The forces in a capacity-protected member shall satisfy the following requirement:

$$F_D \leq F_C \quad (2)$$

where F_D is force demand determined by determined by the

joint-force equilibrium considering plastic hinging capacity of the ductile component multiplied by 1.2 of an overstrength factor; F_C is force capacity limit specified in SDC (Caltrans 2010c) for concrete members and Guides (Caltrans 2001) for steel members.

4.5 *P-Δ Effects*

The *P-Δ* effects tend to increase the displacement and decrease lateral load-carrying capacity of a bridge column. These effects can typically be ignored if the moment ($P_{dl}\Delta_r$) is less than or equal to 20% of the column plastic moment, i.e.

$$P_{dl}\Delta_r \le 0.2\, M_p^{col} \tag{3}$$

where Δ_r is the relative offset between the point of contra-flexure and the base of plastic hinge and P_{dl} is the tributary dead load applied at the center gravity of the bridge column.

4.6 Minimum Lateral Strength

Although providing ductile detailing is essential for achieving the expected performance requirements, each column shall be designed to have a minimum lateral flexural capacity to resist a lateral force of $0.1P_{dl}$ where P_{dl} is the tributary dead load applied at the center gravity of the superstructure.

5. SEISMIC ANALYSIS METHODS FOR DEMAND

For Ordinary Standard Bridges, the following methods are recommended to estimate the displacement demands.

5.1 Equivalent Static Analysis (ESA)

The ESA method specified in Caltrans SDC (Caltrans 2010c) can be used to estimate the displacement demands for simpler structures which have balanced spans, similar bent stiffness, and low skew and seismic response is primarily captured by the fundamental mode of vibration. In the ESA method, the fundamental period is determined using tributary mass and stiffness at each bent. The applied seismic force is the product of the period dependent ARS coefficient and the tributary weight.

5.2 Elastic Dynamic Analysis (EDA)

The EDA is linear elastic multi-mode spectral analysis with the appropriate response spectrum and with an adequate number of modes considered to capture a minimum of 90% mass participation. A minimum of three elements per column and four elements per superstructure span shall be used. The complete quadratic combination (CQC) method is recommended to combine EDA modal results.

5.3 Global and Stand-Alone Analysis

The global analysis specified in Caltrans SDC (Caltrans 2010c) is an elastic dynamic analysis with considering the entire bridge modeled from abutment to abutment. It is often used to determine displacement demands on multi-frame structures. The stand-alone analysis is an elastic dynamic analysis with considering only one individual frame. To avoid having individual frames dependent on the strength and stiffness of adjacent frames, the separate stand-alone model for each frame must meet all requirements of the SDC.

5.4 Effective Stiffness

In both ESA and EDA methods, effective stiffness of the components shall be used in order to obtain realistic evaluation for the structure's period and displacement demands. The effective stiffness of ductile components shall represent the component's actual secant stiffness near yield. The effective stiffness shall include the effects of concrete cracking, reinforcement and axial load for concrete components; residual stresses, out-of-straightness and axial load for steel components; the restraints of the surrounding soil for pile.

For ductile concrete column members, effective moments of inertia, I_{eff} shall be based on cracked section properties and can be determined from the initial slope of the M-ϕ curve between the origin and the point designating first yield of tensile reinforcement. The torsional moment of inertia of concrete column J_{eff} may be taken as 0.2 time J_{gross}. For capacity-protected concrete members, I_{eff} shall be based on their level of cracking. For conventionally reinforced concrete box girder superstructure, I_{eff} can be estimated between 0.5-0.75 times I_{gross}, moment of inertia of a gross section. For pretsressed concrete superstructures, I_{eff} is assumed the same as I_{gross} because prestressing steel limits the cracking of concrete superstructures.

For built-up steel members, effective section properties developed by Duan, Reno and Lynch (2000) may be used.

6. SEISMIC ANALYSIS METHODS FOR CAPACITY

6.1 Inelastic Static Analysis (ISA) – Push Over Analysis

Inelastic Static Analysis (ISA), commonly referred to as the "push over analysis", shall be used to determine the displacement capacity of a bridge. The expected material properties shall be used to model structural members. IAS is a static, nonlinear procedure in which the magnitude of lateral loading is incrementally increased with a certain predefined pattern, until the potential collapse mechanism is achieved.

The simplest method, elastic-plastic hinge analysis, may be used to obtain an upper bound solution. The most accurate method, distributed plasticity analysis, can be used to obtain a better solution. Refined plastic hinge analysis is an alternative that can reasonably achieve both computational efficiency and accuracy.

A pushover analysis example (Akkari and Duan 2000) of a typical reinforced concrete bridge bent frame consisting of a bent cap beam and two circular columns supported on pile foundations is shown in Figure 4. Due to lack of adequate column transverse reinforcement, the columns are retrofitted with 12.7 mm thick steel jacket. Figure 5 shows an

analytical push-over model for the example bridge bent. Figure 6 shows the lateral load vs. displacement response.

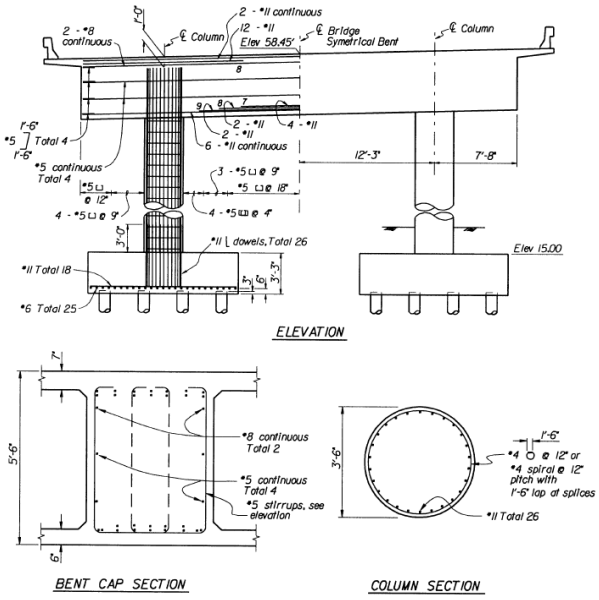

Figure 4. A Typical Reinforced Concrete Bridge Bent

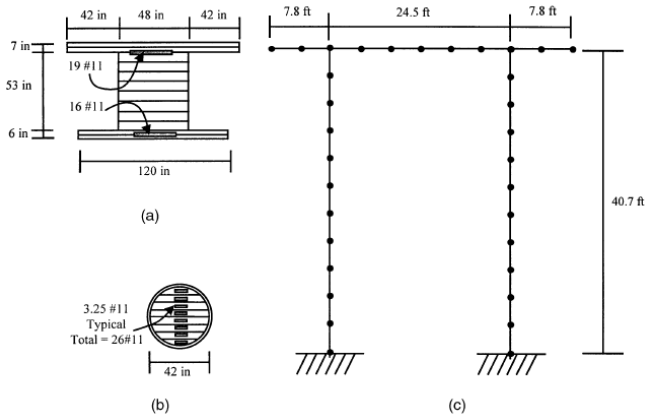

Figure 5. Analytical Model for Example Bridge Bent

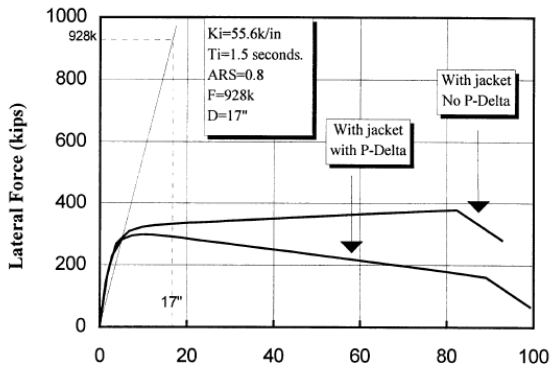

Figure 6. Lateral Load - Displacement Response

6.2 Moment-Curvature Analysis

The main purpose of moment-curvature analysis is to study the section behavior and to provide basic input data for the pushover analysis.

For a reinforced concrete member, the cross section is divided into a proper number of concrete and steel layers or filaments representing the concrete and reinforcing steel. Each concrete and steel layer or filament is assigned its corresponding stress-strain relationships. Confined and un-confined stress-strain relationships are used for the core concrete and for cover concrete, respectively.

For a structural steel member, the section is divided into steel layers or filaments and a typical steel stress-strain relationship is used for tension and compact compression elements, and an equivalent stress-strain relationship with reduced yield stress and strain can be used for a non-compact compression element.

7. SEISMIC DETAILING REQUIREMENTS

7.1 Minimum Seat Width

To prevent unseating of superstructures at hinges, piers and abutments, the seat width shall be available to accommodate the anticipated thermal movement, prestressing shortening, concrete creep and shrinkage, and the relative longitudinal earthquake displacement, and shall not exceed the following minimum seat requirements (Caltrans 2010a):

$$N_{\min} = \text{larger of} \begin{cases} \Delta_{ps} + \Delta_{cr+sh} + \Delta_{temp} + \Delta_{eq} + 100\,(\text{mm}) \\ 600\ \text{mm}\,(\text{For seat width at hinges}) \\ 760\ \text{mm}\,(\text{For seat width at Abutments}) \end{cases} \tag{4}$$

where Δ_{ps}, Δ_{cr+sh}, Δ_{temp} *and* Δ_{eq} are relative displacement due to prestressing, concrete creep and shrinkage, temperature and earthquake, respectively (mm).

7.2 Structural Steel

7.2.1 Limiting Width-to-Thickness Ratios

For capacity-protected components, the width-thickness ratios of compression elements shall not exceed the limiting value λ_r as specified in Caltrans Guide Specification (Caltrans 2001). For ductile components, width-thickness ratios shall not exceed the λ_p as specified in Table 19.13. Welds located in the expected inelastic region of ductile components are preferably complete penetration welds. Partial penetration groove welds are not recommended in these regions. If the fillet welds are only practical solution for an inelastic region, Quality Control (QC) and Quality Assurance (QA) inspection procedures for the Fracture Critical Members shall be followed.

7.2.2 Limiting Slenderness Ratio

The slenderness parameter λ_c for compression members,

and λ_b for flexural members shall not exceed the limiting values, λ_{cp} and λ_{bp}, as specified in the Guide Specifications (Caltrans 2001), respectively.

7.2.3 Limiting Axial Load Ratio

High axial load in column usually results in the early deterioration of strength and ductility.
The ratio of factored axial compression due to seismic load and permanent loads to yield strength (A_gF_y) for columns in ductile moment-resisting frames and single column structures shall not exceed 0.3.

7.2.4 Shear Connectors

Shear connectors shall be provided on the flanges of girders, end cross frames or diaphragms to transfer seismic loads from the concrete deck to the abutments or pier supports. The cross frames or diaphragms at the end of each span are the main components to transfer the lateral seismic loads from the deck down to the bearing locations.

7.3 Concrete

7.3.1 Limiting Longitudinal Reinforcement Ratios

The ratio of longitudinal reinforcement to the gross cross-section of the compression members shall not be less than 0.01 and 0.005 for columns and pier walls, respectively, and more than 0.04.

7.3.2 Plastic Hinge Region

The plastic hinge region for ductile members is defined as the larger of the following:

- 1.5(the cross sectional dimension in the direction of bending)
- Region where the moment exceeds 75% of maximum plastic moment, M_p^{col}
- 0.25(Length of column form the point of maximum moment to the point of contra-flexure).

7.3.2 Transverse Reinforcement in Plastic Hinge Regions

For confinement in plastic hinge regions, in term of the volumetric ratio, ρ_s for columns with circular and interlocking core sections, $\rho_s = 4A_{bh} / D's$, shall be designed to ensure members meet the performance requirements.

The maximum spacing (s) for lateral reinforcement in the plastic end regions shall not exceed the smallest of (1) 20% of the least dimension of the cross-section for columns and one-half of the least cross-section dimension of piers, (2) Six times the nominal diameter of the longitudinal reinforcement and (3) 200 mm.

7.3.3 Joint Proportion and Reinforcement

- Moment-resisting integral connections shall be designed to resist the overstregnth capacity M_p^{col} and associated shear.
- The principal tension stress p_t and compression stress p_c shall not exceed $1.0\sqrt{f_c'}$ (Mpa) and $0.25\, f_c'$, respectively. The bent cap width required for the join shear transfer shall not less than the cross section dimension of the column in the direction of bending plus 600 mm.
- When the principal tension stress $p_t \le 0.29\sqrt{f_c'}$ (MPa), for circular columns, or columns with intersecting spirals, the volumetric ratio of transverse reinforcement in the form of spirals or hoops to be continued into the cap or footing ρ_s shall not less than $0.29\sqrt{f_c'} / f_{yh}$.
- When the principal tension stress $p_t > 0.29\sqrt{f_c'}$ the additional reinforcement shall be provided and well distributed within D/2 from the face of column as specified in Caltrans SDC (Caltrans 2010c).

Figure 7 shows 3-D representation of knee joint shear reinforcement layout.

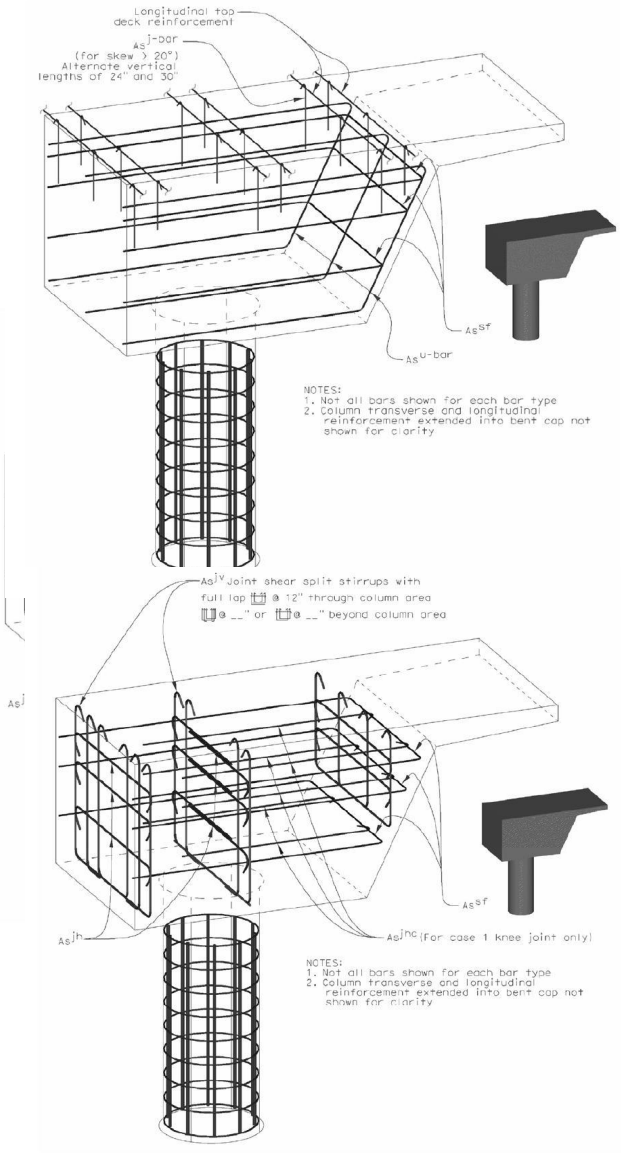

Figure 7. Knee Joint Shear Reinforcement Layout

8. CONCLUSIONS

Caltrans has been using displacement-based design approach for seismic design of highway bridges to ensure that the structural system and its individual members have enough displacement capacities to withstand the deformation imposed by the design earthquake since 1994. Structural components are classified as *Ductile* and *Capacity-protected.* Inelastic deformations are generally expected in substructure components which are pre-identified and well detailed for ductile response. Inelastic behavior in the form of controlled flexural damage may be permitted in some of the steel superstructure components such as end cross frames, shear keys and bearings to prevent damage in other parts of structures. The capacity design concept is used to ensure all other elements not explicitly designed as ductile or sacrificial to be capacity protected such that they remain essentially elastic. Capacity-protected components are designed to resist the force demands determined from the overstrength capacity of ductile components connected. Details such as seat width, bearing assemblies, beam-joints and connections, reinforcement confinements, end cross frames, limiting slenderness ratios, are properly designed to ensure continuity of load path during earthquake and to ensure the design objectives are achieved.

Abstract: A common assumption in the seismic analysis of curved highway bridges is to ignore the curvature and analyze these structures as if they are straight. But this approach may seriously underestimate the forces in the components of the superstructure as shown in this paper for continuous, steel plate, I-girder superstructures supported by bearings on conventional concrete substructures. The load path in a curved superstructure is highly dependent on the degree of curvature because the inherent torsional moments in the superstructure increases with increasing values for the subtended angle. This leads to high cross-frame forces and a distribution of bearing loads that are significantly different from those found in straight bridges. This paper discusses this effect as well as the effect of various modeling techniques on the seismic response of a highly curved, steel I-girder bridge to be tested at University of Nevada, Reno, in Summer 2011.

1 INTRODUCTION

The influence of bridge irregularity is one of the important lessons learned from bridge performance in previous earthquakes. Bridge spans have collapsed or been severely damaged due to non-uniform distributions of stiffness and weight caused by irregular geometry. This irregularity exists in many different forms including variation of span length and weight, column height, presence of skew, and curvature.

Despite the prevalence of curved bridges in urban areas, their seismic behavior is poorly understood. Current U.S and Japanese bridge design specifications provide little guidance on their seismic analysis and design.

A common assumption in the analysis of curved highway bridges is to ignore the curvature and analyze these structures as if they are straight. But for bridges with considerable amount of curvature, this approach may underestimate the forces in the superstructure. Under gravity loads, curved steel I-girder superstructures are subjected to internal torsion which is distributed to the girders through the cross-frames (or diaphragms). The outer girders take more load than the inner girders causing each girder to deflect differently.

The AASHTO LRFD Bridge Design Specifications (AASHTO 2008) permits curved I-girders to be analyzed as a straight girder for determining the major-axis bending moments and shears due to dead and live loads, provided the girders are concentric, the bearing lines are not skewed more than 10^o from the radial direction, all of the girders are about the same stiffness, and the subtended angle of the span is less than 4^o. For bridges with larger curvature, where the lateral flange bending moment can be substantial, the V-load method (United States Steel 1984) is recommended for use in design. In this method, the individual girders are analyzed first as straight to determine the primary major-axis bending moments and shears. These moments and shears are then adjusted using the V-loads, which are a set of self-equilibrating shears between the adjacent girders. The lateral bending moment M_{lat} in the flanges is then approximated using the equation:

$$M_{lat} = \frac{Ml^2}{NRD} \tag{1}$$

where M is the major-axis bending moment, l is the girder unbraced length, R is the girder radius, D is the web depth, and N is a constant taken as either 10 or 12 depending on the desired level of conservatism.

For seismic analysis, the AASHTO LRFD Specifications (AASHTO 2008) and the Guide Specifications for LRFD Seismic Bridge Design (AASHTO 2009) permit curved bridges to be analyzed as if they were straight when the subtended angle is less than 90^o and the bridge has otherwise 'regular' properties, as defined in these specifications.

The Japanese Seismic Specifications for Seismic Design of Highway Bridges (JRA 1996) has language for prevention of unseating of curved bridges during seismic events but provides little information on modeling and seismic analysis of these structures.

In curved steel I-girder bridges, the consideration of geometry is as important as selection of the method of analysis. In general there are three modeling techniques for the analysis of steel I-girder bridges: stick (or spine) model, grillage model, and finite element model. The AASHTO Specifications permit the use of curved stick models for superstructures that do not distort or warp significantly under torsion. For superstructures with multiple girder-lines this distortion may however be large (depending on the cross-frame spacing) and such bridges should be analyzed as grids or continuums. In each case, it is usual to assume the longitudinal beams are straight between nodes.

This paper discusses the results of using different analytical models for calculating response to static lateral loads, and the determination of dynamic modal properties. It also discusses the effect of curvature on response, and the influence of various superstructure components on the seismic load path in horizontally curved steel I-girder bridges.

2 3-SPAN HORIZONTALLY CURVED STEEL I-GIRDER BRIDGE

The geometry and section properties of the bridges used in the analyses presented in this paper, are based on a 3-span, curved, steel I-girder bridge with high degree of curvature (subtended angle is 104^o (1.8 radians)). A 0.4-scale model of this bridge will be tested using the NEES multiple shake tables in the Large-Scale Structures Laboratory at the University of Nevada, Reno in Summer 2011.

The geometry of the prototype and model is summarized in Table 1. The superstructure consists of a reinforced concrete (R/C) deck that is composite with three steel I-girders. The girders are built-up sections consisting of 16 mm by 229 mm flange plates and 10 mm by 660 mm web plate. The R/C deck is 83 mm thick with 19 mm haunch. The piers are single columns with a drop cap.

The model will be used to experimentally study the seismic performance of this bridge in a variety of different configurations including:

- conventional superstructure, columns and bearings without live load (benchmark bridge) and with live load (Figure 1)
- fully isolated superstructure on conventional columns
- partially isolated superstructure with ductile cross-frames on conventional columns (hybrid protective system)
- conventional superstructure on rocking columns, and
- conventional superstructure and columns with abutment interaction and simulated backfill.

The findings of these experimental studies, coupled with analytical investigations, will be used to develop a set of seismic design guidelines for horizontally curved steel bridges.

Table 1 Properties of the 3-Span Curved Bridge

	Prototype	Model
Total length (m)	110.5	44.2
Span lengths (m)	32-46.5-32	12.8-18.6-12.8
Centerline radius (m)	61	24.4
Total width (m)	9.15	3.66
Girder spacing (m)	3.4	1.37
Column height (m)	6.1	2.44
Column diameter (m)	1.52	0.61

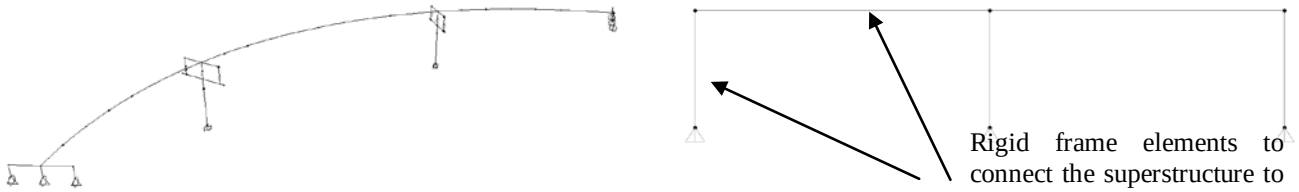
3 MODELING OF HORIZONTALLY CURVED STEEL PLATE GIRDER BRIDGES

The AASHTO/NSBA Guidelines for the Analysis of Steel Girder Bridges (AASHTO/NSBA 2010) provides a detailed discussion of analysis methods for steel girder bridges including guidance on modeling the superstructure from construction to completion.

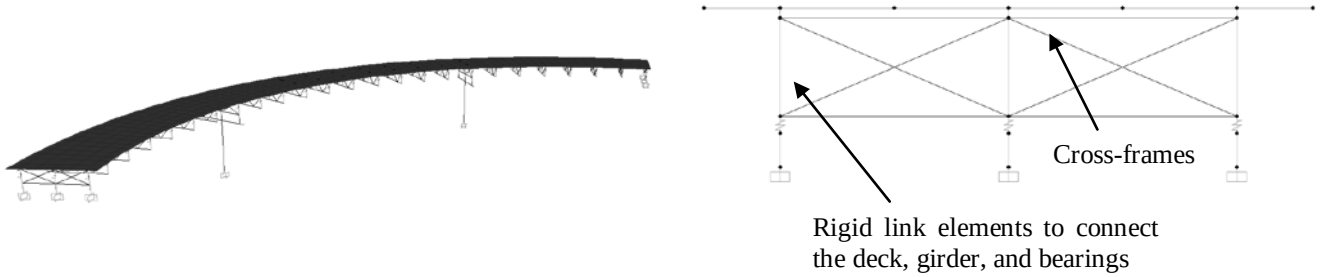
In general, three modeling techniques are recommended for the analysis of steel girder bridges:

- Stick beam (also called 'spine' beam)
- Grillage
- 3D Finite Element Assemblage



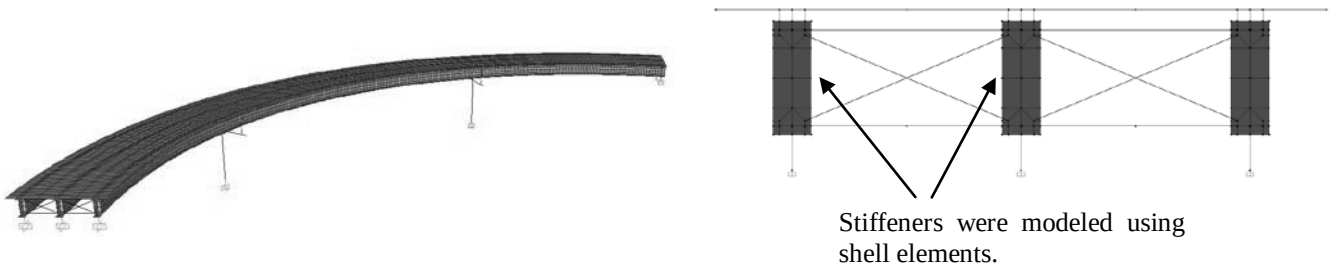
In a stick model (Figure 2a), the superstructure is modeled as a single beam element with equivalent section properties. However stick models created by many computer programs may not include the rotational mass inertia of the superstructure about its longitudinal axis and this should be added to the nodes of the beam, particularly for curved bridges. This model can capture the global response of the bridge with reasonable accuracy including column forces and moments but it does not give good results for local behavior in the superstructure such as torsional rotation, cross-frame and bearing forces. In curved steel bridges, due to geometry, internal torsion is created in the superstructure resulting in an uneven distribution of loads between the girders. The girder on the outside of the curve receives more load and thus has larger deflections than the adjacent girders. Because of this, the deflections obtained from stick models should not be used to determine the camber in the girders. In addition, the effect of cross-frames on the overall structural system is neglected. These frames provide resistance to the torsional moments in the

superstructure and may be subjected to large forces depending on the bridge curvature.



In the grillage model, the individual girders are modeled and are connected transversely by beam elements representing the deck and/or the cross-frames. This modeling technique provides a better representation of the mass across and along the superstructure and thus rotational inertia is implicitly included in this model. However, since the grid elements are located in the same plane, the cross-frames connecting the adjacent girders are modeled using beam elements that have either flexural or shear stiffness. This approach may not be able to capture the actual behavior of cross-frames when subjected to various loadings and it does not provide the cross-frame forces directly. Because the grid elements are located in the same plane, the actual location of bearing supports, which are at the bottom of the girder, may not be modeled correctly. It is noted that horizontal bearing reactions create moments in the superstructure because they are acting at some distance from the superstructure neutral axis. These errors, however, can be lessened through a variation of the grillage model, called the plate-and-beam model.

In the plate-and-beam model (Figure 2b), the deck is modeled as plate or shell elements while the girders are modeled as beam elements. The deck flexibility is modeled accurately and there is better distribution of mass than in the traditional grillage model. The beam element may be placed at the girder center-of-gravity and then connected to the deck and bearings by link elements. Since the superstructure model has "depth", the actual geometry of the cross-frames can be modeled and the bearings can be placed at their correct location.



The 3D Finite Element (FE) model (Figure 2c) is the most rigorous of all the modeling techniques and is regarded as the most accurate. The deck is modeled as shell elements while the girders are modeled by either shell elements for the web and flanges or by combination of shell elements for the web and beam elements for the flanges. Because the superstructure is modeled in detail, information about the stress state of the components is provided. However, this technique can be time-consuming and complicated. Additionally, post-processing is required since the output is in terms of stresses and not moments, shears, and axial loads that are typically used in design calculations.

(c) Finite Element model: 3D view (left) and section at abutments and piers (right)

Figure 2 Structural Models for a Curved Bridge

4 EFFECT OF MODELING

Depending on the complexity and desired level of accuracy, a bridge can be modeled using any of the above techniques. Two cases are given below to illustrate the results given by these modeling techniques for the seismic response of curved girder bridges.

4.1 Static Load Case

Stick, plate-and-beam, and finite element (FE) models of the curved bridge model described in Section 2 were developed in order to compare their response under lateral loading. The assumed boundary conditions are:

a) guided bearings at the abutments that allow translation in the tangential direction but restrain translation in the radial direction
b) pin connection between the girders and pier cap (rotation permitted, translation restrained)

A distributed lateral load (totaling 1,000 kN) was applied to the superstructure of each model in the transverse direction, i.e., normal to the chord joining the two abutments. In the stick model, the distributed load was applied uniformly along the superstructure beam, while in the plate-and-beam and FE models, the loads were distributed equally to each node in the deck. The bearing reactions were then determined and compared as shown in Figure 3.

Using the results of FE model as the baseline, the stick model overestimates the total shear at the abutment by 15%. This overestimation of shear is attributed to the use of rigid frame elements between the superstructure and bearings (see Figure 2a) which stiffens the abutments causing it to attract more load. The most remarkable observation, however, is the difference in vertical reactions at the bearings where the stick model underestimates the reactions by about 50%. This underestimation can have a significant effect on the design of the bearings and other components such as uplift restrainers.

The results from the plate-and-beam model compare well with the FE model although the distribution of radial shears among the bearings varies as much as 9%. This is attributed to the stiffening of the superstructure due to the rigid link elements used to connect the deck, girders and bearings. This suggests that the rigid links should be used with caution because, depending on the stiffness of the cross-frames, the seismic load path might be altered.

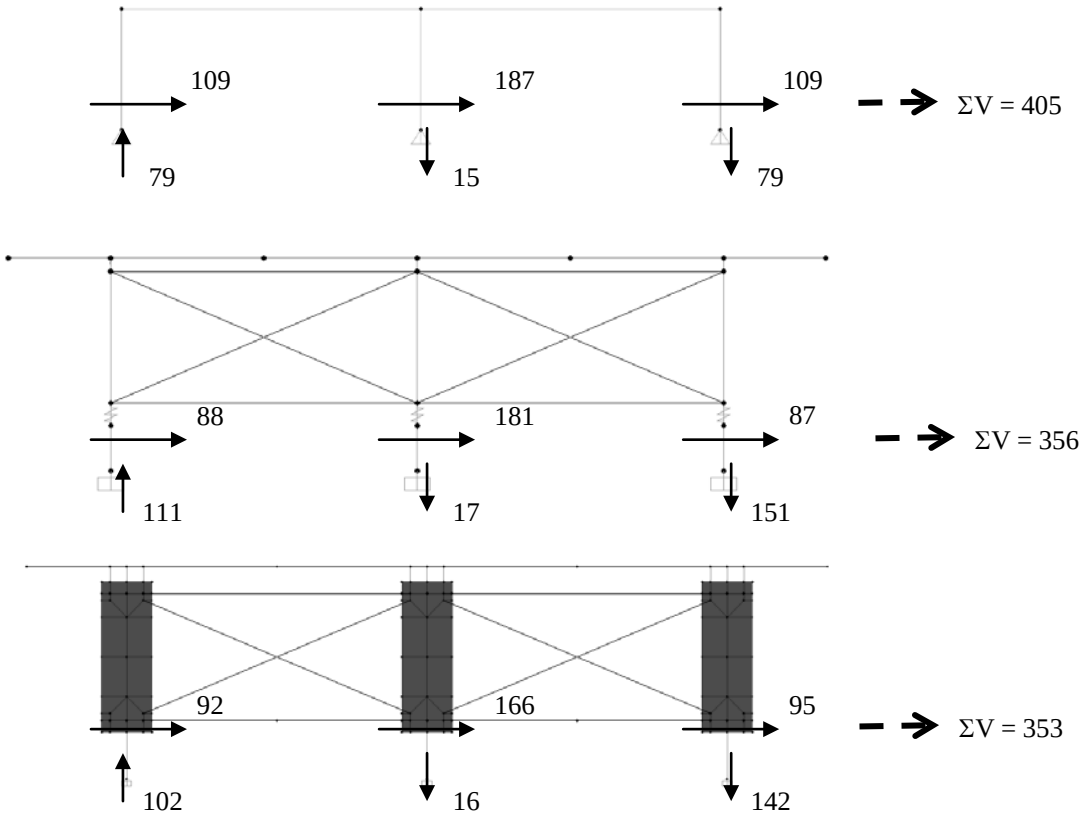

Figure 3 Radial and Vertical Reactions at Abutment due to 1,000 kN Transverse Load on the Superstructure: Stick Model (top), Plate-and-Beam Model (center), Finite Element Model (bottom)

4.2 Dynamic Load Case

To determine how well the three models capture the vibration properties of the curved bridge described in Section 2, modal analyses were performed using each model in turn. The modal periods and modal mass participation ratios of the first five modes of each model are shown in Tables 2 to 4.

