure 10 Failure Mode of Specimen P2

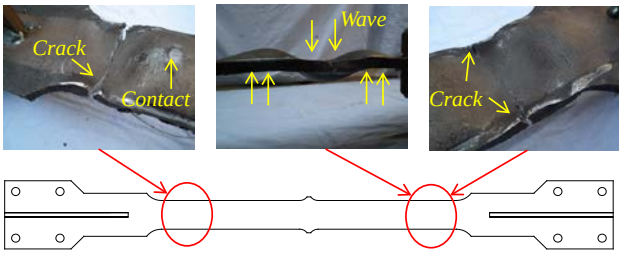

Figure 11 Failure Mode of Specimen P3

4. RESULT DISCUSSION

4.1 Compression strength adjustment factor

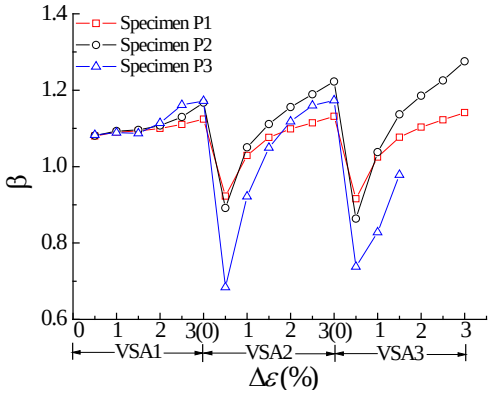
The compression strength adjustment factor is defined as (AISC, 2010)

$$\beta = T_{max} / P_{max} \quad (3)$$

Where T_{max} and P_{max} are the maximum tensile brace force and the maximum compressive brace force at an axial deformation level, respectively. The compression strength adjustment factors of all specimens (for the last cycle of each deformation level) during the three VSA loadings are presented in Figure 12. The β values of all the three specimens increase with the level of strain amplitude during each VSA loading.

During VSA1 loading, the β values of the three specimens remain stable at about 1.10 before the strain amplitude reaches 2.5%. Then the β values of specimen P2 and specimen P3 become greater than the β value of specimen P1 at large strain amplitudes, especially at 2.5% and 3.0%. This phenomenon is caused by the great friction force between the core plate and the inner restraining plates at large strain in Specimen P2 and P3. After test, gridding is found at the core plate of specimen P2 and specimen P3, which is illustrated in Figure 13. The great contact force in a small region of the core plate induces the gridding in spite of the protection of the unbonding materials, increasing the friction force between the core plate and the inner restraining plates. Nevertheless, the β values of the three specimens during the three VSA loadings are smaller than the limiting value of 1.3 in the AISC Seismic Provisions (2010).

It is noted that the β value of specimen P3 at 0.5% during VSA2 and VSA3 loadings lies below the β values of the other two specimens. The reason can be illustrated from the maximum compressive brace force (for the last cycle of each deformation level) during the three VSA loadings, which is plotted in Figure 14. The P_{max} values of specimen P1 and P2 at 0.5% during the three VSA loadings almost remain the same level (240kN-250kN), while the P_{max} value of specimen P3 drops to under 200kN at 0.5% during VSA2 and VSA3 loadings.



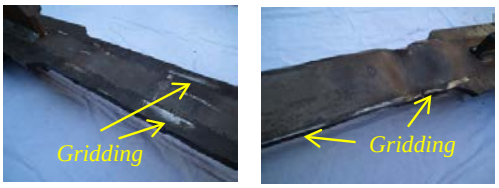


Figure 12 Compression Strength Adjustment Factor

(a) Specimen P2 (b) Specimen P3

Figure 13 Gridding of the brace plate

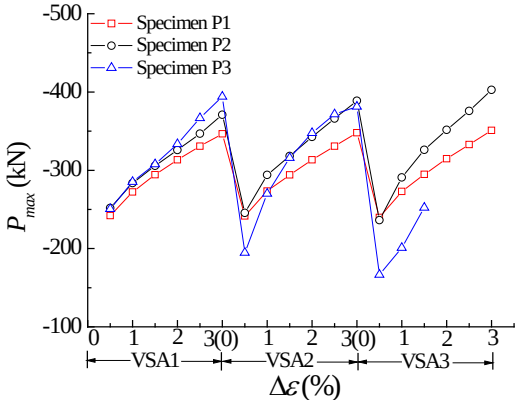

Figure 14 Maximum compressive brace force

4.2 Energy Dissipation and Ductility Capacity

The relationships between the hysteretic energy and cumulative deformation of the three specimens are shown in Figure 15. Specimen P1 has a great hysteretic energy of 1218 kN.m before fracture, while the value of specimen P2 and specimen P3 are only 760 kN.m and 437 kÑ.m, respectively. It is obvious that the low-cycle fatigue properties of the three specimens decrease with the growth of b_u/t. The hysteretic energy of specimen P2 is greater than that of specimen P1 at the same cumulative deformation, for the maximum compressive brace force of specimen P2 is larger at the same deformation level. In addition, the energy dissipation capacity of specimen P3 decreases slightly when the cumulative deformation reaches 1.7m.

All the three specimens reach a maximum ductility

capacity (μ_{max}) of 20.3, exceeding the requirement value (14.4) by the AISC Seismic Provisions (2010) for a response modification coefficient of 8. The cumulative ductility capacities (μ_c) of the three specimens are presented in Figure 16, which are 3489, 2068 and 1256, respectively. It is noted that though the μ_c values of specimen P2 and specimen P3 are much smaller than the value of specimen P1, they are significantly higher than that (200) required by the AISC Seismic Provisions (2010) for uniaxial testing.

4.3 Equivalent Viscous Damping

Equivalent viscous damping (ζ_{eq}) is an important factor for nonlinear analysis of structures, which is also an indicator to evaluate the plump degree of the hysteretic curves. Based on the hysteretic curves of the specimen, equivalent viscous damping of the BRBs can be calculated (Clough and Penzien, 1993) as

$$\zeta_{eq} = \frac{E_d}{4\pi(A_{AOB} + A_{COD})/2} \quad (4)$$

Where E_d is the energy dissipation per cycle; A_{AOB} and A_{COD} are the areas of the triangles, as shown in Figure 16.

The results during the three VSA loadings (for the last cycle of each deformation level) are plotted in Figure 17. The ζ_{eq} value of specimen P1 at the same deformation level remains stable during the three VSA loadings, while the ζ_{eq} value of specimen P2 at the same deformation level degrades gradually with the loading history. The degradation of ζ_{eq} value is more significant for specimen P3, which is coincident with the plump degree of the of the strain-stress curves in Figure 8.

5. CONCLUSIONS

Component tests of three BRB specimens are performed to investigate the performance of the new partial restraining mechanism. The main results are summarized as follows:

(1) The out-of-plane deformation of the BRB in the unrestrained region increases with the growth of b_u/t, which will eventually degrade the low fatigue properties of the BRB. Tests shows that employing a b_u/t less than 5.1 can avoid excessive out-of-plane deformation and strain concentration in the core plate. Nevertheless, the cumulative ductility capacities of the three specimens are sufficient for the requirements in the AISC Seismic Provisions (2010).

(2) Compared with conventional BRBs, the proposed BRBs have a greater compression strength adjustment factor, which is caused by the large contact force between the core plate and the inner restraining plates. In spite of that, the value is smaller than the limiting value of 1.3 in the AISC Seismic Provisions (2010).

(3) Equivalent viscous damping for the proposed BRBs decreases with the loading history and the increase of b_u/t.

Abstract: A new self-centering energy-dissipative brace is developed based on the all-steel buckling-restrained brace to control maximum and residual drift of frame structures subjected to several earthquakes. This energy-dissipative brace employs the steel prestressing tendons as the self-centering system. Therefore, it is called the all-steel self-centering buckling-restrained brace in this paper. To overcome this limitation of the elastic deformation of the prestressing tendons, an enhanced-elongation dual-tendon system has been designed. Theoretical study shows that this dual-tendon system allows for self-centering response over two times the range achieved with the original self-centering system with the prestressing tendons. Furthermore, when the initial prestressing force is larger than the given value, the performance of the self-centering buckling-restrained brace can be achieved. Based on the discussion, one possible realization of this system, which combines the merits of both self-centering devices and buckling-restrained braces, is presented. Numerical results show that if the length of the yielding segment of the steel core is decreased, the performance of the self-centering BRB is improved.

1. INTRODUCTION

To meet the performance-based design philosophy for the seismic design of structures, residual drift of structures should be diminished as much as it can be. Conventional buckling-restrained braces (BRBs) can dissipate energy via yielding of the steel core, but their residual deformations cannot be ignored due to the severe impacts on post-earthquake operation of structures. In some cases, it is much more expensive to repair the structure than to rebuild it due to too large residual deformation and drift. Then in recent years new types of braces aiming at controlling residual deformation and drift have been put forward, which utilized the prestressing tendons to press or pull back the braces so as to diminish the residual deformations of braces and dissipate seismic energy in the meantime. These braces with self-centering property demonstrate a flag-shaped hysteretic response. It means that they dissipate energy well and meanwhile deminish residual drifts of structures perfectly. One of the key points for designing these braces is that the tendons must be prestressed enough and keep in elastic state all over the working process. Otherwise the prestressed force will disappear progressively and self-centering aim cannot be achieved. So large enough elastic strength, elastic strain capacity and stiffness are essential requirements for choosing tendons. Previous studies have successfully adopted aramid polymer fibers (Chistopoulos *et al.* 2008) and E-glass fibers (CHOU *et al.* 2012) as prestressing tendons to press back the original friction energy dissipating braces, proposing new types of braces namely self-centering energy dissipating braces (SCEDs). Results of those studies show that SCEDs can evidently reduce seismic force in the base and the residual drift of the structures in comparison with those installing traditional steel braces in the same positions. However, despite of enough elastic deformation capacity, fibers are difficult to be anchored to the braces and the expenses of anchorages and fibers are relatively high, which extensively affect the applications of those SCEDs to the practical engineering. On the other hand, Zhu *et al.* (2008) exploited super-elastic shape memory alloys (SMAs) as prestressing tendons into SCED braces, and Miller *et al.* (2012) combined SMAs with BRB to develop a new kind of brace called self-centering buckling-restrained brace (SCBRB) for the first time. The two braces above can undergo much larger deformations due to SMAs' super-elasticity, but that SMAs are quite susceptible to temperature variation and their prices are usually much higher than other building materials brings about the same problem as fibers for application to practical engineering. Considering those facts mentioned above, Lu *et al.* (2012) developed a new kind of SCBRB with steel prestressing tendons as the prestressing system. But the braces' deformation capacity is confined in a small scope due to the limitation of elastic strain capacity of the steel prestressing tendons.

In the present paper, a new self-centering buckling-restrained brace with an enhanced-elongation dual-tendon system is developed on the base of the abovementioned

researches and the experimental studies on BRBs that our research group has done. The steel prestressing tendons are chosen as the self-centering system for their relatively high elastic strength, enough stiffness and easy anchoring, along with one realistic superiority for their acceptable expense. Because the components of this SCBRB are all steel materials, it is called the all-steel self-centering buckling-restrained brace in this paper. According to the material experiment, the extreme elastic elongation of prestressing steel tendons is about 0.80%, from which point unloading residual strain is less than 0.02%. To extend SCBRB's extreme elongation capacity, dual-tendons are installed in parallel, actually connected in series by a floating intermediate steel member at working. This paper will first describe the characterization of conventional SCBRBs, then the mechanism of an enhanced-elongation dual-tendon self-centering system and the configuration of this dual-tendon SCBRBs. Finally, a numeral parameter study is conducted on the dual-tendon SCBRBs to evaluate the performance under a cyclic loading.

2. MECHANICS OF SCBRB

2.1 Component Characterization

A conventional SCBRB is commonly composed of two components: a BRB and a self-centering system. The hysteretic response of BRB is shown in Figure 1, which is obtained in experiments of our research group on BRBs. From the hysteretic response, one conclusion can be drawn that BRB demonstrate excellent energy dissipation property and its restoring force model for numeral simulation can be depicted in Figure 2.

The self-centering system's composing elements are mainly prestressing tendons which provide re-centering force and steel tubes or plates passing on inner force. In fact, all the self-centering systems with different tendons such as fibers, SMA rods or wires and steel prestressing tendons can be explained by the same schematic diagram as illustrated in Figure 3. Because tendons need to be prestressed during assembly, the self-centering system will get some compressive deformation before uploading external load as shown in Figure 3(a). The compressive formation u_{ys} can be defined as follows:

$$u_{ys} = \frac{F_0}{K_1 + K_2} \tag{1}$$

Where F_0 is the prestressing force for the system and K_1, K_2 are the two elements' axial stiffness respectively. In most cases, u_{ys} is relatively small for the elements are usually steel tubes with relatively large stiffness. The allover loading process is divided into two stages with a turning point that is when the system's deformation gets back to zero under the external load F_{ys} as shown in Figure 3(b), which can be defined as follows:

$$F_{ys} = \left(K_1 + K_2 + K_s\right) \times u_{ys} \tag{2}$$

Where K_s is the tendon's stiffness. Once the system's deformation returns to zero, the two elements begin to move relative to each other, leaving a gap between them and the tendons kept on elongating. This results in the system's stiffness changing from K_1+K_2+K_s to the tendon's stiffness K_s. When the system is in compression, the same case happens as in tension.

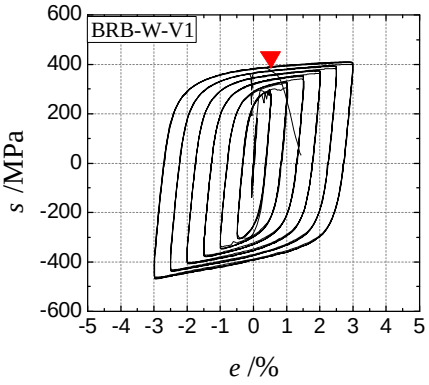

Figure 1 Hysteretic response of BRB specimen

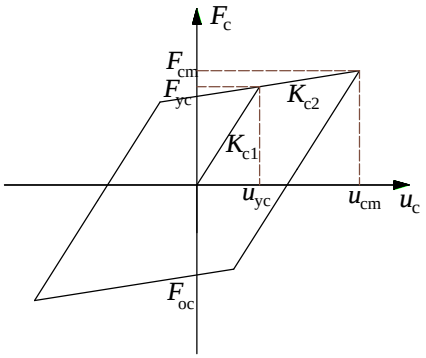

Figure 2 Restoring Force Model of BRB

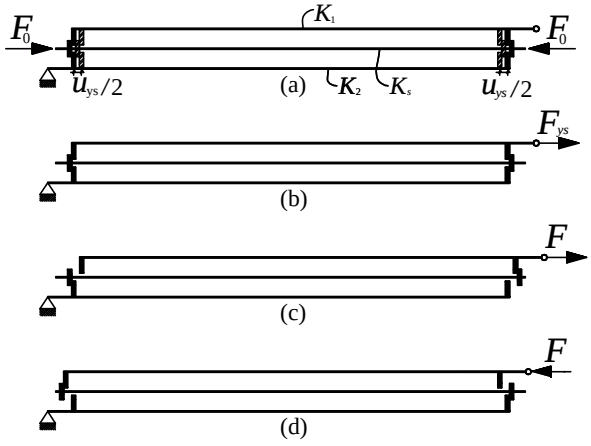

Figure 3 Sketch of Self-Centering System

On the other hand, because K_1+K_2+K_s is greater than K_1+K_2, the turning point external force F_{ys} is reasonably greater than the prestressed force F_0, which will be exploited in latter formula derivation in this paper. When the elements of the self-centering system begin to move relatively, the system's stiffness gets changed like the system got yielded at the point (u_{ys}, F_{ys}). No matter the system is in tension or in compression, this behavior is symmetric. So the restoring force model of self-centering system can be illustrated as Figure 4, where u_m is the maximum elastic deformation of

the self-centering system. And u_m is decided by the elastic deformation capability of prestressing tendons. Besides, there is one fact that the post-yielding stiffness of the system during compression is the stiffness of the two elements and tendons in series. It is a bit different from K_s in tension for the load transferring route on the elements is not the same as that in tension. But as the stiffness of the two elements is relatively quite large, the post-yielding stiffness in compression is almost equivalent to K_s. This will explain the tiny difference of the SCBRBs' numerical response in compression and tension. Figure 5 shows the stress-strain relation of the prestressing tendon employed in this paper. The largest elastic deformation of the prestressing tendon is about 0.8%.

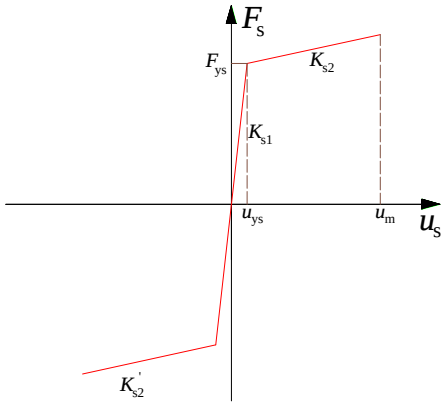

Figure 4 Restoring Force Model of Self-Centering System

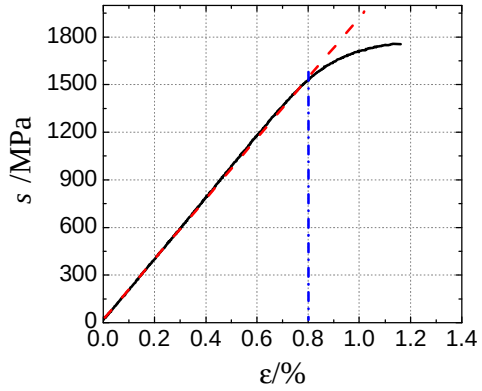

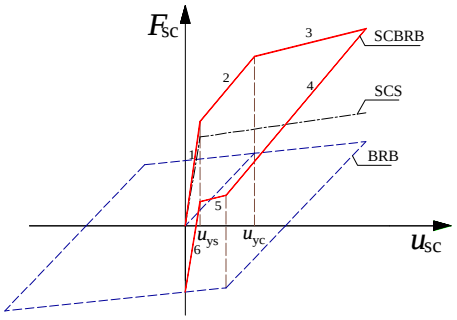

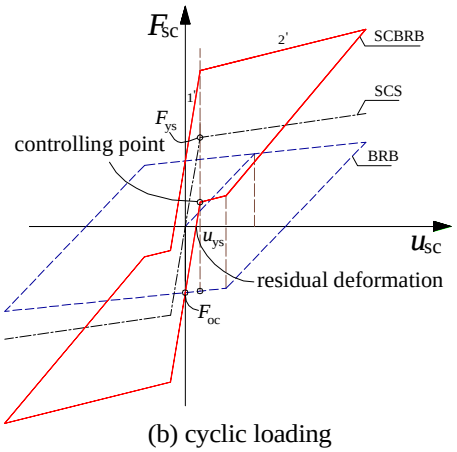

Figure 5 Stress-Strain Relation of Prestressing Tendon

2.2 SCBRB Mechanics

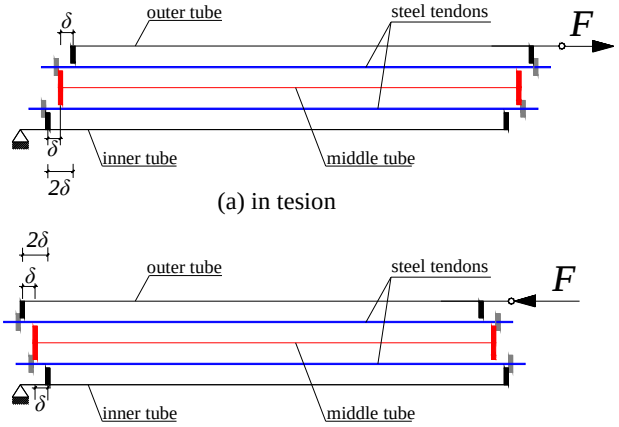
A SCBRB is realized when installing a self-centering system in parallel with a BRB. As the self-centering system and BRB is configured to bear external load jointly any time, the restoring force model of SCBRB is the superposition of them and can be divided into two stages due to the different states that BRB gets during first loading and cyclic loading(see Figure 6). When it is on the first loading procedure, the restoring force curve of SCBRB(see in Figure 6(a)) is composed of three fold lines with two turning points: self-centering system's yielding(u_{ys}, F_{ys}) and BRB's yielding (u_{yc}, F_{yc}); If on the cyclic loading procedure, its stiffness will change only once from the superposition of self-centering system's pre-yielding stiffness and BRB's post-yielding stiffness to that of both components' post-yielding stiffness(as shown in Figure 6(b)). As for unloading stage, the SCBRB's stiffness is just the same superposition of the two components.

(a) first loading

(b) cyclic loading

Figure 6 Restoring Force Model of Self-Centering BRB

Because of the restoring force that self-centering system provides, SCBRB demonstrates a flag-shaped hysteric response with much smaller residual deformation and identical energy dissipating capability as the original BRB. To guarantee this self-centering performance, the controlling point in Figure 6(b) is a key factor for designing the SCBRBs: if the controlling point is greater than zero, the residual deformation will be smaller than u_{ys}, which should be quite a small data due to the relatively large stiffness of elements in self-centering system. Now that the residual deformation is less than u_{ys}, it is convinced that self-centering aim has been achieved for the SCBRB. So in order to keep the controlling point greater than zero, F_{ys} should be greater than F_{oc}. On the other hand, F_{ys} is greater than F_0, so if F_0 is kept greater than F_{oc}, the brace will get re-centered. In other words, when the initial prestressing force is larger than the given value based on the BRB core, the performance of the SCBRB can be achieved.



Based on the analysis above, the tendons in self-centering systems should get large enough elastic strength and modulus of elasticity to press or pull back the BRB core, and enough elastic deformation capacity to satisfy the braces' deformation requirement. Besides, the initial prestressing force of the tendons shouldn't be too large. Otherwise the tendons would be short of elastic deformation capability and get into plastic state due to over-tension. And

consequently, self-centering performance would not be achieved due to the loss of prestressing force in tendons.

3. DESIGN OF DOUAL-TENDON SELF-CENTERING SYSTEM

3.1 Dual-Tendon Self-Centering System

The steel prestressing tendon is in some way a good option as prestressing tendons in SCBRBs for its stable performance such as large enough yielding strength and modulus of elasticity, also for relatively more feasible anchoring. But its elastic deformation capability is only about 0.8% (as shown in Figure 5), setting a severe limitation to the SCBRB's deformation capability. To solve the abovementioned problem, this paper introduces a dual-tendon self-centering system to enhance the elongation of SCBRB with steel prestressing tendons. For the convenience to describe the design and configuration of the dual-tendon SCBRB, this paper will emphasize on a dual-tendon SCBRB with four steel prestressing tendons installed in series (two tendons in each set).

(a) in tesion

(b) in compression

Figure 7 Self-Centering System with Double Tendons

The dual-tendon self-centering system consists of three types of elements: three tubes (outer tube, middle tube and inner tube), two sets of steel prestressing tendons, two pairs of anchorages. As illustrated in Figure 7, one pair of anchor plates is sized to interact with the inner and middle tubes, while the other pair with the middle and outer tubes; the middle tube is not connected with any other elements but clamped by the anchor plates to a "floating" state and its role is to pass on inner force and make the two sets of tendons work in series. The one set of tendons elongates δ under external load, and then the dual-tendon self-centering system deforms 2δ, extending the system's deformation capability successfully.

3.2 SCBRB Configurations

Based on the dual-tendon self-centering system, a dual-tendon SCBRB with four steel prestressing tendons is developed in our research group. Its schematic assembly is illustrated in Figure 8. The inner tube and middle tube take an innovative role of not only passing on inner force but also restraining the BRB core from buckling. The BRB core is welded to inner tube on one end and bolted to the outer tube on the other end, with no abutting to the middle tube via interspaces and slots on the elements. Besides, the outer tube can protect the bolts on middle tube and the left-hand and right-hand joint members are the positions to connect to frame structures.

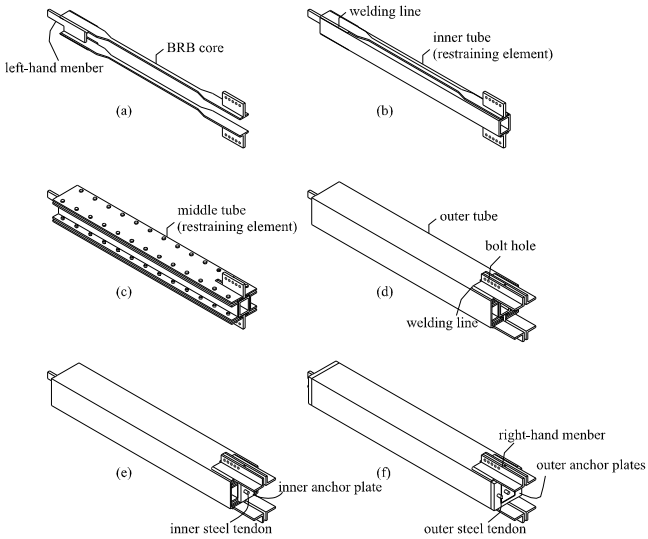


Figure 8 Configurations of All-Steel Self-Centering BRB

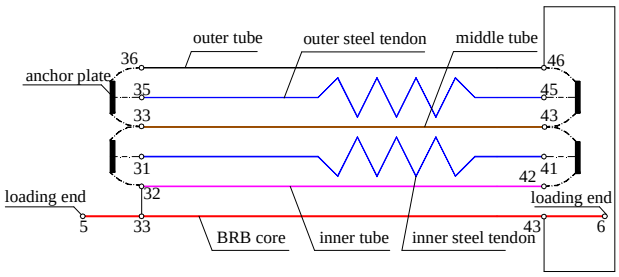
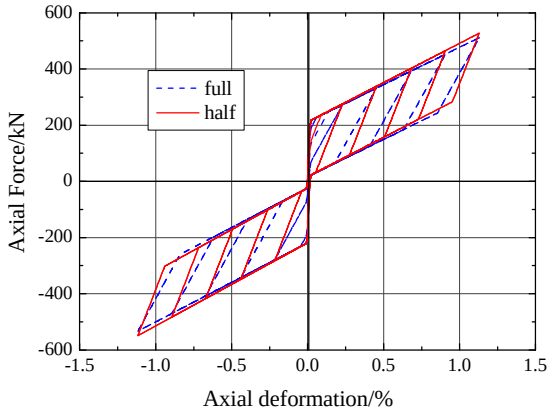
4. NUMERAL SIMULATION OF DOUAL-TENDON SCBRB

4.1 Numeral Model

A numeral model was created using OpenSees to simulate the SCBRB illustrated in the Figure 8. For a SCBRB, the design strength is defined as the summation of the BRB steel core yielding force and the initial prestressing force in the tendons. The SCBRBs simulated in this paper are designed with design strength of 200kN according to the abovementioned concept. Actually, the design strength should be in accordance with practical frame structures, but in order to testify the SCBRB's performance first, the design strength is supposed temporarily.

The schematic diagram of the model is shown in Figure 9.This numeral mode uses a nonlinear beam column element for the BRB core and loading ends, an elastic truss element for the three tubes. Because the steel tendon is not tensed out of its elastic stress all over the loading procedure, it is also modeled using an elastic truss element and the initial strain is imposed to it as pretension force. An elastic no-tension material truss element is exploited to represent the anchor plates for the fact that the anchor plates would be separated from the tubes in tension but get abutted during compression. As for the connection between BRB steel core and the inner and outer tubes, equaldolf command is used for them. And it is the same with the relationship between the two sets of steel tendons and the anchor plates. All material properties used in this model are based on results from experimental tests by our research group.





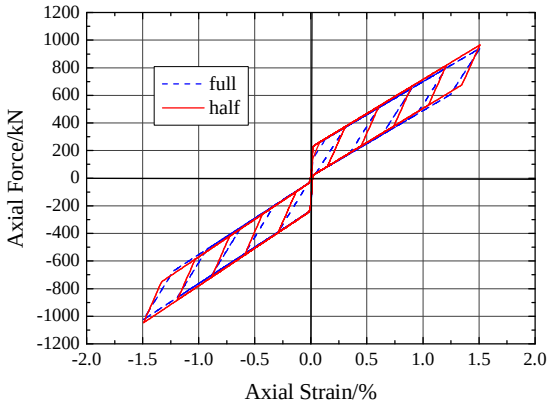


Figure 9 Opensees numerical model

4.2 Numeral Simulation Results

According to the analysis on self-centering system on section 2.2, the initial strain imposed to the two sets of steel tendons should be 0.227%. Since the extreme elastic strain of steel tendons is 0.8%, this dual-tendon SCBRB (with four steel tendons) can achieve an elongation of 1.15% (as shown in Figure 10(a)).

(a) Dual-tendon SCBRB with 2 steel tendons

(b) Dual-tendon SCBRB with 4 steel tendons

Figure 10 Numerical results

On the other hand, if installing four more steel tendons which means two sets of four steel tendons in series, the required initial strain would decrease to 0.113% and the dual-tendon SCBRB can achieve the elongation of 1.49% (as shown in Figure 10(b)). Both the dual-tendon SCBRBs display a full self-centering response. What's more, the length of the yielding segment of the steel core is changed as a parameter. The result is that the SCBRB with steel cores whose yielding segment is half of the brace's length dissipate energy better than that with yielding segment full of the brace's length. As for the extreme force of dual-tendon SCBRB, it is 570kN for the four-tendon brace and 1066kN for the eight-tendon brace. They are in accordance with the extreme force 551kN and 1050kN calculated by using the actual stiffness of each element.

5. CONCLUSIONS

In order to control maximum and residual drift of frame structures subjected to several earthquakes, an enhanced-elongation dual-tendon all steel SCBRB has been developed in this paper. The configuration and numeral simulation of this all-steel dual-tendon SCBRB is illustrated, with the following conclusions: (1) the dual-tendon self-centering system allows the SCBRB to deform twice the range achieved with the original self-centering system with the prestressing tendons, which can generally meet the requirement of traditional frame structures; (2) the key point of designing the SCBRB is to guarantee the initial prestressing force greater than the fixed value based on the steel core. (3) reducing the length of the yielding segment of the steel core can improve a SCBRB's energy-dissipating performance.

Abstract: A new type of steel plate shear wall has been devised which resists out-of-plane buckling without requiring stiffeners. The ring-shaped steel plate shear wall (RS-SPSW) includes a web plate that is cut with a pattern of holes leaving ring-shaped portions of steel connected by diagonal links. The ring shape resists out-of-plane buckling through the mechanics of how a circular ring deforms into an ellipse. It has been shown that the ring's compression diagonal will shorten a similar amount as the tension diagonal elongates, essentially eliminating the slack in the direction perpendicular to the tension field. Because of the unique features of the ring's mode of distortion, the load-deformation response of the resulting RS-SPSW system can exhibit full hysteretic behavior and possess greatly improved stiffness relative to thin unstiffened SPSW. Furthermore, through the introduction of more design variables associated with the geometry of the rings, it is possible to separately tune the strength, stiffness, and ductility of the RS-SPSW system. The RS-SPSW has been validated through testing on small panels, approximately 1 m x 1 m.

1. INTRODUCTION AND MOTIVATION

Steel plate shear walls (SPSW) have been used in numerous buildings as the primary seismic force resisting system for a variety of reasons ranging from reduced cost as compared to concrete shear walls, speed of construction, efficient use of slender wall elements, and minimal architectural wall thickness. As such, SPSW are an important option for seismic load resisting system.

The approach to SPSW design in Japan is inherently different than the form of SPSW used in the United States and Canada. Japanese SPSW as well as pre-1980's SPSW in the United States are designed so that the web plate does not buckle under shear loading (e.g. ENR 1978, Troy and Richard 1979). To prevent buckling, the web plates are stiffened at intermediate points across a shear panel as shown in Figure 1. The web plate undergoes shear yielding without buckling, resulting in substantial energy dissipation and primarily axial forces in the beams and columns.

Conversely, the fact that web plates have post-buckling capacity has been applied in plate girder design for decades (Basler 1961, Porter 1975). Upon buckling, a diagonal tension field develops in the plate, which, along with the boundary members, creates a truss-like system that can resist significant shear. Starting in the 1980's, steel plate shear walls that utilize tension field action were investigated (Thorburn et al. 1983; Timler and Kulak 1983; Tromposch and Kulak 1987). Since these systems allow thinner plates and do not require stiffeners, they can be cheaper, and thus have become more popular than their stiffened counterparts in the United States and Canada. A typical unstiffened steel plate shear wall is shown in Figure 2.

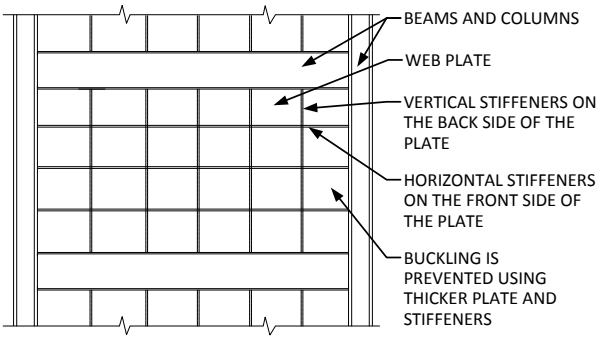

Figure 1 –Stiffened Steel Plate Shear Wall Used in Japan

Unstiffened steel plate shear walls consist of a web plate bounded at the sides by columns, also referred to as vertical boundary elements (VBE), and at the floor levels by beams, also referred to as horizontal boundary elements (HBE). The alternate nomenclature for beams and columns emphasizes the boundary element's role of resisting the tension field developed in the plate.

There are several challenges associated with unstiffened SPSW. The system is inherently challenged by the rivalry between the web plate and the boundary members. The web plate develops incredible strength in tension field action, but does so after buckling at a relatively small lateral load. In the design process, there is a desire to increase plate thickness to limit buckling and increase stiffness. However,

the boundary elements which are subjected to large inward acting forces associated with anchoring the tension field are required to be larger than an equivalent concentrically braced frame to elastically resist the combined axial forces and moments. It is desirable therefore to decrease the plate thickness to minimize the required boundary element sizes. The results of this balancing act are web plates that can be as thin as 1.3 mm and exceptionally large boundary element sizes.

Because of early buckling, SPSW web plates act like tension-only bracing with highly pinched hysteretic behavior, low stiffness, and limited energy dissipation. Current unstiffened SPSW are therefore designed in conjunction with moment connections which often requires even larger column sections and additional connection costs. In short, current unstiffened SPSW design suffers from inherent challenges associated with the buckling behavior that results in low stiffness, low energy dissipation, large boundary elements to resist the tension field, and costly moment connections.

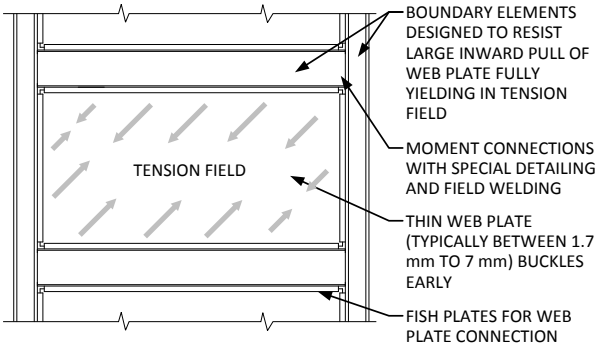

Figure 2 –Un-Stiffened Steel Plate Shear Wall Typical in Canada and the United States

A ring-shaped steel plate shear wall (RS-SPSW) has been devised which is capable of resisting buckling and producing the full hysteretic behavior of stiffened SPSW without requiring stiffeners. The concept for the RS-SPSW is developed in this paper including description of the deformation mode which resists buckling and analytical expressions for strength derived based on plastic mechanism analyses. Experimental tests are then described which are used to verify the expected behavior of the RS-SPSW as well as shed light on the two possible buckling modes and how to prevent them.

2. CONCEPT OF THE RING-SHAPED SPSW

The RS-SPSW consists of a SPSW in which the steel web plate is cut with a pattern of holes leaving ring-shaped portions of steel connected by diagonal links as shown in Figure 3. The ring shape resists out of plane buckling through the mechanics of how a circular ring deforms into an ellipse.

It will be demonstrated in the following paragraphs that the ring's compression diagonal will shorten a similar amount as the tension diagonal is elongating, essentially pulling the plate tight in the direction transverse to the tension, thus resisting the tendency for the plate to buckle. Because of the unique features of the ring's mode of distortion, the load-deformation behavior of the resulting RS-SPSW system can exhibit full hysteretic behavior. Reduced buckling also leads to greatly improved stiffness. Furthermore, through the introduction of more design variables associated with the geometry of the rings, it is possible to separately tune the strength, stiffness, and ductility of the RS-SPSW system. Effectively, the RS-SPSW system is a method for reducing the cost of the SPSW while improving the performance and design flexibility of a steel plate shear wall by strategically removing portions of the web plate.

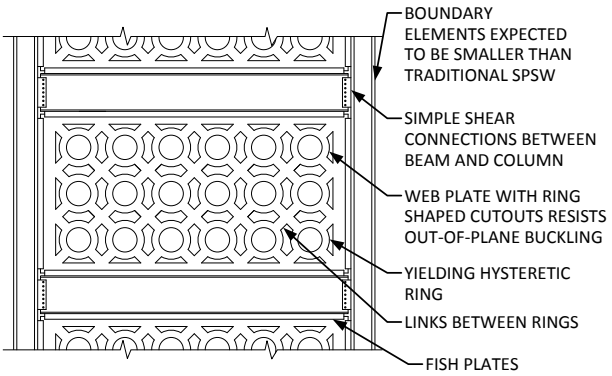

Figure 3 – Ring-Shaped Steel Plate Shear Wall (RS-SPSW)

The ring shape is the critical feature in resisting out-of-plane buckling. Consider one ring from the RS-SPSW panel and the equivalent portion of solid plate from a conventional SPSW panel as shown in Figure 4. As shear is applied to the wall, a diagonal tension is developed in both the ring and the solid plate. The amount of deformation along the tension diagonal is denoted by δ_1 in Figure 4. If the amount of shortening transverse to the tension direction is defined as δ_2, the relationship between δ_1 and δ_2 can be derived for the ring assuming that the perimeter stays constant. The approximate perimeter of an ellipse, $L_{per\text{-}ellipse}$, is given in Eq. (1) where R is the radius of the original circle. The perimeter of the original ring is given by Eq. (2), and when the two perimeters are set equal, the resulting relationship between δ_1 and δ_2 is found to be Eq. (3).

The relationship given by Eq. (3) is labeled as Ring in Figure 4c for an arbitrary value of the radius, R. Because the shortening in the transverse direction is equal to or greater than the elongation in the tension direction, the slack in the transverse direction is removed. That is, the material in the compression diagonal will shorten a similar amount as the tension diagonal is elongating, essentially pulling the plate taught in the transverse direction, thus resisting the tendency for the plate to buckle.

$$L_{per-ellipse} = 2\pi\sqrt{\frac{\left(R+\delta_1\right)^2+\left(R-\delta_2\right)^2}{2}} \quad (1)$$

$$L_{per-circle} = 2\pi R \quad (2)$$

$$\delta_2 = R - \frac{1}{2}\sqrt{4R^2 - 4\delta_1^2 - 8R\delta_1} \quad (3)$$

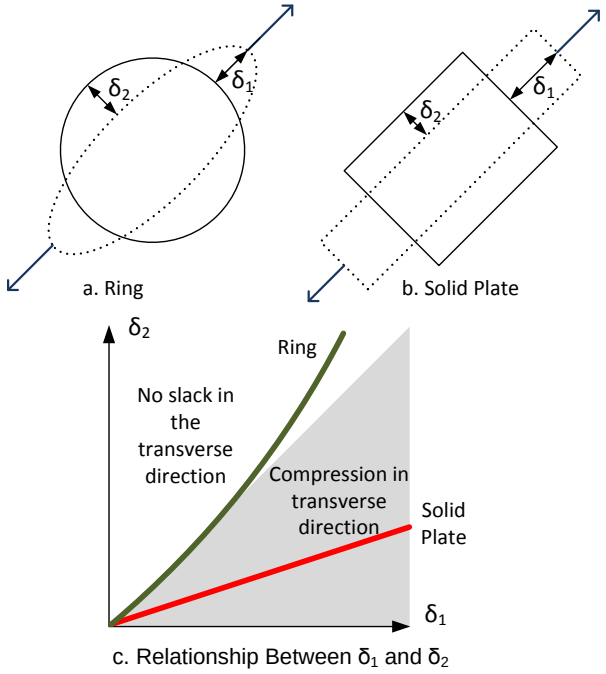

Figure 4 – Mechanics of Ring-Shaped Shear Wall Concept Demonstrating RS-SPSW Resistance to Buckling

The solid plate, on the other hand, experiences transverse shortening approximately equal to the longitudinal elongation multiplied by the Poisson's ratio. For steel, the Poisson's ratio is about 0.3 so the transverse shortening of the plate, δ_2, is approximately 30% of the elongation in the tension direction, δ_1, although this relationship may change when plasticity occurs. For an idealized SPSW panel deformed in pure shear (assuming rigid boundary elements and pinned connections), the elongation in the tension diagonal will equal the shortening of the compression diagonal. However, since the shortening of the solid plate material in the transverse direction is just a fraction of the elongation in the longitudinal direction, there is excess material in the transverse direction leading to buckling of the solid plate.

Preliminary analytical expressions for strength have been derived using plastic mechanism analysis (e.g. Bruneau et al 2011). Interaction between axial forces and flexure were neglected because the effects were generally found to be small (Maurya 2012). The first mechanism considered (shown in Figure 5b), assumes four plastic hinges will form at the intersection of the ring centerline and the centerline of the links connecting the rings. However, since the links have a discrete width, the plastic hinges are forced to occur at the edges of the link as shown in Mechanism 2 (Figure 5c).

The shear loads (horizontal component of the diagonal force) associated with Mechanism 1 (Q_1) and Mechanism 2 (Q_2) were derived in Maurya (2012) and are given by Eq. (5) and Eq. (6) respectively. Both equations are based on the geometry of the ring shown in Figure 5a including the centerline radius, R, the ring width, w_c, the link width, w_L, and the plate thickness, t. The plastic moment capacity, M_p, is given by Eq. (4) as a function of the plate yield strength, F_y. The shear capacity of a solid unstiffened steel plate shear wall, Q_{solid}, as derived in multiple references (e.g. Sabelli and Bruneau 2006), is provided in Eq. (7), and is a function of the web plate clear width, L_{cf}, and the tension field angle, α.

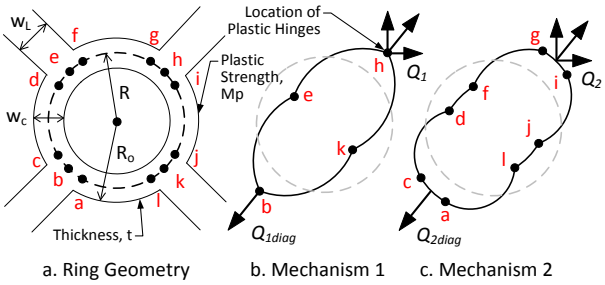

Figure 5 – Plastic Mechanism Analysis to Determine Shear Yield Capacity of the RS-SPSW

$$M_p = \frac{w_c^2 t}{4} F_y \quad (4)$$

$$Q_1 = \frac{2\sqrt{2}M_p}{R} \quad (5)$$

$$Q_2 = \frac{2\sqrt{2}M_p}{R - \frac{w_L}{2}} \quad (6)$$

$$Q_{Solid} = 0.5 F_y t L_{cf} \sin(2\alpha) \quad (7)$$

3. DESIGN OF THE EXPERIMENTAL STUDY

A series of experiments are being conducted at the Thomas M. Murray Structural Engineering Laboratory at Virginia Tech in the United States to validate the RS-SPSW concept, investigate the cyclic hysteretic behavior of these panels, verify strength predictions, and study the buckling modes associated with these plate configurations. The tests are performed on plates that are approximately one meter on each side. This size plate is adequate to investigate the behavior of full scale ring units.

3.1 Test Setup

The test setup shown in Figure 6 is designed to apply shear deformations to a steel plate. The free end shown on the left of Figure 6 is moved up and down using an MTS 243.60 actuator with a force capacity of 650 kN and 1015 kN in tension and compression respectively. The fixed end, shown on the right of Figure 6, is anchored to the strong floor. The web plate is sandwiched between angles on all four edges. The horizontal angles are attached to the vertical elements using 50 mm diameter steel pins. The horizontal angles therefore act as pinned struts that hold a constant distance between the pins creating an arc motion of the free side. Out-of-plane lateral bracing is provided for the actuator and at the middle of the W12x26 free end vertical element. The out-of-plane rotational stiffness of the fixed end reaction frame was considered adequate to restrain out-of-plane motion.

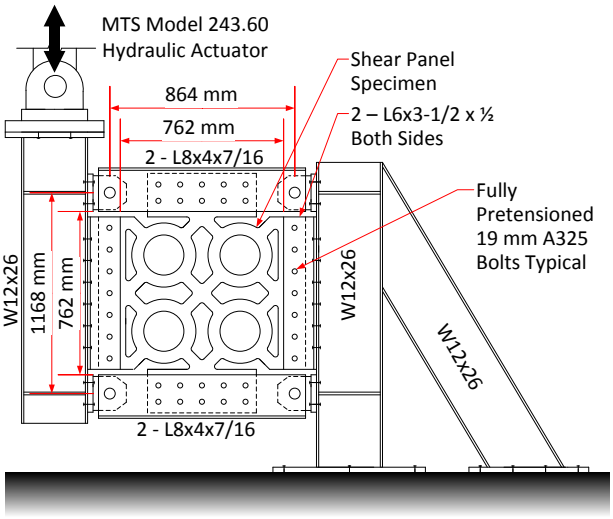

Figure 6 – Test Setup for Panel Shear Experiments

The instrumentation plan is shown schematically in Figure 7 as overlaid on a photograph of the test setup. The built-in actuator LVDT with 508 mm range was used to control the test. The ATC-24 loading protocol was utilized assuming a yield drift equal to 0.5% shear deformation over the 864 mm pin to pin distance. After testing specimen 1, the displacement protocol was amplified for all subsequent specimens by a factor of 1.3 to partially account for elastic deformations in the reaction frames.

A load cell with 1015 kN capacity was attached in line with the actuator. Four string potentiometers were used to measure the in-plane displacements of the test setup. String potentiometer 1 shown in Figure 7 measured the vertical displacement of the frame free end. Differences between the measurements of string potentiometer 1 and the actuator LVDT are due to elastic deformations of the actuator reaction frame. String potentiometers 2, 3, and 4 are used to compute the shear deformations of the web plate. Differences between the computed shear deformation and the displacement measured using string potentiometer 1 are due to deformations in the boundary elements, their connections, and fixed end reaction frame.

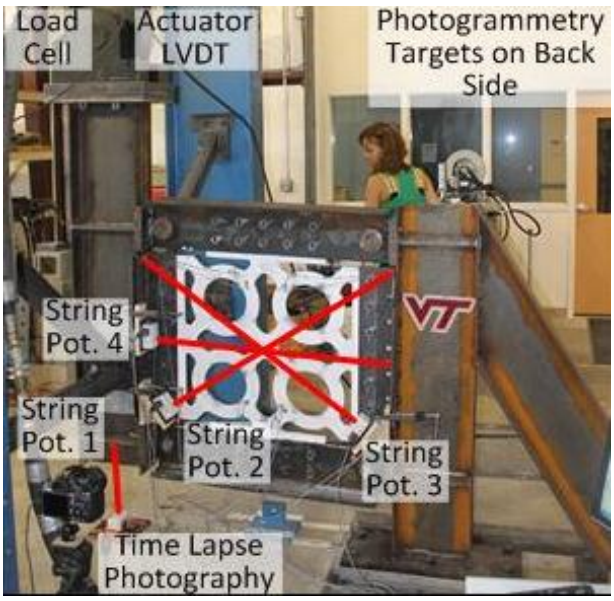

Figure 7 – Photograph of Test Setup with Instrumentation Plan Shown

Photogrammetry was used to track the out-of-plane displacement of the web plates. Data from photogrammetry is being used to understand the buckling modes of the RS-SPSW, identify the onset of buckling, and quantify the magnitudes of out-of-plane displacements. The photogrammetry targets are placed around the inside and outside perimeter of the rings and along the edges of the links connecting the rings. The photogrammetry process is conducted before the beginning of the test and at four times during the test. The photogrammetry targets are shown below in Figure 9, but the results are not discussed in detail in this paper.

3.2 Specimen Design and Fabrication

The test matrix is given in Table 1. The definitions of the outer ring radius, R_o, ring width, w_c, link width, w_L, and plate thickness, t, are shown in Figure 5a. Three nondimensional slenderness parameters are also given in Table 1. The ring slenderness as given by R_o/t and w_c/t are related to lateral torsional buckling of individual legs of the ring. Conversely, the global slenderness of the web plate as given by the ratio of the clear distance between panel supports (a=762 mm) to the panel thickness, t, is related to global shear buckling.

The test matrix was designed to separately study the effect of ring slenderness and global panel slenderness. Specimens 1, 3, and 4 have varying ring slenderness (R_o/t and w_c/t) and are thus intended to investigate the lateral torsional buckling of the ring legs. An unstiffened solid panel is tested for comparison that has significantly higher global panel slenderness to produce the same design shear

capacity. Specimens 1 through 4 are designed to have nominally the same shear capacity to isolate the differences in hysteretic behavior. Future tests will also vary panel slenderness (a/t) and will vary the ring width, w_c, for a fixed ring radius, R_o.

Table 1 – Test Matrix

	t (mm)	R_o (mm)	w_c (mm)	w_L (mm)	R_o / t	a / t	w_c / t
1	13	150	56	56	12	60	4.4
2	2	Solid Plate				400	--
3	13	300	112	112	24	60	8.8
4	13	100	37	37	8	60	2.9
Future Tests:							
5	6	150	46	56	24	120	7.2
6	6	150	56	56	24	120	8.8
7	10	100	37	37	10	80	3.9
8	6	100	37	37	16	120	5.9

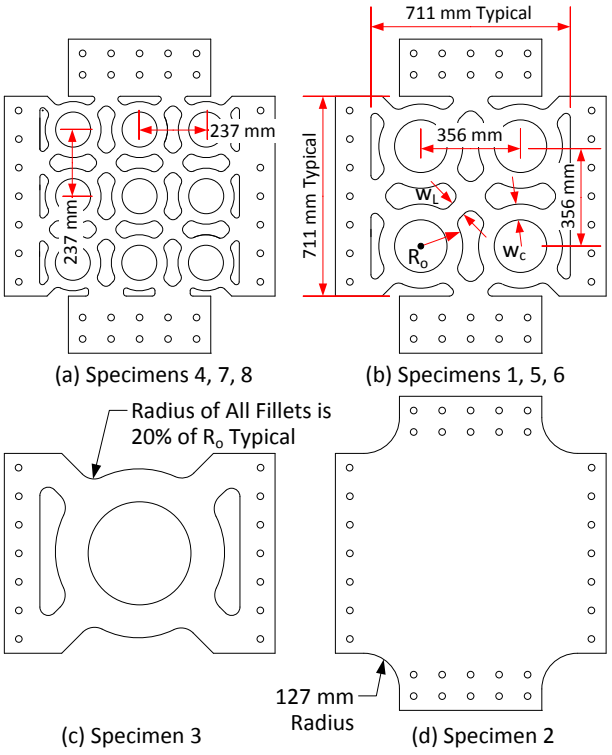

Figure 8 – Geometry of Test Specimens

The panels are shown graphically in Figure 8. The outside ring diameters vary from 100 mm to 300 mm and represent full scale rings that might be used in actual buildings. At the intersection of any two edges (e.g. the intersection of the outer perimeter of the ring and the link), the surface is rounded with a fillet that has a radius equal to 20% of the outside ring radius, R_o. This fillet radius was determined by finite element modeling to reduce the likelihood of fracture (Maurya 2012).

The ring shapes were made using water jet cutting with the highest quality setting. A photograph of the cut edge is shown in Figure 9. Cutting of the web plates to produce the RS-SPSW can be conducted using automated tools operated by computer numerical control (CNC) machines which are common in many fabrication and machine shops. Similarly, many machine shops have capabilities for water jet cutting or laser cutting. As an example, a machine shops near Virginia Tech has the ability to water jet cut sheets of steel as large as 12' x 20' at reasonable cost.

Figure 9 – Close-Up Photograph of Smooth Cut Surface Obtained Using Water Jet Cutting (Photogrammetry Targets Also Shown)

3.3 Material Behavior

Three tension coupons were conducted on the same material used for each plate thickness. All plate of a given thickness was obtained from the same heat (same batch of material). A representative plot of stress versus strain is provided in Figure 10 for both the 13 mm thick steel plate and the 2 mm thick steel plate. The measured yield stress was 331 MPa (48.0 ksi) for the 13 mm thick steel plate and 294 MPa (42.6 ksi) for the 2 mm thick steel sheet.

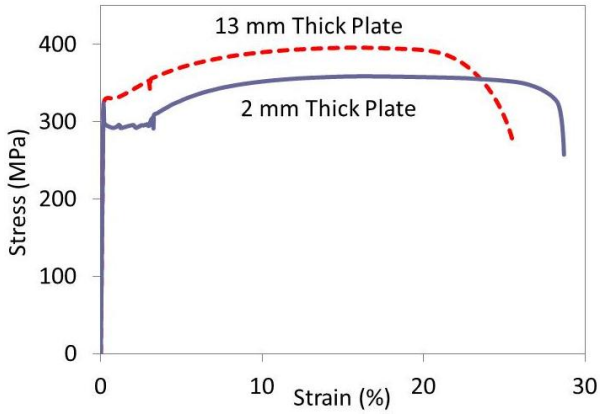

Figure 10 – Representative Material Behavior

4. EXPERIMENTAL RESULTS

The results from the first four specimens are discussed starting with the solid panel and then progressing from the largest ring diameter to the smallest ring diameter. None of the RS-SPSW panels experienced any fractures. The solid panel test did experience tearing and was stopped after the fracture propagated through a large section of the plate. The RS-SPSW tests were ended when there was either a significant loss of load carrying capacity (specimen 3) or when the test setup experienced damage (specimens 1 and 4).

The cyclic shear load-deformation behavior of the solid plate (specimen 2) is shown in Figure 11. The solid plate specimen with no stiffeners represents conventional SPSW construction in the U.S. with the exception of excluding moment connections between the beams and columns. As expected, the very thin web plate buckled at small shear load and a tension field developed as shown in Figure 16a. The corresponding hysteretic behavior was highly pinched as the plate acted in a manner similar to tension-only bracing producing little resistance during load reversal. The energy dissipated during the 4% drift cycle was computed, E_d, and found to be 44% of the energy that would be dissipated by an equivalent elastic perfectly plastic system, E_{EPP}. The comparison is shown graphically in the inset diagram of Figure 11 and tabulated in Table 2. The test was stopped after significant tearing developed in the web plate as shown in Figure 12.

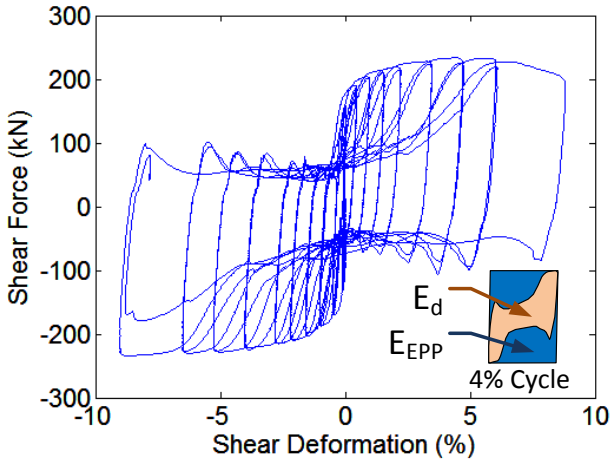

Figure 11 – Hysteretic Behavior of Solid Panel (Specimen 2)

Figure 12 – Tears in the Solid Plate (Specimen 2)

The hysteretic behavior of specimen 3 is shown in Figure 13. This specimen consisted of one large ring with large ring slenderness (R_o/t and w_c/t). The ring experienced lateral torsional buckling of the top and bottom legs of the ring as shown in Figure 16c. The lateral torsional buckling caused considerable deterioration in the strength and energy dissipation capability. The resulting hysteretic behavior was pinched leading to an energy dissipation ratio (E_d / E_{EPP}) of 0.33 for the 4% drift cycle which was 25% less than that of the solid plate.

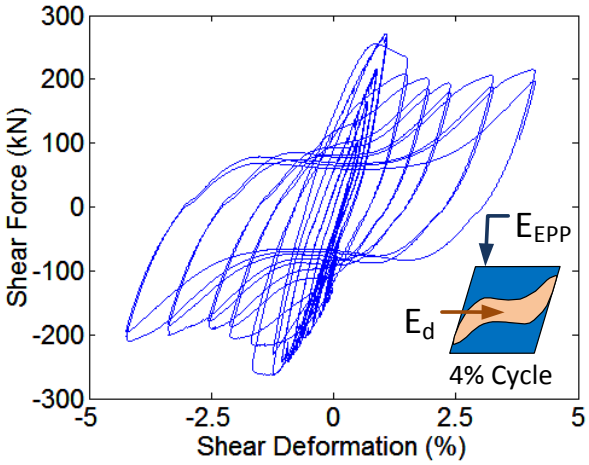

Figure 13 – Hysteretic Behavior of Panel Undergoing Lateral Torsional Buckling (Specimen 3)

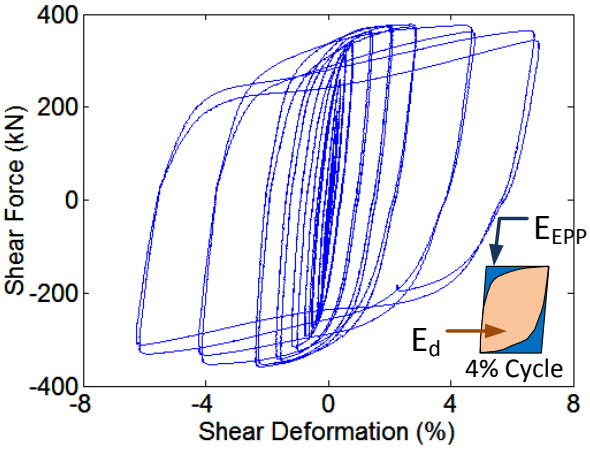

Figure 14 – Hysteretic Behavior Panel Undergoing Minimal Buckling (Specimen 1)

As the ring slenderness, represented by the nondimensional ratios R_o/t and w_c/t, were reduced, the propensity for lateral torsional buckling was reduced. Figure 14 shows behavior of specimen 1 which did not experience buckling until the second cycle at 4% drift. This amount of buckling might be acceptable in a practical design since the web plate might only buckle under extreme earthquake motions and even then, the energy dissipation and strength are only mildly affected. As shown graphically in the inset of Figure 14 and tabulated in Table 2,

the energy dissipation is approximately twice that of the solid plate or the RS-SPSW with high ring slenderness that experienced significant ring leg lateral torsional buckling.

If the ring slenderness is reduced further, buckling can be completely prevented as shown in Figure 15 and figure 16b for specimen 4. The energy dissipation ratio increased 9% as compared to specimen 1. The resulting full hysteretic behavior is similar to systems in which buckling is restrained and provides nearly the maximum amount of hysteretic energy dissipation possible.

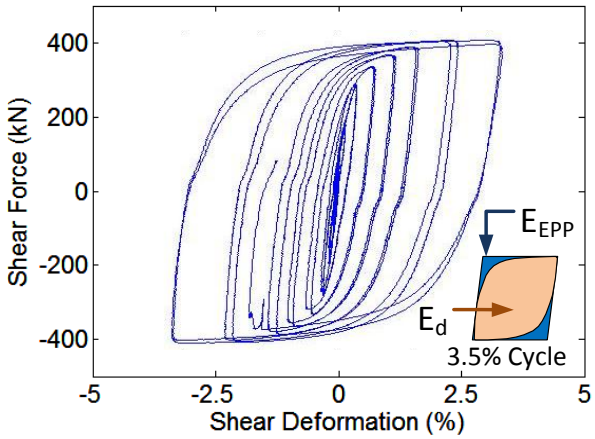

Figure 15 – Hysteretic Behavior of Panel That Experiences No Buckling (Specimen 4)

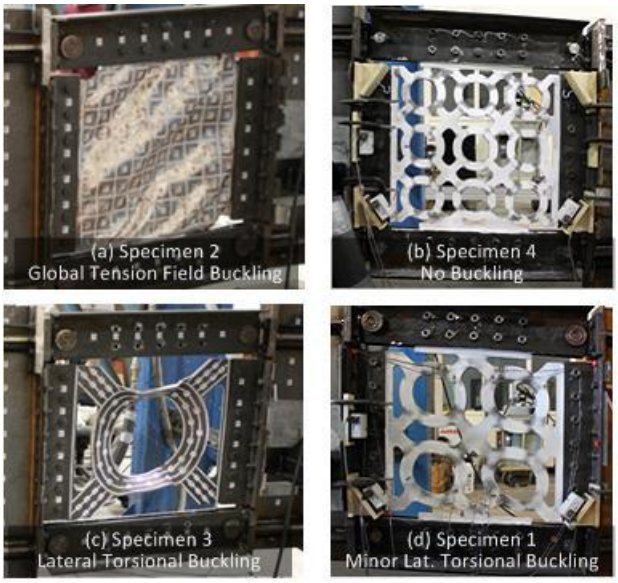

Figure 16 – Photographs of Specimens Demonstrating Buckling Modes

Additional results are provided in Table 2. The measured shear yield force, V_y, was computed as the approximate load at which significant nonlinearity began occurring. The measured ultimate shear strength, V_u, was the maximum shear force recorded during the test. Also presented in Table 2 are the computed shear capacity using plastic mechanism 1 (Q_1) and plastic mechanism 2 (Q_2), the ratio of ultimate strength to yield strength, and the energy dissipation ratio. As described previously, the energy dissipation ratio is computed for the 4% drift cycle as the ratio of the measured dissipated hysteretic energy, E_d, to the hysteretic energy that would be absorbed by an equivalent elastic perfectly plastic system, E_{EPP}.

Table 2 shows that the analytical solution for the RS-SPSW shear capacity can be quite conservative underestimating the capacity by approximately 60%. Further work is being conducted to evaluate whether the boundary conditions in the plate are causing a higher energy plastic mechanism to form. On the other hand, the shear capacity of the solid plate specimen was fairly well predicted by the calculated capacity, Q_{solid}, assuming a tension field angle of α=45°.

The effects of preventing buckling are twofold. First it is evident that the energy dissipation ratio goes up significantly. Secondly, the overstrength of the web plate given by the ratio V_u/V_y increased as buckling was prevented. For the configuration in which buckling was fully prevented, the ultimate strength was 28% greater than the yield strength.

Table 2 – Summary of Test Results

	V_y (kN)	Q_1 (kN)	Q_2 (kN)	V_u (kN)	$\frac{V_u}{V_y}$	$\frac{E_d}{E_{EPP}}$
1	320	154	200	377	1.18	0.79
2	200	Q_{solid} = 220		233	1.17	0.44
3	272	154	200	272	1.00	0.33
4	320	153	199	410	1.28	0.86

5. DISCUSSION AND CONCLUSIONS

Although ongoing work is being conducted to further study the ring shaped steel plate shear wall system, several preliminary observations and conclusions can be made based on the work presented herein.

1. The RS-SPSW system can be designed to prevent buckling without using any stiffeners. This was demonstrated experimentally with a specimen that produced large stiffness and energy dissipation.
2. The added geometric parameters in the RS-SPSW system allow the strength, stiffness, and ductility to be separately tuned to a particular building's needs.
3. RS-SPSW have the potential to reduce cost of SPSW and provide enhanced seismic performance. The reduction in cost compared to stiffened steel plate shear walls would come with the elimination of stiffeners and associated welds. The potential cost savings compared to unstiffened SPSW may be due to elimination of moment connections and resulting reduction in boundary elements sizes.
4. Two distinct buckling modes have been identified associated with RS-SPSW. The global shear

buckling experienced by the solid plate specimen can occur in RS-SPSW for large values of the global panel slenderness. Lateral torsional buckling of ring legs was investigated in the experiments presented herein and found to be related to the ring slenderness.

5. It is expected that both buckling modes can be predicted and prevented based on slenderness parameters. Equations for shear buckling of a solid plate will be examined in future work to determine if they adequately predict global shear buckling of the RS-SPSW panels. Future work will also help develop methods to predict lateral torsional buckling of the ring legs based on ring slenderness.
6. Analytical solutions for shear capacity of RS-SPSW plates were found to be conservative. Further work is being conducted to investigate alternate plastic mechanisms with more constrained boundary conditions.

Abstract: An innovative bridge pier technology for application in seismic regions is under development at the University of California, San Diego, in collaboration with the Pacific Earthquake Engineering Research (PEER) Center. The proposed solution combines a precast composite concrete-steel hollow-core column with recentering behavior and supplemental energy dissipation.
The precast hollow-core column consists of two concentric cylindrical steel shells, with concrete sandwiched in between. The shells act as permanent formwork, the outer one substituting traditional reinforcing cage and providing concrete confinement, the inner one preventing concrete implosion. These features are aimed to improve constructability and to reduce on-site construction burdens.
Large inelastic rotations can be accommodated at the end joints with minimal structural damage: gaps are allowed to open in tension at these locations and to close upon load reversal. Post-tensioned longitudinal bars induce recentering behavior together with gravity forces; rubber pads, in series with these bars at their anchorages, protect bars from yielding. Specifically designed steel devices provide energy dissipation by axial yielding. High-performance mortar and headed reinforcement are used to prevent mortar-joint premature crushing.
Outcomes from dynamic shake-table tests conducted at the PEER-UC Berkeley laboratories, as well as from numerical simulations performed in OpenSees, are summarized herein.

1. INTRODUCTION

Current provisions for seismic design of bridges (Caltrans, 2010; AASHTO, 2012) allow columns to respond beyond the elastic limit and to be damaged under the design earthquake, provided that collapse is prevented. Inelastic behavior is localized within flexural plastic-hinge regions at the bottom and/or top of the columns. These regions may experience some structural damage which may lead to temporary closure of the bridge to the public. However, the consequences could be critical if associated with the interruption of an important road path: obstruction of rescue and recovery operations, and economical losses related to business interruption and displacement of people and goods (Palermo et al., 2008).

While the notion of structural damage is accepted in design, resilient communities expect bridges to survive a moderately strong earthquake with little or no disturbance to traffic: this implies that partial or total bridge closures are tolerated with uneasiness, particularly in heavily congested urban areas. As a consequence, research efforts have been prompted into advanced technologies that reduce residual damage to the main structural elements, and encompass recentering properties which allow the structural system to return to its original position after an earthquake. Moreover, these innovative solutions need to be economically viable when compared to existing technologies (Guerrini et al., 2011).

This paper describes the main outcomes of an experimental and analytical work on a post-tensioned self-centering precast concrete dual-shell steel column, which is an enhancement to the earlier research described in Restrepo et al. (2011) and Guerrini et al. (2012). Use of precast members, replacement of traditional time-consuming reinforcing cages with steel pipes, and adoption of lighter hollow cross-sections are aimed to improve constructability and to reduce on-site burdens. In parallel, the combination of unbonded post-tensioned joint connections with specific energy dissipating devices ensure seismic resilience, in the form of recentering capability, facilitation of structural fuse repair, and minimization of damage to the main structural elements. As a consequence, traffic impacts, environmental disruptions, and life-cycle costs can be reduced.

2. SYSTEM DESCRIPTION

The precast bridge column described here consists of two concentric cylindrical steel shells (*dual-shell* technology) running for its entire height. High-performance concrete is sandwiched in between the shells and longitudinal reinforcement is detailed only between the

column ends and the footing or bent cap (Fig. 1(*a*)). The outer shell acts as permanent formwork, providing also longitudinal and transverse reinforcement, as it works in composite action with the concrete. The inner shell provides permanent formwork too, reducing unnecessary weight and making the technology suitable for prefabrication and rapid erection. It also prevents concrete implosion under large compressive strains which may develop upon gap opening, and delays buckling of energy dissipating dowels which are embedded in the concrete.