The plate-and-beam model compares well with the FE model although it is consistently stiffer than the FE model. Again, this is attributed to the use of rigid link elements between the deck and girders which creates unnecessary stiffening of the superstructure.

The stick model is even stiffer than the plate-and-beam model except for the transverse modes (Modes 2 and 3). Both of these modes are translation in the transverse direction coupled with superstructure flexure and rotation, which is different to the transverse mode of the plate-and-beam and FE models.

These results show that the seismic response provided by the stick model can be significantly in error. The response provided by the plate-and-beam model is reasonable and can be further improved, possibly by using link elements with equivalent girder stiffness between the deck, girders, and bearings.

Table 2 Modal Periods and Mass Participation Ratios: Stick Model

6	0.135	0.000	0.002	0.564

5 EFFECT OF CURVATURE

The AASHTO Specifications (2008) specify the conditions when a curved bridge may be analyzed as if it were straight. Depending on various parameters such as boundary conditions, curvature, skew, and other geometric irregularities, the straight bridge assumption might be able to capture some of the global response. However, this assumption could either underestimate or overestimate the response of local components such as the bearings and cross-frame forces. Bearing forces obtained from a curved bridge can be significantly different than from the corresponding straight bridge due to the difference in boundary conditions, frame action between the piers and abutments, and inherent superstructure torsion. Cross-frame forces must be determined accurately and designed accordingly since they are primary load-carrying members in a curved bridge.

Table 4 Modal Periods and Mass ParticipationRatios: FE Model

Mode	**Period**	**Mass Participating Ratios**		
No.	Sec	X	Y	Z
1	0.795	0.771	0.000	0.000
2	0.532	0.000	0.871	0.001
3	0.350	0.000	0.012	0.039
4	0.172	0.007	0.000	0.000
5	0.150	0.161	0.000	0.000

To determine the effect of curvature, an FE model of a straight bridge with the same properties as the curved bridge model was developed. The cross-frame forces in the two models under dead and seismic loadings were then compared. There are 25 sets of cross-frames in the bridge in Section 2, spaced about 1.83 m apart. The seismic loading was based on a response spectrum defined by a PGA of 0.472g, S_s of 1.135g, and S_1 of 0.41g. This loading was applied in the transverse direction only. The multi-mode spectral analysis method was used to determine the response of the bridge .

Figure 4 shows the comparison of axial forces in one of the diagonal members of the cross-frames under dead load. As shown, the cross-frame forces in a curved bridge can be twice those in the corresponding straight bridge. This discrepancy is most pronounced at the midspan of the center span (cross-frame number 13) and at the piers (cross-frame numbers 8 and 18). The torsional deformations in a curved bridge are largest at the midspan causing axial forces in the nearby cross-frames which are not generated in straight bridges.

Since a curved bridge tends to twist towards the outside of the curve, more load is shifted to the outside bearings at the piers. The pier cap then will have a larger displacement at one end (on the outside of the curve) and smaller displacement at the other end (on the inside of curve). These differential displacements generate forces in the cross-frames. In a straight bridge, cross-frame forces are also generated due to bent cap flexibility but they are smaller because of relatively uniform distribution of bearing forces. At the abutments, the cross-frames forces are small or zero

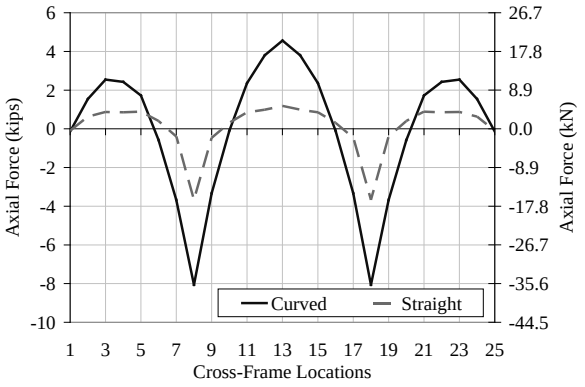

Figure 4 Comparison of Cross-Frame Forces (Diagonal Member) in Curved and Straight Bridge due to Dead Load

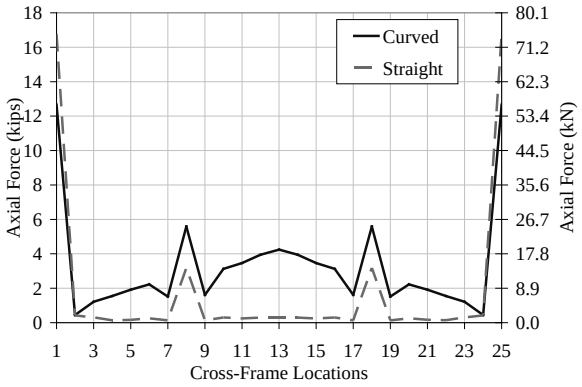

Figure 5 Comparison of Cross-Frame Forces (Diagonal Member) in Curved and Straight Bridge due to Earthquake Loading

because of the near-rigid support provided by the abutment.

Figure 5 shows the comparison of axial forces in one of the diagonal members of the cross-frames under seismic loading. Similar to the observation made under dead load, the discrepancy in the cross-frame forces is largest at midpsan of the center span. Seismic loading in the transverse direction creates frame action in curved bridges due to the offset between the abutments and piers. This frame action results in seismic axial forces in the columns and vertical reactions in the abutment bearings which must be resisted by superstructure torsion (Priestley et al. 1996). This torsion is then resisted by the cross-frames. When added to the dead load effects, this further increases the cross-frame forces in a curved bridge.

However, at the abutments, the cross-frame forces in the straight bridge are larger than those in the curved bridge. This is due to the difference in the boundary conditions in the transverse direction. Since the guided bearings in the curved bridge allow translation in the tangential direction but restrain the radial direction, the transverse direction is only partially restrained. However, in the straight bridge, the abutments are fully restrained in the transverse direction as the guided bearings allow translation in the longitudinal direction only.

As mentioned above, frame action occurs in a curved bridge when subjected to lateral loading in the transverse direction. The transverse lateral loading creates axial forces in the columns due to the offset between the abutments and piers. Depending on the magnitude of seismic force and the amount of offset between the abutments and piers, the columns may be subjected to large fluctuation in axial forces.

6 SEISMIC LOAD PATH

The seismic load path in a straight steel I-girder bridge has been described by Itani et al. (2010). The majority of the inertia loads are generated in the deck slab since the slab and barriers typically account for 80% of the bridge weight.

In the transverse direction, earthquake loading causes transverse bending of the superstructure resulting in transverse reactions at the abutments and piers. Numerical analyses have shown that seismic forces are largely distributed through the deck slab to the ends of the span (Carden et al. 2005a; 2005b; Bahrami et al. 2009) and thus the intermediate cross-frames take very little load. The forces at the ends of the span are then distributed vertically through the abutment and bent cross-frames (Itani 1995; Itani and Rimal 1996; Zahrai and Bruneau 1998) where they are then transmitted to the bearings and shear keys. Since the primary function of the bearings and shear keys is to allow the bridge to expand and contract longitudinally due to temperature variation, the abutments are usually restrained from translation in the transverse direction.

Under longitudinal loading, the load path is from the deck slab to the shear connectors, to the girders, and then to the bearings. This load may be assumed to be distributed uniformly to the shear connectors since they run parallel to the direction of loading and the superstructure is virtually rigid in this direction. If seat-type abutments are used these forces are resisted by the columns alone until the abutment backwall is engaged.

In a curved bridge, the load path is basically the same as that of a straight bridge. However, unlike a straight bridge, the intermediate cross-frames are primary members since they provide torsional rigidity to the superstructure.

Understanding the load path is important particularly in seismic design because it identifies the components that can be designed and detailed to provide energy dissipation during seismic excitation. In straight, steel I-girder bridges, the end cross-frames or diaphragms have been identified analytically (Itani and Rimal 1996; Astaneh-Asl and Donikian 1995; Zahrai and Bruneau 1998) and experimentally (Zahrai

and Bruneau 1999; Carden et al. 2005a; Bahrami et al. 2009) as critical components in the transverse seismic load path. Thus, these components can be designed as ductile members and thereby reduce the forces in a bridge during a transverse earthquake. The cross-frames in a straight bridge have a secondary role during normal operation and can be easily inspected and replaced after an earthquake. It is not clear at this time whether cross-frames in a curved bridge can be designed to play a similar role.

7 EFFECT OF COMPONENT FLEXIBILITIES

As discussed above, the cross-frames, girders, shear connectors, and deck slab are major components in the seismic load path. A parametric study has been conducted to determine the relative importance of these components on the seismic response. Results are briefly described in this section.

7.1 Cross-frames and Girders

Previous research has established that the end cross-frames are an essential component of the seismic load path. Accordingly, a parametric analysis was performed using the FE model of both the curved and straight bridges to determine the effectiveness of the end cross-frames in transferring the seismic forces to the bearings.

This effectiveness was quantified based on the percentage of seismic force transmitted through the end cross-frames. This was accomplished by calculating the ratio of the sum of the horizontal components of cross-frame forces, F_x, to the sum of abutment bearing shears, V_r. In the curved bridge, V_r corresponds to the total abutment radial shear since translation in the tangential direction is free while the radial direction is restrained. In the straight bridge, V_r corresponds to the total abutment transverse shear since translation in the longitudinal direction is free while the transverse direction is restrained.

The lateral loads are applied in the transverse direction and distributed equally among the deck nodes. The ratio F_x / V_r is then plotted as a function of the cross-frame-to-girder lateral stiffness ratio which is defined below.

The cross-frame lateral stiffness is calculated based on the properties of the braces (diagonal members) and is given by:

$$k = \frac{AE}{L}\cos^2(\theta) \tag{2}$$

where, A is the cross-sectional area, E is the modulus of elasticity, L is the brace length, and θ is the angle of the brace measured from the horizontal. Eq. (2) is then multiplied by four to determine the total lateral stiffness since there are four diagonal members in the example bridge.

At the supports, assuming the girder top flange is rigidly connected to the deck and the bottom flange is restrained from translation but free in rotation (i.e. a pin support), the girder deforms by rotation about its longitudinal axis. Then, assuming the girder is fixed against rotation at the location of first intermediate cross-frame due to the restraint provided by the cross-frame, the girder lateral stiffness is given by Carden et al. (2005a) as follows:

$$k_{t\theta} = \frac{k_{\theta g}}{d_{gf}^2} \tag{3}$$

where, $k_{\theta g}$ is the torsional stiffness of the girder between the end and first intermediate cross-frame and is given by Brockenbrough and Johnston (1968) as follows:

$$k_{\theta g} = \frac{J_g G}{a}\frac{1}{\frac{L_1}{a} - \tanh\left(\frac{L_1}{a}\right)} \tag{4}$$

$$a = \frac{d_{gf}}{2}\sqrt{\frac{EI_{gy}}{J_g G}} \tag{5}$$

$$J_g = \sum\left(\frac{bt^3}{3} - 0.21t^4\right) \tag{6}$$

where, L_1 is the length of the girder between the end and first intermediate cross-frames, E is the modulus of elasticity of steel, G is the shear modulus of steel, d_{gf} is the depth of the girder between the center of the flanges, I_{gy} is the moment of inertia of the girder about its weak axis, and b and t are the width and thickness of the plates in the built-up girder.

However, as shown below, it is the flexural stiffness of the bearing stiffeners that has the significant impact on the girder lateral stiffness. Based on the assumption that the top flange is rigidly connected to the deck and a pinned connection to the bottom flange, the flexural stiffness of the bearing stiffener is given by:

$$k_{tb} = \frac{3EI_{ws}}{d_{gf}^3} \tag{7}$$

where, I_{ws} is the moment of inertia of the bearing stiffener.

$$I_{ws} = \frac{t_s b_s^3}{12} \tag{8}$$

where, t_s is the thickness of the bearing stiffener and b_s is the total width of the bearing stiffener including the girder web thickness.

Therefore, the total lateral stiffness of the girder at the supports is given by:

$$K_t = k_{t\theta} + k_{tb} \tag{9}$$

For the bridges used in this parametric study, the lateral stiffness due to girder rotation is 0.88 kN/mm (5 kips/in). This is only 4% of the lateral stiffness provided by the bearing stiffener which is 24.52 kN/mm (140 kips/in). Since there are three girders in the bridge, the total lateral stiffness is 76.18

kN/mm (435 kips/in). Analysis of the FE model without end cross-frames and assuming a rigid deck (similar to the assumption used in developing the above equations) showed that the lateral stiffness is 79.50 kN/mm (454 kips/in), which is close to the calculated stiffness.

Figure 6 shows the relationship between the F_x / V_r ratio and cross-frame-to-girder stiffness ratio. As shown, the percentage of seismic forces transmitted by the end cross-frames increases with increasing stiffness ratio. Since the trend is about the same for both curved and straight bridges, this plot may be used to determine the level of seismic force that the cross-frames should be designed when the base shear is known. One application, for instance, is in capacity-protected design. Suppose the cross-frame-to-girder stiffness ratio is equal to 1.0, the cross-frames will carry about 80% of the base shear and the girders the remaining 20%. Now suppose that, in order to protect the foundation piles from damage, the abutment shear is limited to 1,000kN. In this case the cross-frames must be designed to yield at 800kN of lateral force. Designing the cross-frames to yield at, say, 1,000kN will overload the foundation and potentially damage the supporting piles.

Figure 6 indicates that for stiffness ratios less than 1.0, the girders are carrying most of the lateral load to the supports. This condition could be undesirable since the girders will be subjected to lateral bending. The most desirable condition occurs when the stiffness ratio is of the order of 3.0 since, at this point, the F_x / V_r ratio is almost 1.0 and all of the the seismic load is transferred to the abutments through the cross-frames and the girders carry negligible loads. At stiffness ratios greater than 3.0, the cross-frame forces are higher than the abutment shear. This means that an opposing force develops in the girders, which is transmitted away from the abutments to the piers. This condition could also be undesirable since not only will the girders be subjected to lateral bending but also the column forces will increase.

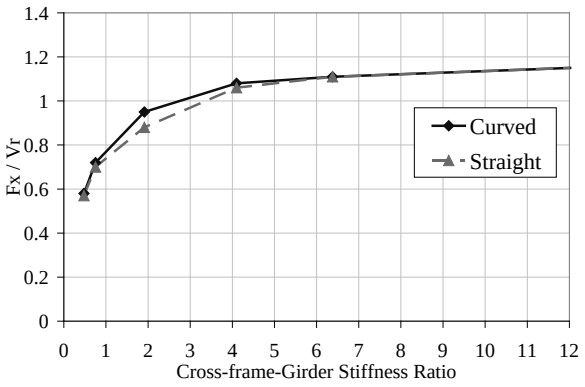

Figure 6 Relationship Between Cross-Frame Forces and Cross-Frame-to-Girder Stiffness Ratio

7.2 Shear Connectors

The primary function of the shear connectors (studs) in steel I-girder bridges is to provide composite action between the deck slab and the girders. As mentioned previously, the shear connectors are one of the main components in the load path in both the transverse and longitudinal directions. Failure of the studs near the supports causes the entire load path to be altered such that the intermediate cross-frames will be subjected to large seismic forces and the girders will be sustain large lateral bending.

A common assumption in analytical modeling of steel I-girder bridges is that the studs are rigid. Thus, a parametric analysis was performed to determine if the flexibility of the studs affects the distribution of seismic forces. As in the previous section, this effect is quantified in terms of the F_x / V_r ratio.

The stud transverse stiffness is determined for each of three conditions:

(a) First, the stud is assumed free to bend along its entire length which means the deck is fully cracked. This represents a lower bound on the stud stiffness.

$$k_b = \frac{12EI}{L^3} \tag{10}$$

where, E is the stud modulus of elasticity, I is the stud moment of inertia, and L is the effective length.

(b) Second, the stud is assumed free to bend along its half length only. This assumption is based on the fact that the stud is unconfined along the haunch thickness and cracking is usually observed at this location. This cracking can extend up to the half length of the stud. The equivalent transverse stiffness including shear deformation is:

$$k = \frac{1}{1/k_b + 1/k_s} \tag{11}$$

where, k_s is the shear stiffness given by Eq. (12).

(c) Third, as an upper bound on stud stiffness, it is assumed that the stud is restrained against bending along its entire length but can deform in shear. The shear stiffness is given by:

$$k_s = \frac{GA}{L} \tag{12}$$

where, G is the stud shear modulus, A is the area of the stud.

The studs used in the bridge model are 10 mm (3/8 in.) with an effective total length of 70 mm (2-3/4 in.). Using the above equations, the stud stiffness for each condition is (a) 2.84 kN/mm (16.24 kips/in) per stud, (b) 19.88 kN/mm (113.5 kips/in) per stud, and (c) 78.10 kN/mm (446 kips/in) per stud. There are three studs per row in each girder.

Figure 7 shows the relationship between the F_x / V_r ratio and stud stiffness. It is seen that stud stiffness has negligible effect on the distribution of seismic loads among the cross-frames and girders. It is also

seen that this observation is independent of the assumption about deck flexibility. However deck flexibility can have a significant effect on the distribution of seismic loads, as discussed in the next section.

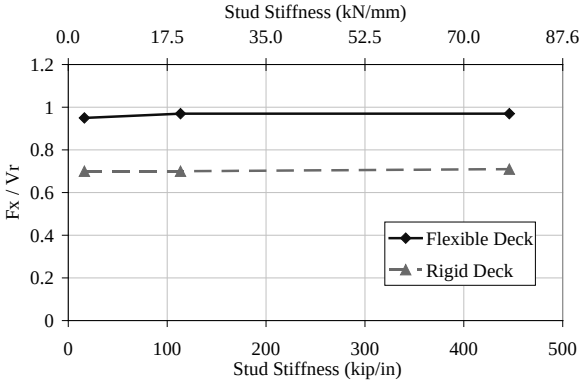

Figure 7 Effect of Shear Connector Stiffness on F_x/V_r

7.3 Deck Slab

The effect of deck flexibility on the distribution of seismic loads among the components is investigated by varying the ratio of the in-plane flexural rigidity (EI) of the deck slab to the transverse rigidity (EI) of the girders. In this study, the girder EI was kept constant while the deck slab EI was varied. The effect on the load distribution was then quantified in terms of the F_x / V_r ratio as before. Figure 8 shows that as the deck-girder stiffness ratio increases, the amount of seismic load transferred by the cross-frames decreases. For a rigid deck, the cross-frames transmit only 70% of the seismic load.

It should be noted that the above observations also apply to straight I-girder bridges.

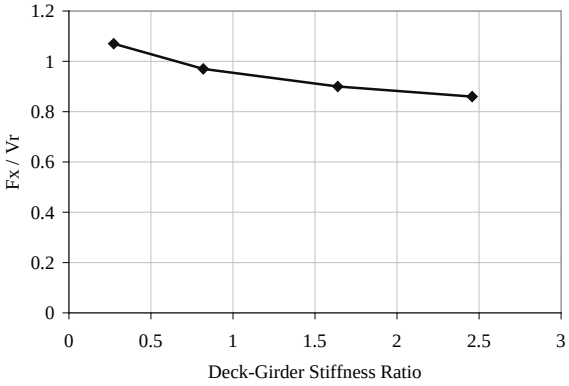

Figure 8 Effect of Deck Stiffness on F_x/V_r

8 CONCLUSIONS

Different modeling techniques used in the analysis of curved steel I-girder bridges have been discussed in this paper. The effect of modeling on response was determined by comparing the seismic response of stick, grillage (plate-and-beam), and finite element models. It has been shown that the seismic response of the stick model can be significantly in error, whereas the response of plate-and-beam model is comparable to that of FE model.

The effect of curvature was determined by comparing the response of straight and curved bridges under dead and seismic loads. It has been shown that the straight bridge assumption can lead to significant underestimation of local component response.

A parametric study was conducted to determine the influence of the relative stiffness of the cross-frames, girders, shear connectors, and deck slab on the distribution of seismic loads (i.e., the seismic load path). The following conclusions were made:

- The cross-frames are most effective in transferring the seismic forces to the bearings when the cross-frame-to-girder stiffness ratio is equal to 3.0.
- Modeling of the shear connectors has negligible effect on the distribution of seismic forces among the cross-frames and girders.
- The seismic forces transmitted by the cross-frames to the bearings decreases as the deck stiffness increases.

The relationships established may be used to proportion the components along the load path for optimal seismic response.

Abstract: This study focused on the performance evaluation of twin-cell hollow composite members subjected to combined cyclic loads. A series of composite members with various sectional aspect ratios were tested under bending, torsion and their combinations. It was observed that the deterioration in strength was lower for member with higher aspect ratio when the member was subjected to combined bending and torsion. It is also found from the test results that the energy dissipation capacities for members with larger aspect ratios were higher when they were subjected to the combined loads. Finally, an empirical expression for strength evaluation of members subjected to combined bending and torsion was proposed for engineering practice purpose.

1. INTRODUCTION

Steel-concrete composite members possess high strength and sufficient ductility thus are suitable structural forms for earthquake-resistant design for bridge constructions [El-Tawil and Deierlein 1999, Inai et al. 2004]. For bridge piers designed for extreme loads, the structural members with excessive dimensions and weight are usually required to sustain the applied loads. This hampers the competitiveness of the designs, and thus should be resolved with modified details. In this regard, the use of hollow sections is a remedy, as lower structural weight could be achieved to reduce the earthquake-induced lateral force and to alleviate the design demands [Bernardo and Lopes 2009, Lopes and Bernardo 2009, Taylor et al. 1995].

In general, the design of composite hollow bridge piers with excessive dimensions will incur concerns on the adequateness of the sectional detailing. For example, the width/thickness ratios of the sectional walls would be large if the light structural weight requirement is to be sustained. In such cases, the achievable strength of the member will be reduced as premature failure would occur in the section's thin walls. In order to mitigate the risk of premature failure in those regions, the sectional stability must be improved. For this purpose, a twin-cell composite section, as shown in Figure 1, is proposed in this study to possibly enhance the member performance.
For bridge piers designed for earthquake-resistant purposes, the structural performance must be validated under general loads induced by the earthquake, particularly torsion and combined loads coupled with torsion, because concrete is vulnerable to the torsion-induced shear. Therefore, this study focused on the performance evaluation of the twin-cell hollow composite members under combined bending and torsion. A series of cyclic loading tests on composite members with various sectional compositions were conducted. Test results were used to investigate the relationship between the member performance and the sectional configurations, and to establish design reference for engineering practice.

2. EXPERIMENTAL PROGRAM

Twelve twin-cell hollow composite specimens, as described in Figure 2, with different aspect ratios were fabricated for testing. The specimens were divided into three categories: 150, 250, and 350 series according to the dimensions of the steel tubes: 150×150×6mm, 250×150×6mm, and 350×150×6mm, respectively. Concrete thickness of all specimens was 100mm. Therefore, the aspect ratios (B/D; width/depth) of the three test series were 1.714, 2.286 and 2.857, respectively. The reinforced concrete was composed of #6 longitudinal bars and #3 stirrups. Stirrup spacings in the confined and unconfined zones were 70mm and 150 mm, respectively. The bottom of the member was clamped by a pair of stiffened platforms so that a rigid boundary condition

could be achieved. A pair of stiffened loading beams were attached to the member tops for load transmission. In order to evaluate the member performance, four load combinations were adopted for testing. These loads included bending, pure torsion, bending and smaller torsion, and bending with larger torsion, respectively. Specimens were labels according to their cross-sections and the applied load combinations, and were listed in Table 1.

For bending tests, a hydraulic actuator was placed at the center of the loading beam and driven by a set of increasing displacement commands, as shown is Figure 3. For the pure torsion tests, the actuator was moved to one end and a stiffened strut with hinged ends was placed at the center of the loading beam. Torsion was generated via the couple action of the actuator and the strut. Combined bending and torsion was generated by the actuator that was eccentrically placed and driven by the same displacement commands as those in the bending tests. The test set-up is shown in Figure 4.

3. FAILURE PATTERNS

Failure of members subjected to bending was initiated by the crack formation at the member bottoms. Concrete spalling was observed during the cyclic loading process. Buckling of the longitudinal bars was observed when members were subjected to large deformation. Plastic hinges were formed when the cover concrete crushed. For members subjected to pure torsion, failure was found to be concentrated at the center portions of the members. Crack widened and spread as twist angles were increased. Concrete spalling due to squeezing of cracked concrete blocks was observed at large distortion. The member's torsional strength deteriorated after the member reached the maximum strength.

For members subjected to lateral load with smaller eccentricity, the damage zone was closer to the bottom of the members. However, when the magnitude of applied torsion increased, the damaged region was shifted to the center portions of the members. The member performance was thus susceptible as less confinement was arranged in those areas. This phenomenon validated the importance of torsional effect on the design of composite members. Typical failure modes of members subjected to various loads are shown in Figure 5.

4. COMPARISONS OF TEST RESULTS

4.1 Strength

Figure 6 shows the typical hysteretic relationships for members subjected to different load combinations. The backbone curves for the members are also compared in Figure 7. It can be found from the figure that the deterioration rates in strength was smaller for member with larger steel strength ratio. This phenomenon can be explained by the effective flexural rigidity of the steel tube because the tube strength contributed major portion of the member strength when the concrete was damaged at large deformation. Therefore, members with larger steel strength ratio could sustain higher member strength.

In order to define the relationship between aspect ratio and the member performance, the achievable strength of members subjected to combined bending and torsion was further evaluated. Figure 8 shows the relationship between normalized bending and torsional strength. It can be found from the figure that member's flexural strength decreased when the torsion magnitude was increased. The relationships can be linearly approximated with adequate accuracy, and expressed as follows:

$$\frac{M}{M_u} + \alpha \cdot (\frac{T}{T_u}) = 1 \qquad (1)$$

in which M and T are the achievable flexural and torsional strength when the members are under combined loading, M_u and T_u are the bending and torsional strength of the section, α is a reduction factor accounting for the torsional effect. The relationships for the three test series were

150 series (B/D=1.714),

$$\frac{M}{M_u} + 0.43942 \cdot (\frac{T}{T_u}) = 1 \qquad (2)$$

250 series (B/D=2.286),

$$\frac{M}{M_u} + 0.32201 \cdot (\frac{T}{T_u}) = 1 \qquad (3)$$

350 series (B/D=2.857),

$$\frac{M}{M_u} + 0.25361 \cdot (\frac{T}{T_u}) = 1 \qquad (4)$$

It can be found from the above equations that the reduction factor α is related to the sectional aspect ratio (B/D), as shown in Figure 9. Therefore, the member strength under combined bending and torsion can be further refined as follows:

$$\frac{M}{M_u} + (0.7119 - 0.16257 \frac{B}{D}) \cdot (\frac{T}{T_u}) = 1 \qquad (5)$$

4.2 Energy Dissipation

Energy dissipation was evaluated using the cumulative area of the hysteretic curve. Figure 10 shows the relationship between the strength and the cumulative energy dissipation for the three test series. In order to investigate the members' performance, the achievable cumulative energy when members reached the failure state, defined by the state at which the member strength dropped to 85% of the member's bending strength, was compared. It can be observed from the comparison that member's energy dissipation capacity was significantly reduced when torsion was presented. It can also be found

from the figure that members with larger sectional aspect ratio maintained sufficient energy dissipation capacity no matter the member were under small eccentric load or large eccentric load. However, for members with smaller sectional aspect ratios, e.g. 150 series and 250 series, the members' energy dissipation could be susceptible when loads coupling with torsion was applied. These phenomena validated the importance of the cross-sectional aspect ratio on the seismic performance of twin-cell hollow composite members.

5. CONCLUSIONS

This study evaluated the performance of twin-cell hollow composite members subjected to combined cyclic loads. A series of composite members with various sectional aspect ratios were tested under bending, torsion and their combinations. It was observed that the deterioration in strength was lower for member with higher aspect ratio when the member was subjected to combined bending and torsion. It is also found from the test results that the energy dissipation capacities for members with larger aspect ratios were higher when they were subjected to the combined loads. Finally, an empirical expression for strength evaluation of members subjected to combined bending and torsion was proposed for engineering practice purpose.

Abstract: Seismic design procedures for reinforced concrete bridges columns in the United States are based on theoretical models that have been calibrated against results from numerous cyclic load tests and shake table experiments. Most if not all of the shake table experiments were performed on scaled specimens due to prior limitations of shake tables. The investigation of the modes of failure of columns built at full-scale and tested under simulated earthquake loading is a critical link to evaluate the basis for the seismic design procedure. To study potential scale effects, full-scale dynamic testing is necessary. For this stipulation, shake table test results of a 1.22-m diameter reinforced concrete bridge column was conducted. This was the first shake table test of a full-scale bridge column detailed with current Caltrans design practices. The objective of testing was to induce nonlinear deformation demands and monitor the dynamic response for comparison with a small-scale shake table test to be conducted at the University of California, Berkeley.

1. INTRODUCTION

Results from the first shake table test of a full-scale bridge column detailed with current Caltrans design practices are presented. For the investigation of scale effects, a 1.22-m diameter reinforced concrete bridge column was tested under simulated historical earthquakes. The column, whose height to diameter aspect ratio was six, was expected to have a flexurally dominated response. To mobilize the column's capacity, a concrete mass weighing 2.32 MN was placed on top of the 7.32-m column.

The objective of testing was to induce nonlinear deformation demands and monitor the dynamic response for comparison with a small-scale shake table test to be conducted at the University of California, Berkeley. Validation of current design practices and analysis methods were of primary interest in this project and can be assessed from the achieved objective.

The test specimen was densely instrumented to obtain high quality response measurements under various earthquake ground motions. A total of ten earthquake simulations were conducted with the larger intensity simulations producing large inelastic response. Tests were conducted over two days on the NEES shake table at the University of California, San Diego's Englekirk Structural Engineering Center between September 20th and 21st, 2010.