Large inelastic rotations can be sustained at the column-footing and column-cap beam joints with minimal structural damage. These rotations are accommodated within the connections themselves, through the formation of gaps at the member interfaces (Fig. 1(*b*)): gaps are allowed to open in tension under severe lateral displacement demand, and to practically close at the end of the excitation. Recentering/rocking capability is provided by gravity forces and unbounded, threaded post-tensioning (PT) bars, designed to remain elastic. The bolted PT bar anchorages at the bent cap and foundation allow for eventual bar replacement, should corrosion or other types of damage be a concern.

Energy dissipation takes place through axial yielding of internal dowels (Restrepo et al., 2007; Restrepo et al., 2011), as shown in Figure 1(*b*), preventing the main structural members from experiencing significant damage. Under strong-intensity earthquake excitation only these devices may undergo multiple cycles within the inelastic range, with possible need of replacement, but the structure is expected to remain functional overall. To transfer tension between the internal dowels and the outer shell, circumferential weld beads are provided on the internal surface of the outer shell, only near its ends (Gebman et al., 2006; Restrepo et al., 2011).

The resulting lateral force-displacement response shows flag-shaped loops as illustrated in Fig. 1(*c*).

3. SHAKE TABLE EXPERIMENT

3.1 Test Specimen

A dual-shell column specimen was built at a 1-to-3 scale at the UC San Diego Powell Structural Engineering Laboratories, and tested on the shake table at the PEER-UC Berkeley Laboratories. It was loaded in a cantilever configuration, with fixed base and an inertial mass applied at the top, as shown in Figure 2. The column had an overall diameter of 0.41 m (16 in.) and a height of 1.32 m (52 in.); the total cantilever span from the base to the center of mass was 2.44 m (96 in.). Column, footing, and loading stub were precast separately, and then connected through grouted dowels and a post-tensioning rod. Three inertial mass blocks were subsequently attached to the loading stub.

The column outer shell had a diameter D_O = 0.41 m (16 in.) and a thickness t_O = 6.4 mm (0.25 in.), that is D_O / t_O = 64. The inner shell had a diameter D_I = 0.25 m (10 in.) and a thickness t_I = 3.2 mm (0.125 in.), that is D_I / t_I = 80. Details are shown in Figure 3. The shells were obtained by folding and welding plates made of Grade 50 A572 steel. In practice, the inner shell would be a corrugated drainage pipe (Restrepo et al., 2011). High-performance, normal-weight concrete was used to cast column, footing, and load stub. The specified concrete compressive strength at 56 days was 62 MPa (9.0 ksi), the ones measured at 28 days, 56 days, and 101 days (day of test) were 60 MPa (8.7 ksi), 66 MPa (9.6 ksi) and 70 MPa (10.2 ksi), respectively.

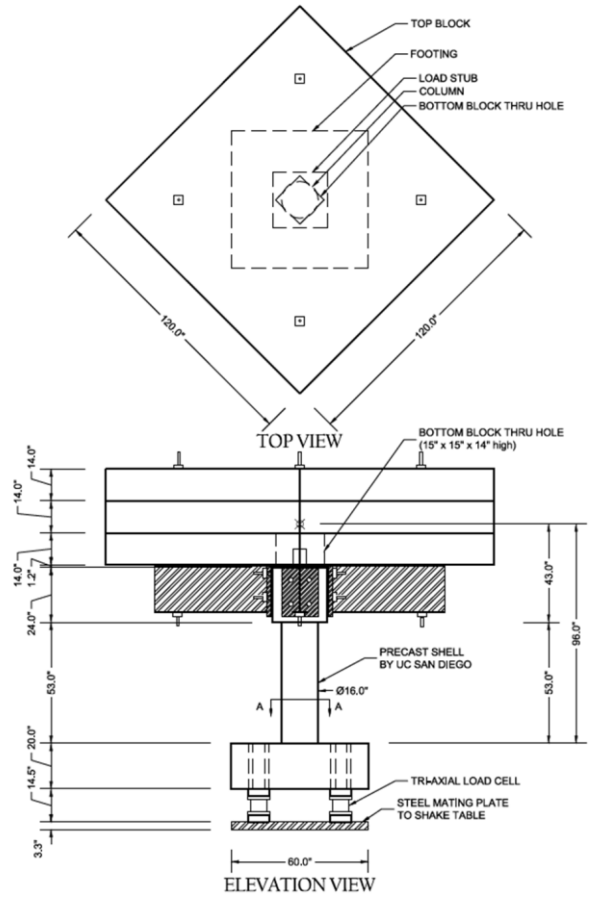

Figure 2 – Test setup and dimensions.

Eight 50.8-mm (2-in.) diameter, 0.48-m (19-in) long, corrugated metal ducts were embedded in the concrete for the installation of the internal energy dissipating dowels at the column bottom (Fig. 3 and 4*(a)*). Eight similar ducts, only 0.38-m (15-in.) long, were placed at the top for grouting the loading stub dowels (Fig. 3 and 5*(a)*). Four circumferential 9.5-mm (3/8-in.) weld beads on the internal surface of the outer shell provided tensile stress transfer between the dowels and the shell at each end.

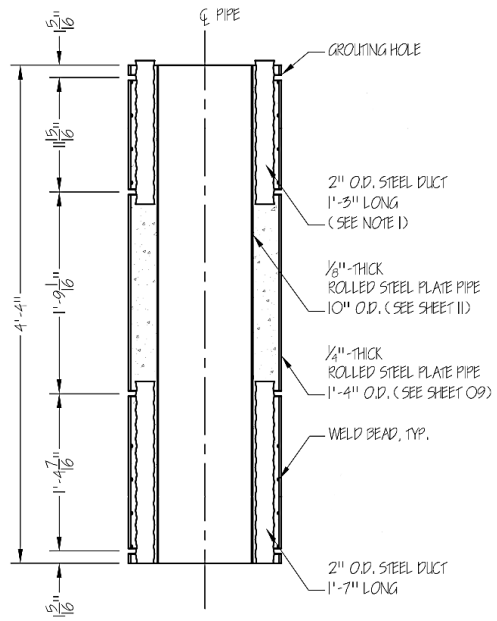

Figure 3 – Column vertical section.

(a) *(b)*

Figure 4 – *(a)* Column base section, with visible metal ducts for dowels and bar heads. *(b)* Footing surface, with visible stainless-steel dowels and bar heads.

(a) *(b)*

Figure 5 – *(a)* Column top section, with visible metal ducts for dowels, post-tensioning threaded bar, and load-stub dowels during stub positioning. *(b)* Post-tensioning bar top anchorage, with polyurethane pad (yellow).

A 19-mm (0.75-in.) thick mortar bed was cast between the column and the footing, to compensate for expected in-situ construction tolerances. Upon rocking, large compressive strains may arise on the mortar; eventually, mortar crushing would cause loss of PT and loss of recentering capacity. Thus, a high-performance mix was used, with the addition of polypropylene fibers in the proportion of 0.035% by weight to increase the mortar toughness. Moreover, the mortar was scraped from underneath the outer shell, to prevent the shell from causing premature crushing under direct compression transfer, a problem noted in earlier experiments (Restrepo et al., 2011). Strengths of 104 MPa (15.1 ksi) and 120 MPa (17.5 ksi) were obtained at 28 and 73 days (day of test), respectively. Eight headed bars were embedded in the column and eight in the footing, with their heads matching at the interface (Fig. 4), to help the mortar transferring compression (Belleri et al., 2013). The upper joint between the column and the load stub, not critical because of the lower bending moment at this location, was realized with the same mortar but without headed bars. All interface surfaces were roughened to improve shear friction. Bond breaker was applied to the surface of the footing, to allow separation from the mortar bed and opening of the gap.

The unit was equipped with eight internal dowels at the column-footing joint, acting as internal energy dissipators (Fig. 4*(b)*). 316LN Grade 75 stainless steel #3 bars were used for this purpose, wrapped with duct-tape wrapping for 152 mm (6 in.) across the interface to destroy the bond within this length. Material testing provided a yield stress of 862 MPa (125 ksi), ultimate strength of 986 MPa (143 ksi), and ultimate strain of 10%. The dowels were tied together with the footing cage and, after the column had been placed on the footing, they were grouted within the column ducts. Similarly, eight dowels were provided to connect the load stub to the column (Fig. 5*(a)*); however, A706 Grade 60 steel reinforcing bars without duct-tape wrapping were used as no yielding was anticipated.

Post-tensioning was provided by a single 44.5-mm (1-3/4 in.) diameter, A722 Grade 150 steel threaded bar (Fig. 5*(a)*). The total effective post-tensioning force was 438 kN (98.5 kips) after losses. The bar ran within the column hollow core, and was screwed into an anchorage device prearranged in the footing, allowing for bar replacement.

Additional bar deformability was provided by placing in series with the post-tensioning bar a polyurethane pad, between the top anchorage plates and the load stub (Fig. 5*(b)*). With this configuration the tensile deformation demand on the bar, due to gap opening, can be partially converted into compressive deformation of the pad, preventing the bar from yielding and avoiding loss of PT and recentering capacity. A disc consisting of 90 Shore-A hardness polyurethane, with a thickness of 47.6 mm (1-7/8 in.), a diameter of 190.5 mm (7.5 in.), and a central hole with a diameter of 57 mm (2-1/4 in.) to accommodate the PT bar, was used for this scope. It had stiffness equal to 1.75×10^5 kN/m (1000 kip/in) when tested at ambient temperature and at a rate of 0.5 kips/sec.

3.2 Test Protocol

The column was subjected to three-dimensional shake-table excitation. The top block provided a translational mass of 2.4×10^4 kg (53 kips), a mass moment of inertia of 2.05 kg-m^2 (6.99×10^4 kip-in^2), and an axial load of 236 kN (53 kips).

A series of 8 ground-motion records from historical events was selected and scaled, based on the displacement demand imposed on a conventional reinforced-concrete column, designed according to Caltrans' Seismic Design Criteria (Caltrans, 2010), carrying the same mass block. The chosen records and the applied scale factors (SF) are summarized in Table 1. EQ1 was selected to maintain the column response within the elastic range. EQ2 and EQ3 represented frequent events with low ductility demands. EQ4 and EQ5 were chosen as design-level excitation. EQ6, EQ7, and EQ8 were intended to bring the conventional reinforced-concrete column to near-collapse conditions. EQ9 was a repeat of EQ5. Free-vibration tests were run at the beginning of the experiment, and white-noise tests were performed between the historical records to assess the dynamic properties of the system.

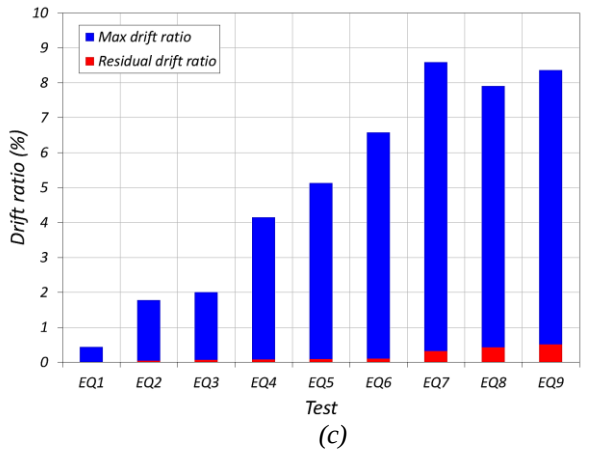
3.3 Test Results

Figures 6*(a)* and 6*(b)* show the hysteretic overturning moment-drift ratio response in the two lateral directions: lateral displacements at the center of mass have been normalized by the height of the center of mass above the column base, and thus, expressed as drift ratios; overturning moments have been normalized by the product of the mass weight times the height of the center of mass above the column base. For drift ratios larger than 0.3%, it was observed that the base joint rotation was contributing to more than 90% of the lateral displacement: for this reason, drift ratios and joint rotations practically coincided. Figure 6*(c)* illustrates the maximum and the residual drift ratio obtained during each run.



At the end of EQ4 the mortar bed was flaking off without crushing. During EQ5 crushing initiated superficially on the north-east and south-west sides, and after EQ8 it extended all the way around the mortar bed (Fig. 7*(a)*). However, only the outermost 25-mm (1-in.) wide ring of mortar was damaged, while the inner portion remained sound. Energy dissipators started fracturing under EQ6 test (6.6% maximum drift ratio), when one dowel fractured on the north-east side. Subsequently, three dowels were heard fracturing during EQ7 and other two during EQ8.

(a) *(b)*

Figure 7 – Damage observed at the end of the test: *(a)* mortar bed superficial crushing; *(b)* stainless-steel dowel buckling and fracture.

After the test, when the column was disassembled from the footing, it was observed that all dowels had buckled and fractured (Fig. 7*(b)*). However, no or negligible permanent deformations of the column concrete and of the steel shells were detected. Some post-tensioning losses were recorded during the test, probably due to mortar damage; at the end of the test they accounted for less than 30% of the initial force (after lock-off and creep losses). Recentering capacity was maintained throughout the test, with residual drift ratios always smaller than 0.6% (Fig. 6*(c)*).

4. NUMERICAL MODELING

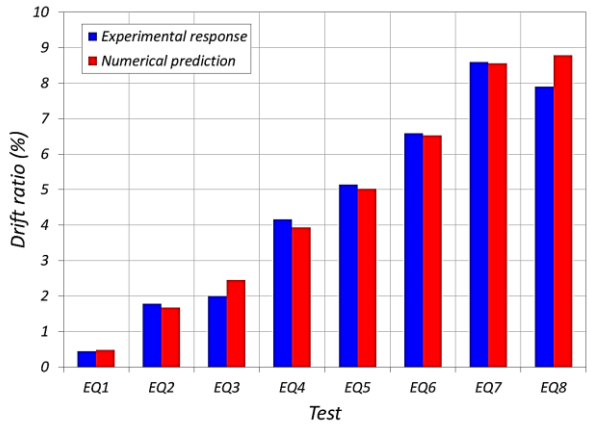
4.1 Model Description

A three-dimensional numerical model of the test was developed and validated with the experimental results. For this purpose the software OpenSees (Mazzoni et al., 2007; McKenna et al., 2010), developed by the Pacific Earthquake Engineering Research Center (PEER), was used. Details can be found in Guerrini (2013).

The column was modeled with two elastic frame elements in series, connected to the mortar bed at the base and to the mass block at the top; the intermediate node was necessary for linking the energy dissipating dowels. The stiffness of the lower column element was based on the hollow concrete section only, as the outer shell does not transfer directly compression at the interface (contact with the mortar is avoided) and tension is resisted by the dowels at that level. For the upper segment the transformed section was considered, accounting for the outer steel shell too. According to ACI (2008) the concrete elastic modulus was taken as $E_c = 57 \cdot \sqrt{1000 \cdot f'_c}$ (ksi), were f'_c (ksi) is the concrete compressive strength on the day of testing, while for the steel shell $E_s = 200$ GPa (29000 ksi) was used. A node was defined at the center of mass of the top block to assign masses and vertical forces; since the deformations of the loading stub and mass block are expected to be negligible, this node was linked to the top of the column with a rigid element.

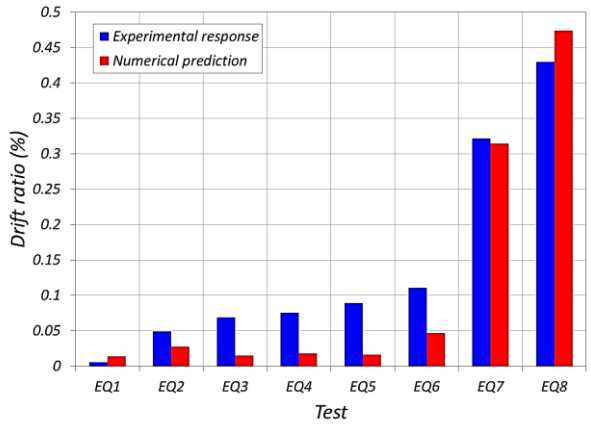
Multiple non-linear truss elements (Taylor, 1977; Vulcano et al., 1987; Carr, 2008) represented the mortar bed between column and footing; their length was set equal to the actual mortar thickness, i.e. 19 mm (0.75 in.). *Concrete01* non-linear material model was applied to these elements; this concrete-specific rule assumes zero tensile strength, consistently with gap opening. Peak compressive stress and strain, and ultimate stress and strain need to be input; a parabola connects the origin to the peak point, and a straight line goes from the peak to the ultimate point; for strains larger than the ultimate one, stresses drop to zero. The initial tangent elastic modulus is automatically derived by fitting a parabola through the origin, being its vertex the peak point. Peak stress and strain of 128 MPa (18.5 ksi) and 0.4%, respectively, were obtained from Mander's model for confined concrete (Mander et al., 1988), assuming a low confinement efficiency coefficient equal to 0.1. The ultimate strain was set to 16%, with a residual stress of 6.9 MPa (1 ksi). Strains in the stress-strain relationship were amplified by the ratio of the theoretical neutral axis depth, taken equal to 63.5 mm (2.5 in.), to the actual thickness of the mortar bed; by doing this, the spread of inelastic behavior within the column concrete, assumed to extend uniformly for a length equal to the neutral axis depth (Restrepo et al., 2007), was approximately taken into account.

The post-tensioning bar was modeled as a non-linear truss element, fixed at the base and connected to the top node of the column. *Steel02* material hysteretic rule (Filippou et al., 1983), based on Giuffré-Menegotto-Pinto model, was assigned to it. An initial stress of 259 MPa (37.5 ksi) was set to represent the effective prestress after losses. An equivalent initial tangent elastic modulus and an equivalent bilinear factor were calculated, accounting for the stiffness of the urethane pad in series with the bar. The yield stress was set equal to 827 MPa (120 ksi). Curvature parameters $R_0 = 18$, $c_{R1} = 0.925$, and $c_{R2} = 0.15$ were chosen, while no isotropic hardening was introduced.



The energy-dissipating dowel bars were represented by non-linear frame elements; the lower ends were fixed to the footing, and the upper ends were connected to the column intermediate node by rigid links. *Steel02* non-linear material model (Filippou et al., 1983) was assigned also to the dissipators. Geometry and material properties reflected the actual ones. However, the yield stress was set equal to 917 MPa (133 ksi) to better match the experimental monotonic stress-strain relationship of the stainless steel. Curvature parameters $R_0 = 18$, $c_{R1} = 0.925$, and $c_{R2} = 0.15$ were chosen, while no isotropic hardening was introduced.

The analysis was performed in two stages: first, the vertical load was applied and held constant; then the time-history analyses were run sequentially, keeping track of the cumulated residual displacements. The Newton-Raphson algorithm was chosen to solve the nonlinear residual equation, and the Newmark method was selected to integrate the equation of motion. Rayleigh damping was used; the contribution of the rigid links was excluded from the stiffness-proportional term, which was based on the initial stiffness. Damping ratios of 1% were assigned to the first two modes (translational in the longitudinal and transverse directions). The analysis was performed under the hypothesis of large displacements, or corotational geometric transformation in OpenSees language.



4.2 Numerical Results

When analyzing the quasi-static cyclic tests of similar recentering dual-shell columns, modeled according to the same strategy, Guerrini et al. (2012) found good agreement between the experimental and numerical results, in terms of force-displacement relationship, cumulative energy dissipated, strain histories of the post-tensioning bars, and hysteretic axial strain-stress response of energy dissipators, up to 5% drift ratio.

The numerical model was here used to predict the maximum and residual drift ratios under the given set of ground motions, with the feedback records from the bare shake table as inputs. Simulations were run up to EQ8, as the ninth run was added to observe the behavior of the damaged specimen under a design-level ground motion. The comparison between predicted and measured drift ratios is shown in Figure 8. Good agreement can be found between the maximum drift ratios, while relative discrepancy is observed on the residual drift ratios when they are in the order of 0.1% or less (EQ1 to EQ6). However, being these quantities very small, the absolute error appears negligible, especially considering that residual drift ratios of 0.3% or larger (EQ7 and EQ8) are accurately predicted.

5. CONCLUSIONS

This paper discussed the experimental performance and numerical modeling of a composite concrete-dual steel shell bridge column technology. This column can be specifically designed for damage minimization at the design earthquake and to display a self-centering response. This technology, ideal for prefabrication, simplifies and accelerates bridge construction, as the outer shell makes the reinforcing cage obsolete, and the inner shell removes unnecessary concrete volume.

The use of a metallic-aggregate mortar bed incorporating polypropylene fibers, in combination with headed bars at the column-footing interface, delayed the mortar from crushing, and allowed this unit to display excellent performance up to 8.6% drift ratio without losing recentering capacity. The polyurethane pad in series with the post-tensioning bar proved to be effective in preventing bar yielding, and consequent losses of prestress and of recentering behavior. Fracture of the energy dissipating dowels occurred at a drift ratio of 6.6%.

The test was simulated in OpenSees environment. An accurate representation of the response was obtained in terms of maximum and residual drift ratio demands up to the final stages of testing.

Abstract: Conventional reinforced concrete bridge columns in high seismic regions are designed to be ductile during earthquakes; however, column damage and residual drift can cause bridges to remain out of service for extended periods during replacement or repair. In this study, a rocking post-tensioned HyFRC bridge column was designed to limit damage and residual drifts and was tested dynamically under earthquake excitation. The column utilized post-tensioned strands, hybrid fiber reinforced concrete (HyFRC), and a combination of unbonded and headed longitudinal reinforcement. HyFRC with a total of 1.5% micro and macro fibers by volume and headed steel reinforcement at a ratio of 1.5% (discontinuous at the foundation) were used in the precast end region to improve the behavior of the rocking interface under high compressive forces. The 1/3 scale cantilevered bridge column was subjected to a sequence of nine scaled ground motion records of increasing intensity chosen to produce specific ductility demands in a conventionally designed reference specimen. The column exhibited excellent re-centering capability and light damage in the HyFRC end region, reaching a drift of 8.0% with an accumulated residual drift of less than 0.4%. Compressive damage was controlled in the end region by the HyFRC and the headed reinforcement.

1. INTRODUCTION

Reinforced concrete bridge columns in seismic regions are designed to be ductile by forming plastic hinges to accommodate inelastic deformations during earthquakes. Code requirements are intended to prevent collapse of bridges under design seismic hazards; however, damage in column plastic hinge regions can cause bridges to be out of service during column repair or replacement (CalTrans 2010). Residual column drift ratios (drifts) are expected following earthquakes if concrete and reinforcing bars incur severe inelastic damage in the plastic hinge.

In this study, a bridge column was designed with an objective of reducing or eliminating residual drifts after earthquakes. This objective was satisfied by several unique design details. First, the column was designed to rock about the foundation to avoid plastic hinge formation by unbonding the flexural reinforcement near the column-foundation interface. Second, fully unbonded, post-tensioned steel strands provided axial pre-compression and overturning resistance. Finally, hybrid fiber reinforced concrete (HyFRC) and headed reinforcing bars (rebar) that terminated at the column-foundation interface were employed to reduce compressive damage during rocking.

The rocking, post-tensioned (RPT) HyFRC bridge column was subjected to dynamic excitation in three directions on the Pacific Earthquake Engineering Research Center's (PEER) Earthquake Simulator in Richmond, CA. Eleven scaled earthquake ground motion records were applied.

A reference column with conventional design details and equivalent geometry and inertial mass was tested using the same ground motion sequence for comparison. During the seventh motion, the reference column reached a drift of 10.8% but had a residual drift of 6.8% and testing was halted. The RPT HyFRC column reached a drift of 8.0% during the same motion but had a residual drift of less than 0.4%.

2. BACKGROUND

The equations of motion for slender, inverted pendulum-type structures (structures that can rock freely about their base) were first introduced by Housner (1963) who recognized their tendency to maintain stability during strong ground shaking. Since then, numerous experimental and analytical studies have verified rocking as an effective means of accommodating inelastic displacement demands in reinforced concrete structures during earthquakes. Rocking systems that utilize unbonded post-tensioning (PT) can have re-centering hysteretic response upon unloading and various methods have been employed to add hysteretic energy

dissipation to such systems in addition to re-centering.

2.1 Columns with Unbonded Post-tensioning and Bonded or Unbonded Mild Steel Reinforcing Bars

Many researchers have investigated the use of unbonded post-tensioning in concrete beam and column assemblages to provide re-centering hysteretic behavior (Mander and Cheng 1997, Cheng 2008). Often these assemblages consisted of precast concrete segments connected by post-tensioned strands (Hewes and Priestly 2002, ElGawady et. al. 2010, Billington and Yoon 2004). In all cases, overturning resistance was provided by the elastic response of the unbonded post-tensioned strands and caused origin-oriented hysteretic behavior upon unloading.

Several analytical studies have investigated the performance of bridge columns built with a combination of mild steel longitudinal reinforcement and unbonded post-tensioning which can provide both hysteretic energy dissipation and column re-centering (Kwan and Billington 2003, Sakai and Mahin 2004). Columns with higher proportions of unbonded post-tensioning showed a greater tendency to re-center but often caused crushing of concrete earlier due to higher compressive stresses. Columns with higher proportions of mild steel reinforcement showed more hysteretic energy dissipation.

Billington and Yoon (2004) showed that a ductile fiber reinforced cement-based composite (DFRCC), a class of high performance fiber reinforced cementitious composites (HPFRCC) that exhibits strain hardening behavior in uniaxial tension, provided more energy dissipation in such systems than normal concrete and maintained its integrity considerably better under high compressive loads. Even with modest transverse reinforcement, the DFRCC did not spall.

Jeong et. al. (2008) tested columns with unbonded mild steel reinforcement and unbonded post-tensioning and found that unbonding the mild steel resulted in a shorter plastic hinge region and lower strains in the bars.

2.2 Columns with Hybrid Fiber Reinforced Concrete

This study considers a column designed to rock containing a combination of unbonded post-tensioning strands and unbonded mild steel reinforcing bars. In addition, the column incorporates hybrid fiber reinforced concrete (HyFRC), a class of tensile strain hardening HPFRCC containing both steel macrofibers and polymer microfibers at a fiber volume fraction of 0.015, in the end region. This material was initially developed for lightly reinforced bridge approach slabs with a performance criterion of maintaining strain compatibility with mild steel reinforcement through the tensile yield strain of steel of 0.2% (Blunt and Ostertag 2009). The material was optimized to have self-compacting properties in the fresh state (SC-HyFRC) to ease placement in densely reinforced structures (Jen et. al. 2012).

Cyclic testing of columns built with HyFRC and unbonded longitudinal reinforcement with no post-tensioning showed less spalling and compressive damage compared to conventionally designed columns with twice the transverse reinforcement under the same drift demands (Panagiotou et. al. 2012, Kumar et. al. 2011). Furthermore, small-scale tests revealed greater post-peak compressive strength and stability in confined HyFRC compared to equally confined normal concrete (Trono et. al. 2011). HyFRC is utilized in this column to improve energy dissipation and compressive damage resistance in the end region where large compressive forces are expected.

2.3 Headed Reinforcement Terminating at the Column-Foundation Interface

In addition to using HyFRC, a second detail which differentiates this column design from previous tests on columns with unbonded post-tensioning and unbonded mild steel reinforcement is the inclusion of headed compression-only reinforcing bars which terminated at the column-foundation interface. The 51x51x13 mm steel plate heads reinforce and confine the HyFRC at the column-foundation interface. Holden et. al. (2003) used a similar design in a precast pre-stressed concrete wall, lining the base of the wall with a steel plate and adding additional plates to the extreme ends of the wall at the base. Belleri et. al. (2013) used headed bars which terminated at the foundation of a rocking wall for the same purpose. To the authors' knowledge, this type of detailing has not been tested in post-tensioned columns, although another column in this test bed had similar detailing (Restrepo and Guerrini 2012).

3. TEST PROGRAM

The RPT HyFRC column was tested as part of PEER's Damage Resistant Re-centering Bridge Columns test bed, a collaborative project from three universities consisting of three different advanced bridge column specimens as well as a reference column with conventional design details for comparison. All four columns had equivalent inertial mass and geometry and were subjected to the same sequence of scaled earthquake ground motion records. This paper focuses on the experimental response of the RPT HyFRC column and draws comparisons with the response of the reference specimen.

3.1 RPT HyFRC Column Design Objectives

There were three specific objectives in the design of the RPT HyFRC column: (1) Minimize or eliminate the likelihood of residual column drifts for imposed drift demands up to 7%, (2) Limit inelastic compression damage at the rocking interface, and (3) Ensure that the post-tensioning remains elastic and prevent fracture of the continuous reinforcement at 7% drift.

To reach these objectives, the proportion of unbonded rebar to axial load (from post-tensioning and inertial mass) was optimized to encourage column re-centering and achieve the target lateral strength. HyFRC and headed reinforcement that terminated at the rocking interface were employed to control inelastic compressive damage at the rocking toe. In addition, the post-tensioning was designed to remain elastic up to column drifts of 7%, and the continuous

longitudinal steel was unbonded over a length sufficient to prevent fracture at 7% drift. Preliminary column design and analysis was conducted using an analytical model built in OpenSEES, but details of the model are not included herein.

3.2 Description of Test Specimens

Details of the RPT HyFRC column and the reference column are shown in Figure 1 and Figure 2, respectively. The design of flexural reinforcement and post-tensioning in the rocking column was chosen to achieve approximately the same lateral strength and stiffness as the reference column. The length scale factor for both specimens was 3.

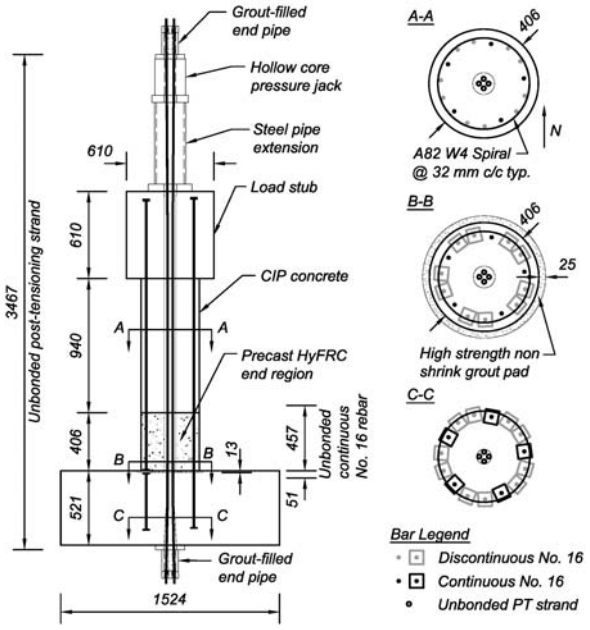

Figure 1 Rocking Post-tensioned HyFRC Column Elevation and Cross Sections

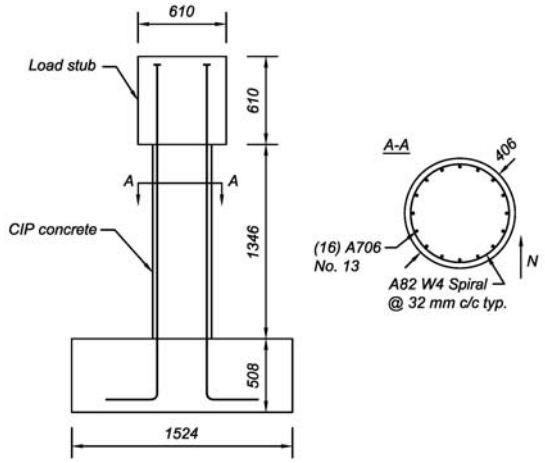

Figure 2 Reference Column Elevation and Cross Section

The RPT HyFRC column contained 15 ASTM A706 Grade 420 No. 16 bars longitudinally. Five of these bars continued from the column into the foundation and were unbonded over the length shown using tightly wrapped duct tape coated with lithium grease. The remaining ten bars terminated at the column-foundation interface with 51x51x13 mm steel heads and were fully bonded to the concrete. Four 15.2 mm dia. ASTM A416 Grade 1860 seven wire strands ran through a corrugated metal duct in the center of the column and were unbonded between their anchorages. As shown in Figure 1, a steel pipe was used to increase the unbonded length of the PT to reduce the chance of yielding the strands (in an actual bridge, the PT could be anchored within the superstructure). The longitudinal steel effective in flexure consisted of the five unbonded No. 16 bars and the four PT strands for a total effective volumetric ratio of $\rho_{l,eff}$ = 1.2%. The volumetric ratio of the discontinuous headed bars terminating at the column-foundation interface was 1.5%. Transverse shear and confinement reinforcement was provided by an ASTM A82 W4 steel spiral (5.7 mm dia.) at 32 mm spacing, for a volumetric ratio of ρ_s = 0.9%. The spiral was discontinuous between the base of the column and the foundation.

The end region was precast with HyFRC and installed onto a wet-set grout pad on the top of the foundation (see Figure 1). The precast element contained ten discontinuous No. 16 headed bars as well as PVC and corrugated metal ducts for the continuous No. 16 bars and PT strands, respectively. No. 16 double-headed bars were also cast in the foundation in the same pattern as the discontinuous bars in the precast end region and terminated at the top of a 13 mm recession in the top of the foundation. These bars acted to distribute the compression from the column above into the foundation (with the high strength grout pad between).

Installation of the precast piece consisted of feeding the five continuous No. 16 bars (which were embedded in the foundation) through the PVC ducts in the precast piece, pouring the wet high strength non-shrink grout into the recession in the top of the foundation, and finally lowering the piece onto the wet grout pad, allowing it to rest on 10 mm shims while the grout cured. Grout was then poured into the void space in the PVC ducts to provide buckling resistance to the unbonded bars.

The remainder of the column was cast in place with normal concrete. Six days prior to testing, the four PT strands were stressed individually to 48% of their yield strength for a total PT force of 455 kN. The end wedge anchor plates fit into specially fabricated steel pipe sections which were filled with grout to a depth of 10 strand diameters (152 mm) after stressing in order to eliminate stress concentrations at the wedge anchors that could lead to premature strand failure. Weld beads on the inside surface of the pipe allowed any increase in strand tensile force during testing to develop in the grout away from the anchorage.

The reference column (Figure 2) was designed with a longitudinal volumetric steel ratio of ρ_l = 1.6% consisting of 16 ASTM A706 Grade 420 No. 13 bars. Transverse reinforcement was continuous into the foundation and consisted of the same A82 W4 smooth steel spiral at the same spacing as the RPT HyFRC column for a spiral volumetric ratio of ρ_s = 0.9%.

3.3 Specimen Material Properties

The HyFRC used in the precast end region of the RPT HyFRC column contained hooked-end steel fibers at 1.3% by volume with a length of 30 mm, a diameter of 0.55 mm, and a yield strength of 1100 MPa. It also contained polyvinyl alcohol (PVA) fibers at 0.2% by volume with a length of 8 mm, a diameter of 0.04 mm, and a yield strength of 1600 MPa. Two chemical admixtures, superplasticizer (SP) and viscosity modifying admixture (VMA), were used to improve the workability of the fresh mix. The material proportions of HyFRC are given in Table 1.

Table 1 HyFRC Material Mix Proportions

kg per cubic meter				*fiber volume %*	
Water	Cement[a]	Fly Ash[b]	Gravel[c]	Steel	PVA
219	*413*	*136*	*418*	*1.3*	*0.2*
Sand[d]	SP	VMA			
1044	*2.3*	*5.6*			

[a]ASTM C150 Type II; [b]ASTM C618 Type C; [c]pea gravel, 9.5 mm MSA; [d]coarse sand, FM = 3.2

The compressive strengths, f_c', of the normal cast-in-place concrete used for the columns and the foundations, the HyFRC, and the high strength non-shrink grout pad are given in Table 2. Concrete and HyFRC compressive strengths were averaged from three 152x304 mm cylinders, while high strength grout strengths were averaged from five 51x51x51 mm cubes.

Table 2 Compressive Strength of Column Materials

	Sampled f_c' (MPa)			
Specimen	*Column*	*Found.*	*HyFRC*	*Grout*
RPT HyFRC	34.5	55.5	44.6[b]	63.8
Reference	22.6[a]	34.7	-	-

[a] 18% lower than design f_c' = 27.6 MPa
[b] average strain at f_c' equal to 0.35%

The A706 No. 16 reinforcing bars used in the RPT HyFRC specimen had an average tested yield strength of 481 MPa and an ultimate strength of 658 MPa. Their tensile stress-strain response is shown in Figure 3(a). The A416 strands had an average tested yield strength of 1704 MPa and a breaking strength of 1874 MPa as shown in Figure 3(b). Finally, the A706 No. 13 bars used in the reference column had an average tested yield strength of 433 MPa and an ultimate strength of 651 MPa as shown in Figure 3(c). In all three cases, strain was measured over 51 mm, stress was calculated assuming nominal cross sectional area, and three coupons of each material were tested. Figure 3(d) shows the stress-strain response of the A82 W4 spiral (after straightening a circularly-deformed sample).

3.4 Test Configuration and Instrumentation

The same test setup was used on the shaking table for both the RPT HyFRC column and the reference column and is shown in Figure 4. Inertial mass was applied in the form of three 3048x3048x356 mm reinforced concrete plates. Wide flange steel cantilevered beams were fixed to the column load stub and the mass plates were fixed to the wide flange steel beams using post-tensioned bars. The total inertial mass applied to the columns was approximately 24500 kg (for a gravity load of 240 kN), and the center of mass was found to be 2438 mm above the top of the foundation. The axial load ratios for RPT HyFRC and reference columns, defined as the gravity load divided by $f_c'A_g$, where f_c' was the tested compressive strength of the column's normal concrete and A_g the gross cross sectional area, were 5.4% and 8.2%, respectively.

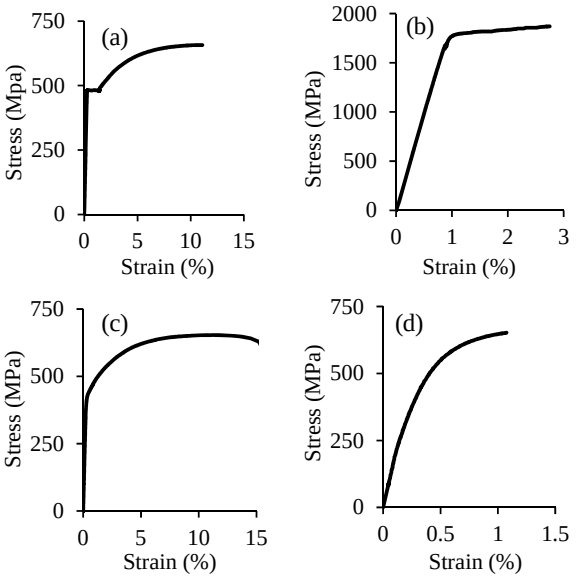

Figure 3 Tensile Stress-Strain Response of (a) A706 No. 16 bars, (b) A416 PT Strand, (c) A706 No. 13 bars, and (d) A82 W4 spiral

Instrumentation for the RPT HyFRC column consisted of five load cells, 30 displacement transducers, and 41 strain gages. Four load cells, 32 displacement transducers, and 54 strain gages were used for the reference column. Thirty-five accelerometers and 21 wire potentiometers were used for both columns. All instruments were sampled at 200 Hz.

Each of the column foundations was fixed upon four tri-axial load cells that measured shear force in two directions and axial force (see Figure 4). The RPT HyFRC column also had a fifth load cell in the form of a hollow core pressure jack (with a pressure transducer) in series with the post-tensioning to measure the PT force during testing.

In both tests, accelerometers were fixed to the foundation, column, and mass plates in both the horizontal and vertical directions at multiple locations. Displacement transducers were fixed to rods embedded in the columns on four sides at discrete heights to estimate the curvature profiles during testing. Seven groups of three wire potentiometers tracked the 3-D displacement at seven points on the specimen—three on the foundation and four on the

mass plates. These displacements were used to resolve three translations and three rotations at the center of mass using the procedure presented in Vithani and Gupta (2002).

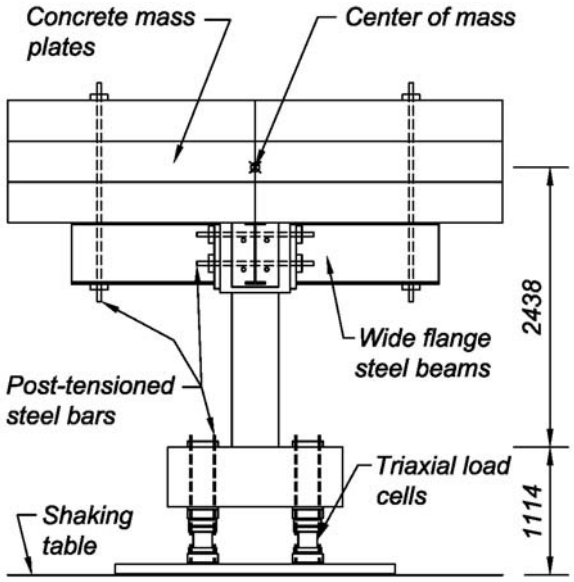

Figure 4 Shaking Table Test Setup

3.5 Shaking Table Test Sequence

A sequence of nine scaled earthquake ground motion records, each with North-South (NS), West-East (WE), and vertical direction components, was chosen by the research group for testing of the RPT HyFRC column, the reference column, and the other columns of the Damage Resistant Re-centering Bridge Columns test bed. Details of each record are given in Table 3. Priority was given to records that satisfied the following criteria: (1) They imposed similar displacements in all test bed columns over the fundamental period range 0.4 to 0.7 seconds, (2) They contained velocity pulses likely to cause large column drifts, and (3) They were generated by strike-slip fault mechanisms.

Time was scaled by $L^{-1/2}$ in order to maintain a scale factor of unity for induced accelerations (the length scale factor, L, was 3). Acceleration values (3 components) were also scaled by a constant for each signal so as to impose specific displacement ductility targets, μ, in the reference column (see Table 3) and comparable peak drifts in all test bed columns. The design level earthquakes were selected to impose a target displacement ductility of 4 (EQ4 and EQ5) to be consistent with the maximum design demand for single column bridge bents according to Caltrans SDC (2010). Some motions were filtered to remove displacement pulses that exceeded the shaking table's limits. Testing of the reference column was stopped after EQ7 due to substantial residual column drift. The RPT HyFRC column was subjected to two additional unplanned ground motions after the first nine since damage and residual drifts had been well controlled during the initial test sequence. Details of these motions are also included in Table 3.

White noise tests (table motions consisting of randomly generated, tri-directional, small-amplitude displacements) were run before each earthquake test for both columns to induce column vibration and evaluate the natural period as damage developed. Prior to the start of any dynamic testing, free vibration tests were performed on both columns by applying a static lateral load and quickly releasing it.

Table 3 Details of Earthquake Tests

4. TEST RESULTS

Dynamic testing confirmed that the RPT HyFRC column achieved its primary objective of minimizing residual column drifts compared to a conventionally designed column. The post-tensioned strands remained elastic and provided enough overturning resistance to re-center the column throughout testing, while the combination of headed compression-only reinforcement and HyFRC in the precast end region limited inelastic compressive damage. Fracture of the continuous unbonded reinforcement was delayed until the eleventh earthquake test when two bars fractured.

4.1 Measured Peak and Residual Column Drifts

Table 4 shows the peak drifts of the RPT HyFRC and reference specimens measured during testing as well as the

residual drifts measured at the end of each test. Figure 5 shows the same data side by side for the first seven EQ tests which were run on both columns. As shown, the RPT HyFRC column showed near perfect re-centering after the first five earthquake tests with residual drifts under 0.1%, even after reaching 4.3% drift during EQ4 and 6.2% drift during EQ5. During EQ7, the RPT HyFRC column reached a drift of 8.0%, but the residual drift remained less than 0.4%. During EQ11, when the column reached 8.8% drift, two unbonded bars fractured but the residual drift was still only 0.9%. Figure 6(a) shows the RPT HyFRC column after EQ11 at the end of testing.

The reference column developed a residual drift of 0.9% after the first five earthquakes, reaching a peak drift of 3.7% during EQ4 and 5.8% during EQ5 (the design level events). Further testing resulted in increased residual drifts in the reference column; EQ6 caused a drift of 6.1% and increased the residual to 1.6%, while EQ7 induced the largest drift of 10.8% which left a residual of 6.8%. Figure 6(b) shows the reference column after EQ7.

Table 4 Measured Peak and Residual Column Drifts

Test	RPT HyFRC Drift[a] (%) peak	residual	Reference Drift[a] (%) peak	residual
EQ1	0.5	0.0	0.4	0.0
EQ2	2.1	0.1	3.5	0.4
EQ3	2.1	0.1	1.5	0.4
EQ4	4.3	0.1	3.7	0.3
EQ5	6.2	0.1	5.8	0.9
EQ6	5.0	0.2	6.1	1.6

4.2 Measured Base Rotation and Rocking Behavior

The RPT HyFRC column was designed to rock about its foundation in order to avoid damage caused by formation of a plastic hinge. Inelastic lateral drifts were accommodated by uplift of the column at the interface with the foundation rather than distributed tensile cracking. This mechanism was verified by comparing the measured base rotations to the lateral drift at the center of mass. Uplift from the foundation was measured by displacement transducers mounted to the column at heights of 52, 64, 67, and 49 mm above the foundation on the N, E, S, and W column faces, respectively. Base rotations, θ_b, in the N-S and W-E directions were calculated as the difference in opposite displacement transducer measurements divided by the horizontal distance between the transducers.

Figures 7(a) and 7(b) show the calculated base rotation plotted against drift of the center of mass in the N-S direction for EQ4 and EQ7 where the column reached peak drifts of 4.3% and 8.0%, respectively. The rocking mechanism is clearly illustrated by the fact that the inelastic column drifts are accommodated almost completely by rotation at the base.

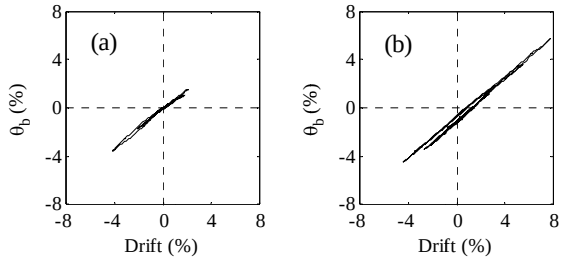

Figure 7 Measured Base Rotation vs. Drift in the NS Direction (N positive) for (a) EQ4 and (b) EQ7

4.3 Measured Overturning Moment vs. Drift Behavior

The hysteretic overturning moment vs. drift response in the N-S direction is shown in Figures 8(a), 8(b), and 8(c) for EQ4, EQ5, and EQ7, respectively. The figures on the left show the response of the reference column, while the figures on the right show the response of the RPT HyFRC column.

The overturning moment was calculated from load cell axial force measurements, corrected for the inertia of the foundation, and normalized by the weight of the inertial mass times the center of mass height.

As shown in Figure 8, the lateral strength of both columns was approximately equal, with inelastic response developing at an overturning moment of approximately 0.3WH. The response shown during EQ4 in Figure 8(a) clearly illustrates the re-centering effect in the RPT HyFRC column (right) as compared to the reference column (left); the reference column unloads and has a residual drift while the RPT HyFRC column unloads through the origin.

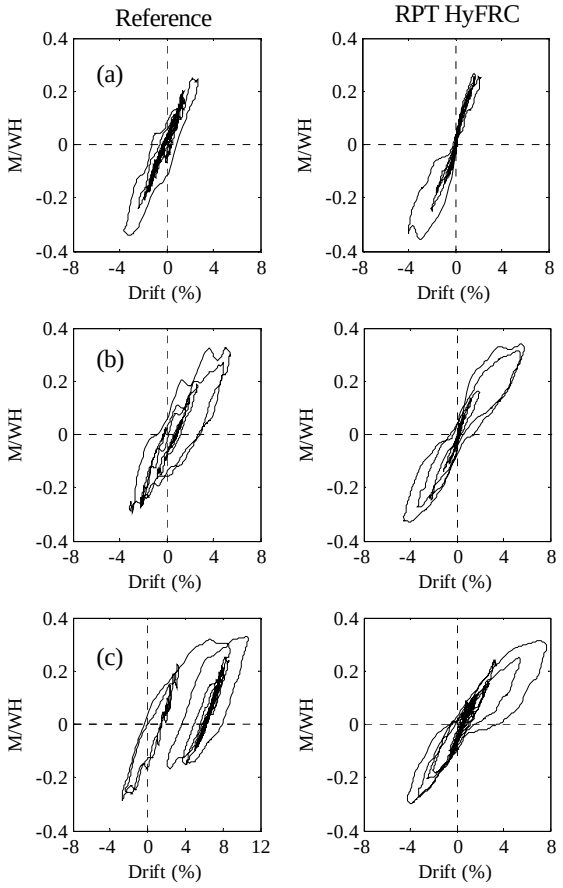

Figure 8 Measured Overturning Moment vs. Drift in the NS Direction for (a) EQ4, (b) EQ5, and (c) EQ7

During EQ5, the reference column reached a peak drift of 5.8% and developed more damage as evidenced by the wider hysteretic loop in the left side of Figure 8(b). In the right side of Figure 8(b), the response of the RPT HyFRC column continues to tend toward the origin upon unloading with only small drifts at zero overturning moment.

Finally, during EQ7, the reference column saw a peak drift of 10.8% and developed a significant residual drift as shown in the left side of Figure 8(c). The hysteretic loop of the RPT HyFRC column widened slightly during EQ7, but the column still re-centered upon unloading as shown in the right side of Figure 8(c).

4.4 Measured Load in the PT Strands

Prior to EQ1, the initial PT load in the RPT HyFRC column was 455 kN (48% yield). By the start of the final test, EQ11, the PT load had only decreased to 432 kN (45% yield) for an accumulated loss of only 5% of the initial load through the duration of all prior tests. The axial force provided by the PT was in addition to the 240 kN inertial mass from the concrete plates. The maximum PT force measured during all tests was 589 kN (62% of yield) which occurred during EQ7. Although there was a slight loss of PT force due to shortening of the column, the strands remained elastic through the duration of testing.

4.5 Measured Peak Tensile and Compressive Strains in the Reinforcing Bars of the RPT HyFRC Column

Table 5 shows the peak compressive strain, ε_c, and tensile strain, ε_t, as measured by strain gages fixed to bars B7 and U1, respectively, during each test. The location of these bars in the RPT HyFRC column cross section is given in Figure 9. The gage on bar B7 was fixed to the bar facing inward at a height 37 mm above the top of the foundation, while the gage on bar U1 was fixed to the bar facing outward at a height 76 mm above the foundation. Table 5 also shows the measured peak drift in the N direction during each EQ test. Drifts in the N direction caused tension in the unbonded bar U1 and compression in the discontinuous headed bar B7.

Table 5 Measured Peak Strains in Bars B7 and U1

Test	Peak Drift N-dir (%)	Peak ε_c Bar B7 (%)	Peak ε_t Bar U1 (%)
EQ1	0.5	-0.05	0.08
EQ2	2.1	-0.11	1.80
EQ3	1.7	-0.16	1.66
EQ4	2.2	-0.13	1.97
EQ5	5.9	-1.79	3.28
EQ6	4.5	-1.92	2.74
EQ7	7.8	-3.14	3.37
EQ8	6.6	-3.64	2.87
EQ9	7.1	-4.04	3.62
EQ10	6.9	-4.10	-
EQ11	8.0	-4.49	-

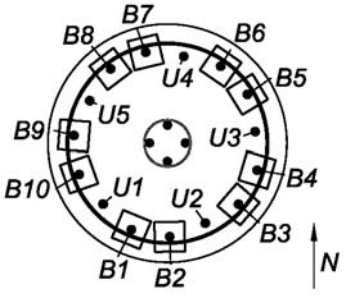

Figure 9 Reinforcing Bar Designations

As shown in Table 5, strains in the unbonded bar U1 were well-controlled by the unbonding of the bar from the surrounding concrete. As the column rocked and reached drifts of 5.9%, 7.8%, and 7.1% in the N direction during EQ5, EQ7, and EQ9, respectively, the measured peak tensile strain in bar U1 remained under 4%. The imposed drift during these tests was accommodated by uplift at the foundation (see Figure 7) and the low strain measurements in Bar U1 confirm that the uplift was distributed as strain over the unbonded length.

The discontinuous headed bars relieved the compressive forces imposed on the precast HyFRC during rocking as evidenced by the high recorded compressive strains in Table 5. Bar B7 yielded in compression, reaching a strain of -1.79%, when the column reached a peak drift of 5.9% in the N direction during EQ5. After yielding, inelastic compressive strains continued to increase during all subsequent tests. Strain gages on the other discontinuous bars B1, B3, B5, and B9 recorded peak compressive strains (over all tests) of 2.4%, 5.7%, 6.0%, and 2.0% but showed no evidence of buckling, and the spiral remained intact through the duration of testing.

4.6 Observed RPT HyFRC Column Damage

As shown by the measured test data, damage to the precast end region of the RPT HyFRC column was limited during testing; the PT strands remained elastic, the unbonded bars avoided fracture during the first ten EQ tests, and the precast end region maintained its integrity with no evidence of bar buckling or spiral fracture and only minor spalling.

The crack at the rocking plane first opened during EQ1 but was only captured in real-time by video cameras mounted on the foundation and was not apparent after the column re-centered. During EQ2, the crack at the rocking plane opened further and inspection showed light compressive scaling/cracking of the HyFRC and grout pad on the NE face of the column as shown in Figure 10(a) approximately 25 mm above the foundation. This cracking progressed slightly after EQ3, as shown in Figure 10(b).

The gap opening at the rocking interface opened significantly during EQ4 and EQ5 as shown in photos of the NE and SE faces of the column in Figure 10(c) and 10(d), respectively. These photos are taken from video of the response when the specimen was at 4.3% drift in the S direction for EQ4 and 6.2% drift in the N direction for EQ5, but in both cases the gap closed and the column re-centered. Figure 10(c) shows that some vertical splitting cracks initiated during EQ3, branching off the compressive cracks on the NE face. Figure 10(d) shows additional compressive cracking on the SE face at a height of approximately 64 mm above the foundation after EQ4.

The HyFRC remained intact with little to no spalling as shown on the four faces of the column in Figure 11(a) through 11(d) after the column reached 8.0% drift in the N direction during EQ7. Vertical splitting cracks that had initiated in prior tests propagated upward but did not extend higher than 200 mm above the foundation. Slight outward bulging of the column base was observed, yet neither spiral fracture nor bar buckling were evident on any face.

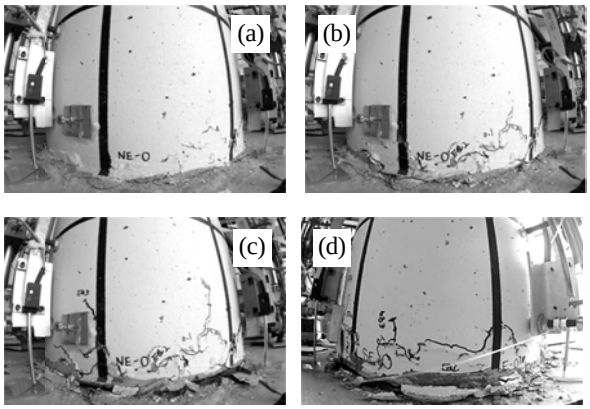

Figure 10 Damage to the Precast HyFRC End Region, (a) NE face after EQ2, (b) NE face after EQ 3, (c) NE face at 4.3% peak drift during EQ4, and (d) SE face at 6.2% peak drift during EQ 5

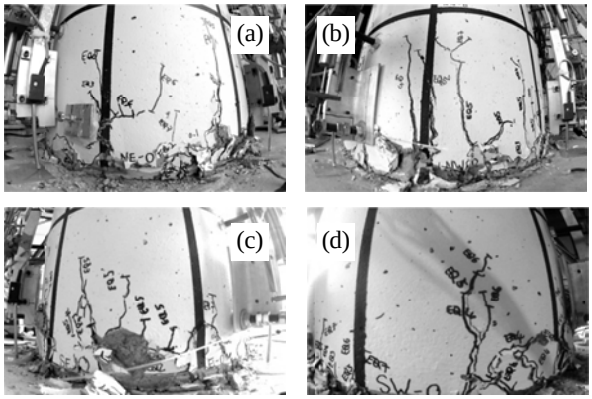

Figure 11 Damage to the Precast HyFRC End Region after EQ7, (a) NE face, (b) NW face, (c) SE face, and (d) SE face

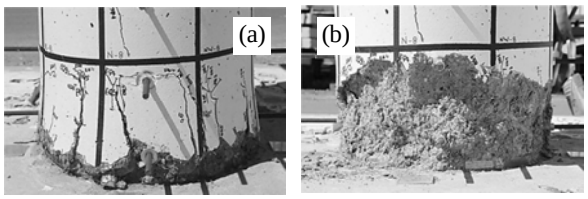

Figure 12 Final RPT HyFRC Damage State, N face (a) before and (b) after damaged HyFRC was removed

Fracture of the unbonded longitudinal bars was delayed until EQ11 when bars U1 and U4 fractured. Even after EQ11, the column residual drift was less than 1%. Figure 12(a) shows the damage state of the N face of the column at the end of testing after instrumentation had been removed. The HyFRC material did not spall from the column face during testing due to the fibers' ability to hold the material together even after splitting and compression cracks had formed. Following testing, damaged HyFRC was removed from the column face manually with a hammer and chisel as shown in Figure 12(b). After the material was removed, it was evident that damage was limited to cover HyFRC below

a height of 200 mm above the foundation and did not penetrate into the HyFRC core confined by the spiral.

4.7 Observed Reference Column Damage

The reference column accommodated the imposed drifts by distributed flexural cracking and eventual plastic hinge formation as imposed drifts increased.

Flexural cracks at spacings between 50 and 125 mm formed up to a height of approximately 600 mm above the foundation after EQ2 when the column reached 3.5% drift and are shown on the NE and NW faces of the column in Figures 13(a) and 13(b), respectively. After EQ6, compression damage in the form of vertical splitting cracks and spalling had extended to a height of 400 mm above the foundation on the SW face of the column as shown in Figure 13(c), and the column had a residual drift of 1.6% in the S direction. Following EQ7, spalling and compressive damage on the S face were substantial as shown in Figure 13(d).

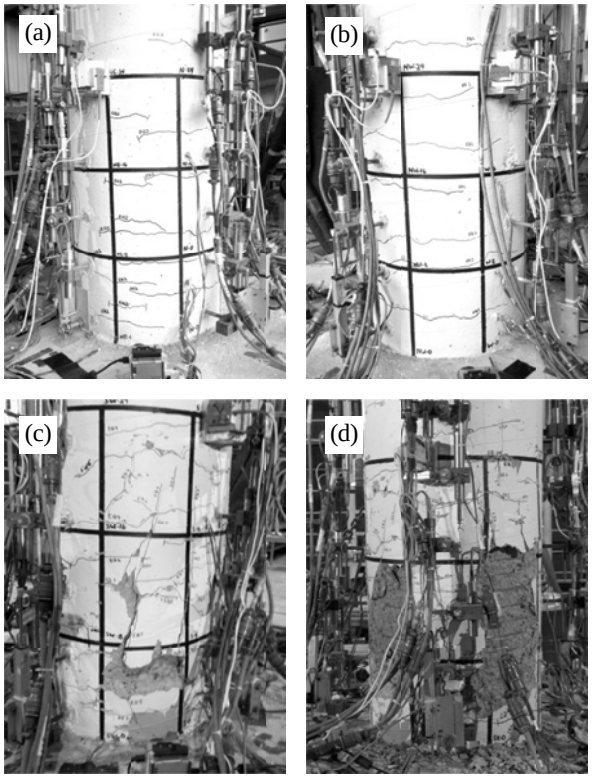

Figure 13 Damage to the Reference Column, (a) NE face after EQ2, (b) NW face after EQ2, (c) SE face after EQ6, and (d) S face after EQ7

5. SUMMARY

This test investigated the dynamic response of a 1/3 scale, rocking, post-tensioned HyFRC bridge column subjected to dynamic loading from scaled earthquake acceleration time history records (three components) on the shaking table. The column was designed to: (1) Minimize or eliminate the likelihood of residual column drifts for design level seismic drift demands up to 7%, (2) Limit inelastic compression damage at the rocking interface, and (3) Ensure that the post-tensioning remains elastic and prevent fracture of the continuous reinforcement at 7% drift.

The RPT HyFRC column consisted of a precast HyFRC end region up to a height of one column diameter (406 mm) containing headed reinforcing bars discontinuous at the column-foundation interface at a volumetric ratio of 1.5% and unbonded continuous reinforcing bars and post-tensioning strands at a volumetric ratio of $\rho_{l,eff}$ = 1.2%. The remainder of the column was cast with normal concrete. Smooth steel wire was used as shear and confinement reinforcement at a volumetric ratio of ρ_s = 0.9%. A reference column having similar geometry, lateral strength, and inertial mass, was also subjected to the same acceleration time histories as the RPT HyFRC column. This column had a volumetric ratio of longitudinal steel of ρ_l = 1.6% and contained the same A82 steel spiral at the same ratio as the RPT HyFRC column.

The test setup was identical in the two tests; accelerometers, linear potentiometers, displacement transducers, and strain gages measured column acceleration, displacement, and strain during testing. Reaction forces were measured with load cells fixed below the rigid foundation.

Seven earthquake tests with increasing ductility targets (in the reference column) were applied to both columns, and the RPT HyFRC column was also subjected to four additional tests.

5.1 Reduction in Residual Column Drifts

Similar peak drifts were imposed in the two columns by the EQ4, EQ5, and EQ6 (less than 20% difference) which targeted μ equal to four, four, and six, respectively, in the reference column. The RPT HyFRC column reached peak drifts of 4.3%, 6.2%, and 5.0% during these tests, but experienced residual drifts of only 0.1%, 0.1%, and 0.2%. The reference column reached peak drifts of 3.7%, 5.8%, and 6.1% during the same tests with residual drifts of 0.3%, 0.9%, and 1.6%. During EQ7, the reference column reached a peak drift of 10.8% due to the large residual of 1.6% after EQ6; following EQ7, the residual drift increased to 6.8%. The RPT HyFRC column showed residual drifts of less than 1% through the duration of testing, reaching peak drifts of 8.0%, 6.8%, 7.2%, 7.2%, and 8.8% with residuals of 0.4%, 0.4%, 0.6%, 0.6%, and 0.9% during EQ7 through EQ11.

5.2 Compressive Damage in the RPT HyFRC Column

The combination of discontinuous headed reinforcing bars and HyFRC in the precast end region prevented major compression damage which aided in preventing residual column drifts caused by damage at the rocking interface.

Measured peak strains over all tests in the discontinuous headed bars reached between 2% and 6% in compression yet buckling was not observed in any test. Spalling of the HyFRC in the precast end region was prevented. Some compressive cracks developed in early tests (Figure 10) on both sides of the column less than 75 mm above the top of the foundation; these cracks slowly propagated vertically as

splitting cracks as testing continued (Figure 11). Post-test inspection showed damage to the HyFRC was limited to the cover material (Figure 12). The spiral did not fracture, although compressive strains in the core material (as measured by strain gages on the headed bars) reached over 6%.

5.3 Behavior of the Unbonded Bars and PT Strands

Fracture of the unbonded bars was prevented for the first ten EQ tests; during EQ11, bars U1 and U4 fractured, likely due to low-cycle fatigue from prior tests. Prior to EQ11 the measured strain in bar U1 remained below 4% as uplift induced strains were spread over the unbonded length.

Losses in the initial PT force were less than 5% over the duration of testing and the force remained well below the expected yield load during testing.

6. CONCLUSIONS

The measured and observed experimental response of the RPT HyFRC column confirmed that the three main design objectives were successfully achieved. Several key observations were drawn from evaluation of the test:

i. Imposed drifts were successfully accommodated by rocking about the column-foundation interface rather than plastic hinge formation.

ii. The overturning resistance provided by the combination of unbonded PT strands and unbonded continuous reinforcing bars encouraged column re-centering behavior, even after yielding the unbonded bars. Residual drifts were significantly lower in the RPT HyFRC column compared to the reference column.

iii. The headed bars helped relieved compression in the HyFRC end region; significant inelastic yielding in compression was observed but buckling was prevented.

iv. Spalling was prevented by the HyFRC and most cracking was limited to below 200 mm from the top of the foundation. Damage to HyFRC was mostly restricted to the cover material.

Abstract: Performance of a four-span curved bridge under multi-directional earthquake loading is investigated through system-level hybrid simulation conducted at the Network for Earthquake Engineering Simulation Laboratory of the University of Illinois. One small-scale and two large-scale piers are tested experimentally using Loading and Boundary Condition Boxes, while a computational model of the bridge deck is concurrently simulated. Due to geometrical asymmetry and combined actions, each pier undergoes six degrees-of-freedom (DOF) motion. The full curved bridge system is tested pseudo-dynamically under an earthquake record at four performance-based scaling levels. To facilitate this hybrid simulation test, a framework is established with respect to communication, coordinate transformation and scaling, data acquisition system. Due to the fact that connections among the specimens, loading boxes and reaction wall may introduce deformations caused by finite stiffness at the fixtures, a high-precision positioning control scheme is developed to compensate for the displacement errors that would otherwise be imposed on the bridge piers. Extensive traditional and advanced non-contact instruments are employed to monitor local and global structural behavior. Using a post-processing toolbox developed in-house, the structural responses of the piers and system-level bridge responses are obtained and represented graphically. Finally, this hybrid test is successfully conducted with the sophisticated control algorithm and dense arrays of advanced instrumentation.

1. INTRODUCTION

Seismic performance assessment of structures is essentially challenging to earthquake engineering. One of major methods to examine seismic performance is structural testing. To date, the common experimenting methods are shaking table, quasi-static, pseudo-dynamic (hybrid simulation), and real-time hybrid simulation testing. Due to limited hydraulic payload, shaking table testing usually requires a scaled model for structural evaluation and may eventually misrepresent structural behavior. Through a slow-loading scheme, quasi-static testing employs predetermined inputs to examine structural performance based on either displacement or force control without considering entire structural systems. Hybrid simulation combines numerical models, time-step integration technique, and experimental specimens to assess structures. Real-time hybrid simulation is an advanced technology for the slow-rate hybrid simulation, but the required hydraulic power for real-time testing is substantially huge with respect to full-scale testing. For understanding structural dynamics, hybrid simulation is nowadays the most available method to investigate seismic performance of large- or full-scale structures through multi-dimensional loadings.

Structural behavior of bridges is quite complicated. Piers in a bridge are usually subjected to combinations of actions and deformations under spatially-complex earthquake ground motions. The combinations contain the features of structural configurations and the interaction between input and response characteristics. As impacted by the combined actions and loadings, the bridge piers may result in large deformations and substantial damages. To understand the effects of the combined actions and loadings, further experimental evaluation over an entire bridge is of need (Silva et al. 2009, Arias-Acosta and Sanders 2010).

To evaluate the combined actions on bridge piers, the full loading and boundary conditions should be considered. In the George E. Brown Network for Earthquake Engineering Simulation (NEES), the Multi-Axial Full-scale Sub-Structuring Testing and Simulation (MUST-SIM) facility at the University of Illinois at Urbana-Champaign (UIUC) has a unique 6DOF loading platform featuring a state-of-the-art, six-actuator, self-reaction loading system, namely the Load and Boundary Condition Box (LBCB) (Nakata et al. 2007). By combining strong wall and floor, one loading point of LBCBs enables applications of

displacement or force at each DOF, resulting in multiple loading points over different LBCBs. A series of LBCBs offer an opportunity to test various components of a structure at the same time. This feature also benefits the hybrid simulation for the assessment of the system-level responses in a structure such as a bridge.

A hybrid simulation framework has been developed for the MUST-SIM facility at the University of Illinois (Kwon and Elnashai 2007). This framework, named UI-SimCor, facilitates the hybrid testing at UIUC to integrate a number of finite element (FE) tools (e.g., ZEUS-NL by Elnashai et al. 2002 and OpenSees by McKenna and Fenves 2011) and realizes the distributed hybrid testing to communicate in different protocols. With the advanced testing capability, this framework can control up to total 18 DOF displacements or forces using the large-scale facility in the MUST-SIM laboratory. Moreover, this framework is flexible to incorporate the three $1/5^{th}$-scale LBCBs with multi-scale specimens in hybrid testing.