2. TEST SETUP

The test specimen included a cantilevered reinforced concrete column, footing, and superstructure mass, see Figure 1. The column represented a full scale bridge column designed to current Caltrans design guidelines, but was not modeled after an existing prototype bridge column. The column's footing was secured to the shake table with post-tensioning to prevent decompression under maximum expected overturning moment and provide shear transfer without sliding. The superstructure mass provided the appropriate column axial load and mass necessary to generate the forces inducing nonlinear response.

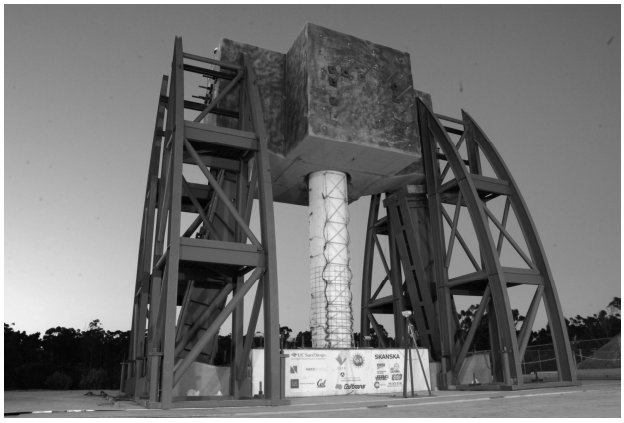

Figure 1 Test setup

The column was designed according to Caltrans Seismic Design Criteria (Caltrans, 2006) and Bridge Design Specifications (Caltrans, 2004). The 1.22-m diameter cantilever column spanned 7.31 m above the footing. The longitudinal reinforcement consisted of eighteen #11 (35.8-mm diameter) bars evenly spaced around the column perimeter. Butt-welded, double #5 (15.9-mm diameter) hoops, spaced at 152 mm on-center were used as transverse reinforcement. The term "double" refers to two hoops bundled together at each 152 mm spacing. Clear cover to the hoops was 51 mm. Column reinforcement layout and the test specimen's geometry are provided in Figure 2.

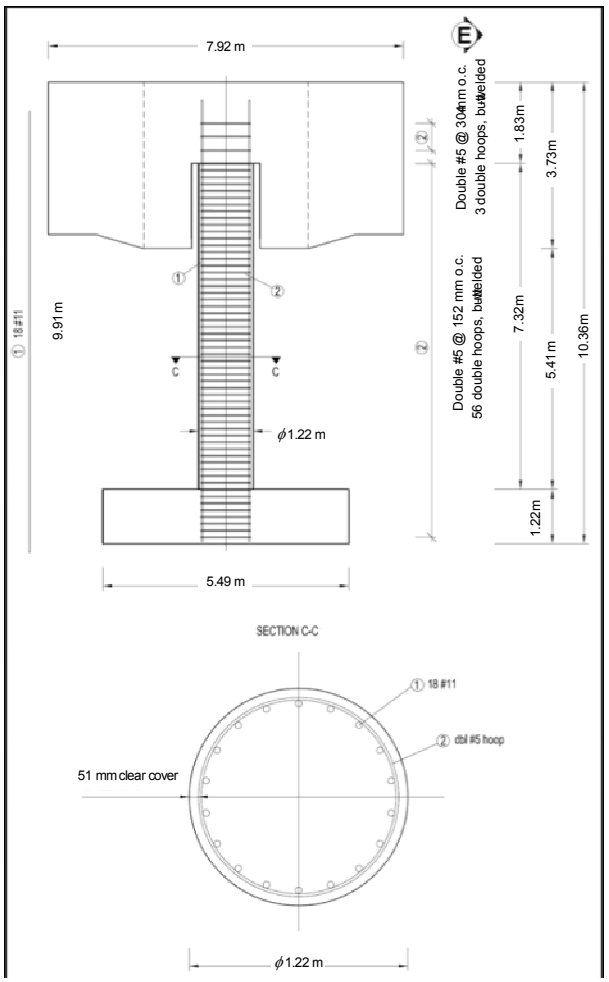

Figure 2 Reinforcing details of the test specimen

A longitudinal reinforcement ratio, ρ_l, of 1.55%, typical of current practice, was provided for the column. The transverse reinforcement provided a volumetric confining ratio, ρ_s, of 0.953%. Reinforcement complied with minimum and maximum requirements (Caltrans, 2004 and Caltrans, 2006).

The estimated axial load at the column base was 2.53 MN. Accounting for the measured concrete strength at day one of testing, this axial load produced an axial load ratio of 5.34%.

The superstructure block's geometry was designed so its center of mass was located at the top of the column. To ensure an unencumbered column height of 7.32 m, a blockout was provided between the column and the block for the bottom 1.91 m of the block. A 1.52-m diameter corrugated pipe embedded in the block resulted in a 152.4-mm gap between the block and the column. The corrugated pipe was utilized as stay-in-place formwork.

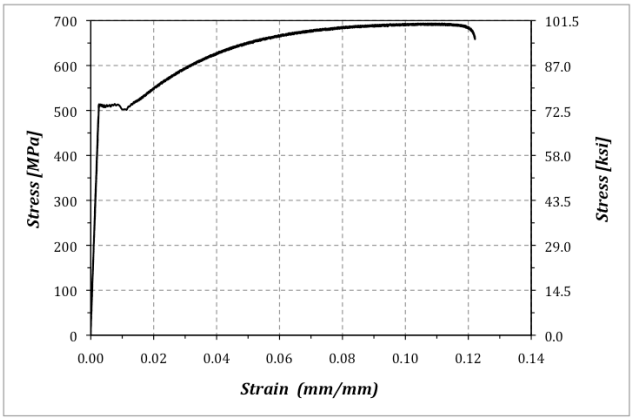
Safety restraints, secured to the shake table, surrounded the test specimen to provide protection to site personnel and equipment. To preclude out-of-plane motion, the safety restraints located at the corners of the specimen were fitted with guides. Pairs of steel tubes were aligned in the direction of shaking and welded to the arched safety towers. A clear 6.4 mm gap between the guides and concrete blocks was greased to reduce friction should contact initiate between the blocks and the restraint towers.

To limit the column displacement to a 10% drift ratio and prevent a gravity load collapse, inclined safety columns were placed on either side of the column in the direction of shaking. Large timbers secured to the safety columns were incorporated to dissipate energy at impact between the superstructure mass and the columns.

3. MATERIAL PROPERTIES

The specified concrete strength of the column was 27.6 MPa. Maximum aggregate size was 25.4 mm. At the time of casting, 152.4-mm diameter by 304.8-mm high concrete test cylinders were taken. These provided an average concrete unit weight of 23.58 kN/m3. Cylinders were tested under monotonic compression in sets of three samples at twenty-nine, forty-two, and forty-three days. Commencement of shake table testing corresponded to an age of forty-two days in the column concrete. The forty-three day age corresponded to the second day of shake table testing. Of the three samples in a set, two samples were taken from the first batch of concrete delivered to the site and one sample was from the second batch of concrete. This gave emphasis to the concrete strength in the plastic hinge region. Table 1 summarizes the results of these compression tests.

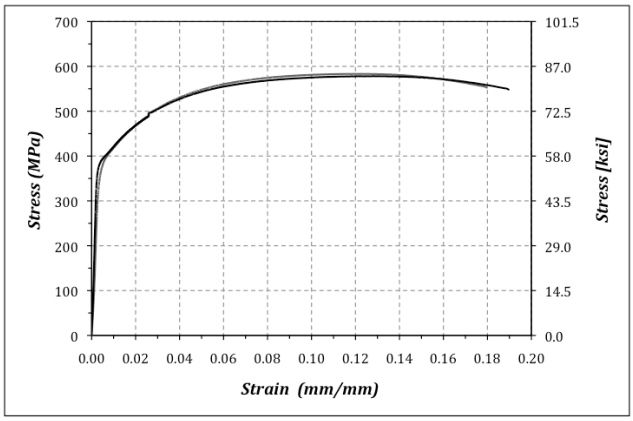
Table 1 Column concrete strength



Age	f'_c
(Days)	(MPa)
29	40.3 *
42	40.9 +
43	42.0 ‡

* Average of three samples
+ Average of five samples
‡ Average of six samples

Column longitudinal and transverse reinforcement was specified as Grade 60 (414 MPa) steel conforming to ASTM A706. The #11 (35.8-mm diameter) longitudinal reinforcement had a yield strength of 518.5 MPa and an



ultimate strength of 706.7 MPa. These strengths were obtained from monotonic tension tests. A complete stress-strain curve for this reinforcement is provided in Figure 3.

Figure 3 Column longitudinal reinforcement stress-strain relationship

Samples taken from the #5 (15.9-mm diameter) transverse hoops tested under monotonic tension did not exhibit a yield plateau. The peak stress was 592.2 MPa. A full stress-strain relationship of two samples is provided in Figure 4. These samples were cut from three bent hoops outside of the weld-affected region. The butt welds of the three sample hoops were also tested and all failed outside of the weld. Yield strength based on the mill cert of the straight #5 bars was expected to be 454 MPa and the ultimate tensile strength was expected to be 600 MPa.

Figure 4 Column transverse hoop reinforcement stress-strain relationship

4. LOADING PROTOCOL

A total of ten earthquake simulation tests were conducted. The intended loading protocol consisted of six simulated earthquake tests. Four historical earthquake recordings were selected as shake table input motions. A site of San Francisco, California, was considered for the seismic hazard. Therefore, earthquake recordings from a strike slip fault mechanism were given preference. Three input motions were selected from the 1989 Loma Prieta earthquake. The fourth record was sourced from the Takatori station during the 1995 Kobe earthquake. These records are identified in Table 2. Each of the recordings was obtained from the PEER's strong motion database (PEER, 2007).

Table 2 Ground motion selections

Test	Target displacement ductility	Scale factor	Table PGA (g)
EQ1	1.0	1.0	-0.199
EQ2	2.0	1.0	0.409
EQ3	4.0	1.0	0.526
EQ4	2.0	1.0	0.454
EQ5	8.0	-0.8	-0.533
EQ6	4.0	1.0	-0.512
EQ7	Not applicable	1.0	0.646
EQ8	Not applicable	-1.2	-0.829
EQ9	Not applicable	1.2	0.819
EQ10	Not applicable	1.2	0.851

Input motions were selected based on their ability to produce a target displacement, in terms of displacement ductility, in the test specimen without scaling. The target drifts were anticipated from linear elastic displacement response spectra and nonlinear dynamic time history analyses using a lumped plasticity column model. Based on the nonlinear analytical demands, the Takatori record for EQ5 was scaled down to 80% of the original record to produce the targeted displacement in the analytical model. The polarity of this record was inverted based on analytically predicted residual drifts. The targeted displacement ductility, scale factor, and resulting peak ground acceleration (PGA) are identified with the test name in Table 3.

Table 3 Ground motion scale factors

Test	Earthquake	Station	Comp-onent
EQ1	Loma Prieta	Agnew State Hospital	090
EQ2	Loma Prieta	Corralitos	090

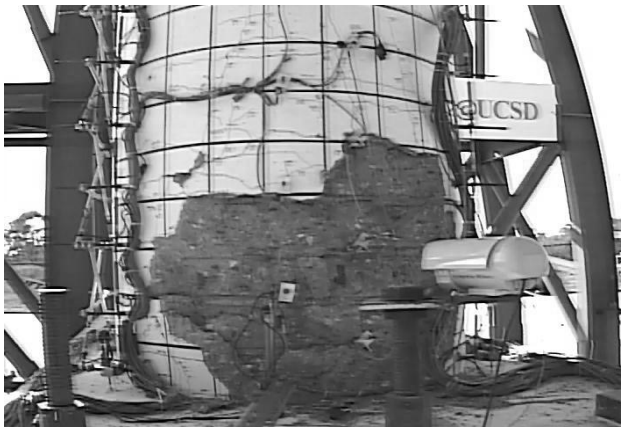
EQ6	Loma Prieta	LGPC	000
EQ7	Kobe	Takatori	000
EQ8	Kobe	Takatori	000
EQ9	Kobe	Takatori	000
EQ10	Kobe	Takatori	000



Before the first earthquake simulation, two white noise table motions were conducted. A white noise table motion with a 0.03-g root mean square amplitude was used to check the instrumentation for quality control assurance. The same input motion was repeated before testing commenced and then repeated between subsequent

earthquake tests. This was implemented to observe the period shift and mode shape changes caused by damage accumulation.

5. RESULTS

The results summarized pertain to the extended scope of testing. This includes the last four tests referred to as EQ7 through EQ10. As a result of the prior six earthquake simulations, the column was damaged and had a fully developed plastic hinge. Concrete had spalled at the base of the column, and cracks extended the visible height of the column. Figure # is a view of the East face of the column's base post-EQ6 test. The residual displacement caused by the preceding tests was 50 mm or 0.68% residual drift ratio.

Figure 3 Column base post-EQ6

The objective of extended testing was to initiate failure and bring the column to a near-collapse condition. This was implemented with the Takatori record of the 1995 Kobe earthquake at various scaled amplitudes.

5.1 Test EQ7

In test EQ7, the Takatori motion was utilized at 100% of the original record. This resulted in a peak drift ratio of 7.56%. A residual drift ratio of -1.98%, or -145 mm column displacement, remained post-test.

A post-test view of the East face of the column base is shown in Figure 4. Although not visible in this figure, further spalling was produced and more of the longitudinal bars were exposed as the spalling penetrated deeper into the face of the column.

The peak column base moment was 7,378 kN-m, see Figure 5. This was the maximum overturning moment obtained in any of the tests. The peak shear force was 817 kN, the second largest shear force obtained in any of the tests. The lateral shear force and displacement response is shown in Figure 6.

Figure 4 Column base post-EQ7

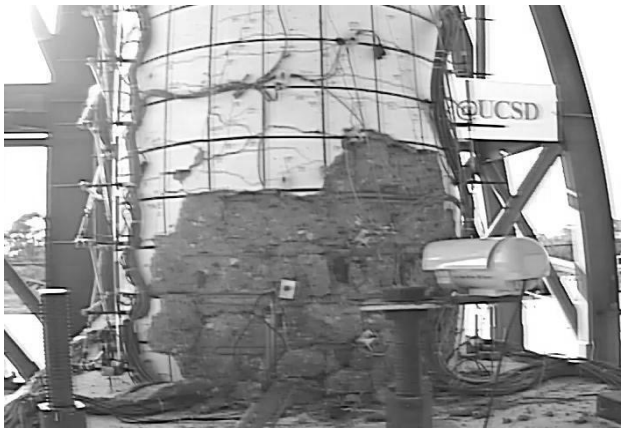


Figure 5 EQ7 moment-curvature relationship

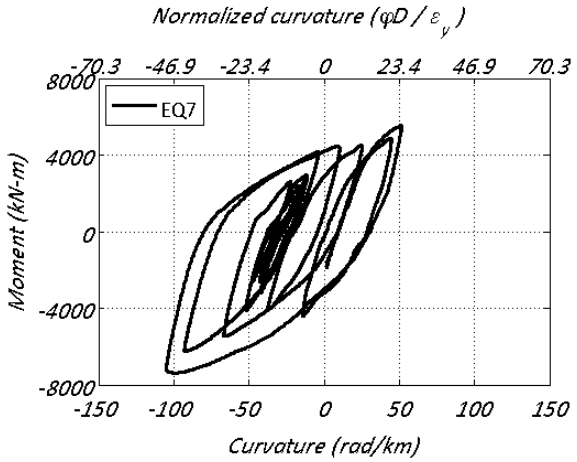

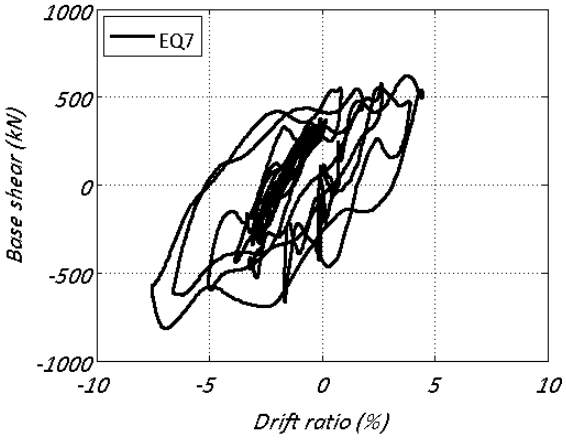

Figure 6 EQ7 shear-drift ratio relationship

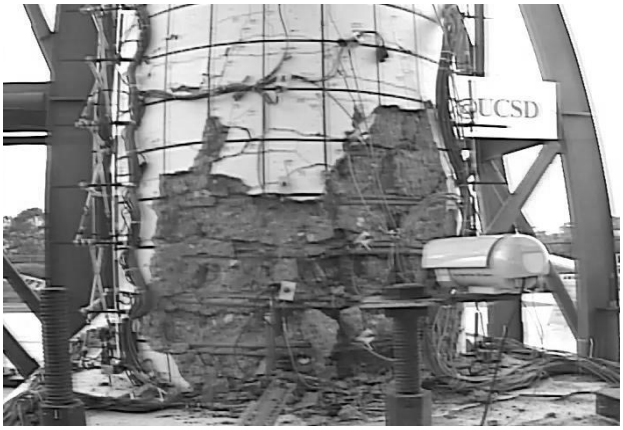


5.2 Test EQ8

A scale factor of -1.2 was used with the original Takatori record in test EQ8. This imposed a 606 mm column displacement. The corresponding drift ratio was 8.28%. The residual displacement was 97 mm at the top of the column, which normalizes to 1.33% residual drift ratio.

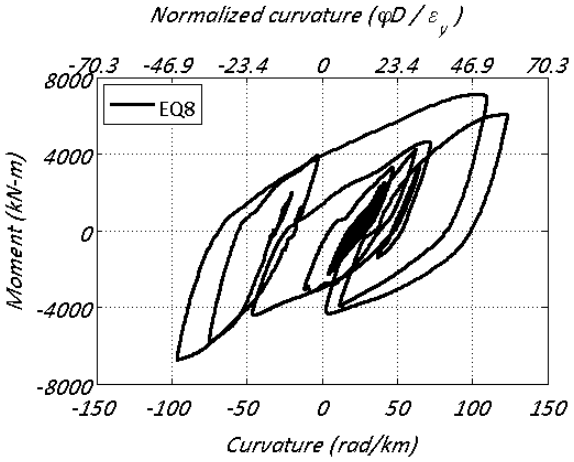
A post-test view of the East face of the column base is shown in Figure 7. In this figure, the two exposed longitudinal reinforcing bars on the right side of the column

centerline have fractured. Neither the fracture nor the bar's buckled shape are apparent in this figure. This was the first damage beyond concrete cracking and spalling induced in the test specimen.

Figure 7 Column base post-EQ8

The peak column base moment was 7,117 kN-m see Figure 8. The peak shear force was 745 kN, see Figure 9.

Figure 8 EQ8 moment-curvature relationship



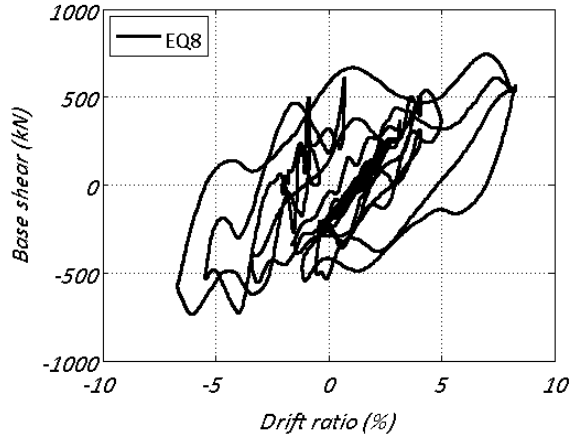


Figure 9 EQ8 shear-drift ratio relationship

5.3 Test EQ9

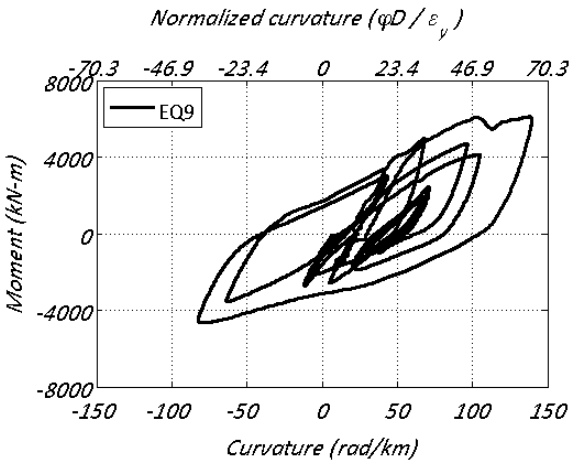
Reversing the polarity of the previous test, a scale factor of 1.2 was used with the original Takatori record for test EQ9. Early in the time history, a third longitudinal reinforcing bar fractured on the East face of the column. A post-test view of the East face of the column base is shown in Figure 10, but the fractures are not apparent. Two reinforcing bars fractured on the West face during this test. This is evident as a drop in moment capacity at about 110 rad/km in the moment-curvature relationship of Figure 11.

Figure 10 Column base post-EQ9

The peak column displacement was 635 mm corresponding to a drift ratio of 8.69%. A residual displacement of 225 mm, or 3.07% residual drift ratio, remained post-test.

The peak column base moment was 6,111 kN-m. This is 83% of the peak moment achieved in test EQ7. Stiffness degradation is apparent in the moment-curvature response, see Figure 11. The peak shear force was 742 kN. The lateral shear force-displacement response is shown in Figure 12.

Figure 11 EQ9 moment-curvature relationship



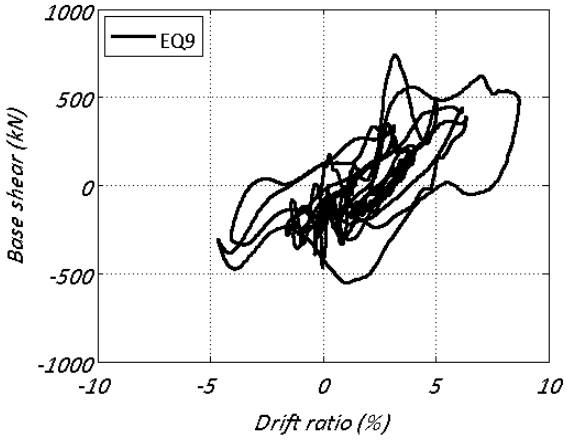


Figure 12 EQ9 shear-drift ratio relationship

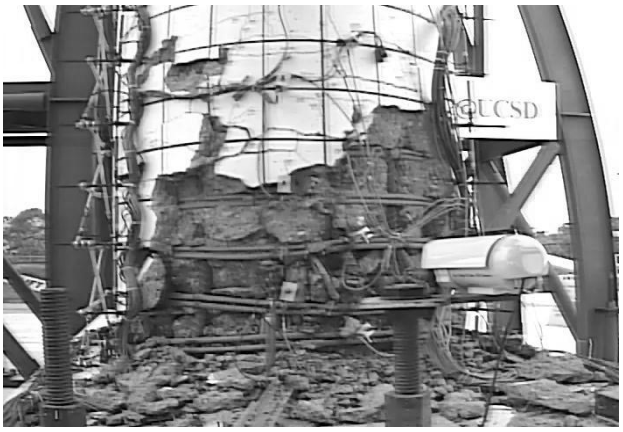

5.4 Test EQ10

The same scale factor of 1.2 was utilized with the Takatori record as in test EQ9. Prior tests resulted in a reduced column capacity caused by the fracture of five longitudinal bars. A sixth longitudinal reinforcing bar fractured during this test. This was the fourth bar to fracture on the East face of the column. However, the superstructure mass impacted the East safety column before this fracture occurred. During impact, the column displaced 757 mm. The drift ratio at impact was 10.34%.

A post-test view of the East face of the column base is shown in Figure 13. Vertical offset of the transverse hoops caused by the buckled longitudinal reinforcement is evident in this figure. However, the transverse reinforcement did not fracture.

Figure 13 Column base post-EQ10

The derived moment and shear force are heavily influenced at impact, and are therefore not reported. These peak moment and shear force are also omitted for this reason from Table 4, which contains a summary of several response quantities for each test. The drift ratio, longitudinal strain, base moment, base shear, and average base curvature are provided in terms of peak demand.

Table 4 Peak response quantities

Test	Peak drift ratio	Peak longitudinal strain	Peak moment	Peak shear	Peak curvature
	(%)	(mm/mm)	(MN-m)	(kN)	(rad/km)
EQ1	0.85	0.0022	3.93	500	6.8
EQ2	1.82	0.0132	5.87	698	15.6
EQ3	4.93	0.0298	6.60	887	60.8

* Impacted the East safety column at peak displacement.

3. CONCLUSIONS

Ten earthquake simulations were conducted on a full-scale bridge column built to current Caltrans design specifications. Damage occurred in a concentrated plastic hinge at the base of the column. The response was dominated by a flexural plastic hinge, and shear capacity was maintained throughout testing.

Column cracks extended the accessible height of the column by testing completion. However, concrete spalling, longitudinal bar buckling, and longitudinal bar fracture were located within 1.22-m, or one column diameter, of the base of the column. Four longitudinal bars on the East face of the column fractured. Two longitudinal bars on the West face fractured and an additional two bars developed cracks which did not propagate through the bar diameter. All of the exposed longitudinal bars exhibited buckling deformation. Transverse hoops did not fracture and the concrete core remained largely intact.

To further the investigation on scale effects of reinforced concrete bridge columns, a scaled replica will be constructed and tested at University of California, Berkeley. This direct comparison of failure modes is a critical link to assess the consequence or validity of relying on small-scale tests for the development of seismic design procedures of reinforced concrete columns.

Abstract: In the Mid Niigata Prefecture Earthquake in 2004, the damage of a bridge pier was found mitigated by the collision between the girder and the abutment. In the seismic response analysis, it is thus important to include the effect of collision. A simple and practical method of simulating collision in the numerical analysis is the introduction of a spring where the collision occurs. However, the constant of such a collision spring is yet to be formulated well. In this study, an appropriate collision-spring constant is investigated for simulating the collisions between girders and between a girder and an abutment. A small collision-spring constant tends to cause the large overlap of colliding bodies while a large collision-spring constant tends to cause many fictitious collisions during the real collision. Various girder-girder-collision and abutment-girder-collision models are analyzed, based on which formulas for the collision-spring constants are proposed. The response analysis of a bridge under seismic loading is then conducted to see the effect of the collision.

1. INTRODUCTION

Collision between bridge girders and/or between an abutment and a bridge girder may take place during earthquake. In the Mid Niigata Prefecture Earthquake in 2004, collision between an abutment and a bridge girder occurred indeed in a PC girder bridge (Photo 1) and a study revealed that the damage could have been much worse if not for the collision (Kosa et al. 2005). The collision can thus play an important role in the behavior of a bridge during earthquake: without including the effect of the collision, the analysis of a bridge behavior during earthquake can be quite misleading.

A simple and practical method of simulating collision in the numerical analysis is the introduction of a spring where the collision occurs. Nevertheless, not much research on the appropriate collision-spring constant has been conducted. To the best of the authors' knowledge, Kawashima (1981) is the only one who has proposed a formula for the collision-spring constant. The application of the formula is however limited to the case in which the colliding bodies are identical and modeled by the finite elements of equal length.

The colliding girders of a bridge are not always identical; an abutment and a girder are very different structures; and the size of a finite element used for modeling a girder usually varies along the girder axis. Therefore, the formula proposed by Kawashima (1981) may not be always applicable in practice. In such cases, an appropriate collision-spring constant is not known at the current stage of development.

Against the background of the above information, an appropriate value of the collision-spring constant between colliding bodies that have different stiffnesses is investigated in the present study. To be specific, the collisions between two girders and between a girder and an abutment are considered first. The response analysis of a bridge under seismic loading is then conducted. In all the analyses, the finite element software Y-FIBER3D (Yamato 2000) is used.

Photo 1 Collision between Abutment and Girder

2. ANALYSIS MODELS

The behavior of the collision spring is illustrated in Figure 1. The relative displacement is the distance between the two bodies, the relative displacement equal to zero corresponding to the initial state that has some gap (initial gap) between the bodies; the initial gap is introduced in bridge design to avoid contact due to temperature rise etc.

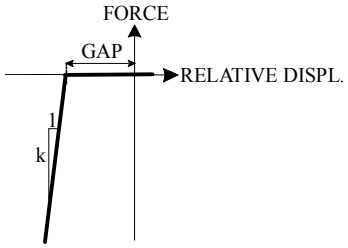

Figure 1 Characteristics of Collision Spring

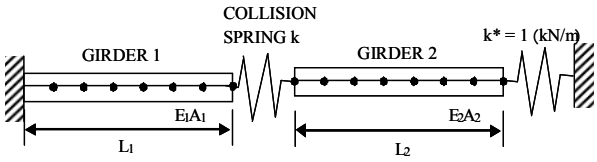

Figure 2 Girder-Girder Analysis Model

The relative displacement is positive when the gap becomes longer than that in the initial state while it is negative when the gap shortens. Only when the gap is closed completely, the two bodies are in actual contact. Figure 1 shows these characteristics of the collision spring. The slope k shown in Figure 1 is the collision-spring constant to be studied in the present study.

Kawashima's formula (Kawashima1981) for the spring constant is given by

$$k = \frac{nEA}{L} \tag{1}$$

where n is the number of finite elements, E is Young's modulus, A is the cross-sectional area and L is the girder length. The formula indicates that the collision-spring constant can be set equal to the axial stiffness of the finite element. The present study is to utilize the axial stiffness of the element as well and the analysis models are set up from this viewpoint.

The simulation of the collision by a spring is practical, yet it is quite an approximation of the behavior so that the overlap of the two bodies and the repetitive short collisions during the real collision period of time are unavoidable. The overlap becomes larger as the collision-spring constant is smaller; and more small collisions occur as the collision-spring constant is larger. The collision-spring constant that does not evoke those fictitious phenomena excessively is considered appropriate (Kawashima 1981).

By conducting seismic response analysis with various collision-spring constants, formulas for appropriate collision-spring constants are to be investigated herein. To this end, a simple triangular seismic wave is applied in the girder-axial direction in the response analysis. Time increment of 1/50000 sec is employed throughout this study.

2.1 Girder-Girder Collision

Figure 2 shows the analysis model to study collision between two girders. The girders are modeled by two-node beam elements, and a collision spring is placed between the girders. The spring with a very small spring constant at the right end of the right girder is introduced to prevent the free movement of the girder in the dynamic analysis. In this analysis model, Young's moduli of the two girders, E_1 and E_2, are both 2×10^5 N/mm^2, their girder lengths, L_1 and L_2, are both 50 m and the initial gap between the two girders is 0.15 m and the Rayleigh damping constant is 0.02.

The axial stiffness of a bridge girder usually falls in the range from 5.0×10^5 to 5.0×10^6 kN/m. Based on this observation, three values of 5.0×10^5, 1.0×10^6 and 5.0×10^6 kN/m are employed in the present study. In addition, three different values are used for the axial stiffness of an element in the vicinity of collision. The combination of them yields 9 analysis models as shown in Table 1. The element length Le in Table 1 is applied to those elements located in the region within 5 m from the collision point in Model GG1-GG3 and 6 m from the collision point in the other models. In the remaining region, the lengths of the elements are all 1 m.