Utilizing LBCBs in hybrid simulation, large reaction forces on the reaction wall can cause ineligible deformations and subsequently introduce displacement errors being imposed to the specimens. These displacement errors are essentially critical for the experimental components and numerical integration in hybrid simulation. As indicated in Shing and Mahin (1987) and Shing and Mahin (1990), these deformations between the LBCBs and strong wall would propagate errors throughout the test and affect spurious energy to the structure. To avoid the incorrect displacements being imposed to the specimens, a displacement correcting scheme should be accompanied in controlling LBCBs.

Prior to large-scale testing, small-scale approaches give a preview of the hybrid simulation test and validate functionality of all details in the hybrid simulation framework. Due to economic considerations, large-scale hybrid simulation may only have a one-time chance to fulfill; however, the inexpensive small-scale testing offers an alternative way to verify all features in terms of software and communication first (Holub 2009). In addition, limitations in hardware (e.g., the actuator strokes, resolutions, and control schemes) can be discovered in advance. With the efforts involved in small-scale testing, a successful large-scale hybrid simulation test is foreseeable.

Dense instrumentation definitely helps researchers to explore structural performance during a hybrid simulation test and to process data afterwards. One of the key instruments in the MUST-SIM facility is the non-contact measurement machine, namely K-Series DMM from Nikon Metrology (2012) (the former name is the Krypton system). This machine can detect three-dimensional (3D) displacements on specimens as long as the LED targets are attached to them. Due to the capability of this machine, the detailed behavior of structures can be investigated by adequate data analysis. The high-resolution displacement measurements obtained from this machine can be converted into strain maps over the specimen dimension. For localizing the specific portions, the 3D displacements in a certain region can be transformed into 6DOF motions. During a hybrid simulation test, the curvature can be calculated by multiple LED displacements and then illustrate the moment hysteresis performance online. These methods featuring the non-contact instrumentation interpret the measurements closer to the numerical analysis.

In this study, seismic performance of a four-span curved bridge is evaluated via hybrid simulation under multi-directional earthquake loading. This experiment is carried out by the MUST-SIM facility in the Network for Earthquake Engineering Simulation Laboratory at the University of Illinois. Three physical concrete piers are tested using the Loading and Boundary Condition Boxes, while the bridge deck is computationally modeled and concurrently simulated. To realize this hybrid simulation test, a hybrid simulation framework is established in terms of software, hardware, and communication protocols. For advancing the hybrid simulation in the MUST-SIM NEES site, two additional components are recently developed to enhance the framework. A 6DOF high-precision positioning control scheme is built to achieve accurate displacements on the specimens. A post-processing toolbox is also developed to further investigate the structural responses of the piers and system-level bridge responses based on the non-contact instrumentation. Prior to the large-scale hybrid simulation test, a small-scale approach is employed to validate the hybrid simulation framework. With the completed framework, the curved bridge is successfully evaluated using three LBCBs in hybrid simulation. The associated results obtained from dense arrays of advanced instrumentation are also discussed in this study.

2. HYBRID SIMULATION FRAMEWORK

The MUST-SIM facility utilizes 6DOF LBCBs to fulfill hybrid simulation tests for complex structural systems. A hybrid simulation framework was initiated by Nakata et al. (2007) and Kwon and Elnashai (2007). To further improve the quality of hybrid simulation tests, a number of functions were continuously developed and added into this framework by researchers until now. Figure 1 highlights the current hybrid simulation used for the MUST-SIM NEES facility. This section reviews the existing components as well as provides the details of the recently developed components in this framework.

2.1 Loading and Boundary Condition Boxes

The Loading and Boundary Condition Box (LBCB) consists of six actuators that create 6DOF movements on the loading platform. Each actuator can produce 1,101 kN (216 kips) in tension and 1,383 kN (328 kips) in compression. In terms of the 6DOF displacement capacity, each LBCB can generate ±250mm (10 in), ±125mm (5 in), ±125 mm (5 in) in the *x*-, *y*-, *z*- directions and ±16°, ±11.8°, ±16° in the roll, pitch, yaw directions. Moreover, the maximum force capacity is 1,921/2,918 kN (432/656 kips), 960/1,459 kN

(216/328 kips), 2,882/4,377 kN (648/984 kips) in the *x*-, *y*-, *z*- directions, where both numbers indicate the tension and compression capacity, respectively. The moment capacity is 862 kN-m (636 kip-ft), 1152 kN-m (850 kips-ft), 862 kN-m (636 kip-ft) in the roll, pitch, yaw directions.

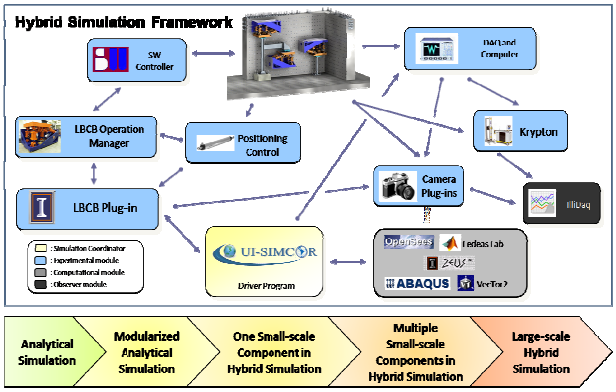

Figure 1 Illustration of The Current Hybrid Simulation Framework

2.2 Shore Western Controller

The Shore Western (SW) Controller is to control all six actuators in LBCB (Shore Western Manufacturing 2012). The control scheme used in the controller is the proportional-integral-derivative (P.I.D.) loop under the displacement feedback. Each actuator is controlled by an independent P.I.D. loop, and these actuators are rated to generate relatively slow movements. Furthermore, the controller also serves as a data acquisition (DAQ) system to output the signals from the displacement transducers and load cells.

2.3 Operation Manager

The operation manager (OM) is an agent to convert the commands from the Cartesian space to the actuator space. Owing to the orientation of the actuators in LBCBs, every command sent in the Cartesian Space will move all six actuators simultaneously. To attain high accuracy in displacements, OM acquires the readings from and sends the commands to the Shore Western Controller with a high sampling rate (Nakata et al. 2007).

OM moves LBCBs under the displacement control. For the multi-DOF displacement commands, OM can send the signals directly to the SW controller. Additionally, OM employs a mixed-mode control scheme to command forces, and these forces are converted into displacements based on the current specimen stiffness or maximum displacement increments with respect to force changes. Each DOF can only be specified with a displacement or force command at a time, while mixed displacement and force commands can be concurrently applied to multiple DOFs.

OM can also impose displacements about the control point in the specimen coordinates. The control point is defined as the loading point of interest to users. At the point, the specimen will displace identically to the loading protocol. Furthermore, OM contains a transformation matrix that maps the displacements of specimens into LBCBs. Thus, the loading axes will be aligned with the specimen coordinates. All these features ensure displacements being correctly imposed to the specimens during tests.

2.4 LBCB Plug-in

The LBCB Plug-in is an interface that implements users-defined functions in a test and communicates data to other modules. This interface can preprocess the loading protocol in accordance to the received responses from the specimen. For instance, the force commands can be calculated by the corresponding displacements obtained from the previous step. The interface also provides a coordinate transformation to alter the axes that corresponds to the finite element model in hybrid simulation. Moreover, the LBCB Plug-in handles all triggers for the modules that are directly associated with the loading protocol, e.g., DAQ, non-contact instrumentation machines, and camera plug-ins.

2.5 UI-SIMCOR

The Multi-site Substructure Pseudo-dynamic Simulation Coordinator (UI-SimCor) is a hybrid simulation coordinator, developed in the MUST-SIM NEES site at UIUC (Kwon et al. 2007). The core of this coordinator is to communicate the components between the specimens and modularized FE solvers (e.g., ZEUS-NL and OpenSees) and to calculate dynamic response based on the integration scheme. To launch a hybrid simulation test through UI-SimCor, the initial stiffness matrices are first established among all experimental and computational components. As LBCBs are capable of applying the gravity forces, the static loading can be added to the entire system before (pseudo-) dynamic testing. These static loading will generate the corresponding displacements from the predetermined stiffness and eventually achieve the target forces. Note that UI-SimCor is not specific to LBCBs and is implementable in the majority of hybrid simulation facilities. Given the mass and damping matrices, the dynamic testing by UI-SimCor will impose displacements to the specimens, sense the achieved displacements and forces, obtain the restoring forces from both experimental and computational components, and then execute next step. In fact, UI-SimCor bridges the experimental specimens into the structural FE model by the integration scheme.

Owing to the limited hydraulic power and laboratory space, hybrid simulation tests may face a scaling issue. UI-SimCor accounts for the scaling factors with respect to the specimen dimensions and forces, resulting in four types of scaling parameters: 1) translational displacements, 2) rotational displacements, 3) translational forces, and 4) moments. In the scaling parameters, the unit conversion is also considered and can fit the unit systems used in both FE tools and experimental facility. Therefore, UI-Simcor can conduct multi-scale responses in distributed hybrid simulation.

2.6 Miscellaneous Modules

The MUST-SIM facility is also known for dense instrumentation in structural testing. The data acquisition

software, named IlliDaq, is a platform that handles all the measurements together. The system can support multi-hundred channels, and the measurement types range from strain gauges, displacement transducers, inclinometers, load cells, and etc. As LBCBs are currently capable of slow-movement tests, these measurements are stored in a step-wise format. In addition, this DAQ platform can also display the results during a test (multiple windows over several screens) and derive the calculated responses based on the predetermined equations such as the curvatures computed by steel strain gauges. To secure all measurements, this platform can upload data to the web repository. All these functions in the DAQ platform provide a flexible environment to explore the behavior of structures.

To visualize the structural responses, the MUST-SIM facility employs a number of digital single-lens reflex (DSLR) cameras. These still pictures taken from the DSLR cameras are triggered and synchronized to the loading steps by the Camera Plug-in. The Camera Plug-in triggers cameras after LBCB accomplishes executing a step. These pictures can be consequently merged together to make a video with respect to the loading history. These visualized data provides an additional option to reinvestigate tests.

The Krypton Plug-in is a part of IlliDaq that acquires the non-contact instrumentation measurements and sends the step-wise data back to the DAQ platform. As mentioned earlier, the Krypton system runs on an independent machine. Thus, the Krypton Plug-in transforms the data format and subsequently synchronizes the data sets with IlliDaq. The data obtained from the Krypton system will then have the same step stamps on measurements.

2.7 High-precision Positioning Control Scheme

Due to finite stiffness and large reaction forces, the fixture between the reaction (strong) wall and LBCBs may induce small elastic deformations or slight slippages. These small movements can cause substantial errors to specimens in terms of forces. To compensate these movements, a high-precision positioning control scheme is developed and added to the hybrid simulation framework. In this control scheme, a 6DOF displacement monitoring strategy is to employ six or more displacement transducers for detecting the actual 6DOF displacements, while a deformation correction method is to introduce the additional movements for achieving the target displacements. Utilizing these two features, the displacements can be accurately achieved.

Figure 2 demonstrates the proposed monitoring strategy for 6DOF displacements. Six displacement transducers (using LVDTs as an example) are instrumented between the specimen and reaction wall. The setup is assumed to be in a rigid-body motion throughout a test. All free-pin locations of LVDTs are directly connected to the top of the specimen, while the fixed-pin locations of LVDTs are supported by solid brackets and connected to the reaction wall. To be fully aware of all 6DOF displacements, the LVDT locations are recommended to follow the proposed configuration, i.e., one LVDT in the first axis, two LVDTs in the second axis, and three LVDTs in the third axis. Note that these LVDTs could be skewed. Then, the three axes in the Cartesian space are defined in accordance to the specimen space in which the sensor space is equivalent to the specimen space. Therefore, the conversion from the Cartesian space to the sensor space is written by

$$\mathbf{x}_{i,\text{new}}^{\text{free}} = \mathbf{T}_1\mathbf{T}_2\mathbf{T}_3\mathbf{x}_{i,\text{original}}^{\text{free}} + \begin{bmatrix} x^{\text{cp}} \\ y^{\text{cp}} \\ z^{\text{cp}} \end{bmatrix} \qquad (1)$$

$$d_i = \left\|\mathbf{x}_{i,\text{new}}^{\text{free}} - \mathbf{x}_i^{\text{fixed}}\right\| - \left\|\mathbf{x}_{i,\text{original}}^{\text{free}} - \mathbf{x}_i^{\text{fixed}}\right\|$$

where

$$\mathbf{T}_1 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\left(\theta_x^{\text{cp}}\right) & -\sin\left(\theta_x^{\text{cp}}\right) \\ 0 & \sin\left(\theta_x^{\text{cp}}\right) & \cos\left(\theta_x^{\text{cp}}\right) \end{bmatrix}, \mathbf{T}_2 = \begin{bmatrix} \cos\left(\theta_y^{\text{cp}}\right) & 0 & \sin\left(\theta_y^{\text{cp}}\right) \\ 0 & 1 & 0 \\ -\sin\left(\theta_y^{\text{cp}}\right) & 0 & \cos\left(\theta_y^{\text{cp}}\right) \end{bmatrix},$$

$$\mathbf{T}_3 = \begin{bmatrix} \cos\left(\theta_z^{\text{cp}}\right) & -\sin\left(\theta_z^{\text{cp}}\right) & 0 \\ \sin\left(\theta_z^{\text{cp}}\right) & \cos\left(\theta_z^{\text{cp}}\right) & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

$\mathbf{x}^{\text{cp}} = \begin{bmatrix} x^{\text{cp}} & y^{\text{cp}} & z^{\text{cp}} & \theta_x^{\text{cp}} & \theta_y^{\text{cp}} & \theta_z^{\text{cp}} \end{bmatrix}^T$ is a given displacement vector in the 6 DOFs at the control point; $\mathbf{x}_{i,\text{original}}^{\text{free}}$ and $\mathbf{x}_i^{\text{fixed}}$ are respectively the initial free-pin and fixed-pin coordinates of the i-th LVDT; $\mathbf{x}_{i,\text{new}}^{\text{free}}$ is the updated free-pin coordinates of the i-th LVDT; d_i is the differential displacement of the i-th LVDT after the specimen moved. This conversion is straightforward; however, the inverse conversion from the sensor space to the Cartesian space is a highly nonlinear problem requiring a nonlinear solver to obtain the displacements at the control point. To prevent a convergent issue, a number of constraints can be added and given by

$$\left\|\mathbf{x}_{i,\text{new}}^{\text{free}} - \mathbf{x}_{j,\text{new}}^{\text{free}}\right\| = \left\|\mathbf{x}_{i,\text{original}}^{\text{free}} - \mathbf{x}_{j,\text{original}}^{\text{free}}\right\|, \; i, j = 1 \sim n \qquad (2)$$

where n is the number of LVDTs used. Because all free pins travel in the rigid-body motion, the distance from one pin to another is constant. Based on the configuration in Figure 1, the total number of the constraints is 15. To solve the nonlinear problem, the Newton Raphson method or commercial toolbox such as the Matlab optimization toolbox (Matlab 2012) can be used.

Elastic deformation is defined as the slight movement at the reaction fixtures of hydraulic actuators or the slippage between the loading surfaces and specimen. As the movement is introduced, the internal displacement transducers of hydraulic actuators cannot impose consistent displacements to a specimen. As a result, the measured displacements from hydraulic actuators are no longer correct, even though the readings have presented to achieve the target displacements. To account for the deformations, an online iterative process should be performed in order to eliminate the unexpected displacements. Using the solution of the combined Eqs. (1-2), the current displacement of a specimen is therefore available. The command for actuators

or LBCB boxes is then adjusted and given by

$$\mathbf{x}_{l,k+1}^{\text{cmd}} = \mathbf{x}_{l,k}^{\text{cmd}} + \left(\mathbf{x}_{l}^{\text{target}} - \mathbf{x}_{l,k}^{\text{cp}}\right) \tag{3}$$

where $\mathbf{x}_{l,k}^{\text{cmd}}$ and $\mathbf{x}_{l,k+1}^{\text{cmd}}$ represent the commands at the iterative k-th and (k+1)-th correction steps in the l-th time step; $\mathbf{x}_{l}^{\text{target}}$ and $\mathbf{x}_{l,k}^{\text{cp}}$ indicate the target displacement and current position at the control point. This process often needs more than one correction steps within a time step. The process will be accomplished until a predefined tolerance is met and given by

$$\begin{aligned} &\left|y_{l}^{\text{target}} - y_{l,k}^{\text{cp}}\right| \le m, \\ &y \in \mathbf{x} = \left\{x \quad y \quad z \quad \theta_x \quad \theta_y \quad \theta_z\right\}, \\ &m \in \left\{\delta_x \quad \delta_y \quad \delta_z \quad \delta_{\theta_x} \quad \delta_{\theta_y} \quad \delta_{\theta_z}\right\} \end{aligned} \tag{4}$$

where δ indicates the tolerance in terms of DOFs. In Eq. (4), each controlled DOF must satisfy the condition. To avoid the overshooting behavior, Eq. (3) may consider a correction factor to lower the correction amount in a correction step. Even though the displacement error satisfies the tolerance, a small amount of errors still exists. A preliminary adjustment, which is the deviation between the achieved and target displacements in the last time step, is then used to compensate prior to introducing correction steps. By combining these two features, a complete correction procedure is presented by

$$\begin{aligned} \mathbf{x}_{l,0}^{\text{cmd}} &= \mathbf{x}_{l}^{\text{target}} + \alpha\left(\mathbf{x}_{l-1}^{\text{target}} - \mathbf{x}_{l-1}^{\text{cp}}\right), \ \alpha = 0 \text{ or } 1 \\ \mathbf{x}_{l,k+1}^{\text{cmd}} &= \mathbf{x}_{l,k}^{\text{cmd}} + \beta\left(\mathbf{x}_{l}^{\text{target}} - \mathbf{x}_{l,k}^{\text{cp}}\right), \ \beta = 0 \sim 1 \end{aligned} \tag{5}$$

where α and β could be manually adjusted at each time step.

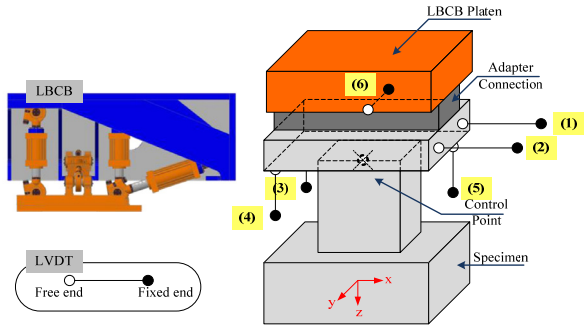

Figure 2 Illustration of 6DOF Displacement Monitoring Configuration

2.8 Post-processing Toolbox

For advancing the use of the Krypton measurements, the data processing methods in this framework comprise the estimation of three types of strains, 6DOF displacements, and curvatures over the structural dimensions. For strains, the normal and shear types are calculated with respect to the coordinates of the testing structure. The 6DOF displacements are generated from a group of LEDs with respect to a specific cross section. The curvatures are approximated from the vertical deformations of LEDs in a line and then computed over the axial loading direction. The followings provide the derivations for each method.

As the Krypton measurements provide 2D or 3D LED positions, plane strains can be calculated from these data. First, the strain calculation needs to accompany a uniform grid of LEDs aligned with the loading direction. For example, LEDs should be attached to a building column or bridge pier with an uniform spaced grid of which two directions are parallel and perpendicular to the structural axis (see Figure 3-a). Each square from four LEDs forms a number of elements derived from interpolating the measured positions into fine meshes, as shown in Figure 3-b. The nodes in these fine meshes are then derived from a quadratic form and given by

$$\begin{cases} x_{ij} = \left[(1-m)(1-n) \quad m(1-n) \quad mn \quad (1-m)n\right]\left[x_1 \quad x_2 \quad x_3 \quad x_4\right]^T \\ y_{ij} = \left[(1-n)(1-m) \quad m(1-n) \quad mn \quad (1-m)n\right]\left[y_1 \quad y_2 \quad y_3 \quad y_4\right]^T \end{cases} \tag{6}$$

where m and n range from 0 to 1, and i and j indicate the element number. The number of spacing can be different in the x and y directions. Subsequently, the normal strains in an element are illustrated in Figure 3-c and calculated by

$$\varepsilon_{x,k} = \frac{l_{x,k} - l_{x,0}}{l_{x,0}}, \ \varepsilon_{y,k} = \frac{l_{y,k} - l_{y,0}}{l_{y,0}} \tag{7}$$

where

$$\begin{aligned} l_{x,k}^2 &= \frac{1}{4}\left(x_{ij,k} + x_{i(j+1),k} - x_{(i+1)j,k} - x_{(i+1)(j+1),k}\right)^2 + \\ &\frac{1}{4}\left(y_{ij,k} + y_{i(j+1),k} - y_{(i+1)j,k} - y_{(i+1)(j+1),k}\right)^2 \\ l_{y,k}^2 &= \frac{1}{4}\left(x_{ij,k} + x_{(i+1)j,k} - x_{i(j+1),k} - x_{(i+1)(j+1),k}\right)^2 + \\ &\frac{1}{4}\left(y_{ij,k} + y_{(i+1)j,k} - y_{i(j+1),k} - y_{(i+1)(j+1),k}\right)^2 \end{aligned}$$

k denotes the k-th step of a test, and 0 means the initial step. The shear strain illustrated in Figure 3-d is derived from

$$\begin{aligned} \gamma_{xy,k} = &\frac{x_{ij,k} + x_{(i+1)j,k} + x_{(i+1)(j+1),k} + x_{i(j+1),k}}{4l_{y,0}} + \\ &\frac{y_{ij,k} + y_{(i+1)j,k} + y_{(i+1)(j+1),k} + y_{i(j+1),k}}{4l_{x,0}} - \\ &\frac{x_{ij,0} + x_{(i+1)j,0} + x_{(i+1)(j+1),0} + x_{i(j+1),0}}{4l_{y,0}} - \\ &\frac{y_{ij,0} + y_{(i+1)j,0} + y_{(i+1)(j+1),0} + y_{i(j+1),0}}{4l_{x,0}} \end{aligned} \tag{8}$$

From these two equations, the normal strains, ε_x and ε_y, are respectively formulated along the axial and transverse directions, while the shear strains, γ_{xy}, have a sign convection identical to the coordinates. The calculated strains in Eqs. (7-8) can be interpreted as the strains at the center point of an element or the constant strains in the entire element.

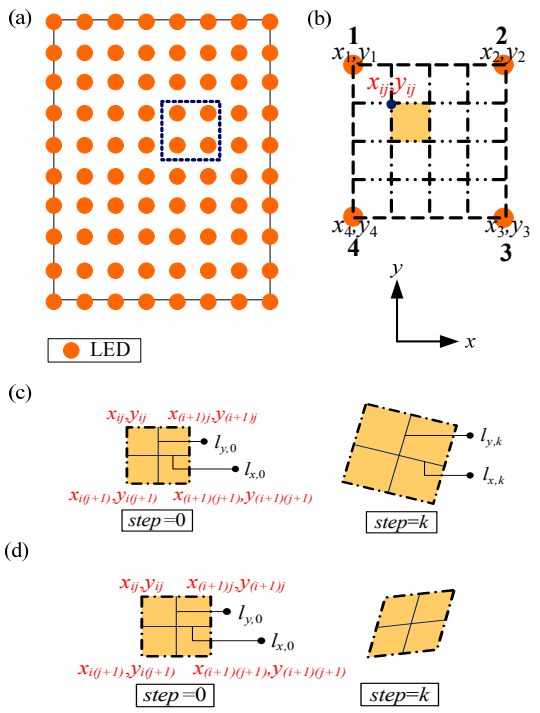

Figure 3 Illustration of Strain Calculation: 1) LED Grid, 2) Interpolation, 3) Normal Strain, and 4) Shear Strain

The Krypton measurements in the static approach only result in LED 3D positions with respect to the user-defined coordinates. With a certain group of LEDs, these position data can be converted into 6DOF displacements that can inform the local behavior of interest. The conversion can be computed by Eq. (1) with an appropriate solver. In this problem, at least three LEDs should be involved in the 6DOF displacement conversion. While this problem only contains six variables as the 6DOF displacements, considering data from only two LEDs may introduce a geometric symmetry, resulting in incorrect rotations. Moreover, the origin in the grouped LEDs can be offset to a point which is different from the one in the coordinates, defined for the entire LEDs. By selecting an appropriate group of LEDs, 6DOF displacements can be generated with respect to the region of this group.

To approximate the real-time curvatures, an approach is proposed based on the absolute LED positions. Assume that four grouped LEDs are attached near the neutral axis, as shown in Figure 4. The curvature can be subsequently estimated by

$$\kappa = \frac{\theta_{12} - \theta_{34}}{h}, \quad \theta_{12} = \frac{y_2 - y_1}{d}, \quad \theta_{34} = \frac{y_3 - y_4}{d} \qquad (9)$$

where κ is the curvature at the center of this four-LED group. In this equation, the rotations are assumed to be constant over the cross section along the perpendicular direction of the neutral axis, e.g., the horizontal direction in Figure 4. As long as h is relatively small, the curvature will be very close to the calculation using the rotations obtained from the 6DOF displacement conversion.

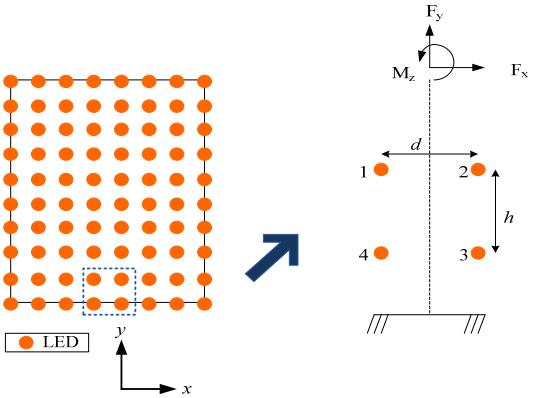

Figure 4 Illustration of Curvature Estimation

2.9 Small-scale Validation

The small-scale validation is to assess the hybrid simulation framework with all newly developed features as well as the existing components using scaled models. This validation process is conducted by different levels of simulation. First, an analytical model of the entire structure is simulated in the FE tool which will be used in the final hybrid test. The modularized analytical simulation is then performed in UI-SimCor so that the integration scheme with the parameters used (e.g., integration time step) can be confirmed. By adding one single experimental small-scale component, the hybrid simulation framework is tested with the communication between UI-SimCor and LBCB Plug-in, coordinate transformation, scaling, and high-precision positioning control scheme. Thus, all the experimental components are employed in the small-scale approach in order to verify the multi-platform communication (e.g. Camera Plug-ins) and hardware limitations (e.g., specimen positions connecting to LBCBs, actuator strokes and forces, and external sensor resolution in terms of the high-precision positioning control scheme). After validating the hybrid simulation framework through a series of simulation tests, a large-scale hybrid simulation test can be implemented.

3. DEVELOPMENT OF A FOUR-SPAN CURVED BRIDGE

Reinforced concrete bridge piers are subjected to a combination of forces and deformations due to spatially complex ground motions, structural or geometry configuration, and the interaction between input and response characteristics. Motivated by the impact of combined actions on piers and overall system response, a four-span curved bridge structure is developed and experimental evaluated using hybrid testing through the unique capabilities of the MUST-SIM facility at UIUC. This bridge test is a part of the Combined Actions on Bridge Earthquake Research (CABER) project, sponsored by National Science Foundation (NSF). Prior to this curved bridge hybrid test, the CABER team has investigated a wide variety of topics associated with the combined actions on

bridge columns. For example, Prakash et al. (2010) explored circular RC columns subjected to axial force, bending, and torsion that interact with shear. Blearbi incorporated the experimental findings of bridge columns to the performance-based evaluation under combined loadings. Xu and Zhang (2012) studied the axial-shear-flexure interaction for the reinforced concrete columns under combined actions. Kim et al. (2011) experimentally investigated a bridge structure subjected to both horizontal and vertical ground motions. Arias-Acosta and Sanders (2010) and Moustafa et al. (2011) employed shaking table testing to study seismic performance of reinforced concrete bridges under bi-directional horizontal excitations. As for this hybrid simulation test, the main objective is to experimentally investigate the four-span curved bridge subjected to bi-directional horizontal ground motions.

The curved bridge is developed based on a seismic design example used by the National Cooperative Highway Research Program (NCHRP) Project 12-49. The prototype bridge is composed of five continuous spans of 30 m (100 ft) each, with four two-pier bents. A box girder on the piers is used to support the superstructure. In this study, some design parameters, addressed in the NCHRP example, are modified. The modification includes reducing from five to four spans and shortening the overall length appropriately, creating non-uniform span lengths, adding curvature to the bridge, and moving to single-pier bents. The resulting geometry was selected via an analytical parametric study to identify a case that generated sufficient torsional response in the piers to investigate higher levels of combined actions.

The overall dimensions of this bridge are presented in Figure 5. The bridge deck is 120 m (400 ft) in total length with a radius of 198 m (660 ft). The cross section of the deck is a box girder with a surface width of 6.6 m (22 ft). Above each pier, the box girder is supported by a 4.8-m (16-ft) cap beam with a cross section of 1.5m (5 ft) x 2.0 m (6.75 ft). The piers are 1.2 m (4 ft) diameter, with 28#10 bars as longitudinal reinforcement, distributed evenly. Transverse reinforcement is a #5 continuous spiral stirrup. The pier lengths are 8.6, 11.3, and 6.8 m (28.5, 37.5, and 22.5ft).

In the experiment, the bridge deck, cap beams, and abutments are modeled analytically using Zeus-NL (Elnashai et al. 2002). The outer two piers are tested at a 1:3 scale, while the inner pier is tested at a 1:20 scale. The 1:3 scale piers are therefore constructed with a 0.4-m (16-in) diameter, and 17#4 longitudinal bars and a #3 spiral at 5-cm (2-in) pitch and 1.9-cm (3/4-in) cover. The resulting heights are 2.9 and 2.3 m (9.5 and 7.5 ft) respectively. Due to the limitation of the laboratory space, the inner pier is down scaled to 1/20th. The resulting dimensions are 57.2-cm (22.5-in) height and 6.1-cm (2.4-in) diameter.

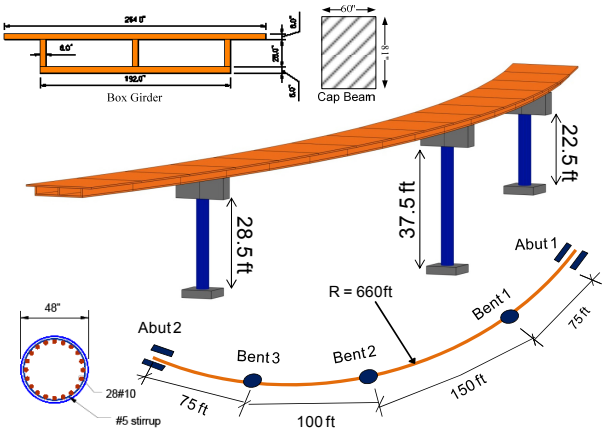

Figure 5 Dimensions of The Curved Bridge

4. HYBRID SIMULATION RESULTS

Circular reinforced concrete piers of a four-span curved bridge are experimentally investigated through large-scale hybrid simulation under bi-directional earthquake loadings. The boundary conditions of the piers are controlled in all six DOFs. The experiment is performed by the MUST-SIM facility at UIUC. In this hybrid test, the bridge structure is composed of one small-scale and two large-scale experimental piers. The curved bridge deck and abutments are modeled analytically in Zeus-NL. This hybrid simulation test is novel because of a) geometric irregularities and varying pier response characteristics, b) multi-directional motions of the applied earthquake record, c) a curved bridge deck and combined actions with torsion, and d) system-level interaction between three experimental piers in two testing facilities with numerical models of deck, restraints, and abutments.

Figure 6 illustrates the experimental setup of this hybrid test. Two large-scale piers representing the outer piers in a bridge are tested by the large-scale LBCBs, while one small-scale pier representing the center pier is tested by the 1/5th-scale LBCB. Extensive instrumentation is employed for the large-scale piers. For example, 170-channel conventional sensors are instrumented including 152 strain gages, 6 string potentiometers, and 12 LVDTs. For the non-contact instrumentation, 200 Krypton LEDs are attached on both large-scale piers. 12 DSLR cameras are placed in different locations in order to capture the pier motions every step. The applied earthquake record is a synthetically generated accelerogram representative of the seismic zone corresponding to Seattle, WA. Four performance levels per 10 seconds are considered and correspond: 1) cracking performance level at 0.08 times of the most credible earthquake (MCE), 2) yielding performance level at 0.30 MCE, 3) design performance level at 1.00 MCE, and 4) failure level at 2.00 MCE, as shown in Figure 7. 100% of this earthquake record is applied to the transverse direction of the bridge, while a 25% scaled version of the record is applied in the longitudinal direction.

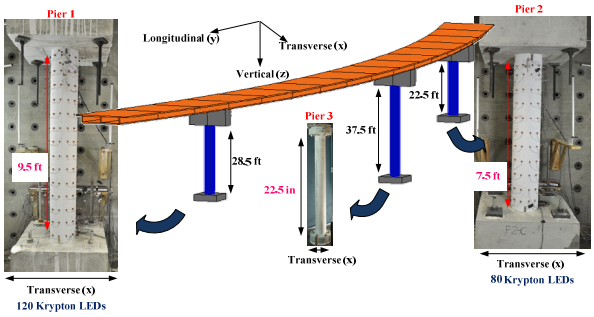

Figure 6 Hybrid Simulation Setup of The Four-span Curved Bridge

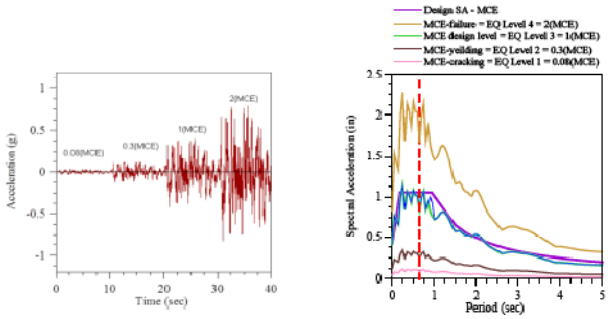

Figure 7 Earthquake Record Used in This Hybrid Test

Figure 8 demonstrates the displacement time histories of the two large-scale piers. The transverse, longitudinal, and vertical directions are denoted as x, y, and z in this figure. The test is ended at 39.72 seconds because the horizontal actuators of the LBCB run out the strokes on the top of the tall pier (the left one in Figure 6). Moreover, the coordinates presented in this figure are in the full scale that corresponds to the analytical model. The maximum drifts of the tall pier reach 5.9% and 1.8% along the transverse and longitudinal directions, while the short pier has 3.3% and 0.6% maximum drifts along the same directions. The maximum transverse rotation and torsion are 3.15° and 1.27° on the tall pier and 2.23° and 0.90° on the short pier. For the center pier, the maximum drifts in the transverse and longitudinal directions are 6.4% and 0.7%, while the maximum transverse rotation and torsion are 3.04° and 1.10°. More results will be documented and published in the near future.

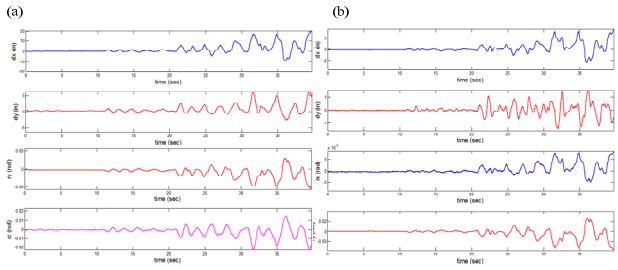

Figure 8 Displacement Responses of The Large-scale Piers: (a) Tall Pier and (b) Short Pier

To demonstrate the high-precision positioning control scheme, the achieved 6DOF displacements are compared to the target ones in the large-scale piers, as shown in Figure 9.

All the units are in the 1/3rd scale (equivalent to the LBCB coordinates). The translational and rotational tolerances are set as 0.127 mm (0.005 in) and 5×10^{-4} radians. The translational tolerances are increased to 0.254 mm (0.01 in) at the time the specimens have large displacements, i.e., during the last 10 seconds of the earthquake record. Due to the 75-cm (30-inch) LVDTs, the moment arms are sufficiently large for monitoring the rotations. The deformation correction is often controlled by the translations, resulting in the consistently small errors for rotations. The results exhibit that the high-precision positioning control scheme produces very accurate displacements to piers. The errors are always within the predetermined tolerances. Consequently, the experimental results are reliable and accurate for this hybrid simulation test.

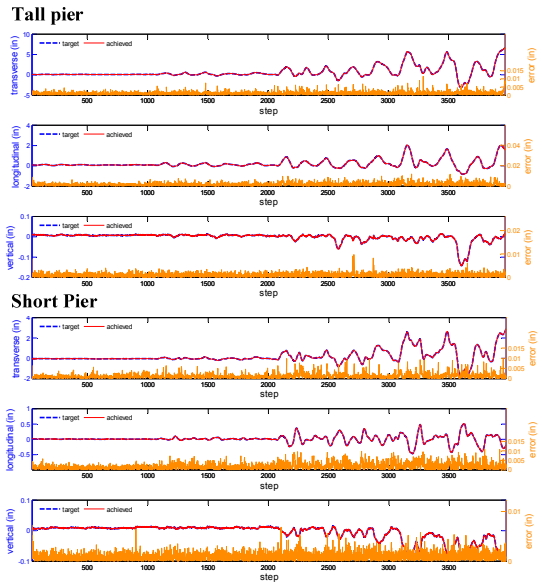

Figure 9 Errors Between Target and Achieved Displacements in Large-scale Piers

In the small-scale validation, the procedures illustrated in Figure 1 are all conducted. The purely analytical modeling is simulated using Zeus-NL. The modularized analytical simulation is performed through UI-SimCor with the Zeus-NL tool in which three piers are modeled linearly. The first small-scale hybrid simulation is carried out with the center pier as the experimental component, while the outer piers are still simulated as linear columns. In this hybrid simulation test, the center pier is scaled to 1/20th that is identical to the large-scale hybrid simulation test. The last test in the small-scale validation is the three-pier small-scale hybrid simulation where the three piers are all scaled to 1/20th. To demonstrate the effectiveness of the small-scale validation, the displacements of the three-pier small-scale hybrid simulation are compared to those of the large-scale test. Figure 10 illustrates the two transverse displacements, transverse rotation, and torsion of the outer tall and center piers. The units are equivalent to the coordinates in the full-scale bridge, and the data shown are the piers subjected to the design performance level at 1.0 MCE (20~30

seconds). This figure shows that the small-scale results are able to inform the response levels in the large-scale test and only small errors are found between two tests. Therefore, the small-scale validation is necessitated for examining the hybrid simulation framework as well as ensuring the feasibility of the large-scale hybrid test.

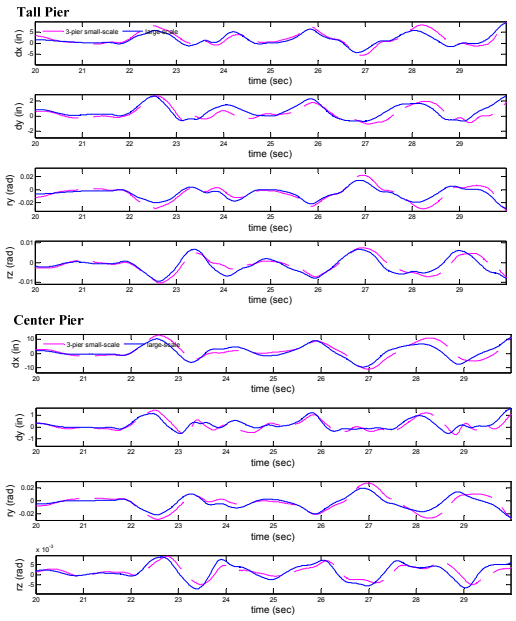

Figure 10 Displacement Responses Between Small-scale and Large-scale Hybrid Simulation Tests

As mentioned earlier, a post-processing toolbox is developed for the non-contact instrumentation measurements. After this hybrid test, the toolbox is also applied to the large-scale piers in order to investigate the detailed behavior. First, strain maps can predict or indicate the cracks of structures during testing. Figure 11 demonstrates vertical strains maps before and after a large crack happens in the tall pier. As can be seen in this figure, the yellow portion indicates the crack position near the bottom of the pier. Because the strains are calculated from the LED positions, the corresponding strains around the crack may overestimate the true surface strain of this concrete pier. However, this strain still gives a good indication of cracks and informs damages in a early time. By inspecting the changes in a strain map, the cracks can be notified in advance if the crack strains are known.

Strain maps also provide a good indication of concrete spalling. In Figure 12, a series of strain maps are compared to the corresponding still pictures. Although these strain maps may overestimate strains near the concrete damages, these strain maps still exhibit an early prediction of concrete spalling. Prior to the occurrence of a peak response, moderate strains are found around the spalling location. With an increase of forces applied at top of the pier, tensile strains in this region are enlarged. When the spalling is visible, the strain map has shown severe damages in an early time. The strains, generated from the LED positions, offer an opportunity to detect damages before they are visibly found.

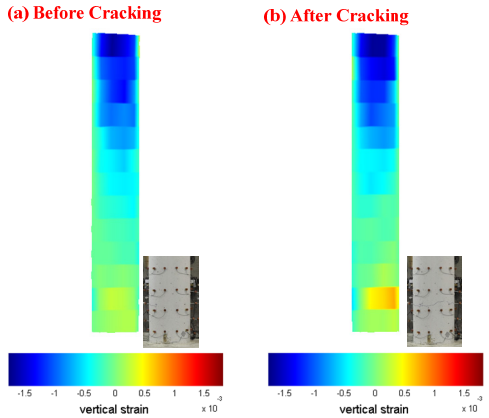

Figure 11 Indication of Cracks: (a) Before Cracking and (b) After Cracking

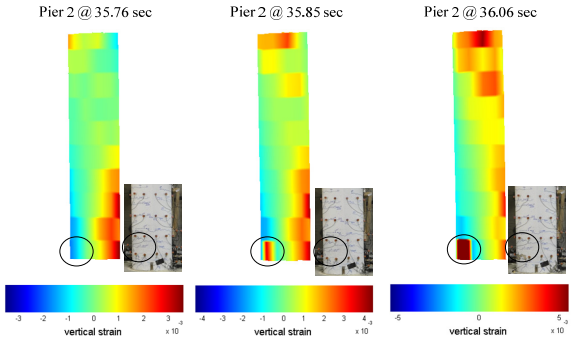

Figure 12 Concrete Spalling Indication from Strain Maps

Structural behavior can be informed from the strain maps. This experiment is conducted by LBCBs which can concurrently impose moments and shear forces at the top of the piers. As shown in Figure 13, the moment distribution along the axial direction of the pier is consistent with the vertical strain map. In this figure, the moment (M_y) imposed at top is positive, while the resulting moment (M_y) at bottom is negative due to the positive shear force (F_x) at top. Obviously, the pier has a double-curvature behavior induced by the complex loadings. Moreover, the positive shear force (F_x) at top, combined with other DOF loadings, results in the shear strain map shown in Figure 13. Because the strain map created in this figure is projected to the *x*-*z* plane, the contribution from the moment (M_x) and force (F_y) is minor. Thus, the most shear strains are induced from the combination of the shear and torsional forces. Additionally, the torsion at top dominates the horizontal strains of the pier, with a combination of the shear force, as shown in Figure 14. The negative torsion at top introduces positive and negative shear strains at the negative and positive *x* direction due to the 3D strains that are projected to the *x*-*z* plane. With the positive shear force at top, the absolute value of the negative strain is greater than the value of the positive strain. Using the strain map, the structural behavior can be easily investigated in comparison with forces.

5. CONCLUSIONS

Hybrid testing of a four-span curved bridge structure subjected to bi-directional ground motions was successfully performed by the Multi-Axial Full-scale Sub-Structuring Testing and Simulation facility at the University of Illinois at Urbana-Champaign. In this hybrid simulation test, one small-scale and two large-scale piers were experimentally evaluated using the Loading and Boundary Condition Boxes, while the bridge deck and abutments were computationally modeled in Zeus-NL. Four performance-based levels of an earthquake record were selected to assess the curved bridge. As a result, the performance of all piers and the system-level responses of the bridge were significantly influenced by the 6DOF combined loadings that had been shown in the visualization data.

Prior to the hybrid test, two additional components were developed to complete the hybrid simulation framework. The high-precision positioning control scheme was established to compensate the elastic deformation between the reaction wall and LBCBs, resulting in accurate displacements being imposed to the piers. With the post-processing toolbox, the pier and system-level responses were graphically presented for further investigation on the combined actions of the bridge. Moreover, two small-scale validation tests confirmed all the components in hybrid simulation and enabled the large-scale hybrid test. Finally, the hybrid test of this curved bridge was accomplished by the well-prepared hybrid simulation framework.

Abstract: Numerical modeling method was developed for fire sprinkler piping systems and used to generate seismic fragility parameters. The model accounts for inelastic response of threaded joints, braces, hangers, and wire restrainers. The model incorporates a nonlinear hinge model developed for threaded tee joints based on experiments conducted at the University at Buffalo. The hinge model may be adapted to different pipe diameters. This modeling technique was used to simulate the seismic response of the fire sprinkler system of the University of California, San Francisco (UCSF) Hospital using a suite of ninety-six artificially generated tri-axial acceleration. Component fragility parameters were obtained for wire restrainers, pipe hangers, and threaded pipe joints. Three system damage states were defined and a joint probabilistic seismic demand model was utilized to obtain system-level fragility parameters.

1. INTRODUCTION

In recent major earthquakes such as the 2010 Chile earthquake, most of the hospitals in the central south region of Chile were subjected to strong ground motion. A total of sixteen hospitals were inspected after the earthquake (Miranda et al., 2012). Four hospitals were closed due to the loss of functionality, and approximately 75% of function was lost in the remaining twelve (Gupta et al., 2011). The damages to the piping system were mainly associated with pipe hanger failures, failed sprinkler heads due to contact with ceilings elements, leakage of threaded joints, etc. After the great 2011 Tohoku Pacific Earthquake, many structures were inspected. In that earthquake, damage to fire protection systems and plumbing accounted for 10% and 27% of the entire cost of equipment damage, respectively. The damage to the piping adds up to approximately 50% of the total cost with the damage to sprinkler heads second to that. During this earthquake 42% of the damaged piping systems also showed signs of water leakage (Mizutani et al., 2012).

Several experiments have been conducted on piping systems during the last 20 years such as bending tests on sixteen simply supported pipe specimens (Antaki and Guzy, 1998), dynamic tests of twenty pipe specimens (Antaki and Guzy, 1998), shaking table experiments on four hospital piping assemblies (Zaghi et al, 2012), monotonic and cyclic tests on forty-eight pipe tee joints (Tian et. al, 2012a), dynamic analyses of full-scale piping systems (Soroushian et at, 2012a), and dynamic tests of six piping subsystem configurations (Tian,2012).

However, the limited quantitative data collected from past earthquakes and the limitations of system-level experimental studies necessitates reliable system-level numerical tools to allow for a better understanding of the seismic response of piping systems. Also, piping fragility information are yet to be generated to assist the technical community in assessing, managing, and reducing seismic risks.

After the validation of a numerical model for piping systems, a comprehensive fire sprinkler system layout incorporating a variety of commonly used sprinkler piping components was adopted from the medical center building of the University of California, San Francisco (UCSF). Using the OpenSees software (Mazzoni, 2007), the entire three-dimensional piping model was numerical simulated by incorporating approximately nine-hundred inelastic elements for threaded joints, main distribution lines, pipe branches, braces, hangers, wire restrainers, and sprinkler heads. A real-time element removal algorithm was utilized to capture the progression of damage. The numerical model was subjected to a suite of ninety-six artificial tri-axial acceleration histories. The horizontal components of motion

were generated in accordance with the ICC-AC156: Acceptance Criteria for Seismic Certification by Shake-Table Testing of Nonstructural Components acceleration spectra (ICC, 2010), and the ASCE/SEI 7-05 (ASCE, 2005) vertical acceleration spectra were used for generation of the vertical acceleration components.

2. PIPING TEE JOINT TESTS AT THE UNIVERSITY AT BUFFALO

A total of forty-eight tee joints comprised of four different materials, diameters, and joint types were tested at the University at Buffalo NEES site. A diverse database was developed on the cyclic response and damage states of tee joints; however, the main focus of this study was the results of the black iron threaded joint for pipe diameters of 3/4 in., 1 in., 2 in., 4 in., and 6 in. comprising twenty experiments.

The test setup was composed of two pipe runs with a length of L on each side of the tee joint specimen. One end of each segment of the pipe run was attached to the tee joint and the other end was supported using a moment free connection connected to a load cell. One end of a perpendicular pipe segment was attached to the tee joint, and the other end was connected to an actuator which applied a mid-span point load (Figure 1). To capture the leakage during the test, all of the specimens were pressurized with water at 40 psi. The moment demand of each tee joint was calculated by multiplying the force measured by the shear load cells by the distance L. The cord rotation was measured using linear potentiometers attached to each side of the tee joint. Additional details of the test setup are presented in Tian et al. (2012a).

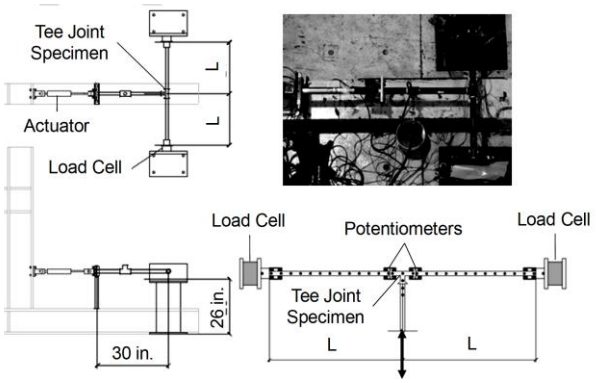

Figure 1 Tee Joint Experimental Set-Up (Tian et al. 2012a).

3. DEVELOPMENT OF AN NUMERICAL MODEL FOR PIPING TEE-JOINTS

The experimental data for tee joints was utilized by the authors to develop an adaptable nonlinear hinge model in OpensSees (Mazzoni, 2007) for the threaded joint of different pipe diameters. The "Pinching4" uniaxial material along with a "zeroLength" element were used to simulate the moment-rotation response of a threaded tee joint connecting two piping nodes (Mazzoni, 2007). The "Pinching4" material enabled the simulation of pinched load-deflection responses accounting for degradations under cyclic loading for different pipe diameters. This material requires the definition of 39 parameters (Figure 2) including the shape of the backbone curve, pinching parameters, damage parameters, etc. A detailed description of these parameters can be found in OpenSees (2012).

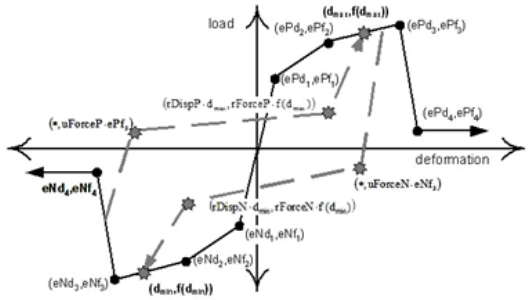

Figure 2 Pinching4 Material Properties (OpenSees, 2012)

3.1 Validation of Numerical Model with Experimental Data for Tee Joint Components

The material model was calibrated using the tee joint moment-rotation hysteresis of all pipe diameters. The moment-rotation hysteresis curve, the value of cumulative hysteresis energy, and moment histories of each pipe were used in the calibration process. The support rotation history was imputed to the model for each of the three varying diameter experiments. Due to the malfunction of some of the potentiometers, the moment-rotation data was not available on both sides of the tee joint for some of the experiments, but at least three moment-rotation data sets were available for each pipe diameter. Figure 3 shows the aforementioned three characteristics of the calibrated model for one of the 3/4" tee joints. The shape of the curve, dissipated energy, and

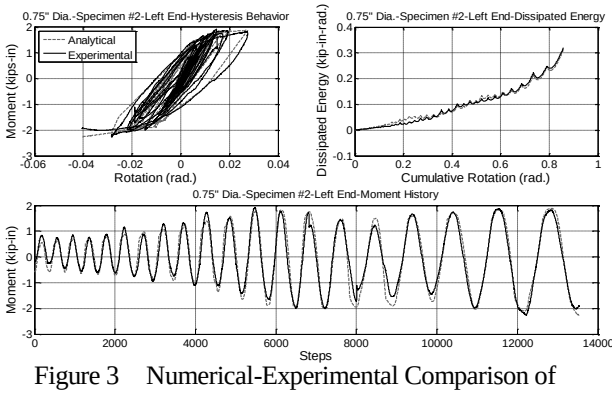

Figure 3 Numerical-Experimental Comparison of Second 3/4" Specimen on Left Side of Tee Joint

the moment magnitudes were considered simultaneously in the calibration process to achieve the best numerical model. After performing a sensitivity analysis on the material parameters, 10 parameters out of 39 parameters were assigned a fixed value independent of the pipe diameter.

The OpenSees "Pinching4" material parameters *gK1* to *gK4*, and *gKLim*, all of which define the unloading stiffness degradation characteristic of the material, were set to the same value as *gK* (Mazzoni, 2007). The "cyclic damage" was used to determine cyclic stiffness and strength degradation, and in all the cases, the *gD* and *gF* material parameters were assumed to be zero. The rest of parameters were used to fit the numerical data to the experimental data. Figure 4 illustrates comparisons of sample numerical and experimental data for four different pipe diameters. Each material parameter has a consistent relationship with the pipe diameter. This allows for the determination of these parameters for other pipe diameters through interpolation.

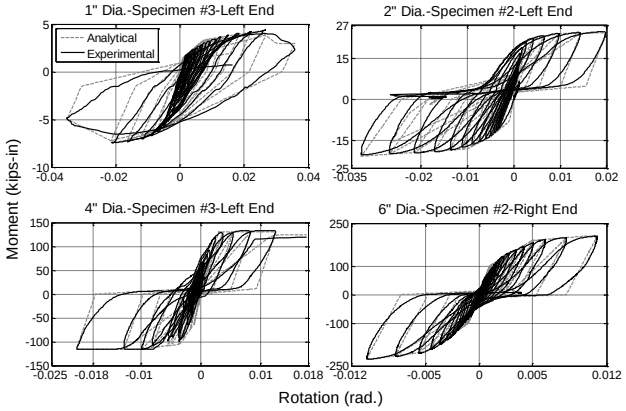

Figure 4 Sample Numerical-Experimental Hysteresis Comparisons of Different Pipe Diameters

Throughout the calibration process, a total of twenty sets of twenty-nine parameters for the "Pinching4" material were optimized based on all available experimental data. Although the results for each set of experiments were quite similar, there were minor discrepancies between the material parameters for the individual experiments of each set. For the future numerical studies of the sprinkler piping systems, one suite of material parameters was selected as the generic parameters for each pipe diameter, called generic model hereafter. To develop this generic model the following assumption were made. 1) A symmetric moment-rotation hysteresis behavior was used, 2) the first point of the backbone curve, ePd_1 (Figure 2), was defined as 0.001 rad. This enabled the use of the average experimental moment values corresponding to 0.001 rad., 3) the rest of the three nonlinear rotation points of the backbone curve of the generic model, ePd_2, ePd_3, ePd_4 (Figure 2), were set to 0.005, 0.01, and 0.023 rad., respectively based on the calibrated backbone curve parameters of each set, 4) a linear interpolation was used to find the moment corresponding to the above mentioned rotations where the moment values at the calibrated backbone curves are unavailable. The average of these moment values for each set were used for ePf_2, ePf_3, and ePf_4 (Figure 2) to define the backbone curve, 5) the average calibrated values were used for the rest of the parameters needed to define the generic hysteresis response. Figure 5 shows the comparison of the generic model with sample experimental data from each set. Table 1 also shows the generic model parameters obtained using the previously mentioned assumptions.

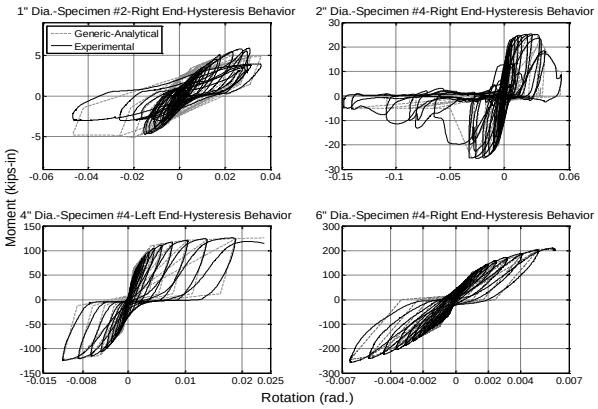

Figure 5 Sample Generic Numerical-Experimental Hysteresis Comparison of Different Pipe Diameters

Based on pipe location and required water pressure, a wide range of pipe diameters is commonly used in sprinkler piping layouts. The test matrix of the University at Buffalo did not include all the pipe diameters that are typically found in a system. Thus, a procedure is proposed to fill this gap in the experimental data and enable estimation of the parameters of the generic hysteresis model for the missing pipe diameters. This methodology is explained in the following steps. First, the parameters of the generic models based on the experimental data were plotted against the pipe

diameter. The values of the moments corresponding to 0.001, 0.005, 0.01, and 0.023 rad. can be plotted against the pipe diameter since these rotations were kept constant for all diameters. Then, the best polynomial curve was fit to the

data for each parameter. Using these algebraic functions of pipe diameter, the modeling parameters were obtained for those pipe diameters that were not tested at the University at Buffalo. Table 1 shows the values of the modeling parameters obtained from this methodology. Figure 6 shows the trends of the modeling parameters for the "Pinching4" material (OpenSees, 2012) with respect to the pipe diameter.

4. FRAGILITY STUDIES

The fragility curves presented herein were obtained from a comprehensive three-dimensional nonlinear model of a typical hospital sprinkler piping system.

4.1 Specifications of Hospital Fire Sprinkler Piping System

The piping system modeled in this study was adopted from the sprinkler system of the University of California (UCSF) Medical Center Building. In this study, a slight modification was implemented on the original system by redesigning the hangers and braces to meet the minimum spacing requirement of NFPA 13: Standard for the Installation of Sprinkler Systems (NFPA, 2011). Also the bracing system was changed from cable bracing to solid sway bracing which is more common in construction. The final system incorporates a variety of commonly used components such as mains runs and branch lines of various diameters, hangers, seismic braces, wire restraints, tee joints, elbow joints, and sprinkler drops and heads. It also contains a sufficiently large quantity of each component which enables a better statistical evaluation of the seismic performance of each component within the system.

The piping system shown in Figure 7 covers an area of approximately 17000 sf. It is 250 ft long and 176 ft wide and has more than 900 threaded joints (649 1-in., 185 1.25-in., 28 1.5-in., 7 2-in., 41 2.5-in, 34 3-in, and 29 4-in diameter joints). A plenum height (the distance between the supporting structural floor and the ceiling system) of 4 ft is used. The piping system is suspended 2.5 ft below the supporting floor, thus the sprinkler drops are1.5-ft long. The sprinkler piping system is connected and braced to the supporting floor with 1-in diameter longitudinal and lateral pipe sway braces (only on main runs), 3/8-in all-threaded hangers, and 12-gauge wire restraints. The sway braces and wire restraints are oriented at 45 degree angles with respect to the plane of the supporting floor.

The piping layout was composed of 4 major areas. Area 1 is composed of main run pipes with total length of 154 ft with diameters varying from 2.5- to 4-in. These pipes feed 23 1.25-in. and 1-in diameter branch lines and 61 sprinkler heads. In Area 2, main run pipes are 97 ft long with 4-in diameter. This pipe supplies the water for 4 1.25-in. and 1-in. branch lines and 15 sprinkler heads. Area 3 integrates 97 ft of 3- and 2.5-in. diameter main runs with 15 branch lines ranging in diameter from 1.5- to 1-in., and a total of 44 sprinkler heads. Area 4 consists of 82 ft of main distribution line varying in diameter from 4- to 2-in. The main distribution line feeds 16 1.5- to 1-in. branch lines. In this area, the main line and branch line supply 47 sprinkler heads.

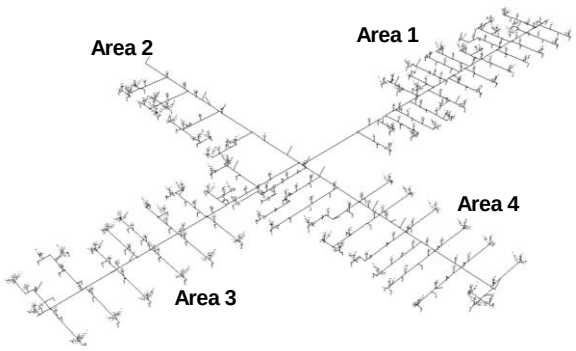

Figure 7 3-D View of UCSF Medical Center Sprinkler Piping System

4.2 Definition of the Numerical Model

The model of the introduced piping subsystem was developed in OpenSees. The pipes including the main runs, branch lines, and sprinkler drops were modeled with "Force-Based Beam-Column" (Mazzoni, 2007) elements with elastic gross section properties of the pipes. The threaded fittings of the branch lines and drop pipes were modeled using one "zeroLength" element on the either end of the pipes. These elements were defined using the nonlinear "Pinching4" material for the rotational degrees of freedom (DOFs) based on the specified characteristics of Table 1, while an elastic material with properties of the pipe cross section were used for the other DOFs. The hangers were modeled using "Force-Based Beam-Column" elements with a fiber-section consisting of the Giuffre-Menegotto-Pinto steel material (CEB, 1996), which is implemented in OpenSess as "Steel02" material. A modulus of elasticity of 29,000 ksi, yield strength of 85 ksi (Goodwin et al., 2007), and hardening slope ratio of 1% were assigned to the hangers. These hangers had pin connection to the pipes. The wire restrainers were modeled using pinned "truss" elements along with a tension only "Elastic-Perfectly Plastic (EPP) Gap" material with the modulus of elasticity of 29,000 ksi and tensile strength of 80 ksi (USG, 2010). The rigid seismic braces were modeled with "Force-Based Beam-Column" elements using elastic section properties of the 1-in. pipe. The connection of the seismic braces was assumed to be rigid at both ends. The schematic of the elements and materials are presented in Figure 8. The mass of the piping system was determined using the wet weight of the pipes. An additional mass of 0.5 lb was used for each sprinkler head. Mass and weight of the system were concentrated at the nodal points. A Rayleigh damping was used for the analysis and 3% damping was assigned to the first and the third modes.

A real time element removal algorithm was incorporated in the analyses to capture the progression of

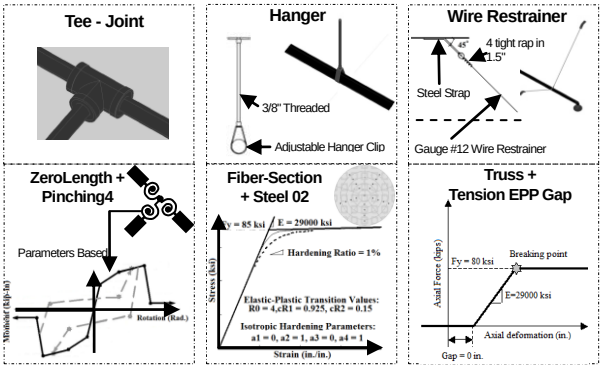

Figure 8 Schematic of the Numerical Models for Main Components

damage to the piping system during seismic excitations. The element removal algorithm enables the model to redistribute the forces after failure occurs in an element using the "remove element" command in OpenSees software (Mazzoni, 2007). This algorithm was set to remove the wire restrainers after reaching their rupture capacity, 0.4 kips from USG (2010). Due to the large spectrum of hanger clip details, the failure force of the pipe hangers was calculated based on the minimum NFPA 13 (NFPA13, 2011) requirements. NFPA 13 mandates that the hangers shall be designed to support five times the weight of the water-filled pipe plus 250 lb at each point of support. The hanger axial forces were calculated after the dead load analysis was concluded. During the response history analyses the program triggered the "remove element" command when the axial force of a hanger reached the five times the recorded axial force plus 250 lb. The first five vibration modes of the model were obtained as 1.22, 1.2, 1.19, 1.17, and 1.16 sec, respectively.

4.3 Generation of the Input Motions

The seismic response of the piping system is evaluated using a suite of 96 synthetic triaxial acceleration which represent floor motions. Input motions were developed by Soroushian et. al, (2012b) using the spectrum-matching procedure. The suites were generated for uniform distribution of SDS values varying from 0.1 g to 3 g and five different height ratios of 0, 0.25, 0.5, 0.75, and 1.0 considering site classes D, E, and F. Acceleration spectra were produced for the horizontal directions following ICC-AC156 (ICC, 2010) parameters while the vertical acceleration response spectrum introduced in ASCE/SEI 7-05 New Chapter 23 (ASCE, 2005) was adopted for the vertical motions.

The statistical distribution of the peak floor accelerations and the median 16th, 84th, and 97th percentile of the 5% damped elastic spectrum for the horizontal and vertical components are presented in Figure 9. The nonlinear numerical model of the UCSF piping system was subjected to the described 96 sets of triaxial motions. The maximum responses of the piping system, including joint rotations, hanger and brace forces, and nodal displacements were recorded.

4.4 Fragility Analysis

The seismic vulnerability of a structural or

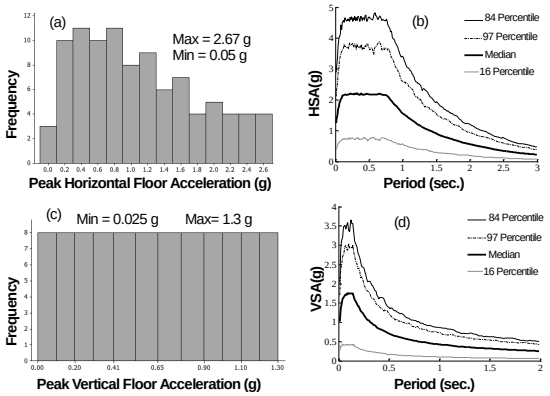

Figure 9 (a) Distribution of Peak Horizontal Floor Acceleration , (b) Horizontal Spectral Floor Acceleration, (c) Distribution of Peak Vertical Floor Acceleration, (d) Vertical Spectral Floor Acceleration (Soroushian et. al., 2012b)

nonstructural component can be graphically represented through the generation of numerical fragility curves. Fragility curves are probabilistic representations of exceeding a capacity or limit state in terms of intensity measures (*IMs*), peak floor acceleration in this case, and engineering demand parameters (*EDPs*) as a measure of piping response. The relationship of the demand, *EDPs*, and floor acceleration, *IMs*, can be approximately represented with the standard normal cumulative distribution function shown in Equation (1) (Nielson and DesRoches, 2007):

$$P(EDP \geq C \mid IM) = \Phi\left(\frac{\ln(S_d / S_c)}{\sqrt{\beta_{EDP|IM}^{\ 2} + \beta_C^{\ 2}}}\right) \qquad (1)$$

Where S_d is the median of the demand estimate as a function of *IM*, S_c is the median estimate of the capacity, $\beta_{d|IM}$ is the logarithmic standard deviation of the demand with respect to the intensity measure, β_c is the logarithmic standard deviation of component capacities, and $\Phi[\cdot]$ is standard normal cumulative distribution.

4.5 Capacity Parameters and Component Demands

The capacities of the pipe hangers and wire restrainers were determined from the median percentage of failed hangers or wire restrainers, θ_{break} , and the logarithmic standard deviation of the rotational capacity, β_C. A constant value of 0.4 was assigned to β_C which is the most frequently used value for this parameter in nonstructural components (ATC 58, 2009). Three damage states (*DS*) were defined for the percentage of failed hangers and wire restrainers. *DS1* represents 5% loss of hangers and 10% loss of restrainers, *DS2* represents 10% loss hangers and 20% loss of restrainers, and *DS3* represents 15% loss of hangers and 30% loss of restrainers. Values of θ_{break} and β_C for the previously defined damage states are presented in Table 2.