As realized in Table 1, in Models GG1-GG3, the two girders have the same axial stiffness of the girder and the same axial stiffness of the element; in Models GG4-GG7, only either the axial stiffness of the girder or the axial stiffness of the element is the same; and in Models GG8 and GG9, neither the axial stiffness of the girder nor the axial stiffness of the element is the same.

2.2 Abutment-Girder Collision

Figure 3 is the abutment-girder collision model. The girder assumes the same material and structural characteristics as those of the girder-girder collision model. The spring with a very small spring constant at the right end of the girder is also used in the abutment-girder collision model.

For the axial stiffness of the girder, the same values as those of the girder-girder collision model, 5.0×10^5, 1.0×10^6, and 5.0×10^6 kN/m, are utilized. The abutment is modeled by a spring, as is often the case with the models in existing studies. Four values of the spring constant k_A are assumed for the abutment: 1.0×10^5, 1.0×10^6, 1.0×10^7 and 3.0×10^8 kN/m.

The combination gives 12 abutment-girder collision analysis models. In all these models, the element length of 0.5 m is used in the region within 5 m from the collision point and the element length of 1 m is employed for the remaining region.

3. PROPOSED FORMULA

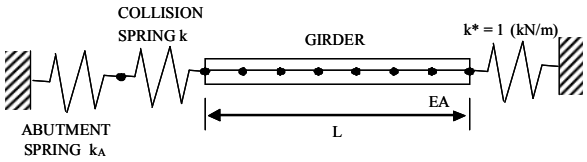

Figure 3 Abutment-Girder Analysis Model

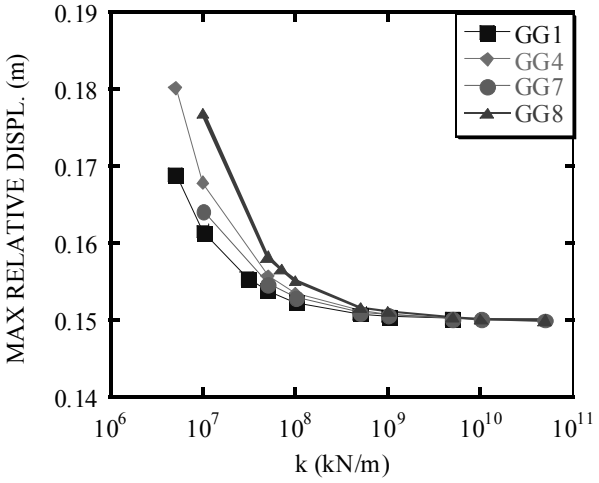

Figure 4 Variation of Maximum Relative Displacement with Collision-Spring Constant

collision-spring constant. As the collision-spring constant becomes lager, the maximum relative displacement decreases. For the sake of clarity, the results of only four models are given in Figure 4, but the others yield the same tendency.

To determine the allowable relative displacement, the

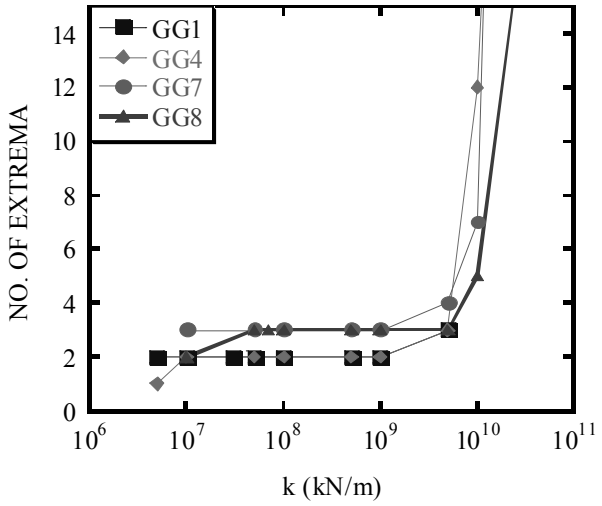

Figure 5 Relationships between Number of Extrema of Relative Velocity and Collision-Spring Constant

girder-girder analysis models to which Eq. (1) is applicable are set up additionally. These models are basically the same as GG2 and GG3, but the two girder models are discretized by the beam elements of equal length entirely.

The maximum relative displacement in the seismic response analysis of the additional analysis models is found 0.157 m. In the present study, 0.157 m is then employed for the allowable relative displacement. That is, the collision-spring constant that gives the maximum relative displacement less than 0.157 m is to be judged appropriate. As Figure 4 indicates, this criterion gives the lower bound of the collision-spring constant.

To investigate the phenomenon of the repetitive short collisions during the real collision period of time, the extrema in the variation of the relative velocity with time during the collision is counted. Figure 5 shows the relationships between the number of extrema thus obtained

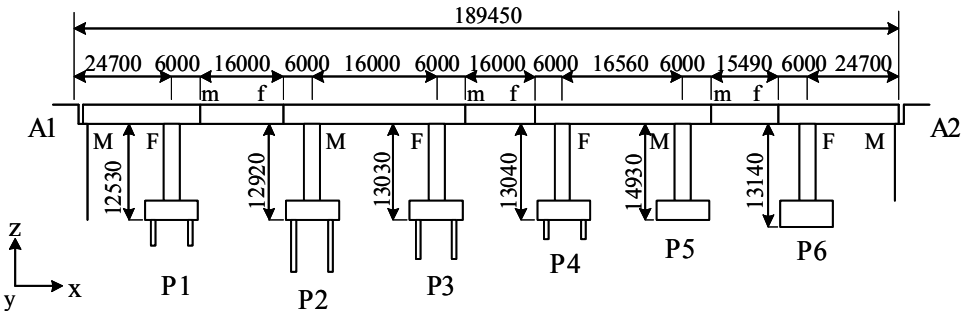

Figure 6 Bridge Model (Units: mm)

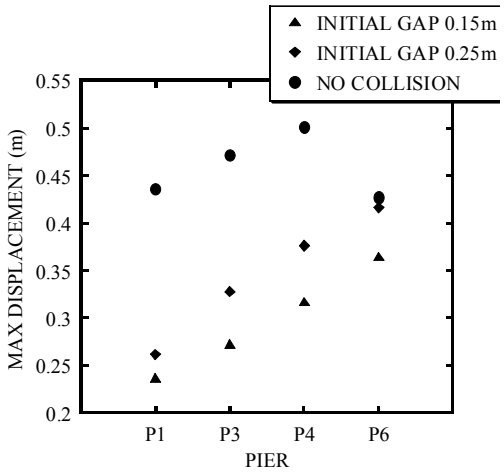

Figure 7 Maximum Horizontal Displacement of Piers

and the collision-spring constant. A tendency for the number of extrema to increase with the collision-spring constant is recognized. For the sake of clarity, the results of only four models are given in Figure 5, but the others yield the same tendency.

The analysis of the additional models shows threeextrema in the relative velocity, so that three extrema are considered allowable. As Figure 5 indicates, the criterion gives the upper bound of the collision-spring constant.

Based on the results of the seismic response analysis of the 9 models in Table 1, the following formula is proposed for the collision-spring constant that satisfies the criteria mentioned above:

$$k = \frac{2k_1k_2}{k_1 + k_2} \tag{2}$$

Where

$$k_1 = \frac{E_1A_1}{L_1^e}, \quad k_2 = \frac{E_2A_2}{L_2^e} \tag{3}$$

It is noted that Eq. (2) becomes Eq. (1) when the two girders are identical.

3.2 Abutment-Girder Collision

The abutment-girder collision is studied similarly, and the same tendencies as those in the girder-girder collision are recognized. The criteria employed to derive Eq. (2) are used also for the abutment-girder collision, and the following formula for the collision-spring constant is obtained:

$$\log_{10} k = 4.8 - 0.6 \times \log_{10}\left(\frac{k_A + k_G}{k_A k_G}\right) \tag{4}$$

where k_G is the axial stiffness of the element having the collision point.

4. RESPONSE ANALYSIS OF GIRDER BRIDGE

A bridge model is constructed based on an existing bridge and analyzed. Figure 6 shows the schematic of the bridge: it is a 7-span cantilever girder bridge and the length is 189.45 m. In the figure, M, F, m and f stand for a movable bearing support, a fixed bearing support, a movable hinge and a fixed hinge, respectively. An abutment is assumed at each end of the bridge.

The superstructure is a composite girder with four steel I-shaped girders and a concrete deck. The bridge piers are made of concrete, having the rectangular cross section of 2.2 m × 10.6 m at the top and 3.6 m × 13.6 m at the bottom. The nonlinear material behaviors of steel and concrete are assumed with the yield stress of steel σ_y and the compressive strength of concrete σ_{ck} equal to 360 N/mm^2 and 21 N/mm^2, respectively. The behavior of the foundation is modeled by springs whose constants are given by Design Specifications of Highway Bridges (Japan Road Association 2002). The collision-spring constants are determined by the formulas proposed above.

The seismic wave in the form of acceleration recorded during the Mid Niigata Prefecture Earthquake in 2004 is used for the analysis. Two initial gaps are assumed: 0.15 m and 0.25 m. The analysis that ignores the collision effect is also conducted.

Figure 7 summarize the results of the maximum horizontal displacements of four piers (P1, P3, P4 and P6). It is clearly observed in this figure that the collisions suppress the movement of the bridge, possibly mitigating the

damages of the piers.

5. CONCLUDING REMARKS

To include the effect of the collisions in the finite element analysis, the collision spring is often used. Yet an appropriate constant of the collision spring is not available in the literature except when two colliding bodies are identical. The present study tackled this issue and, through numerical study, it proposed the formulas for acceptable collision-spring constants between girders and between a girder and an abutment, respectively. The dynamic response analysis of a girder bridge was then conducted and the significant effect of the collisions was indeed observed, clearly showing the importance of the collision effect.

Abstract: This paper summarizes the analyses of the sensitivity of a two-span single column bridge in California to variations in structural and ground motion properties. A similar study has been conducted for other bridge configurations as part of a comprehensive study of performance-based assessment of skewed bridges, starting from seismic excitation modeling to modeling techniques that best represent the skewed abutment response for such bridges. Recent earthquakes have shown that skewed bridges tend to rotate about their vertical axes under seismic excitation and that this motion can cause excessive column hinging and unseating of the deck. In this study, we explore modeling techniques that capture the essence of skewed bridge response. By using these models, we quantify the sensitivity of response to variations in the bridge's geometric parameters and the type of seismic excitation. We also gauge state-of-the-art ground motion selection and scaling methodologies for assessing the response of such bridges in comparison to a "high-end prediction" that is based on a large number of simulations. The over-arching aim in this study is to reach to a set of practical guidelines for design of skewed bridges in high seismic regions, which when followed minimizes the damages that result in downtime losses usually deemed as the most important type of loss in highway network systems.

1. INTRODUCTION

Skewed bridges are required when the alignment of crossing roadways are not a right angle. Current state of practice for design of such bridges (Caltrans SDC 2006) comprises using a seat-type abutment to lessen demand on foundation and allows more movement of the superstructure during seismic excitation. Despite having a fair amount knowledge of their performance under service conditions, seismic performance of skewed bridges during past earthquakes were not well predicted. Transversely, the exterior shear keys are designed as a fuse and break off under intense impact. Similarly, under longitudinal excitation, the backwall is designed to break off and allow the generation of passive pressures on the backfill soil. The demand imposed on seat-type abutment's foundation is less than that for a diaphragm abutment, due to freedom of movement of the superstructure in different directions.

Much research has been conducted on seismic response of regular or non-skewed bridges (see, for example, Aviram et al. 2008, Johnson et al. 2009, Kotsoglou and Pantazopoulou 2010, Mackie and Stojadinovic 2007, Paraskeva et al. 2006). Observations from past earthquakes indicate that the unseating of the bridge deck due to in-plane rotation is the primary mode of failure in skewed bridges (Jennings 1971, Ghobarah and Tso 1974, Wakefield et al. 1991, Meng and Lui 2000). This rotational response is exacerbated once the bridge is subjected to near field motions (Shamsabadi et al. 2006). However, there still remains significant uncertainty in models that can predict this mode of failure. Understanding the seismic behavior of skewed bridges and improving the modeling and design guidelines for this type of bridge are the main objectives of this research.

This paper summarizes an attempt for bracketing the skew bridge response through a performance-based assessment methodology. The particular performance-based methodology adopted herein is that proposed by the Pacific Earthquake Engineering Research (PEER) Center, with specific extensions we have devised for bridges. Through this approach, the sensitivity of skewed bridge response to variations in bridge geometric parameters and type of seismic excitation is quantified. The primary focus is on the ground motion selection/scaling and structural modeling techniques.

Nonlinear structural response is often highly sensitive to the selection and modification (e.g., scaling) of input ground motions and, not surprisingly, many ground motion selection and modification methods have been proposed to date. Nevertheless, there is no systematic study that provides impartial guidance to engineers and delineates appropriate methods for use in a specific application. This is problematic because the predicted structural response can

vary dramatically depending on the prescribed ground motion. The engineer's choice of ground motion selection and modification method can lead to an over-designed, or worse, unsafe structure.

2. PERFORMANCE-BASED SEISMIC ASSESSMENT

Performance-Based (seismic) Assessment, PBA, has been the focus of much research in the past decade (e.g., Cornell and Krawinkler 2000, Krawinkler and Miranda 2004, Mackie and Stojadinovic 2007). Researchers have faced up to challenges such as: identifying performance objectives that are quantifiable and meaningful for engineers and stakeholders alike, identifying representations of ground motion intensity that well relate to seismic hazard at the site and the global bridge response characteristics, and many other advances whose enumeration does not fit into this brief introduction. The new challenge facing researchers is to transfer these sophisticated developments to the practicing engineers through relatively simple but comprehensive procedures that facilitate implementation.

Researchers at the Pacific Earthquake Engineering Research (PEER) Center have developed a sophisticated PBA methodology, which utilizes a chain of four random variables: Intensity Measure (*IM*), Engineering Demand Parameter (*EDP*), Damage Measure (*DM*), and Decision Variable (*DV*). *IM* is a scalar or vector (Baker and Cornell, 2006) quantity that represents the intensity of a ground motion. Traditionally, the elastic spectral acceleration at the first mode period of the structural system, $Sa(T_1)$, is used as an *IM*. However, recent studies show that using a vector valued *IM* in which the shape of the ground motion spectrum is considered in the ground motion selection and scaling process can lead to better estimation of the structural response. *EDP* is a bridge response parameter (e.g., maximum deck rotation, column drift ratio) and is estimated through nonlinear response analysis of the bridge model subjected to a ground motion. *DM* is the representation of damage (e.g., cracks in columns) and is determined based on repair strategy and many other considerations. Ultimately, *DV* is a measure of performance, with a focus on three major loss categories: direct ($) losses, downtime losses, and life losses. The PEER PBA methodology is completed by following a flow from *IM* to *DV* according to Equation (1) (the PEER framework equation):

$$\lambda(DV) = \iiint G(DV \mid DM) \cdot dG(DM \mid EDP) \cdot dG(EDP \mid IM) \cdot d\lambda(IM) \quad (1)$$

In Equation (1), $\lambda(DV)$ is the desired realization of the *DV* (e.g., mean annual frequency of exceedance) and the *G* functions represent complementary cumulative distribution functions. For instance, for downtime performance (i.e., average annual downtime for a given bridge) one can complete the PBA methodology as follows: intensity measures, *IM*s, (e.g., spectral acceleration at the first mode period of the structure, $Sa(T_1)$), are determined from seismic hazard analysis; relevant engineering demand parameters, EDPs, (e.g., deck rotation, column drift ratio) are predicted from structural analysis for given values of *IM*s (and representative ground motions); component/system damage states are developed from repair strategies and *DM*s fragility curves are developed for each component/system; and finally, predictions are made on *DV*s (i.e., total amount of downtime losses of the bridge).

This paper briefly goes through two important aspects of the PBA for bridges. First, the sensitivity of bridge response to variation in ground motion and structural properties, and second, the accuracy of various ground motion selection and scaling processes by which a more accurate estimate of bridge is obtained.

3. GROUND MOTIONS

Nonlinear dynamic analysis of structures is becoming increasingly prevalent in code and regulatory documents prescribing design and analysis. A recurring challenge for both practicing engineers and developers of these documents is the selection and modification of ground motions for these nonlinear dynamic analyses. Our investigation in addressing the effects ground motion model on bridge response is focused on two issues. First, we investigate the sensitivity of bridge response to standardized sets of ground motions each representing a typical geotechnical system located in an active seismic region like California. Second, we focus on ground motion selection and scaling procedures to identify the superior procedure by which a small subset (e.g., seven) of ground motions can provide an acceptable estimate of median bridge response.

To investigate the sensitivity of bridge response to typical ground motions in California sites, three sets of ground motions were selected by the PEER Transportation Research Program (Jayaram et al. 2010). Theses sets are denoted as "Soil," "Rock," and "Pulse," each of which comprise forty ground motions. Figures 1, 2, and 3, show the fault-normal and fault-parallel spectra for these ground motion sets, respectively. These ground motions are not location specific and rather are standardized to accommodate comparative evaluations. These ground motions are selected from a subset of the PEER NGA Project ground motion library (PEER 2010) with ground motions from mid- to large-magnitude earthquakes at close distances. Selected ground motions have a variety of spectral shapes, durations, and directivity periods. For each set, the mean and variance of the natural logarithm of spectral acceleration match $M_w = 7$ and $R = 10$km generic scenario in California.

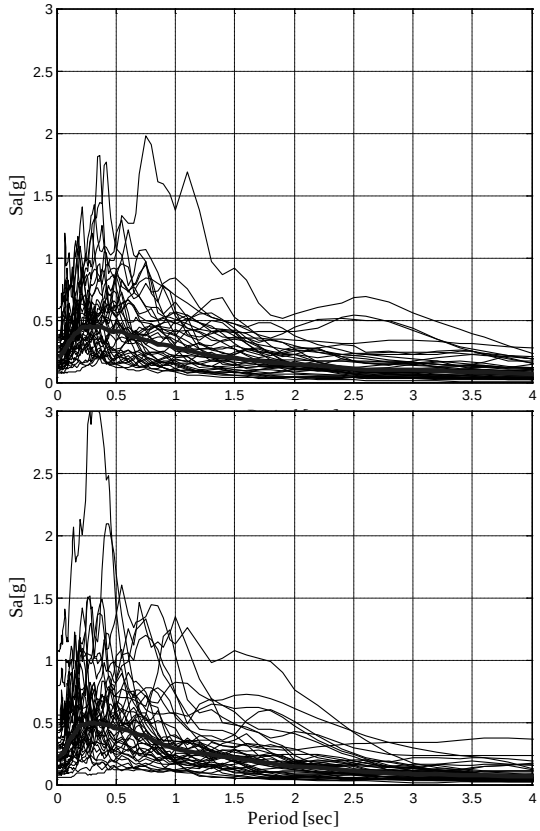

Figure 1 Response spectra of selected ground motions for soil sites. (a) Fault normal comp., (b) fault parallel comp.

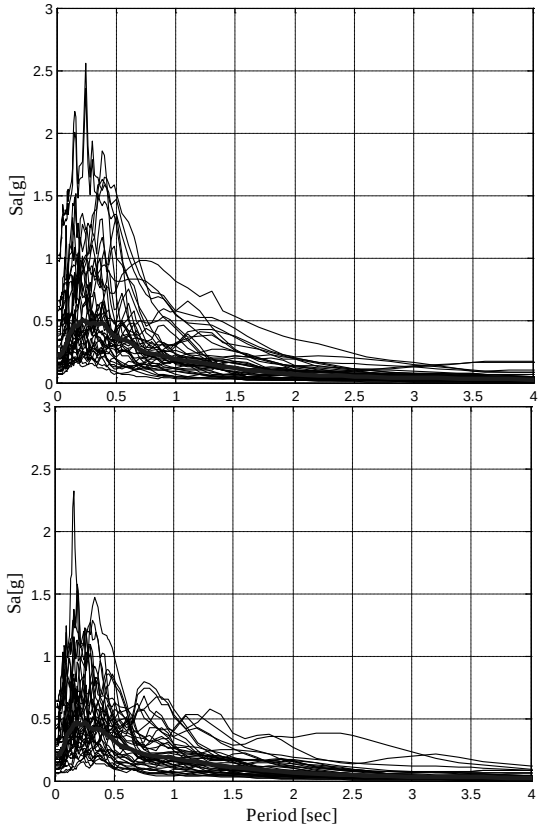

Figure 2 Response spectra of selected ground motions for rock sites. (a) Fault normal comp., (b) fault parallel comp.

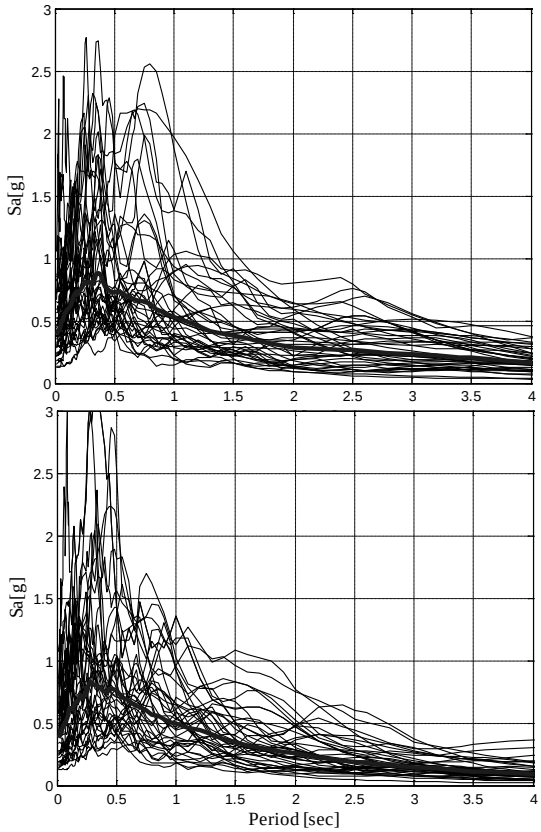

Figure 3 Response spectra of selected pulse type ground motions. (a) Fault normal comp., (b) fault parallel comp.

We investigated the accuracy of ground motion selection and scaling methods to estimate the median bridge response for the M_w = 7 and R = 10km generic scenario. This investigation has two parts. First we obtain the best estimate for the bridge response parameter (e.g., column drift, unseating deformation), denoted as POC (i.e. Point Of Comparison), using a large set of ground motions and a sophisticated mathematical regression form, for the target generic scenario M_w = 7 and R = 10km. Second, we obtain the similar bridge response parameters using smaller sets of ground motions each selected based on a predefined ground motion selection and scaling procedure and compare with POC. Estimation of POC is possible with a large set of ground motions. This large set of ground motions were selected from the PEER-NGA Database available from the Pacific Earthquake Engineering Research Center (PEER 2010). The ground motion set selected for this part of the investigation includes 117 horizontal ground motion pairs selected based on the following detailed criteria. These criteria are similar to those used in the FEMA P695 (ATC-63) project (FEMA 2009). The selected ground motions are from earthquakes with $6.5 \leq M_w \leq 7.5$ recorded on soft rock or stiff soil (Site Classes A-D, with Vs > 180 m/s), all of records come from either strike-slip or reverse (thrust) sources (with only a few records coming from subduction sources) with source-to-site distances from 0-20 km. To ensure that the ground motion recording and processing maintained the important range of frequency contents, only ground motions with useable frequencies

down to at least 0.25 Hz are included in the ground motion record set. Figure 4 provide the spectra of the ground motions included in the set (for each individual ground motion component), and the median spectrum.

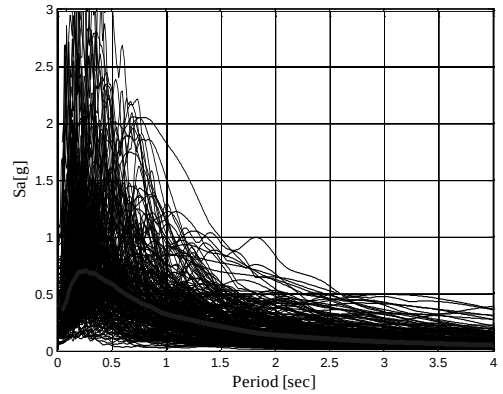

Figure 4 Spectra of ground motions included in the $M_w = 7$ $R = 10$km ground motion set for estimation of POC.

The development of the POC prediction involved: (a) selecting a large bin of records consistent with the target scenario as described in the previous paragraph, (b) completing bridge response analyses using the set of records scaled by arbitrary factors of 1.0, 2.0, 4.0, and 8.0, (c) completing regression analysis (which is designed to remove the effect of scaling bias) to relate bridge response parameters to the important ground motion parameters, and then (d) integrating the regression equation over the proper distributions of the ground motion parameters used in the regression model. Details of calculation of POC can be found in PEER GMSM (2009).

Two ground motion selection and scaling methods are investigated in this study. One is based on fist mode spectral acceleration, denoted as $Sa(T_1)$, and the other is based on the Conditional Mean Spectrum, denoted as CMS. In the $Sa(T_1)$ method, ground motions are selected and scaled from a representative bin for the target scenario, and amplitude scaled to ensure the spectral acceleration at the first mode period in the longitudinal direction matches the target spectral acceleration at the same period. Previous research has shown that spectral shape is an important factor in selection and scaling ground motions. The expected spectra tend to have a "peak" with richer frequency content near the period used to define the ground motion intensity (typically the fundamental period of the structure). Baker and Cornell (2006) showed that proper spectral shape for a given ground motion scenario and associated ε value; this spectrum has been termed a Conditional Mean Spectrum (CMS), as it is the mean response spectrum at all periods, conditional on knowledge of $Sa(T_1)$.

4. ANALYTICAL MODEL

For the purpose of this paper, we have selected a two-Span on single-column bridge (viz., Jack Tone Road Overcrossing). The Jack Tone Road On-Ramp Overcrossing is located in City of Ripon in California, is a two-span bridge with 67.2 m total length, and spans of 33.105 m and 34.095 m. The superstructure is a three-cell continuous reinforced concrete box-girder. The bent cap is integral with the deck and a single concrete column. The column of the bent is 1.68 m in diameter supported on steel piles. The longitudinal reinforcing steel ratio of the column is approximately 2%. The bridge has non-skewed, seat-type abutments with four elastomeric bearing pads per each. The case study bridge is part of a matrix of bridges with geometric characteristics representative of common bridges in California have been studied. These bridges are recently designed (built after 2000) and are located in Southern California, which is a region with high seismicity.

The analytical model of the case study bridge is shown in Figure 5. The bridge structure is modeled through the OpenSees (McKenna et al. 2000) Finite Element Analysis software. The present modeling assumptions generally follow the guidelines proposed by Aviram et al. (2008) and Kaviani et al. (2010) as well as SDC (2006). The three-dimensional spine-model of the bridge structure with line elements located at the centroid of the cross sections following the alignment of the bridge is used. To capture the response of the entire bridge system and individual components under specific seismic demand characteristics, three-dimensional modeling is implemented. The models developed for skewed bridges *do* incorporate nonlinear behavior of individual components. These components include column plastic hinges, abutment transverse and longitudinal springs, and abutment gap components. For simplicity, the superstructure, the cap beam, and the foundation springs are considered as linear elastic components.

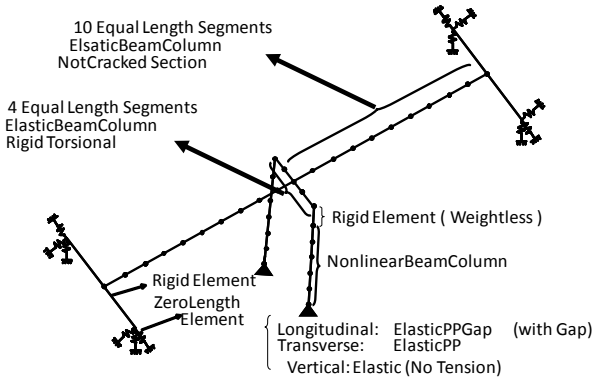

Figure 5 Conceptual depiction of the analytical model for skewed bridges in OpenSees

4.1 Columns

The concrete considered for modeling the columns is based on an enhanced version of the concrete model proposed by Chang and Mander (1994), available in OpenSees under the name *Concrete07* (J. Waugh et al. 2008). The core concrete is confined by circular hoops or spirals,

while the cover concrete is unconfined. The maximum strain in compression for the confined concrete is governed by the first hoop fracture, and it is set equal to 0.025. The compressive strength of the unconfined concrete is equal to 35MPa and its initial Young's modulus is equal to 28GPa, according to SDC (2006), Section 3.2. The characteristics of the confined concrete depend on the level of transverse confinement, which is determined by the circular hoops or spirals of the columns. Figure 6 shows the backbone curves for confined and unconfined concrete used in the column of Bridge 1.

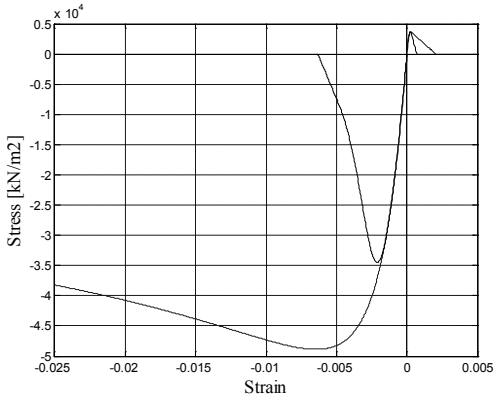

Figure 6 Backbone curves for concrete and steel (negative values refer to compression)

The reinforcing steel is assumed to have an elastic-perfectly plastic behavior. The type of material available in the library of materials of OpenSees that is used is *Steel01*. It is a simple model with no ultimate strain and no hardening after yielding. This material model is selected for its simplicity and the fact that it better represents the behavior of the bridges used in this study compared to other available steel material models. The yielding strength of the steel is equal to 475MPa, and the Young's Modulus, equal to 200GPa, according to SDC (2006), Section 3.2. The maximum strain in tension depends on the type of the steel and the size of the reinforcing bars, and it is equal to 0.09.

4.2 Abutment

The model of the abutments is based on the simplified model developed by Aviram et al. (2008) as part of the project they conducted to establish general guidelines for nonlinear analysis of bridges in California. Each abutment is modeled with a rigid element of length equal to the superstructure width, connected through a rigid joint to the superstructure centerline, and with a zero-length element at each.

In the longitudinal direction, the response is governed by a gap material. The material does not work in tension. In compression, it behaves as an elastic – perfectly plastic material when it reaches the gap length. The gap is defined by the plans, and the stiffness and the ultimate strength are defined according to Caltrans SDC (2006), Section 7.8. The rotation about the longitudinal direction is not allowed.

In the transverse direction; the response is governed by an elastic material that only works in compression. The abutment stiffness and the back wall strength for the longitudinal direction are modified by factors corresponding to wall effectiveness (C_L) of 2/3 and participation coefficients (C_w) of 4/3. The wing wall is assumed to be 1/3 of the back wall length.

In the vertical direction; the response is governed by an elastic material with zero tensile strength. After reaching a vertical deformation in compression equal to the maximum allowed by the bearing pads, the stiffness changes and tends to infinity.

5. SUMMARY OF FINDINGS

The sensitivity of seismic response of case study skewed bridge to variations of structural and ground motion properties was investigated. We focus our study on two major bridge response parameters that affect the bridge performance: deck rotation and column drift ratio. Figure 7 shows the effect of the deck rotation during the M_w = 8.0 Offshore Maule earthquake in Chile, signifying the importance of this parameter in investigating performance of skewed bridges.

Figure 7 Bridge deck rotation during M_w = 8.0 Offshore Maule earthquake in Chile. [*Image Source: Carlos Cabrera*]

Our investigation shows that deck rotation is highly sensitive to bridge structural properties and ground motion characteristics. Figure 8 shows the variation of deck rotation as function of abutment skew angle for the case study bridge for three different types of ground motions. The solid lines show the estimated median, and the individual data points are depicted with solid dots on the plot. Figure 9 shows a similar plot, however, the two spans are not equal in length (i.e., Asymmetrical span).

Investigation of Figure 8 and 9 shows that by increasing abutment skew angle from 0 to 30 degrees, median estimate of deck rotation increases regardless of applied type ground motion or span configuration. However, for higher abutment skew angles, ranging from 30 to 60 degrees deck rotation decreases for the symmetrical span bridge whereas an increasing trend continues for asymmetrical span one. This behavior is particularly pronounced in for pulse-like ground motion.

We conclude that this type of behavior for deck rotation in large abutment skew angles is due to the effect of the abutment gap size orientation. The gap element is always perpendicular to the abutment alignment (Figure 10). In other words, for a skewed abutment, the gap element will skew with the same rate to stay perpendicular to the abutment. Therefore, the distance in global longitudinal direction (X direction) increases by skew angle. Consequently, the springs which connect to the gap element and simulate the backwall engagement in response, contribute less efficiently to seismic response when smaller skew angles of abutment are present. Therefore, the larger the gap size the smaller the deck rotation.

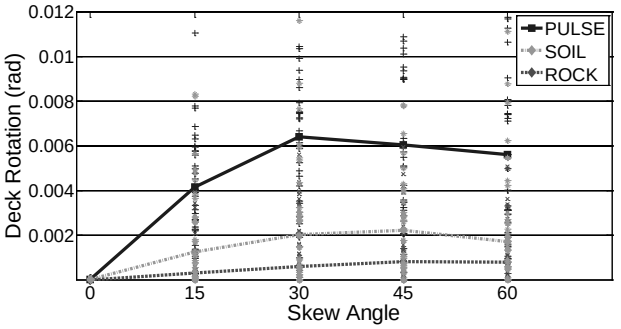

Figure 8 Variation of deck rotation due to ground motion characteristics and abutment skew angle for sym. deck.

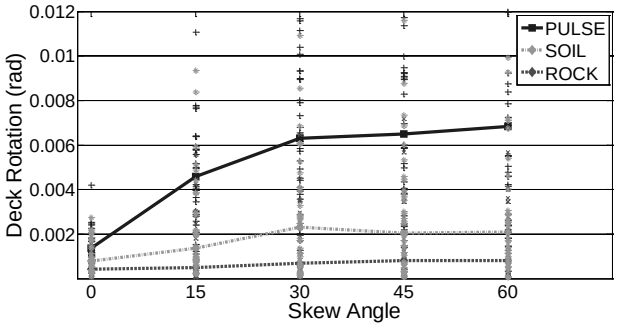

Figure 9 Variation of deck rotation due to ground motion characteristics and abutment skew angle for Asym. deck.

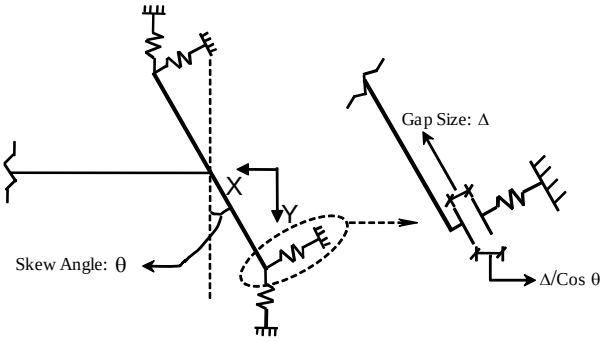

Figure 10 Effect of abutment skew angle on effective gap size.

Column drift ratio for the two-span single column case study is not sensitive to abutment skew angle, see Figures 11 and 12. This behavior is due to the nature of vibration for the single column bridge in which the rotation of the deck increases as the skew angle increases but the column usually remains near the center of rotation.

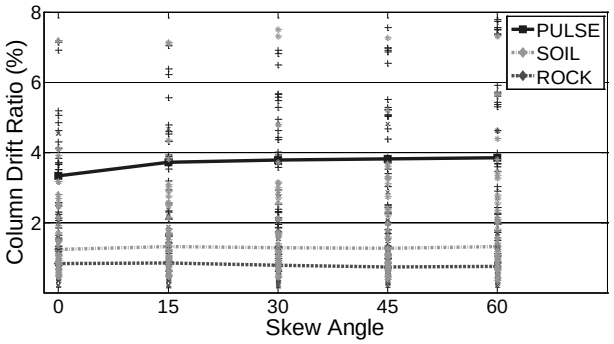

Figure 11 Variation of col. drift ratio due to ground motion characteristics and abutment skew angle for sym. deck.

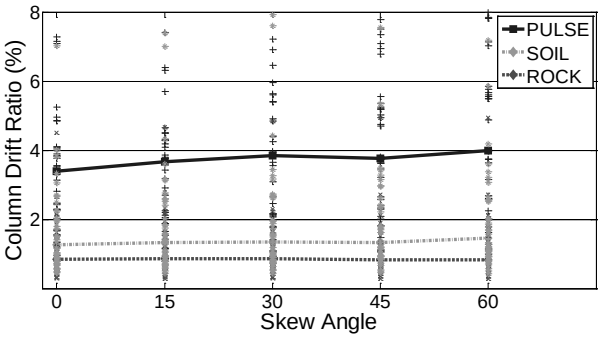

Figure 12 Variation of col. drift ratio due to ground motion characteristics and abutment skew angle for Asym. deck.

Our investigation shows that the ground motion selection scaling methods that use spectral acceleration at the first mode period can well predict the response of the case study bridge and these estimates of the median response is comparable with the estimated median obtained using ground motions selected and scaled using the conditional mean spectrum and the POC. Figure 13 shows the variation of estimated column drift ratio for the case study bridge as function of ground motion selection and scaling methods. The blue dots show the analysis results for each individual ground motion in the selected set and the median estimate of each set is marked with a solid short line. The red line represents the estimated median using the detailed and sophisticated analysis denoted as POC. This The set denoted with $Sa(T_1)$, is set of 84 records all selected based on the bridge fundamental period in the longitudinal direction. Each of CMS1, CMS2, CMS 3, and CMS 4 comprise seven ground motion selected and scaled according to conditional mean spectrum. CMS 5 is similar to other CMS sets; however, it includes 40 ground motions. All ground motions were applied in the longitudinal direction. The similarity between estimated median from using $Sa(T_1)$ and CMS, and with POC is due to small nonlinear behavior of the bridge in

applied ground motions. We postulate using bidirectional ground motions could potentially change the conclusion drawn here. Investigation about this hypothesis is underway.

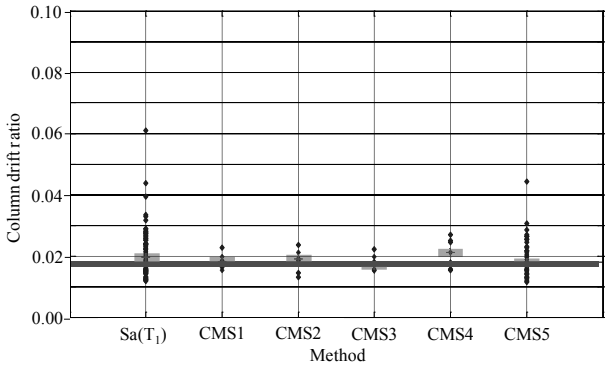

Figure 13 Comparison between estimated column drift ratio from various sets of ground motions and the POC.

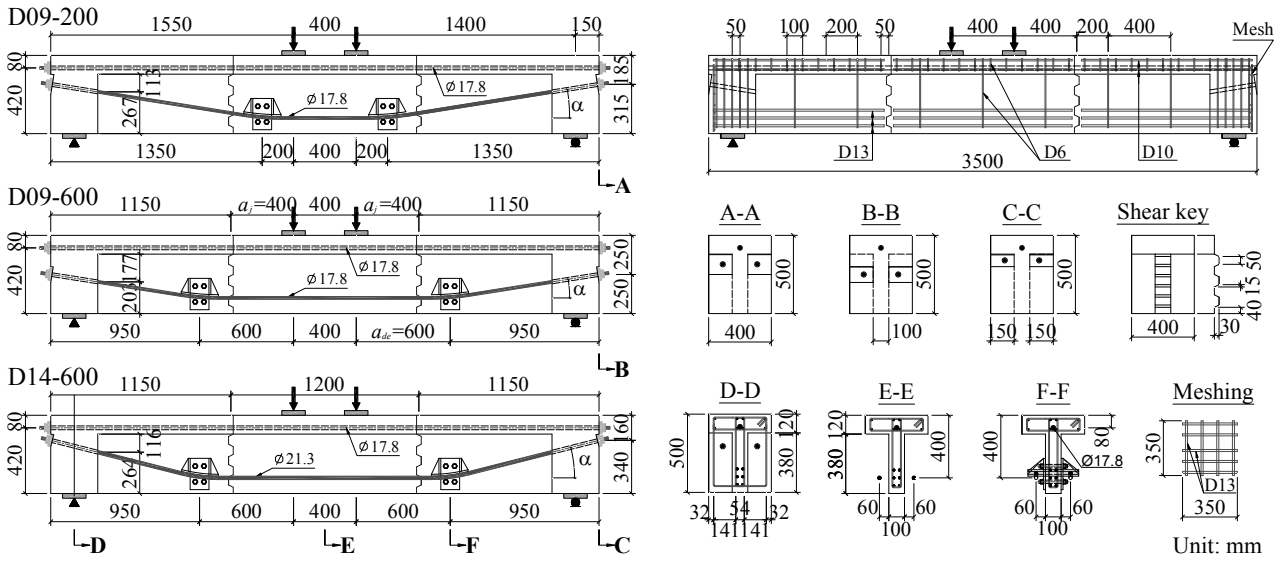
Abstract: This paper presents an experimental result of the structural behavior of segmental concrete beams prestressed with external draped tendons under the shear behavior. The inclined angle of draped tendons and the location of deviators on a shear span are main parameters. The effects of the inclined angle of draped tendons and location of deviators on a deviator force that affects the shear mechanism, such as propagation of cracks, joint opening and shear carrying capacity of segmental concrete beams are investigated. The experimental result shows that shear capacity of segmental beams with draped tendons was higher than that of segmental beams with straight external tendons.

1. INTRODUCTION

Prestressed concrete structures can absorb considerable energy before failure due to impact and thus show improved performance under seismic condition. Precast segmental construction is widely used in bridge structures, because of substantial cost and time saving in construction. In the beginning, internal tendon technology has been used for segmental technology where tendons are located inside the concrete cross section. However, problems such as leakage at epoxy joints or corrosion in tendons may cause damage in segmental bridges. So, the application of external prestressing to precast segmental structures has been used as an innovative method in segmental concrete technology.



Both straight tendon profile and draped tendon profile have been applied in a segmental concrete beam with external tendons. The difference comparing to the internal tendons is that the prestressing force from external tendons only acts on the structure at the deviators and the ends of a beam through anchorages. The draped profile has been used to alleviate congestion in anchorage zones, to reduce concrete stresses at transfer and to provide a vertical component for shear in the high shear and low moment zone in a simply supported beam. A straight external tendon profile was conducted in the author's previous study (Nguyen et al. 2010). It was concluded that the effect of deviator force in a shear span on the shear capacity is insignificant. However, test data to investigate the effect of draped external tendons on the shear behavior of segmental concrete beams are very limited. Several researchers reported the experimental results focusing on the shear behavior of monolithic concrete beams with draped internal tendons (MacGregor et al. 1960 and Rezai-Joeabi et al. 1986). Some studies focused on flexural behavior of monolithic concrete beams with draped external tendons (Tan and Ng 1997). In addition, in almost current codes, e.g. JSCE Standards 2002, the contribution of draped tendons on the shear capacity has been considered via the vertical component of prestressing force without considering the effect of location of deviators. Therefore, the effect of deviator force such as location of deviators and inclined angle of tendons on the behavior of segmental joint and shear behavior of segmental beams is necessary to be evaluated.

This paper presents experimental and nonlinear finite element analysis results of the structural behavior of segmental concrete beams prestressed with draped external tendons. The paper focuses on the response of the segmental concrete beams under the shear behavior considering the effect of draped external tendons. The inclined angle of draped tendons and the location of deviators on a shear span are main parameters. The effects of the inclined angle of draped tendons and location of deviators on a deviator force that affects the shear mechanism, such as propagation of cracks, joint opening and shear carrying capacity of segmental concrete beams are investigated.

2. TEST PROGRAM

2.1 Detail of testing beams

Figure 1 shows the detail of specimens in this study. Three simply supported concrete beams designed to fail in

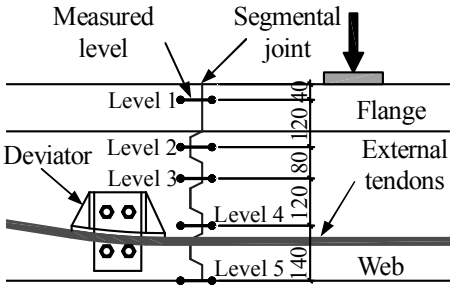
	21.3	1649	1879	188.7	312.5



shear with a/d ratio of 3.5 were used. The distance, a_j from the loading point to the joint position in a shear span used in these beams was 1.0d, where d was the effective depth of the beam at deviators. Test specimens were T-shaped section concrete beams with the span length of 3.2 m. The concrete stress at the upper fiber of the segmental beams was about 0 N/mm^2. The concrete stress was about 19 N/mm^2 (positive means compression) at the lower fiber. The inclined angle α of tendons was 9 and 14.2 deg. The location of the deviator from the loading point, a_{de} was 0.5d (200 mm) and 1.5d (600 mm). So the name of beams is D09-200, D09-600 and D14-600. Thus, D09-200 means that the inclined angle α was 9 deg. and a_{de} was 200 mm. Table 1 tabulates the tested segmental beams and the other parameters.

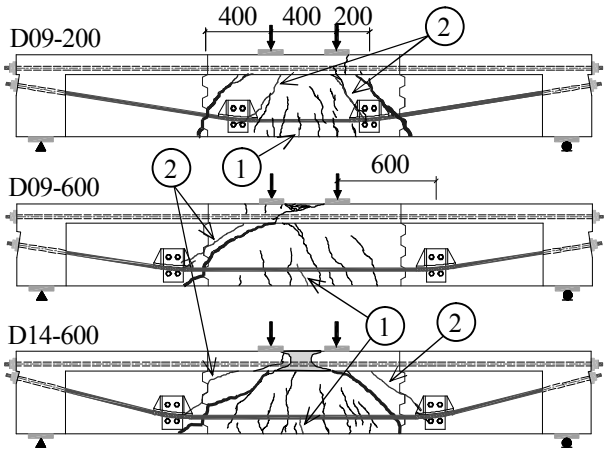
2.2 Materials

The match-cast method was used for casting the segmental beams. In this method, the ending segments of each beam were cast first with a wood shear key as an end formwork. Two days later the formwork was removed and the ending segments themselves were used as the ending formworks for the middle segment in order to provide a perfect matching between the two segments. The design compressive strength of concrete, f'_c was specified as 65.0 N/mm^2 at 28 days. The actual compressive and tensile strengths of concrete are tabulated in Table 1. Epoxy resin was used to connect concrete segments. The tensile and bending strengths of the epoxy resin were about 25 N/mm^2 and 40 N/mm^2, respectively.

(a) Measuring joint opening in D09-200

(b) Measuring joint opening in D09-600 and D14-600

Fig. 2 Measuring at 5 levels of each segmental joint



The arrangement of reinforcement in the beam is shown in Fig. 1(b). The non-prestressed steel bars were deformed bars. In all beams, six deformed bars with a nominal diameter of 13 mm (D13), and eight deformed bars with a nominal diameter of 10 mm (D10) were provided as internal longitudinal reinforcement at the bottom and the top flange, respectively. Deformed bars with a nominal diameter of 6 mm (D6) were used for stirrups having at an interval of 400 mm. Stirrups were also provided at the top flange with an interval of 100 mm. Meshing with D13 was utilized at the end of each beam to resist local stress due to prestressing force. The average mechanical properties of the steel bars are given in Table 2.

One unbonded internal tendon of type SWPR19L with a nominal diameter of 17.8 mm was provided in the top flange of the beams. The draped external tendons used for D09-200 and D09-600 were 19-wire type SWPR19L with a nominal diameter of 17.8 mm. The draped external tendons used for D14-600 was 19-wire type SWPR19L with a nominal diameter of 21.3 mm. The mechanical properties of the tendons are given in Table 3. The external tendons were arranged as shown in Fig. 1(a) and were stretched for four days before testing. Steel deviators were connected on the web of the beams by M22 bolts prefabricated in the web of the beams.

2.3 Loading method and measurements

The beams were subjected to a two-point loading test with a distance of 400 mm between two loading points as shown in Fig. 1(a). The applied load was increased monotonically by means of displacement control method.

Various measuring devices were utilized in order to measure the displacement of the beam, as well as joint opening and stress increment in the external tendons. Strain in the tendons was measured by electrical strain gauges at the middles between anchorage and deviators and at the middle of external tendons. Meanwhile, displacement transducers were mounted at the midspan, deviators and the supports of the beams to monitor the vertical deflection. At the same time, joint opening was measured at five levels on the both segmental joints of each beam as shown in Fig. 2. Levels 1 and 2 were measured by pie-gauges while levels 3, 4 and 5 were measured by transducers.

Fig. 3 Crack patterns

3. RESULTS AND DISCUSSION

3.1 Generals about Testing Beams

D09-600 was first tested. For the safety, applied load was stopped when the stress in the draped lower tendons became about 1434 N/mm^2 (79 percent of the yield strength of tendons). D09-600, therefore, did not reach totally failure. D14-600 was secondly tested. The applied load was provided until the beam was totally failed. D09-200 was last tested. Until the stress in the draped lower tendon reached the yield strength the applied load was stopped. At the stopped load stage D09-200 had not been totally failed.

3.2 Crack patterns

Figure 3 presents the crack pattern of the tested beams. Some flexural cracks first formed in the maximum moment zone between the loading points. Then flexural shear cracks occurred. Despite the difference in location of deviators and the inclined angle of draped tendons, one diagonal crack was observed to be formed from a deviator to the loading point. After the occurrence of diagonal cracks from deviators the dominant diagonal crack occurred at the lower corner the ending segment toward the loading point. In D14-600 at the ultimate stage dominant diagonal crack penetrated into the

Beams	α (deg.)	P_{cr} kN	P_{dcr} kN	P_{sh} kN	P_u kN
D09-200	9.0	280	338.4	360.2	489.2
D09-600	9.0	287.3	327.3	364.1	431.6
D14-600	14.2	285.6	408.1	417.5	523.4
SJ10-19	0	290.5	-	381.7	453.9

Note:
P_{cr} is load at the first flexural crack,
P_{dcr} is load at the diagonal crack formed from deviator,
P_{sh} is load at the dominant diagonal crack,
P_u is the peak load.

top flange near the loading point. After the peak load, the crushing occurred near the loading point. In D09-200 and D09-600, before the applied load was stopped the dominant diagonal cracks were observed to penetrate into the top flange. Some cracks were seen on the top flange of a beam near the loading points. It means that these two beams, D09-200 and D09-600, were close to the ultimate state when the applied load was stopped.

3.3 Joint opening

Joint opening was measured at 5 levels in both segmental joints of each beam as shown in Fig. 2. Figure 4 shows the joint opening observed in segmental joint on the right of D09-200 that was the critical segmental joint. Because cracks were observed in the top flange near the loading point and the joint opening was larger. The segmental joint expressed closing the levels 1 and 2. Joint opening in the levels 3 and 4 was very small, 0.04 and 0.09 mm, respectively. Joint opening observed in level 5 where dominant diagonal crack propagated was 11.13 mm.

Figures 5 and 6 show the joint opening observed in segmental joint on the left of D09-600 and the right of D14-600 that were the critical segmental joint. The segmental joint expressed closing in levels 1 and 2 of D09-600 and D14-600. The diagonal crack from deviator was formed and passed, therefore, the level 3 joint opening of D09-600 and D14-600 was 0.28 and 0.17 mm, respectively. In the stopping load of D09-600, joint opening at level 4 was 7.57 mm. Joint opening at level 5 could not be recorded, because the failure in the lower shear key in the ending segment was occurred when the dominant diagonal crack was formed as shown in Fig. 3. At the ultimate stage of D14-600, joint opening of levels 4 and 5 was 6.25 and 7.75 mm, respectively. It noted that the joint opening of SJ10-19 in the previous test was 10.5 mm at the peak load (Nguyen et al. 2010).

The smaller inclined angle of tendon was, the larger joint opening was. Joint opening in D09-200 was larger than that in D09-600 and D14-600. In both D09-600 and D14-600 the joint opening did not connect between the diagonal crack from deviator and the dominant diagonal crack as shown in Fig. 3. It means that the height of opening joint was not affected by the diagonal crack from the deviator.

3.4 Load-Deflection Curves

Figure 7 presents the load-deflection curves of the testing beams and referred beam, e.g. SJ10-19 (Nguyen et al.

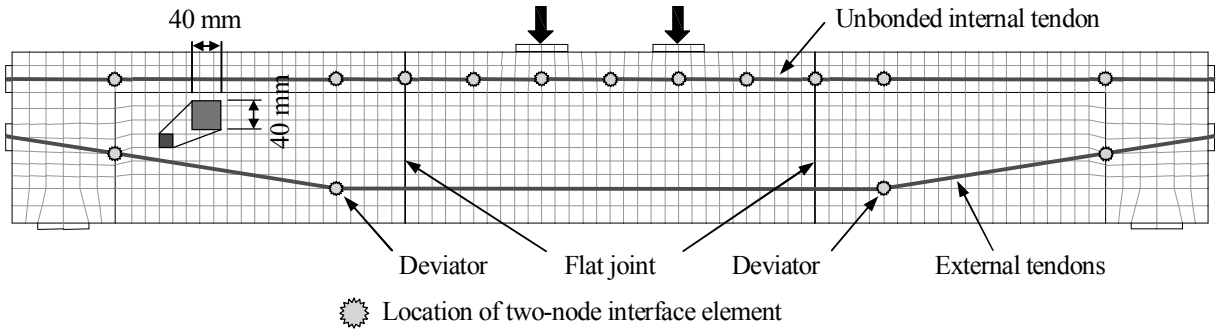

Fig. 8 Mesh for finite element discretization

2010) where incline angle α was of 0 deg. Even though there was a difference of location of deviators and the inclined angle of external tendons, all the segmental beams exhibited the similar linear elastic behavior in the beginning. Linear behavior was prolonged until the first flexural crack occurred with the load, P_{cr} as tabulated in Table 4. The load of first flexural crack was affected insignificantly by the location of deviator and the inclined angle of external tendons. The load at the first flexural crack of segmental beams with draped external tendons was very close to that of the segmental beams with straight external tendons (Nguyen et al. 2010). The load at the diagonal crack from deviator was not affected by the location of deviator, D09-200 and D09-600. In D14-600, higher inclined angle and area of draped external tendons, the load at the diagonal crack from deviator was higher than that of D09-200 and D09-600. The load at the dominant diagonal crack was not affected by the location of deviator. The load at dominant crack of D14-600, higher inclined angle and area of draped external tendons, was higher than that of D09-600 and 09-200 about 13 percent. Because of stopping before failure, the maximum load of D09-600 was smaller that the ultimate load of the segmental beams with straight external tendons. However, the maximum load of D09-200 and the ultimate load of D14-600 were higher than the ultimate load of the beam with straight external tendons, SJ10-19 [5] about 8 and 15 percent, respectively.

3.5 Failure mechanism

The linear elastic behavior of segmental beams was not affected by the location of deviator, inclined angle of draped tendons and area of external tendons. It was expressed by the load at the first flexural crack to be similar. Compared with the same area of external tendons, the load at the dominant diagonal crack of segmental beams with inclined angle of 9 deg., D09-200 and D09-600, was smaller than that of the segmental beam with straight tendons, SJ10-19. It was because that the segmental beams with draped tendons exhibited reduced stiffness (Tan and Ng 1997) higher than beams with straight tendons. However, in D14-600 with inclined angle of 14.2 deg. and higher in tendon area the loads at the diagonal crack from a deviator and the dominant diagonal crack were higher than that of D09-200 and D09-600, inclined angle of 9 deg., and straight tendon SJ10-19 as well. It means that the stiffness of external tendons also affected the stiffness of segmental beams with draped tendons.

The crack from deviator was not formed in segmental beams with straight tendons (Nguyen et al. 2010 and Sivaleepunth et al. 2009). In segmental beams with draped tendons the diagonal cracks from deviators, however, was formed before the occurrence of the dominant diagonal crack from segmental joint to the loading point. It means that deviator force was arisen and it affected the shear transfer mechanism in the segmental beams with draped tendon. The formation of the dominant diagonal crack from segmental joint to the loading point demonstrated that the local behavior of segmental joint (MacGregor et al. 1989) affected significantly the behavior of segmental beams. Although there was a difference in location of deviator and inclined angle of draped tendons, the shear failure mode was designated in the tested beams as the shear compression failure mode. First, the dominant diagonal crack was formed toward the loading point. Finally, the failure took place with the crushing of concrete near the loading point in the shear span. The results of this experiment show that the shear carrying capacity of segmental concrete beams with draped external tendons was higher than that of segmental beams with straight external tendons.

4. FEM ANALYSYS

4.1 Description of models

The nonlinear finite element method (FEM) using DIANA computer program has been conducted to examine the shear mechanism with the effect of draped external tendons. The concrete beams were modeled by means of four-node quadrilateral isoparametric plane stress element as shown in Fig. 8. The behavior of concrete in compression and tension was modeled according to the model proposed by Thorenfeldt et al. 1987 and Hordijk's model (Hordijk 1991), respectively. Longitudinal reinforcements were modeled by means of the embedded reinforcement element. Tendons were modeled by a two-node truss element. A bilinear elasto-plastic constitutive model appropriately represents the stress–strain relationship of reinforcing bars and tendons. The properties of concrete, reinforcing bars and external tendons are shown in Tables 1, 2 and 3.

To represent the interfacial behavior between external

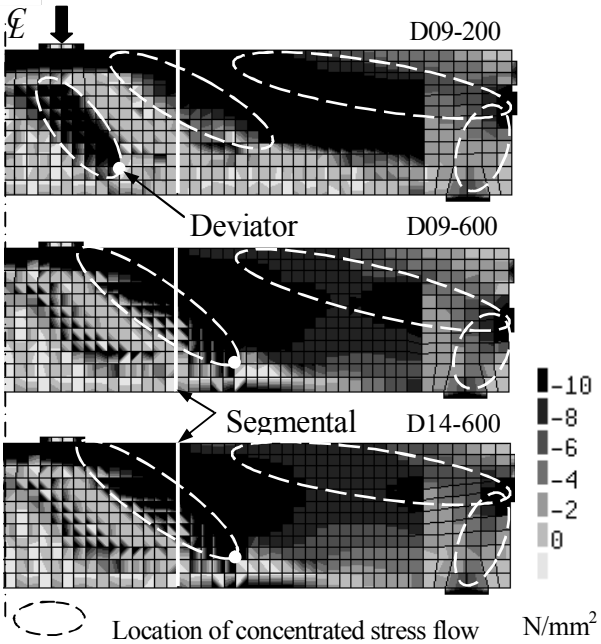

Fig. 9 Principal compressive stress at peak load

tendons and deviators or a concrete beam, the two-node interface element in DIANA system was applied. The stiffness of this interface element was adopted from Sivaleepunth et al. 2009 in order to neglect the friction between tendons and deviators or concrete at beam ends. Two-node interface element was also provided in some positions to model unbonded internal tendon in the top flange as shown in Fig. 8.

Figure 8 also shows that the flat joint model (Turmo et al. 2006) has been applied to reproduce the real geometry of joint by using the two-line interface element in DIANA system. Flat joints have fewer degree of freedom which means less computer calculation time. This can be beneficial especially for complex geometries such as shear keys. The discrete crack model is selected for the interface elements of segmental joints. The normal stiffness, k_n, and tangential stiffness, k_t, in the elastic stage for flat joint model was 10^5 N/mm^3 for segmental beams with draped tendons. The tensile strength of the epoxy is higher than that of concrete. Therefore, the tensile strength of concrete, f_t was selected to model the segmental joint in the nonlinear FEM analysis.

4.2 FEM Results

In order to validate the FEM model, the results obtained from the numerical analysis were compared with the experimental results. Figure 7 also shows a good agreement of the load and deflection curves between the experimental results and FEM analysis. Figure 9 shows the principal compressive stress of all beams at the peak load. It can be seen that one concentrated stress flow formed from the deviator to the loading point. This concentrated stress flow explained the formation to the diagonal crack from the deviator to the loading point. From the anchorage there are two concentrated stress flows. One is formed from the anchorage to support. Other is tended toward the loading point. It means that not only deviator force but also the transfer behavior of prestressing force from anchorage affected the shear transfer mechanism and also the shear failure mechanism in segmental concrete beams with draped external tendons.

5. CONCLUSIONS

The shear failure mechanism and the shear carrying capacity of segmental concrete beams with draped external tendon were discussed in this paper. The shear behavior of segmental concrete beams with draped external tendons was similar to that of segmental concrete beams with straight external tendons in the linear stage. After the linear stage the stiffness of segmental beams with draped tendons exhibited reduced stiffness to compare with segmental beams with straight tendons and was affected by the area of draped tendons. The deviator force, affected by the location of deviator and the inclined angle of draped tendons, and the transfer behavior of prestressing force from anchorage affected significantly on the shear transfer mechanism of segmental concrete beams with draped external tendons. The shear compression failure mode was observed for the segmental concrete beams with draped external tendons. Shear capacity of segmental concrete beams with draped external tendons was higher than that of segmental beams with straight external tendons.

Abstract: E-Defense shake table experiments on a full-size bridge column using polypropylene fiber reinforced cement composites (PFRC) at the potential plastic hinge and part of the footing is presented. The column is 7.5 m tall with 1.8 m by 1.8 m square section designed based on the 2002 Japan design code. The column was excited using a ground motion with 80% of the original intensity of the near-field ground motion recorded at the JR Takatori station during the 1995 Kobe, Japan earthquake. Excitations were repeated under increased mass and increased intensity of ground motion. The use of PFRC mitigated cover and core damage, local buckling of longitudinal bars and deformation of tie bars even after six times of excitation. The damage sustained was much less than the normal damage of regular reinforced concrete columns.

1. INTRODUCTION

A large scale bridge experimental program was conducted in 2007-2010 by the National Research Institute for Earth Science and Disaster Prevention (NIED), Japan (Nakashima et al. 2008). In the program, shake table experiments were conducted for two typical reinforced concrete columns which failed during the 1995 Kobe, Japan earthquake (C1-1 and C1-2 experiments), a typical reinforced concrete column designed in accordance with the 2002 Japan design code (JRA, 2002) (C1-5 experiment) and a new generation column using polypropylene fiber reinforced cement composites (PFRC) for enhancing the damage control and ductility (C1-6 experiment). The experiments were conducted using the E-Defense shake table where the table is 20 m by 15 m and has a payload of 1200 tf (12 MN). The maximum stroke of the table is 1 m and 0.5 m in the lateral and vertical directions, respectively. It was designed so that the ground motions during the 1995 Kobe earthquake can be generated.