The capacity of each pipe diameter was determined from the median rotational threshold corresponding to the first leakage of the joint, θ_{leak} . For the pipe diameters that were tested at the University at Buffalo, θ_{leak} and β_C were borrowed from the work done by Tian et al. (2012a) and are

presented in Table 2. For the rest of pipes, θ_{leak} (rad.) was calculated using Equation (2) (Tian et al., 2012a).

$$\theta_{leak} = \frac{2\bar{s}}{D_0} \quad (2)$$

In this equation $\bar{s}$ is a constant value of 0.019in. for threaded pipe joints and D_0 (in.) is the outside pipe diameter. Table 2 shows that the values of θ_{leak} calculated using Equation (2) correspond very well with the experimentally determined values; therefore, this equation provides a good approximation for the median rotational capacity at first leakage for those pipe diameters that were not previously tested. Also for each pipe diameter in this group, values of β_C were calculated by linear interpolation between two adjacent previously tested diameters.

Table 2 Damage States of Piping Components

Pipe Name	Experiment		Eq. (2)	Interpolation
	θ_{leak}	β_c	θ_{leak}	β_c

1.5" Pipe	NA	NA	0.020	0.120
2.5" Pipe	NA	NA	0.013	0.125
3" Pipe	NA	NA	0.011	0.155
3.5" Pipe	NA	NA	0.010	0.186
5" Pipe	NA	NA	0.007	0.210
Component Name	**DS1**	**DS2**	**DS3**	
	θ_{break}	θ_{break}	θ_{break}	β_c
Hangers	5%	10%	15%	0.4
Restrainers	10%	20%	30%	0.4

The response of a piping system can significantly vary due to its geometry. As an example, for the same pipe section, the rotational demands on long (more than 2-ft long) armovers are generally larger than on straight drops (Soroushian et al., 2012a). Therefore, it is necessary to categorize the *EDPs* to better represent the physical damage. To do so, *EDPs* of branch line pipes were categorized based on the pipe diameter and the type of branch line (with or without armovers).

The damage parameters of the piping system were defined as: 1) percentage of failed wire restrainers, 2) percentage of broken hangers, 3) the maximum rotation at the tee armovers and elbow armovers, 4) the maximum rotation at critical joints of the branch lines, and 5) rotation of fittings on the main runs.

Component demands were then considered with respect to the *PFA* of the floor motion that generated the demand. A regression analysis of this data is used to estimate the parameters (S_d and $\beta_{d|IM}$) of the probabilistic seismic demand models using Equation (3, 4) (Cornell et. al., 2002):

$$S_d = aIM^b \quad (3)$$

$$\beta_{d|IM} \cong \sqrt{\frac{\sum_{i=1}^{N}\left(\ln(d_i - \ln(aIM^b))^2\right)}{N-2}} \quad (4)$$

In Equations (3) and (4), S_d and $\beta_{d|IM}$ are the median estimate of the demand and the logarithmic standard deviation of the demand, respectively. The parameter d_i is the peak demand and corresponds to i^{th} floor motion (out of total N motions).

4.6 Component Fragility Curves

After calculating estimated demand and capacity parameters, the fragility curves of different piping components can be obtained from Equation (1). Figure 10 shows the piping component fragility curves using this equation.

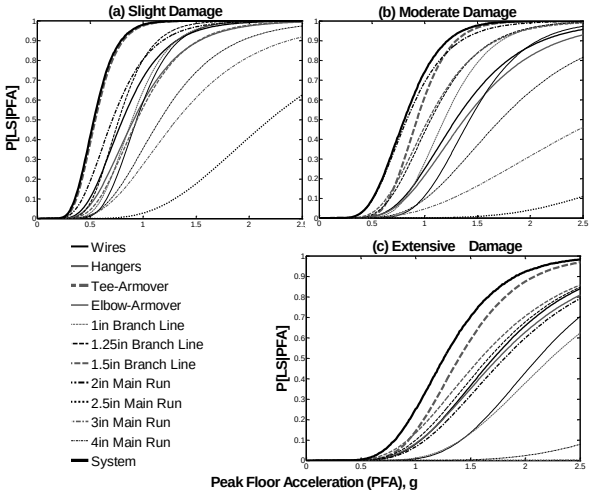

Figure 10 Component fragility curves for piping system

The curves show that the response of tee-armovers is the most dominant component in the vulnerability of piping systems in nearly all damage states. The dominancy of larger diameter branch line pipes (1.5 and 1.25 in.) on overall vulnerability of piping system increases in higher limit states. In higher limit states the pipe hangers start to yield, and more wire restrainers fail. As a result, the branch lines behave like cantilevers, and the demand on these pipe diameters, which usually have only connections to the main

* ESTIMATED MEDIAN VALUES ARE MUCH LARGER THAN CAN BE APPROPRIATELY EXTRAPOLATED FROM REGRESSION ANALYSES

runs, increases. Thus, the general trend is that the demand on the largest and smallest main runs (4in and 2in) is higher. Because these size of pipes are mainly located at the beginning and end of branch lines combined with the existence of solid sway braces, the bending demand at these locations is generally higher than at other locations. Table 3 shows the median and dispersion values for the seismic fragility curves of piping system components.

4.7 System Level Fragility Studies

The assessment of seismic vulnerability for the entire piping system must be made by combining the effects of the various system components. The probability that the piping reaches or goes beyond a particular limit state ($Fail_{system}$) is the union of the probabilities that each of the components will reach that same limit state ($Fail_{component-i}$), as shown in Equation (5) (Nielson and DesRoches, 2007a) :

$$P\left[Fail_{System}\right] = \bigcup_{i=1}^{n} P\left[Fail_{Component-i}\right] \quad (5)$$

4.8 System Limit States

A limit state is a metric that describes the post-earthquake functionality or the level of damage experienced by a component or system subjected to a certain intensity measure. While only a single limit state may exist for certain components within a piping system, multiple limit states can be described for the entire system based on the percentages of component failures. Only one component-level limit state is considered for each of the three components used to develop the piping system fragility curves. These component levels are described as: the break point of the pipe hangers, the break point of the wire restrainers, and leaking threshold at the pipe joints. The leakage limit state, however, is presented as the percentage of the number of the pipe joints for which rotations exceed the leakage threshold. Three system-level limit states corresponding to three increasing levels of system damage were defined to characterize the seismic response of the entire piping system. These limit states were determined based on the percentage of failed hangers and wire restrainers, and the probability that the rotational capacity of the pipe joints would exceed leaking threshold. Brief definitions of each system-level limit state are provided in here.

LIMIT STATE 1: Slight Damage

Limit state 1 (*LS1*) corresponds to loss of 10% of the wire restrainers, loss of 5% if the pipe hangers, and 3% of the pipe joints exceed their leakage rotational capacity.

LIMIT STATE 2: Moderate Damage

Limit state 2 (*LS2*) accounts for loss of 20% of the wire restrainers, 10% of the pipe hangers, and leaked pipe joints exceed 16% of their total number.

LIMIT STATE 3: Extensive Damage

Limit state 3 (*LS3*) is based on more than loss of 30% of the wire restrainers, more than 15% loss of pipe hangers, and 50% leaked pipe joints.

4.9 Joint Probabilistic Seismic Demand Model

A joint probabilistic seismic demand model (*JPSDM*) was used in this study to estimate the piping system level fragility. A *JPSDM* is developed by assessing the demands placed on individual components (marginal distribution) through regression analysis. A covariance matrix is calculated by estimating the correlation coefficients between the demands placed on the various components. Using the capacity parameters and the *JPSDM*, Equation (5) can be evaluated using a Monte Carlo simulation. A Monte Carlo simulation is used to compare some level of correlation realizations between component demands using the *JPSDM* defined by a conditional joint normal distribution in the transformed space and statistically independent component capacities to calculate the probability of system failure. This procedure is applied for each damage state for various levels of IMs.

As previously stated, armovers contribute to the vulnerability of the piping system more than the other components. A simple approach was used to estimate the relative change in the median values of the fragility curves. The median values of the system fragility curves were calculated without considering the armover component demands in the *JPSDMs*. Then the armover component demands were added to the *JPSDMs*, and the percent change in the median value of system fragility curves with and without considering the armovers was calculated. A positive change indicates a less vulnerable piping system. Also the use of over braced main runs may reduce the vulnerability of main runs. To compare the difference between all of the optional configurations, 4 different system level fragility curves were developed, namely, "All"

Table 4 Medians and Dispersions for 4 Different Piping System

System Name	Slight			Moderate			Extensive		
	Median λ	Difference (%)	Dispersion ζ	Median λ	Difference (%)	Dispersion ζ	Median λ	Difference (%)	Dispersion ζ
ALL	0.53	NA	0.31	0.81	NA	0.33	1.26	NA	0.34
w/o Armovers	0.64	20.23	0.35	0.82	1.36	0.37	1.32	5.02	0.36
w/o Main Run	0.54	0.54	0.31	0.88	8.65	0.30	1.27	1.13	0.34
w/o Main Run & Armovers	0.68	27.56	0.32	0.95	17.48	0.34	1.34	6.94	0.37

(considering all the components), "w/o Armovers" (Removing armover demands from *JPSDMs*), "w/o main runs" (Removing main run demands from JPSDMs), and "w/o main runs & Armovers " (Removing both main run and armover demand from *JPSDMs*). Figure 11 shows the piping system fragility curves for the four different cases. Table 4 presents the lognormal parameters (median, λ, and logarithmic standard deviation or dispersion, ζ) that characterize the piping system fragility from regression analysis based on all 4 different cases.

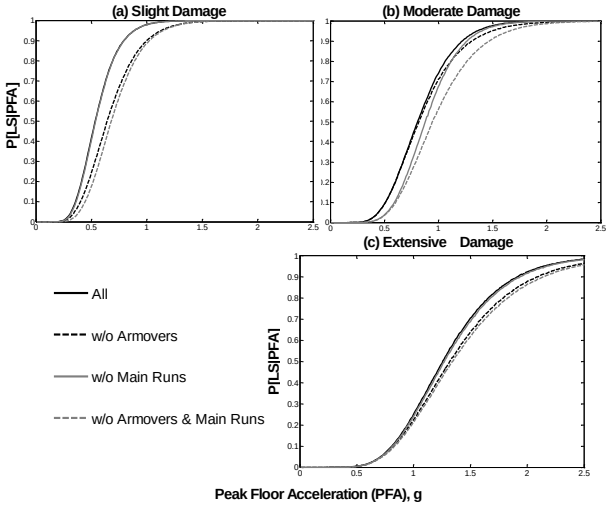

Figure11 System Fragility Curves for Different Piping System Condition

Table 4 shows that armover drops can increase the chance of reaching the slight damage state (which corresponds to the first leaking of the piping system) by 20%. In the other damage states, leaking is not only limited to the armovers. Therefore the probability increased by only 1.4% and 5% for the moderate and extensive damage states, respectively. Using other types of joints or increasing the number of piping braces (to force the main run to move like rigid body instead of bending) will improve the moderate damage state probability by 9%. In the slight damage state the contribution of main run leaking is negligible compare to the contribution from the armovers, so the probability improvement is only 0.5%. When considering progressive damage during an earthquake, the first leaking occurs during the low intensity portion of the ground motion. The presence of the generated hinges created during these lower intensities decreases the demand the rest of the joints experience at higher intensities. As a result, the probability difference at extensive state level is only 1%. In case 4 which is related to the piping system without long armovers and improved main runs, the reduction in probability of the slight, moderate, and extensive limit states is 27%, 18%, and 7%, respectively. Figure 19 shows the piping system fragility curves for the four different cases.

5. SUMMARY AND CONCLUSIONS

In this study a series of nonlinear threaded joint hinges were developed for various pipe diameters based on a previous component experiments. An numerical model was developed and validated using subsystem experimental data. Following the validation of the numerical model, a full fire sprinkler system layout incorporating a variety of common sprinkler piping systems was adopted from the University of California, San Francisco (UCSF) medical center building and was numerically simulated in OpenSees. Seismic fragility curves were generated using this comprehensive three-dimensional model including approximately 900 inelastic members modeling threaded joints, main distribution lines, pipe branches, braces, hangers, wire restrainers, and sprinkler heads subjected to a suite of artificial ground motions. A real time element removal algorithm was incorporated in the analyses to capture the progressive damage of the piping system during seismic excitation. The conclusions made are listed below:

- Among the component fragility curves, long armovers with tee joint connections to the branch lines were the most vulnerable components of the piping system, while long armovers with elbow attachment to the branch lines experienced less damage compared to the other branch line components.
- The dominancy of larger diameter branch line pipes (1.5in and 1.25in.) on overall vulnerability of the piping system increases at higher limit states. This increase can be attributed to the progressive damage during an earthquake. At higher limit states the pipe hangers start to yield, more wire restrainers fail, and as a result, the branch lines will behave as cantilevers. Therefore the demand on these pipe diameters which mainly have connections to main runs, will increase.
- The smallest and largest main run pipe diameters experienced more damage compared to the other pipe diameters. The largest and smallest pipe diameters are generally located at the beginning and end of main run line, respectively. In these locations the rotational demand is higher because of the sway braces required by code.
- The system fragility curves show that the existence of armover drops can increase the chance of reaching the slight damage state (which corresponds to first leaking of piping system) by 20%. At the other damage state levels, the leaking is not only limited to the armovers, therefore, the increase in probability of reaching the moderate and extensive damage is 1.4% and 5%, respectively.
- Using other types of joints (like groove fitting) or increasing the number of piping braces on main runs (to force the main run move like rigid body instead of bending) will decrease the probability of reaching the moderate damage state by 9%.
- When considering progressive damage during an earthquake, the first leaking occurs on a main run pipe during a smaller intensity portion of the motion. The

generated hinges occurring at low intensity levels reduce the demands on the rest of the joints at higher intensity levels. As a result, the probability difference at the extensive damage level is only 1%.

- In a large or poorly detailed piping layout, the piping system might experience leaking at very few locations, but it is highly unlikely that a smaller piping system will reach this rotational demand.
- Piping systems without long armovers and main runs having improved joints or a larger number of braces see reductions in probability of 27%, 18%, and 7% for the slight, moderate, and extensive damage states, respectively.

CEILING SYSTEMS DESIGN AND INSTALLATION LESSONS FROM THE CANTERBURY EARTHQUAKES

Rajesh P Dhakal[1)], and Gregory MacRae[1)]

1) Associate Professor, Department of Civil and Natural Resources Engineering, University of Canterbury, New Zealand
rajesh.dhakal@canterbury.ac.nz, gregory.macrae@canterbury.ac.nz

Abstract: Damage to ceiling systems resulted in a substantial financial loss to building owners in the Canterbury earthquakes. In some buildings, collapse of ceilings could easily have resulted in severe injury to occupants. This paper summarizes the types of ceiling damage observed in the Canterbury earthquakes, and draws useful lessons from the observed performance of different types of ceiling systems. Existing ceiling manufacturing and installing practices/regulations in New Zealand are critically scrutinized to identify deficiencies, and measures are suggested to improve the practice so that the damage to ceilings and the resulting loss are minimized in future earthquakes.

1. INTRODUCTION

Ceiling systems consist of the ceiling itself, and all the components that may interact with the ceilings. Some common elements interacting with ceilings are partitions, bulk heads, heating, ventilating and air conditioning (HVAC) equipment, electrical equipment, and fire sprinklers. Excessive movement or failure of one of these elements can result in damage to, and/or collapse of, part of a ceiling. Needless to say, utmost care should be taken in installing any of these elements so that the performance of other interacting elements is not adversely affected.

In New Zealand, while there is no restriction on the types of ceiling that may be used in different situations, ceilings in residential dwellings and small ceilings in commercial buildings are commonly constructed with gypsum board. Moderate and large ceilings are more often suspended on a cold-formed steel grid, into which ceiling tiles sit as shown in Figure 1. In these ceilings, the tiles can move a few millimeters in different directions within the grids, so force must be transferred through the grid members, rather than directly between the neighboring tiles. A number of manufacturers provide grid ceilings.

Suspended ceilings are commonly designed to be either fixed to the perimeter walls, or they may be floating. The fixed ceilings are connected to the perimeter walls at least on two sides. When bracing the ceiling off the walls, lateral inertial ceiling forces are taken axially through the tee rails in each direction, to the walls. Axial loads (tension and compression) are at their highest near the walls and at their lowest towards the centre of the room. Each tee rail will be in tension at one end and in compression at the opposite end.

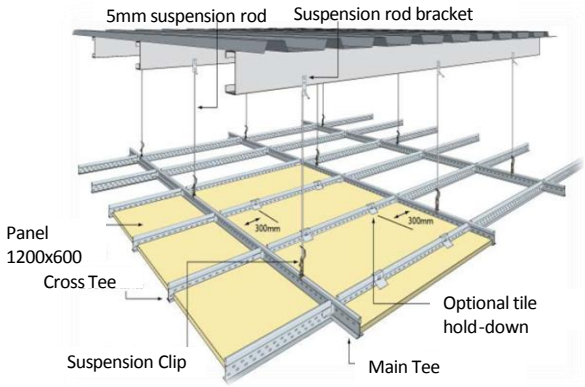

Figure 1. Typical ceiling configuration not showing seismic bracing (based on Rondo, 2009)

On the other hand, floating ceilings are not connected to the wall in any side, but they are braced to the floor or roof above to prevent large movements under service conditions, as well as to transfer horizontal earthquake induced inertia forces. Bracing is normally provided in the form of inclined rods connected to the ceiling grid in one end and the floor at the other end. Typically this system is adopted if tee lengths exceed the maximum length determined for perimeter fixed ceilings.

2. CURRENT DESIGN AND INSTALLATION SPECIFICATIONS FOR CEILINGS IN NZ

Since suspended ceilings are generally developed by companies and are sold as proprietary systems, construction details, element capacities, as well as analysis methods to obtain element demands from global loads are generally provided by companies in their

literature, or through discussion with their engineering staff. Mainly, the following documents are used for ceiling system design and installation in New Zealand:

1. NZS 1170.5:2004 – Structural design actions Part 5- Earthquake Actions Section 8 "Requirements for Parts and Components"
2. AS/NZS 2785:2000 – Suspended Ceilings: Design and Installation
3. NZS 4219:2009 – Seismic performance of engineering systems in a building.

In addition to these three, the following standards used in NZ are also relevant to ceiling design/installation and performance assessments:

- Ministry of Works PW/81/10/1:1985 - Guidelines for the Seismic Design of Public Buildings: Appendix D Suspended Ceilings and Associated Fittings and Fixtures
- AS/NZS 1170.1:2002 - Structural design actions - Permanent, imposed and other actions
- AS/NZS 1530.3:1999 - Methods for fire test on building materials, components and structures - Simultaneous determination of ignitability, flame propagation, heat release and smoke release
- AS 2946:1991 - Suspended ceilings, recessed luminaries and air diffusers – Interface requirements for physical compatibility
- ISO 6308:1980 - Gypsum plasterboard - Specification
- ASTM E1414-11 - Standard test method for airborne sound attenuation between rooms sharing a common ceiling plenum (two room method)

In addition to the abovementioned standards, a number of proprietary guides exist in the industry. As these generally follow loading standards older than NZS 1170.5 and may not necessarily be current, it is the designer's responsibility to ensure that they are current before using these guides. Moreover, information on international practice is also available from groups such as the US Federal Emergency Management Agency (FEMA). Until July 2011, only AS/NZS 1170 was listed as a compliance document to the NZ Building Code as specified by the Department of Building and Housing (DBH). However, in 2011, the DBH also listed NZS 4219:2009 as a compliance document for ceiling (DBH 2011).

Some of the key specifications (related to ceilings) provided in the abovementioned regulatory documents are given below:

2.1 NZS 1170.5:2004

1. All parts of structures including permanent, non-structural components and their connections, and permanent services and equipment supported by structures, shall be designed for the earthquake actions specified in this Section.
2. Buildings parts are divided into seven categories, among which ceilings feature in the following categories:
   - Auditorium ceilings: P.2 (Part representing a hazard to a crowd of greater than 100 people within the building)
   - Light suspended ceilings: P.7 (All other parts)
3. Auditorium ceilings (i.e. category P.2) are designed for ultimate limit state (ULS) whereas suspended ceilings (i.e. category P.7) are designed for serviceability limit state (SLS1).
4. Ceilings directly attached/framed to the structure/walls be designed for ductility 3 or less and a suspended ceiling shall not be designed for ductility greater than 2.

2.2 AS/NZS 2785:2000

1. The aim is to provide a ceiling system that has adequate strength and serviceability, is stable and durable, and satisfies other objectives such as economy and ease of construction.
2. Ceiling systems shall be designed and installed in such a manner that the suspension and frame will remain structurally sound, without maintenance, for a period of 15 years.
3. The following limit states are recommended:
   - Ultimate limit state (for life safety): A ceiling has adequate strength if the probability of failure of the system or components is acceptably low throughout its intended life.
   - Serviceability limit state (for operational continuity and business interruption): A ceiling is serviceable if the probability of loss of serviceability of the system of the components is acceptably low and the ceiling maintains its intended performance level throughout its intended life.
4. The methods to design for the ultimate limit state are given as:
   - The ultimate limit state is reached when the ceiling system or part thereof ruptures, becomes unstable, or loses equilibrium.
   - The member or component shall be proportioned such that the design action effect (calculated for the specified loads/actions and load combinations) is not greater than the design ultimate strength (strength reduction factor times the nominal capacity obtained from the material standard or tests).
   - Ceiling hangers shall be proportioned such that the failure or removal of a single hanger does not trigger a progressive collapse of the ceiling system.
5. The method to design for the serviceability limit state is given as:
   - The total deflection of the ceiling shall take into consideration the deflection of the suspension system, and remain within the specified limits (between L/250 and L/600).

2.3 NZS 4219:2009

1. Suspended ceilings are outside the scope of this standard; only equipments interacting with ceilings are covered by this standard. Where service loads are greater than 3 kg/m^2, the ceiling designer should be advised.
2. Suspended ceilings should be designed and constructed in accordance with AS/NZS 2785.
3. Equipment supported by the ceiling not exceeding 10 kg shall be positively fixed to the suspension system but not supported by the ceiling panels or tiles.
4. Suspended ceilings, equipments in ceiling voids and supported by the ceiling are considered as dead load.
5. Service loads greater than 3 kg/m^2 (0.03 kPa) need special consideration.
6. Equipment with a mass less than 10 kg shall be supported by the grid of the suspended ceiling system. Equipment exceeding 10 kg mass shall be supported independently of the ceiling.
7. Equipment supported independently of the ceiling shall have a clearance of 25 mm all round to allow independent movement between component and the ceiling.
8. Ceiling suspension components (hangers, braces, and so forth) shall be located with specified clearances. A minimum of 50 mm clearance in the vertical and horizontal direction is recommended between restrained components (i.e. ceiling hangers and braces).
9. A minimum clearance of 150 mm in horizontal and 50 mm in vertical direction is recommended between unrestrained components and restrained components.
10. All fixings of hanging luminaries shall be positive, locking type to prevent disengagement.
11. Where luminaries are recessed or surface-mounted on suspended ceilings, they shall be positively clamped to the ceiling suspension systems. Clamping shall be by means of screw and nuts or locking-type clamping devices.

3. ISSUES WITH CURRENT NZ DESIGN PROCEDURES AND PRACTICE FOR CEILINGS

A number of concerns have been expressed by designers, contractors and fabricators on different aspects of the existing ceiling design and installation practice. Some of these concerns are listed below:

3.1 Performance Objectives

- Suspended ceilings are included in the least important category (Category 7 in the recommendations in NZS 1170.5 Clause C8.1) considering the lowest level of design demand (SLS1). The required design level for ceilings may be too low as evidenced by the fact that a number of ceilings were replaced several times in Christchurch during the Canterbury earthquake sequence.
- Life safety threat from ceilings is not fully acknowledged. There were fatalities resulting from ceiling damage in the 2011 Japan earthquake. It is only a good fortune that there was no life loss as a result of the several ceiling collapses in the 2010-2011 Canterbury earthquakes. It seems that ceilings should be designed to have no possibility of causing death/injury during ULS shaking to be consistent with the NZ Building Code.
- If performance objectives become too conservative, this may mean that suspended ceilings will stop being a reasonable design option. This could have a significant adverse effect on the suspended ceiling industry.

3.2 Ceiling Standards

- Some standards are not up-to-date and reference out-of-date standards (e.g. AS/NZS 2815).
- The standards do not emphasize or state specific requirements to ensure good ceiling system performance, such as the gap-size between a floating ceiling and the wall, or how to consider interactions with specific service components.
- Floor acceleration profiles in current standards (NZS1170.5 and NZS4219) are the same up the building height for all building types. In reality, different building types have different accelerations at different heights, so this may result in some conservatism/non-conservatism.

3.3. Assessment of Ceiling Capacity for Design

- Test protocols are available for ceilings. Many of these require shaking table testing, which is too demanding.
- There is no method of relating test protocol results to design.

3.4 Ceiling Design Practice Issues

- No generic information is available on the principles involved in designing ceilings and providing bracing.
- There is a lack of generic design examples, especially regarding lateral bracing.
- Often ceiling systems are designed by engineers who are not the building designers and information necessary for ceiling design is not readily available. This includes the likely accelerations and drifts. It takes time and cost to obtain these parameters from an analysis of the building, and requires knowledge of things such as the soil conditions if the analysis is to be done accurately.
- Ceiling examples are often not checked.
- The documents required by AS/NZS 2785 (Appendix C) for conducting basic design of ceilings (i.e. drawings and documentation on

interaction of the ceiling system and building services) are seldom provided at tender or consent time.

3.5 Installation Issues

- There is a significant amount of poor installation.
- The NZS 4219 recommended minimum clearances between the ceiling and equipment supported independently of ceilings are often not being adhered to in practice.
- Component connection is often inadequate.
- Inappropriate connection of ceilings to suspended services (such as ducts), or a lack of ceiling support being provide around services.
- There is a lack of training opportunity for installers. Hence, many installers have very limited training. No training is required for installation in general.
- While NZS 4219 requires all fixings between hangings of luminaries along with ceiling grid system to be positive (locking type) to prevent disengagement, there are no examples and illustrative sketches provided; thereby leaving room for misinterpretation leading to faulty details.
- Often, there is a lack of inspection.
- Ceiling inspectors are often not trained.

3.6 Political Issues

- Ceiling design is generally considered as an afterthought, rather than as part of the major building contract.
- The tasks of building structure design/construction, service equipment design and placement, partition design/installation and ceiling design/installation are often conducted separately or with little interaction between these groups. Therefore, coordination often does not occur to ensure that each of these parts acts as required.
- Often ceiling design has not been completed at the time of the tender for installation. Also, fees for ceiling design are seldom included in the tender. Responsible contractors, who pay for the ceiling design and pay the building design engineer, therefore have a high contract price. Other installers, who do not perform the full design have lower contract prices and often win the contracts. As a result, the current system discourages rigorous design.
- Anecdotal evidence suggests that the prices for ceilings in Christchurch are some of the lowest in NZ. Also, the quality of installation is correspondingly low.
- Changes to building use or occupancy often result in changes to the building internal layout with movement of partitions and installation of different ceilings. This can result in poor seismic behavior if appropriate precautions are not made.

4. SUMMARY OF CEILING DAMAGE OBSERVED IN CANTERBURY EARTHQUAKES

The damage observed to suspended ceilings described below during the recent Canterbury earthquakes includes that sustained during the September 2010 Darfield earthquake (Dhakal 2010; MacRae et al 2011) as well as the February 22nd and 13th June 2011 Christchurch earthquakes (Dhakal et al 2011). This has been organized by damage type: grid damage; perimeter damage; interaction with other components; grid spreading; and combinations of different damage types.

4.1 Grid Damage

Grid damage results from excessive force on the grid members or connections. This then results in ceiling grid distortion under compression and subsequent buckling of the grid members or failure of the connections while the perimeter connections remain intact. Below are several examples of ceiling grid damage observed in the Canterbury earthquakes.

Figure 2a. Damage resulting from disconnection of cross-tee from the main beam resulting in localized collapse of the grid and loss of tiles (Photos: K Hogg)

Figure 2b. Damage to grid members due to excessive compression force (Photos: K Hogg)

Figure 2c. Damage resulting from main beam splice failure (left) and cross-tee disconnection with main beam (right) (Photos: Hush Interior Ltd)

Figure 2d. Damage resulting from main beam splice connection (left) and buckling of cross-tee connections and main beam splice failure (right) (Photos: K Hogg)

The uniformly distributed mass (in the form of tiles) in a ceiling generates uniformly distributed inertial force, and the accumulated inertial force which causes axial compression in the grid members becomes greater near the supports (i.e. the perimeter) than in the middle (Paganotti et al 2011). In general, the observed compression damage of grid members was hence more severe near the perimeter, whereas failures due to tension and connection fracture did not follow a specific spatial pattern.

4.2 Perimeter Damage

Perimeter damage results from the main tee or cross-tee losing seating on the perimeter angle around the ceiling. Loss of seating can result due to a lack of a rivet to connect the grid member to the angle or failure of the rivet itself. This results in the grid members and tiles dropping from the ceiling. Edge perimeter hanging wires can prevent the member and tiles from falling, however, this can result in the tile and members being forced back into the angle causing damage to the tiles and members; see Figure 3a (right) below.

Figure 3a. Damage caused by disconnection of main beams and cross-tees. Note damage to panels at right which have not dropped from the ceiling but have been forced back into the wall angle causing damage (Photos: Hush Interior Ltd)

Figure 3b. Damage caused by failure of rivet between main beam/cross-tee and wall angle (Photos: Hush Interior Ltd.)

Common current practice is to connect the grid members to the perimeter angle with centre single-size riveting which only connects to the face cap. Such a riveting system was found to be inadequate. In some cases, the inadequate rivets were observed to fail in tension, leaving only the aluminum cap to hold the system together. In other cases, the rivets were also found to have ripped through the steel wall angles and tee rails. Probably, the standards need to provide detail specifications on the number, size and locations of rivets for such perimeter connections.

In one case, during repair after the February earthquake damage, engineered tee connections were provided with an increased number and diameter of rivets. This detail survived the June 13 earthquake and the quakes afterwards. Only the trim suffered a small amount of distortion. A photo of this connection is shown in Figure 3c.

Figure 3c. Perimeter connection with increased number/diameter of rivets (Photo: K Hogg)

4.3 Interaction with other Equipments

Damage to suspended ceilings can result from force transferred from services above the ceiling into the ceiling itself. In a standard installation of a suspended ceiling the hanger wires are placed at 1200 mm centre. However, the presence of services (such as HVAC) above the ceiling can mean this is not possible. As a result suspended ceilings are sometimes partially hung from services within the ceiling (most commonly HVAC ducting and plant). As this plant is rarely secured properly, when it moves it imparts force into the ceiling, causing damage. Additionally, services above the ceiling moving during an earthquake can impact the hanging wires of the suspended ceiling, once again imparting force into the ceiling. Suspended ceilings are not designed to take the additional force from this plant. Grills within the ceiling plane were often observed to have fallen from the ceiling and localized loss of tiles often occurred around the location of these grills. Some instances of ceiling failures resulting from the interaction with the services are shown in the figures that follow.

Figure 4a. Damage caused by interaction with services above the ceiling (Photos: Hush Interiors Ltd.)

Figure 4b. Damage caused by unbraced AC ducts swaying o or causing damage (Photos: R Dhakal, K Hogg)

In some buildings the ducting sizes make it difficult to provide hangers at the required spacing and the service heights provided were too low to provide proper bridging under services. Figure 4c below shows cases like these.

Figure 4c. Damaged ceiling with inadequate service height (Photos: K Hogg)

Interaction with partition walls also caused damage to some ceilings braced to the walls. Some internal walls extend to the floor above and are fixed either directly to the floor or beam or through inclined braces which are required to minimize buckling of slender walls. In some cases the ceiling may also be supported on these internal walls. The braces of these walls are close to the ceiling hangers and other equipment braces and are likely to interact with the system. It was found that the failure of the braces (some of which fell off) could easily have caused significant damage to the ceilings (see Fig 4d left).

Figure 4d. Interaction between internal walls and ceiling (Photos: K Hogg)

In some cases, the partition walls stopped at the ceiling level and were braced by ceilings. Obviously, in such cases the ceiling needs to cater for the wall as well. Glazed partitions fall into this category, and due to small aluminum sections they are difficult to brace. In some buildings, such wall partitions were found to be out of plumb and in one glazed partition, glass jumped out of the top track (see Fig 4d right).

4.4 Grid Spreading

The suspended ceilings discussed in the previous sections are all two-way exposed grid systems. That is, they consist of a two-way grid of inverted 'T' shaped members hung from the ceiling above. The panels are then dropped in and rest on the flanges of the inverted 'T' sections.

The damage shown in the photos below occurred to grids that are different to the two-way type grid discussed in the previous sections of this report. The grids below consist of main beams spanning one way and hung from the structure above. There are typically no transverse runners (except where the ceiling may have been retrofitted with these). The drop-in panels prevent the grids from spreading apart during an earthquake. However, if panels do drop out there are no members to stop the grids moving apart (spreading) and causing further panels to fall from the ceiling. Also, as opposed to the two-way systems discussed above, the panels are not supported on all four edges by the grid system. The panels are instead interlocked, so when one panel falls it leaves the next panel susceptible to falling.

Figure 5. Damage caused by grid spreading causing the panels to fall from the ceiling (Photos: T Abu and Hush Interior Ltd)

4.5 Other Types of Damage

Damage to suspended ceilings can also result from elements that are connected to the ceiling but should be independent of it. Common examples of this are timber or steel framed bulkheads and partitions. Partitions, in particular, should not rely on lateral support during an earthquake from the suspended ceiling. Unless it is considered explicitly in design, this type of construction applies extra force into the ceiling and can result in damage (see Fig 6a for example).

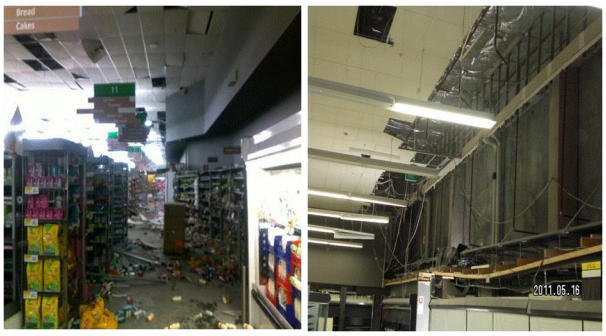

Figure 6a. Damage due to interaction between bulkheads and ceiling (Photos: K Hogg)

In some cases damages were attributable to the interaction between ceilings and bulkheads. Bulkheads hanging from tiled ceilings dropped when the ceiling perimeter detail failed. In a building it was found that during renovation, bulkheads were removed but no bracing was put in place to take the ceiling load. In such cases, the partition loads change during alterations and ceiling line load increases, hence it is advisable to provide bracing to take care of the increased load on ceiling.

The above forms of damage can occur simultaneously during an earthquake causing widespread damage to a single ceiling system. Some examples of this are shown in the figures below.

Figure 6b. Widespread damage of a single ceiling (Photos: R Dhakal, T Abu and Hush Interior Ltd.)

4.6 Summary of Observations

- Compression failure generally occurred closer to the perimeter (than the middle) of two way grids.
- Compression failures were observed to be more severe and more extensive in larger ceilings.
- Ceilings with heavier tiles/panels were observed to undergo more severe damage compared to those of the same size with lighter tiles in the similar shaking region.
- Observed damage in ceilings was very severe in many cases and it was only a coincidence that nobody was killed due to ceiling failure in these earthquakes. As the 2011 Japan earthquake has proved, heavy ceiling tiles falling from several meters can easily be fatal. Even in rooms without heavy tiles, cross members bent down like skewers, causing a major hazard for anyone evacuating the building.
- Interactions with services above the ceilings, partition walls and bulkheads were found to cause many ceiling failures. This was most significant when services/walls were not constrained and interacted with the ceiling.
- Some ceilings were replaced several times during the earthquakes indicating that they were not able to sustain the levels of shaking imposed.
- Poor performance often resulted from poor system installation.

5. RECOMMENDED PRACTICE – DESIGN AND INSTALLATION GUIDANCE FOR CEILING SYSTEMS

A series of brain storming meetings was held between ceiling researchers and practitioners (designers, manufacturers, installers etc) to scrutinize the observed ceiling damage and to come up with immediate measures to improve the performance of ceiling systems in future earthquakes. As a result, the following "recommended practice" guidelines are proposed for ceiling systems, which include the ceiling itself, and all interacting elements:

5.1 Technical recommendations

1. All ceiling systems be designed and installed following appropriate standards.
   - NZS 1170.5:2004: for calculating the seismic demand on ceiling systems
   - NZS 4219:2009: for designing services and their interaction with the ceiling
   - AS/NZS 2785:2000: for designing ceilings
2. While using NZS 1170.5 to determine the design limit state, ceilings shall be placed in the following categories:
   - P.2 – Auditorium ceilings
   - P.3 – Suspended ceilings with one way or two way grid systems
   - P.4 – Suspended ceilings with heavy (more than 10kg) tiles
   - P.7 – All other ceilings
3. If interstorey displacements are not available from the design engineer and they are not computed explicitly, then:
   - the minimum ULS drift ratio demand shall be of 2.5% at all stories
   - the minimum SLS1 drift ratio demand shall be one third of the ULS value above
4. If floor accelerations are not available from the design engineer and they are not computed explicitly, then:

- the minimum ULS acceleration demand shall be 3 times the zone factor, Z, at all levels
- the minimum SLS1 acceleration demand shall be one third of the ULS value above

5. Ceiling connections shall be designed for a ductility of 1.25 for the ULS unless it is shown that another value is satisfactory.
6. Equipment with mass less than 5 kg (per m^2 of ceiling area) may be supported by the grid of the suspended ceiling system, and those exceeding 5 kg mass shall be supported independently of the ceiling. This recommendation overrides the existing statement in Clause 5.13 in NZS 4219:2009.

5.2 Regulatory recommendations

1. If the installer is required to provide the ceiling system design, the following is to be provided by the building design engineer in the tender documents:
   - floor accelerations for SLS and ULS actions.
   - interstorey displacements for SLS and ULS actions.
2. Design and detailing of ceilings and components interacting with ceilings (giving due consideration to the interactions between them) is to be undertaken under the supervision of a Chartered Professional Engineer.
3. Construction of ceilings and services is to be undertaken by a trained and experienced installer.
4. Construction review is to be undertaken by a suitably qualified engineer; preferably the designer.
5. Structural modifications to components interacting with ceiling systems shall consider the implication of the modification to the ceiling.
6. For quality control, the building consent documentation is to define who is responsible for the following design, installation and certification/review processes:
   - Producer Statement 1 (PS1) – Design
   - Producer Statement 3 (PS3) – Construction
   - Producer Statement 4 (PS4) – Construction Review

   If the ceiling is a design and supply item the tender documents shall spell out the requirement for each of these.
7. AS/NZS 2785 needs to be updated in line with the seismic demand stated in NZS 1170.5.
8. Training programmes and qualifications need to be made available for installers.

It is likely that some clients will request buildings and non-structural components, such as ceilings, be designed for greater performance than that associated only with life safety. Also insurance companies may require this in Christchurch and elsewhere as a result of the significant damage resulting from the Canterbury earthquakes. Improved performance may be obtained by designing components greater levels of ground shaking, such as the NZS 1170.5 Maximum Considered Event (MCE) which is defined as being 1.8 times the NZS 1170.5 Ultimate Limit State (ULS) Event. Alternatively, it is possible to design for higher serviceability criteria. In addition, damage may be minimized by using the details recommended below.

6. BEST PRACTICE DETAILING GUIDE FOR CEILINGS

1. Rivets should be placed on the side of a T-section, to go through two, rather than one piece of steel which is the case if they are placed in the middle.

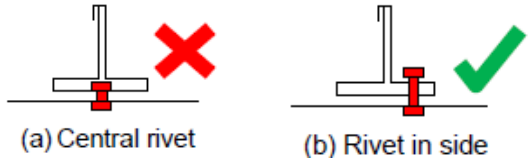

Figure 7a. Locations of rivets in T-rails (Elevation)

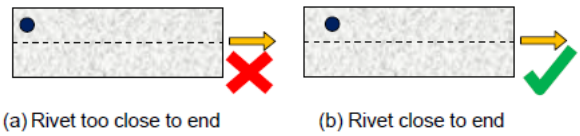
2. Rivets be placed with sufficient distance to the end of T-rails so they can develop their full strength.



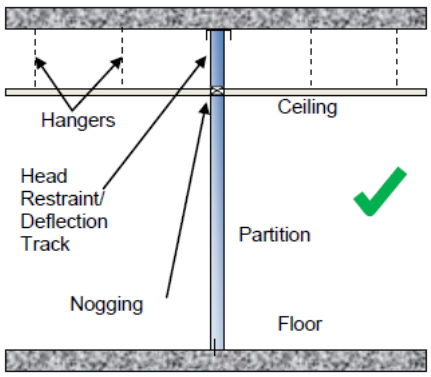


Figure 7b. Locations of rivets in T-rails (Plan)

3. It should be clear whether partitions are bracing the ceiling, ceiling is bracing the partitions, or whether they are independently braced as shown in the Figures below. A head-restraint can be used at the top of the partition. This restrains the partition in the out-of-plane direction. Note that hangers which go to the bottom end of a vertical brace must resist both compression as well as tension, as shown in Figure 7c, in order to prevent large ceiling swinging displacements.
4. Ceilings should be protected from ducts hanging from floor preferably by strongbacks with sufficient space for bridging.
5. Flexible chords should be used for fire sprinklers, or sufficient gaps should be provided in the ceiling so that large forces are not imposed.
6. Lighter tiles should be used rather than heavy tiles as light ceiling systems are likely to sustain less earthquake damage.

Abstract: In the Great East Japan Earthquake, many ceilings were damaged in the northern Pacific coast area including the Tokyo area and some people were injured and killed by ceiling failures unfortunately. Furthermore, after the shock, it took a long time to restore ceilings. The fact let us know it was a problem of great urgency to reduce such damage of ceilings from the view point of the business continuity plan. We focus on the Japanese style of ceiling with steel furring. The damage patterns of such ceilings are classified into two categories. One is that ceiling surface falls in a great mass and another is that a part of ceiling board falls in the circumference of ceiling. We show that each pattern of damage is caused with a quite different reason.

1. INTRODUCTION

The significant damage of ceiling had been observed in the recent earthquakes of the 2001 Geiyo earthquake, the 2003 Tokachi-oki earthquake, the 2005 Miyagi-ken-oki earthquake and so on. We had experienced that ceiling failure injured or killed persons during an earthquake and impaired functions of buildings after earthquakes. The similar but much greater scale of ceiling failures occurred at the Great East Japan Earthquake happened on 11th of March, 2011 though we had cautioned about such risk through our research. Many engineers had misunderstood that ceiling failures had been caused by the bad construction and they had not examined their consideration had been true or not. After 3.11, the situation changed completely.

The epicenter of the Great East Japan Earthquake was off the coast of Miyagi prefecture and its magnitude was over 9. A lot of ceilings were damaged at wide area in the northern Pacific coast including the Tokyo area far from the epicenter (Fig.1). Such damages revealed the fact that many existing ceilings might fail under not so great earthquake. After then, the Architecture Institute of Japan or the Ministry of Land, Infrastructure, Transport and Tourism begun to tackle the mission to mitigate ceiling failures. Some committees have been set up to make a draft of the seismic code for ceiling. One of authors participates in such committees.

There are two types of ceiling system as the Japan style and the western (US) style. The Japan style one is more popular than the western style. Regarding the extent of damage, the damage of the Japan style one was much severer than the western one quantitatively and qualitatively. Then we have focused on the Japan style of ceiling. We have studied the

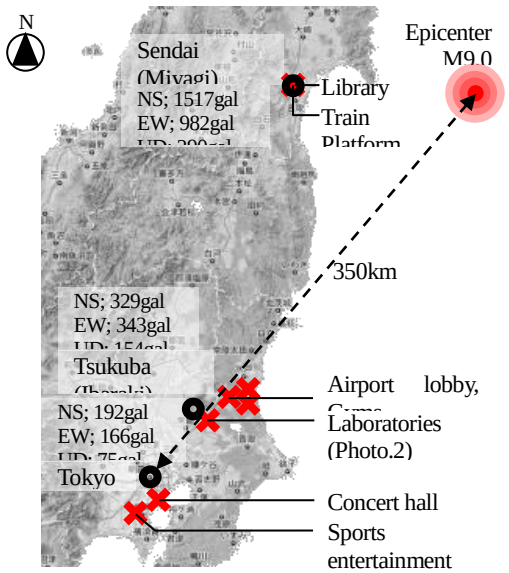

Figure 1 Map of ceiling damages examples by Great East Japan Earthquake

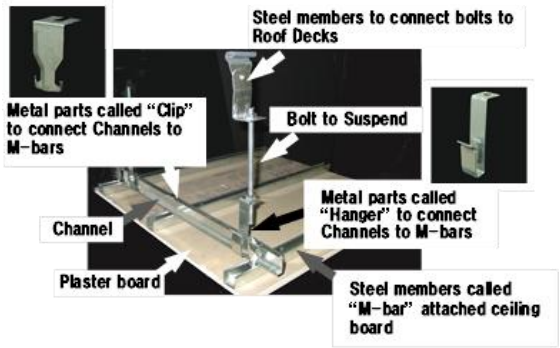

Figure 2 Japan style of ceiling

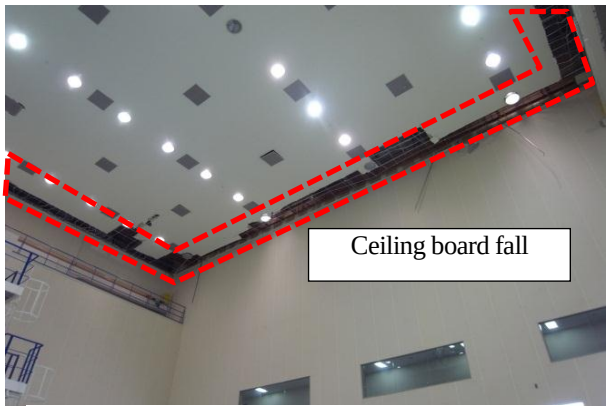
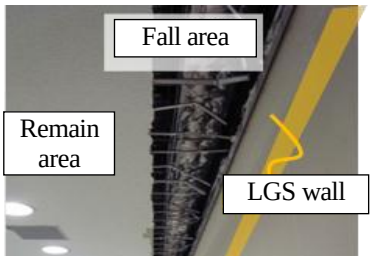
performance of the ceiling during earthquakes through experimental and numerical results until now. Recently we have found out the reason why ceiling fell down. In Fig.2, the Japan style of ceiling is shown. The Japan style one consists of steel furring and gypsum board. Its standard weight per unit area is approximate 150kN/m2. The Japan style one is heavier than the western one because a urethane board is used in the western style one instead of a gypsum board in Japan. The heavier weight causes severer damage in the Japan style one. The most important feature of the Japan style is the existence of unique metal joint parts which are called "hanger" and "clip" as shown in Fig.2. Though these metal parts have the enough strength to carry the self-weight of ceiling, it is known that they can be easily detached by horizontal force by an earthquake.



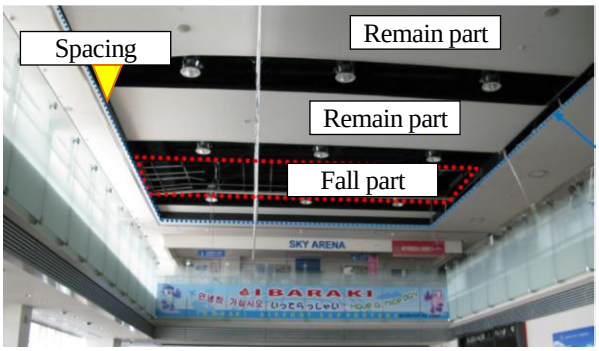
In this paper, we classify the damage patterns of ceiling into two categories. One is that ceiling surface falls in a great mass and another is that a part of ceiling board falls in the circumference of ceiling. We show that each pattern of damage is caused with a quite different reason.

2. Damage Patterns of Ceiling in Earthquakes



In this section, two typical damage patterns of ceiling are shown. First one is that a part of ceiling board falls in the circumference of ceiling and another is that ceiling surface falls in a great mass. The occasion for each pattern of damage is quite different. The former is caused by the buckling behavior of ceiling surface while the latter is by the detachment behavior of metal joint parts between steel furring. The reason is obvious from the observation of the damage condition. However, the patterns of damage are not always independent each other. In the most tragic ceiling failure, one pattern of damage transitions into another pattern.

The first example in Photo.1 and 2 is the damage of ceiling boards at the laboratories in Tsukuba. The peak of horizontal ground acceleration was recorded 343cm/sec2. As shown in Photo.2, only gypsum boards fell down and steel furring remains original position though it have buckled. At the circumference area of ceiling, the membrane compressive stress is greater than one at other area since an inertia force on the ceiling surface accumulates. Then, the ends of ceiling are easy to suffer damage generally.



The second in Photo.3 is the ceiling damage at an airport in Ibaraki. In this case, the ceiling fell down in the great mass and both gypsum board and steel furring fell down. This pattern of damage is caused by the detachment of metal joint part called "Clip". Once the detachment of "Clip" occurs, the chain of the detachment can easily happen. As a result, ceiling falls in the great mass. The spacing between ceiling and the surrounding component can be seen. And bracing members are set for ceiling not to swing during

Photograph 1 Pattern 1 of ceiling failure

Photograph 2 Pattern 1 of ceiling failure

Photograph 3 Pattern 2 of ceiling failure

Photograph 4 Ceiling failure by combination of Pattern 1 and 2

an earthquake. The method with the spacing and bracing members are recommended by the Ministry of Land, Infrastructure, Transport and Tourism (ML IT).

The last example in Photo.4 is the ceiling damage at the top floor of an eight-story building in Yokohama. A few persons were injured. The peak of horizontal ground acceleration was recorded 165gal. The roof of the building is formed by truss beams that cover over 34m span. In this case, there were not spacing. The surrounding wall also suffered serious damage. I guess that the ceiling which had lost counterparts fell down.

3. Structural Characteristics of Ceiling Surface under Static Loading

In the previous section, we showed two typical damage of ceiling. We have already published the characteristics of metal joint parts used at the connection between steel furring and the mechanism/process of damage. Then, we focus on the characteristics of ceiling surface. Especially, consider why/how a ceiling surface buckles.

3.1 Compression Test of Ceiling Surface

At first, the compression test of ceiling surface was executed. Fig.3 shows test specimen. The ceiling surface is made of gypsum boards (thickness: 9.5mm) which are attached to M-bars by screws and the steel furring members are suspended with bolts of which outer diameter is 9mm. The spacing of bolts is about 850mm and its length is 1,500mm. As the stress condition on the ceiling surface becomes the uniform uniaxial compression state, the displacement on one edge is controlled by using the H-shaped beam (H-400x400) while another opposite side of edge is fixed by using the same size of H-shaped beam as shown in Photo.5.

Fig.4 shows the relationships between compressive resultant stress and stretch for the respective direction load. The compressive resultant stress means the compressive force by unit length. According to the results, the maximum compressive strength reaches to about 12kN/m. After the maximum strength, the compressive force decreases immediately. The deformation at the post maximum strength shows in Photo.6. It can be understood that both ceiling surface and hanging bolts buckle.

Unfortunately, the compression test was executed only for one test specimen. So, the process to collapse is not obvious through the test result. Is the maximum compressive strength determined by instability of ceiling surface? Of course, it is right but it should be considered why ceiling surface falls into the unstable condition.

3.2 Numerical Analysis for Compression Test of Ceiling Surface

Here, we investigate the unstable behavior of ceiling surface under uniaxial compression force by numerical analysis. To validate a numerical model, we compare the numerical result with the experimental result. See Fig.5 shows the relationship between compressive resultant stress and shortening. The numerical result is close to the

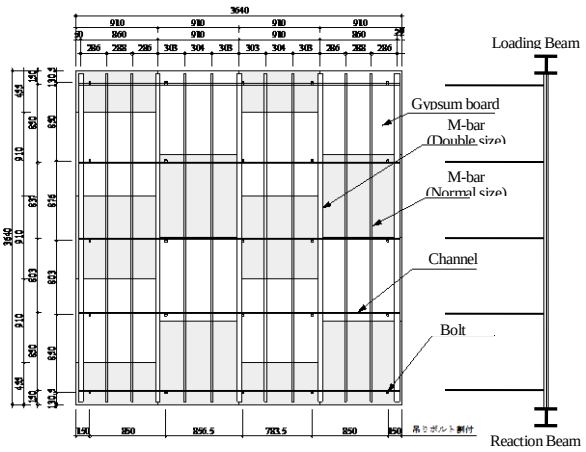


Figure 3 Test specimen

Photograph 5 Loading edge

Figure 4 Compression vs. shortening

Photograph 6 Deformation after peak

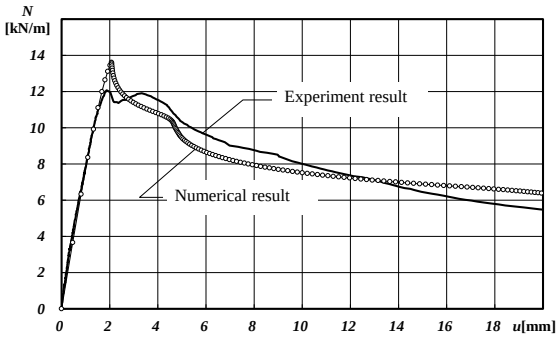

Figure 5 Comparison of numerical and experimental results

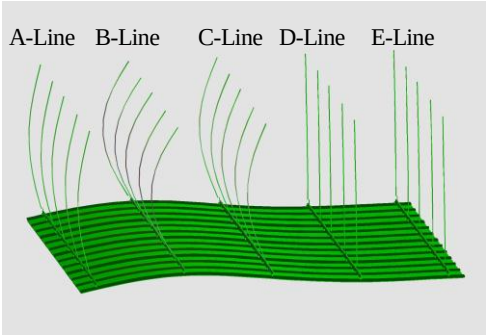

Figure 6 Deformation by numerical

experimental one. And the deformation by numerical analysis also agrees with the observed at the experiment (See Photo.6 and Fig.6). Then, the present numerical model can be considered to be appropriate.

Using the above model, the results obtained by using models with various lengths of bolts are shown in Fig.7. The longer bolts become, the less the compression strengths of ceiling surfaces become. The relationship between compression strength and bolt length is shown in Fig.8. Fig.9 shows the relationship between axial forces on bolts and the shortening of the ceiling surface. By comparing Fig.7 with Fig.9, the maximum compression strengths are determined with the buckling of bolts. Namely, the ceiling surface falls into unstable condition when the bolts buckle. The reason is that the restriction effect of bolts on the out-of-plane deformation of ceiling surface vanishes as soon as bolts buckle. Then, though the longer bolts are sometimes used, a ceiling surface with such bolts is more dangerous than one with the shorter bolts. A lot of engineers think the stress acts on a bolt is tensile and its slenderness ratio is meaningless. However, it is understood that the thought is entirely wrong through the numerical results. The strength of the bolt can be calculated with the formula of Euler's buckling for the pin ended column (Solid line in Fig.10).

The compressive strength of 12kN/m for the bolt length of 1,500mm (See Fig.8) is enough to resist the inertia force by an earthquake. For example, supposing the mass per unit area of ceiling surface [m] and response acceleration on ceiling surface [Sa] are 15kg/m2 and twice of the gravity (2x9.8m/sec2), the limit of ceiling length Llimit can be calculated as following.

$$mL_{limit}S_a < N_{\max}$$

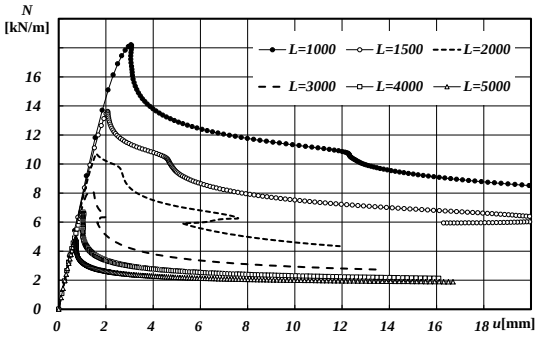

Figure 7 Influence of bolt length

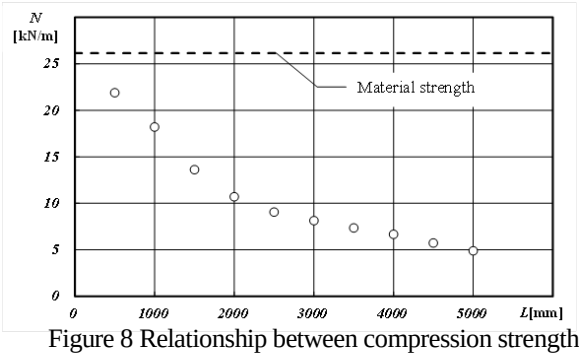

Figure 8 Relationship between compression strength of ceiling surface and bolt length

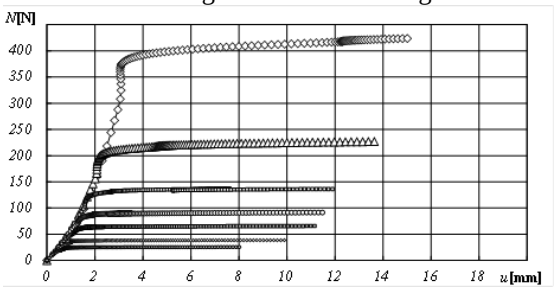

Figure 9 Bolt axial force vs. shortening

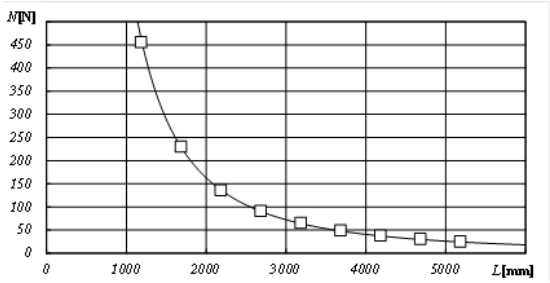

Figure 10 Relationship between bolt axial force and bolt length

$$L_{limit} < \frac{N_{\max}}{mS_a} = \frac{12{,}000^{\mathrm{N/m}}}{15^{\mathrm{kg/m^2}} \times 19.6^{\mathrm{m/sec^2}}} \cong 40\,\mathrm{m} \qquad (1)$$

If this result is true, why the Japan style of ceiling smaller than L_{limit} fell down in earthquakes as shown in Photos.1 and 2? It is thought that the cause of ceiling failure is the impact force generates when ceiling surface collides with a surrounding component like a wall. In this section, the spacing between ceiling surface and the surrounding components is supposed to be zero. But, it is impossible to set the spacing to zero and there is always some unavoidable spacing by the gap of construction actually. So, we

investigate the relationship between the spacing and the impact force in the next section.

3. Impact Force at the End of Ceiling Surface

Now consider the simple model with one mass and two springs as shown in Fig.11 where M is a mass of a ceiling surface and K is a spring constant which represents a surrounding component. It can be considered that the impact force reaches the maximum value when the situation becomes the stationary vibration condition. Readers can understand the fact is right by imaging an old toy called "Clackers". At the time, the mass repeats pounding and leaving behavior alternately. The assumptions that The natural period of ceiling system is assumed to be infinite because the spring constant as a pendulum is much smaller than one of the surrounding component are introduced for the simplicity. It can be led from this assumption that the time in which the mass keeps in contact state is much shorter than the time in which the mass leave the spring. Similarly, the damping effect to the motion of the mass can be neglected during leaving condition. Then the velocity of the mass during leaving is constant. As a result, the period of the stationary vibration state is determined only with the velocity of the mass.

$$T = 4\frac{d}{v} \qquad (2)$$

where T is the period in the stationary condition, d is a spacing and v is a velocity of the mass (See Fig.12). If we can obtain the velocity of the mass, the impact force, F_{impact} can be found by using Eq.(3).

$$F_{impact} = \sqrt{MK}\,v \qquad (3)$$

We make use of the balance of momentum before and after collision. Assuming that the value of K is great, the maximum response displacement is nearly equal to the spacing. Then Eq.(2) can be rewritten in the form;

$$T = 4\frac{u_{\max}}{v_{\max}} \qquad T = 4\frac{S_d(T)}{S_v(T)} \qquad (4.a,b)$$

where S_d and S_v are the values of displacement and velocity response spectra for target input acceleration.

Strictly speaking, the present problem is not a harmonic oscillator problem. Therefore, Eq.(4.a) is a just approximate expression. However, our objective in this paper is that we show the method which engineers can conveniently estimate the approximate intensity of impact force at the collision. From such view point, the expression of the second equation in Eq.(4) is enough. Though by using Eq.(4.b), we can find the period in the stationary condition, Eq.(4.b) is a nonlinear equation. Here, we suggest the convenient method to find the maximum velocity according to Eq.(4.b). Figs.14 and 15 show the displacement response spectrum and the velocity response spectrum for the target input acceleration as shown in Fig.13. From these response spectra, the relationship between the velocity response and displacement response can be obtained as shown in Fig.16.

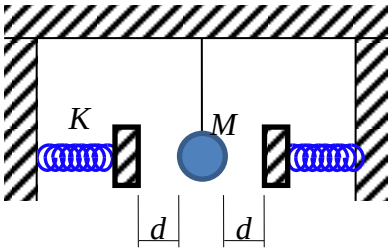

Figure 11 Model

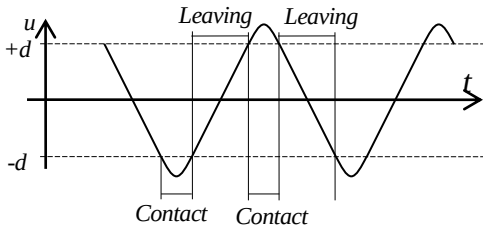

Figure 12 Stationary condition

If the spacing is set to any value, the maximum velocity can be found using Fig.16. For examples, in case that the spacing is 2cm or 10cm, the maximum velocity becomes around 25cm/sec or 62cm/sec respectively. Inserting these values into Eq.(4.b) gives the periods of 0.32sec and 0.65sec. These results are shorter since the displacement response corresponding to these periods is smaller than the spacing. It is inconsistent. Exactly speaking, it is necessary to iteratively process data for eliminating such inconsistence. Therefore, it

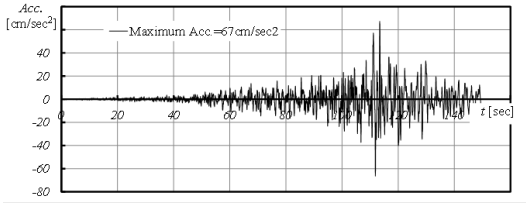

Figure 13 Input acceleration

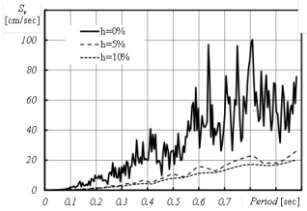

Figure 14 Velocity response spectrum

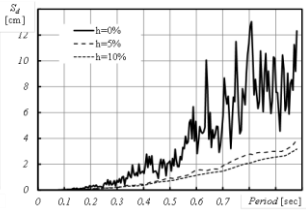

Figure 15 Displacement response spectrum

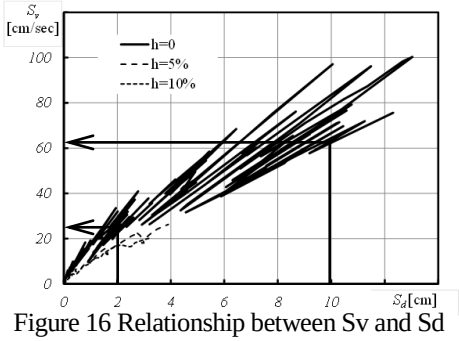

Figure 16 Relationship between Sv and Sd

can be said that the velocities found above, is just approximate. However, it is our objective to suggest the convenient prediction method and the values are adopted. Here, consider the case of M=450kg and K=4,500kN/m. Substituting in Eq.(3) from each value gives impact force;

$$F_{impact} = \sqrt{450 \times 4{,}500{,}000} \times 0.25 = 11.25 \times 10^3 \, N$$

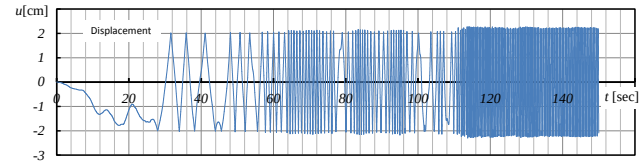
for spacing =2cm (5.a)

$$F_{impact} = \sqrt{450 \times 4{,}500{,}000} \times 0.62 = 27.9 \times 10^3 \, N$$

for spacing=10cm (5.b)

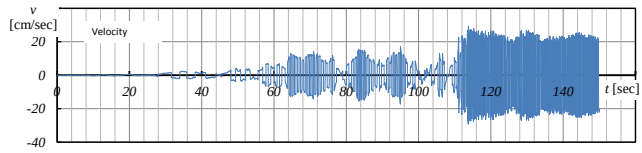
We calculated numerical examples to validate our prediction method. The values of the mass and spring constant are 450kg and 45,000kN/m and the values of spacing are 2cm and 10cm. The damping effect is neglected. Numerical results are shown in Figs.17 and 18. The values of the maximum velocity and impact force are 29.2cm/sec, 13.2kN for spacing of 2cm and 66.8cm/sec, 29.1kN for spacing of 10cm. These values approximately agree with our prediction ones. The present prediction method is useful to estimate the velocity and impact force approximately though the above mentioned inconsistence is involved.

It is noted that the maximum velocity can be determined only by the value of spacing and response spectra of input-acceleration while the impact force can not be calculated by using the value of the system like a mass and spring constant.



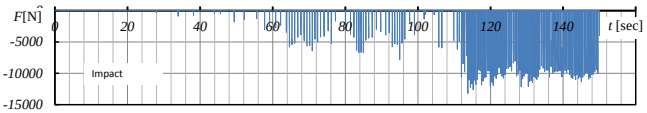
The maximum values of impact forces become much greater in comparison with the ordinary inertia force. For example, in case of the spacing 2cm, the impact force reaches 13.2kN. The value corresponds to around 3G (because the mass is set to 450kg) though the maximum value of input acceleration is not so much. The reason why such great impact force occurs is to make spring constant great and to neglect the damping effect. Therefore, these values should be appropriately evaluated based on the actual situation when engineers consider the reason of ceiling damage. On the other hand, the fact is useful for engineers to consider the seismic design of ceiling. Namely, they should find the suitable stiffness and damping ratio of the surrounding component to degenerate the impact force.

3. CONCLUSIONS



We investigated the behavior of ceiling with steel furring during an earthquake. Especially, we focused on the ceiling without the spacing between ceiling surface and the surrounding component. The obtained results were summarized as followings.

#1. The static compression strength of ceiling surface is enough great to resist the horizontal force in an earthquake except the ceiling suspended with too long bolts.



#2. The greater the impact force occurs at the collision of the ceiling surface and the surrounding component becomes, the larger the spacing is. The spacing should be as small as possible or apply any special device like a damper.

Abstract: Partition walls with light-gauge steel stud, also known as dry-wall, are commonly used in Taiwan since the 1980's. In the past 20 years, there are some modifications by providing lightweight-mortar infill (LIMI) between two surface panels to provide a higher standard for soundproofing and burglary protection. Although LIMI wall is gradually accepted with good response, there are some observed earthquake damages of collapse and flooding caused by water-pipe shear-off. These damage may pose serious consequence that warrant special investigation. This paper summarized a series of full-scale experiment of LIMI walls. Because partition walls are displacement-sensitive elements, two prototypes of LIMI walls were tested separately in plane and out-of-plane cyclically with displacement controlled actuators. Intersection walls in T and L shape were also tested with loading exerted from in-plane direction. Different types of construction details to improve the seismic capacity of LIMI walls were developed to increase the seismic capacity of the prototype LIMI. The test results indicated that the collapse story-drift ratio can be increased from 3% to 5% while the water pipe's rupture story-drift ratio can be increased from 1.5% to 4%.

1. INTRODUCTION

The partition walls in a building are important non-structural components, of which the functions may include partitioning the space, sound-proofing, prevent burglary and securing privacy. In 1980's, the dry-wall (DW) system was first introduced from the USA. This system has the advantages of lightweight structures, ensured quality, and accelerated construction. Due to these advantages, it was commonly used in the construction of commercial, hospital and residential buildings in which the traditional RC and brick partition walls are replaced. However, the DW systems still have problems, such as inadequate strength to hang objects, poor soundproofing, and vulnerable to burglary. To satisfy the needs of the users in Taiwan, the lightweight-mortar infilled stud wall system (LIMI) was developed and Taiwan is distinctive in using this technique.

Although the LIMI system is more appropriate for general living requirements, the seismic behaviors and sturdiness of this system under earthquakes have not been extensively studied. Some post-earthquake survey reports in Taiwan revealed that the building structures could resist small to moderate seismic events without damage, but the LIMI system could have been easily damaged. Damages may include not only the fracture of water pipes to cause flooding in a building, but it may also cause out-of-plane collapse and threaten lives.

This paper aims at the studying on the inter-story drift performances of the LIMI system. The results will be analyzed and discussed for future design specifications in Taiwan.

2. THE LIGHTWEIGHT-MOTAR INFILLED STUD WALL SYSTEM IN TAIWAN

The construction of LIMI system assimilates the grouting formwork of RC walls and is a special technique developed due to the living habits of Taiwanese people. This system is similar to the DW system, since they only differ in interior materials; while the former is filled with lightweight mortar, the latter mainly uses insulation material such as TFRB or FR4.

Figure 1 shows the typical LIMI system in Taiwan. This system consists of horizontally laid out U-shaped tracks and vertical C-shaped studs as its main frames. The U-shaped tracks act as the top and bottom tracks, fixed on the structural components such as slabs or beams with powder-driven nails. The vertical C-shape studs are cut into an appropriate length according to the height of the wall and then are fit snug-tight in the U-shaped tracks. For the LIMI systems, because of the heavy mass of the partition walls

and the pressure during the process of grouting, the stud space are closer with a general distance between each stud ranges from 24-30 cm. If the end studs of the partition walls shown in Figure 2 come into contact with the structural components like columns or walls, they also have to be fixed on the structural components with powder-driven nails, like the U-shaped tracks. After the frame is installed, the surface panels (fiber cement boards) are then fastened to studs as well as the bottom track with tapping screws, whose spacing is 10 cm. There is a 1- cm clearance (see Figure 2) kept between the panels and the structure members. At last, holes were dig on the surface panels and mortar enters from them. The lightweight mortar for grouting is composed of cement, sand and Styrofoam pellets, of which the percentage is 1:2:4.

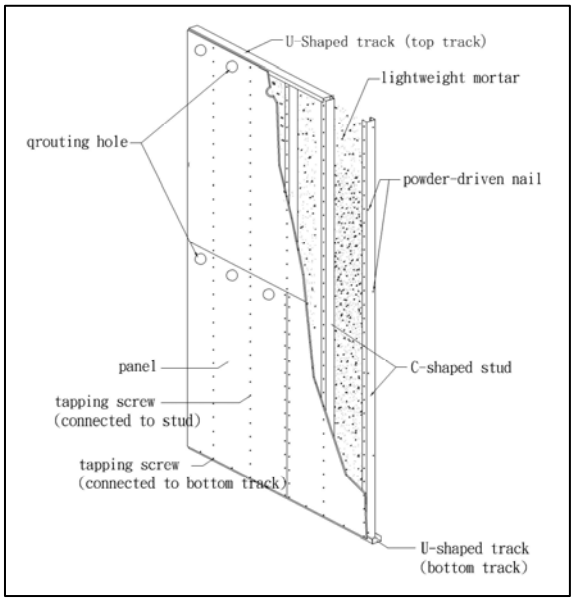

Figure 1 Typical construction of the LIMI system

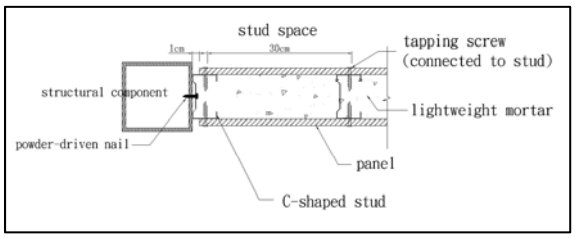

Figure 2 Details of the LIMI system

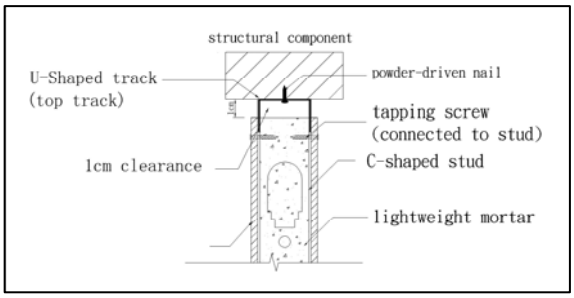

Figure 3 Details of the LIMI system

To prevent the LIMI from carrying vertical dead loads from the upper structures, the studs should not be connected directly with the top track web and the distance between them will be 1-1.5 cm. Similarly, there should be a 1 cm clearance between the mortar and the top track web during grouting (see Figure 3).

The major characteristics of the LIMI system are as follows:

1. Thickness and weight: The thickness of the LIMI system is about 7.5-9 cm. The weight is 60~160kgf/m².
2. Construction: The construction goes fast, and on average a worker per day can accomplish 12 m² of the wall.
3. Fireproofing, moisture-proofing and sound-proofing: The fireproofing capacity can last for 1-2 hours, and the other two functions are satisfied especially the characteristic of sound-proofing is much better than the DW system.
4. Object-hanging: As the walls are solid due to grouting, the characteristic of object-hanging is similar to that of RC walls.
5. Guard against theft: It works better than the DW system and this is one of the reasons why the LIMI system is commonly used in recent years.

3. EXPERIMENTAL PROGRAM

Full-scale specimens of the LIMI system were constructed in this study. Since the partition walls are considered displacement sensitive, the experimental loading steps were displacement controlled by an actuator. The specimens were tested with lateral cyclic loading, and the damage patterns were investigated and recorded during each drift level. This study included two groups of experiments. The first group was to study the seismic performances of the current practice of the LIMI system in Taiwan. The second group experimented on retrofitted tests of partition walls to minimize the possibility of damage during earthquakes.

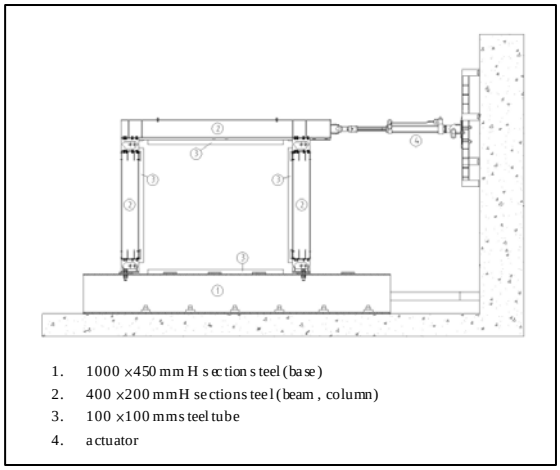

Figure 4 Details of the test frame

A steel test frame shown in Figure 4, composed of one 1000 ×450 mm H section steel (base) and three 400 ×200 mm H section steel, served as beam and column, was built. The joints of the frame were designed as hinges. Inside the frame were 100 ×100 mm steel tubes, which represented the building structures and allowed the specimens to be

constructed on the frame. The actuator was connected to the H section beam, and the cyclic loading was applied from the actuator through the frame to the specimens to simulate the partition walls under earthquakes. The specimens were tested by FEMA-461 experimental program (Figure 5), which provided recommended testing, loading history, and documentation procedures for the investigation of the seismic performance of the partition walls. The actuator was displacement controlled with the velocity of 1.38mm/sec, and 12 different drift levels were tested in sequence (0.15%, 0.21%, 0.29%, 0.41%, 0.57%, 0.8%, 1.1%, 1.5%, 2.1%, 3.0%, 4.0% and 5.0%). The damage conditions were recorded during each level until the specimens damaged seriously or about to overturn.

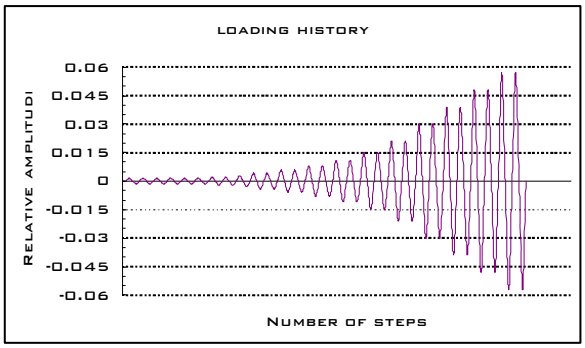

Figure 5 Displacement-controlled loading history

A total of seven specimens (W1, W2, …, W7) were tested in this study. Four single specimens were subjected to the in-plane and out-of-plane loading respectively, and the other 3 specimens were combinations of both in-plane and out-of-plane walls in T and L shape. The out-of-plane specimens were 2720 mm high and 1400 mm long, while the in-plane specimens were 2720 mm high and 3250 mm long. About the L shape and T shape specimens, the out-of-plane walls were 800 ×2720 mm for the former and 1500 ×2720 mm for the latter, and the in-plane walls were 800 ×2250 mm for both. The thickness of the walls was 77 mm including two 6 mm surface panels and the interior mortar. Each specimen had PVC water piping inside.

Figure 6 (a)W1, (b) W2, (c)W3, and (d)W4

Specimens from W1 to W4 followed the typical LIMI system construction practices in Taiwan. Both W1 and W2 were single wall specimens, and W1 specimen was tested out-of plane while W2 was tested in-plane. W3 and W4 specimens were combinations of two perpendicular walls, and the types of W3 and W4 were T shape wall and L shape wall. Figure 6 shows the pictures of the specimens.

W5 and W6 specimens were the comparison groups to W2, which were also subjected to in-plane loading. Details of W5 specimen were almost the same as W2 but adjusted the distance between each powder-driven nail from 60 cm to 30 cm. W6 specimen changed parts of the typical construction especially at the end studs. The end studs in W2 specimen were fastened both to the structural components and the panels; nevertheless, the end studs in W6 were only fastened to the structural components. Additional studs shown in Figure 7 were installed near the end studs and the panels were fastened on them. Between the end stud and the additional stud was filled with TFRB in order to satisfy the fireproofing capacity. In addition, the panels and the bottom track were fixed together in W2 but separated in W6, and the PVC water pipe was wrapped by ceramic fiber carton in W6 specimen. Figure 8 shows the improved construction in W6 specimen.

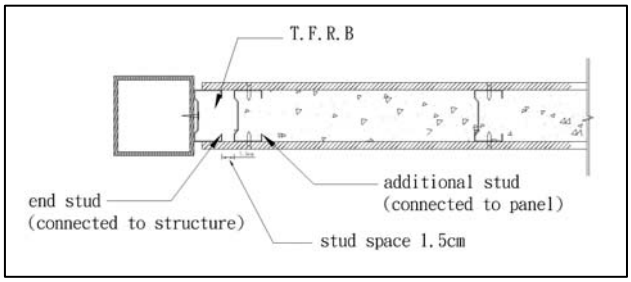

Figure 7 Details of W6 specimen

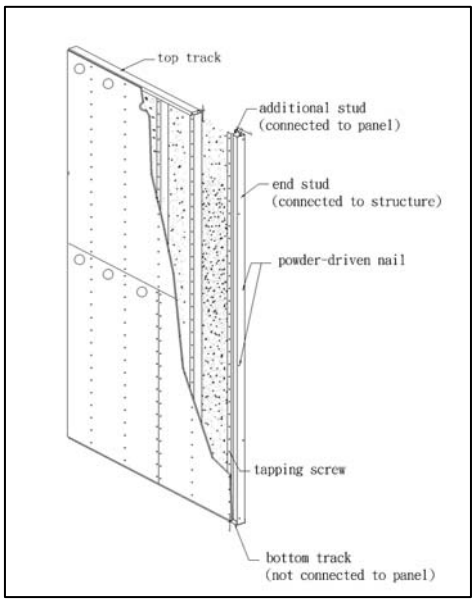

Figure 8 Construction s of W6 specimen

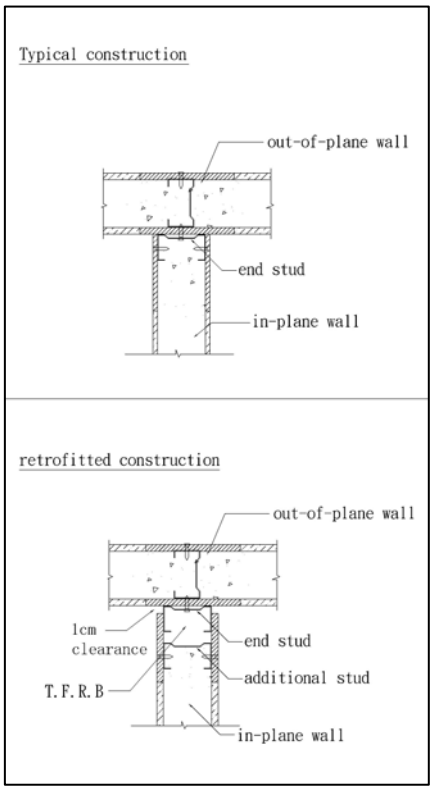
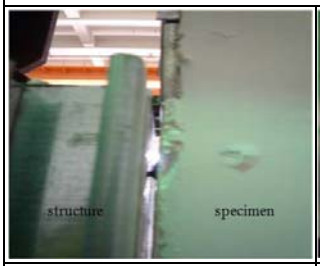
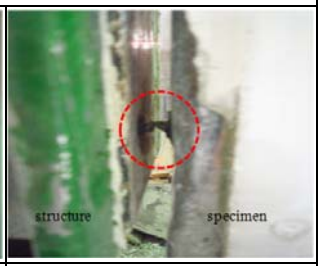
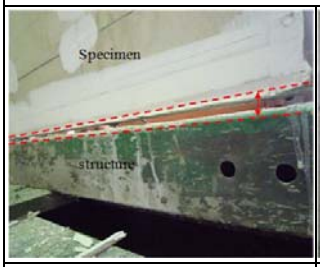
W7 specimen was T shape walls and the construction was similar to W6. In comparison with W3 specimen, who has panels of the in-plane wall directly connected to the out-of-plane wall, a 1cm spacing was left in W7 specimen (see Figure 9).









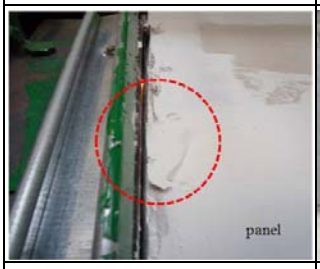


Figure 9 Details of W7 specimen

4. EXPERIMENTAL PROGRAM

Some typical damage patterns of the current LIMI system have been revealed in the first group of the experiments. Failure happened mainly on the end studs, bottom tracks, panels, the water piping and the junction of two walls. Since the end studs were directly fastened to the structures with powder-driven nails, the inter-story drift from the structures was firstly transferred to the interfaces and then to the specimens. Therefore the initial visible damage to the specimens was the separation of the end studs from the structure components. With increasing drift levels, the specimens were uplifted and the bottom tracks were pulled out from the structures. Slight panel damage appeared generally at the top corners and the damage progressed throughout testing. For T and L shape specimens, the connections between two walls were easily damaged and the fracture of the water pipe was observed in all specimens at large drifts. Table 1 lists the typical damage patterns observed from the experiments.

Table 2 shows the earlier stage of different damage patterns in the first group of experiments. From the results, damage to the W1 specimen was very limited and the specimen was almost remained intact. This condition revealed that the out-of-plane loading posed little threat to the partition walls. Compared with W1, obvious and severe damage occurred in the W2 specimen, which was subjected to the in-plane loading. The first failure sign at a drift ratio of 0.8% resulted in separation of the end studs from the structure components. Subsequently, separation zone increased throughout testing and isolated the LIMI from the structures.

Table1 Typical damage patterns

1. End studs failure	
	
Separation between the end studs and the structure components.	Most of the nail heads were pulled out from the end studs and the nails were also damaged.
2. Bottom tracks failure	
	
The specimens were uplifted from the structures.	Some nails were directly pulled out from the structures.
3. Panels failure	4. Water pipe failure
	
Local cracking of the panels.	Shear failure of the water pipe.
5. Junction failure of two walls	
	
Separation at the junction of two walls.	The top track flanges were bended and the out-of-plane walls leaned.

At a drift ratio of 1.5%, separation spread apparently along the interfaces and most of the nail heads were pulled out from the end studs. Other than stud separation, screw embedding was observed at a drift ratio of 1.5%, and the screws were pulled into the fiber cement boards. However, this failure mode was not severe and could be repaired with mud and paint. Failure of the track fasteners occurred only at the bottom. In comparison with the top track, the bottom track was attached to the surface panel but the top track wasn't. While the loading made the specimen rotate and

slide, the powder-driven nails at bottom track were engaged in uplift and shear. The fastener failure appeared to have occurred in two primary modes: the fasteners were threaded through the bottom track and, less frequently, they were tilted. These failure modes were observed at a drift ratio of 1.5%.

Table2 Damage progression of W1, W2, W3 and W4 specimens

Damage pattern	inter-story drift ratio			
End Studs failure	Visible separation appeared between the end studs and the structure components.			
	W1	W2	W3	W4
	none	0.8%	0.8%	0.8%
	Some nail heads were pulled out from the end studs.

	Widespread collapse of the panels.			
	W1	W2	W3	W4
	none	2.1%	3.0%	3.0%
Water pipe failure	shear failure of the water pipe.			
	W1	W2	W3	W4
	none	2.1%	2.1%	3.0%
Junction failure	Visible separation appeared at the junction of two walls.			
	W1	W2	W3	W4
	none	none	0.8%	0.8%
	The separation spread widely throughout the junction.			
	W1	W2	W3	W4
	none	none	1.5%	1.5%
	Both the top and the bottom tracks were damaged and the out-of-plane walls started to move.			
	W1	W2	W3	W4
	none	none	1.5%	1.5%
	Severe damage to the top track flanges and the walls leaned seriously.			
	W1	W2	W3	W4
	none	none	3.0%	3.0%

The 1 cm clearance between the panels and the structure components was lost as testing progressed. Subsequently, at large drifts the panels came into contact with the structures and were under compression and shear. The panels sustained localized cracking at the top corners of the walls at a drift ratio of 1.1%, and widespread damage appeared at a drift ratio of 2.1%. At the same drift level, the water piping experienced shear failure.

For W3 and W4 specimens, the damage progression of the in-plane walls resembled that in W2. But another significant failure occurred at the out-of-plane walls. As the specimens were cycled back and forth, the intersection at in-plane and out-of-plane walls was damaged most severely. In addition to the separation appeared at the junction, the top track flanges were bended and no longer restrict the out-of-plane walls. The separation was visible at a drift ratio of 0.8% and was totally separated at a 1.5% drift ratio. At a drift ratio of 3.0%, the out-of-plane walls leaned seriously and the testing stopped in fear of collapse.

Table 3 shows the results of W5 and W6 specimens. An intention of strengthening the shear resistance was applied in W5. From the results, it seemed that increasing the number of powder-driven nails had only small contribution to the water piping. The other damage patterns of W5 were observed at the same drift levels as that of W2. The retrofit construction in W6 specimen intended to reduce the connection between the partition walls and the structure components. The end studs and the bottom tracks fastened to the structures were not attached to the specimen. Despite the end stud flanges were squeezed by the additional studs at a drift ratio of 1.5%, damage to the fasteners was very limited. As the results, the bottom track remained intact and the shear failure of the water piping was finally appeared at a 4.0% inter-story drift ratio. Besides, widespread fall-off of cracked panels occurred at a very large drift ratio of 5%. The testing results of W7 specimens were shown in Table 4. In comparison with the results of W3 specimen, many problems had been improved.

5. CONCLUSION

According to the testing result, the rotational behavior seems to be the major problem of the current LIMI system and causes the fasteners to be pulled out easily. This situation is because of the partition walls are tightly connected to the structural components, therefore the partition walls were damaged easily as soon as the structures deformed. A retrofit construction is applied in this study which reduces the connection between the partition walls and the structural components, and the results have significantly improved with the retrofit details. The retrofit construction has made the partition walls slid rather than rotate and delayed the deformation and the damage of the walls and the water piping against the story-drift. Most important of all, the boundary conditions of the walls remained intact, which efficiently prevents the partition walls from overturning out-of-plane.

Abstract: To secure safety when furniture is fixed to wall, seismic resistance should be examined with an entire system which furniture, fixture and wall are combined. And, it should be considered by dynamic experiment. In this research, simple evaluation method for seismic resistance of furniture fixation wall system was established. Eleven kinds of specimen systems those seismic resistance were different from each other were selected. Those systems were constructed on a vibration table, and shaken by some kinds of real seismic waves. Amplitude of the input wave was gradually increased until specimen systems were destroyed, and limit accelerations were recorded. Then, the same specimen systems were shaken by a simple input wave based on the sine wave. This simple input wave could be generated by the simple vibration table, consisted of truck, crank shaft and power machinery. And, a suit combination of frequency and cycle number of the sine wave was discovered which destroyed systems in similar state to real seismic waves. This method of shaking a system by the simple input wave enables to grasp seismic resistance by degree of the limit accelerations. Then, it becomes possible to find out a low-quality system, and to exclude one.

1. INTRODUCTION

Furniture fixation is an important earthquake-proof method. There are a lot of cases of fixing furniture to walls compared with floors or ceilings. Therefore, to secure safety when furniture is fixed to wall, seismic resistance must be examined with an entire system which furniture, fixture and wall are combined. And, it should be considered by dynamic experiment. However, there is no general evaluation method at present, and pull-off strength of fixtures is shown at best.

The seismic resistance of non-structural systems is rarely examined in detail while designing each individual building like structural systems. Besides, furniture and fixtures are ready-made products in most cases, and there is infinity of combinations among furniture, fixture and non-structural element. Therefore, it is impossible to test all combinations by a complex large-scale test method that imitates an actual situation. To put it simply, as for the

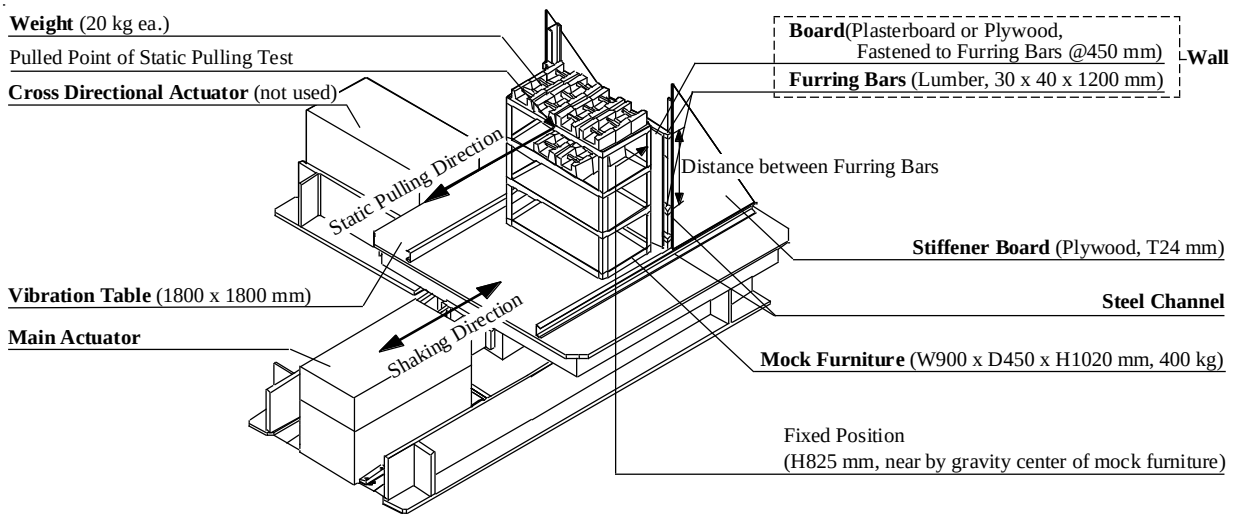

Figure 1 Outline of Specimen on Vibration Table

11	600 mm	Plywood (9.5 mm)	16 mm x 2	16 mm x 4 (Screws)	Center between Furring Bars

evaluation of the seismic resistance, it only has to be able to grasp the degree, ranks, or weak points roughly. And it is demanded to be a handy and universal method on practical use.

The purpose of this research is to establish an outline of a simple evaluation method for seismic resistance of furniture fixation wall system. In this thesis, a simple input wave which is essential to this method was examined.

2. SPECIMEN OUTLINE AND EXPERIMENT ITEMS

Figure 1 shows the outline of specimen on vibration table. As shown in the figure, steel channels and stiffener boards (triangle plywood) are fixed on a vibration table. Then, a specimen wall was constructed by lumber furring bars, a plasterboard or plywood and screws fastening the board to furring bars. Finally, mock furniture was fastened to the wall by a specimen fixture (screws or anchors). In this experiment, the horizontal vibration table of CUEE, Tokyo Tech was used.

The mock furniture imitated a bookshelf of ordinary size and shape in offices. A mass is about 400 kg, and a height of gravity center is about 880 mm. These are supposed that documents are fully stored to the bookshelf. The mock furniture is fastened to a specimen wall near the height of gravity center.

By changing distance between furring bars, material and thickness of the board, length and number of screws, stiffness of specimen wall can vary. And by changing length and number of screws or anchors, the position in which the mock furniture is fixed to the board, hardness to pull off resistance of specimen fixture can vary. By such a way, eleven kinds of specimens with a different seismic resistance were set. Table 1 shows the outline of specimens.

Experiment items of these specimens were as follows:

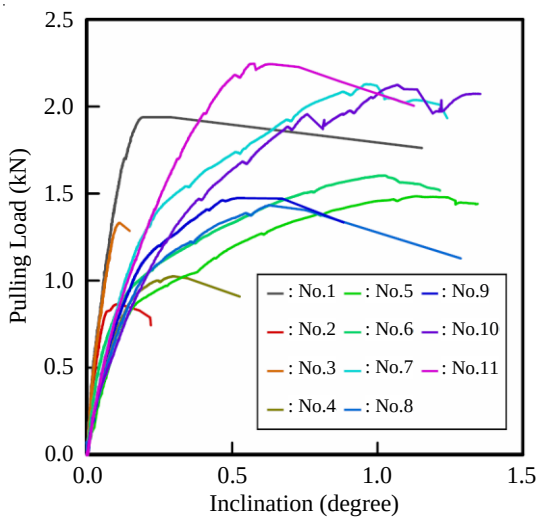

Figure 2 Relation between Pulling Load and Inclination of Mock Furniture

-- Static pulling test
-- Measurement of predominant frequency
-- Vibration test by real seismic waves
-- Vibration test by simple input waves

3. STATIC PULLING TEST

At first, a static pulling test was carried out. At the test, the top of the mock furniture is pulled horizontally as shown in Figure 1, and the load and the inclination of furniture during pulling is measured.

Figure 2 shows the relation between the load and the inclination. In all specimens, the load became maximum when the specimen was completely destroyed. Then, the maximum load was measured as “Destruction Load”, and the inclination at that time was measured as “Destruction

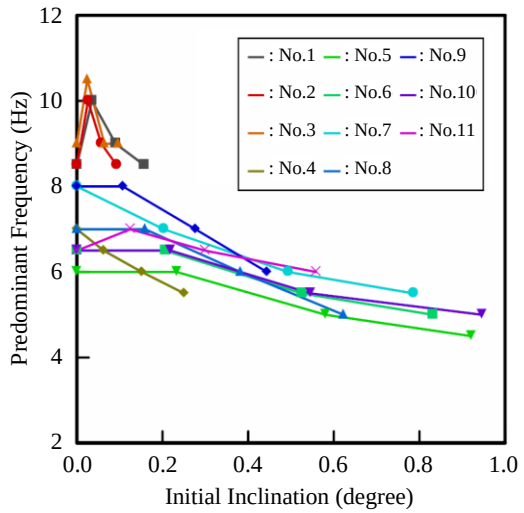

Figure 3 Relation between Predomination Frequency and Initial Inclination of Mock Furniture

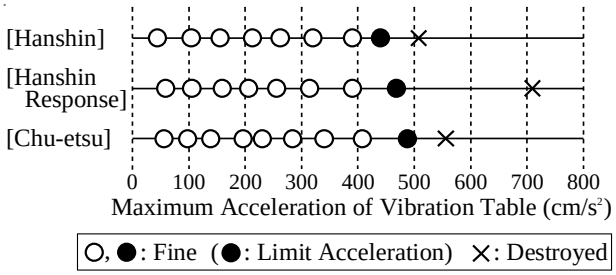

Figure 4 Relation between State of Specimen and Maximum Acceleration (Example of Specimen No. 6 by Shaking Real Seismic Wave)

Inclination". And destruction parts of each specimen were recorded too. The column "Static Pulling Test" of Table 2 shows destruction parts of each specimen in this test.

4. MEASUREMENT OF PREDOMINANT FREQUENCY

Predominant frequencies of each specimen were measured by tapping at the top of the mock furniture with hammer. Additionally, predominant frequencies of pull-apart vibration were also measured. At that time, the top of the mock furniture was pulled till prescribed "Initial Inclination" by all specimens. The initial inclinations were three kinds, 20, 50 and 80 % of destruction inclinations measured in Chapter 3.

Figure 3 shows the relation between predominant frequency and initial inclination. The frequency of zero degrees inclination is the result of hammer tapping. The following is probed from this figure:

-- Predominant frequencies of zero degrees inclination are in the range from 6.0 to 9.0 Hz.
-- When the initial inclination becomes large, predominant frequency varies. The changing tendency differs according to the specimen, and is not uniform.

This result suggests that it is impossible to describe vibration characteristics of the complex furniture fixation wall system as a simple vibration system. In another view, this result also suggests that the resonance is rarely occurred in the system by real seismic waves or simple input waves.

5. VIBRATION TEST BY REAL SEISMIC WAVES

By using the vibration table, vibration test by real seismic waves was carried out, and states of specimen after shaking ("Fine" or "Destroyed") were observed. Input waves

are three real seismic waves as follows:

[Hanshin]: The Great Hanshin earthquake (1995), N-S direction

[Hanshin Response]: Building response wave by [Hanshin], recorded at tenth floor of ten story RC building of which natural frequency is 2.52 Hz and damping ratio is 2 %

[Chu-etsu]: The Chu-etsu earthquake (2004), E-W direction

At first, each specimen was shaken by one input wave of about 50 cm/s^2 in maximum acceleration. Afterwards, the amplitude was increased by 50 cm/s^2 at every test until the specimen was finally destroyed. After the test, the destruction parts of the specimen were recorded. Additionally, behaviors of the specimen during shaking were recorded with video camera. According to this procedure, all specimens were tested by all input waves.

Figure 4 shows the example of the relation between the state of specimen after shaking and the maximum acceleration of vibration table. In this figure, circle symbols mean the state of "Fine", and cross symbol means the state of "Destroyed". Then, the maximum acceleration among "Fine", (shown in black) was recorded as "Limit Acceleration". Additionally, the column "Vibration Test by Real Seismic Waves" of Table 2 shows destruction parts of each specimen in this test.

6. VIBRATION TEST BY SIMPLE INPUT WAVES

The video that recorded the experiment of Chapter 5 was examined in detail. Then, specimen was destroyed in the vicinity to which the amplitude reached in the maximum. In other words, destruction did not advanced gradually while shaking. This discovery suggests that states of specimens are predominantly affected by a few time of the shaking in the vicinity to the maximum amplitude.

As explained above, the concept of the simple input wave based on the sine wave was set as shown in Figure 5.

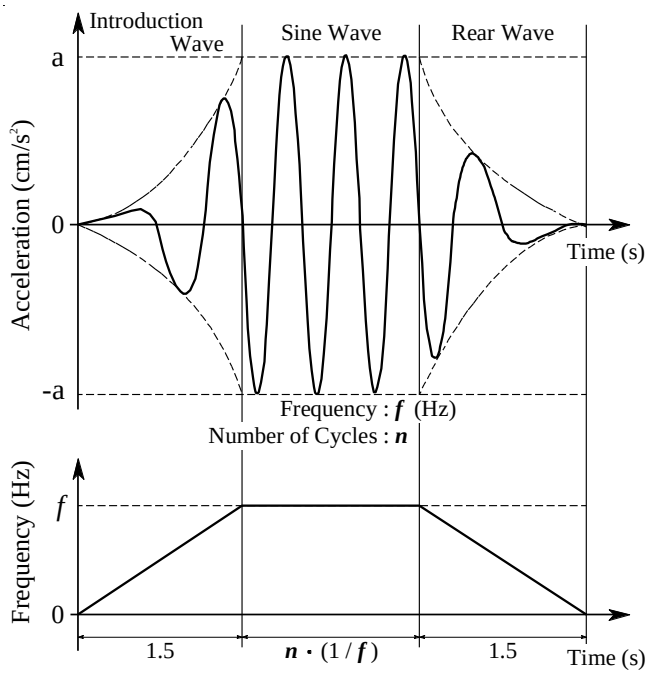

Figure 5 Outline of Simple Input Wave (Example of [2.0 Hz 3 Cycles])

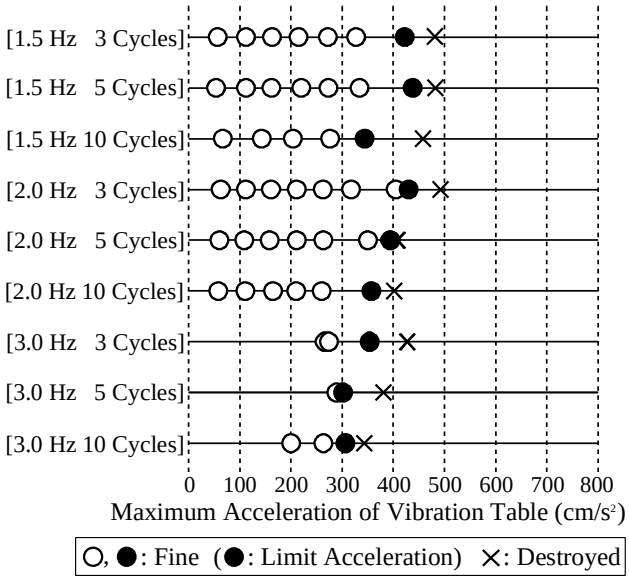

Figure 6 Relation between State of Specimen and Maximum Acceleration (Example of Specimen No. 6 by Shaking Simple Input Wave)

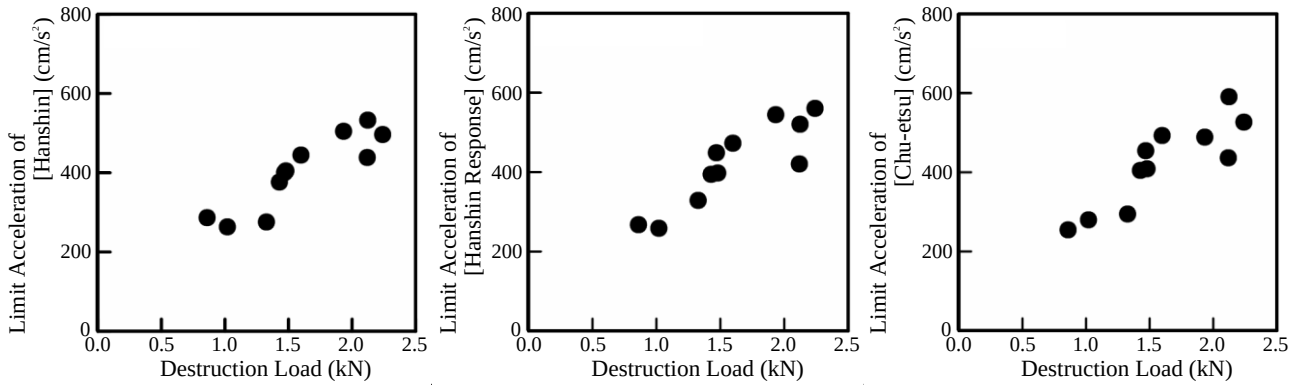

Figure 7 Relation between Limit Acceleration of Vibration Test and Destruction Load of Static Pulling Test

This is a replacement of the maximum amplitude part of real seismic waves. To reduce impacts at the beginning and the ending of shaking, the introduction wave and the rear wave were set. The continuance times of those are 1.5 sec. This input wave was proposed by authors as the simple input wave for evaluating the seismic resistance of furniture fixation free-access floors, and the appropriateness of this wave was confirmed [1].

In this thesis, the applicability of this simple input wave was examined. Specifically, several frequencies and numbers of cycles in the sine wave part were temporarily chosen according to the range of real seismic waves, and specimens were shaken by those combinations. Frequencies "*f*" are three kinds of 1.5, 2.0 and 3.0 Hz. And, numbers of cycles "*n*" are three kinds of 3, 5 and 10. Combined frequencies and cycles, there are nine kinds of input waves.

By using these waves, the same test as Chapter 5 was carried out. Then, limit accelerations and destruction parts of each specimen were recorded.

Figure 6 shows the example of the relation between the state of specimen after shaking and the maximum acceleration of vibration table. Additionally, the column "Vibration Test by Simple Input Waves" of Table 2 shows destruction parts of each specimen in this test.

7. CONSIDERATION

7.1 Comparison of Static Pulling Test to Vibration Test by Real Seismic Waves

Figure 7 shows the relation between limit acceleration of vibration test by real seismic waves (Chapter 5) and destruction load of static pulling test (Chapter 3). When seeing in detail, ranks of some specimens are different. Moreover, according to Table 2, the destruction parts are different in specimen No.10.

As explained above, it is concluded that to grasp ranks or weak points of furniture fixation wall system by static methods might be difficult.

7.2 Effect of Frequency and Number of Cycles of Simple Input Wave

Figure 8 shows some examples of comparison of limit accelerations among simple input waves of different frequency "*f*" (Chapter 6). Ranks of each specimen are almost corresponding. As mentioned Chapter 4, the predominant frequencies of specimens are in the range from 6.0 to 9.0 Hz. Though, in Figure 8, no appearance of resonance is shown. The same result was obtained from the other number of cycles. This result confirms that the resonance is hardly occurred in furniture fixation wall system.

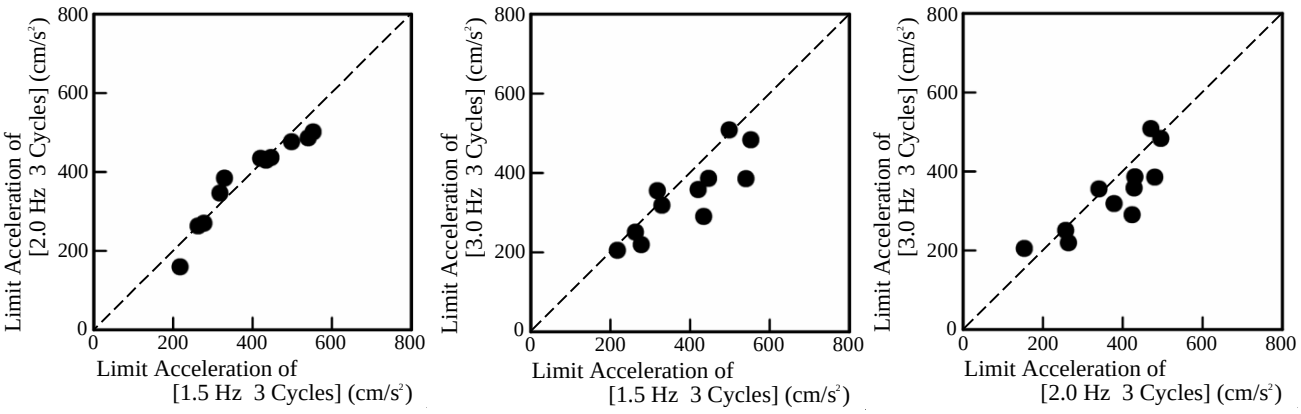

Figure 8 Comparison of Limit Acceleration among Simple Input Waves of Different Frequency (Example of 3 Cycles)

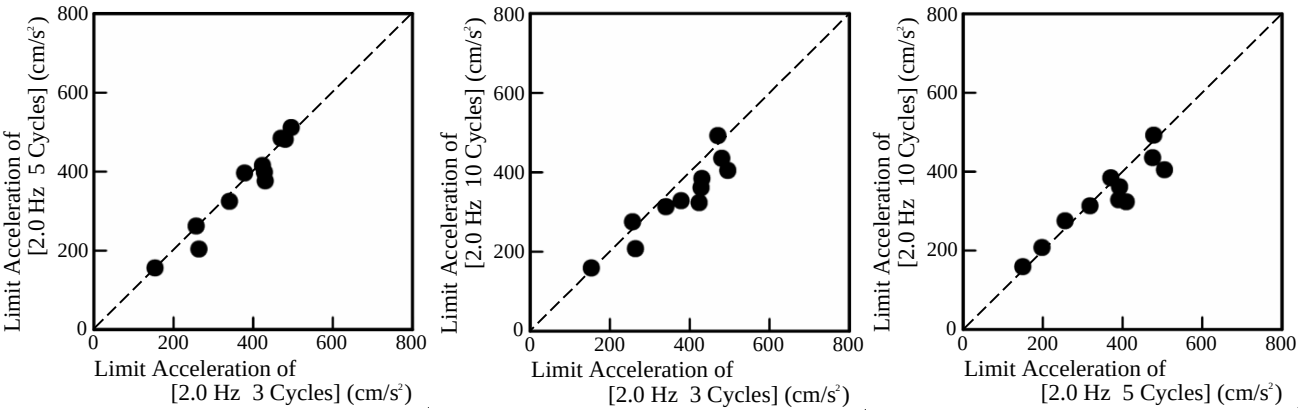

Figure 9 Comparison of Limit Acceleration among Simple Input Waves of Different Number of Cycle (Example of 2.0 Hz)

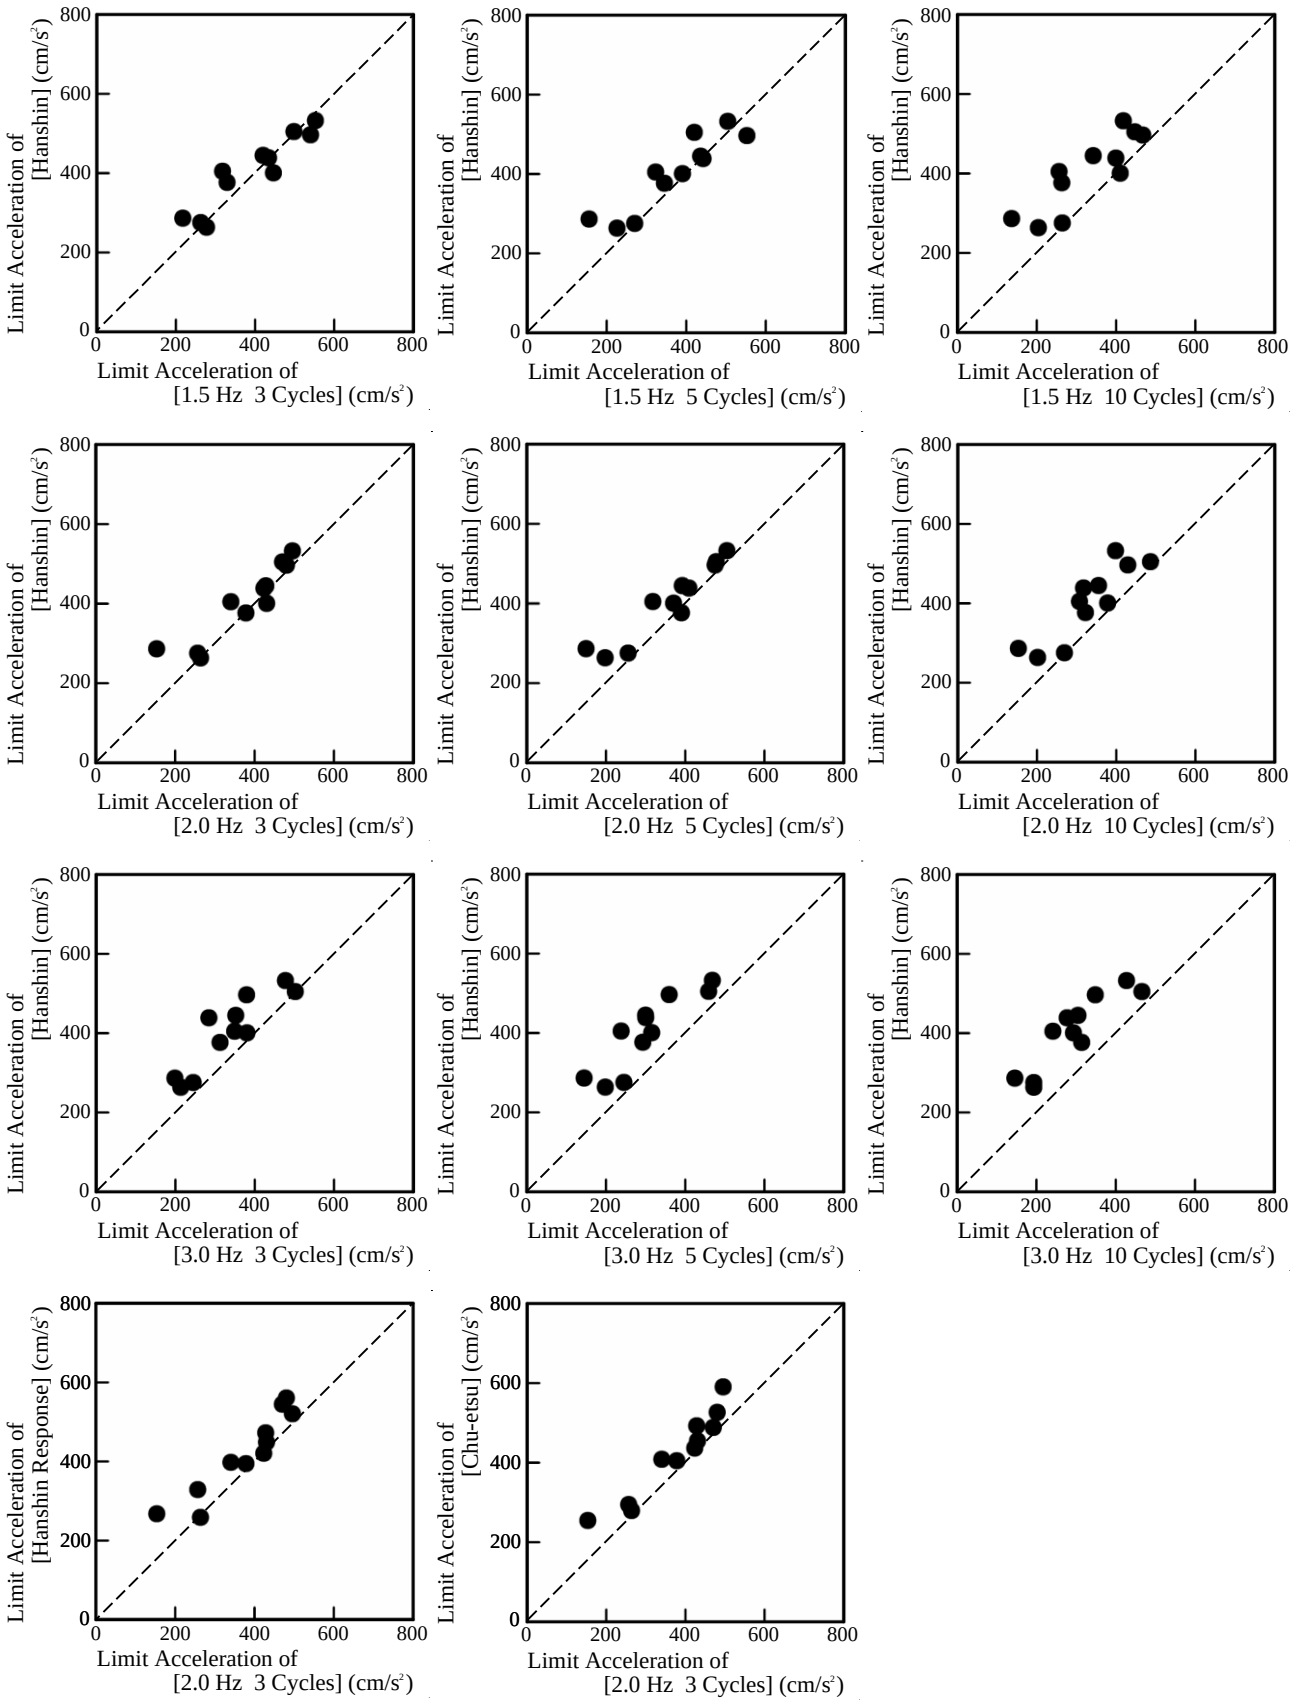

Figure 10 Examples of Comparison of Limit Acceleration between Real Seismic Waves and Simple Input Waves

By the way, limit accelerations of 1.5 Hz and that of 2.0 Hz are similar in each cycle number. But, that of 3.0 Hz is comparatively smaller. Therefore, when the frequency "f" is fixed larger than 3.0 Hz, the limit acceleration might become smaller.

On the other hands, figure 9 shows some examples of comparison of limit accelerations among simple input waves of different number of cycles "n". Ranks of each specimen are almost corresponding. But, when the frequency "f" is 1.5 or 2.0 Hz, limit accelerations of 10 cycles are comparatively smaller than that of 3 and 5 cycles. And when the frequency "f" is 3.0 Hz, limit accelerations of 5 and 10 cycles are comparatively smaller than that of 3 cycles. In other words, the limit acceleration tends to become small gradually as cycle number increases.

7.3 Comparison of Real Seismic Waves to Simple Input Waves

Figure 10 shows examples of comparison of limit accelerations between real seismic waves (Chapter 5) and simple input waves (Chapter 6). As shown in this figure, twenty-seven kinds of combinations (three kinds of real seismic waves and nine kinds of simple input waves) were examined. The following is obtained from this figure:

-- When the frequency "f" is 1.5 or 2.0 Hz and number of cycles "n" is 3 or 5, limit accelerations of simple input waves are similar to those of real seismic waves.
-- When the frequency "f" is 1.5 or 2.0 Hz and number of cycles "n" is 10, limit accelerations of simple input waves are comparatively smaller than those of real seismic waves.
-- When the frequency "f" is 3.0 Hz, limit accelerations of simple input waves are comparatively smaller than those of real seismic waves. This tendency becomes remarkable as cycle number increases.

Moreover, according to Table 2, destruction parts of simple input waves and those of real seismic waves correspond. In other words, weak points of furniture fixation wall systems should be grasped by simple input waves.

As explained above, it is concluded that the simple input wave which main part is the sine wave of 1.5 or 2.0 Hz and 3 or 5 cycles is suit. In this thesis, considering the correspondence with the past research [1] about free-access floor, the simple input wave of 2.0 Hz and 3 cycles will be used as the input wave to evaluate the seismic resistance of furniture fixation wall systems.

8. CONCLUSION

The simple input wave which is essential to establish a simple evaluation method for seismic resistance of furniture fixation wall system was examined. The system consists of complex combinations among furniture, fixture and wall, and it is impossible to grasp ranks or weak points of the system by static methods. Though it was clarified that the simple vibration test based on the sine wave enable to emulate vibration tests by real seismic waves. Considering the correspondence with the past research [1] about free-access floor's seismic resistance, the simple input wave based on 2.0 Hz and 3 cycles of sine wave is set as the appropriate input wave.

The simple vibration table to realize this input wave was already developed by authors [1]. It consists of truck, crank shaft and power machinery. In the future, the simple evaluation method for seismic resistance of entire system will be suggested based on the result of this research.

Abstract: In the Great East Japan Earthquake in March 2011, the building equipments such as pipe systems, duct, cable rack and ceiling, were damaged a lot while main structural members in building were not damaged. For example, pipes, cable racks and ducts were ruptured in the hanging bolt and fell down. It occurs the building cannot be used over a long period of time. In this study, the behavior of building equipments is investigated by conducting the vibration test to verify the cause of damage. Especially, the damage on sprinkler piping and hanger bolt is investigated by simulating its rupturing mechanism by experiment.

1. INTRODUCTION

In the Great East Japan Earthquake in March 2011, the building equipments such as pipe systems, duct, cable rack and ceiling, were damaged a lot while main structural members in building were not damaged. For example, pipes, cable racks and ducts were ruptured in the hanging bolt and fell down. It occurs the building cannot be used over a long period of time. In this study, the behavior of building equipments is investigated by conducting the vibration test to verify the cause of damage.

2. EXAMPLE OF DAMAGE OF RUPURE ON THE SPRINKLER PIPING AND ITS EXPERIMENTAL SIMULATION

2.1 Outline of example of damage on the sprinkler piping

The amusement center had a lot of damages on building equipment under the Great East Japan Earthquake. It is 8 stories steel structure building. Although there was no serious damage in a building main part, the ceiling of the amusement center on the eighth floor fell extensively. About 80 percent of ceilings fell down and damage was also seen many in equipment such as rupture of sprinkler piping, fall of a fan coil, and fall of an air outlet box. The damage situation of sprinkler piping is shown in Photo. 1.

The sprinkler piping is shown in Fig.1. A 1.4m branch pipe is connected to the main pipe in the vertical direction. Two or four flexible pipes are connected to the branch pipe and sprinkler head is connected to the ceiling. In the investigation after the earthquake, sprinkler piping was

Photo.1 The damage situation of sprinkler piping

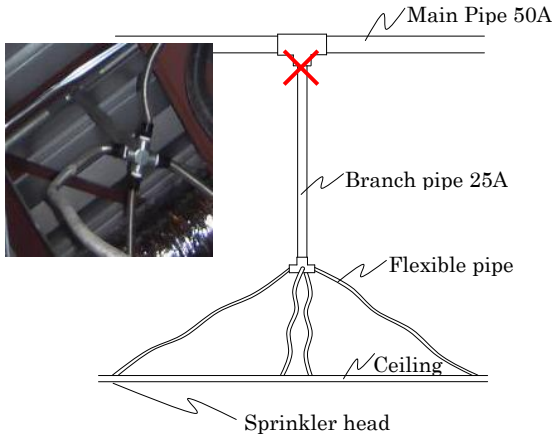

Figure. 1 Branching part of the sprinkler piping

ruptured at eight places among 50 junctions between a main pipe and a branch pipe.

2.2Outline of experiment

The experiment is conducted at the Tokyo Institute of Technology, Suzukake-dai campus in the structural testing laboratory. The carbon steel pipe for ordinary piping 25A is used for the specimen of sprinkler piping (henceforth, SP piping). A thread part is cutting as well as piping with damage. Table 1 shows pipe type used for the experiment.

2.3 Experiment method

An experiment is conducted by using the hydraulic servo fatigue tester(SAGINOMIYA SEISAKUSHO FT-2, maximum loading of 20 kN, henceforth, autograph). The SP piping is set in the shape of cantilever beam. The experiment is carried out by loading to make connection screw part of SP piping rupturing as shown in Photo. 2 and Fig. 2. A screw part of SP piping is examined, where about 5 equal divisions are thrust among ten mountains by the whole screw thread of a taper part as shown in Fig. 3. In addition, the seal tape is wound around the thread part.

2.4 Measurement method and Experiment Case

The stress acting on SP piping is measured with strain gauges on the upper and lower sides of it when the SP piping is loaded in the end part of it by an autograph as shown in Photo.4. In addition, a gap between SP piping and loading part is considered by measuring with the piston type displacement gage. The experimental condition for every case is shown in Table 2.

In Cases from 1-1 to 1-5 (specimen1), the loaded displacement is set as ±3 [mm], and the up-and-down loading is repeated three times. After that, it is carried out until the specimen is ruptured with increasing displacement at 2 [mm] intervals. In Case 2-1 (specimen2), the up-and-down loading displacement is set as ±11 [mm], and it is repeated 20 times. In Case 3-1 (specimen3), the loading displacement is set as 35 [mm] and the experiment is conducted to make the specimen ruptured by 1 time of loading.

Photo.3 Connection part of SP piping after loading

2.5 Experiment result

A Relationship between moment(M) of connection part of SP piping and displacement of end part of pipe in Cases from 1-1 to 1-5. is shown in Fig.4. The secondary section moment with considering cutting part is 12,841mm^4 and without consideration, it is 37,110mm^4. Although it is mostly in agreement with the descending slope which the relation between M and displacement calculated in consideration of the cross-sectional deficit by the machined thread of SP piping terminal area in Case 1-1, a descending slope becomes loose and a stiffness of pipe is decreasing as a loading displacement is increasing. Moreover, in case the loading displacement is ±11 [mm], M in the maximum displacement begins to decrease from the 7th loading, and it becomes about 1/4 of the beginning at the 10th loading. As shown in Photo.3, the connection part of SP piping at this time is ruptured and has a crack. The photo.3 shows the inside of a specimen.

The result of Case 2-1 and 3-1 is shown in Fig. 5. The specimen of Case 2-1 is ruptured by the 5.5th loading, although the stiffness at the first time is strong as compared with the specimen of case 1-5.

In Case 3-1, the specimen is ruptured after the M increases up to 560 kN-mm by 25 mm of displacement. From this result, when SP piping is loaded repeatedly, it is ruptured by about 75% of stress where M is about 430kN-mm compared with the stress fractured by one time of loading.

3. EXAMPLE OF DAMAGE OF RUPURE ON THE HANGER BOLT AND ITS EXPERIMENTAL SIMULATION

3.1 Example of damage on the hanger bolt

The damage Case 1 is shown in Fig. 6. A 100 mm hanger bolt which hung a 200A pipe was ruptured at anchor part, and piping fell down in the steel structure factory. The damage Case 2 is shown in Fig.7. A hanging bolt which hung the ceiling concealment package was ruptured at anchor part, and the ceiling board dropped. The damage Case 3 is shown in Fig.8. A hanger bolt which hung the large-sized fan coil unit was ruptured, and the hanger bolt which hung apparatus was also ruptured.

3.2 Investigation of rupture at hanger bolt by shaking table test

In order to simulate the rupture of hanger bolt, the real large shaking table test is conducted as shown in Photo.4. The response under the Great East Japan Earthquake in the fifth floor of 5 stories steel building which exists really is used as a input wave in the experiment as shown in Fig.9-10.

3.3 Experiment result

Table 3 shows experiment results. A 20cm hanger bolt which hung 200A piping is ruptured in 104~105 seconds regardless of existence of vibration stopper.

About apparatus (total enthalpy heat exchanger), two 50cm hanger bolt are ruptured without vibration stopper. In other cases, although a hanger bolt is not ruptured, it is separated from metal fittings of apparatus and the damage is seen in vibration stopper (simplified mold).

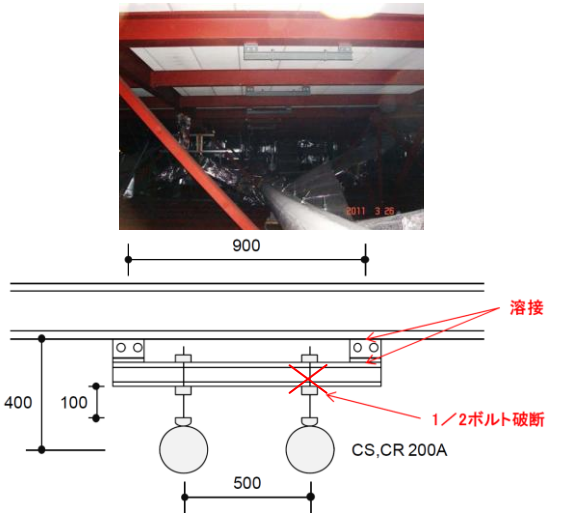

Figure.6 Damage Case 1 on hanger bolt

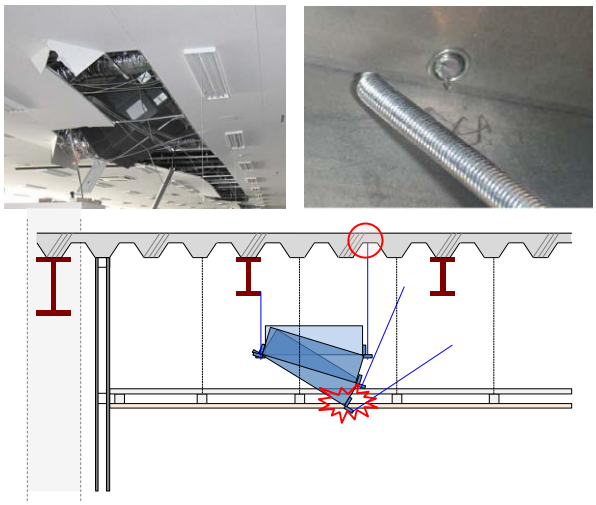

Figure.7 Damage Case 2 on hanger bolt

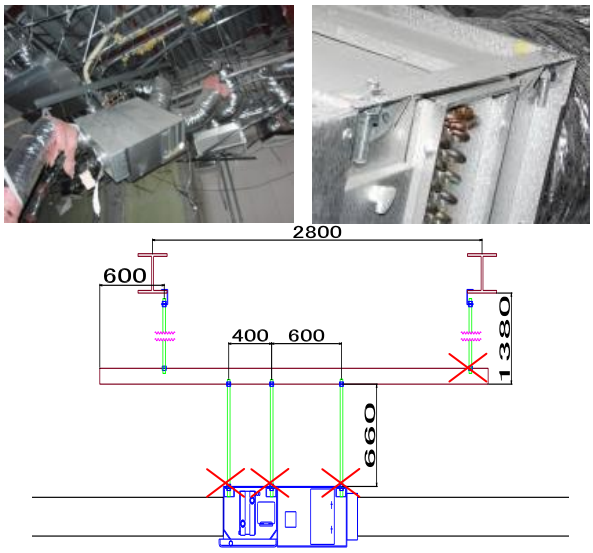

Figure.8 Damage Case 3 on hanger bolt

4. CONCLUSIONS

The behavior of the building equipment under the seismic excitation is conducted by vibration test. Especially, the damage on sprinkler piping and hanger bolt is investigated by simulating its rupturing mechanism by experiment.

Abstract: The seismic collapse risk of a structure is largely influenced by the intensity and other characteristics of the earthquake ground motions. This study addresses the influence of the shape of the ground motion spectra and the ground motion duration on the structural collapse capacity, as determined by nonlinear response history analysis. The conditional spectrum is proposed as a more realistic characterization of spectral shape, compared to the commonly used uniform hazard spectrum. Ground motion duration is another important characteristic, which is quantified in terms of significant duration. The effects of spectral shape and duration on the estimated collapse capacity of a 5-story steel moment frame are demonstrated. Spectrally equivalent long and short duration record sets are employed to isolate the effects of duration. Preliminary findings indicate that cyclic strength and stiffness deterioration of components and accumulation of drift due to ratcheting can significantly reduce structural collapse capacity under long duration shaking.

1. INTRODUCTION

Calculation of the probability of structural collapse is an integral part of performance-based earthquake engineering. The intensity of ground excitation that causes structural collapse is a random variable, which is often defined by a lognormal cumulative distribution function called the collapse fragility curve – relating ground motion intensity to the probability of collapse. The collapse capacity is a common metric to evaluate the life-safety of buildings and an important component in loss assessment.

The process of estimating the collapse capacity of a structure first involves the creation of a nonlinear numerical model of the structure. Since collapse occurs after the structure has undergone large inelastic deformations, modeling the behavior of structural components at these large inelastic deformations is essential to obtain an accurate estimate of the collapse capacity. This behavior includes the cyclic and in-cycle deterioration of component strength and stiffness (see discussion of cyclic and in-cycle deterioration in FEMA Report 440, 2005).

The next step involves the selection of ground motions at different intensity levels where the characteristics of the chosen ground motions at each intensity level, such as response spectral shape (which acts as a surrogate for frequency content), duration and pulse-like characteristics closely match the characteristics of the ground motions that can be expected at the building site (NIST 2011). Choosing ground motions without ensuring this match in characteristics can lead to erroneous estimates of collapse capacity. This particular study addresses the effects of two of these characteristics: response spectral shape and duration. It is assumed that the expected values of ground motion characteristics for a particular site can be obtained either from seismic hazard curves or from seismic hazard deaggregation.

When different sets of ground motions are chosen at each intensity level, the analysis is called a Multiple Stripe Analysis (Jalayer 2003). On the other hand, where the same set of ground motions is scaled to different intensity levels, the analysis is called an Incremental Dynamic Analysis or IDA (Vamvatsikos and Cornell 2002, 2004). Multiple Stripe Analysis is considered to be more realistic and accurate than IDA since the expected spectral shape and other ground motion characteristics are likely to vary depending on the intensity level. This is in contrast to the linear scaling in the basic IDA procedure, which only addresses the change in ground motion intensity.

Nonlinear dynamic analysis is then conducted using the selected ground motion sets at each intensity level. During each analysis run, the structure is assumed to have collapsed if an unbounded increase in deformations is observed, or if the deformations exceed a rational pre-defined threshold (Haselton and Deierlein 2007). Residual deformations and other damage measures may be considered as an added layer of refinement in the performance assessment. The probability of collapse at each intensity level is then computed as the fraction of ground motions at the intensity level that causes collapse. The collapse fragility curve is then obtained by fitting a lognormal cumulative distribution function through these data points. Naturally, the number of ground motions used at each intensity level influences the accuracy of this estimate.

In this study, the reasons why response spectral shape and duration must be taken into account in ground motion selection are discussed. Finally, the effects of these two parameters on the collapse capacity of a 5-story steel special moment frame are demonstrated.

2. EFFECT OF SPECTRAL SHAPE

While a ground motion's intensity (represented here by $S_a(T_1, 5\%)$, the pseudo spectral acceleration at the 1st mode period and 5% of critical damping) alone is a strong predictor of structural response, it is well known that a structure will respond differently to two different ground motions even if they are scaled to have the same intensity. The reason for this is twofold. First, any multi-degree-of-freedom structure has many modes of vibration with different periods. Therefore, the response of such a structure is related not only to the response spectral ordinate of the ground motion at the fundamental mode period, but also to the ordinates at lower periods corresponding to the higher modes. Secondly, the spectral ordinate at any period is computed assuming linear elastic response, whereas the actual nonlinear response would usually lead to an effective elongation of the natural periods.

Due to the aforementioned reasons, spectral ordinates at periods lower and higher than the fundamental period of a structure influence its dynamic response. This effect of the spectral ordinates at all periods other than the fundamental period is referred to as the spectral shape effect. Statistical studies indicate that if two ground motions have the same $S_a(T_1, 5\%)$, and ground motion #1 has higher spectral ordinates at all other periods than ground motion #2, then ground motion #1 is more likely to result in a lower collapse capacity than ground motion #2 (Baker and Cornell 2008; Haselton et al. 2011).

This effect of spectral shape has large implications on the ground motion selection procedure, or more specifically, the response spectrum that should be used as a target for ground motion selection at each intensity level. As noted previously, the target response spectrum should be representative of the response spectra of ground motions that are expected to be observed at the site. One commonly used target response spectrum is the uniform hazard spectrum, UHS, whose ordinate at each period T is the $S_a(T, 5\%)$ value that has a specified probability of being exceeded each year, defined by the hazard level (hazard levels and spectral intensities being related by the traditional seismic hazard curve). These ordinates are obtained from Probabilistic Seismic Hazard Analysis, $PSHA$ (Kramer 1996; McGuire 2004) conducted at each individual period. As indicated in previous studies, such as Baker and Cornell (2006), traditional $PSHA$ ignores the joint probability of exceedance of a number of spectral ordinates at different periods. Therefore, once the $S_a(T_1, 5\%)$ corresponding to a certain probability of exceedance has been determined, it is conservatively assumed that expected ground motion spectral ordinates at other periods are exceeded with the same probability. Hence, it is conservative to use the UHS as the target response spectrum.