C1-5 experiment was conducted using the E-Defense shake table with a ground motion 80% of the original intensity of the near-field ground motion recorded at the JR Takatori station during the 1995 Kobe earthquake. This is referred herein as the E-Takatori ground motion. The column performed satisfactorily under this ground motion. However, when the excitations were repeated under much stronger intensity and longer duration near-field ground motion, the column suffered extensive damage with blocks of crushed core concrete spilling out like explosion from the steel cage (Kawashima et al. 2010). Such failure was never seen in past quasi-static cyclic or hybrid loading experiments. Therefore, it is expected to develop columns which contribute to construct damage free bridges using materials that mitigate such damage under severe seismic loading.

Prior to the C1-6 experiment, a series of cyclic loading experiments were conducted on 1.68 m high, 0.4 m by 0.4 m square cantilever regular high strength concrete column and a column each using steel fiber reinforced concrete and polypropylene fiber reinforced cement composite at the plastic hinge region and the footing for deciding the material of C1-6 column (Kawashima et al. 2011). The polypropylene fiber reinforced cement composite column had superior performance in mitigating cover and core concrete damage, longitudinal bar buckling and deformation of tie bars at the plastic hinge region resulting from the crack control capability of polypropylene fiber reinforced cement composite. As a result, C1-6 column was built using

polypropylene fiber reinforced cement composite at the plastic hinge region and a part of the footing.

High performance fiber reinforced cement composites (HPFRCC) are materials that exhibit multiple fine cracks upon loading in tension which leads to improvement in toughness, fatigue resistance and deformation capacity (Matsumoto and Mihashi 2002). Engineered cementitious composite (ECC) is an HPRCC that has tensile strain capacity of about 0.03 to 0.05 resulting from the formation of closely spaced micro cracks due to the bridging action of fibers (Li and Leung, 1992). It has low elastic stiffness compared to concrete, and larger strain at peak compressive strength, due to the absence of course aggregates (Li et al. 1995). Polypropylene fiber reinforced cement composite, referred herein as PFRC, belongs to the class of ECC.

Previous investigations have shown the positive effects of using HPFRCC for structural members subjected to seismic loads. Kosa et al (2007) examined the use of this material with polyvynil alcohol (PVA) fibers for the seismic strengthening of scaled bridge piers similar to concrete jacketing. They found that a pier using HPFRCC on the cover concrete can provide confinement effect as much as the pier whose entire cross section was constructed of this material. Furthermore, the deformation capacity and the energy absorption capacity were also significantly improved compared with a pier constructed of ordinary concrete.

Saiidi et al. (2009) investigated the effect of incorporating ECC with polyvynil alcohol (PVA) fibers and shape-memory alloys (SMA) on model columns subjected to cyclic loading. Use of PVA-ECC substantially reduced damage in the plastic hinge. Furthermore, the combination of PVA-ECC and SMA led to larger drift capacity compared to the conventional steel reinforced concrete column.

This study aims to investigate the effect of PFRC for enhancing the damage control and ductility capacity of a full-size bridge column subjected to a strong near-field ground motion using the E-Defense shake table. This column is called herein as C1-6 column. The information obtained from the shake table experiments can provide reliable data for verification of structure performance and can provide an insight on the response of such structures subjected to real earthquake conditions.

2. E-DEFENSE SHAKE-TABLE EXCITATIONS

2.1 Column Configuration and Properties

C1-6 column is a 7.5 m tall, 1.8 m by 1.8 m square, cantilever column shown in Figure 1. It was designed based on the 2002 Japan design code assuming moderate soil condition under the Type II design ground motion (near-field ground motion). PFRC was used at a part of the footing with a depth of 0.60 m below the column base and a depth of 2.7 m above the column base to minimize the cost. The 2.7 m depth of PFRC is three times the code specified plastic hinge length of one-half the column width (0.90 m). This height was set to avoid failure at the PFRC-concrete interface. The 0.60 m depth of PFRC at the footing was provided to minimize damage. Regular concrete with design compressive strength of 30 MPa was used in the other parts of the column. The actual 28-day cylinder compressive strength of concrete was 41 MPa.

The design compressive strength of PFRC was 40 MPa. PFRC was made by combining cement mortar, fine aggregates with maximum grain size of 0.30 mm, water and 3% volume of polypropylene fibers. Monofilament polypropylene fibers with diameter of 42.6 μ m, length of 12 mm, tensile strength of 482 MPa, Young's modulus of 5 GPa and density of 0.91 kg/m^3 were used (Hirata et al. 2009). Superplasticizers were added to improve the workability of the mix. The actual 28-day cylinder compressive strength of PFRC was 36 MPa with a strain at peak of 0.47%.

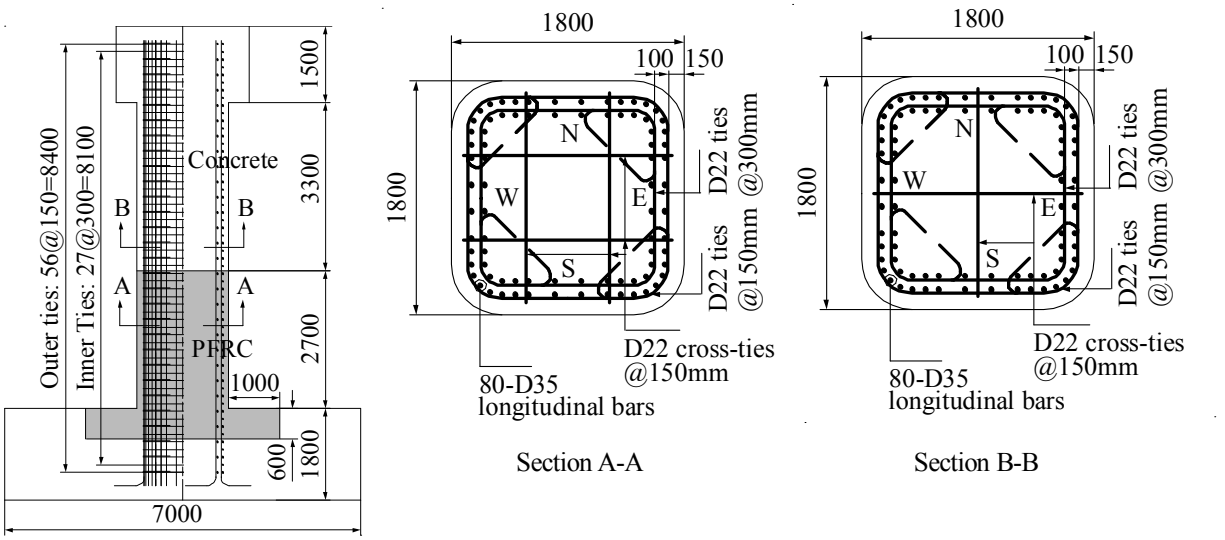

Figure 1 C1-6 column configuration and dimensions (mm)

Eighty-35 mm diameter deformed longitudinal bars were provided in two layers. The corresponding reinforcement ratio ρ_l was 2.47%. The nominal yield strength of longitudinal bars was 345 MPa (SD345) and the actual yield strength was 386 MPa at 0.2% strain. Deformed 22 mm diameter ties with 135 degree bent hooks lap-spliced with 40 times the bar diameter were provided. The outer ties were spaced at 150 mm and the inner ties were spaced at 300 mm throughout the column height. Cross-ties with 180 degree hooks at 150 mm spacing were provided as shown in Figure 1 to increase confinement of the square ties. Volumetric tie reinforcement ratio ρ_s within a height of 2.7 m from the column base was 1.72%. The nominal yield strength of ties was 345 MPa (SD345) and the actual yield strength was 396 MPa at 0.2% strain. Concrete cover of 150 mm was provided.

2.2 Experiment Set-up and Shake-Table Excitations

Photo 1 shows the experiment set-up using the E-Defense shake table. Four mass blocks were set on the column through two simply supported decks. Note that the decks were not designed to idealize the stiffness and strength of real decks. Each deck was supported by the column on one side and by the steel end support on the other side. Tributary mass to the column by two decks including four weights was 307 tf (3011 kN) and 215 tf (2109 kN) in the longitudinal and transverse directions, respectively. The column was excited using the E-Takatori ground motion with the EW, NS and UD components, shown in Figure 2, applied in the longitudinal, transverse and vertical directions of the column, respectively. This ground motion is referred herein as the 100% E-Takatori ground motion.

Shake table excitations were conducted six times. Excitations were repeated to clarify column performance when subjected to much stronger and longer duration near-field ground motion. The column was excited twice with 100% E-Takatori ground motion (1-100%(1) and 1-100%(2) excitations). After the mass in the longitudinal direction was increased by 21% from 307 tf to 372 tf, excitations were conducted with 100% E-Takatori ground motion once (2-100% excitation) and 125% E-Takatori ground motion three times (2-125%(1), 2-125%(2) and 2-125%(3) excitations).

3. EFFECT OF POLYPROPYLENE FIBER REINFORCED CEMENT COMPOSITE ON COLUMN SEISMIC PERFORMANCE

3.1 Progress of Failure

Photos 2 to 4 show the damage progress within 1.2 m from the column base at the SW and NE corner during 1-100%(1), 2-100% and 2-125%(3) excitations at the instance of peak response displacement where the SW corner was subjected to compression while the NE corner was subjected to tension. As shown in Photo 2, during 1-100%(1) excitation, only micro cracks were observed around the column. During 1-100%(2) excitation, very thin flexural cracks as wide as 0.1 - 0.2 mm occurred within 1.6 m from the base all around the column.

During 2-100% excitation, with the mass increased by 21%, damage progressed as shown in Photo 3. Flexural cracks propagated and a crack 0.6 m from the column base at the NE corner opened about 8 mm at the peak response displacement. After the excitation, the maximum residual crack at the above location was 1 - 2 mm wide. Although only flexural cracks occurred all around the column with the cover concrete remaining as a whole shell due to the bridging action of fibers, vertical hairline cracks started to occur at the NE and SW corners within 0.6 m from the column base due to the large strut action of cover concrete shell resulting from the footing reaction when the column was laterally displaced.

During 2-125%(1) excitation, in which the seismic excitation intensity was increased by 25%, at the peak response displacement, the crack 0.6 m from the base opened to 14 mm at the NE corner which was subjected to tension while a vertical crack opened to 9 mm at the opposite SW corner subjected to compression. As the loading progressed, at the SW corner subjected to tension, a crack 1.2 m from the base opened to 9 mm and vertical cracks started to widen at the opposite NE corner.

Succeeding excitations resulted to further propagation of flexural cracks within 2 m from the base around the column and the widening of the vertical crack at the SW

corner. As shown in Photo 4, the damage progressed during 2-125%(3) excitation wherein at the peak response displacement, the crack 0.6 m from the base at the NE corner opened to 20 mm and the vertical crack at the SW corner opened to 15 mm. Note that at the NW corner, cover concrete spalled within 200 mm from the column base when it was subjected to compression while flexural cracks opened to 13 mm at the opposite SE corner subjected to tension. After the excitation, the cracks which opened to over 10 mm during the excitation almost closed with widths of only 5 - 8 mm in flexural cracks and 7 - 12 mm in vertical cracks. Moreover, majority of other small cracks closed to hairline cracks after the excitations due to the fiber bridging action of fibers. Cover concrete spalling was much restricted and there were no exposed longitudinal bars and ties in C1-6 column after 2-125%(3) excitation.

To investigate how the damage progressed in the core and in the longitudinal bars at the NE corner after 2-125%(3) excitation, the column was opened at the area shown in Photo 5. Note that removal of cover concrete in the fiber mixed concrete was very difficult because of its solid nature compared to that of regular reinforced concrete.

(d) Crack on PFRC cover concrete

Photo 5 Damage of PFRC cover concrete and longitudinal bars at the NE corner after 2-125%(3) excitation

In Photo 5, only the outer and inner longitudinal bars and inner ties can be seen because outer ties and a part of the PFRC cover concrete were removed. Maximum lateral offset among three outer longitudinal bars from their original vertical axis was 8 mm. On the other hand, the inner longitudinal bars did not buckle because they were constrained by the undamaged concrete between the outer and inner longitudinal bars. At the SW corner which was subjected to the largest compression during the peak response displacement, the maximum lateral offset of the outer longitudinal bars due to local buckling was 5 mm which was much less than the buckling of bars at the NE corner. In general, local bar buckling was limited.

At the location where crack opening of 20 mm was observed, it was found that the crack occurred only in the PFRC cover concrete with a depth of 110 mm and did not propagate into the core concrete. Also shown is the block of cover concrete that was removed at the bottom right portion where the presence of fibers held the cover concrete together preventing the disintegration of cover concrete. Hence, it is worthy to note that even after six times of excitation, the damage sustained by C1-6 column was much less than the damage of regular reinforced concrete columns.

3.2 Response Acceleration and Displacement

The principal response angle θ_P is defined to identify the principal response direction when the maximum column response displacement occurs . It is given by

$$\theta_P = \tan^{-1}\left(\frac{u_{TR}}{u_{LG}}\right) \qquad (1)$$

where u_{LG} and u_{TR} are the response displacements in the longitudinal and transverse directions, respectively.

Figure 3 shows the acceleration and displacement at the top of column in the principal response direction and Table 1 summarizes the peak acceleration, displacement, residual displacement and moment at each excitation. The principal response angle θ_P varied from 194 to 205 degrees during the six excitations which was almost at the NE-SW direction. The measured peak response acceleration during the series of excitations varied from 13-20 m/s^2.

Due to the high acceleration pulse in the input ground motion, the column experienced high amplitude displacement during each excitation. The peak response displacement was equal to 0.078 m (1% drift) during 1-100%(1) excitation and progressed to 0.45 m (6% drift) during 2-125%(3) excitation. As the excitation progressed with increasing intensity of ground motion, the response displacements increased due to column stiffness deterioration resulting from the damage. The residual displacement was only -0.004 m (0.05% drift) after 2-100% excitation, increased to -0.037 m (0.49% drift) after 2-125%(2) excitation then decreased to -0.013 m (0.13% drift) after the last excitation. Since the allowable residual drift for a cantilever column based on the 2002 JRA code is 1%, the residual drift of the column was still smaller than the allowable limit. It is important to note that residual displacement not only increases but also decreases during seismic excitations because it is more affected by the ratio of post elastic stiffness to elastic stiffness as well as the instantaneous structure period [MacRae and Kawashima, 1997].

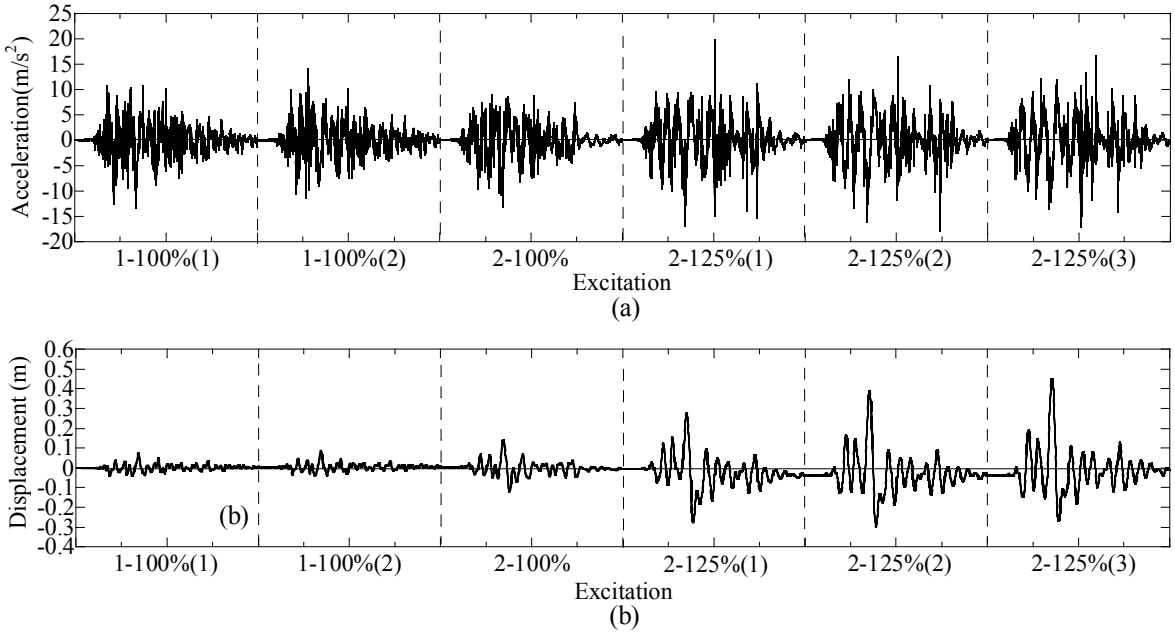

Figure 3 Column response in the principal direction: (a) acceleration and (b) displacement

3.3 Moment and Ductility Capacity

The bending moment at the column base was evaluated as

$$M_k = M_{Bk} + M_{Ck} \tag{2}$$

where M_{Bk} and M_{Ck} represent the moment based on measured load cell forces and based on pier and column mass accelerations, respectively, and are given by

$$M_{Bk} = \sum_{i=1}^{N} \left\{ F_{Lki} h_{Li} - V_{Li} \left(x_{ki} + u_k \right) \right\} \tag{3}$$

$$M_{Ck} = \int_0^{h_B} m_C \ddot{u}_{Ck} dz + \int_{h_B}^{h} m_B \ddot{u}_{Bk} dz \tag{4}$$

where F_{Lki} is the inertia force measured by the i-th load cell in the k direction (k = LG and TR corresponding to the longitudinal and transverse directions, respectively); V_{Li} is the vertical force measured by the i-th load cell in the k direction; h_{Li} is the height from the base to the i-th load cell; x_{ki} is the load cell coordinate in the k direction from the column center; u_k is the response displacement at top of column in the k direction; N is the load cell number ($N = 32$); z is the coordinate of the column from the base upward; m_C and m_B are the mass per unit length of the column and pier cap, respectively; $\ddot{u}_{Ck}$ is the column acceleration response; $\ddot{u}_{Bk}$ is the pier cap acceleration response; h_B is the height from base to the bottom of the pier cap and h is the height from base to the top of pier cap.

Figure 4 shows the hysteresis of moment at the base vs. displacement at the top of the column in the principal response direction. The hysteresis during the entire six times of excitation is stable with sufficient energy dissipation. As summarized in Table 1, the peak moment gradually increased as the excitation progressed. A maximum capacity of 25.3 MNm at 5.2% drift was developed during 2-125%(2) excitation. During this excitation, flexural cracks further propagated all around the column and the vertical cracks at the SW corner widened as described in 3.1. During the subsequent 2-125%(3) excitation, the peak drift increased to 6% while the peak moment slightly deteriorated by 2%. It should be noted that even during the 2-125%(3) excitation, the moment vs. lateral displacement hysteresis was still very stable.

3.4 Strains of Longitudinal and Tie Bars

Figure 5 shows strains of longitudinal and tie bars of C1-6 column at the plastic hinge zone (300-400 mm from the base) at the SW corner where the most extensive damage occurred. Only strains during 1-100%(1), 2-100%, 2-125%(1) and 2-125%(3) excitations are shown due to space limitation. Because longitudinal bars were set in two layers, strains of both the outer and inner longitudinal bars and tie bars are shown here. Noting that the yield strain of both longitudinal and tie bars was nearly 2,000 μ, the longitudinal bars started to yield in tension during 1-100%(1) while tie bars started to yield in tension during 2-125%(1) excitation. The outer and inner longitudinal bars and tie bars exhibited similar response however the amplitude of strains were generally larger in the outer longitudinal and tie bars than the respective inner longitudinal and tie bars.The difference of strain amplitude between outer and inner tie bars is particularly large during and after 2-125%(1) excitation resulting from local buckling of longitudinal bars, which will be described later.

An interesting point in Figure 5 is that the compression strains of the outer and inner longitudinal bars became larger than tension strains during and after 2-125%(1) excitation. For example, compression strain of the outer longitudinal bar reached 19,000 μ while tension strain reached 18,000 μ during 2-125%(1) excitation. This obviously

Table 1 Column response in the principal response direction

Excitation	θ_P (Degrees)	$\ddot{u}_P$ (m/s^2)	u_P (m)	u_P Drift (%)	Residual displacement (m)	M_P (MNm)
1-100%(1)	201.9	-13.4	0.078	1.0	0.005	20.5
1-100%(2)	193.5	14.2	0.089	1.2	0.007	21.8
2-100%	196.0	-13.0	0.144	1.9	-0.004	24.0
2-125%(1)	201.1	19.9	0.280	3.7	-0.035	24.3
2-125%(2)	204.8	-17.9	0.392	5.2	-0.037	25.3
2-125%(3)	204.6	-17.1	0.450	6.0	-0.013	24.9

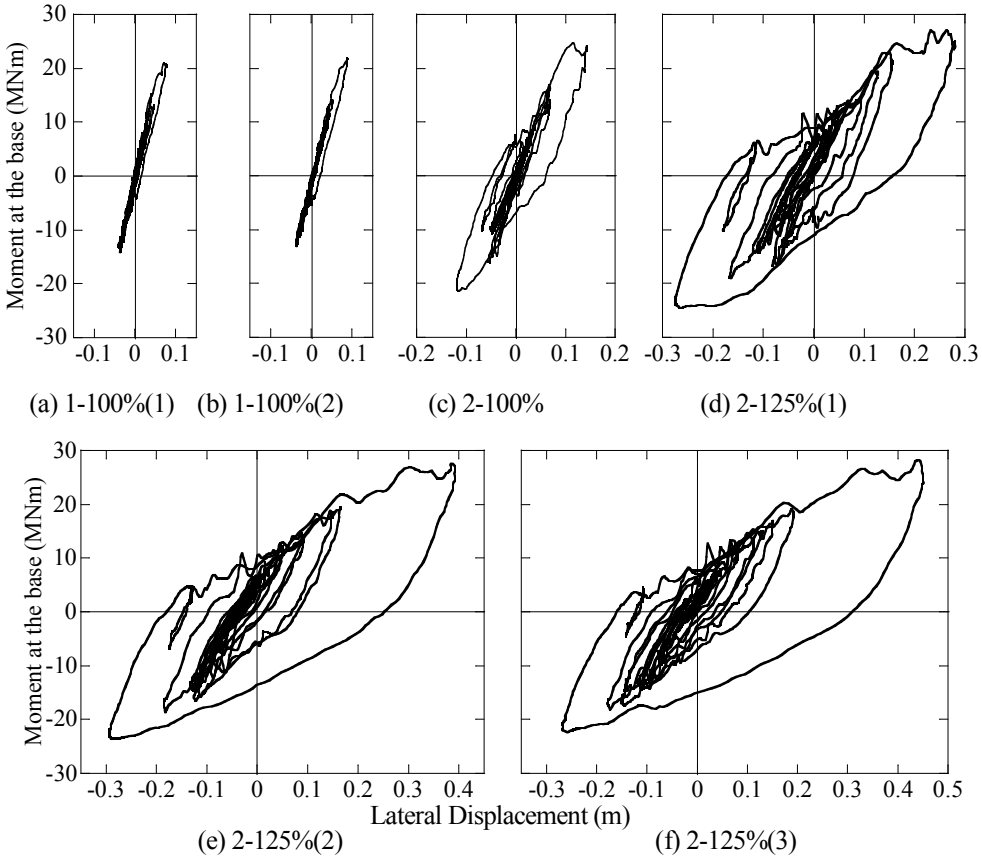

Figure 4 Hysteresis of moment at the base vs. displacement at the top of column in the principal direction

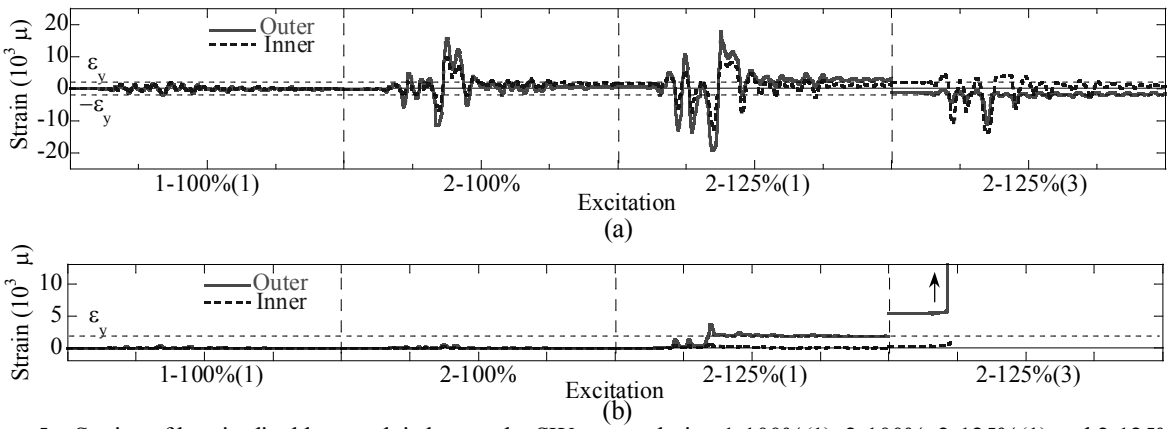

Figure 5 Strains of longitudinal bars and tie bars at the SW corner during 1-100%(1), 2-100%, 2-125%(1) and 2-125%(3) excitations: (a) Longitudinal bars at 300 mm from the base and (b) tie bars at 400 mm from the base

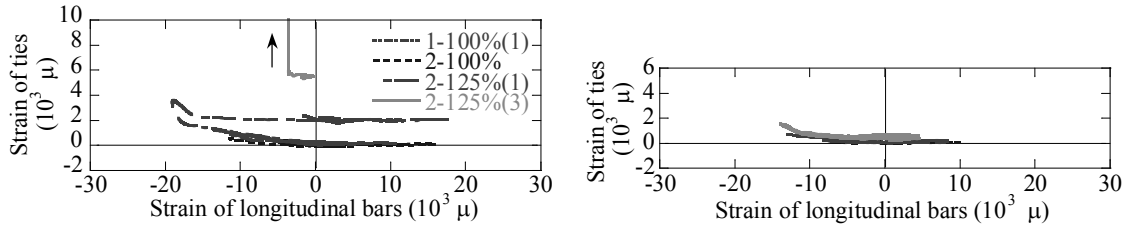

Figure 6 Strain of a tie at 400 mm from the base vs. strain of a longitudinal bar at 300 mm from the base at the SW corner of C1-6 column: (a) Outer bars and (b) inner bars

resulted from the low elastic modulus of PFRC. The large compression strain must have caused the longitudinal bar to buckle. However, in spite of the bar buckling, as described in 3.1, spalling of cover concrete did not occur indicating that the presence of fibers made the cover concrete remain as a whole shell.

On the other hand, the tie bar was still elastic during 1-100%(1) until 2-100% excitations. At the instance when compression strain of the outer longitudinal bar sharply increased during 2-125%(1) excitation, the outer tie strain started to increase to 3,700 μ , indicating that the tie resisted the longitudinal bar buckling. Compression strain of the inner longitudinal bar also sharply increased at the same time, however, the inner tie strain did not increase indicating that the inner longitudinal bar did not buckle. This was because confinement for bar buckling was larger at the inner longitudinal bar than the outer longitudinal bar due to the resistance of core concrete between outer and inner ties which was still intact as shown in Photo 5.

Figure 6 further shows the interaction of a longitudinal bar with a tie bar for outer and inner bars. The tie strains during 2-125%(3) excitation were larger than 5,000 μ and only reliable data are shown here. A sharp increase of the outer tie strain resulting from restraining local buckling of the outer longitudinal bar under high compression strain is clearly seen during and after 2-125%(1) excitation while the inner tie strain remained below 2,000 μ because inner longitudinal bars did not yet buckle.

4. CONCLUSIONS

A series of shake table experiments of a full-size bridge column using polypropylene fiber reinforced cement composites (PFRC) at the potential plastic hinge and part of the footing, referred herein as C1-6 column, were conducted. Based on the results presented, the following conclusions were deduced:

a) PFRC did not have the brittle compression failure of regular reinforced concrete under repeated large inelastic deformation due to the bridging mechanism of fibers. This prevented the brittle crushing of cover and core concrete.

b) As a consequence of a), the use of PFRC reduced buckling of longitudinal bars and deformation of tie bars thus mitigating the damage of C1-6 column even after six times of strong excitations.

c) As a result of the damage mitigation properties of PFRC, the column had a stable flexural capacity and enhanced ductility reaching until 6% drift.

Abstract: An innovative bridge column technology for application in seismic regions is being developed, designed, and tested at UC San Diego Structural Engineering Department. This element combines a precast concrete hollow-core column with pre-tensioning or on-site post-tensioning and added energy dissipation.
The column consists of two steel shells that run for the full-height of the column, with concrete sandwiched in between. The outer shell acts as permanent formwork, and provides longitudinal and transverse reinforcement. The inner shell also behaves as permanent formwork, and prevents concrete implosion under large compressive strains. Constructability is enhanced by the use of a precast element of reduced weight (hollow-core section) without a reinforcing cage.
Large plastic rotations can be attained with minimal structural damage: column-cap and column-foundation joints are allowed to open in tension under severe earthquake excitation, and to close subsequently upon load reversal. Re-centering behavior is ensured by pre- or post-tensioned tendons, designed to respond elastically. A special connection between column, bent-cap, foundation, and tendon allows for eventual tendon replacement in the post-tensioned layout. Energy dissipation is provided by external devices yielding in flexure, which can be easily replaced if damaged.
Analytical and experimental work is currently in progress.

1. INTRODUCTION

During the last three decades of the 20th century, failure of bridges in densely populated areas of California and Japan under strong earthquakes resulted in a significant evolution of the seismic design approach for these infrastructures. Concepts such as ductility and capacity design were gradually understood and incorporated into practice standards, leading to the current design codes such as the California Department of Transportation's (Caltrans) *Seismic Design Criteria* (Caltrans, 2006).

While the notion of structural damage is accepted in design, resilient communities expect bridges to survive a moderately strong earthquake with little or no disturbance to traffic. This implies that partial or total bridge closures are tolerated with uneasiness, particularly in heavily congested urban areas. As a consequence, research efforts have been prompted into advanced technologies that reduce residual damage to the main structural elements, and encompass self-centering properties which allow the structural system to return to its original position after an earthquake. Moreover, these innovative solutions need to be economically viable when compared to existing technologies.

Replacement of existing infrastructure or construction of new facilities in congested and economically or environmentally sensitive areas is an issue faced by many communities worldwide. For this reason Caltrans, through a Federal Highway Administration's (FHWA) initiative, is moving forward towards the development of Accelerated Bridge Construction (ABC) technologies. Among the several goals of this initiative, reduction of on-site construction time, traffic impact, environmental disruption, and life-cycle costs, require technologies characterized by enhanced constructability.

As an example the State of California, as well as many other countries, is currently planning a new high-speed railway infrastructure, which will connect the largest urban and industrial areas of the State. The size of the required investment, and the social and economic impact caused by an eventual service interruption, make accelerated construction and seismic resilience one of the main concerns for the design of bridges along this transportation facility.