The conditional spectrum has been suggested as an alternative target response spectrum that overcomes the shortcomings of the UHS (Baker and Cornell 2006; Baker 2011; Lin et al. 2012). The conditional spectrum is defined by the conditional mean and standard deviation of the spectral ordinates at all other periods, given a spectral ordinate at a period known as the conditioning period. The conditioning period is often chosen as the 1st mode period of the structure, although other periods could be used. The conditional mean and standard deviation of spectral ordinates are obtained using seismic hazard deaggregation information and regression equations based on statistical observations of correlations between spectral ordinates (Baker and Jayaram 2008). Therefore, given a specified $S_a(T_1, 5\%)$, the conditional spectrum defines the mean and standard deviation of the expected spectral ordinates at all other periods. A procedure has been developed by Jayaram et al. (2011) to select a set of ground motions that match a target mean and standard deviation spectrum. While the conditional spectrum is not without its own challenges, such as the need to define a structure-dependent conditioning period, it provides a much more realistic representation of the seismic hazard than the UHS.

The UHS and conditional mean spectrum at the 2% in 50 year hazard level, for a site in San Francisco, are plotted in Figure 1. A set of 20 ground motions was selected from the PEER NGA West2 database (Ancheta et al. 2012) to match this UHS. Since the shape of the UHS does not change considerably at different intensity levels, this ground motion set was used to conduct an IDA. On the other hand, since the shape of the conditional spectrum changes considerably at different intensity levels, for the Multiple Stripe Analyses different sets of 20 ground motions were chosen to match the conditional spectra for 11 different intensity levels. As described later, collapse analyses using these three alternative ground motion sets were conducted: (1) an *IDA* using a single set matched to the 2% in 50 year UHS, (2) a Multiple Stripe Analysis using 11 different sets, each matched and scaled to the conditional spectra at 11 different intensities, and (3) an IDA using a single set of motions matched to the conditional spectrum at the 2% in 50 year hazard level.

3. EFFECT OF DURATION

After ground motion intensity and spectral shape have been accounted for, it is important to ensure that the durations of the selected set of ground motions match the expected ground motion duration at each intensity level (Bradley 2011). The expected durations could be obtained from seismic hazard deaggregation and a prediction model for duration. The reason duration is expected to influence the predicted collapse capacity is that structural components are known to deteriorate in strength and stiffness under cyclic loading. Therefore the longer the duration of shaking, the larger the number of deformation cycles each component is subjected to, which implies a larger deterioration in strength and stiffness. Moreover, once the

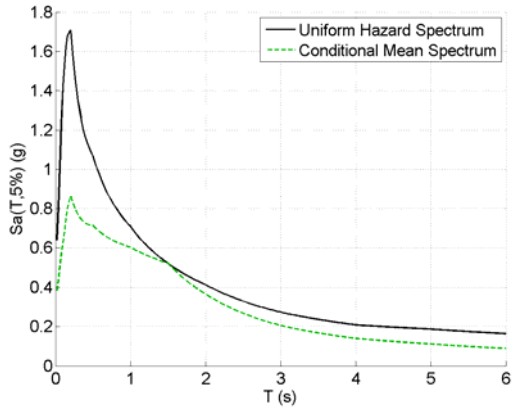

Figure 1: 2% in 50 year uniform hazard spectrum and conditional mean spectrum

structure has suffered inelastic deformations and deteriorated, long duration shaking further hastens sidesway collapse by ratcheting of deformations and drifts. Ratcheting is the phenomenon by which lateral inelastic deformations that occur early in a response history lead to amplified P-Δ moments that hasten subsequent sidesway collapse of the structure under later inelastic excursions in the same direction (Gupta and Krawinkler 2000).

Accurate evaluation of duration effects requires realistic nonlinear numerical models that incorporate in-cycle and cyclic deterioration of strength and stiffness (Ibarra et al. 2005; Lignos and Krawinkler 2011). As demonstrated below using a 5-story steel special moment frame, when included in the model, the combined effects of deterioration and ratcheting under long duration ground motions lead to significantly lower collapse capacities than short duration ground motions of similar intensity and spectral shape. The more ductile a structure and the faster the rate of deterioration, the larger the expected effect of duration of shaking (Ibarra and Krawinkler 2005).

Before the effect of ground motion duration on the predicted collapse capacity of a structure can be quantified, a suitable metric must first be chosen to measure the duration of strong shaking in an accelerogram. The observed correlation between ground motion duration and collapse capacity will largely depend on the chosen duration metric. A number of alternatives exist for defining the duration of an accelerogram (Bommer and Martinez-Pereira 1999). Among these, the following were identified as potential candidates:

- **Bracketed duration** is the time elapsed between the first and last excursions of the accelerogram above a certain acceleration threshold (commonly used thresholds are 0.05g and 0.10g).

- **Significant duration** is the time interval over which a specific percentage of the total energy represented by the integral $\int a^2 dt$ is accumulated, where a represents the ground acceleration. The commonly used ranges are 5% to 95% and 5% to 75% of the calculated energy.

- **Arias Intensity** $= \frac{\pi}{2g}\int_0^{t_{max}} a^2 dt$
  is a measure of the energy contained in an accelerogram, where t_{max} represents the length of the accelerogram. Although not purely a metric of duration, Arias Intensity is considered here since it involves integration over time and is expected to be correlated to the duration of strong shaking.

- **Cumulative Absolute Velocity** $(CAV) = \int_0^{t_{max}} |a| dt$
  is considered for the same reasons as the Arias Intensity above.

- $\boldsymbol{I_D} = \frac{\int_0^{t_{max}} a^2 dt}{PGA \times PGV}$
  is a dimensionless duration metric proposed by Cosenza and Manfredi (1997), with PGA and PGV representing the peak ground acceleration and peak ground velocity respectively.

Each of the metrics defined above were evaluated against the following properties desired in a robust metric of ground motion duration for performance-based structural assessments:

- The duration metric should not be strongly correlated to commonly used intensity measures like pseudo spectral acceleration, since it is proposed that duration be considered *in addition* to intensity and spectral shape. As such, the duration metric should provide new information not quantified by those other measures.
- The duration metric should be unaffected by the process of scaling a ground motion since analysis procedures like IDA that involve ground motion scaling would then require the re-evaluation of ground motion duration at each new intensity level.
- The duration metric should not bias the spectral shape of the chosen ground motions. In other words, long duration ground motions selected on the basis of the duration metric should not have any peculiarities in their spectral shapes.

The comparison of all the selected duration metrics against these criteria is presented in Table 1. As shown, based on the qualitative assessment of the characteristics, significant duration appears to be the most robust measure for duration.

Table 1: Comparison of the selected duration metrics

Desired Properties	**Bracketed duration**	**Significant duration**	**Arias Intensity**	**CAV**	$\boldsymbol{I_D}$
Not strongly correlated to common intensity measures	×	✓	×	×	✓
Unaffected by scaling	×	✓	×	×	✓
Does not bias spectral shape	✓	✓	✓	✓	×

To further evaluate the alternative duration metrics, *IDAs* were conducted on several structures using a set of long and short duration ground motions, where the variation in predicted collapse capacity was plotted against each of the alternative ground motion metrics. It was observed that the 5-95% significant duration, referred to as t_{5-95}, best captured the expected decreasing trend in collapse capacity with duration. Based on this data and the comparison in Table 1, the 5-95% significant duration is considered as the best duration metric to screen ground motions for analysis (Foschaar et al. 2011).

One of the challenges faced in the evaluation of duration in ground motion selection criteria has been the scarcity of long duration ground motions. Such long duration motions are expected to occur in sites where the hazard is dominated by large magnitude subduction zone earthquakes and certain soft soil conditions. The recent 2008 Wenchuan, 2010 Chile and 2011 Tohoku earthquakes have dramatically increased the available inventory of long duration motions. Nevertheless, finding recorded ground motions that both match a target response spectrum and provide a wide distribution of short to long durations remains a challenge.

To demonstrate the effect of ground motion duration on collapse capacity, a long duration record set was created containing ground motions recorded from the 1974 Lima - Peru, 1979 Imperial Valley - USA, 1985 Valparaiso - Chile, 2003 Hokkaido - Japan, 2008 Wenchuan - China, 2010 Maule - Chile, 2010 El Mayor Cucapah - USA and 2010 Tohoku - Japan earthquakes. About 3700 horizontal record pairs were acquired in total from all these events. These were baseline corrected and filtered based on the recommendations of Boore and Bommer (2005) and Boore (2005). To avoid using low intensity and short duration records, record pairs with a mean PGA of both components < 0.1g, mean PGV < 10cm/s or t_{5-95} < 45s were screened out. To prevent a single well-recorded event from dominating the selected record set, a maximum of only 25 record pairs were retained from each event. After the entire screening process, the resulting long duration record set contained 79 two-component record pairs.

A second set of short duration ground motions was selected with a spectral shape that matches that of the long duration record set. For each record in the long duration set, a corresponding short duration record was selected from the PEER NGA West2 database with t_{5-95} < 45s and a closely matching spectral shape. This corresponding set with matching spectral shapes was created so that any difference in the collapse capacities predicted by the two sets could be attributed to the difference in their durations. Figure 2 shows the comparison of the response spectra and time histories of one of the 158 pairs of long and short duration spectrally equivalent records. Figure 3 shows a comparison of the durations (t_{5-95}) of all the ground motions in each set. Both sets of ground motions were then used to conduct individual *IDAs* on the model of a 5-story steel special moment frame.

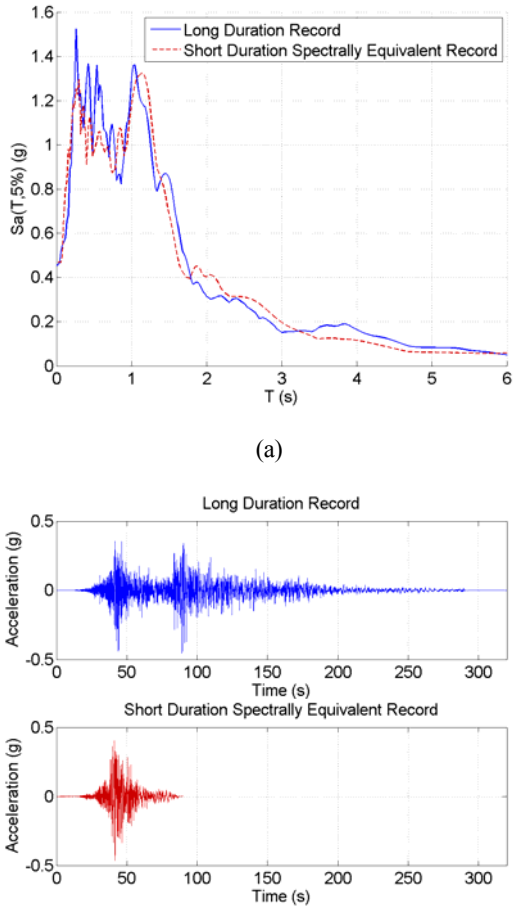

Figure 2: Comparison of (a) response spectra and (b) time series of a long and short duration record pair

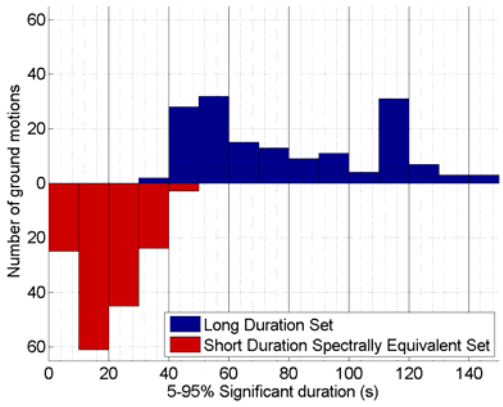

Figure 3: Comparison of the durations (t_{5-95}) of records in the long and short duration spectrally equivalent sets

4. ANALYSIS OF A 5-STORY STEEL SPECIAL MOMENT FRAME

The 2-dimensional numerical model of a 5-story steel special moment frame was created in OpenSees, the Open System for Earthquake Engineering Simulation (McKenna et al. 2006). A schematic of the elevation view of the frame is shown in Figure 4. The lumped plasticity approach was used to model material nonlinearity. The beams and columns were modeled using linear elastic elements. The hysteretic behavior of the panel zones was modeled using a tri-linear backbone curve. Zero-length plastic hinges were located at the two ends of each column and at each RBS cut. The hysteretic behavior of the plastic hinges was modeled using the Modified Ibarra-Medina-Krawinkler bilinear material model that includes a post-capping negative stiffness branch of the backbone curve to capture in-cycle deterioration, as well as an algorithm that cyclically deteriorates strength and stiffness based on the cumulative hysteretic energy dissipated (Ibarra et al. 2005). The contribution of the adjacent gravity system to the destabilizing P-Δ effect was modeled using a pin-ended leaning column. Rayleigh damping of 2.5% was assigned to the linear elastic elements of the frame.

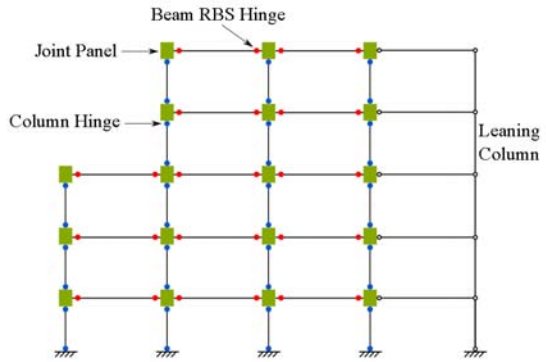

Figure 4: Schematic of the 5-story steel special moment frame model

The fundamental period of the structure was found to be 1.5s. The engineering demand parameter monitored during the nonlinear dynamic analyses was the peak story drift ratio (SDR), defined as the maximum lateral displacement of a story relative to the story below, expressed as a fraction of the corresponding story height, over all the stories and the entire duration of shaking. A peak SDR threshold of 10% was used to indicate structural collapse. The types of analyses performed, the record sets used in each analysis, as well as the collapse capacities computed as $S_a(1.5s, 5\%)$ are summarized in Table 2. The collapse fragility curves estimated from each of the five analyses are plotted in Figure 5.

Comparing the results of analyses #1 and #2, in the context of this example, targeting ground motions to the UHS instead of the conditional spectrum resulted in an under-estimation of the geometric mean collapse capacity by 22%. Comparing the

results of analyses #2 and #3, it can be inferred that in the context of this example, conducting IDA instead of Multiple Stripe Analysis resulted in an additional difference of 22% in the geometric mean collapse capacity. Finally, conducting IDA using the UHS instead of the conditional spectrum Multiple Stripe analysis (#1 versus #3) led to an under-estimation of the geometric mean collapse capacity by 39%. These results are consistent with the observations made by Baker and Cornell (2006) that the UHS is a conservative choice for a target spectrum and that the changing spectral shape of the conditional spectrum at different intensity levels should be accounted for by the Multiple Stripe Analysis technique.

The results of analyses #4 and #5 indicate that with spectral shape being controlled for, the use of long duration ground motions reduced the geometric mean collapse capacity by 41%. Figure 6 shows a scatter plot of the collapse capacities predicted by each long and short duration spectrally equivalent record pair. The fact that nearly all the points lie above the 1:1 line indicates that on most occasions, within each record pair, the longer duration record predicts a lower collapse capacity. As shown in Figure 7, the decrease in collapse capacity as a function of ground motion duration (t_{5-95}) is clearly evident.

Figure 8 shows the IDA curves of the two record sets. The IDA curves indicate that the short duration ground motions on average reach a peak SDR of 7.2% before causing collapse. In contrast, the long duration ground motions reach a peak SDR of only 4.3% before collapse. This is believed to suggest that when large inelastic deformations begin to occur in the structure, aided by the resulting deterioration in strength and stiffness, a long duration ground motion is more likely to lead to structural collapse by ratcheting.

Finally, it can be argued that in the absence of a comprehensive description of the site hazard, the result of analysis #3 is expected to be most accurate since it best accounts for the effect of spectral shape. It does however neglect the effect of duration, which is expected to play a secondary role. An analysis that accounts for both spectral shape and duration is expected to produce the most accurate estimate of collapse capacity, but this would require further work to create the necessary framework to select appropriate ground motions that account for spectral shape as well as duration.

5. CONCLUSION

In any performance-based assessment, the chosen ground motions create the link between hazard analysis and demand analysis. Therefore it is critical to ensure that all the characteristics of the chosen ground motions are consistent with the site hazard to produce an accurate estimate of the demands. The effects of ground motion spectral shape and duration are particularly important for evaluating collapse under extreme (rare) ground motions. The 5-story steel special moment frame example illustrates these effects of ground motion spectral shape and duration.

With regard to spectral shape, it was argued and demonstrated that the conditional spectrum is a more accurate choice for a target spectrum than the UHS, which is

conservative in nature. With regard to duration, the 5-95% significant duration ($\boldsymbol{t_{5-95}}$) was identified as the duration metric best suited for use within the performance-based framework, where the collapse capacity is conditioned on ground motion intensity. It was also shown that the effect of ground motion duration on predicted collapse capacity could be quantified using spectrally equivalent record sets whose ground motions varied only in duration, represented by t_{5-95}. It should also be emphasized that the detection of ground motion duration effects requires the use of a realistic numerical model that accurately captures component deterioration. It is recognized that a number of previous studies on the effect of ground motion duration on structural damage have produced mixed and inconclusive results (Hancock and Bommer 2006). The reasons for this are believed to be (1) the use of structural models that did not incorporate deterioration, (2) the study of mildly nonlinear rather than collapsing systems, and (3) the use of inefficient duration metrics.

Consideration of both spectral shape and duration requires understanding of the seismic hazard at the site of interest so that ground motions for analysis can be selected to have spectral shapes and durations consistent with those expected at the site. Notably, spectral shape and duration values of ground motions are expected to differ for low-intensity and high-intensity ground motions, even for the same site. Therefore where possible, a different set of ground motions should be chosen at each intensity level to accurately account for these differences. This implies that Multiple Stripe Analysis, rather than IDA, is needed for collapse capacity estimation.

LOW DAMAGE CONSTRUCTION – SOME SYSTEMS ISSUES

Gregory MacRae

Civil and Natural Resources Engineering, University of Canterbury, Christchurch, New Zealand
gregory.macrae@canterbury.ac.nz

Abstract: This paper describes a number of approaches used to create "low damage" structures. It is shown that a number of low damage techniques and approaches, including post-tensioned beam approaches, rocking structures and others, may result in low-damage elements but not necessarily in low damage building systems. This paper draws on a report provided to and disseminated by the Royal Commission for the Canterbury Earthquakes. It encourages engineers to use "low-damage" technology that will result in low damage building systems.

1. INTRODUCTION

Recent earthquakes have required the demolition of a large number of structures while the life-safety design criteria has been satisfied. As a result there has been a research emphasis and some implementation of *low damage construction* (LDC) techniques. However, these techniques are not all equal, and while some damage may be reduced, other types of damage remain, or may be greater, as a result of different factors affecting the behaviour.

This discussion paper describes a number of LDC techniques and describes them in terms of their ability to actually result in low damage.

Since no structure can withstand an infinitely strong earthquake, it is necessary to firstly describe the performance objectives for LDC. MacRae (2010) proposed that a low damage structure have the performance objectives shown in Figure 1. Here one target level is provided for buildings of all importance levels (or groupings). It is considered that different importance factors provide different probabilities of meeting that performance level. The same effect may be expressed by multiple target performance lines for the same type of structure with the same probability of meeting each one (Buchanan et al., 2011). According to Figure 1, LDC related to the whole building requires that the building be immediately occupiable under Maximum Considered Event (MCE) level (very large) shaking and fully operational under many Design Basis Events (DBE).

The building consists not only of the seismic frame, but also the gravity frame, the slab and the non-structural elements/contents. Any assessment of a building should therefore consider all these effects. Chanchi et al. (2012) have described seismic sustainability of some steel structures in terms of:

- Damage
- Element replaceability
- Slab damage, and
- Structural permanent displacements.

Recently, Lin et al. (2012) have attempted to quantify the effect of earthquake shaking on building contents movement, but the principles developed relate to the damage of other acceleration dependent non-structural elements.

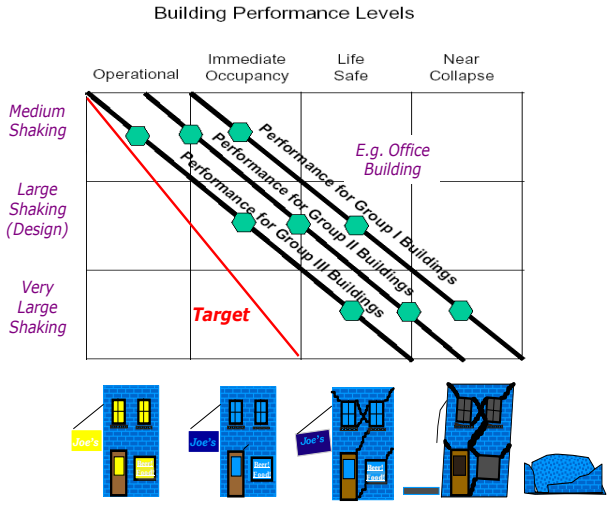

Figure 1. Possible Target Performance Objective for LDC (MacRae, 2010, based on Hamburger, PEER).

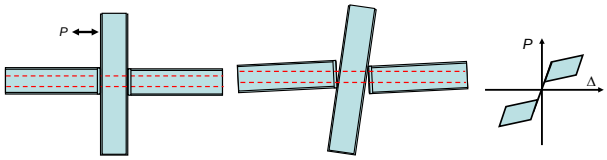
2. ELASTICALLY RESPONDING STRUCTURES

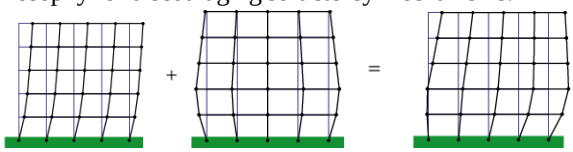
Structures designed in zones of low seismicity, or those which use very high strength materials in higher seismic zones, may respond elastically. Elastic response is associated with no damage and no permanent displacements. These structures are generally more expensive than traditional building designs since larger members/connections, and/or higher strength materials may be required. Also, unanchored contents movement is greater than that for yielding structures (Lin et al. 2012).



3. BASE-ISOLATED STRUCTURES

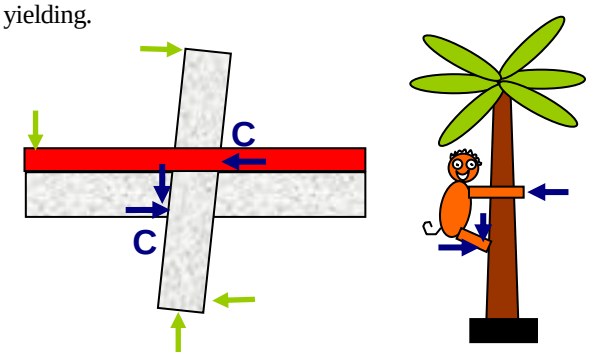
Base isolated structures have been designed around the world for many years. They are used extensively in countries like Japan where the cost of an isolated structure may be less

than that for a conventional structure (Wada, 2010). In some western countries, like NZ and the USA, they are currently not popular, possibly as a result of perceived additional initial cost. Also, when base-isolators are placed on soft-soils, the displacements may be greater than on stiff soils, and this may be regarded as another disadvantage of base isolation. In fact, the soft-soil effect is likely to increase the demands of all relatively stiff structures. It seems reasonable to use base isolation on softer soils as long as the isolator displacement demand is less than its capacity. Another benefit of base isolation is that the building structural interstorey drifts and the floor accelerations are generally not large. This means that non-structural elements and contents require less detailing if damage is to be avoided.



4. BEAM GAPPING SYSTEMS

When a beam is post-tensioned to a column with an unbounded cable, it may undergo significant deformations without damage as the beam end rocks on the column face as shown in Figure 2a&b (Priestley and MacRae, 1996). They "ideal" hysteretic shape is non-linear elastic, unless an energy dissipation device is used and energy is absorbed as shown in Figure 2c.



(a) Subassembly (b) Deformed Shape (c) Hysteresis
Figure 2. Post-Tensioned Beam Deformation and Hysteretic Behaviour (MacRae, 2010)

However, the column is part of a frame, and the gapping at the beam ends causes the distance between the column centerlines to move out as shown in a study by Kim et al. (2004). This causes the beams at some levels to be in compression, while at other levels the columns pull away from the beams placing them in tension (MacRae 2010, 2011). This change in axial force modifies the moments applied from the beams to the columns. This effect can only be mitigated if the columns are made to be flexible/weak, which is the opposite of the strong-column weak-beam philosophy for discouraging soft-storey mechanisms.

(a) Conventional (b) Gapping (c) Combined
Figure 3. Gapping Effects (Kim et al., 2004)

Another major issue relates to the building slab. Most buildings have slabs connected to the beams either side of the joint. The slab wraps around the column and under lateral column drifts, the forces resulting from the slab effect alone can be seen in Figure 4. When gapping at the beam ends occurs, the slab must extend (i.e. be damaged). A figure of such damage is shown in Figure 5. This slab damage is not appropriate for LDC. Such slab damage will only occur if the slab is weak. If the slab is strong, then the gap will not open so the desired mechanism will not occur. This may result in other undesirable failure modes such as column yielding.

(a) Subassembly (b) Monkey Idealization
Figure 4. Additional Forces on Column (tree) due to Slab (monkey) Extending around Column

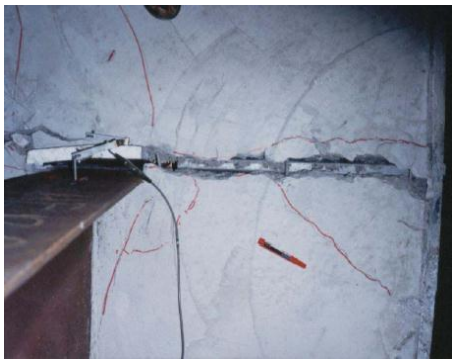


Figure 5. Slab Damage in a Post-Tensioned Beam Subassembly (Clifton, 2005)

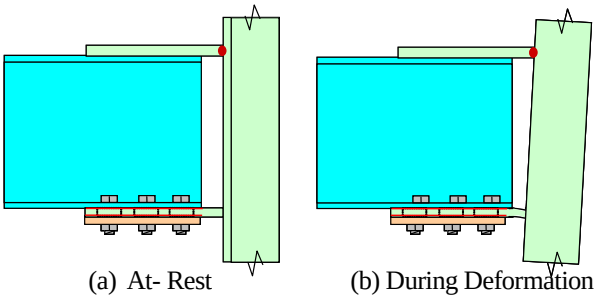
Attempts have been made to allow a gapping system work. For example Garlock et al. (2010) proposed connecting the floor diaphragm only to the gravity frame and that the seismic frame transfer forces to the gravity frame through floor-beams bending out-of-plane. This system is very difficult to tune as too low a stiffness of the floor beams results in the seismic frames being isolated from the gravity system, and too high a stiffness results in the gaps not opening. Together with difficulties when considering 3-D response, the approach does not seem practicable as described by MacRae (2010, 2011).

Another approach has been used, and it does work in some cases. This involves connecting the floor slab to only one bay of each seismic frame in each direction, putting a gap around the column, and allowing the beam to slide on the other bays. This has been tested Lin et al. (2009) and used in real construction in Wellington by Dunning-Thornton at the Victoria University campus in 2010. There are still a number of issues with this construction type. Proper analysis of the system is not easy. Also for very tall frames, the column demand issues described in Figure 3 occur. For frames with a large numbers of bays it is not reasonable to transfer all of



the slab inertia forces through only one bay. However, it is possible to design short buildings with few bays using this technique. Here, special care is required in the analysis and detailing to obtain a "boutique" solution (Buchanan et al. 2011). It is not a general solution for general moment frames.

For the reasons cited above, not a large number of these post-tensioned beam buildings have been constructed. In fact, the NZ Structural Engineering Society (SESOC) does not recommend these systems. It has been stated that they work well in all buildings without floor slabs as long as the extra column demands (as shown in Figure 3) are appropriately considered (Buchanan et al. 2012). While there are some advocates of this system it seems to the author than except for buildings which remain essentially elastic (such as some timber structures), the potential for such systems is limited.

5. NON-TEARING FLOOR SOLUTIONS

Non-tearing methods avoid the beam growth issues which push columns apart. Extensive studies have been conducted on steel structures (E.g. Danner and Clifton, 1995, MacRae et al. 2010) and recent work is being conducted on reinforced concrete structures. Here, the top of the beam is connected to the column. As the column moves over, the gap between the bottom of the beam and the column changes. This is shown in Figure 6 for a friction-type connection. Normally, other components are provided to carry the beam shear force and energy dissipation may occur with a number of different systems/devices including lead dissipaters, and yielding rods.

Since columns are not pushed apart, the floor slab does not tear as it sits on top of the beam. This means that it is easier to understand the behaviour and to perform an appropriate analysis. Since inelasticity occurs in the device/system at the bottom of the beam, the frame is not damaged. Furthermore, it is possible to use devices which have fully self-centering characteristics or with some self-centering properties (E.g. Khoo et al., 2011). Even if these are not used and bolted friction connections are used, then it is possible to unbolt the connection, and straighten the building after a very significant event. If friction connections are used, the bolts can stretch and be replaced. This system (with friction connections) has been implemented in a number of buildings in NZ (MacRae et al., 2010). The same principle can also be used for dissipative braces.

(a) At- Rest (b) During Deformation

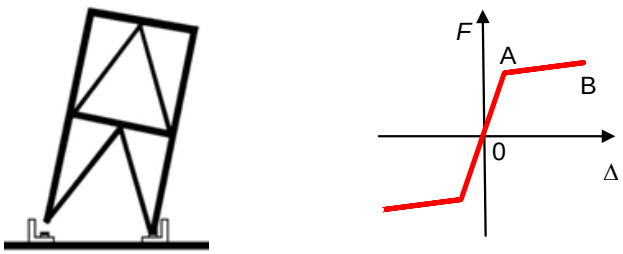


Figure 6. Non-Tearing Slab System (from MacRae 2011)

6. ROCKING SYSTEMS

Rocking structures, deforming like that shown in Figure 7a, have the characteristics that they are stiff and are likely to have low displacements. Since nonlinearity occurs as a result of uplift, it is possible that they should have little, or no, damage. The uplifting elements many be frames (such as concentrically braced frames) or walls (such as a concrete, timber or steel shear walls) and these elements do not need to be designed for large ductility as they are expected to remain essentially elastic. There are no/little tension demands on the foundations, so foundations can be smaller than that used for traditional designs.

If lateral force resistance is provided by gravity forces, elastic post-tensioning, and elastic gravity frame interaction when the rocking frame/wall uplifts, then there is no permanent displacement and the hysteresis loop is that shown in Figure 7b. However, if there is a bilinear, or similar, dissipater used, the system will have a static permanent displacement. That is, the displacement is no longer zero at zero lateral force. Due to dynamic effects, if the dissipater strength is less than the strength at uplift, permanent displacements are likely to be small.

Rocking structures have been built for many years (E.g. the 1981 South Rangitikei Rail Bridge). In addition to gravity forces, rocking frames/walls may use a post-tensioning system. These may be springs holding the base of the frame to the foundation (Gledhill et al., 2007), or post-tensioning cables over the height of the frame (E.g. Deierlein et al., 2009, Sause et al. 2010). The disadvantages of springs is that they may be expensive, while member sizes over the frame height must be increased to carry the post-tensioning forces from cables over the height. It is also possible to avoid post-tensioning and use energy dissipation systems to provide the required uplift resistance.

(a) Frame (Chanchi 2010) (b) Rocking - no dissipaters

Figure 7. Rocking Behaviour of Steel Structure

Issues with rocking frames/walls are described by MacRae and Clifton (2013). These include:

(i) an increase in lateral stiffness at high velocity during unloading which creates extra content movement (Lin et al. 2012). This effect can be addressed with appropriate restraint/anchorage of the contents.

(ii) gravity frame/slab demands due to vertical uplift. These can result in yielding/damage to the gravity frame and the slab and permanent displacements appropriate care is not

taken. Sause et al. (2010) use a separated rocking wall to avoid these issues.

7. OTHER SYSTEMS

A number of other systems which significantly reduce damage are available, including supplemental damping systems. While these can be very effective at reducing both forces and displacements, they are expensive for general buildings and are seldom used. Structures with tuned mass seem to be better suited to reduce wind rather than general earthquake loadings as a result of their narrow frequency response. Active control has still not received universal acceptance as a result of concerns related to cost, effectiveness and reliability. Many LDC systems are available and continue to be developed. How good they are depends on how well they reduce the demands on all elements of the total building system.

8. CONCLUSIONS

In order to make more resilient and sustainable cities, it is necessary to not only ensure life safety, but also to protect the infrastructure so that it can continue to be used after major earthquake shaking. A number of methods of low damage construction have recently been proposed and advocated. This paper shows that not all low damage approaches are equal, and some have more benefits than others. In particular, it is shown that it is not the performance of the device itself, but that within the building system which must be considered if low damage building system performance is desired.

Abstract: Existing RC buildings constructed according to relatively older regulations may lack of seismic resistance. Especially, public buildings such as schools or hospitals need to be retrofitted by efficient techniques considering their importance during and also after an earthquake. Buckling Restrained Braces (BRBs), being one of the popular retrofitting tools in recent years, may increase structural strength and at the same time reduce seismic response of a building by absorbing energy. This paper proposes a simplified method for designing the necessary amount of BRB for retrofitting the existing RC buildings. The method is based on equivalent linearization techniques and results are confirmed with non-linear time history analysis using high intensity seismic wave. The results show that, the RC building retrofitted with BRB responds as predicted by the proposed method and the drifts are much smaller than the original building.

1. INTRODUCTION

The catastrophic earthquakes is the past 2 decades resulted in life and economic losses worldwide while the authorities introduced new and comprehensive earthquake resistant building codes and regulations in almost every region. However the existing buildings that are not constructed according to these codes are lacking in seismic resistance as observed during surveys carried out after recent earthquakes. Therefore it is important to retrofit such existing buildings and enhance their seismic performance.

Existing framed structures may be suitably retrofitted by using diagonal braces. However, due to buckling of the brace compression members and material softening, the hysteretic behavior of conventional steel braces is unreliable. Alternatively, buckling-restrained braces (BRBs) being elasto-plastic dampers, may be employed as diagonal braces in seismic retrofitting of steel and RC frames designed for gravity loads only.

Previously several researchers have proposed simplified theories to predict the seismic performance of passive control systems. For such purpose equivalent damping and equivalent period of these systems are proposed by idealizing them as single-degree-of-freedom (SDOF) systems or other equivalent linearization techniques.(Kasai et al. 1998, Takeuchi et al. 2002 and Ichkawa et al. 2002) These studies are using elastic type structures such as steel buildings for the building model.

This paper proposes a simplified method to predict the seismic performance of a non-linear RC building retrofitted by BRB during a major seismic event. Equivalent damping of the retrofitted building is proposed by idealizing it as a linear SDOF system. By extending the SDOF theory, a seismically deficient 5-story RC building is upgraded by BRBs. Extensive multi-degree-of-freedom nonlinear time history analyses are performed for the retrofitted RC building using high intensity earthquake. The retrofitted system responded as predicted by the SOOF theory which showed much smaller drifts than the original RC frame, keeping frame members safe against major earthquakes.

2. EQUIVALENT LINEARIZATION METHOD

Proposed equivalent linearization method is carried out by the following 6 steps.

Step 1: Evaluating structural behavior of the existing building:

The strength of existing building is evaluated by non-linear push-over analysis. Obtained push-over curves are substituted with Takeda degrading tri-linear model. Yielding displacement for each story is assumed to be identical for the simplicity of the method.

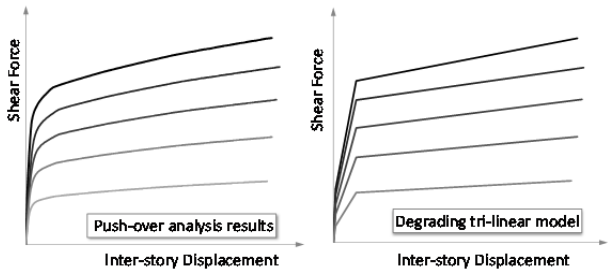

Figure 1.Push-over results and tri-linear degrading model for each story.

The details of degrading tri-linear behavior model of RC frame for each story are shown in Figure 2.

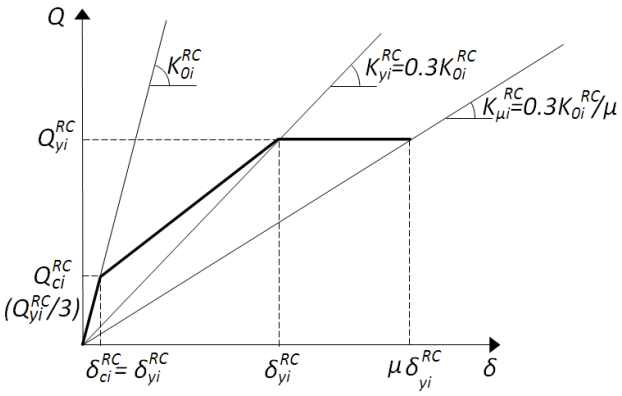

Figure 2.Degrading tri-linear model for i^{th} story of RC frame.

In Figure 2, Q_{yi}^{RC} is the yield shear force; Q_{ci}^{RC} is the crack shear force; δ_{yi}^{RC} is the yield displacement; δ_{ci}^{RC} is the crack displacement; K_{0i}^{RC} is the initial stiffness; K_{yi}^{RC} is the yielding point secant stiffness; $K_{\mu i}^{RC}$ is the post-yielding secant stiffness and μ is the ductility ratio for target displacement, each parameter being defined for an i^{th} story. Although the push-over results shows a hardening effect after yielding, in the BRB design method the post-yielding phase is assumed perfectly plastic.

Step 2: Defining an equivalent SDOF model:

The response prediction of the existing RC building and the evaluation of necessary damping are performed through equivalent linearization. For this purpose an equivalent SDOF model is introduced (Figure 3). In this step the equivalent height and mass of relevant SDOF model is calculated with the following equations.

$$H_{eq}=\frac{\sum_{i=1}^{N} m_i \cdot {}_s u_i \cdot H_i}{\sum_{i=1}^{N} m_i \cdot {}_s u_i},\quad M_{eq}=\frac{\left(\sum_{i=1}^{N} m_i \cdot {}_s u_i\right)^2}{\sum_{i=1}^{N} m_i \cdot {}_s u_i^2} \qquad (1)$$

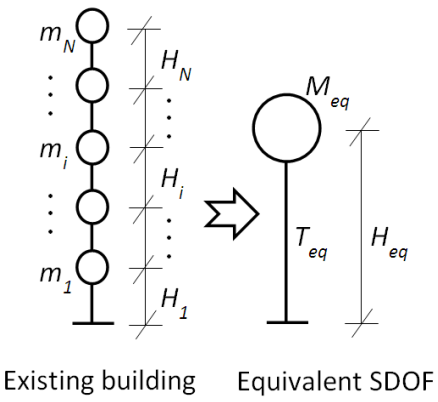

Figure 3.Equivalent SDOF system.

Where m_i , u_i and H_i are the mass, mode vector component and height of i^{th} story, respectively. For obtaining the equivalent period T_{eq}^{RC}, the initial period of the structure T_0 is calculated through eigenvalue analysis and modified for the target displacement. Here, T_{eq}^{RC} represents the equivalent period corresponding to the secant stiffness of target response point. As T_0 is known, equivalent period T_{eq}^{RC} may be evaluated by the following equation.

$$T_{eq}^{RC}=\sqrt{\frac{\mu}{0.3}}T_0 \qquad (2)$$

Using the equivalent period, equivalent stiffness of the SDOF model for target displacement is obtained as follows:

$$K_{\mu}^{RC}=M_{eq}\left(\frac{2\pi}{T_{eq}}\right)^2 \qquad (3)$$

Step 3: Evaluation of existing equivalent damping h_{eq}^{RC}

The equivalent damping of the RC frame h_{eqi}^{RC} for each story is individually calculated with the following equation.

$$h_{eqi}^{RC}=\frac{\Delta W_i^{RC}}{4\pi W_{ei}^{RC}}\cdot 0.8+h_0^{RC}=h_{eq}^{RC} \qquad (4)$$

Where ΔW_i^{RC} is the area of hysteresis loop in one cycle for i^{th} story, W_{ei}^{RC} is the equivalent potential energy of the i^{th} story, h_0^{RC} is the frame damping factor which is assumed to be proportional to the instantaneous tangential stiffness (Figure 4) and 0.8 is the reduction factor for the average loop is smaller than the maximum loop (Kasai et al. 2004). As the yielding displacement of each story was assumed to be identical, same equivalent damping factor is obtained for each story. Therefore the equivalent damping for the overall RC frame h_{eq}^{RC}, which may be obtained by the weighted mean of individual damping factors of each story, is equivalent to that of one story.

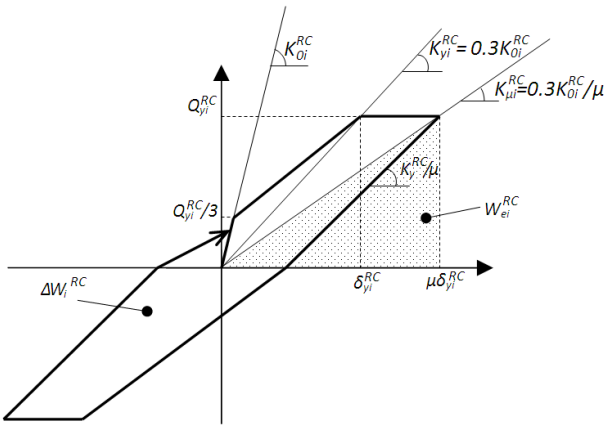

Figure 4. Typical hysteresis loop for RC frame

Step 4.Evaluating the equivalent stiffness of BRB on SDOF model.

Force displacement relation of the BRB is assumed to be elastic-perfectly-plastic and the yielding point drift is approximately 1/830 of story height (H_{eq}/830 for SDOF model). As the BRB is attached to the building through a steel frame, the stiffness of the BRB is evaluated including the effect of the steel frame. The elastic range of the steel frame is beyond the target displacement and depending on actual design experience it is assumed that the steel frame increases the stiffness of BRB 30% approximately (Figure 5). The initial equivalent stiffness of BRB, K_{μ}^{BRB} is evaluated by assuming the amount of maximum shear force supported by BRB, Q_y^{BRB} is equivalent to 30% of the equivalent weight of SDOF model.

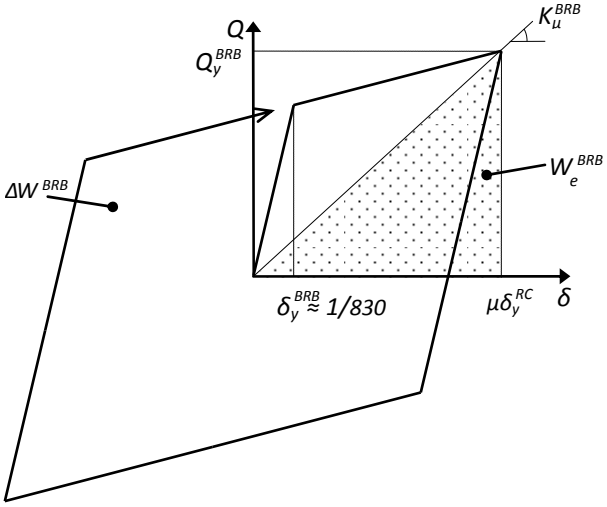

Figure 5. BRB hysteresis loop including steel frame effect.

Step 5: Evaluating the equivalent damping of SDOF model with BRB.

The equivalent damping ratio of SDOF model with BRB, h_{eq}^{Σ} is then evaluated for target displacement with the following equation.

$$h_{eq}^{\Sigma} = \frac{\Delta W^{BRB}}{4\pi W_e^{\Sigma}} \cdot 0.8 + \left(h_{eq}^{RC}\right)\frac{K_{\mu}^{RC}}{K_{\mu}^{\Sigma}} \qquad (5)$$

Where W_e^{Σ} is the equivalent potential energy of the RC frame with BRB, ΔW^{BRB} is the area of BRB hysteresis loop in one cycle, K_{μ}^{Σ} is the equivalent stiffness of the SDOF model with BRB (Figure 6).

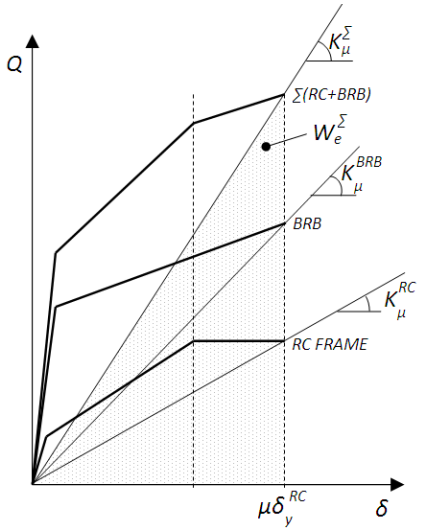

Figure 6. Overall behavior of SDOF model with BRB.

The effect of increased damping on the seismic response is evaluated with the following equation.

$$\delta_{eq}^{\Sigma} = \delta_{eq}^{RC}\frac{T_{eq}^{\Sigma}}{T_{eq}^{RC}} \cdot \sqrt{\frac{1+25h_{eq}^{RC}}{1+25h_{eq}^{\Sigma}}} \qquad (6)$$

In Eq.6 δ_{eq}^{Σ} is the displacement response of the SDOF model with BRB, δ_{eq}^{RC} is the spectral displacement response of the SDOF model and T_{eq}^{Σ} is the equivalent period for the SDOF model with BRB. As clearly seen in the equation, the displacement response of the retrofitted model is reduced by the increased damping and stiffness (therefore reduction of equivalent period). In this step, if the evaluated displacement response does not satisfy the target drift ratios, amount of BRB is adjusted at Step 4 and the method is repeated until satisfactory result is obtained.

Step 6: Evaluating the amount of BRB for each story and validation.

In this step the amount of BRB for each story of the RC building is obtained according to the BRB amount obtained at previous step. As the stiffness ratio of BRB and RC frame is determined for SDOF model ($K_{\mu}^{BRB}/K_{\mu}^{RC}$) the same ratio is used to decide the amount of BRB in the actual building. Instead of K_{μ}^{RC}, $K_{\mu i}^{RC}$ which is obtained by push-over analysis at Step 1 is used.

For validation of the method, the obtained BRB amount is incorporated in each story and time-history analysis with the same seismic wave used for SDOF model is carried out.

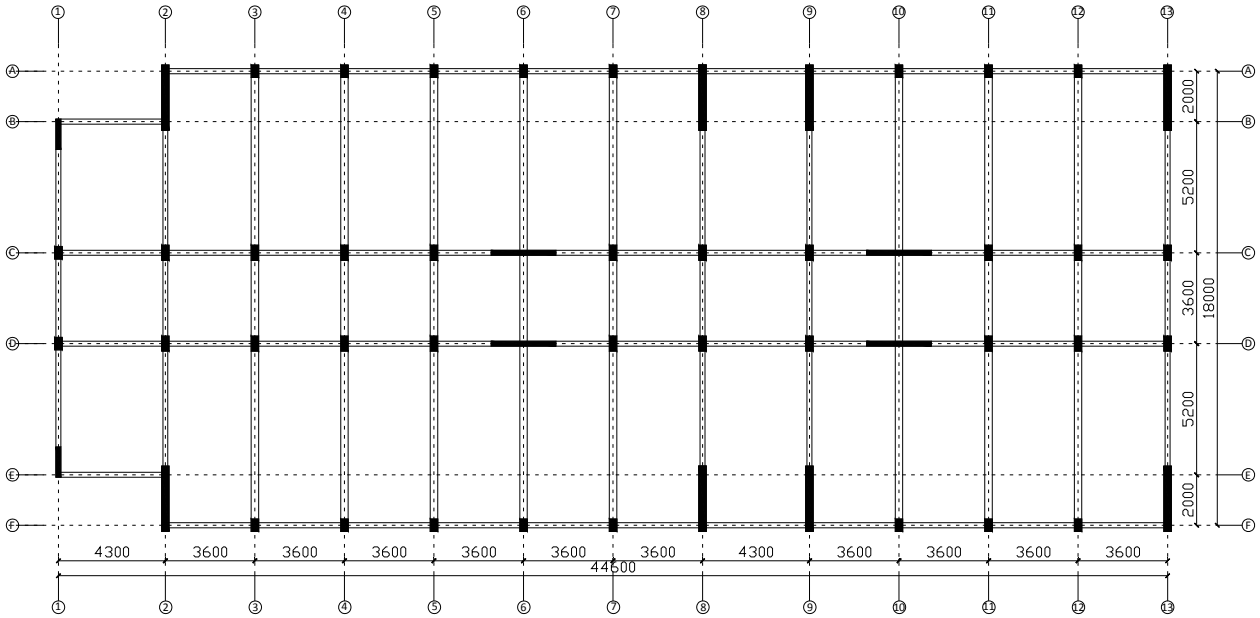

Figure 7 Plan of the RC school building

3. ORIGINAL 5 STORY RC BUILDING AND RESPONSE REDUCTION

A 5-story RC school building in Turkey is used for validation of the method. (Figure 7 and 8) The school building is constructed at 1992 in Istanbul which is a high risk seismic zone. Average concrete compressive strength is 20MPa and structural member section sizes as well as the reinforcement bar amount do not satisfy the current design code. Story height for each story is H_i=3.2m.

In this study the investigation of the building and evaluation of the structural performance before and after BRB retrofitting will be carried out in the longitudinal direction only, which is the weaker direction.

Figure 8. 5-story RC school building in Turkey

The target story drift for this study is 1/150. As for the seismic wave, BCJ-L2 from the Japanese design code is used. The acceleration and displacement response spectrum for BCJ-L2 is given in the following Figures 9 and 10.

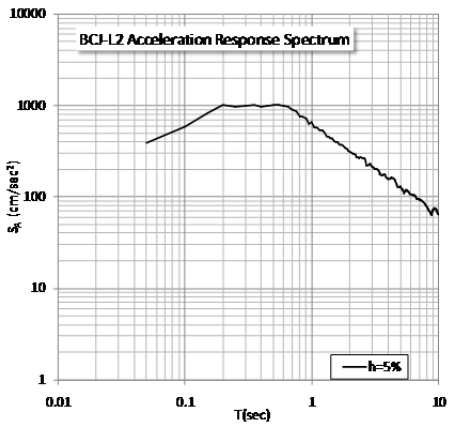

Figure 9. BCJ-L2 Acceleration response spectrum (h=5%)

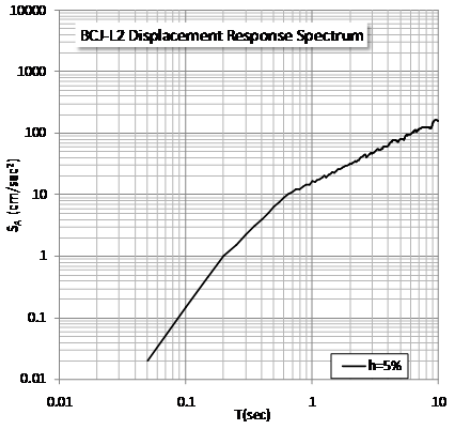

Figure10. BCJ-L2 Displacement response spectrum (h=5%)

By using the proposed BRB design method the amount of BRB to be used is evaluated and time history analysis is carried out for the RC frame with and without BRB. For the time history analysis the same seismic wave, BCJ-L2 is used.

The frame damping factor which is assumed to be proportional to the instantaneous tangential stiffness is taken as h_0^{RC} =0.05. The BRB installation on the RC frame is applied through a steel frame as shown in Fig.11. The steel frame is attached to the RC frame by chemical anchors and shear bolts to transfer sufficient shear force.

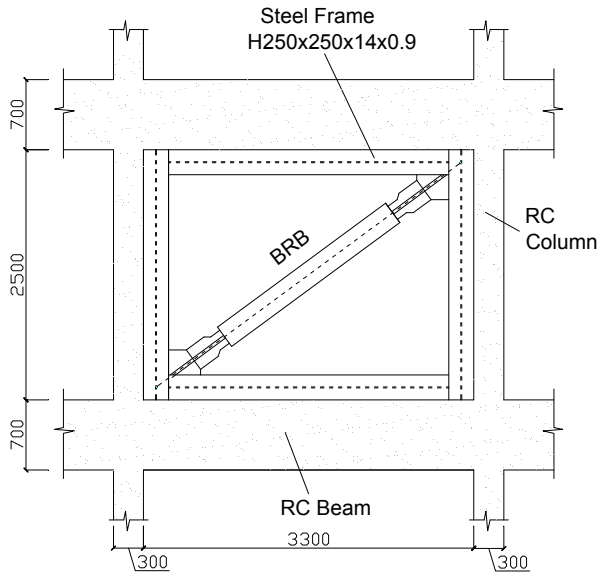

Figure 11. Installation of BRB on the RC frame

The push over analysis results for the sample school building is given in Table 1. As seen on the table, yield displacement values for each story are chosen to be the same for the simplicity of the method.

Table 1. Push-over analysis results for sample building.

	K_{0i}^{RC} (kN/mm)	Q_{ci}^{RC} (kN)	δ_{yi}^{RC} (mm)
5F	377.78	1700	15
4F	644.44	2900	15
3F	866.67	3900	15
2F	1077.78	4850	15
1F	1222.22	5500	15

By eigenvalue analysis the initial period of the structure is calculated to be T_0=0.7sec. while equivalent height and equivalent mass of the structure is calculated by Eq. 1 as H_{eq} =10.5 m and M_{eq} =4433.47 tons respectively. As the target story drift ratio is 1/150, target ductility is μ=1.42 and by using Eq.2 and Eq.3equivalent period and equivalent stiffness of the SDOF model is calculated as T_{eq}=1.54 sec and K_μ^{RC} =73.8 kN/mm, respectively.

In step 3 the equivalent damping of the RC frame is calculated as h_{eq}^{RC} =0.12. By following Step 4 initial equivalent stiffness of BRB is evaluated as K_μ^{BRB} =186.4 kN/mm assuming that the amount of maximum shear force supported by BRB is equivalent to 30% of the equivalent weight of SDOF model. By using the evaluated maximum shear force supported by BRB in Eq.5 the equivalent damping ratio of SDOF model with BRB is evaluated for target displacement as h_{eq}^{Σ} =0.26.

The effect of increased damping on the seismic response is then evaluated by Eq.6 where spectral displacement response of the SDOF RC model is calculated as δ_{eq}^{RC} =18.04cm (≈1/58 story drift). The obtained result is δ_{eq}^{Σ} =6.05cm (≈1/148 story drift) which is satisfactory, therefore initially selected amount of BRB is considered to be effective. In the next stage the ratio of BRB stiffness to the stiffness of RC frame obtained for the equivalent SDOF model ($K_\mu^{BRB} / K_\mu^{RC} = 2.52$) is used to evaluate the amount of BRB for actual RC building.

As for BRB used to retrofit the sample school building, ones with core cross-sectional area A_{core}=55.5cm^2 and yield strength $\sigma_{y\text{-}core}$=225N/mm^2 are selected. The steel frame used to attach the BRB to RC frame is made of H-250.250.14.9 section and the material yield strength is $\sigma_{y\text{-}sf}$=325N/mm^2. The total shear force supported by one set of BRB and steel frame including the application angle to the RC frame is calculated to be Q_y^{BRB} =1230kN.

The number of BRB to be placed on each floor, n_i^{BRB} is calculated depending on the target shear force to be supported by BRBs on each floor by Eq.7 and results are summarized at Table 2.

$$n_i^{BRB} = \frac{K_{\mu i}^{BRB} \cdot \mu \cdot \delta_{yi}^{RC}}{Q_y^{BRB}} \qquad (7)$$

Table 2. Number of BRB to be used on each floor.

	$K_{\mu i}^{RC}$ (kN/mm)	K_μ^{BRB} / K_μ^{RC}	$K_{\mu i}^{RC}$ (kN/mm)	n_i^{BRB}
5F	79.81	2.52	201.58	4
4F	136.15		343.87	6
3F	183.10		462.45	8
2F	227.70		575.10	10
1F	258.22		652.17	12

The maximum inter-story displacement of the original RC frame and the RC frame retrofitted with designed number of BRB is shown in Figure 12. As shown in the figure after the BRB retrofitting the exceeding displacement values of the original RC frame is prevented and target displacement is successfully achieved.

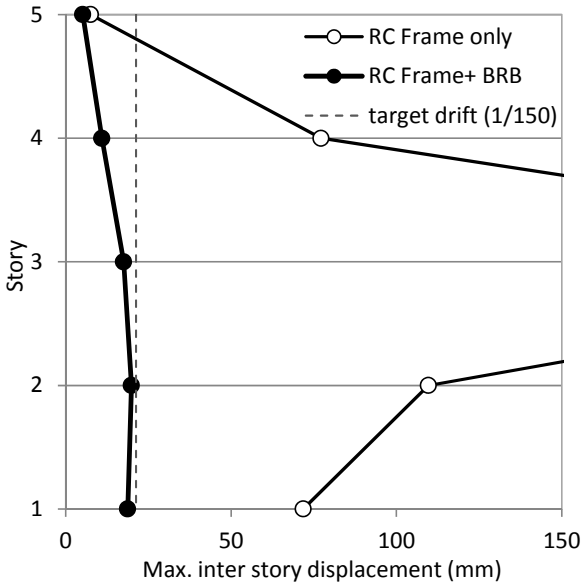

Figure 12. Max. inter-story displacement distribution.

As the steel frame remains elastic within the target drift range this component helps reducing the residual displacement after a severe earthquake motion. The inter-story displacement time-history of the 1st story is shown for the original RC frame and the BRB retrofitted RC frame in Figure 13. As seen in the figure while the original RC frame has significant residual displacement, the retrofitted RC frame has almost no residual displacement after the earthquake.

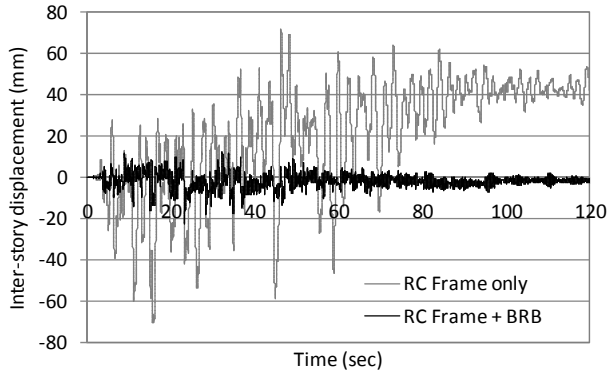

Figure 13. Inter-story displacement time-history (1st story.)

4. CONCLUSIONS

By proposed equivalent linearization method the necessary amount of BRB to retrofit a seismically insufficient RC frame is determined and target drifts are successfully obtained. The results are confirmed by non-linear time history analysis and the accuracy of the proposed method is validated.

Moreover, the residual displacement of the RC frame is significantly reduced after the application of BRB.

Abstract: Recent earthquakes have provided lots of examples of ground surface ruptures along the active faults and cause damages to buildings, roads and lifelines. Most of available structural design codes are based on the seismic acceleration during earthquakes while neglecting displacements due to earthquakes. A few design codes are considering the effects of ground surface deformation. Therefore, knowledge of the fault rupture is necessary and some effective design guideline should be developed based on that. The main objective of this study is evolution of ground surface deformation due to earthquake for civil design engineering.
Empirical study shows that ground surface deformations are generally characterized as: discontinuous deformations (raptures) and continuous deformations (deflection). Study shows that ground surface deformation is dependent on some parameters. The important parameters can be categorized in three main categories: source fault (i.e. moment magnitude of earthquake, fault type, slip, dip angle and depth of hypocenter), material type in ground between source fault and ground surface (i.e. incompetent and competent materials) and the type of structures (i.e. importance and shape).
Generally ground surface deformations tend to happen for shallow earthquake with large moment magnitude. Also by increasing thickness of incompetent material, deformation type changes from rupture to deflection.

1. INTRODUCTION

Recent earthquakes have provided lots of examples of ground surface deformations along the active faults and have caused damages to buildings, roads and lifelines. Some examples of earthquakes and damaged caused by ground surface rupture were discussed in following parts:

1.1 1999 Chi-Chi Earthquake

The September 20, 1999 Chi-chi Earthquake with M_w 7.6, happened on the Chelungpu Fault in Taiwan. As shown in Figure1-a, a building was rotated (Dong et al., 2003). This earthquake affected lifeline and infrastructures such as roads and highway. As shown in Figure 2, the Shih-Kang Dam was seriously damaged due to 7 meters vertical displacement in its foundation ground along the Chelungpu Fault (Kelson et al., 2001).

This earthquake also provided examples of deflection on the ground surface. As shown in Figure 3, the structure was stable and safe, however due to ground surface deflection it was necessary to rebuild the structure (Bray, 2009).

Figure 1: Buildings located on the fault and rotated in 1999-Chi-Chi Earthquake: (Dong et al., 2003)

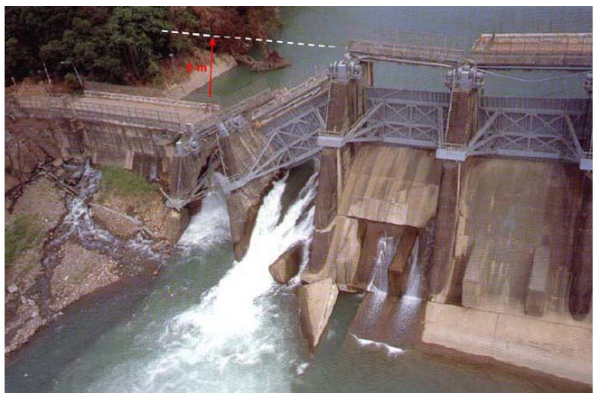

Figure 2: Looking toward the right abutment of Shihkang Dam after 1999 Chi-Chi Earthquake (Kelson et al., 2001)

Figure 3: Continuous deformation in the 1999 Chi-Chi Earthquake (Bray, 2009)

1.2 1999 Kocaeli and Duzce Earthquake

On August 17, 1999 Kocaeli, MW 7.6 earthquake and few days later in November 12, 1999 Duzce M_W 7.3 Earthquake happened along the North Anatoly Fault in Turkey.

Structural damages in some cases were because of unsafe design, poor construction technique and used of non standard materials. Moreover there were some damages caused by ground surface rupture as well. For example as shown in Figure 4, a four-story building collapsed due to ground surface rupture (Lettis et al., 2000)

Figure 4: Four-story building collapsed from surface rupture on right side of photo, west of Golcuk Naval Base (Lettis et al., 2000)

1.3 2002 Denali Earthquake

On November 3, 2002 M_w 7.9 earthquake happened in Denali Fault in Alaska. This particular earthquake was the largest strike-slip earthquake that ever happened in North America in almost 150 years.

The Denali Fault crossed almost all the Alaska as shown in Figure 5. There were no causalities, as there was no human habitation in Alaska. However the Trans-Alaskan Pipeline System (TAPS) across the Denali Fault experienced dislocation of 9 m (Hall et al., 2003). As the pipeline was designed for 11 m displacement; it could survive during this event as shown in Figure 6.

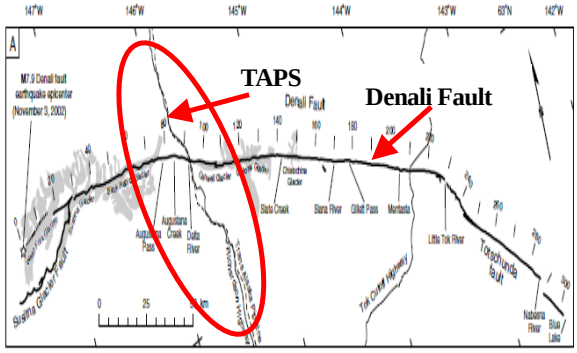

Figure 5: Map of Denali fault and TAPS crossing fault (Haeussler et al., 2004)

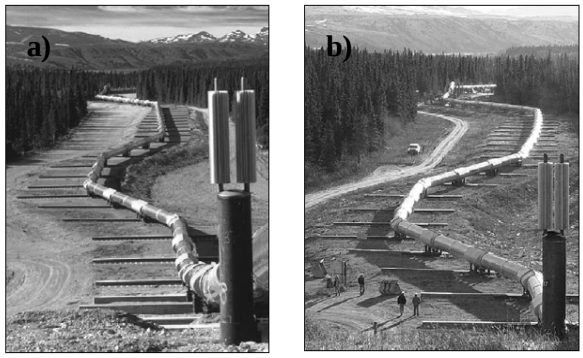

Figure 6: TAPS crossing of Denali Fault before and after earthquake, looking south. Note movement and bowed segment after fault displacement, which acts to compress the pipeline crossing segment: a) before earthquake and b) after earthquake (Hall et al., 2003)

1.4 2007 Niigata-Chuetsu-Oki Earthquake

On July 17, 2007 a M_W 6.8 Niigata-Chuetsu-Oki Earthquake happened in Japan. The epicenter was located 19 km from the site of Kashiwazaki-Kariwa Power Plant. All units in operational automatically shut down safely in response to the earthquake, and there were no significant damages despite large shaking. However there were small displacements of inclination not greater than 1/27,000 (Tani, 2010).

1.5 Ground Surface deformation Type

The ground surface deformations as shown in Figure 7 are generally characterized as:

1- Discontinuous deformations or fault ruptures

2- Continuous deformations or deflection without marked rupture

These examples show that ground surface deformation has great effect on the infrastructures and structures. However in some case such as 2007 Niigata-Chuetsu-Oki Earthquake, due to small value of displacement there is no serious damage related to top ground surface rupture. Therefore the effect of ground surface deformation should

be considered in the civil engineering design. There are some methods to determine the ground surface deformation due to earthquake and the summery of these methods are presented in following section.

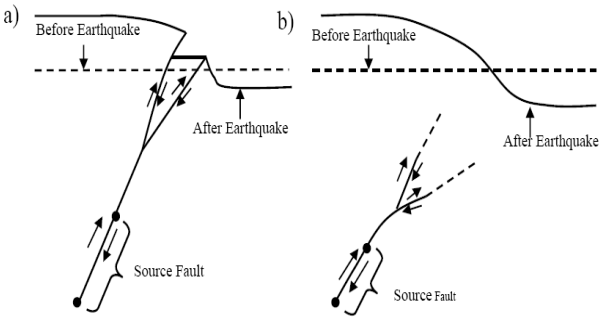

Figure 7: Two types of ground surface deformation:
a) Discontinuous deformation (Fault Rupture) and
b) Continuous deformation (Deflection)

2. CURRENT METHOD

Wells & Coppersmish (1994) defined some empirical relationships by gathered information for several past earthquakes all around world and for all kind of fault type. In their studies, relationship between moment magnitude of earthquake, rupture length, rupture width and surface displacement are discussed. There are some limitations in their studies: They did not consider the oblique fault. They only considered the average lines, and the ignored the upper limit boundary. However average line is not a sufficient guideline for some infrastructure and hence contingency is not enough. It is necessary to know whether the ground surface displacement is horizontal or vertical. However they did not specify the type of surface displacement. Also they did not mention that how to define the possibility of ground surface rupture.

Bray (2009) proposed a mitigation measure for engineered system as shown in Table 1. This system can be used as a guideline for design of structure near active fault based on ground surface rupture hazard. . In this method there are four main sections: land use planning section (avoid area to build structure with potential of ground surface rupture), engineering geology section (specifies location of active fault and estimate the ground surface rupture offset), geotechnical engineering section (some geotechnical techniques to spread the rupture offset) and structural engineering section (some recommendation structural methods to stabilized structure against rupture). However there is no any detail for land use planning section and engineering geology sections. In land use planning section, mentioned that based on Alquits-Priolo Act of 1972 in California, it is recommended that, we should avoid building any structure of human occupancy across the active fault and the safe distance is 50ft (15 m) (Figure 8). There is no reference to specify this number and for all fault type and all types of ground same breadth was proposed. In engineering geology section only some general information about the importance of engineering geology was present and there is no any detail about type of materials and effect of each type on ground surface rupture was presented.

Table 1 Mitigation measures for engineered system (Bray, 2009)

LAND USE PLANNING
Avoid area with the potential for surface fault rupture
ENGINEERING GEOLOGY
Identify and avoid primary faults Establish non-arbitrary setbacks based on fault and ground condition Estimate amount and type of potential fault displacement
GEOTECHICAL ENGINEERING
Construct ductile earth fills to spread out fault displacement Install soil reinforcement Use slip layers to decouple ground movements from foundation Keep the base of all foundation elements at the same elevation Avoid protrusions that would act like cleats to lock the building into ground Place compressible materials adjacent to walls and utilities For dams, use thick, ductile clay cores, thick upstream "crack-stopper" zones, thick downstream filters zone, thick chimney drains, and rockfill zone at the downstream face Increase freeboard, minimize reservoir height, and enlarge crest width Site outlet works and spillway off the fault trace
STRUCTURAL ENGINEERING
Design strong, ductile foundation, such as thickened reinforced mat foundations, waffle slabs, and post-tensioned slabs Do not use piles or piers that tie structure into the ground Design structure to be flexible and with isolation joints Install "catcher bents" or ties for bridge spans that must cross over faults

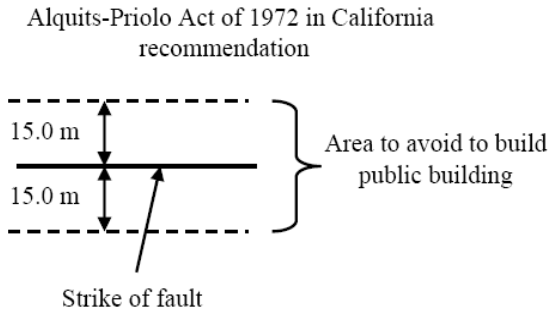

Figure 8: Alquist-Priolo Act of 1972 in California recommendation to avoid to build public structures around the active fault

3. PROBLEM STETMENT

Most of the available structural design codes are based on seismic accelerations or velocity while neglecting displacements during earthquakes. A few design codes are considering the ground surface deformation effects. For example as mentioned before, in California there is recommendation to avoid to build the public structures 15.0 m from the active fault in each side. However this recommendation is general and there is no clear and specific input parameters and Procedure. Therefore, it is necessary to study the ground surface deformation phenomena along the active fault and try to improve the design procedures for civil engineering.

To understand the ground surface deformations due to earthquakes, the important factors should be specified. As shown in Figure 9, there are three main factors as input to determine ground surface deformation:

1- Source fault
2- Ground between source fault and ground surface
3- Surface topography

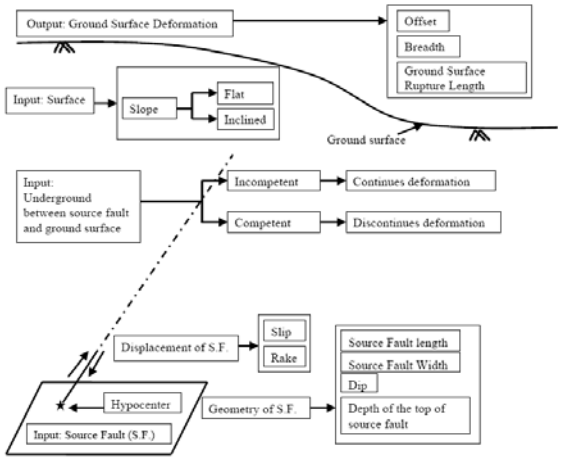

Figure 9: Important input parameters to determine ground surface deformation and list output phenomena of ground surface deformation

Source fault have great influence on ground surface deformation. Source fault has two main sub-factors: geometry and fault displacement. For the geometry, the length, the width, the dip angle of the source fault and the depth of the top of source fault are shown. For the fault displacement, the slip and the rake angle are determined. Source fault also can be specify as point source based on moment magnitude of earthquake and depth of hypocenter.

The other important factor is ground between source fault and ground surface. Generally there are two main sub-factors: "Incompetent material" and "Competent material"

In competent material, deformation occurs in remarkable shear zone. Rupture can be used to identify remarkable shear zone. In incompetent material, deformation happens in non-remarkable shear zone and many small shear zones appear, unlike that in competent material. Deflection can be used to identify non-remarkable shear zone.

Also Surface topography is another parameter which effects the ground surface deformations. Huang & Yen (1997) found that the topographic correction is in the order of five present of fault dislocation.

4. OBJECTIVE OF THIS STUDY

As mentioned ground surface deformation in some earthquakes reached to the ground and caused some damaged. However in some earthquakes, there is no significant ground surface deformation. In cased of ground surface deformation happened, there are two general types of ground surface deformation: rupture and deflection.

The objective of this study is determination of ground surface deformation type due to earthquake for civil design engineering.

5. DETERMINATION OF GROUND SURCFACE DEFORMATION TYPE

Existing literature reviews were conducted to collect information about ground surface deformation for previous earthquakes. The information of field data of ground surface deformation occurred in the past earthquakes was gathered are shown in tables. They are mostly from some data centers such as U.S. Geological Survey (U.S.G.S.), Southern California Earthquake Data Center (SCEDC) and also from some geotechnical journals (i.e. Bulletin of Seismological Society of America, Earthquake Spectra, Engineering Geology, Earth Planets Space and etc.) cited under references. The focus of this study is inland earthquake.

In next step definition of ground surface deformation and earthquake parameters were specified and unreliable data were ignored. The reliable field data was used for analyzed in following parts.

A model should be developed to specify the ground surface deformation type. Ground surface deformation depends on some parameters such as:

1- Moment magnitude of earthquake (M_w).

Mw can be used to show the effect of source fault.

2- Depth of hypocenter (D_h).

The hypocenter is the point within the earth where an earthquake rupture starts. The source fault can be modeled as point source using M_w and D_h.

3- Ground between source fault and ground surface.

There are two types of geological structures, competent material and incompetent material. As shown in Figure 10a, competent material, deformation occurs in remarkable shear zone. Rupture can identify remarkable shear zone. As shown in Figure 10b, incompetent material deformation happens in non-remarkable shear zone and many small shear zones appear, unlike competent material.

Deflection can identify non-remarkable shear zone. As shown in Figure 11, remarkable shear zone (competent material) can be identified as brittle behaviour and non-remarkable shear zone (incompetent material) can be identified as ductile behaviour.

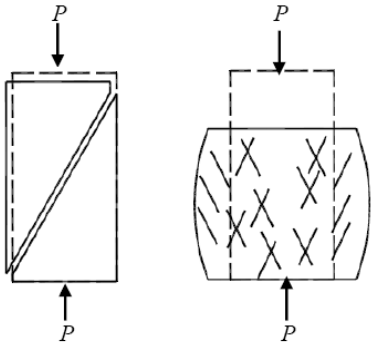

Figure 10: Definition of geological structures for: (a) Competent material, and (b) Incompetent material

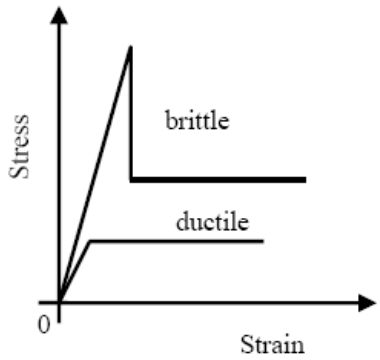

Figure 11: Brittle and ductile behaviour based on stress and strain relationship

The brittle and ductile behaviors can be specified by Young's module (E). As in field applications, velocity of secondary wave, (V_s) can be measured quite easily. Therefore V_s should be used in the model. The relationship between Young module (E) and velocity of secondary wave (V_s) was given in Eq. (1).

$$V_S = \sqrt{\frac{E}{2\rho(1+\upsilon)}} \qquad (1)$$

Where ν is Poisson's ratio and ρ is density. As a general case, the value of V_s was calculated based on E= 42000 MPa, ν= 0.2 and ρ= 2500 kg/m3 (Hoek, 2001). V_s = 800 m/s was specified to determine competent and incompetent material. In some studies, velocity of primary wave (V_p) was used. V_p can be determined from Eq. (2).

Using Eq. (2) and the same values for E, ν and ρ, Vp = 1300 m/s was specified to determine competent and incompetent material.

$$V_P = \sqrt{\frac{E(1-\nu)}{2\rho(1+\upsilon)(1+2\upsilon)}} \qquad (2)$$

If there is no information about shear or primary wave velocity, then the geological classification should be used. Hard rock, metamorphic and igneous, sandstone and shale without intensive fractures were considered as competent material (Table 2). Stiff and soft soils, average and poor rocks and so on were considered as incompetent material (Table 2-1). In case of discrepancy between shear wave velocity, pressure wave velocity and geological classification, shear velocity should be selected as the first priority. Pressure wave velocity should be selected as the second priority.

Table 2 Classification of competent and incompetent material

Material type (Definition)	V_s (m/s)	V_p (m/s)	Classification of ground
Incompetent (Deflection happens)	≤ 800	≤ 1300	Soft soil; Stiff clay and sand soils; Loose to dense sands; Medium to stiff/hard clays; Water-saturated alluvial deposits weak rock; Stiff soil; Deeply weathered and highly fractured bedrock; Soils with more than 20% gravel
Competent (Rupture)	> 800	> 1300	Hard rock; Mostly metamorphic and igneous rock; Fresh conglomerates; Sand stones and shales without intensive fractures

In the step, the data of pervious earthquakes was gathered based on literature reviewed. The source fault was considered as point source and moment magnitude of earthquake and depth of hypocenter was specified for each earthquake. Also the thickness of incompetent material ($H_{InCom.}$) and type of ground surface deformation (i.e. No deformation, Deflection and Rupture) was specified. The data was shown in Table 3.

The relationship between moment magnitude of earthquake (M_w) and hypocenter depth (D_h) was shown in Figure 2-3. As shown in Figure 12 deformation (i.e., rupture or deflection) happened during earthquake with D_h smaller than 20.0 km. For earthquake with D_h higher than 20.0 km there was no remarkable deformation. The upper limit and lower limit to specify the type of deformation were shown in Figure 12b.

Selection between the upper limit and lower limit lines should be done for each area, based on structure type. Structures type can be specified based on their shape and important (Table 4). There are two types of structures based on shape: linear (i.e. pipeline, highway, road, railway) and separate. Structures can also classify based on importance. There are two types of structures based on importance: essential (i.e. infrastructure, government office and etc) and standard (i.e. residual building, local road and etc). In case of essential structure, the contingency should be high. Therefore the upper limit should be used to specify type of

deformation and for standard structure the lower limit can be used.

D.T.: Deformation Type; R: Rupture; D: Deflection; No.Def: No Deformation; N.D.: No Data

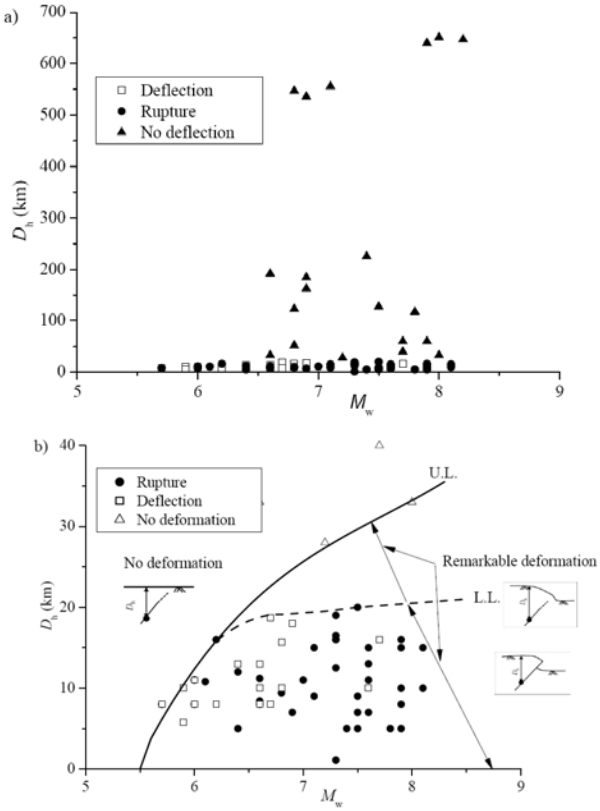

Figure 12: Relationship between moment magnitudes of earthquake vs. depth of hypocenter: (a) full rage of D_h, and (b) $D_h \leq 40$ km

The next parameter is geological structure (thickness of incompetent material). The relationship between moment magnitude of earthquake (M_w) and incompetent material thickness ($H_{InCom.}$) was shown in Figure 13. There are three main areas in Figure 13. In the first area, remarkable rupture happens. In the second area, deflection happens. In the third area, deformation might not happen.

Table 4 Classification of structural type

Imp. \ Shape	Linear	Separate
Essential	Highway main road High speed and main train railway Main pipeline	Power plant and dam Refinery Hospital, Fire Station Governmental office Structure containing toxic
Standard	Local road Local train railway Local pile line	Structure containing toxic

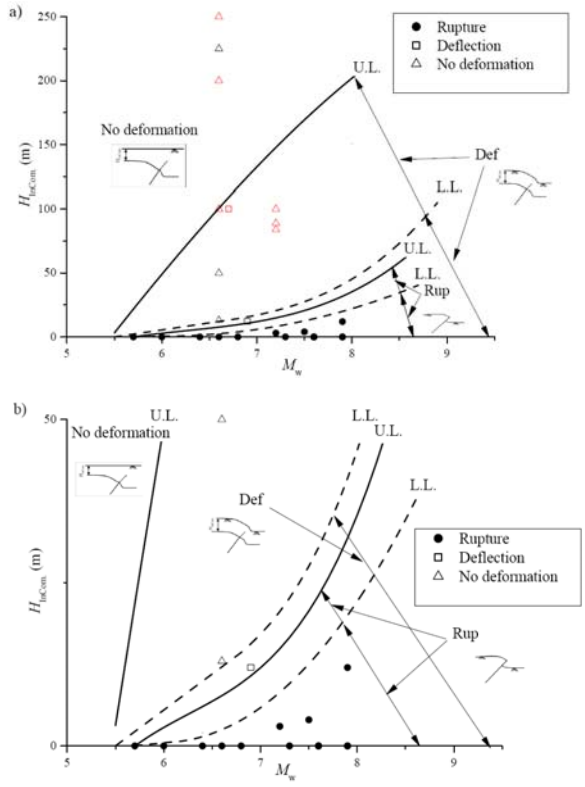

Figure 13: Relationship between moment magnitudes of earthquake vs. incompetent material thickness to specify type of deformation for: (a) full rage of HI_{ncom}, and (b) $H_{Incom} \leq 50$ m

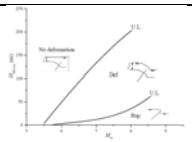
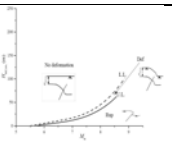
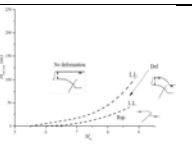
In the first area, for earthquakes with Mw higher than 5.7, there is a possibility of ground surface rupture. The upper and lower limit boundaries between ground surface rupture and deflection was specified. The lower limit is based on the highest HInCom from the ground surface rupture of past earthquakes. The upper limit is based on the

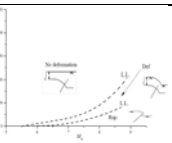
lowest HInCom from the ground deformation of past earthquakes.

In the second area, ground surface deformation changed to deflection with increasing H_{InCom}. This study showed that for earthquakes with M_w higher than 5.8, there is a possibility of ground surface deflection. The upper and lower limit boundaries between ground surface deflection and no deformation were specified. Ground surface rupture is easier to distinguish than ground surface deflection and no deformation. Therefore, gap between upper limit and lower limit in second area is larger than first area (ground surface rupture).









Selection between the upper limit and lower limit lines should be done for each area, based on structure type. Structures type can be specified based on their shape and important (Table 4).

Linear essential structures sometimes need to cross the active fault. Ground surface deformation has serious effects on linear essential structures. Therefore, higher contingency should be considered and, hence the upper limit was selected as the boundary line between ground surface deformation types (Table 5).

Separate essential structures should be avoided the active fault. However the minimum distance should be considered. The upper limit should be considered as boundary between ground surface rupture and deflection. The effect of ground surface deflection is not as much as ground surface rupture. There are not many records of deflection effects on separate essential structures. Therefore, the lower limit was selected as the boundary between ground surface deflection and no deformation area.

For standard structure (linear and separate) the lower limit can be used as boundary between different deformation types.

6. CONCLUSIONS

Ground surface deformation depends on some parameters such as: Moment magnitude of earthquake, depth of hypocenter and material types in ground between source fault and ground surface. Material type in ground between source fault and ground surface can be classified in two types: "Incompetent material" and "Competent material". Competent material can be identified as brittle behaviour and incompetent material can be identified as ductile behaviour. The velocity of secondary wave (V_s) can be used to specify the ductile and brittle behaviour. Compartment materials have V_s higher than 800 m/s and in the case of incompetent martial the Vs is less than 800 m/s. Generally ground surface deformation is happened for shallow earthquake with large moment magnitude. Based on relationship between moment magnitude of earthquake (M_w) and thickness of incompetent material (H_{InCom}), type of deformation can be determined. There are three main areas depend on M_w and H_{InCom}: remarkable rupture area, deflection area and no deformation area. The boundaries between deformation types can be specified based on structure type. Structures type can be determined based on their shape and importance. There are two types of structures based on shape: linear and separate. Structures can also be classified based on importance. There are two types of structures based on importance: essential and standard.

Abstract: The selection of intensity measure (IM) has a significant effect on the result of incremental dynamic analysis (IDA), especially for tall buildings. Considering higher mode contributions, this paper proposes a structure-specific power-law form IM, which is suitable for IDA of tall buildings. This suggested IM, in the form of S_{12} or S_{123}, contains two or three elastic spectral values corresponding to the first two or three periods, and the modal mass participation proportion is used as the power for each mode considered. The IDA of a super-tall SRC frame - RC tube structure is performed to demonstrate the efficiency of the proposed S_{12} or S_{123} compared with other IMs including PGA, PGV, S_a, and S^*. It is concluded that the IM of PGV is more efficient than PGA as well as one spectral value-based S_a and two spectral value-based S^*. But it is less efficient than the proposed S_{12} and S_{123}. For the structure-specific IM, the more modes are considered, the more efficient IM is. S_{123} is recommended for the IDA of tall buildings.

1. INTRODUCTION

1.1 The significance of IMs

Incremental Dynamic analysis (IDA), proposed by Vamvatsikos (2002), is a parameter analysis method based on nonlinear dynamic analysis. It involves performing nonlinear dynamic analysis of the structural model to a suite of ground motion records, each scaled to multiple levels of intensity, and recording the responses at each level to form IDA curves of response versus intensity. The approach has the potential to provide dynamic capacity curves for different ground motion levels and describe the variation of engineering demand parameters (EDPs) with changes in ground motion intensity measures (IMs). It is believed to be the most promising method for its accurate estimation of the seismic performance of structures and is of great interest in Performance-based Earthquake Engineering (PBEE) (Zhou *et al*., 2010).

An IDA curve combines the IM of a site-specific ground motion with EDP from nonlinear dynamic analysis of the given structure. For IDA curves, it is an unavoidable fact that the curves display large record-to-record variability. This observed dispersion is closely connected to the IM used. Different IM generates various IDA curves for a given EDP. Some IMs are more efficient than others, better capturing and explaining the differences from record to record. Thus, the selection of IM has a significant influence on the result of IDA.

1.2 Existing IMs

Currently, the most frequently used IM is the peak ground acceleration (PGA) and the spectral acceleration at the fundamental period of the structure, $S_a(T_1, 5\%)$ or S_a for simplicity. S_a has been demonstrated to be more efficient than the PGA (Shome, 1999). The higher efficiency of S_a with respect to PGA can be ascribed to the fact that S_a is a structure-specific IM while PGA is not, which means that the former may better capture the seismic responses on a specific structure. Obviously, S_a is an accurate measure for single-degree-of-freedom (SDOF) systems or first-mode-dominated structures in the elastic range. Some studies have demonstrated, however, that S_a may not be particularly efficient nor sufficient for certain kinds of structures, such as tall, long-period buildings. (Shome, 1999)

A number of IMs has been proposed, attempting to avoid the major shortcomings of S_a, i.e., ignoring both the contributions of higher modes to the overall dynamic responses and the increase of the fundamental period of the structure associated with nonlinear behavior. Those attempts can be classified as two categories: elastic spectra based and inelastic spectra based.

For elastic spectra bases IMs, spectral values at periods of high modes are considered to incorporate higher-mode effect or at a larger period to incorporate the period lengthening effect. Cordova *et al*. (2000) proposed a two-parameter scalar IM that accounts for the period lengthening, as given in Eq. (1).

$$S^* = S_a(T_1)^{1-\alpha} \cdot S_a(T_f)^{\alpha} \tag{1}$$

where T_1 is the first mode period and T_f is a longer period

that presents the inelastic (damaged) structure. α and the ratio T_f/T_1 are determined by calibration to optimize the IM by minimizing the variability in computed results. A pair of T_f/T_1=2 and α=0.5 is suggested for general application. A significant advantage of S^* is the possibility of obtaining its corresponding attenuation law that is a linear combination of the attenuation functions for the spectral acceleration values $S_a(T_1)$ and $S_a(T_f)$.

Luco and Cornell (2007) put forward an IM named $IM_{1I\&2E}$, which takes into account both second mode frequency content and inelasticity, is a SRSS combination of inelastic spectral value at the first-mode period and the elastic spectral value at the second-mode period. The practical applicability of the approach is at present limited by the difficulties related to the computation of the corresponding hazard curve.

Mehanny (2009) proposed a power-law form elastic spectrum shape-dependent IM by making modification on the IM proposed by Cordova (Cordova *et al*., 2000). The modification is substituting the pre-calibrated constant-value ratio T_f/T_1 by a self-adaptive multiplier that is function of the nominal relative lateral strength R. R is defined as the lateral strength required to maintain the system elastic, F_e, relative to the lateral yielding strength, F_y, of the system. The IM is written as:

$$IM = S_a(T_1)^{1-\alpha} \cdot S_a\left(\sqrt{R} \cdot T_1\right)^{\alpha} \tag{1}$$

The IM of peak ground velocity (PGV) and peak ground displacement (PGD) has also been studied and would not be discussed here. In a word, the IMs mentioned above are scalar intensity; while recently, researchers have been focusing on intensity vectors (Baker and Cornell, 2004). A vector IM consists of two parameter such as S_a along with a measure of spectral shape. The use of a vector IM is appealing, but it is still involving many unsolved problems including the scaling techniques and uncertain hazard calculations.

1.3 The aim of this paper

Given the existing IMs above, this paper proposes a practical structure-specific IM for the IDA of tall, long period buildings with significant contribution of high modes to the structural responses. In the proposed IM, the elastic spectral values at major periods are added to incorporate the high-mode contribution, and the modal mass participation proportion is used to weight the contribution of various modes. The IDA of a super-tall steel reinforced concrete (SRC) frame – reinforced concrete (RC) tube structure is performed to verify the efficiency of the proposed IM compared with popular scalar IMs.

2. AN IM CONSIDERING THE HIGH-MODE EFFECT FOR TALL BUILDINGS

High-mode effect should be considered in the IDA of tall buildings. The structure-specific IM is proposed for tall buildings as given in Eqs. (2) and (3), in which spectral accelerations at major periods are the bottom number and corresponding modal mass participation proportions are the exponent.

When the first two modes are considered, the IM is shown in the form in Eq. (2):

$$S_{12} = S_a(T_1,\xi)^{\alpha} \cdot S_a(T_2,\xi)^{\beta} \tag{2}$$
$$\alpha = m_1/(m_1+m_2)$$
$$\beta = m_2/(m_1+m_2)$$

When the first three modes are considered, the IM is shown in the form in Eq. (3):

$$S_{12} = S_a(T_1,\xi)^{\alpha} \cdot S_a(T_2,\xi)^{\beta} \cdot S_a(T_3,\xi)^{\gamma} \tag{3}$$
$$\alpha = m_1/(m_1+m_2+m_3)$$
$$\beta = m_2/(m_1+m_2+m_3)$$
$$\gamma = m_3/(m_1+m_2+m_3)$$

where α, β, γ are modal mass participation proportions corresponding to the first three periods, respectively. m_1, m_2, m_3 are modal mass participation factors corresponding to the first three periods, respectively.

It can be seen that more modes can be considered in the proposed IMs. Generally, the total modal participation mass of the first three modes is no less than 80% of the whole structural mass in one direction, which is sufficient to get accurate results for engineering applications considering the computation time.

3. THE IDA OF A SUPER-TALL BUILDING USING THE PROPOSED IM

3.1 Structural description

The most popular system for tall buildings in China has recently been transferred from traditional RC shear wall structures to SRC frame-RC core wall structures. Thus, a 50-story SRC frame-RC core wall structure is designed as the target building in the paper. The story height is 4m and the total height is 200m. The plan layout is shown in Figure 1 and dimension of members is listed in Table 1. Table 2 gives the material properties of the model.

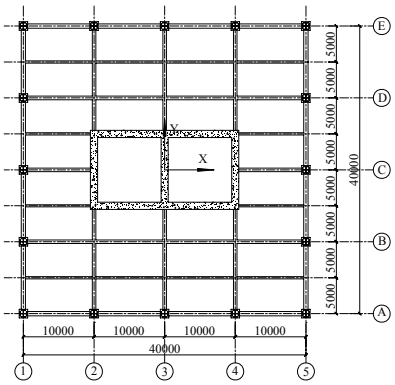

Figure 1 Play layout of the structure

3.2 Finite element model

The analytical software ABAQUS is used to build finite element model and conduct nonlinear dynamic analysis. Beams and columns are modeled using a first-order 3D Timoshenko beam element (B31), in which the transverse shear deformation is allowed. The linear, reduced-integration, quadrilateral shell element (S4R) in which in-plane bending

Table 1 Cross-sectional dimensions of structural members

Member	Location		Concrete (mm)	Steel (mm)
Beam	Peripheral beam	1-20	-	600x950x20x40
		21-35	-	500x900x20x40
		36-50	-	500x800x20x40
	Primary beam	1-50	-	500x800x20x40
	Secondary beam	1-20	-	300x500x14x25
Column	1-20		1200	600x900x35
	21-35		1000	500x700x35
	36-50		800	400x500x20
Wall	1-20		1000	-
	21-35		800	-
	36-50		600	-

Table 2 Material properties

Concrete grade	Design values of strength (MPa)		Poisson ratio	Modulus of elasticity (MPa)
	Compressive	Tensile		
C35 (beam, slab)	16.7	1.57	0.2	3.15E+4
C60 (wall, column)	27.5	2.04	0.2	3.60E+4
Steel grade	Yield stress	Ultimate stress	Ultimate strain	Modulus of elasticity
Q345 (t>35)	295	384	0.025	2.06E+5
Q345 (t<35)	328	426	0.025	2.06E+5

and shear and out-of-plane bending can be simulated simultaneously. The discrete model is used to simulate the reinforcement and steel in beams and columns, and the smeared layer model is employed for reinforcement in shear walls and slabs.

The isotropic bilinear kinematics hardening model is used for reinforcement and steel, in which Bauschinger effect is considered. During the cyclic loading, no degradation is developed. The ratio of ultimate strength to the yield strength is 1.2 for reinforcement and 1.3 for steel. The ultimate plastic strain corresponding to the ultimate stress is considered as 0.025.

Since there is no proper concrete material model available for B31 element in ABAQUS, a user material subroutine is wrote and incorporated into ABAQUS via VUMAT subroutine. This user-defined material uses the uniaxial concrete constitutive model proposed by Mander *et al*. (1988a and 1988b), which takes into account the influence of various types of confinement by defining an effective lateral confining stress.

The finite element model is shown in Figure 2 with 78957 nodes and 53772 elements in total.

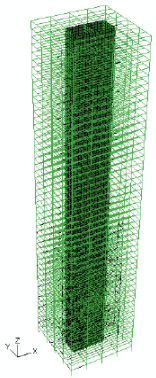

Figure 2 Finite element model

3.3 Dynamic properties

The dynamic properties and modal mass participation factors of the model are tabulated in Table 3.

Table 3 Dynamic properties and model mass participation factors

No.	Period (s)	Mode shape	Modal participation mass (kg)	Total mass (kg)	Modal mass participation factor	Modal mass participation proportion	
						For S_{12}	For S_{123}

3.4 Earthquake ground motion selection

Previous study (Shome, 1999) has shown that ten to twenty ground motions are usually enough to provide sufficient accuracy in the estimation of seismic demand. Consequently, a suite of fifteen earthquake records are chosen from Strong Motion Database of Pacific Earthquake Engineering Research Center to simulate the earthquake scenarios (Table 4). Two aspects have been considered when selecting the ground motions: (1) soil condition of the site. According to *Chinese Code for Seismic Design of*

Buildings (GB50011-2010), the site soil is categorized as Type III, which is defined as the soil whose overlaying thickness is between 15 and 80m and the equivalent shear velocity is no more than 150m/s; or whose overlaying thickness is larger than 50m and the equivalent shear velocity is between 150 and 250 m/s. (2) design response spectrum specified in Chinese code. Figure 3 shows the response spectra of the ground motions and design spectrum.

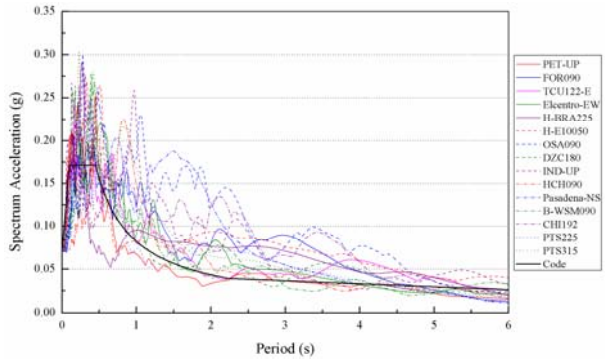

Figure 3 Response spectra of selected ground motions and design spectrum (ξ=4%)

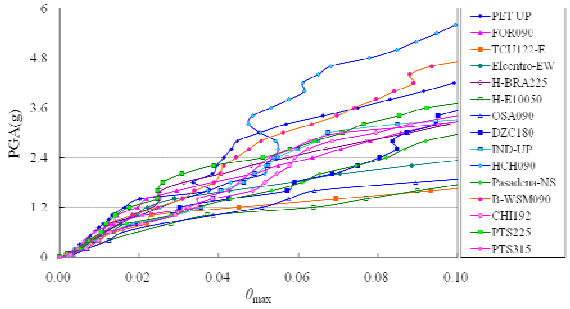
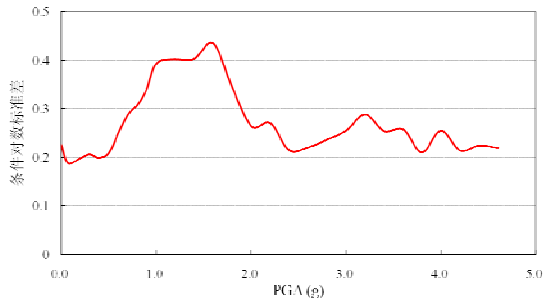
3.5 Incremental Dynamic Analysis



The IDA entails appropriately scaling each record to cover the entire range of structural response, from elasticity, to yielding, and finally global dynamic instability. In the analysis, the ground motion is input in Y direction. All records are scaled by PGA. According to Chinese code, the building is designed based on the minor earthquake level with a PGA of 0.07g. The corresponding PGAs under moderate and major levels are 0.2g and 0.4g, respectively. Thus, the PGAs for IDA begin with 0.07g, and then 0.1g, 0.2g, 0.4g, 0.6g, ….

Several considerations for comparing IMs are: (1) Desirable properties of an IM are efficiency, sufficiency, scaling robustness and the hazard computability (Luco and Cornell, 2007; Tothong and Cornell, 2007). An efficient IM is defined as the one that results in a relatively small dispersion of structural response given the level of ground motion intensity. Only efficiency is used here for the comparison of IMs. (2) As a measure of the dispersion, the standard deviation of the logarithm of the EDPs is applied, which is a natural choice for values approximately log-normally distributed (Shome, 1999). The average of the standard deviations under each IM is taken to evaluate the efficiency of IMs. (3) Based on the modal mass participation proportions in Table 3, S_{12} and S_{123} is written as Eq. (4). (4) The maximum inter-story drift ratio θ_{max} is taken as EDP.



$$S_{12} = S_a(T_1,4\%)^{0.77} \cdot S_a(T_2,4\%)^{0.23} \tag{4}$$

$$S_{123} = S_a(T_1,4\%)^{0.71} \cdot S_a(T_2,4\%)^{0.21} \cdot S_a(T_3,4\%)^{0.08}$$

Six IMs, including PGA, PGV, S_a, S^*, S_{12} and S_{123}, are chosen to be compared for the IDA of the building. The IDA curves and logarithm standard deviations are given in Figure 4~9.

Figure 8 IDA curves and dispersion analysis for the IM of S_{12}

(a) θ_{max}- S_{123} curves

(b) $\sigma_{\ln EDP|SI23}$

Figure 9 IDA curves and dispersion analysis for the IM of S_{123}

Table 5 The average of the standard deviation of the conditional logarithm

IM	PGA	PGV	S_a	S^*	S_{12}	S_{123}
Average of logarithm standard deviation of EDP	0.268	0.228	0.264	0.241	0.221	0.209
Compared to S_a	1.02	0.86	1.00	0.91	0.84	0.79

The average of the logarithm standard deviation is listed in Table 5. It can be seen that for peak value-based IMs, PGV is more efficient than PGA. PGV is also better than the one spectral value-based IM, S_a. Among the two spectral value-based IMs, the proposed S_{12} is more efficient than S^*. The average for S_{123} is the smallest, which means S_{123} is the most efficient IM among six IMs. It is concluded that the more modes are considered, the better IM is.

4. CONCLUSIONS

The power of incremental dynamic analysis (IDA) as an analytical method has been paid much attention in the earthquake engineering. Since IDA curves are the relationship between the intensity measure (IM) of ground motions and structural response referred as engineering demand parameter (EDP), it displays large record-to-record variability. This observed dispersion is closely connected to the IM applied. The existing IMs are neither particularly efficient nor sufficient for tall, long-period buildings. A structure-specific IM, named S_{12} or S_{123}, is thus proposed for tall buildings. The IM is defined in the power-laws form, in which the spectral accelerations at major periods are the bottom number and corresponding modal mass participation proportions are the exponent. Accordingly, the high-mode contribution is considered in the proposed IM. A super-tall building is introduced to compare the six IMs, including PGA, PGV, S_a, S^*, S_{12} and S_{123}. The conclusions could be reached as follows.

(1) Even for tall buildings, the IM of S_a (the spectral acceleration at the first period) demonstrates obvious advantage compared with PGA.

(2) PGV is more efficient than PGA as well as one spectral value-based S_a and two spectral value-based S^*. But it is less efficient than the proposed S_{12} and S_{123}.

(3) For the structure-specific IM, the more modes are considered, the more efficient IM is. S_{123} is recommended for the incremental dynamic analysis of tall buildings.

Abstract: Rocking foundations have shown performance advantages that could benefit the seismic performance of structures. Cumulative settlement is one of the primary potential detrimental aspects of rocking foundations. It is well known that permanent deformations, especially settlement, can accumulate with every cycle of rocking of a shallow foundation. New data obtained at UC Davis and the Kyoto University is analyzed with previously collected data to confirm that previously established equations for moment capacity and methods for assessing residual settlement apply to foundations with different shapes, embedment depths and soil types. The ratio of the actual footing area divided by the footing area required to support the vertical loads, A/A_c, and the aspect ratio of the critical contact area B/L_c are correlated to the moment capacity and the magnitude of normalized residual settlement or uplift (s/L) as a function of cumulative rotation. The iterative procedure for calculation of A_c is illustrated. Recent analysis of settlement-rotation data from previous experiments clearly shows a significant influence of footing shape on residual settlement and uplift behavior. For a given cumulative rotation, footing settlement increases as A/A_c decreases and footings with smaller B/L_c ratio, tend to suffer greater normalized settlement or greater normalized uplift than footings with larger B/L_c ratios.

1. INTRODUCTION

Gajan and Kutter (2008), Deng et al. (2011), Hakhamaneshi et al. (2012a&b), Liu et al. (2012), Anastasopoulos et al. (2010), and Pecker and Chatzigogos (2010) and others have indicated that adoption of rocking foundations on competent soils can absorb seismic energy, reduce the demand on the columns and improve the seismic performance of soil-foundation-superstructure systems. If the moment capacity of the footing is designed to be smaller than the moment capacity of the column, footing rocking will occur instead of column hinging. On the other hand, in a conventional fix-based structural configuration, almost all energy will be dissipated through inelastic flexural behavior of the superstructure components, e.g. hinging columns. Foundation rocking behavior effectively transfers the ductility demand from the hinging column to the footing-soil interface. Despite the advantages of rocking over hinging, design codes often favor column hinging over footing rocking. For example, the California Department of Transportation seismic design criteria (Caltrans 2010) states that "foundation components shall be designed to remain essentially elastic when resisting the plastic hinging moments". New Zealand Structure Design Actions (2004) states that "rocking components may be included in the structures, but special studies on the superstructure behaviors shall be mandatorily performed".

2. LITERATURE REVIEW

2.1 Previous Research

The early work of Housner (1963) theoretically illustrated the beneficial self-centering mechanism of a rocking rigid block. Researchers have since incorporated this concept into rigid shear-walls founded on shallow footings, while also foundation capacity mobilization was considered. Bartlett (1976) and Wiessing (1979) conducted a series of 1-g tests and studied the behavior of rocking shallow foundations on clay and sand. Bartlett found that rocking foundations reduce the seismic force on the structure by lengthening its natural period. Wiessing reported a continuous settlement of the foundations during rocking and a progressive rounding of the soil interface with large amplitudes of footing rotation, which led to loss of the contact area due to the softening of the system.

Rosebrook (2001a&b) and Gajan (2003) conducted numerous experiments on shear wall structures supported by rocking shallow foundation and studied the nonlinear load-deformation behavior of the foundation during cyclic

and dynamic loading. They reported that the moment and shear capacity of a rocking shallow footing depends on its geometry, initial vertical static factor of safety and the moment to shear ratio of the applied load. They saw similarities in the load-deformation behavior of rocking shallow footings when subjected to lateral cyclic loading and dynamic base shaking. Deng et al. (2009a,b and 2010) tested models that included column flexibility, column hinges, and soil-footing-column-bridge deck systems. They reported superior seismic performance and stability of bridges supported on rocking rigid foundations as opposed to hinging column systems with rigid foundations.

2.2 Current Research

Previous research efforts have contributed significantly to the development of the idea of nonlinear analysis in performance-based evaluation. One of the limitations of the work done by Bartlett (1976) and Wiessing (1979), however, is that the experiments were conducted at smaller confining stresses and the reduced scale 1-g models tested seem unrealistic and unable to fully capture the nonlinear prototype footing behavior. Previous centrifuge tests have characterized the behavior of rocking foundations on sand, but fewer analyses have been done on the effects of shape of the footing on the rocking behavior of a foundation. In an effort to fill this research gap, a new series of centrifuge tests (the MAHS test series) is being performed to examine the footing rocking behavior on sandy soil, with emphasis on the effect of shape of the footing on the soil-footing interface deformation.

3. CONCEPT OF ROCKING FOUNDATIONS

3.1 Estimation of Critical Contact Length (L_c)

Consider a vertical load (*V*) applied to the center of gravity of the structure as shown in Figure 1. A horizontal load (*H*) is also applied at a height (*h)* above the base of the footing with length of *L* (in the plane of rocking), width of B (perpendicular to the plane of rocking), and area of $A = B \cdot L$. These loads can cause the center (point O in Figure 1) of the footing to rotate (θ), slide horizontally (*u*) and settle (*s*). The soil exerts a resultant force on the footing, which consists of a sliding resistance force (*F),* and a normal force (*R)*. For rigid soil, the sliding is expected to occur first if the applied horizontal force is equal to the frictional resistance of the soil-footing interface and the applied moment about the base of the footing ($M \approx H \cdot h$) is smaller than the resisting moment *(V·L/2)*. At large rotation demands, the $p-\Delta$ moment should also be included in the moment applied at the soil-footing interface. On the other hand, if the horizontal load is applied at a height greater than *L/(2μ)* (where μ is the coefficient of friction), the footing will tip about its corner. For non-rigid soil, as the footing rocks, it does not bear on a sharp corner of the footing. Instead, a minimum contact area, A_c is required to support the vertical loads. The moving of the contact area results in a curve interface, with localized bearing failure apparent near the edges in Figure 1. Rosebrook and Kutter (2001a&b), Gajan and Kutter (2008), Deng and Kutter (2012) and Hakhamaneshi et al. (2012a&b) showed that the amount of settlement during rocking can be correlated to the contact area, the amplitude of footing rotation and the ratio (A/A_c), which is approximately equal to the traditional factor of safety with respect to bearing capacity.

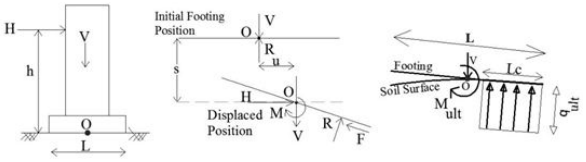

Figure 1 Schematics of a Rocking Footing

The ultimate bearing pressure (q_b) under purely vertical load is characterized by conventional Equation (1):

$$q_b = (s_q \cdot d_q) \cdot q_0 \cdot N_q + 0.5 \cdot (s_\gamma \cdot d_\gamma) \cdot \gamma \cdot B \cdot N_\gamma \quad (1)$$

where N_q and N_γ are bearing capacity factors, d_q and d_γ are depth factors for the q_0 and γ terms; s_q and s_γ are shape factors for the loaded area, B is the width of the shorter side of the soil-footing contact area and q_0 is the soil surcharge pressure and γ is the unit weight of the soil.

Gajan and Kutter (2008) and Deng et al. (2011) showed that for rocking rectangular footings, when they are loaded along the length of the footing, the critical contact length, L_c, is directly related to the critical contact area: $L_c = A_c/B$. The value of L_c represents the minimum length of the footing required to support the vertical load when the soil bearing capacity is fully mobilized on the rectangular contact area. With the knowledge of ultimate bearing capacity (q_b), one can analytically determine L_c by using the conventional equation of $L_c = V/(q_b \cdot B)$. Deng et al. (2011) showed that as L_c becomes the shorter side of the assumed critical contact area, a trial L_c may be plugged into the Equation (1) as B for calculating the bearing capacity of the soil in the contact area (q_{bLc}). Therefore, Equation (1) can be written for the critical contact area as Equation (2a) for $L_c < B$ and Equation (2b) for $L_c \geq B$ (shape factors s_q and s_γ should be updated accordingly).

$$q_{bLc} = (s_q \cdot d_q) \cdot q_0 \cdot N_q + 0.5 \cdot (s_\gamma \cdot d_\gamma) \cdot \gamma \cdot L_c \cdot N_\gamma \quad (2a)$$

$$q_{bLc} = (s_q \cdot d_q) \cdot q_0 \cdot N_q + 0.5 \cdot (s_\gamma \cdot d_\gamma) \cdot \gamma \cdot B \cdot N_\gamma \quad (2b)$$

Under the condition of rocking capacity being fully mobilized, Equation (3) holds as:

$$q_{bLc} \cdot B \cdot L_c = V \quad (3)$$

Since L_c appears in both Equations (2) & (3), iteration may be required to determine L_c.

3.2 Moment Capacity of a Rocking Footing

Gajan and Kutter (2008) examined the relations

between the moment capacity of the footing, net settlement and energy dissipated during footing rocking with various critical contact area ratios *(A/A$_c$)*. Gajan and Kutter (2008) and Deng and Kutter (2012) observed that when the external applied moment approaches the resisting moment capacity of the footing (denoted as $M_{c\text{-}foot}$) in Equation (4), the footing rocking is about to occur.

$$M_{c-foot} = 0.5 \cdot V \cdot L \cdot (1 - A_c / A) \quad (4)$$

Estimation of rocking moment capacity depends on the accuracy of L_c and q_{bLc} which depend on bearing capacity factors N_q and N_γ , shape factor (s_q) and depth factor (d_q) which are all functions of the soil's friction angle. Therefore, in order to obtain a reasonable estimate of moment capacity, we need to have an accurate measure of the friction angle. As suggested by Deng and Kutter (2012), an initial friction angle is assumed which will determine the bearing capacity, shape and depth factors. Ultimate bearing pressure (q_b) is calculated using Equation (1) and the corresponding representative mean confining stress of the sand under the footing (σ_{mp}) is calculated using De Beer (1965) method as shown in Equation (5):

$$\sigma_{mp} = 0.25 \cdot (q_b + 3q_0) \cdot [(1 + \tan^2\phi) \cdot (1 + \sin\phi)]^{-1} \quad (5)$$

Friction angle is calculated using Bolton's dilatancy relationships (1986) as shown in Equation (6). This value is compared with the initial estimate until a match is achieved.

$$\phi_{tc} = \phi_{cv} + 3 \cdot [D_r \cdot (10 - \ln(100\sigma_{mp} / 100kPa) - 1] \cdot \pi / 180 \quad (6)$$

In this equation, D_r is the relative density of sand and ϕ_{cv} is the constant volume friction angle of the sand. Iteration is done until an accurate measure of friction angle is achieved. Critical contact length (L_c), bearing capacity of the soil in the contact area (q_{bLc}) and theoretical rocking moment capacity ($M_{c\text{-}foot}$) can now be calculated accurately using Equations (2)-(4).

4. TEST PROGRAM

4.1 Dynamic Tests on Toyoura Sand (TAM Test)

A series of dynamic centrifuge tests were conducted using the geotechnical centrifuge at Disaster Prevention Research Institute, Kyoto University. Two different soil-foundation-superstructure models were dynamically tested (three different input motions for each structure) at a centrifugal acceleration of 50g. Tamura et. al (2012) explain the details of the models, test setup, time histories of the soil and structure response and the moment-rotation hysteretic behavior of the footings. However, they did not provide a theoretical value for the moment capacity of the footings. Table 1 summarizes the properties of the soil and the footings needed to perform the iteration explained in Section 3 to obtain a theoretical estimate of the rocking moment capacity. All the properties presented in this paper are in model scale. The scaling laws for centrifuge tests were described in Kutter (1995). In this table, footing properties are as follows: "L" is the length of the footing parallel to the direction of shaking, "B" is the width of the footing perpendicular to the direction of shaking, "t" is the thickness of the footing, "D" represents the initial embedment and "V" includes the total weight (footing plus soil above the footing and superstructure), supported by the footing. Sand profile properties are the maximum and minimum void ratio (e-max and e-min) and the relative density of the sand (D_r).

Table 1 Soil & Footing properties in TAM test series (model scale)

Property	High Rise (H)	Low Rise (L)
L (mm)	50	50
B (mm)	80	80
t (mm)	10	10
D (mm)	8	8
V (kN)	0.707	0.701
Height (mm)	149	92
Sand	Toyoura	Toyoura
e-max	0.997	0.997
e-min	0.597	0.597
D_r (%)	90	90

Table 2 summarizes the results of the iteration explained in section 3 which is further used to obtain the theoretical rocking moment capacity as shown in Equation (4).

Table 2 Summary of the iteration results in TAM test

Quantity	High Rise	Low Rise
Φ(°)	43.1	43.1
q_b (kPa)	3114	3114
FS_v	17.6	17.8
L_c (mm)	6	5.73
A/A_c	8.89	8.75
$M_{c\text{-}foot}$ (N.m)	15.7	15.4

4.2 Slow Cyclic Tests on Nevada Sand (MAHS Test)

A series of lateral slow cyclic centrifuge tests were conducted at the center for geotechnical modeling at UC Davis using the 1m radius (Schaevitz) centrifuge. Three different soil-foundation-superstructure models were tested at a centrifugal acceleration of 35g. A stiff shear-wall

structure was made out of steel and tested under slow lateral cyclic displacement controlled loading for each footing. The loading protocol involved application of 3 cycles of constant amplitude, with amplitudes doubled to cause the footing rotate from 0.1% to 6%. Figure 2 shows the applied sinusoidal displacement time history to the structures. All the rotations reported in this paper are actually the tangent of the rotation angle (i.e. 1% rotation indicates that the tangent of the rotation angle is 0.01).

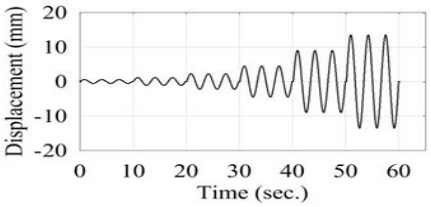

Figure 2 Displacement-controlled time history of the actuator for lateral slow cyclic tests

The properties of the footings and soil can be found in Table 3. The Long-Narrow (LN) footing has a longer length in the direction of cycling than the Short-Wide (SW) footing. On the other hand, the Short-Wide footing has a longer width, perpendicular to the direction of cycling than the other two footings. The Very-Long-Narrow (VLN) footing has the largest length and the smallest width.

Table 3 Soil & Footing properties in MAHS test series

Soil/Footing Props.	Long Narrow (LN)	Short Wide (SW)	Very Long Narrow (VLN)
L (mm)	150	110	210
B (mm)	90	170	30
t (mm)	31.75	31.75	31.75
D (mm)	31.75	31.75	31.75
V (kN)	2.841	3.931	1.435
Sand	Nevada	Nevada	Nevada
e-max	0.887	0.887	0.887
e-min	0.511	0.511	0.511
D_r (%)	82	82	80

Table 4 summarizes the results of the iteration process explained in Section 3 which is further used to obtain the theoretical rocking moment capacity of these three footings, using Equation (4).

Table 4 Summary of the iteration results in MAHS test

Quantity	Long Narrow	Short Wide	Very Long Narrow
$\Phi(^\circ)$	37.8	37.6	38.5
q_b (kPa)	2460	2619	1826
FS_v	11.7	12.4	8.7
L_c (mm)	17.1	12.7	21.4
A/A_c	8.8	8.7	9.8
$M_{c\text{-}foot}$ (N.m)	188.8	191.3	135.3

5. LOAD-DEFORMATION PLOTS

5.1 Dynamic Tests on Toyoura Sand (TAM Test)

Figure 3 shows the moment vs. rotation relationships measured in the dynamic tests on the footings with different A/A_c ratios, as shown in Table 1. Tamura et al. (2012) plotted these graphs without the theoretical estimate of the rocking moment capacity. The critical contact length (L_c) is being calculated using the iteration process in Section 3, and rocking moment capacity of these footings is calculated and plotted below. The rocking moment is normalized by *VL/2* which represents moment capacity for rocking on a rigid interface (A/A_c = infinity in Equation (4)). The time history of the three different applied ground motions are summarized in Tamura et al. (2012).

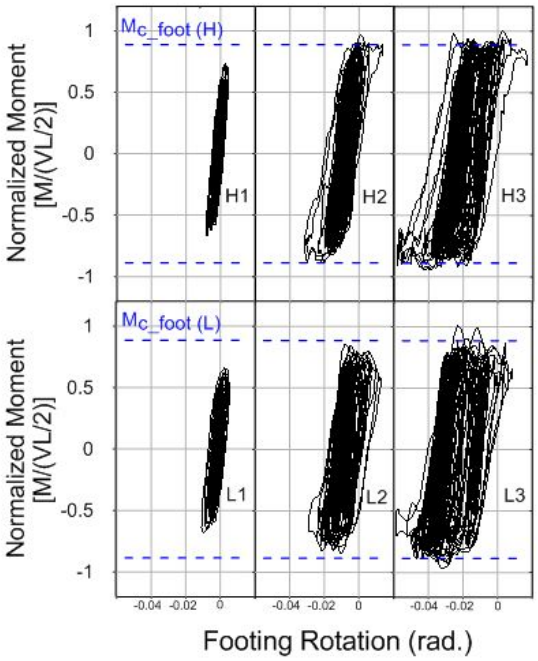

Figure 3 Moment-Rotation plots of the High-rise (H) and Low-rise (L) structures for three different ground motions

For the cases shown in Figure 3 above, the rocking moment capacity of the footing is reached initially at rotation

amplitude of about 1%. The moment vs. rotation behavior of the footing shows a stiff response for rotations less than about 0.5%. As the cumulative rotation increases, this relationship becomes nonlinear and foundation soil's rotational stiffness degrades. This nonlinearity is affected by the rounding of the soil beneath the rocking footing and the local bearing failure along the moving contact interface.

5.2 Slow Cyclic Tests on Nevada Sand (MAHS Test)

The moment-rotation behavior of the footings in Table 3 are summarized in Figure 4 below. As is the case in Figure 3 also, for rotations smaller than about 0.5%, the moment-rotation plots show a stiff response, but as the amplitude of rotation increases, the moment-rotation plots show a nonlinear behavior where the rotational stiffness degrades as the amplitude of oscillation increases. The rocking moment capacity is reached at about 1.3% amplitude of rotation. The moment capacity undergoes very small degradation at very large amplitudes of rotations (5-6%). Even for large amplitudes of rotation, the footing continues to rock with minimal degradation in capacity. The tendency is very similar to those reported by Deng and Kutter (2012) and Gajan and Kutter (2008). In both scenarios the moment capacity is preserved even at large rotation.

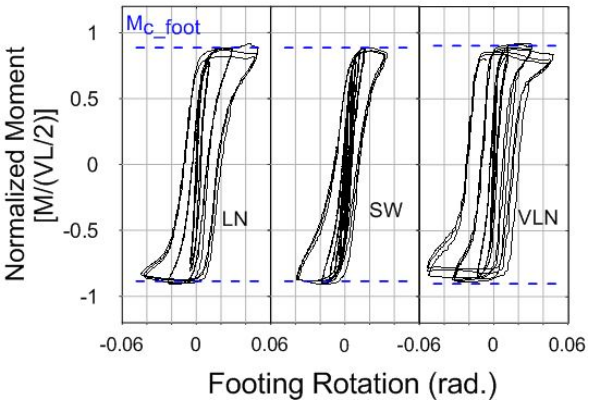

Figure 4 Moment-Rotation Plots of the Footings shown in Table 3 (MAHS Test)

The method explained in Section 3 regarding estimation of L_c by iteration seems to provide us with a relatively accurate measure of the rocking moment capacity in the scenarios shown in Figures 3 and 4.

6. FOOTING SETTLEMENT CORRELATIONS

6.1 Effect of A/A_c on the Settlement and Uplift

As rocking proceeds, we expect the soil beneath the foundation to lose its flat shape and become rounded at the edges. This leads to a reduction in the contact area between the footing and the foundation and a progressive bearing failure causes the foundation to settle. Gajan at al. (2008) used the data from centrifuge tests mainly on sand, to relate the settlement of the foundation per cycle of footing rotation to the amplitude of rotation. The results were grouped in categories based on the A/A_c ratio. Deng and Kutter (2012) added data on sand with larger values of A/A_c (values more typical of bridge foundations on granular soils). They noted that for very large rotations and large A/A_c values, the footing tended to have a residual uplift associated with sand falling into the gap under the footing as it rocked. Instead of considering settlement on a cycle by cycle basis as suggested by Gajan and Kutter (2008), Deng and Kutter (2012) and Hakhamaneshi et al. (2012a&b) suggested correlating the cumulative footing rotation (θ_{cum}) to the normalized footing settlement (s/L) and further extended the correlation to include foundations on both sand and clay. The footing's cumulative rotation (θ_{cum}) is obtained by summing up the absolute value of all the local maxima and minima ($extrema_i$) for which the amplitude exceeds a threshold rotation (θ_t is set empirically at 1 mrad in this study). Rotations smaller than the threshold value are assumed to cause an elastic response to the rocking without leading to any residual settlement or uplift. In this study, the procedure proposed by (Hakhamaneshi et al. (2012b) and Deng and Kutter (2012) for obtaining the cumulative rotation has been modified by subtracting the elastic rotation for each cycle by introducing the $-N\cdot\theta_t$ in Equation (7). Figure 5 illustrates the determination of extrema and the rotation threshold used to determine footing cumulative rotation.

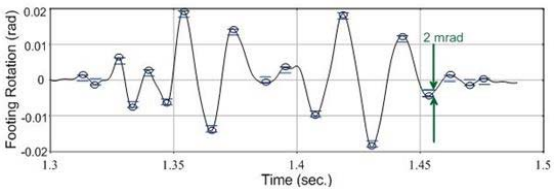

Figure 5 Schematic of illustrating thresholding procedure to obtain the Cumulative Rotation of a Rocking Footing

$$\theta_{cum} = \Sigma_{i=1}^{N} \left| extrema_i \right| - (N \cdot 0.001) \; for \; \left| extrema_i - extrema_{i-1} \right| \geq 0.002 rad. \quad (7)$$

The data from the TAM and MAHS test series on Toyoura and Nevada sand are added to the aforementioned datasets on sand (Gajan and Kutter (2008) and Deng and Kutter (2012)) and clay (Rosebrook and Kutter (2001a&b) and Hakhamaneshi et al. (2012a)). Table 5 summarizes the scope of parameters varied during these experiments and provides us the ranges of the footing properties being tested. In this table, "Test ID" specifies the name of each experiment test series; "Loading" differentiates whether the event was a Slow Cyclic (SC) test or Dynamic shaking (Dyn) test and "Soil" type specifies whether the soil profile was made out of Sand or Clay. The letter inside the parenthesis differentiates the type of sand used (Nevada or Toyoura). "A" is the area of the footing and equal to $B \cdot L$, where as illustrated in Figure 6, "B" is the width of the footing parallel to the axis of rocking and "L" is the length of the footing in the plane of rocking. A_c is the critical contact area of the footing and is equal to $B \cdot L_c$ where L_c is determined through the iteration process explained in Section 3.

Table 5 Details of the data points gathered from the past and current centrifuge tests

Test ID	Soil	Loading	A/A_c	B/L_c
KRR	Sand (N)	SC	2-4	0.72-2
LJD	Sand (N)	SC/Dyn	8-30	5-30
MAH01	Clay	SC/Dyn	1.2-11	2.5-18
SSG	Sand (N)	SC/Dyn	2.2-15.9	0.5-4
MAHS	Sand (N)	SC	8.7-9.8	1.4-13.4
TAM	Sand (T)	Dyn	8.7-8.9	13-14

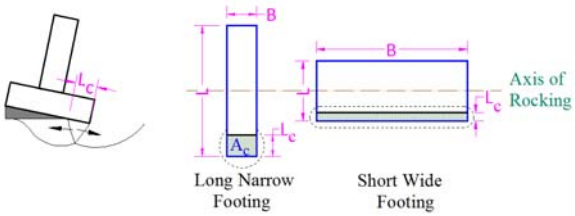

Figure 6 Bearing failure mechanism in footings with different aspect ratios

Figure 7 plots the normalized cumulative residual settlement with respect to the updated footing cumulative rotation for many events of the test series described in Table 5. The current data points are differentiated from the previous experiments by not being color filled. A conservative envelope, indicated by the straight lines in the graph encloses most of the data points from A/A_c groups. These boundaries set previously by Deng and Kutter (2012) seem to be conservative for the current data as the settlements for the same A/A_c ratio seem to be smaller. It is promising that the current data points do not exceed these boundaries and is consistent with the previous data. The similarity in the relationships for sand (Nevada and Toyoura) and clay indicates that the effect of changing soil type can be reasonably accounted for through the effect on A/A_c. From Figure 7, it is apparent that if A/A_c>8, the settlement is always smaller than 1% of the length of the foundation even at cumulative footing rotations up to 0.3 radians. Furthermore, we suggest that such small settlements would likely be considered to be acceptable performance during a major seismic event.

For design purposes, Deng and Kutter (2012) proposed a procedure for estimating the footing's cumulative rotation of footings in bridge structure. They suggested that the design lateral displacement of bridge deck (D_d) may be obtained from the spectral displacement, given the period of the structure. The design amplitude of footing rotation (d) is estimated by dividing the design displacement of the deck by the column height (H_c). Depending on the magnitude of an earthquake, it may be reasonable to assume that foundation undergoes two full cycles of rotation with the design amplitude, so Equation (9) is used to correlate the design rotation to the dynamic settlement. Note that during two full cycles of rotation, the cumulative rotation calculated using Equation (8) would be four times the half amplitude of rotation. The constant "*const*" in Equations (8) and (9) is the slope of the appropriate line such as those indicated in Figure 7 (Deng and Kutter 2012), depending on the static factor of safety with respect to bearing capacity (expressed in terms of footing areas A/A_c) and the footing shape (accounted for by the ratio B/L_c).

$$s = const \cdot L \cdot \theta_{cum} \quad (8)$$

$$s = 4 \cdot const \cdot L \cdot d \quad (9)$$

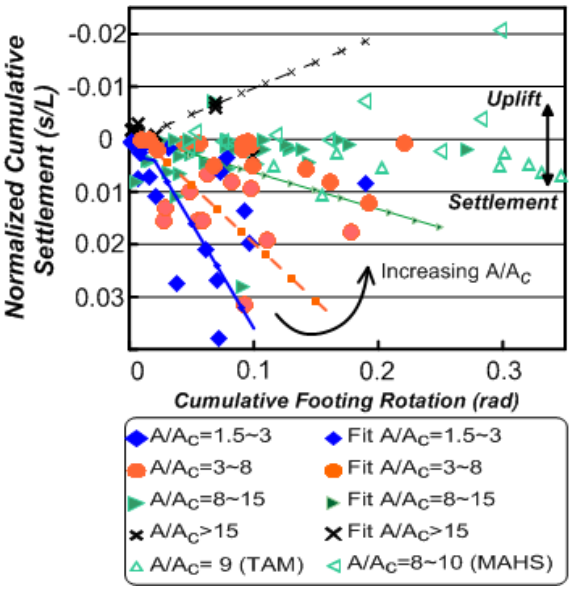

Figure 7 Cumulative normalized residual settlement-cumulative footing rotation grouped into different A/A_c ratios

6.2 Effect of B/L_c on Residual Settlement and Uplift

The aspect ratio (B/L_c) is introduced to characterize the shape of the critical contact area. A footing with high aspect ratio would be like the Short Wide footing in Figure 6. For a footing with large aspect ratio of the critical contact area, the soil deformations associated with the localized bearing failure would be expected to be primarily in the plane of rotation as indicated by the arrows in Figure 6; for this case, perhaps about half of the soil that is displaced due to bearing failure of the strip-shaped loaded area gets pushed back under the footing, and the other half gets pushed away from the footing, accounting for settlement. As the footing becomes longer and narrower (LN & VLN), the contact shape could become square, at which point out of plane soil displacements associated with bearing failure become significant and a smaller fraction of the displaced soil would be pushed back into the gap under the footing. If other factors (e.g., A/A_c) are held constant while varying footing shape, due to a greater proportion of soil being pushed away from the footing, one may expect greater settlements for rocking of long narrow footings than for short wide footings.

To isolate the effect of footing shape, Hakhamaneshi et al. (2012b) grouped the data in Figure 7 based on their critical contact area ratio (A/A_c) and for each group, they divided the data into different subcategories based on their aspect ratio. They reported a consistent trend indicating that as B/L_c ratio increased, normalized settlement (s/L) decreased. However, the majority of the footings they studied did not experience residual uplift and the effect of aspect ratio was mainly studied in cases where the foundation settled. The MAHS data series allow us to study the effect of B/L_c ratio on the uplift of the foundations also. These footings were embedded while having a large A/A_c ratio. As these footings rock, a portion of the surrounding sand falls into the gap (created during rocking) below the footing, and the center of the footing will uplift. At smaller amplitudes of rotation we expect small amount of sand to fall in to the gap, having minimal effects on the uplift of the foundation. However, at larger amplitudes, considerable amount of sand falls in to the gap which will overcome the partial settlements due to the localized bearing failure.

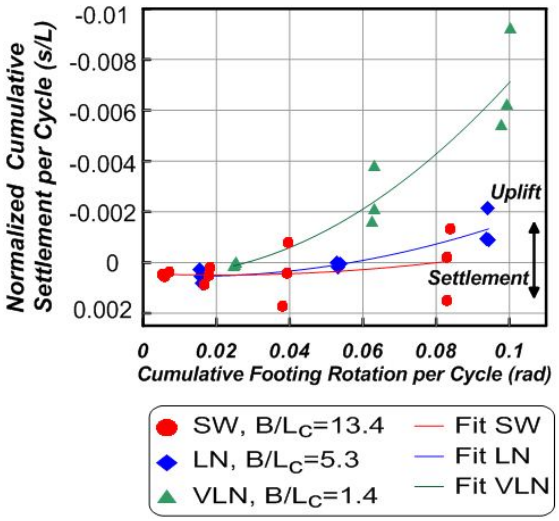

Figure 8 Normalized cumulative footing rotation per cycle-normalized cumulative (residual) settlement per cycle relation for MAHS footings ($8.5 < A/A_c < 10$)

Figure 8 plots the normalized cyclic cumulative settlement versus cyclic cumulative footing rotation of the three footings tested in the MAHS series. The Very-Long-Narrow (VLN) footing seems to undergo the largest uplift. For this footing, the aspect ratio (B/L_c) is close to unity, meaning that the critical contact area becomes like a square shape and sand can fall into the gap from both in-plane and out-of-plane of rocking. At large rotation demands, the VLN footing seems to uplift almost 3-4 times the Long-Narrow (LN) and Short-Wide (SW) footings. At small rotation demands, the VLN footing seems not to uplift considerably more than the LN and SW footings, but all of the settlements are quite small.

7. CONCLUSIONS

Researchers at UC Davis (e.g., Rosebrook and Kutter (2001a&b), Gajan et al. (2005), Deng et al. (2011), Hakhamaneshi et al. (2012a&b)) and elsewhere have shown that moment capacity of a rocking footing on sandy or clayey soil suffers little degradation during cyclic loading and the capacity can be accurately predicted as long as the axial load on the footing, the sizes of the foundations, and the term ($1\text{-}A_c/A$) in equation (4), can be determined. An iterative calculation procedure to determine the critical contact area, A_c, previously described by Deng and Kutter (2012), is illustrated in the present paper.

The previous rocking tests at Davis included both dynamic shaking and slow cyclic loading and used one type of sand (dry Nevada sand), and two types of cohesive soil (Yolo Loam, a clayey silt, and San Francisco Bay Mud, a high plasticity clay). For the present paper, new data is introduced to extend the validation for different soil types and different footing shapes: Data from Tamura et al. (2012) involved dynamic shaking using Toyoura sand, and data from the new MAHS test series was added to study rocking of rectangular footings of different aspect ratio. It was confirmed that rocking moment capacity shown in Equation (4) holds for rectangular footings on sandy or clayey soil, and that it is insensitive to loading type (cyclic or dynamic), especially if A/A_c is large. The effect of changing soil type and footing shape is reasonably accounted for through the effect on A/A_c.

The effect of footing shape on the normalized settlement (s/L) and uplift (-s/L) of the rocking footings is studied through the aspect ratio of the critical contact area (B/L_c). Hakhamaneshi et al. (2012b) found that under the same factor of safety (A/A_c), wide rectangular rocking footings (with higher B/L_c) settle less than narrow rocking footings. They reported that due to less lateral confinement around the rocking edge for narrow footings and the three-dimensional failure mechanism, a larger fraction of soil is pushed out from under the footing, hence larger normalized settlements (s/L) are expected for narrow footings. They also reported that for wide footings, lateral confinement reduces out-of-plane soil displacements and settlements. They did not however describe the effect of aspect ratio on the residual uplift of rocking footings.

The results of the new MAHS test series show that for footings with large A/Ac embedded in sand, that rocking generally results in residual uplift. This residual uplift could be attributed to sand falling into the gap as the footing rocks. Based on the findings of this paper, the magnitude of normalized residual uplift (-s/L) is greater for footings with small aspect ratio of the critical contact area (B/L_c), especially at large amplitudes of rotation. This increased residual uplift for narrow footings may be attributed to the fact that sand can fall into the gap from the sides of the footing as well as the end of the footing.