In response to the mentioned needs, researchers at UC San Diego are developing *Advanced Precast Concrete Dual-shell Steel Column* systems. Employment of precast technologies, replacement of traditional time-consuming reinforcing cages with steel pipes, and use of hollow cross-sections resulting in weight reduction by elimination of unnecessary concrete, are aimed to improve constructability and in particular to reduce on-site burdens. In parallel, the combination of pre- or post-tensioned joint connections and added energy dissipators ensure seismic resilience, in the form of self-centering capability, facilitation of structural fuse repair, and minimization of residual structural damage.

The proposed columns are an extension of the steel jacket concept used by Caltrans for retrofitting deficient columns, of the research work on Cast-In-Steel-Shell piles funded by Caltrans (Gebman, Ashford, and Restrepo, 2006), of the studies on self-centering precast walls performed at UC Berkeley (Sakai and Mahin, 2004) and in New Zealand (Rahman and Restrepo, 2000), and of the precast post-tensioned rocking systems developed within the PRESSS program (Priestley and Tao, 1993).

2. DIFFERENT LAYOUTS FOR PRECAST CONCRETE DUAL-SHELL STEEL COLUMNS

2.1 Background

A few years ago, researchers at UC San Diego (Tobolski, 2010) investigated the lateral response of a precast column unit featuring the dual-shell and re-centering characteristics under discussion. The test prototype is depicted in Figure 1. The column consists of two steel shells that run for the full-height of the column with high-performance concrete sandwiched in between the shells. Both shells act as permanent formwork during concrete casting. The outer one substitutes longitudinal and transverse reinforcement, with stresses being transferred between steel and concrete through weld beads on the internal surface of the shell. The inner shell prevents concrete implosion under large compressive strains.

This type of bent assembly is designed to attain large nonlinear drift rotations with minimum structural damage, which differs from the accepted performance criteria for columns being incorporated into bridge construction nowadays. Column-cap and column-foundation joints are allowed to open in tension during a strong and rare earthquake, and to close subsequently upon load reversal as shown in Figure 2(a).

In this particular configuration, re-centering behavior is ensured by unbonded tendons, designed to remain elastic even during a strong shake. Energy dissipation is provided by mild steel bars yielding axially across the joints; these bars are left partially unbonded to concentrate yielding at the

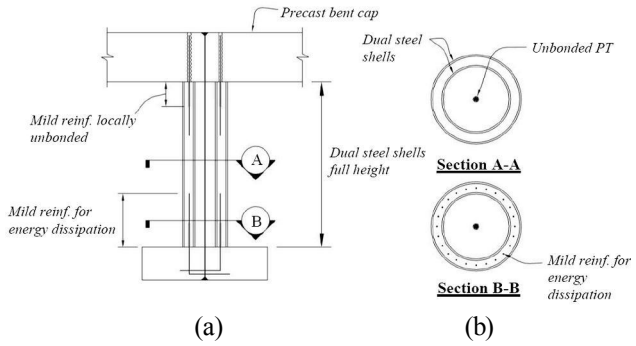

Figure 1 – Advanced Precast Concrete Dual-shell Steel Column, post-tensioned connections with internal energy dissipators: (a) global layout, and (b) cross-sections.

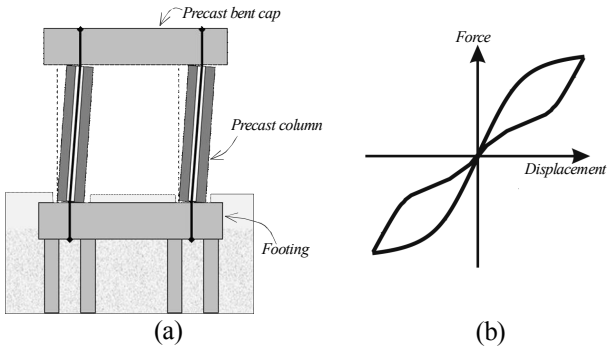

Figure 2 – Hybrid system: (a) swaying bent with opening joints, and (b) flag-shaped force-displacement response.

desired locations (Figure 1). The combination of self-centering capability and added energy dissipation makes the proposed technology to be part of the *hybrid systems* family. A typical flag-shaped hysteretic force-displacement response is sketched in Figure 2(b).

During testing, under large joint opening, the mortar sealing the column-cap interface crushed due to high compressive strains, leading to some post-tensioning force losses. To overcome this inconvenience, polymer-modified mortar is being employed in future specimens.

2.2 Internal and External Energy Dissipators

As mentioned before, energy dissipation in the form of yielding is concentrated within specific components, preventing the remaining members to suffer significant damage. After a strong-intensity shake, only these dissipators are expected to undergo multiple cycles within the inelastic range of response, with possible need of replacement.

The use of mild steel longitudinal bars, crossing the column-cap and column-footing interface, has been proven to be effective in terms of dissipative behavior (Tobolski, 2010) and offers the advantage of avoiding aesthetic interference. As shown in Figure 3, these devices are embedded in the column concrete and protrude within the footing or bent-cap without any visible impact.

However, this layout presents some drawbacks. During plant operations, the presence of mild steel bars would interfere with concrete casting, given the narrow space left in between the two shells. Moreover, the eventual replacement of damaged dissipators would require cutting and repairing the outer steel shell, which may have a thickness of several centimeters, to reach the embedded bars. These inconveniences would make construction and repair more time-consuming and expensive, compared to other solutions.

For this reason, the use of external devices instead of mild steel bars could be advantageous. Tests on hybrid masonry shear-walls have been conducted in New Zealand employing external energy dissipators (Toranzo, 2002). An example of such devices and their possible location around

Figure 3 – Column end at the column-cap interface. Mild steel bars protruding out of the column, subsequently embedded in the bent-cap concrete, work as energy disispators.

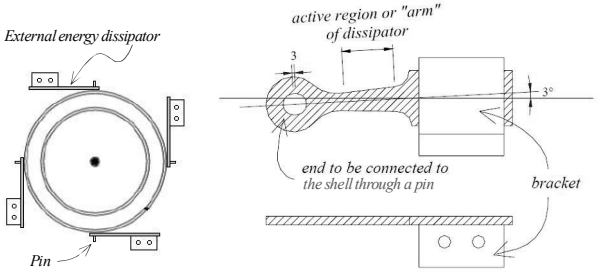

Figure 4 – External energy dissipators: (a) location around the column perimeter, and (b) sketch of device features.

the column perimeter at the column-cap or column-footing interface, are shown in Figure 4.

The proposed external dissipator consists of a stainless steel lever, connected to the outer shell through a pin, and fixed to the footing or the bent-cap through a steel bracket. The lever acts as a cantilever with a transverse force applied to its free end. It is tapered, such that flexural yield may spread throughout its length instead of being concentrated in a narrow portion. The lever longitudinal axis is slightly sloped downward to the free end, to minimize the interaction between axial and flexural stiffness during joint rotation. The slenderness of the arm is limited in order to prevent local or global buckling, allowing for full plasticity development on both tensile and compressive sides.

The pin connecting the lever to the column must transfer only a force transverse to the arm, to prevent weak-axis bending or twisting of the lever. A spherical pin can satisfy this requirement. The fixed end of the lever is welded to a bracket, which is bolted into the footing or the cap. To protect this joint from premature failure, capacity-design principle are applied: in particular, the lever width is increased close to the connection to prevent plasticity from spreading into this region, and welds and bolts are proportioned for the moment transferred by the enlarged cross-section.

Figure 5 depicts an external dissipator during testing in New Zealand: it is shown in its undeflected (a) and deflected (b) configurations, together with its hysteretic response (c).

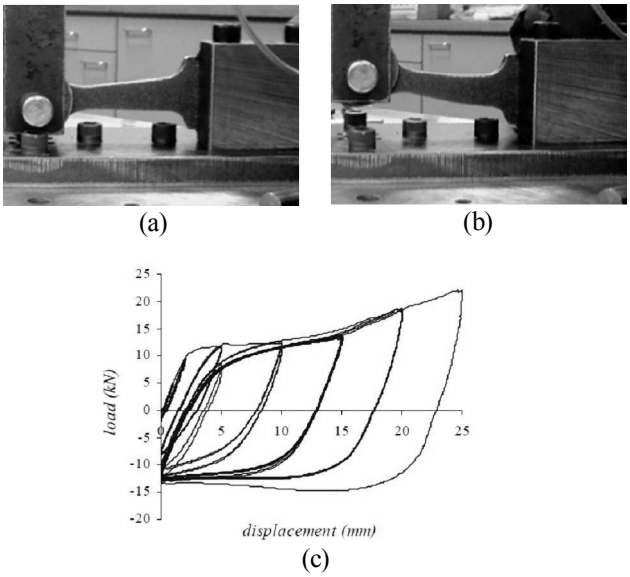

Figure 5 – Testing of external energy dissipators in New Zealand: (a) undeflected configuration, (b) deflected configuration, and (c) hysteretic behavior.

2.3 Post-tensioned and Pre-tensioned Connection

For the specimens of hybrid columns tested at UC San Diego, post-tensioning was employed to confer self-centering capability to the structural system. This technology has proven to be effective and reliable for the scope under investigation, even though post-tensioning losses were recorded due to mortar crushing at the interface in one of these tests. The use of special mortars, such as polymer-modified or fiber-reinforced ones, should provide a valid solution to this problem.

A more insidious issue is represented by eventual corrosion of the post-tensioning tendon, exposed to air and moisture inside the hollow core. This phenomenon may cause serious damage to the tendon, up to the need of replacing it. A special footing-column-cap connection is needed to make the replacement operations easier: different possible solutions are being compared in terms of feasibility and cost. The common idea is to allow for pulling the tendon out from the bent-cap top, leaving the column in place. Minimizing bridge operation disruption is a fundamental objective to be fulfilled with this system.

An alternative is represented by a pre-tensioned connection, with tendons running through the concrete between the shells (Figure 6). This layout allow for better protection of the tendons, reducing the risk of corrosion and the need of replacement.

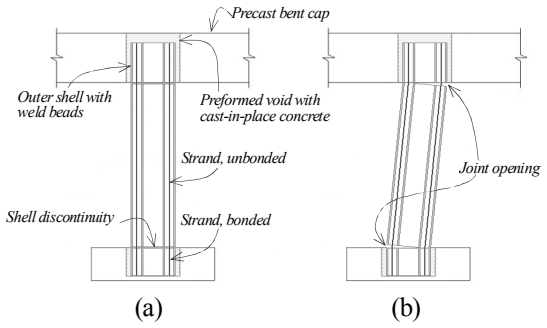

Figure 6 – Pre-tensioned connection: (a) global layout, and (b) deflected configuration.

The precast column unit extends and develops within preformed cavities in the footing and bent-cap, filled with concrete after assemblage. Internal force transfer between the outer shell and the surrounding concrete is enhanced by weld beads on the exterior surface of the shell. The steel shells are discontinuous at locations where joints will open, allowing relative rotation between three segments of the element. Re-centering behavior is ensured by pre-tensioned strands running between the shells for the entire length of the precast unit. These strands are bonded to the concrete within the end segments, anchored in the cap and footing, while they are debonded through greased PVC sheathing along the central segment. Energy dissipation is achieved in the system through the use of stainless steel levers anchored between the end segments and the central segment (not sketched in Figure 6 to avoid graphic congestion).

3. EXPERIMENTAL PROGRAM

Two specimens are being tested at the UC San Diego Powell Laboratories. They represent the column-cap joint of a prototype bent assembly, as illustrated in Figure 7, and they have similar dimensions and testing setup as previous experiments conducted by UC san Diego researchers (Tobolski, 2010). Design is conform to AASHTO *Seismic Guide Specifications* (AASHTO 2009). One specimen combines post-tensioned connection with external energy dissipators, while the other one includes pre-tensioned connection and external dissipators.

In both cases, the column has an outer diameter of 20 in. (0.5 m) and a nominal length of 57.5 in. (1.46 m), thus an aspect ratio of 2.9. The cap beam is simply supported at the inflection points; it has a pin-to-pin length of 10 ft (3.05 m) and a square cross section with 25-in. (0.64-m) sides. The column external shell is made of ASTM A572 GR 50 steel; it has an outer diameter of 20 in. (0.5 m) and a thickness of 0.25 in. (6.35 mm), resulting in a longitudinal reinforcement ratio 0f 5.19%. The inner shell is a corrugated steel pipe with a nominal diameter of 1 ft (0.30 m). Concrete strength at 28 days is specified as 7 ksi (48.3 MPa).

The post-tensioned specimen has a concentric tendon made of high-strength, low-relaxation steel with a specified ultimate strength of 270 ksi (1860 MPa) and yield strength of 245 ksi (1690 MPa). Five 0.6-in. (15.24-mm) strands, stressed at 75% GUTS, run inside a PVC pipe in the hollow core of the column, to reduce the risk of corrosion. These strands are anchored to the cap-beam through a wedge plate. The same prestressing force is applied to the pre-tensioned specimen. In this case, five 0.6-in. (15.24-mm) or seven 0.5-in. (12.7-mm) strands are distributed within the concrete between the steel shells. Here the strands develop along the end segment of the precast column, embedded in the bent-cap (see Figure 6).

External energy dissipators are being designed to induce the same forces on the specimen as the mild steel bars previously used. Four to six devices are disposed around the perimeter as shown in Figure 4. Details are currently under review.

The loading protocol consists of displacement time-histories applied to the free end of the column, subjected to a constant axial force. These time-histories are derived from the response of the prototype structure to selected ground motions, and are applied to induce the correct strain rates on the specimens.

4. CONCLUSIONS

The proposed system is expected to yield a superior performance compared to traditionally cast-in-place bridge bents. Previous tests have proven the ability of hybrid systems, similar to the one under development, in terms of re-centering behavior and energy dissipation. Some drawbacks observed during those tests are being addressed, such as: compressive strength of the mortar at column-cap and column-footing interface; tendon corrosion and eventual replacement; and accessibility of energy dissipators.

Testing of the first unit, which incorporates a post-tensioned tendon, will take place at the University of California, San Diego, Powell Structural Engineering Laboratories during Winter and Spring 2011.

Abstract: A series of analyses and small scale experimental tests are performed for circular reinforced concrete bridge piers. These studies are in preparation for a large-scale hybrid simulation of a curved three-pier bridge structure subjected to multi-directional earthquake loading. The small scale tests serve as a proof of concept for six degree of freedom control of the experimental piers. The effects of combined actions resulting from geometrical asymmetry and multi-directional earthquake loading are studied. Specific effort is focused on the interaction effects of applying torsional and lateral loads to the piers.

Small scale specimens are carefully fabricated considering similitude relationships and scaling effects. A series of small scale tests are performed to assess the interaction effects of shear and torsion. In addition, the capacity envelope under individual actions is determined experimentally for scaled down specimens from the curved three-pier bridge. Analysis is performed in OpenSees, and a parametric study is conducted to determine the effects of geometry on torsional and lateral loads sustained by the piers. These results are used in preparation for a small-scale hybrid proof-of-concept to be followed by large-scale testing.

1. INTRODUCTION

Bridge columns can be subjected to various combined loading conditions resulting from complex earthquake ground motions coupled with irregular geometry and asymmetry of the bridge structure itself. The objective of the Network for Earthquake Engineering Simulation (NEES) Combined Actions on Bridge Earthquake Response (CABER) project is to develop a fundamental understanding of the effects of these combined actions on the performance of reinforced concrete (RC) columns and the resulting system response. The investigations are motivated by the inadequacy of existing analytical solutions and lack of experimental data for use in improving model behavior.

Experimental tests have been performed under different combinations of multi-directional bending, shear, axial load, and torsion. Columns have been tested quasi-statically at the Missouri University of Science and Technology (MST), pseudo-dynamically at the University of Illinois at Urbana-Champaign (UIUC), and dynamically at the University of Nevada, Reno (UNR). The remaining task of the CABER project is the hybrid testing of a curved three-pier bridge under multidirectional earthquake loading. The experiment will be performed leveraging the unique capabilities of the NEES Multi-Axial Full-Scale Sub-Structures Testing and Simulation (MUST-SIM) Facility at the University of Illinois, Urbana-Champaign.

A series of small-scale experimental tests were performed on circular reinforced concrete bridge piers to demonstrate structural principles. Five 1/16-scale specimens were tested cyclically under a combination of shear and torsion loads. Small-scale fabrication and microconcrete mix design were modeled based on previous studies on similitude requirements (Holub, 2005). Tests included shear-only, torsion-only, and shear-torsion interaction tests with ratios of 1:3, 1:1, and 3:1 as defined by elastic properties of the specimens observed in the first two tests void of interaction effects.

A single small-scale load and boundary condition box (LBCB) shown in Figure 1 was used to apply displacement input motions. The LBCBs are able to simulate complex loading representative of seismic motion in all six degrees of freedom, with the goal of understanding the response of complex structural systems under realistic loading. Forces and displacements were read from internal load cells and linear variable differential transformer (LVDT) readings of the LBCB. Four external linear potentiometers were used to confirm the LVDT displacement readings. Critical structural values are reported, and these experimental results are compared to the predicted results obtained through analysis methods and code calculations. Combined shear and torsion loading states were used to develop an interaction diagram and illustrate the combined effects of the two types of structural demand.

Figure 1 Small scale set-up with LBCB

A second set of small-scale specimens were tested to develop capacity envelopes under individual actions for scaled properties of the curved three-pier bridge. Analysis of the piers from the curved bridge is performed in OpenSees, and a parametric study is conducted to determine the effects of geometry on torsional and lateral loads sustained by the piers. These results are used in preparation for a small-scale hybrid proof-of-concept to be followed by large-scale testing.

2. HYBRID METHODOLOGY

The Hybrid simulation is enabled by the 6DOF loading equipment and simulation-coordinator software available at the Illinois MUST-SIM testing facility. These features of the UIUC equipment site enable the following hybrid simulation:

- Two 1/3-scale piers will be tested in the large-scale MUST-SIM facility using 6DOF Load and Boundary Condition Boxes (LBCBs).
- One 1/20-scale pier will be tested in the portable LBCB reaction frame of the small-scale MUST-SIM facility.
- Superstructure and abutments are modeled analytically using OpenSees.

Hybrid analysis using experimental and analytical components is enabled through the use of the University of Illinois simulation coordinator (UI-SimCor). The acceleration time history step will be passed into UI-SimCor, which performs numerical time integration and passes displacement targets to the experimental and analytical components of the hybrid simulation. Forces are measured and calculated from the two components and read back into UI-SimCor to command displacements to balance the equations of equilibrium before taking the next step in the earthquake time history.

3. GEOMETRY

Overall geometry of the prototype bridge is based on a seismic design example from the Federal Highway Administration (FHWA). The curved geometry and spacing of the piers is critical to the level of combined response generated in the structure. The skewed geometry shown in the OpenSees wire-frame model (Figure 2) develops torsional, flexural, shear, and axial stresses in the supporting members.

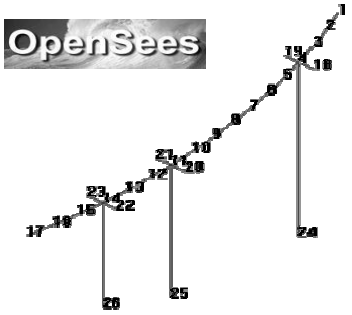

Figure 2 OpenSees model of skewed geometry with optimal pier locations

A parametric study was performed using this OpenSees model to determine the most reasonable column locations that generate maximum torsional moments in the piers. This objective is selected because the torsional component of interaction is specifically of interest in this study. Special effort was made to ensure that the distribution of piers represents a realistic and viable structural design option. The torsional and flexural moment time-history plots resulting from the selected case are shown in Figures 3 and 4, respectively.

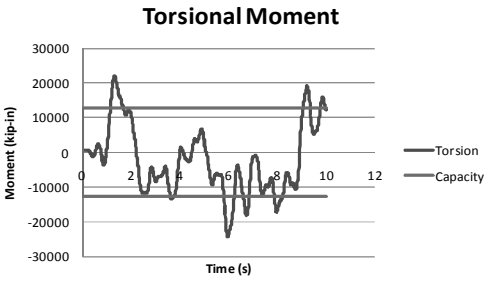

Figure 3 Torsional moment time history

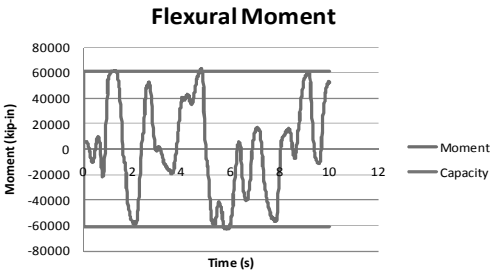

Figure 4 Flexural moment time history

4. SEISMIC DEMAND

The applied earthquake record is a synthetically generated accelerogram from Washington State. SPECTRA was used to generate the response spectrum, and SIMQKE was used to generate time history records.

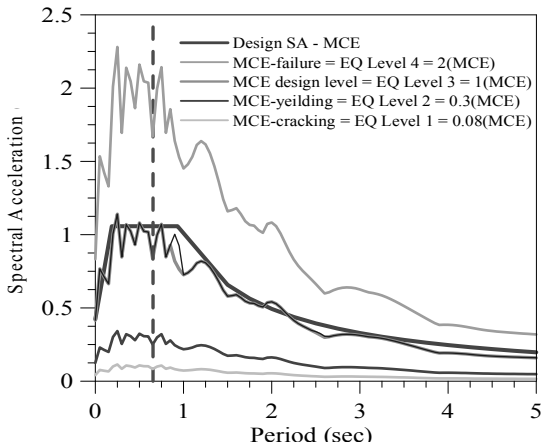

Figure 5 Response spectra of seismic demands

The record will be applied as a sequence of imposed records scaled to four levels corresponding to estimates of the states of structural response listed below. The four levels of scaling are represented as ratios of the Maximum Credible Earthquake (MCE), with definition and response spectra for each level plotted in Figure 5.

5. MATERIALS AND SIMILITUDE

Similitude relationships for the small scale test specimens are based on extensive studies by Holub (2005) where a methodology for consistent and accurate small scale fabrication of reinforced concrete piers was developed. A micro-concrete mix is prepared using appropriately scaled and graded aggregate, along with Type III cement to achieve the desired characteristics, including an early compressive strength of approximately 4 ksi.

The initial set of specimens were produced for this project with the intent of performing five small-scale tests. All specimens consisted of a column with a height of 9.5 in. and a diameter of 2.4 in. The end caps on each column had a height of 1.5 in. and a diameter of 5.0 in. Twenty 4-40 threaded rods were used to provide the longitudinal reinforcement. The rods were annealed for one hour at 1000°F. The spiral reinforcement is provided by smooth annealed wire with a diameter of 0.0348 in. The spiral reinforcement coils were spaced at approximately 3/8 inches.

The scaled down versions of the 3-peir simulation have longitudinal reinforcement provided using 3-48 threaded rods to achieve symmetry in the flexural steel at the desired reinforcement ratio. These rods are heat treated in order to achieve the desired stress-strain response. Transverse reinforcement is smooth black annealed wire of 0.0348 inch diameter. The reinforcement cage prior to enclosure of formwork is shown in Figure 6. Piers are cast using PVC and wood forms. Micro-concrete is poured and consolidated using a vibrating table, specimens are cured for 7 days prior to form removal, and are painted and capped with Hydrocal before finally being ready for testing any time after reaching 21 day strength.

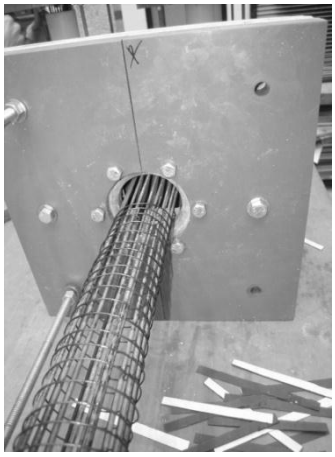

Figure 6 Small scale fabrication of reinforcement

6. SMALL SCALE TESTING PROGRAM

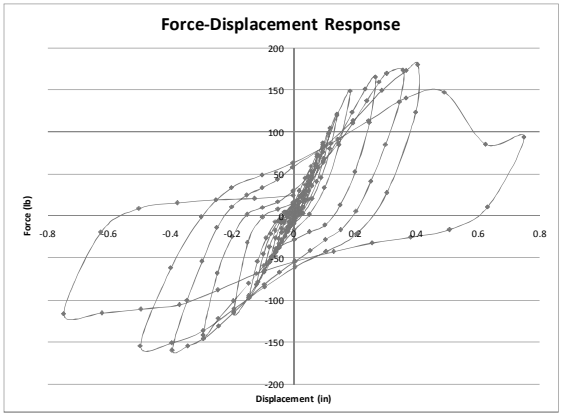
Lateral and rotational actions were applied cyclically with increased amplitude to two sets of small-scale test specimens. The first set of 5 specimens consist of cyclic loading patterns were used for the tests to more closely simulate dynamic loading conditions. The LBCB was given cyclic displacement and/or rotation commands. For each test, the loading protocol was provided via an input file uploaded to the LBCB Plugin. Displacements and rotations were applied in one direction, returned to zero, and then applied in the opposite direction. This pattern was repeated with increasing displacements and rotations after each successive cycle until the specimen lost significant torsional and shear capacity.

The second set of specimens have geometry and material properties identical to the pier that will be included in the final hybrid simulation. The purpose of these simple tests were to confirm the anticipated maximum lateral and rotational capacities of the piers, as well as to test a newly designed reaction frame and updated control systems and software of the small scale facility.

7. RESULTS

The results of the five tests performed are discussed below. Key performance points of yield, peak, loss of

strength, and ultimate limit states are defined according to hysteretic response curves for force-displacement and moment-rotation relationships. Yield is defined as the loss of stiffness, where the specimen enters the inelastic response region. The peak limit state is the maximum strength value achieved by the specimen in units of either force or moment. The first significant drop in load resistance was selected as the loss of strength point, and is often coincidental with large cracks developing. Finally, the ultimate limit state is selected to give an indication of the ductility that can be achieved while still resisting a nominal load on the specimen. An example of one response curve and the four performance states are provided in Figure 7 and Table 1, respectively. Photos of each specimen are provided in Figure 8 at the four corresponding points during the experimental testing.



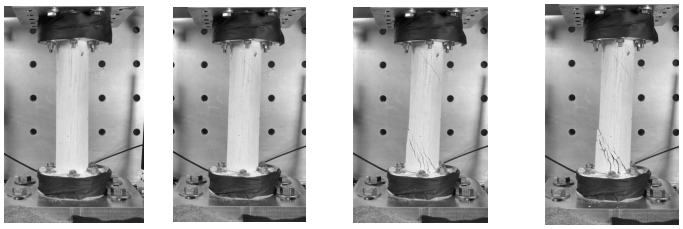


Figure 7 Cyclic force-displacement response curve for 3:1 shear to torsion loading.

Table 1 Performance limit states under 3:1 loading

3:1 Shear to Torsion Ratio				
Shear Test Curves	Force (lb)	Displacement (in)	Moment (in-lb)	Rotation (degrees)
Yield	121.2	0.14	92.4	0.09
Peak	180.3	0.40	139.2	0.17
Strength Loss	147.3	0.49	127.6	0.26
Ultimate	94.1	0.75	36.6	0.61

(a) Yield (b) Peak (c)Strength Loss (d) Ultimate

Figure 8 Photos corresponding to lateral performance limit states for 3:1 shear to torsion loading.

Backbone curves of each specimen are created from the four limit state points defined from the hysteretic responses like those shown in Figure 7 and Table 1. These points are used to provide rough estimates of the peak response of the piers, allowing for more natural comparison of the effects of each loading profile on the specimens. This provides the best visual representation for examining the effects of shear and torsion interaction on the behavior of the bridge piers.

The yield points show that lateral yield force decreases as torsion is added to the loading profile as expected. This yielding will occur earlier as torsion is additive on one face of the pier, causing an increase in shear stress. In addition to lower force capacity, lateral yielding also occurs at a smaller displacement, indicating that deformation capacity is reduced. The inverse is also true as shown by the rotational yield moment, with the exception that the relationship between the loading case with equal application of shear and torsion exhibits a higher yield moment than anticipated when compared to the load application of shear and torsion that is biased toward torsion. Apart from this case, the application of shear reduces the moment and rotational values at which torsional yielding occurs. Hence, it is clear that interaction effects result in inelastic behavior occurring at lower force and moment values than the cases where either of the single components of loading is applied.

It should be noted that minimal amounts of torsion relative to the shear force present do not seem to have a drastic effect on lateral capacities. However, even a very small shear force introduced into a system undergoing rotational input severely reduces the moment and rotation capacity of the structure. Regardless, it is evident that there is a threshold for each limit state where the combined shear and torsion interaction results in specimens more vulnerable to shear or torsional failure than if the other loading component was not present, as can be seen in Figure 9.

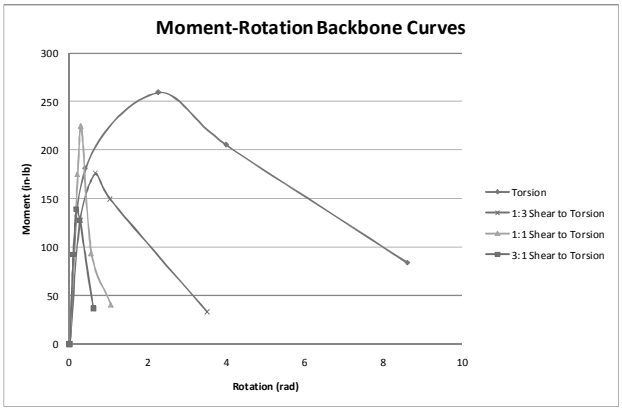

Figure 9 Comparison of backbone curves derived from rotational performance limits

The results of the two additional small scale tests reveal that the small scale fabrication has achieved the desired capacity to achieve reasonable similitude in future hybrid tests. Analysis of the small-scale sections were performed

using Response-2000, and the lateral capacity was estimated at approximately 700 pounds (corresponding to an ultimate moment of 7.1 in-kips) which is 10% above the capacity shown in the results displayed in Figure 10.

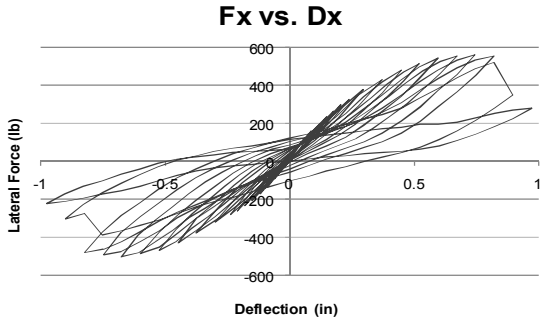

Figure 10 Lateral force-deflection hysteresis

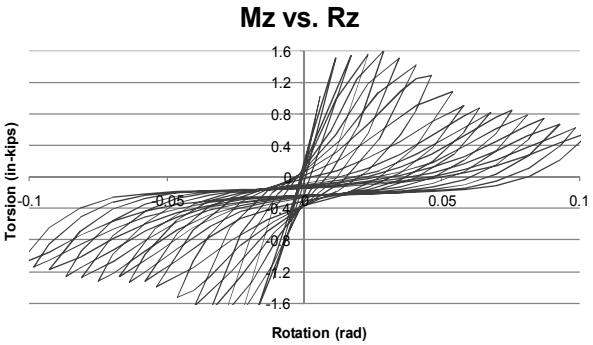

Figure 11 Torsional moment-rotation hysteresis

Torsional capacity was predicted using ACI 318-08 Eq. 11-21 and is conservatively estimated to be 1.3 in-kips. The experimental results (Figure 11) show torsional moments achieving approximately 25% above the code prediction due to conservative safety factors. At full scale, this torsional moment is equivalent to nearly 13,000 in-kips. This is the value that was used for torsional capacity in the parametric study for determining the final configuration of the 3 Pier Hybrid Simulation. It has been shown that rigorous replication of the small scale fabrication techniques developed for this concept test will result in small scale piers with consistent behavior, which is desired in order to apply realistic combined actions to the large-scale specimens.