In summary, for footings on sand, normalized residual settlement occurs for A/A_c less than about ten and the magnitude of settlement increases as A/A_c decreases. For

embedded footings in sand, if A/A_c is greater than ten, normalized residual uplift may result. For a given cumulative rotation, the magnitudes of both residual normalized settlement or residual normalized uplift increase as B/L_c decreases.

Abstract: This study investigates the response of base isolated structures considering inelastic behavior of the superstructure under earthquake excitations. The objective is to clearly show the influence of superstructure yielding on the response of the structure and to check the feasibility of applying steady state approach to the estimation of maximum displacement. In this study, a 5-story base isolated structure is idealized as a 2DOF model. The superstructure is assumed to have elastoplastic behavior while the isolation system is viscoelastic with various combinations of isolation system periods and damping ratios. Results indicate that superstructure yielding significantly increases the maximum superstructure displacement but has only a minor effect on the isolation level response. Estimation of the maximum response is based on the steady state response to harmonic excitation. An equivalent viscoelastic SDOF system is derived by treating the elastoplastic superstructure as an equivalent viscoelastic element. The maximum displacement can be estimated from earthquake response spectrum and the separated to the superstructure and isolation system displacements. The estimation shows good agreement with results from response history analysis.

1. INTRODUCTION

In recent years base isolation has become increasingly used as an effective design to mitigate earthquake damage. Many types of structures have been built using this approach. The idea behind the concept of base isolation is quite simple. A layer of horizontally flexible elements called isolators is added between the structure above and its base, thereby decoupling the building from ground motions. For low and middle rise building that vibration period is short, base isolation greatly elongates the period of the structures out from predominant period of general earthquakes and reduce seismic demand.

The expected behavior of base isolated structure is schematically shown as in Figure 1(a). Large displacement is concentrated at the isolation level and the structure above is in the elastic range. Previous studies on base isolated structures have primarily focused on this case. However, for an earthquake greater than the design basis, insufficient seismic gap may cause pounding, as shown in Figure 1(b), which can causes high impact forces and significant damage especially for the acceleration-sensitive components. On the other hand, yielding of superstructure may occur as in Figure 1(c) and affect the response behavior.

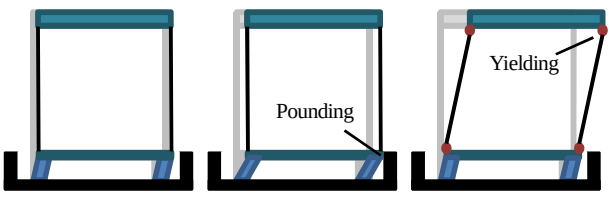

Figure 1 Possible mode of behavior of base isolated structures

Designed according to modern seismic provisions, base isolated structures are required to remain essentially elastic in the expected Design Basis Earthquake (DBE). Additionally, a separation distance must be provided to accommodate expected displacement in a Maximum Considered Earthquake (MCE). Therefore, yielding of superstructure is supposed to occur before pounding with surrounding walls. As yielding happens, reduction of stiffness allows superstructure to take part of the energy. As a result, the base ceases to move further, hence, pounding is unexpected. However, little consideration is given to this situation. Therefore, objective of this study is to investigate the response of base isolated structure having nonlinear behavior of superstructure. The effects of yielding of superstructure on the maximum displacement of superstructure and isolation level will be explained. Moreover, some theoretical considerations to the estimation of maximum displacement of the base isolated structure based on steady state response assumption will be described to check the feasibility of applying steady state approach to the estimation of the response under actual ground motion. This is to provide an effective tool for practice engineers in the design of base isolated structures.

2. TIME HISTORY ANALYSIS

2.1 Analysis model

In this study, a 5-story base isolated structure is idealized as a 2DOF model as shown in Figure 2. Assume equal floor masses with one additional isolation level, the

ratio between base mass m_b and superstructure mass m_s can be expressed as

$$\frac{m_b}{m_s} = \frac{1}{N} = 0.2 \tag{1}$$

The isolation system is assumed to have viscoelastic behavior. Given isolation period T_b and isolation damping ratio ζ_b, isolation system stiffness k_b and damping coefficient c_b are computed as in the following equations:

$$k_b = (m_s + m_b)\frac{4\pi^2}{T_b^2} \qquad c_b = \frac{4\pi\zeta_b}{T_b}(m_s + m_b) \tag{2}$$

The superstructure is characterized as an elastoplastic element having elastic stiffness k_{so}, damping coefficient c_{so}, superstructure yield strength f_{sy}, and post-yield stiffness ratio p. For a given superstructure elastic period T_{so}, superstructure damping ratio ζ_{so}, we can define the elastic properties of the superstructure as

$$k_{so} = m_s \frac{4\pi^2}{T_{so}^2} \qquad c_{so} = \frac{4\pi\zeta_{so}}{T_{so}} m_s \tag{3}$$

To avoid scatterness of the response data, superstructure yield strength is varied based on the maximum elastic superstructure force f_{se} for each particular ground motion. Given a strength reduction factor R, superstructure yield strength f_{sy} is computed based on the definitions as follows:

$$R = \frac{f_{se}}{f_{sy}} \tag{4}$$

Given the parameters mentioned above, time history analyses are able to conduct. Note that the same R gives different values of superstructure yield strength for different combinations of T_b, ζ_b, T_{so}, ζ_{so} and ground motion depending on the elastic responses. Responses considered in this study are the maximum total displacement of the system u_o, and the maximum superstructure and isolation system displacement u_{so} and u_{bo}, respectively.

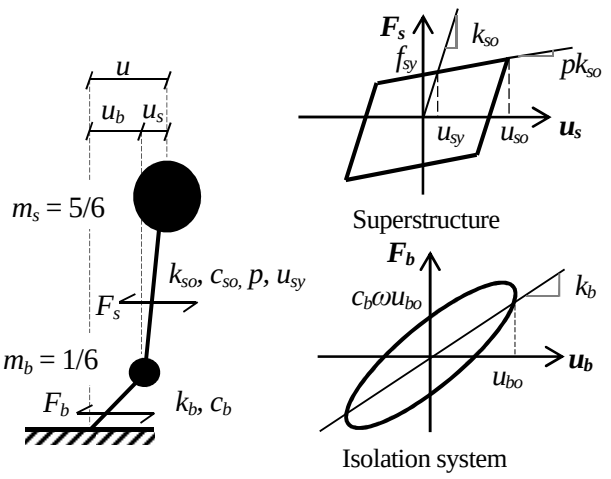

Figure 2 Idealization of base isolated structures

The SAC suite of ground motions for the Maximum Considered Earthquake (MCE) level for the Los Angeles area, LA21-LA40, is used. Following modern US building code provisions, the superstructure is expected to remain elastic for the expected Design Basis Earthquake (DBE), an event whose response spectrum is 2/3 of the MCE (McGuire 2004, Somerville et al. 1998). Thus, the structure designed according to the code is represented by the model having R = 1.5.

2.2 Trends of the maximum response

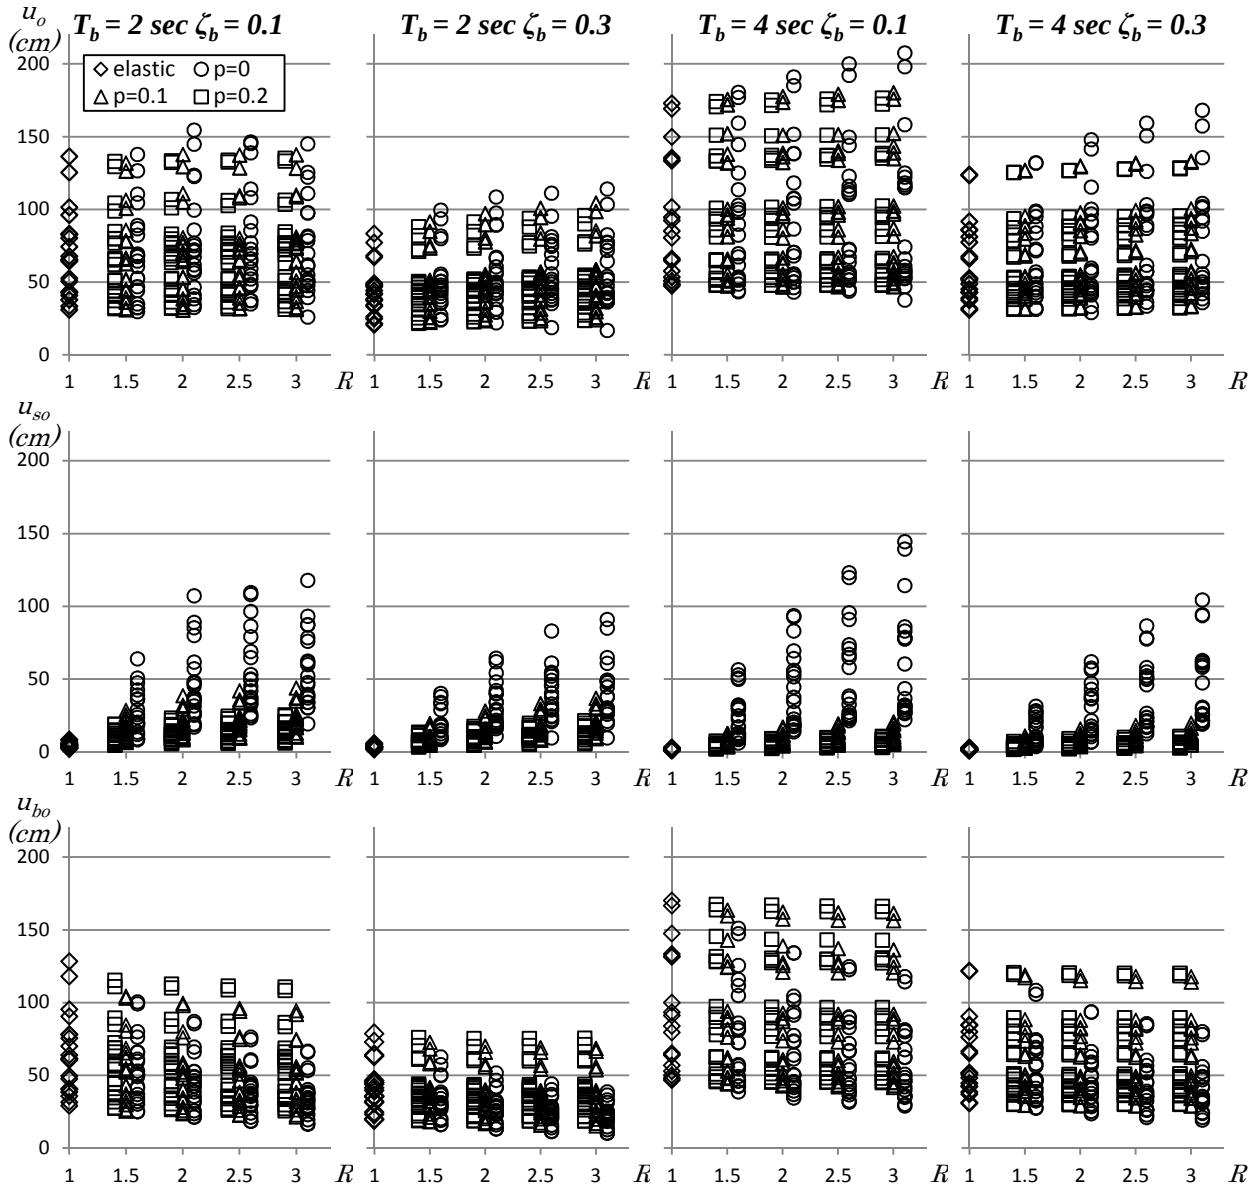
Figure 3 shows the maximum displacement observed from time history model. Four isolation systems are considered, each column in the figure represents each isolation system including the system having isolation system period T_b equals to 2 and 4 sec., and isolation system damping ratio ζ_b of 0.10 and 0.30. In this study, Superstructure elastic period is fixed at the approximation by the formula $T_s = 0.1N$ where N represents number of stories, therefore T_s = 0.5 sec. Superstructure damping ratio ζ_s is assumed as 0.02. Top, middle, and bottom lines present total, superstructure, and isolation system displacements, respectively. In each graph, the x-axis represents superstructure strength reduction ratio R equals to 1, 1.5, 2, 2.5, and 3.

When R = 1 that is the superstructure is elastic, 20 diamond data points in each graph represent the maximum response from time history model subjected to 20 SAC ground motions. Obviously, longer isolation system period significantly increases the maximum total and isolation system displacement but not much affects the superstructure displacement. However, larger damping results in a minor reduction of all the response.

Considering yielding of superstructure, 3 types of data points – circle, triangular and square – represents post-yield stiffness ratio p is 0, 0.1, and 0.2, respectively for each R. When p = 0, yielding significantly affects the maximum response. As R increases, superstructure peak displacement increases and isolation system peak displacement reduces. This is because yielding of superstructure takes a large portion of energy input so that the base ceased to move further. However, as p increases, the effect is less obvious. When p = 0.2, total and isolation system displacement is about the same for each isolation system properties and not much affected by yielding of superstructure.

3. ESTIMATION OF MAXIMUM DISPLACEMENT

Estimation of the maximum response is done by converting the elastoplastic superstructure to an equivalent viscoelastic system having equivalent superstructure stiffness k_s and equivalent superstructure damping coefficient c_s as in Figure 4(a). With these obtained equivalent viscoelastic properties of superstructure, together with the viscoelastic isolation system and ignoring isolation system mass m_b, we can idealize base isolated structures as a



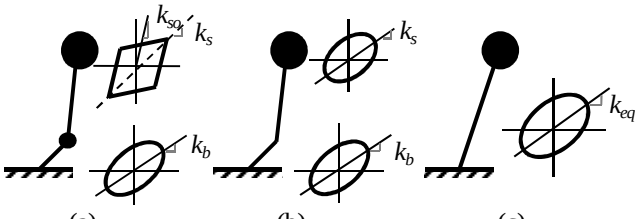


Figure 3 Maximum responses from time history model of base isolated structures under 20 SAC ground motions

system having two viscoelastic springs connected in series, as shown in Figure 4(b). In this way, we can combine the system into a SDOF system having the system stiffness k_{eq} and damping coefficient c_{eq} (Figure 4(c)), in which the peak displacement u_o can be estimated from the elastic response spectrum and then separated to the maximum superstructure and isolation level displacement.

(a) (b) (c)

Figure 4 Equivalent system representations

3.1 Equivalent viscoelastic superstructure

To address the elastoplastic behavior of superstructure, an equivalent viscoelastic system is developed to have equal maximum deformation and energy dissipation. Equivalent superstructure stiffness $k_s(\mu)$ is geometrically defined as a function of excitation frequency ω and ductility demand $\mu = u_{so}/u_{sy}$ as follows (Kasai and Kawanabe 2005):

$$k_s(\mu) = k_{so}\left(\frac{1+p\mu-p}{\mu}\right) \tag{5}$$

The equivalent superstructure damping coefficient $c_S(\omega,\mu)$ is defined as

$$c_s(\omega,\mu) = \frac{E_D(\omega,\mu)}{\pi\omega u_{so}^{\ 2}} = c_{so} + \frac{4}{\pi}\frac{k_{so}}{\omega}\frac{(\mu-1)(1-p)}{\mu^2} \tag{6}$$

3.2 Equivalent system

Consider a base isolated structure as a system having two viscoelastic springs connected in series subjected to a harmonic excitation with the excitation frequency ω (Figure 4b). For a given k_b, c_b, k_s, and c_s, complex stiffness of superstructure and isolation system can be defined as

$$K_b^* = k_b + c_b\omega i \qquad K_s^* = k_s + c_s\omega i \tag{7}$$

We can combine those two springs in the system into an equivalent viscoelastic spring with complex stiffness as follows (Kasai and Fu 1995):

$$K_{eq}^* = \frac{K_s^* K_b^*}{K_s^* + K_b^*} = K'_{eq}\left(1+\eta_{eq} i\right) \tag{8}$$

Where

$$K'_{eq} = \frac{\left(k_s+k_b\right)\left(k_s k_b - c_s c_b \omega^2\right)+\left(c_s+c_b\right)\left(k_s c_b + k_b c_s\right)\omega^2}{\left(k_s+k_b\right)^2+\left(c_s+c_b\right)^2\omega^2} \tag{9}$$

$$\eta_{eq} = \frac{\left(k_s+k_b\right)\left(k_s c_b + k_b c_s\right)\omega - \left(c_s+c_b\right)\left(k_s k_b - c_s c_b \omega^2\right)\omega}{\left(k_s+k_b\right)\left(k_s k_b - c_s c_b \omega^2\right)+\left(c_s+c_b\right)\left(k_s c_b + k_b c_s\right)\omega^2} \tag{10}$$

Then, equivalent frequency ω_{eq} of the whole structure is defined as

$$\omega_{eq} = \sqrt{\frac{K'_{eq}}{m}} \tag{11}$$

This may be written in form of equivalent period T_{eq}

$$T_{eq} = \frac{2\pi}{\omega_{eq}} \tag{12}$$

And equivalent damping ratio ζ_{eq} of the whole structure is

$$\zeta_{eq} = \frac{E_d}{4\pi E_s}\frac{\omega_{eq}}{\omega} = \frac{\pi c_{eq}\omega u_o^{\,2}}{4\pi\left(\frac{1}{2}\pi k_{eq} u_o^{\,2}\right)}\frac{\omega_{eq}}{\omega} = \frac{\eta_{eq}}{2}\frac{\omega_{eq}}{\omega} \tag{13}$$

However, k_s is a function of ductility demand μ and c_s is a function of ductility demand μ and excitation frequency ω. Therefore, to estimate the equivalent period and damping ratio of the structure, we have to assume a value of μ. Next, assuming $\omega = \omega_{eq}$, we can estimate the equivalent superstructure stiffness and system stiffness as the equations described above, and the maximum total displacement u_o from elastic response spectrum of ground motion in use, $S_d(T_{eq},\zeta_{eq})$. Then, the maximum superstructure displacement u_{so} and the maximum isolation level displacement u_{bo} can be estimated using

$$\frac{u_{so}}{u_o} = \frac{\left|K_{eq}^*\right|}{\left|K_s^*\right|} \qquad \frac{u_{bo}}{u_o} = \frac{\left|K_{eq}^*\right|}{\left|K_b^*\right|} \tag{14}$$

Compare with the ductility demand firstly assumed and do iterations until the relation $u_{so} = \mu u_{sy}$ is satisfied.

3.3 Estimation result

Figure 5 and 6 describe the accuracy of the estimation result. Comparison between the maximum displacement observed from time history model (x-axis) and the estimation response (y-axis) is presented. In Figure 5, superstructure is elastic with superstructure period T_{so} = 0.5 sec and superstructure damping ratio ζ_{so} = 0.02. Three graphs present total, superstructure, and isolation system maximum displacement, from left. In each graph, 4 types of data point represent 4 isolation systems including T_b = 2 and 4 sec with ζ_b = 0.1 and 0.3.

Average of the maximum response from time history model subjected to 20 SAC ground motions, together with the coefficient m of linear relation, $y_i = mx_i$, using least square method to best-fit the data is presented in Table 1. The estimation gets along well with the response observed from the model. However, an increase in damping ratio results in higher scatterness in the estimation.

Table 1 Estimation of the response of base isolated structure having elastic superstructure

T_b	ζ_b	u_o			u_{so}		
		$\bar{x}$	m	R^2	$\bar{x}$	m	R^2
2	0.1	68.72	1.012	0.976	4.240	0.986	0.973
	0.3	44.50	1.06	0.885	3.346	0.959	0.783
4	0.1	92.54	0.987	0.977	1.523	0.948	0.972
	0.3	63.91	0.955	0.906	1.482	0.744	0.721

To evaluate the estimation for the system having elastoplastic superstructure, Figure 6 shows the maximum displacement from the estimation compared with time history results. Each column represents each of the four isolation system considered. In each graph, each data point presents each superstructure post-yield stiffness ratio p = 0, 0.1, and 0.2. For each p, 80 points if shown representing the structure having superstructure strength reduction factor R = 1.5, 2, 2.5, and 3 subjected to 20 SAC ground motions.

The estimated total displacement u_o and isolation system displacement u_{bo} match well even when superstructure is considered as elastoplastic. However, a reduction of post-yield stiffness reduces accuracy of the estimation. Superstructure maximum displacement is underestimated, especially when p is reduced to 0. This may be explained as u_{so} is directly sensitive to the equivalent superstructure stiffness k_s and damping coefficient c_s (see Eq.(14)) which is defined from the steady state assumption in which the maximum displacement should be stable. But

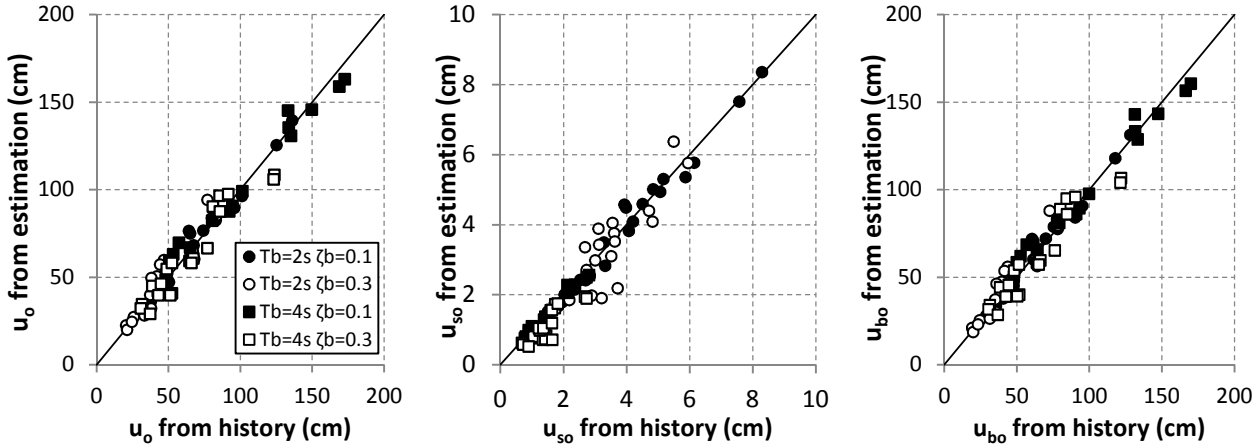

Figure 5 The estimated maximum displacement compare with time history response of base isolated structure having elastic superstructure

Table 2 Estimation of the response of base isolated structure having elastoplastic superstructure

T_b	ζ_b	u_o						u_{so}					
		$p = 0$		$p = 0.1$		$p = 0.2$		$p = 0$		$p = 0.1$		$p = 0.2$	
		m	R^2	m	R^2	m	R^2	m	R^2	m	R^2	m	R^2
2	0.1	0.806	0.824	0.942	0.915	0.964	0.954	0.315	0.691	0.610	0.779	0.747	0.864
	0.3	0.870	0.711	0.974	0.857	1.005	0.864	0.491	0.652	0.688	0.821	0.765	0.798
4	0.1	0.865	0.824	0.973	0.965	0.990	0.974	0.311	0.584	0.675	0.849	0.796	0.926
	0.3	0.819	0.774	0.946	0.891	0.965	0.905	0.438	0.680	0.601	0.724	0.655	0.686

for actual ground motions, the maximum displacement is supposed to occur just once in an excitation and not well represents every cycle. Therefore, using the maximum superstructure to estimate the equivalent stiffness of superstructure for an actual excitation may mislead the damping too high. But the trend is constant, as we can observe from Table 2. Therefore, some adjustments may be possible later on.

4. CONCLUSIONS

Parametric studies of the response of base isolated structures considering yielding of the superstructure have been described. Result proves that this simple model could be used to study the responses of base isolation structures.

An increase in isolation period (softer isolator) significantly increases the maximum isolation level displacement but not much affects the maximum superstructure displacement. An increase in isolation damping results in minor reductions in all response, particularly for long period cases. Superstructure yielding significantly increases the maximum superstructure displacement but has only a minor effect on the isolation level response.

For the estimation of the maximum displacement considering nonlinear behavior of superstructure, theoretical considerations have been described and showing the good trend along with the history results from the model. The estimation of maximum total and isolation level displacements match well. However, more improvements are needed for the maximum superstructure displacement, especially when superstructure post-yield stiffness is low.

Future study will be focused on a complete and accurate method to estimate the maximum displacement of base isolated structures from the elastic response spectra. In addition, a method of selecting a good combination of superstructure strength and separation distance to obtain the minimum damage of the base isolated structure will be considered.

Abstract: This paper compares the observed and analytically predicted performance of three reinforced concrete buildings in Christchurch, New Zealand which have been subjected to the 2010 – 2011 Canterbury Earthquake Sequence. The studied buildings belong to a large, institutional organization, located on three campuses around central Christchurch. Structural archetypes vary from 1950's non-ductile concrete shear wall construction to 1980's ductile reinforced concrete moment frame and shear wall buildings.

None of the buildings involved in the study collapsed as a result of the earthquake sequence; however, some had sustained structural damage which was documented as part of an immediate post-earthquake evaluation survey. Ground motion records were also available from nearby recording stations.

Nonlinear finite element models were developed for each building and subjected to the nearby recorded ground motions to compare predicted and observed performance. In general, the analytical models indicated worse performance than was observed. Sources of uncertainty and potential conservatism in the modeling approaches were systemically evaluated. Soil-structure interaction assumptions were identified as having a significant influence on the predicted performance, and highlighted important issues for consideration in subsequent Detailed Earthquake Evaluations undertaken in accordance with current New Zealand industry best practice.

1. BACKGROUND

The 2010 – 2011 Canterbury Earthquake Sequence has resulted in extensive and severe damage to the city of Christchurch, New Zealand. The Sequence commenced with a M7.1 earthquake on September 4, 2010 near Darfield, approximately 40 km west of Christchurch. This earthquake generally caused moderate levels of damage in the city, with more severe damage occurring to unreinforced masonry buildings and widespread liquefaction in the eastern residential suburbs. On February 22, 2011, a M6.3 earthquake struck near Lyttleton, approximately 10 km to the south-east of Christchurch at a depth of 5 km. Shaking intensities of MM9 were felt across the city with peak ground accelerations of 1.75 g horizontal and 2.2 g vertical, recorded in the Port Hills, between Christchurch and Lyttleton. Since the September 4, 2010 earthquake there have been over 10,000 earthquakes, with over 40 measuring greater than M5.

The Lyttleton event of February 22, 2011 caused the greatest damage to buildings in Christchurch, including the collapse of two multi-story reinforced concrete office buildings and a number of low-rise unreinforced masonry buildings. The death toll from this earthquake was 185. It is estimated that 1,200 buildings in the downtown district of Christchurch will be demolished as a result of the Canterbury Earthquake Sequence (Hare et al. 2012).

2. BASIS OF STUDY

The downtown district of Christchurch was relatively well instrumented with distributed ground motion recording stations that captured the ground motion time histories from the Sequence.

The Authors were engaged to undertake Detailed Engineering Evaluations (DEE) of a number of reinforced concrete buildings located within the downtown district. These evaluations utilized the nonlinear dynamic procedure (NDP) in accordance with ASCE 41 (ASCE, 2006), in conjunction with the DEE Guidelines (EAG, 2011) and NZS 1170.5 (SNZ, 2005). None of the buildings evaluated collapsed or suffered significant structural damage as a result of the earthquake sequence. All of the buildings evaluated are owned by a large institutional organization.

As all of the buildings were located within 2 km of one or more recording stations, this presented the opportunity to compare the observed versus analytically predicted performance of the buildings in response to the February 22,

2011 earthquake.

Owing to time and resource constraints at the beginning of many of these evaluations, the structural analyses were often progressed in advance of receipt of geotechnical engineering recommendations for foundation evaluation. As geotechnical information became available for each building, these recommendations (typically soil bearing capacity and stiffness) were incorporated into the structural model and the analysis rerun. This approach provided an opportunity to examine the significance of incrementally incorporating various soil-structure interaction effects into the structural analysis.

The general purpose nonlinear analysis program, ANSR-II (Mondkar and Powell, 1979) was used to undertake the structural analysis. Previous studies have validated the capability of the program to reasonably predict the global response of reinforced concrete structures for the purposes of a design office environment (Kelly, 2007).

3. CODE APPROACHES TO SOIL-STRUCTURE INTERACTION

Documents such as ASCE 41-06 and FEMA 440 provide guidance on the effects of soil-structure interaction; however, the New Zealand Loading Standard for Earthquake Actions, NZS 1170.5, does not include any specific requirements to consider soil-structure interaction. although the Commentary C6.1.1 mentions that:

Foundation flexibility shall be included in the modeling of the structure. Ignoring foundation flexibility will be conservative with respect to strength but non-conservative with respect to deflections.

Foundations, including piles, and the supporting soils with which they interact should be treated as part of the overall building structure and analyzed as such.

Flexibility of foundations affects the response characteristics of the building by affecting period, drift and the like, and affects the relative participation between dissimilar systems in the resistance of lateral loads, such as between walls and frames.

No further guidance or references are provided in the Commentary to NZS 1170.5 in terms of how to include foundation flexibility in the analysis model. It is understood that industry practice in New Zealand to-date has typically been to ignore soil-structure interaction (Oliver, 2012, personal correspondence) and kinematic interaction.

For the purpose of this study, guidance was sought from ASCE 41-06 for the implementation of soil-structure interaction, specifically consideration of foundation flexibility and kinematic interaction effects.

4. BUILDINGS STUDIED

For this study three, existing reinforced concrete buildings were selected. General characteristics are outlined in Table 1 below, with further details provided in the following sub-sections.

Building ID	Year constructed	# stories	# basement levels	NZS 1170.4 soil class
D	Late-1980's	4	1	D
L	Late-1980's	3	1	D
A	Early 1950's	5	1	C

	Lateral systems		Foundation
Building ID	A	B	
D	Core walls	Core walls	Mat slab
L	Concrete frame	Concrete walls	Piles
A	Punched concrete walls	Punched concrete walls	Mat slab & isolated footings

Table 1: General characteristics of buildings studied

4.1 Building D

Building D is a four-story concrete building constructed in the late 1980's. The building has four separate concrete cores and with coupled shear walls that form the lateral force resisting system for the structure. The core walls are founded on a mat foundation. The gravity framing consists of a two way concrete slab supported by concrete columns.

Figure 1: Building D, plan view

4.2 Building L

Building L is a three-story reinforced concrete structure that is founded on a pile foundation and was constructed in the late 1980's. The roof consists of structural steel and timber framing. Lateral load resistance for Building L is provided by concrete shear walls in the transverse direction and a concrete moment resisting frame in the longitudinal direction. Gravity loads are resisted by a two-way

spanning concrete slab and a center row of interior gravity columns.

Figure 2: Building L, elevation

4.3 Building A

Building A is a five-story reinforced concrete building constructed in the early 1950's. As the building predates modern building codes that considered capacity-design principles and ductile detailing requirements such as NZS 3101 (SNZ, 2006), the building is considered to be "non-ductile" relative to the Buildings D and L. The structure has an L-shaped floor plan configuration which introduces a reentrant corner. Lateral loads are resisted by a combination of transverse concrete shear walls and exterior concrete piers and spandrels. Gravity loads are resisted by a concrete slab supported by concrete beams and columns. The foundation consists of a combination of isolated footings and an interior mat slab.

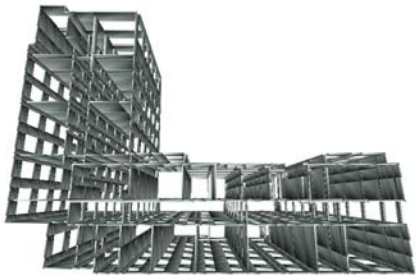

Figure 4: Building A, plan view

4.4 Dynamic Characteristics & Kinematic Interaction

For this study the response of the analytical models was evaluated using ground motions recorded from the Lyttleton event. The ground motions used for the analysis were selected from the nearest recording station to the subject buildings, either: Christchurch Hospital (CHHC) recording station or the Cashmere High School (CMHS) recording station. The 5% damped spectra of the records used in the analysis are shown Figure 5 below.

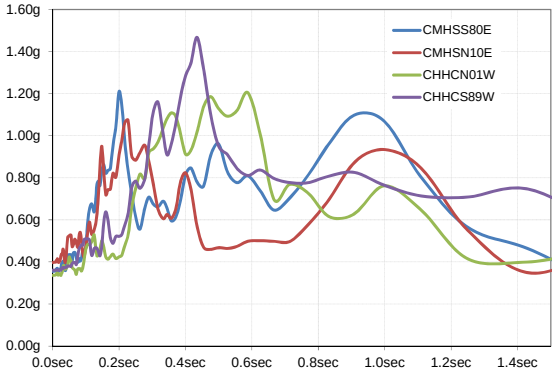

Figure 5: 5% damped spectra for Lyttleton Earthquake at Christchurch Hospital and Cashmere High School recording stations

Two types of kinematic interaction: base slab averaging and embedment, were considered and approximated using each buildings' fundamental modes of vibration. The provisions outlined in section 4.5.1 of ASCE 41-06 were followed to account for base slab averaging and embedment.

The reduction factor for base slab averaging (RRS_{bsa}) was calculated using equation 4-11 of ASCE 41-06.

The reduction factor for foundation embedment was determined using equation 4-12 of ASCE 41-06.

$$RRS_{bsa} = 1 - \frac{1}{14}\cdot 100\left(\frac{b_e}{T}\right)^1 \cdot 2 \geq \text{value for } T = 0.2 \text{ sec.} \quad \text{(eqn 4-11)}$$

$$RRS_f = \cos\left(\frac{2\pi e}{T n v_s}\right) \geq \text{value for } T = 0.2 \text{ sec.} \quad \text{(eqn 4-12)}$$

To simplify the implementation of the base slab averaging and embedment modifications, the acceleration time histories were simply modified by a single amplitude scalar based on the reduction factors for base slab averaging and embedment determined at the fundamental modes of vibration. As these factors become smaller with decreasing period, it is conservative to base the scale factor upon the fundamental periods of vibration for each building.

As can be seen in Table 2 the reduction factor, based on the average of each direction, for input ground motion varies from 0.83 to 0.92 for the buildings studied.

	Fundamental period (seconds)			Lyttleton record scale factor		
Building ID	**A**	**B**	**Nearest recording station**	**R_{TA}**	**R_{TB}**	**R_{avg}**
D	0.41	0.37	CHHC	0.84	0.82	**0.83**
L	0.60	0.13	CHHC	0.97	0.83	**0.91**
A	0.40	0.30	CMHS	0.93	0.90	**0.92**

Table 2: Building periods & record scale factors to account for base slab averaging & embedment

Figure 6 illustrates the reduction in spectral response that could be expected at all periods, if the CHHC record were to be spectrally matched to account for base slab averaging and embedment effects at Building D. As can be seen from the figure, a more significant reduction in spectral response is expected at periods less than 0.2 seconds than is otherwise implied by the factors listed in Table 2.

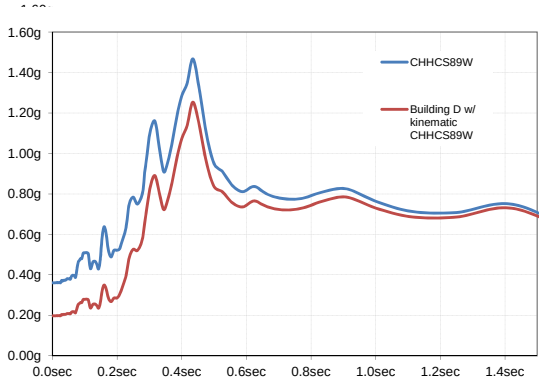

Figure 6: Lyttleton event scaled at all periods to account or base slab averaging and embedment effects at Building D

4.5 Foundation Flexibility

Flexibility and strength of the founding soils was included in the analysis through use of yielding soil spring and yielding pile elements, as applicable to the building foundation type.

For Buildings A and D which have mat and spread footing foundations tri-linear compression-only gap elements were used to permit foundation uplift. Gap properties were estimated by using tributary footing areas and the sub-grade modulus of the soil, as provided by the project Geotechnical Engineers. The first yield of the gap element was typically set at 85% of the ultimate soil strength, with the second yield occurring at the ultimate strength, after which point the gap becomes perfectly plastic. The second slope of the force-deformation relationship was set at 10% of the initial stiffness.

For Building L, the compression and tension stiffness of the piles differ, based on recommendations from the Geotechnical Engineer. Thus, the piles were modeled using gap and hook elements in parallel. The gap element was modeled as a compression-only truss with compression stiffness and strength equal to that of the pile in compression, and the hook element was modeled with the tension stiffness and strength of the pile. The elements follow an elastic unloading pattern. The relationship also accounts for cyclic stress reduction. As evidence of liquefaction at the site was found during post-earthquake damage surveys, an effort was made to include the effect of pile-tip liquefaction on the pile capacity and stiffness.

4.6 Scenarios Evaluated

The following scenarios were evaluated to quantify their effects on expected building performance:

1. Rocking but rigid foundations (no soil flexibility or yielding permitted.) This scenario reflected the initial absence of geotechnical input, and was deemed the "baseline scenario."

2. Rocking foundations with soil stiffness and strength included. This scenario incorporated recommendations from the Geotechnical Engineer. For the purpose of this study, soil strength and stiffness parameters were based on expected (average) values.

3. Rocking foundations, yielding soil springs (per Scenario 2), with base slab averaging and embedment effects included.

4. Rocking foundations, yielding soil springs, base slab averaging and embedment effects (per Scenario 3), with vertical acceleration component of the time history and vertical seismic mass included. Vertical masses were lumped directly to the vertical load resisting elements, which is believed to be conservative, as the majority of the vertical modes of vibration are concentrated in the short period range which coincides with the peak vertical spectral accelerations in the Lyttleton event.

The scenarios and identification codes are summarized in Table 3.

Building ID	Scenario ID			
	1	2	3	4
	Rigid rocking foundations	Per 1 + yielding soil springs	Per 2 + base slab averaging & embedment	Per 3 + vertical mass & acceleration
D	D1	D2	D3	D4
A	A1	A2	A3	A4
L	L1	L2	L3	L4

Table 3: Scenarios evaluated

The horizontal components of the records were run at orientations of 0 and 90 degrees and the results enveloped. This was due to uncertainty of the building's exact orientation with respect to the ground motion experienced at the site, given their distances from the recording stations.

5. MODELED PERFORMANCE

For comparison of the various scenarios, performance was characterized by global drifts and component acceptance criteria in accordance with ASCE 41-06.

5.1 Building D

Figure 7 compares the X and Z direction interstory drifts for the various scenarios investigated. As can be seen from the graphs the drift demands are relatively low for the Lyttleton event. The general trend is that a small increase in drift results from the introduction of foundation flexibility. Thus, D2 drifts are slightly increased from D1, with exception of the 3rd floor to Plant level in the X-direction

where the relatively flexible Plant level shows a significant increase. The introduction of kinematic effects slightly reduces global drift demand relative to scenarios the rigid foundation (D1) and flexible foundation (D2). There does not appear to be a significant difference in drifts from the introduction of vertical accelerations when comparing D3 drifts to D4 drifts.

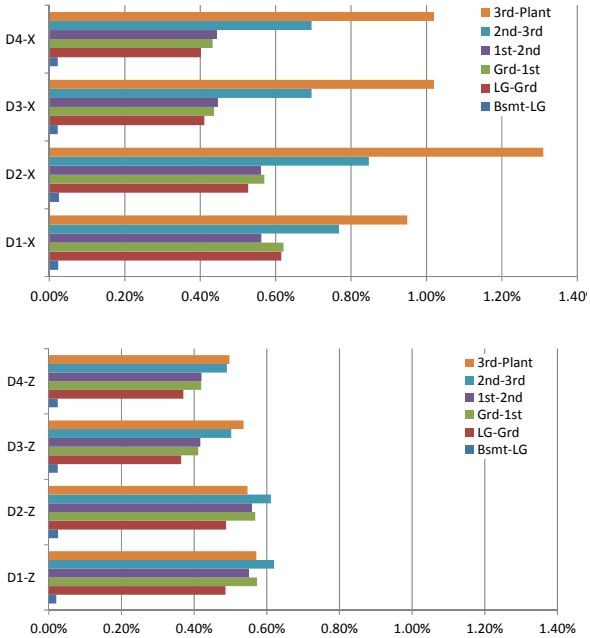

Figure 7: Building D, drifts at center of diaphragm for Scenarios 1 – 4

For comparison of structural component performance the total numbers of elements that exceed ASCE 41 acceptance criteria (secondary criteria) are given in Table 4 below. Immediate occupancy (IO), Life Safety (LS) and Collapse Prevention (CP) criteria are used for comparison between the various scenarios investigated.

	Model + Scenario			
Criteria	**D1**	**D2**	**D3**	**D4**
IO < n < LS	24	22	13	14
LS < n < CP	0	0	0	0
n > CP	1	0	0	0

Table 4: Building D, component damage count

For the D1 scenario one beam element exceeded Collapse Prevention acceptance criteria and 24 elements exceeded Immediate Occupancy but were still below Life Safety. The introduction of foundation flexibility removed the aforementioned beam element that from the >CP category and reclassified it as between IO and LS. A small decrease in the total number of elements >IO is also evident between D1 and D2. The introduction of kinematic effects had a significant effect on expected performance, with the number of elements exceeding the IO acceptance criteria roughly halving.

5.2 Building A

Figure 8 below compares the X and Z-direction drifts for Scenarios 1 through 4. As can be seen from the drift comparison between A1 and A2, the introduction of flexible soil springs resulted in a significant increase drift over the all floors of the building. The drifts in the Z-direction are slightly higher than the X-direction; however, overall the drifts are relatively low due to the stiffness of the building.

The top floor drifts (5th-6th) appear to be much larger than the stories below. However, this is not the actual performance, as the drifts reported are at the center of diaphragm and the building steps significantly at the 5th floor, thus the center of diaphragm coordinates differ significantly between the floors given an artificial appearance of higher drifts.

The introduction of kinematic effects (A3) does decrease the drifts slightly from A2; however the drifts are still higher than the rigid foundation model. The introduction of vertical accelerations (A4) does not appear to have a significant effect on drifts.

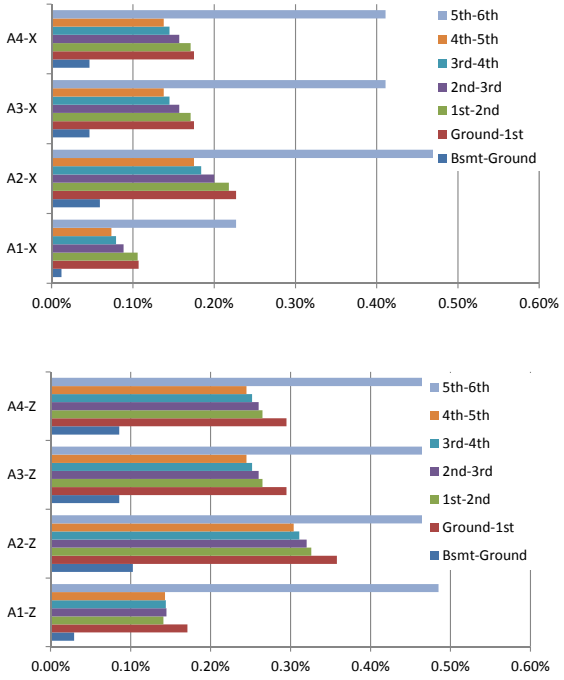

Figure 8: Building A, drifts at center of diaphragm for Scenarios 1 – 4

Table 5 provides a comparison of the element performance between the scenarios investigated. The acceptance criteria are for secondary components per ASCE 41-06.

The introduction of foundation flexibility significantly increases the number of elements that are damaged during the Lyttleton event. The increased deformations associated

with foundation flexibility cannot be readily accommodated by the non-ductile concrete detailing that is prevalent throughout the building

The majority of the increase in damaged elements for A2 is still less than the LS limit; however, seven elements exceeded LS and three elements were predicted to exceed CP.

Inclusion of kinematic effects, although only representing a small scalar decrease in the input motion, significantly decreases the predicted number of damaged elements, although still more extensive than the baseline case A1.

There is no effect on damaged elements with the introduction of vertical accelerations when comparing A3 to A4.

	Model + Scenario			
Criteria	**A1**	**A2**	**A3**	**A4**
IO < n < LS	17	94	49	49
LS < n < CP	0	7	3	3
n > CP	0	3	0	0

Table 5: Building A, component damage count

5.3 Building L

From review of the drift profiles for Building L there is a small decrease in the drift demand due to the introduction of foundation flexibility (L1 versus L2).

The introduction of kinematic effects (L3) reduces the drift demands slightly at the lower floors (Ground to 1st Floor and 1st to 2nd Floor); however, there is a significant reduction in drift demand in the longitudinal frame (X) direction for the 2nd Floor to Roof.

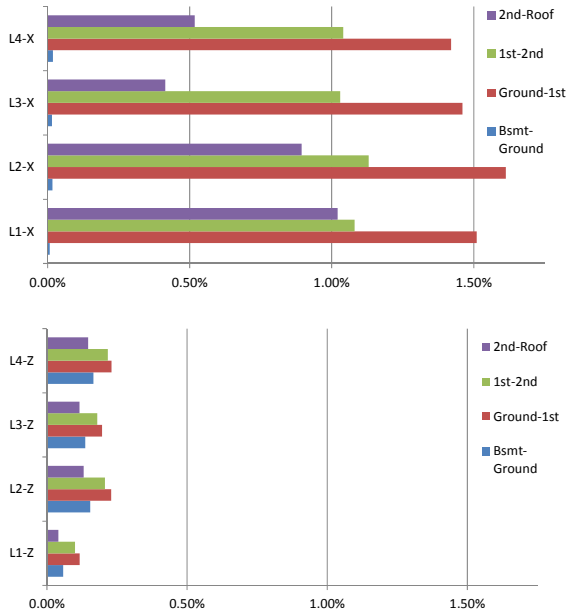

Figure 9: Building L, drifts at center of diaphragm for Scenarios 1 – 4

Table 6 below provides a comparison of the element performance between the scenarios investigated for Building L. As with Buildings D and A, secondary component acceptance criteria were used.

The majority of the elements that exceed IO are the 1st Floor beams that resist lateral forces in the longitudinal frame direction (X-direction). These beam elements, although below LS for secondary components, exceed the primary component acceptance criteria for LS plastic rotations. The relevance of this categorization becomes more apparent when compared with the observed performance of the building (described in the following section) as these beams showed no signs of damage as a result of the Lyttleton event.

	Model + Scenario			
Criteria	**L1**	**L2**	**L3**	**L4**
IO < n < LS	12	21	16	21
LS < n < CP	0	0	0	1
n > CP	0	0	0	0

Table 6: Building L, component damage count

6. OBSERVED PERFORMANCE

The following sub-sections describe the observed performance and damage characteristics of each building by the authors following the Lyttleton event.

6.1 Building D

A level survey of Building D undertaken after the Lyttleton event measured a 90 mm differential settlement over the building footprint (approximately 60 m x 40 m). The north raft appears relatively level but the south raft appears to have tilted to the south.

Moderate cracking was observed in the internal shear walls in the cores. The maximum diagonal crack width observed was 0.4 mm, but most were 0.3 mm or less; however, the transient crack widths may have been larger during shaking. Cracking was noted over the height of the cores. The analytical model predicted hinging at the base of the core walls, but also indicated higher drift demands at the upper levels where the core walls reduce in length which also suggests plastic hinging at multiple floors. Strain-hardening testing was completed on a sample of steel reinforcing bars crossing cracks in the core walls at the Lower Ground Floor. This indicated between 18 and 41 % loss in strain capacity of these bars.

A continuous and large crack, greater than 2.0 mm in width, was observed in the Lower Ground suspended floor slab, this extends east-west and is approximately between the two raft foundations. Strain-hardening testing was undertaken on the steel reinforcement which runs across the crack, and indicated between 12 and 35 % loss in strain capacity of these bars.

Cracking was observed in the stair flights over the full height of the building. The stairs are constructed with no mid

height landing support and support themselves by developing tension and compression struts in the stair flights. The stairs are therefore connected both vertically and horizontally, floor to floor, and thus subjected to the interstory drift demands. They were not included in the analysis model.

Only very minor cracking was noted to concrete beams and columns.

In general, the observed damage was less severe than predicted by the analysis scenarios.

6.2 Building A

The building damage was considered to be relatively minor with exceptions of:

- Cracking at east end of Ground Floor: The most significant damage observed was at the east end of the Ground Floor. Horizontal cracks were noted on both sides of the corridor in the east end wall at around 1.3 m above the floor. These continued around into the corridor walls also.
- On the north side of the corridor a horizontal offset in both directions was noted. When the vertical reinforcement was exposed, it was shown to be bent, see Figure 10.

Figure 10: Building A, steel reinforcement exposed at crack location in computer room

- In this same area the concrete ground floor slab also exhibited significant cracking; the widest crack was 8 mm. It appears that most of this damage was caused by differential movement between Building A and an adjacent structure. The buildings are connected at the basement level and it appears that the lower part of Building A may have moved with the adjacent structure.
- The width of the cracks in this area suggests that bond between the steel reinforcement (plain, undeformed reinforcing bars) and the concrete has been lost at the vertical steel reinforcement lap splices at these locations.
- Concrete transfer beams: At the Ground Floor the building steps out on the north side. To support the structure above this point there are concrete transfer beams in the floor slab. Each end of these beams was inspected and cracks up to 1 mm wide were noted.
- Seismic Joints: Damage to the cover plates over seismic joints with the adjacent structure show that there was significant differential movement between the buildings during the earthquakes. There is also some indication of residual horizontal displacement of approximately 35 mm at Level 5.
- Ground settlement damage: Some possible ground settlement has occurred under and around the building. Residual displacement is noted at the seismic joints and cracking at the interface with the adjacent building demonstrate that some ground movement had occurred.
- Additionally, minor damage (cracking < 1 mm) was observed to the following:
  - Concrete walls and piers between windows
  - Stair walls
  - Cracking in the insitu concrete floor slabs
  - Brick infill panels and risers
  - Brick veneer
  - Exterior concrete window surrounds

As noted above, the structural damage that was evident is at or near areas of the structure where differential settlement has occurred.

6.3 Building L

Typically the damage to Building L was relatively minor with the exceptions of:

- Cracking to the full height pre-cast panel connections around the stair at the north end of the building. This has likely been caused by the interstory drifts in the longitudinal (frame) direction.
- Damage to the ceilings (due in part to the ceiling support system) however the ceiling at roof level had significant damage which would have been caused by the deformations at that level.
- Differential settlement: The levels survey indicated differential settlement along the length of the building.
- The majority of the structural damage predicted in the analysis model was in the 1st Floor concrete beams in the frame direction. From the analyses, most of these beams exceeded the primary Life Safety acceptance criteria, suggesting moderate plastic rotation demands; whereas the observed performance of the frames indicated only a few hairline cracks in the beams and no cracking at the base of the Ground Floor columns.

In general, it was found that the observed performance of Building L was better than the analytically predicted performance regardless of the scenario considered. This indicates that the analysis model is conservative even with the reduction for kinematic effects.

7. CONCLUSIONS

As part of this study the observed seismic performance of three existing buildings in Christchurch subjected to the 2011 Lyttleton event were compared to the predicted performance of non-linear analytical models of the subject buildings. In general the observed performance of the buildings was found to be better than that predicted by the

analytical models.

Significant contributors to these differences are attributed to the inclusion of soil-structure interaction effects. Specifically: foundation flexibility and strength, kinematic effects and vertical accelerations were investigated.

From this study it is found that the inclusion of foundation flexibility increases overall building drifts and deformations, attributed to increased base rotations (flexibility) and period lengthening. The increase in deformations appeared to be accommodated readily by Buildings D and L, which were detailed in accordance with modern building code requirements for ductility. Foundation flexibility appeared to be increase predicted damage of the older, non-ductile building included in this study, well in excess of observed damage.

The kinematic effects of base slab averaging and foundation embedment are found to be beneficial for all buildings included in this study and generally appeared to bring the predicted performance closer to observed performance; however, in general the models were still conservative relative to the observed performance. This suggests that these procedures can be applied with confidence in the design office and for use with future Detailed Engineering Evaluations.

The inclusion of the vertical acceleration component and mass had a slightly detrimental impact upon expected performance. However, given the conservatism in the assumed vertical mass distribution, further study is recommended to more appropriately capture the mass distribution and associated vertical modes of vibration.

For future studies it is also recommended that additional non-ductile buildings be included in the sample and that longer period structures be included.

GLOBAL EXPERIENCE: SEISMIC RISK REDUCTION AND DISASTER RECONSTRUCTION PROGRAMS

H. Kit Miyamoto[1], and Amir SJ Gilani[2],

1) President, Miyamoto International, Los Angeles, CA
2) Senior Associate, Miyamoto International, Sacramento, CA

kit@miyamotointernational.com, agilani@miyamotointernational.com

Abstract: Nearly 40% of the largest cities in the world and hundreds of millions of people live in areas that can experience major earthquakes, resulting in large numbers of casualties, and placing a large burden on the regional and national economy. Earthquakes in Haiti and Christchurch have had long-term impact on society. The 2010 Haiti Earthquake affected 3 million people and over 300,000 people are still displaced. An unprecedented reconstruction effort, incorporating local materials and masons but based on international standard, is currently underway to repair and strengthen 120,000 damaged buildings, allowing people to return to safe homes and produce a seismically resilient community in this developing country. The 2011 earthquakes effecting New Zealand showed the need for seismic risk mitigation programs in developed countries. In New Zealand, older and newer buildings were damaged. The damage to these buildings was not unexpected because the building codes only focus on life safety rather than developing earthquake resilient communities. Over 50% of the 2400 buildings in the downtown area required demolition. Over $10 billion dollars in insurance loss is expected, resulting in a drop in the insurance capacity and threatening the country's investment environment. This issue is being dealt with by reducing the overall seismic risk for both public and private buildings. In Bangkok, where the effects of long distance and long duration of earthquakes are a serious concern due to soft soil, the commercial sector has initiated a seismic strengthening program for high rise buildings. A systematic seismic risk reduction program is critical, by understanding the limitations of the building codes. A seismically resilient community can be built if both public and commercial sectors rigorously participate in a broader program.

1. INTRODUCTION

The In the past several years, major earthquakes have affected both developed and developing countries. Although the consequences differ, the end result is similar because these events have caused casualties, affected local and national economies, and had long-term negative effects on communities. The adverse effects of earthquakes in developing and developed countries are attributed to different causes. In developing countries, the main culprit is the lack of an effective seismic code, education, licensing, and quality-control system. Buildings are designed and constructed without adequate provisions for seismic forces or a quality-control system. As a result, these buildings do not have a mechanism to resist earthquake loading and thus can be severely damaged or collapse in moderate or major seismic events. By contrast, in developed countries, the concept of seismic design is well developed and based on extensive research. However, the intent of the building codes in these countries is not to prevent damage but to provide a minimum of life safety. This philosophy is primarily due to financial constraints facing both private and public developers, and a lack of information. As such, in the event of major earthquakes, buildings in developed countries would likely not collapse. However, it is likely that these structures would sustain significant damage (as implied in the building codes) that would likely result in both financial losses and the need to replace or repair the buildings.

One common factor for Haiti, New Zealand, Japan, and similar recent events is that the earthquakes had magnitudes that were unexpected. In other words, the available design codes had underestimated and intensity of seismic events that could occur. This case was observed in China (2008), Italy (2009), Haiti (2010), New Zealand (2011), and Japan (2011), and it points to the need for either additional safety measures in design or better understanding of probable seismic events for a locale. Examples of earthquake damage and the consequences of such damage from two recent events are presented in the following sections.

2. OVERVIEW OF RECENT MAJOR EARTHQUAKES WORLDWIDE

2.1 2010 Haiti Earthquake

The catastrophic 2010 Haiti earthquake has had a tragic effect on the lives of more than 3 million people, including over 200,000 casualties, over 1,000,000 displaced people, and financial losses that crippled the country's economy.

Thousands of buildings collapse, including the United Nations (U.N) headquarters Port-au-Prince; as shown in Figure 1.

Figure 1 Collapsed UN building (UNDP Global 2010)

Similar to past and recent events in other developing countries such as Indonesia, Pakistan, and Turkey, the main causes of the devastation can be attributed to several factors. Among them: This earthquake caused devastation disproportional to its magnitude. If any form of standard of seismic design and construction had been used in Haiti, many lives and much of the economic loss could have been avoided. The main observed factors that exacerbated this tragedy were the following: a) Design and construction practices had not considered earthquake forces properly. In addition, many engineers and contractors had neither formal education nor experience in earthquake-resistant design methodologies. b) Absence of an accepted building or seismic engineering code, and proper quality control system in design, and construction. In addition, no formal building review process was in place. c) The rapid growth of low-income neighbourhoods due to migration into the city from outlying areas. In these neighbourhoods, unsafe housing had been built using substandard construction materials and practices. d) Lack of preparedness by the national government, local agencies, international organizations, emergency responders, and citizens for a major earthquake. Many of the structures in Haiti as well as other developing countries are constructed of either what is referred to as non-ductile concrete, unreinforced masonry (URM), or other stone-type block construction. These particular building types are seismically vulnerable and pose a life-safety hazard. An example of poor construction in Haiti is shown in Figure 2.

Figure **2** Example of poor construction in Haiti

2.2 2011 New Zealand Earthquake

The magnitude-6.3 February 2011, New Zealand, earthquake caused more than 160 deaths and damage costing over US$20 billion. Many buildings were damaged; over 30% of the brick and stone buildings in the central business district (CBD) either collapsed or sustained major damage (see Figure 3) resulting in total closure of the CBD for period of several months because many of the remaining buildings were considered unsafe (Miyamoto International 2011).

Figure **3** Collapsed masonry buildings in the CBD

As of this writing, the CBD is still partially closed, resulting in severe economic losses. In addition, the unprecedented damage has brought the construction industry to a halt because of the difficulty in obtaining insurance. Most of the deaths from this earthquake occurred after people had been buried under collapsed buildings, such as nonductile concrete structures downtown (see **Error! Reference source not found.**). This was a shallow (5-km epicentral depth) earthquake, and its epicenter was less than 6 km from the east side of Christchurch. As such, it caused significantly more damage and casualties than did the magnitude 7.0, September 2010 earthquake (which had no direct fatalities). The 2011 Earthquake caused extensive liquefaction and ground failure, which also led to

widespread loss of water and electricity. The severity of this earthquake was unexpected in Christchurch and points to the same problem that exists in many other urban areas that are close to active faults. The level of damage to modern (post-1980) construction was alarming. Over 50% of the building stock—more than 1,300 buildings—are expected to be claimed as total losses. Many of these buildings were designed and constructed using modern seismic codes. Nonetheless, they sustained significant structural and nonstructural damage, and many have to be demolished. Similar observations were made following the 2010 Chile earthquake. In both countries, modern seismic codes are advanced and local engineers are quite capable, and there are tight construction standards. It is important to note that the building codes likely did what they were intended to do: that is, to provide life safety and prevent collapse. However, the codes do not have provisions for either the building condition after an earthquake or financial losses as a result of an earthquake.

Figure 4. Collapsed nonductile concrete building in the CBD

3. RESPONSE TO THE RECENT EARTHQUAKES

In the aftermath of the subject earthquakes, the authors and other engineers mobilized as part of the response teams. The primary goals of the teams were to:

- Develop methodologies for seismic risk reduction,
- Devise robust and resilient reconstruction methods. In the following sections, the approach and results to date are summarized.

3.1 Response to the Haiti Earthquake

Immediately after the earthquake, the team was mobilized with the primary goal of evaluating and/or repairing as many buildings as possible to allow citizens to leave temporary camps and return to their houses (Miyamoto, Gilani, and Wong 2011). A two-step procedure was undertaken: (a) perform damage assessment of approximately 400,000 buildings, and (b) develop earthquake-resistant, cost-effective, and robust reconstruction techniques. Key components of these programs were having international engineers educate and train local Haitian engineers, and having international construction experts train local Haitian masons. In addition, training manuals were developed, and emphasis was placed on local materials and techniques to additionally stimulate the local economy.

Table 1 summarizes the results of the damage assessment program. Over 50% of the buildings were tagged as green, or safe for occupancy. This allowed hundreds of thousands of people to return home.

Table 1. Results of damage assessment

Category	**Green**	**Yellow**	**Red**
No. of buildings	213,000	102,000	80,000
Percentage	54%	26%	20%

The seismic rehabilitation of thousands of buildings that is currently under way (see 0) will allow many more thousands to return home, and provide a safe and seismically resilient community for citizens. At the time of this paper, over 9,000 houses have been reconstructed under various programs; see 0.

Figure 5. Example of acceptable reconstruction in Haiti

Table 2. Results of damage assessment

Program	Description	Houses

UNOPS	Shelter Repair	800
PADF	Yellow Houses Repairs	3,839
Total		9,564

3.1 Response to the Christchurch Earthquake

New Zealand has one of the most advanced seismic codes in the world. However, the city of Christchurch was not ready for the earthquake that hit it, and the engineering community was unprepared to deal with the aftermath of the event. As such, the initial decisions were to demolish all buildings that had been deemed unsafe, and either reconstruct the areas deemed unsafe or leave them as open space. Experience has shown that many vulnerable structures can be upgraded to comply with the current seismic standards using systematic rehabilitation methods. The first step in this process is condition assessment. This key component is currently missing in New Zealand. To address this issue, the authors are developing a risk assessment algorithm that is uniquely suitable for New Zealand construction but relies on worldwide knowledge in seismic assessment and rehabilitation. The objective of this program is to characterize risk for individual buildings, and thus to present owners with the financial cost of doing nothing, rehabilitating the structure, or demolishing and reconstructing the structure. Experience has shown that the assessment-reconstruction alternative is the preferred and the optimal (as related to benefit-cost ratio) option for many structures.

4. COMPONENTS OF RISK ANALYSIS AND RESILIENT RECONSTRUCTION

One of the disturbing observations in recent earthquakes has been the damage to modern buildings that had been designed according to modern seismic codes. Although these buildings have survived, the level of damage and the associated cost of the damage and repair have been high. Consequently, the current building code approach (that is, prevent collapse but tolerate damage) has been questioned. Performance-based engineering (PBE) provides an alternative to code-based prescriptive design. PBE involves selecting various targets or desired objectives for a given intensity of earthquake input. Such an approach relies on sound engineering judgment, involves direct communication between structural engineers and owners, and requires that the structural performance and the seismic hazard be known with a certain level of confidence. The concept of PBE directly ties to managing seismic risk: The owner is given the option of choosing the level of risk that can be tolerated and the cost associated with that level. For example, 0 presents a typical PBE matrix. The rows correspond to the intensity of a seismic event, and the columns indicate the expected level of performance. In this matrix, the limited, standard, and enhanced objectives for seismic rehabilitation are shown as red, yellow, and green entries, respectively.

Table 3 PBE matrix

Seismic event	Operational	Immediate Occupancy	Life Safety	Collapse Prevention
Typical				
Design				
Rare				

In risk management language, this matrix is also directly related to what is commonly referred to as “probable maximum loss” (PML). PML implies the level of damage (casualties, financial loss, and loss of income) that can be expected for a given building at a given level of earthquake. As shown in 0, seismic rehabilitation and/or reconstruction should be such that this example building whose analyzed performance was above acceptable PML level and thus inadequate—would be strengthened so that its post-retrofit damage index is below the PML threshold resulting in significant risk reduction. The low level of PML in this example was achieved by using an innovative seismic protective device (such as isolators and dampers) which protect structural and nonstructural components. The concept of PML is especially relevant to developing countries and for critical facilities in these countries. In many instances in these countries, the level of seismic hazard and the risk associated with it are not well known. By conducting a preliminary (often referred to as a “phase I”) analysis, an approximate but accurate estimate of the PML for a given structure and/or group of buildings in a facility can be determined quickly. This PML estimate can then be used to prioritize the buildings for further analysis and possible retrofit within the allocated budget.

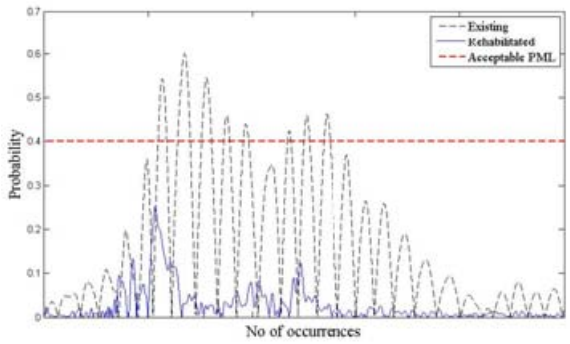

Figure 6. Example of PML analysis

5. ADDED VALUE TO INTEGRATIVE RISK MANAGEMENT

The lessons learned from earthquakes such as those in Haiti and New Zealand and the concepts presented in this paper have global applications. For example, under the auspices of the World Bank (WB), a multiyear program was developed and managed to ensure the systematic upgrade of essential facilities in Istanbul, Turkey. As a result, by the end of the program, over 2,000 critical buildings were retrofitted or reconstructed, including schools that now provide safety to students. Schools have been noted as one of the most vulnerable building types in past earthquakes, causing thousands of casualties. Similar to the program in Turkey, a new rehabilitation guideline and training manual is currently under development in Romania. This document is based on state-of-the-art research and knowledge in the United States and incorporates specific considerations for Romanian design and construction. It will be used to make communities more resilient in Romania.

CONCLUSIONS

Recent earthquakes have caused damage worldwide and have demonstrated the vulnerability of many cities in both developing and developed countries. To address such vulnerability and reduce the global seismic risk, the following are recommended:

- Educate private and public entities on the limitations of code-based design. As an alternative, investigate the application of PBE, which relates probabilistic performance to seismic hazard and can assist in decision making by stakeholders.
- Building codes, by definition, count on select components and modes of response to dissipate seismic energy. Although effective in preventing collapse, this approach, by definition, implies damage to these components. Seismic protective devices are readily available to protect structures and mitigate such damage.
- Vulnerable buildings such as nonductile concrete and URM structures are well-known; effective and inexpensive retrofit concepts are also known. It is important to train engineers in developing countries and undertake a systematic program of rehabilitation and reconstruction for this group of vulnerable structures.
- For developing countries, risk assessment and PML are critical tools because it is not feasible to retrofit all vulnerable structures, given the limited resources. PML and the ensuing benefit-cost analysis can be used to rank buildings for assessment and possible upgrade to help maximize protection of life and infrastructure.

REGIONAL PREDICTIONS OF EARTHQUAKE-INDUCED LANDSLIDES: A STUDY OF THE NIIGATA-KEN CHUETSU EARTHQUAKE

Yubing Wang[1] and Ellen M. Rathje[2]

1) Graduate Research Assistant, Dept. of Civil, Architectural and Environmental Engineering, Univ. of Texas, Austin, TX, USA

wangyubing1987@hotmail.com, e.rathje@mail.utexas.edu

Abstract: Earthquake-induced landslides are a significant seismic hazard that can generate significant economic losses. To gauge the potential for this hazard, regional seismic landslide maps are developed based on estimates of rigid sliding block displacement from empirical predictive models. Previous earthquakes with well-documented landslide inventories provide opportunities to evaluate these regional predictions of earthquake-induced landslides. This paper investigates the landslide inventory from the 2004 Niigata-ken Chuetsu earthquake (M_w=6.6) and compares this inventory with predictions of sliding displacement. The distribution of landslides as a function of slope angle and geologic unit are summarized for this earthquake and compared with the distributions from the 1994 Northridge earthquake (M_w=6.7). Regional predictions of sliding displacement are made using ground motion estimates from ShakeMap®, yield accelerations computed using best-estimate shear strengths assigned to geologic units, and an empirical displacement model using PGA and PGV. Comparisons with the observed landslides indicate that only 40% of the landslides are captured. Larger percentages of the landslides can be captured by modifying various parameters in the yield acceleration calculation (e.g., shear strength), but these changes result in a significant over-prediction in the total landslide area. These results indicate that improvements to regional seismic landslide mapping can only be made with improvements in mapping the spatial variation in shear strengths within geologic units.

1. INTRODUCTION