8. CONCLUSIONS AND FUTURE WORK

A series of small-scale experimental tests were successfully performed on circular reinforced concrete bridge piers to demonstrate structural principles such as shear-torsion interaction. The five 1/16-scale specimens were tested cyclically under shear-only, torsion-only, and shear-torsion interaction tests with ratios of 1:3, 1:1, and 3:1 as determined by elastic properties of the specimens loaded in only one method. A comprehensive program for data acquisition using the facilities of the MUST-SIM NEES facility was employed, with the use of internal and external sensors, LBCB load cells, and external cameras. Forces and displacements are reported, along with moments and rotations, and the resulting behaviors of the specimens are discussed. Critical structural values are reported for each test, and these experimental results are compared to the predicted results obtained through analysis methods and code calculations. Combined shear and torsion loading states are used to develop an interaction diagram and illustrate the combined effects of different loading scenarios. An educational outreach video was also produced to illustrate structural concepts using the results from this experimental program.

Based on analytical analyses and two additional small scale proof tests, it has been determined that the small scale fabrication techniques, 6DOF loading and boundary condition boxes, and simulation coordinating software will provide an adequate means of testing the complete hybrid framework in the small scale facility. The parametric study on interaction effects resulting from various bridge geometry has provided an arrangement of piers that will be used in this test. Earthquake demand has been determined based off of applied ratios to the MCE record. The experimental tests have shown that the facility is capable of accurately capturing the effects of these combined actions. The results from these proof of concept tests will help to determine instrumentation plans and other data acquisition details for the final full scale hybrid simulation. Further studies will be performed to ensure that the magnitude and characteristics of the applied seismic motion will result in levels of actions that demonstrate the combined response of the structure in three dimensions.

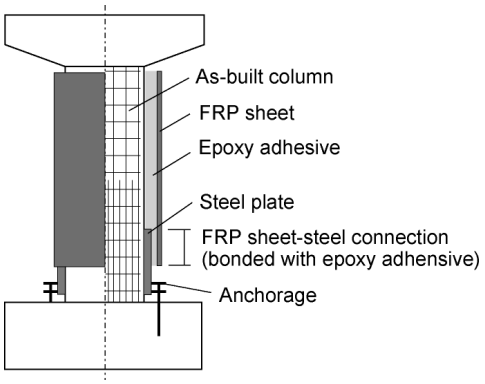
Abstract: This research was conducted with the purpose to obtain basic knowledges for establishing a method for designing carbon fiber reinforced polymer (CFRP) sheet-steel plate connection that can be employed in seismic retrofit of reinforced concrete (RC) bridge columns. Bonding behavior between CFRP sheet and steel plate including effective bond length and relationships between interfacial bond stress and relative displacement were investigated based on double-lap bond tests. Effective bond lengths were determined for the cases with different thickness of CFRP sheet. A bond stress-slip model that can be used for estimating bonding capacity of the connection was proposed based on the test results. Furthermore, the validity of the proposed bond stress-slip model was estimated by three dimensional FEM analyses.

1. INTRODUCTION

Carbon fiber reinforced polymer (CFRP) sheet is often used for seismic retrofit of reinforced concrete (RC) highway bridge columns attributing to the light-weight, high strength and outstanding workability. A typical application of CFRP sheet in seismic retrofit of RC bridge columns in Japan is used for enhancing flexural and/or shear strength of the sections at which the longitudinal reinforcements were cut off prematurely with insufficient development length. In some other cases, CFRP sheet is also used for enhancing ductility of RC bridge columns by jacketing around the plastic hinge in the circumferential direction.

However, due to the reason that the elongation of CFRP sheet is rather lower before fracture, it is not easy to apply CFRP sheet for enhancing the flexural strength around the bottom of RC bridge columns where plastic deformation is expected to occur during the large earthquakes. On the other hand, seismic retrofit method using CFRP sheet will be efficient for the bridges under severe construction work conditions for the reasons such as that it can reduce the construction period, increasing of the death weight after retrofit is little, and so on. With the purpose to develop a retrofit method using CFRP sheet for seismic retrofit of RC bridge columns including the flexural strength of the base, a method by means of using combination of CFRP sheet and steel jacketing as shown in Figure 1 is being studied by the authors. This method takes advantage of both steel plate and CFRP sheet. Steel jacketing is adopted for strengthening the flexural capacity of column base and CFRP sheet jacketing is adopted for strengthening the other sections of the column.



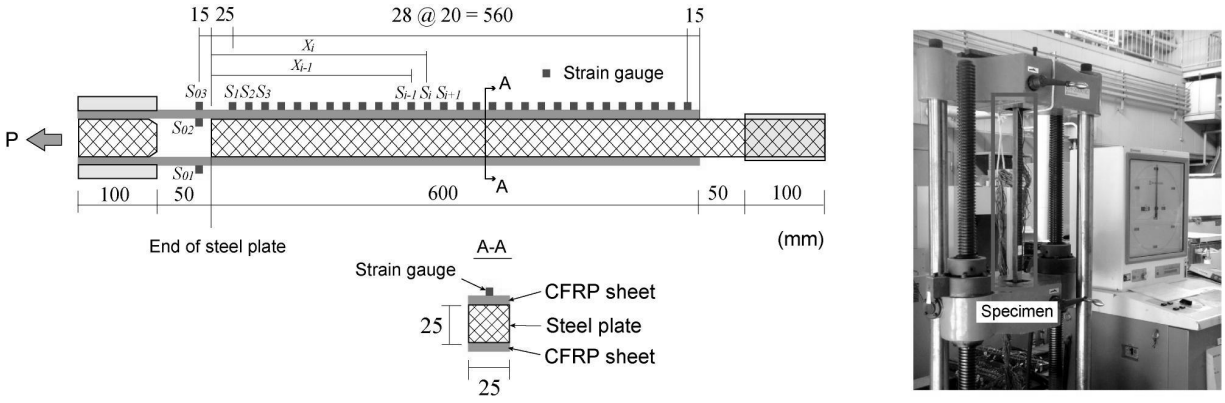


Figure 1 Schematic of seismic retrofit method using combination of FRP sheet and steel jacketing

In this method, CFRP sheet is bonded to the steel plate with epoxy adhesive. It can be noted that bonding capacity of the connection between CFRP sheet and steel plate is a key issue for this method because the longitudinal force induced by the additional anchor bolts that are used for enhancing the flexural strength of the columns must be transferred to the CFRP sheet. In order to design a CFRP sheet-steel plate connection, bonding force that can be transferred by the connection and a minimum bond length that is needed to ensure the bonding force are required to be understood. According to the previous researches (Nozaka et al. 2005, Teng et al. 2006), there is an effective bond length for the CFRP sheet-steel plate connection that is the minimum bond length to ensure the bonding force. Bonding force does not increase even applying a bond length longer than the effective bond length. It is also known that bonding

(a) Details of specimen (b) Setup of tests

Figure 2 Details of specimens and setup of tests

force is mainly affected by the thickness of CFRP sheet and it can be evaluated by using a bond stress-slip model that represents the bonding capacity of the CFRP sheet-steel plate interface (Teng et al. 2006). Consequently, effective bond length and bond stress-slip model are required to be determined for designing a CFRP sheet-steel plate connection.

With the above point of view, in this study, bonding behavior between CFRP sheet and steel plate including effective bond length and bond stress-slip model were investigated through double-lap bond tests with the purpose to obtain basic knowledges for establishing a design method for the CFRP sheet-steel plate connection. Three dimensional FEM analyses were also carried out for estimating the validity of the proposed bond stress-slip model. This paper provides descriptions of the details of tests, FEM analysis methods and results obtained from the experimental and analytical studies.

2. TEST SPECIMENS AND PRECEDURE

Four series of double-lap shear bond tests as shown in Table 1 were designed in this study. Figure 2(a) shows the details of the double-lap shear specimens. Three specimens with same condition were tested for each series. Parameters of the specimens including the thickness of CFRP sheet, the thickness of steel plate and bond length were designed based on the following considerations. The thicknesses of CFRP sheet were varied from 0.333 to 1.332 mm to investigate the influence of the thickness of CFRP sheet on bonding behavior. Here, the thicknesses are the design thickness and correspond to 1 to 4 layers of CFRP sheet with a fiber mass per unit area of 600g/m^2. SS400 steel plates with a thickness of 25mm were used for each of the specimens. The thickness of the steel plate was designed as 25mm in order to ensure that the steel plate does not yield during the tests. CFRP sheet with a length of 50mm at the end of the steel plate that was not being bonded with steel plate was employed to determine the initiation of debonding between CFRP sheet and steel plate. Bond length of 600mm was applied for each of the specimens. This bond length is several times longer than the effective bond length that can be estimated based on the previous researches (Nozaka et al. 2005, Teng et al. 2006). The purpose of using a longer bond length is to investigate the varying of the distribution of strain in CFRP sheet with the progress of debonding between CFRP sheet and steel plate.

Table 1 List of specimens

Series	Thickness of CFRP sheet	Numbers of specimens for each series
Case-1	1 layer, t_f = 0.333mm	3 (No.1, No.2, No.3)
Case-2	2 layer, t_f = 0.666mm	3 (No.1, No.2, No.3)
Case-3	3 layer, t_f = 0.999mm	3 (No.1, No.2, No.3)
Case-4	4 layer, t_f = 1.332mm	3 (No.1, No.2, No.3)

Table 2 Material properties

Materials	Items	Values
CFRP sheet	Fiber mass per unit area (g/m^2)	600
	Design thickness (mm)	0.333
	Young's modulus (N/mm^2)	2.65×10^5
	Tensile strength (N/mm^2)	3,400
Epoxy adhesive	Young's modulus (N/mm^2)	2.202×10^3
	Compressive strength (N/mm^2)	71.8
	Tensile strength (N/mm^2)	47.0
	Tensile shear strength (N/mm^2)	17.6

Surface of steel plate to be bonded with CFRP sheet was grinded with a disc sander. All the specimens were cured for 7 days at ambient temperature after the epoxy adhesive was applied. Strain gauges were placed on CFRP sheet at intervals of 20 mm to measure the strain induced in CFRP sheet in details.

Table 2 shows the material properties of CFRP sheet and epoxy adhesive. The values of Young's modulus and strengths were obtained from tests.

All the tests were performed under unidirectional tensile force with a loading speed of 0.5-1.0 mm per minute. Figure 2(b) shows the setup of the tests.

3. TEST RESULTS

The effective bond length and relationships between

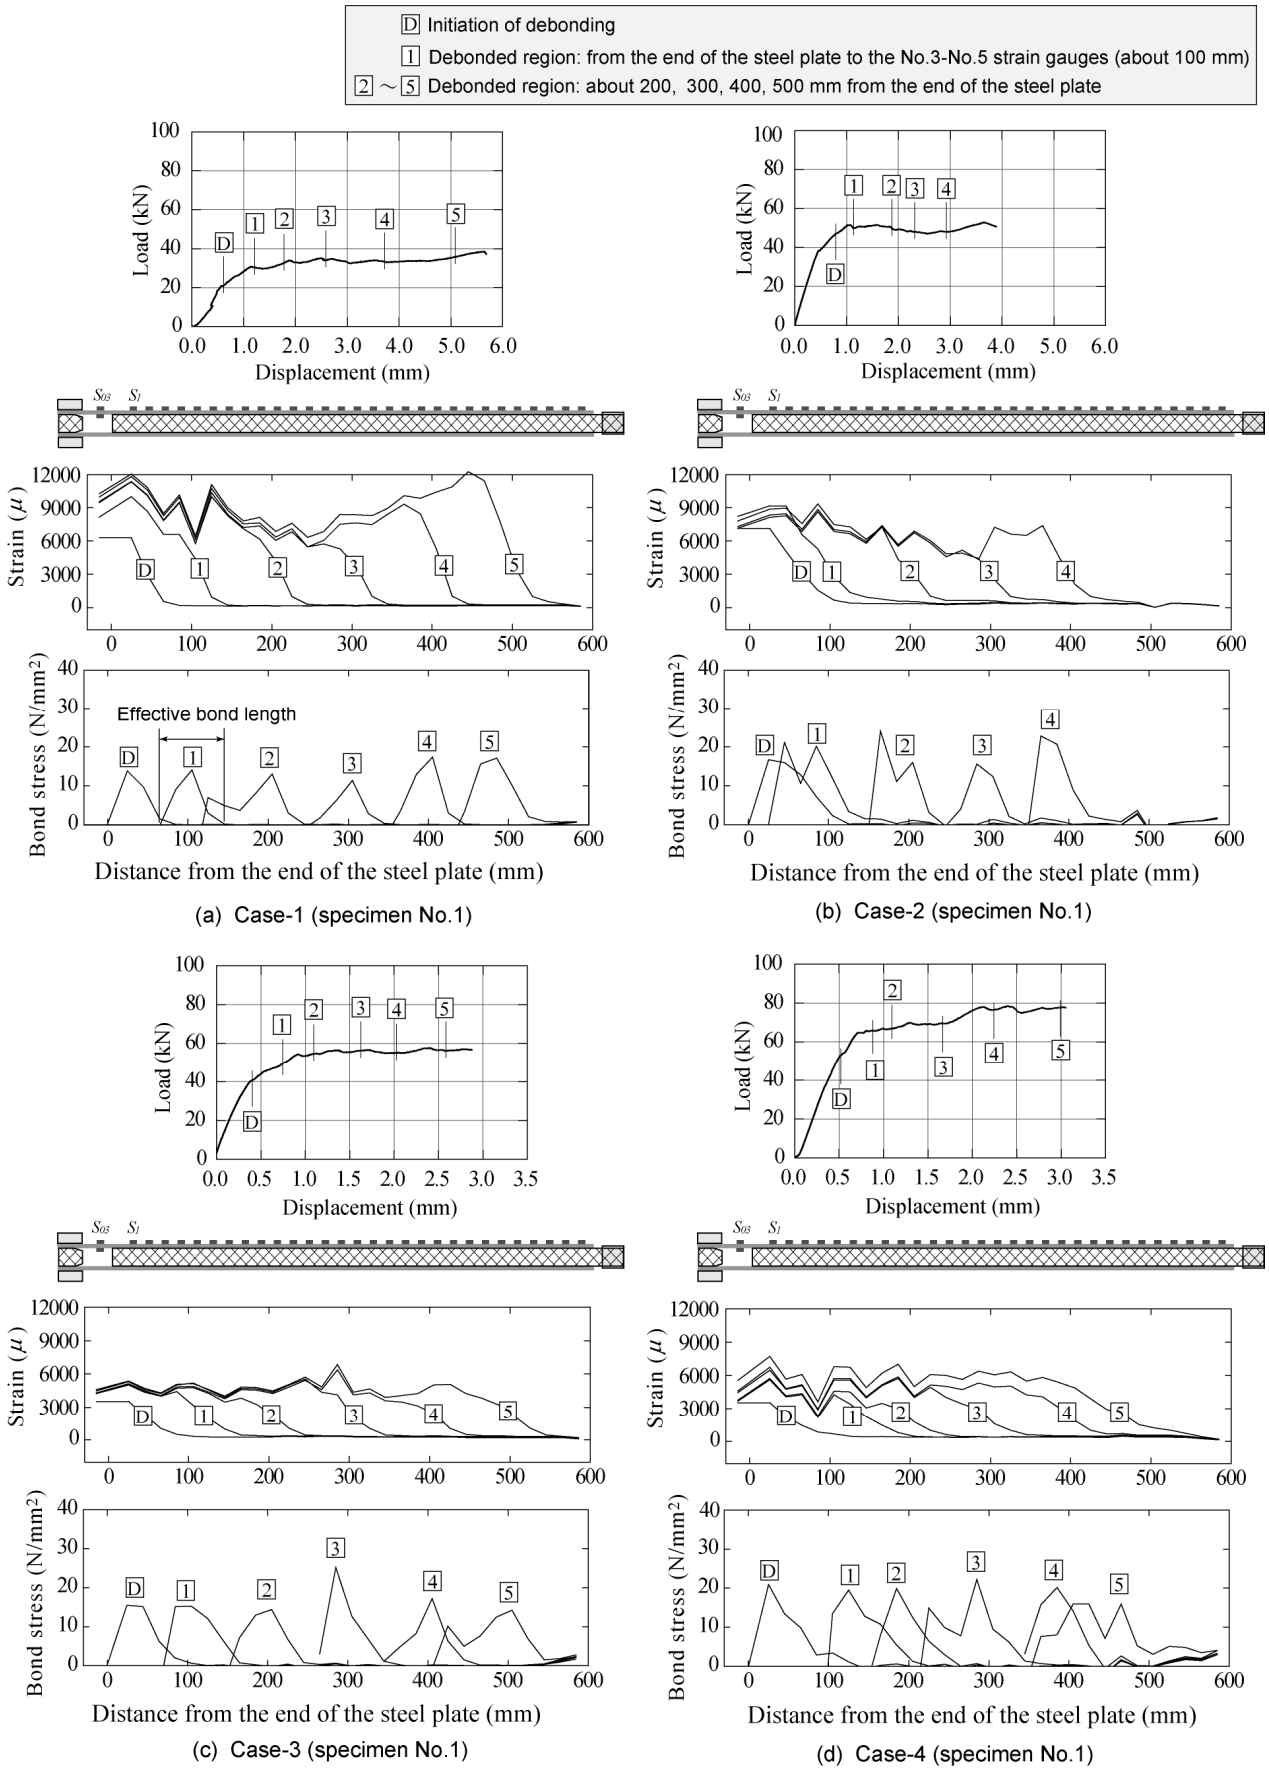

Figure 3 Test results of load-displacement curves, strain distributions in CFRP sheet and interfacial bond stress

Table 3 Debonding strains and effective bond lengths

Series	Debonding strains (μ)		Effective bond length
	No.1, No.2, No.3	Average	
Case-1	6311, 8263, 5728	6763	80-100 mm
Case-2	7127, 6640	6884	100-160 mm
Case-3	3513, 4604, 4937	4351	120-180 mm
Case-4	3555, 5450, 4285	4430	140-200 mm

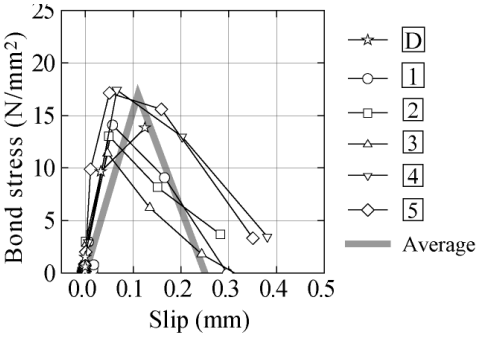

Figure 4 Bond stress-slip curves (case-1)

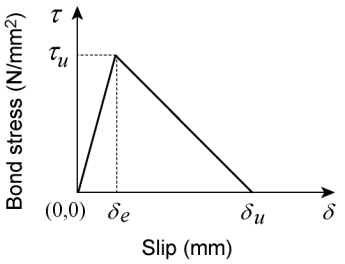

Figure 5 Bond stress-slip model

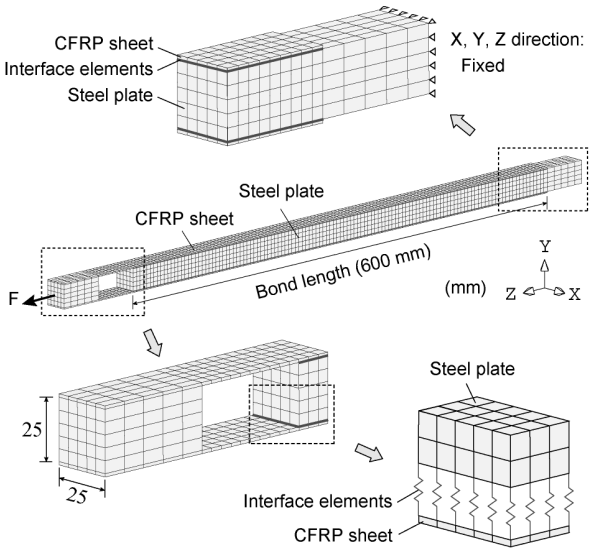

Figure 6 FEM model

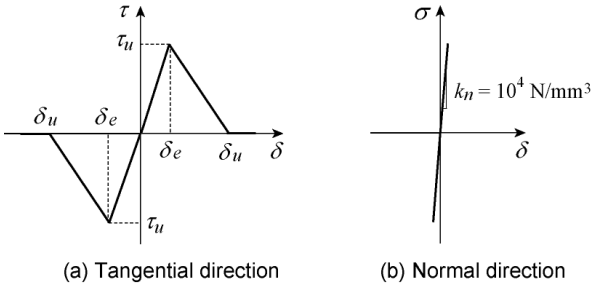

Figure 7 Stress-relative displacement models

interfacial bond stress and relative displacement (slip) were investigated based on the discussions on the following items: relationships between load and displacement of CFRP sheet at the end of steel plate, distributions of strain in CFRP sheet and distributions of interfacial bond stress along the bond length. Figure 3 shows the test results of specimens No.1 for each of the four series. Here, interfacial bond stress τ was calculated from the strain in CFRP sheet using the equation $\tau = d\varepsilon(x)/dx \cdot E_f \cdot t_f$, where E_f and t_f are the Young's modulus and thickness of CFRP sheet respectively. Effective bond length was considered as the distance of the two points at which bond stress is zero as shown in Figure 3(a). Results of specimen No.3 of case-2 were not included in the following discussion because debonding of the CFRP sheet occurred prematurely due to the defects in the bonding condition.

Table 3 shows the results of debonding strains and effective bond lengths obtained based on the distributions of strain in CFRP sheet and distributions of bond stress. Here, debonding strain is defined as the strain occurred in CFRP sheet at the end of the steel plate when debonding initiated. The debonding strain can be employed to evaluate the bonding capacity of the connection. In this research, the debonding strains were determined with the average of strain gauges S_{02} and S_{03} at the point of the debonding initiated (Zhang et al. 2010). It can be noted that the debonding strain decreases with the increasing of the thickness of CFRP sheet. The lowest value was about 3,500 microstrains for the specimens No.1 of both case-3 and case-4. Furthermore, it was determined that the effective bond lengths were about 80-100, 100-160, 120-180 and 140-200 mm for case-1 to case-4 respectively. As the thickness of CFRP sheet increases, the length of the effective bond length increases.

Figure 4 shows bond stress-slip curves for specimen No.1 of case-1. It can be seen that the shape of the bond stress-slip curves show approximately a triangle shape. The same trend was also confirmed from the other tests. Based on this observation, the relationship between bond stress and slip was assumed as a bilinear model as shown in Figure 5. Three parameters of this model including maximum bond stress τ_u, relative displacements δ_e and δ_u were determined as the average values of the results of point 1 for all of the specimens. Only the results of point 1 were used for determining the parameters because of the following two reasons. One is that the relative displacements δ_u cannot be calculated yet at point D when the debonding initiated and the other is that the variations of the stain values become notable after point 2 when the debonded region becomes longer. The values of τ_u, δ_e and δ_u obtained from the test results were 17.0 N/mm^2, 0.11 mm and 0.25 mm, respectively. Consequently, the fracture energy G_f of the CFRP sheet-steel plate interface that was considered as the area of the triangle was evaluated as 2.13 N/mm.

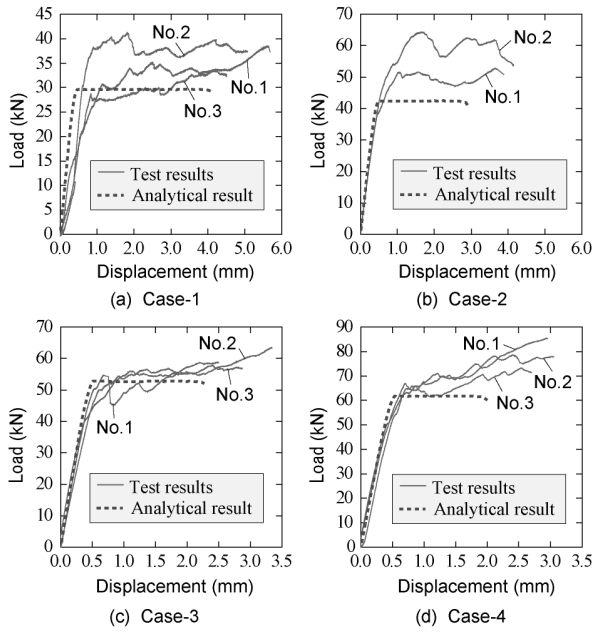

Figure 8 Comparisons of load-displacement curves

4. EVALUATION OF THE BOND STRESS-SLIP MODEL BASED ON FEM ANALYSES

Three-dimensional FEM analyses were carried out for all of the specimens listed in Table 1 in order to estimate the validity of the bond stress-slip model proposed in this research. Figure 6 shows the FEM model adopted in the analyses. The steel plate and CFRP sheet were modeled with 8-node solid element. Interface elements were applied between the steel plate and CFRP sheet to model the stress and relative displacement of the interface. Interface element is a type of element that can be used to model the discontinuous behavior between two surfaces by means of applying a rational stress-relative displacement model (DIANA 9.3, 2008). Figure 7 shows the stress-relative displacement models adopted for the two directions of the interface. The behavior of the interface in the tangential direction was defined by the bond stress-slip model proposed in the previous section. The behavior in the normal direction was defined as linear with a stiffness k_n of 10^4 N/mm^3. Here, the value of k_n was decided considering the stability of the analyses (DIANA 9.3, 2008). Both the steel plate and CFRP sheet were modeled as elastic materials because the steel plate did not yield and the CFRP sheet did not fracture during the tests.

Figure 8 shows the comparisons of load-displacement curves. The analytical results show that load increases sharply in the early stage of loading and then keep a constant value. It was confirmed from the stress and strain condition in the interface elements that once the relative displacement of the interface element at the end of the steel plate exceeds δ_u as shown in Figure 5, the load will not increase and the curve become flat. This means that the load will not increase after the debonding occurred. Figure 9 shows the comparisons of the strain distributions in CFRP sheet and

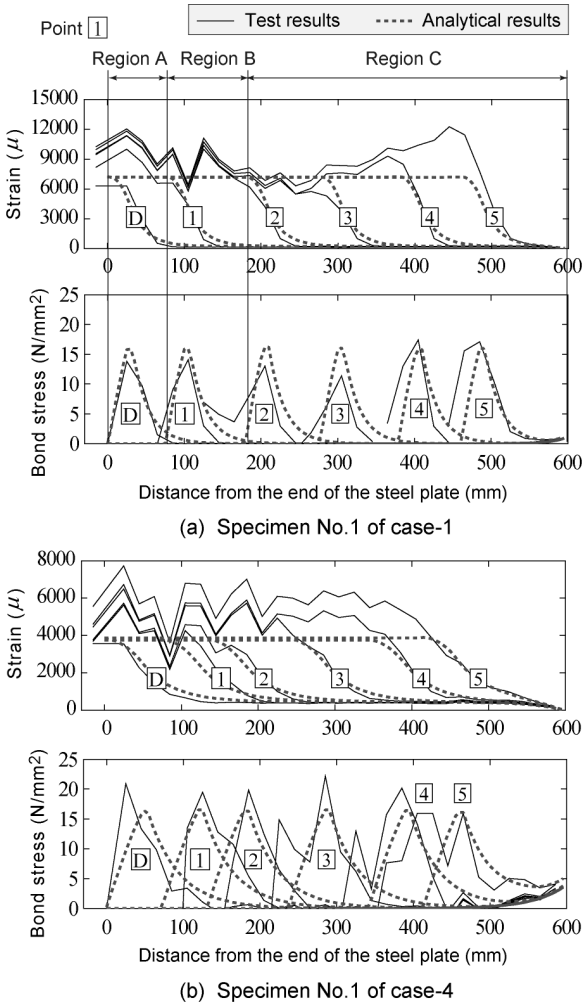

Figure 9 Comparisons of distributions of strain in CFRP sheet and distributions of bond stress

bond stress for specimens No.1 of case-1 and case-4 as examples. Here, strain distribution of CFRP sheet can be divided into three regions as shown in Figure 9 (a). Region A is the region in which debonding occurred entirely. Region B in the region in which interfacial bond stress occurred. Region C is region in which interfacial bond stress do not occur yet. Region B is the region that contributes to the bond force of the connection. It should be noticed that CFRP sheet in region A is debonded entirely from the steel plate and the strain is not affected by the bond stress-slip model. Strain distribution of CFRP sheet in region A may be affected by the length of the region A and progress condition of the debonding of the CFRP sheets bonded on the two side of the steel plate. Based on the same consideration, the load after the debonding occurred is not only affected by the bonding capacity, but also affected by other factors such as the debonding condition of the CFRP sheets. Therefore, comparisons of the load-displacement curves after debonding occurred and the strain distribution of CFRP sheet in the region A were not considered in this paper taking into account of the purpose of the analytical study.

Figures 8 and 9 show that analytical results including load-displacement curves before debonding occurred, strain

distribution of CFRP sheet and bond stress in the region B agree approximately with the test results. This indicates that FEM analysis adopting the bond stress-slip model proposed in the pervious section can provide a good simulation of the bonding behavior of the CFRP sheet-steel plate connection. It can also be considered that the validity of the proposed bond stress-slip model was confirmed by the comparisons.

5. CONCLUSIONS

In this study, bonding behavior between CFRP sheet and steel plate were studied experimentally and analytically with the purpose to obtain basic knowledges for establishing a design method for CFRP sheet-steel plate connection. Effective bond lengths for CFRP sheet-steel plate connection with different thickness of CFRP sheet were investigated. It was confirmed that the effective bond lengths were about 80-100, 100-160, 120-180 and 140-200 mm for the cases bonded with CFRP sheet with thickness of 0.333, 0.666, 0.999 and 1.32 mm respectively. Relationship between bond stress and slip of the interface between CFRP sheet and steel plate was assumed as a bilinear model and the parameters of the model were studied. The values of maximum shear stress τ_u , relative displacement δ_e and δ_u were determined as 17.0 N/mm^2, 0.11 mm and 0.25 mm, respectively. The fracture energy of the CFRP sheet-steel plate interface was evaluated as 2.13 N/mm. Furthermore, the validity of the proposed bond stress-slip model was confirmed by comparing the results obtained from three dimensional FEM analyses with the test results.

Abstract: Pitting corrosion of reinforcing steel can lead to a considerable decrease in reliability over time in reinforced concrete members and structural systems. Older structures that have undergone long-term structural deterioration are likely to be at higher risk during extreme events like earthquakes than similar structures that have recently been built. This paper presents a simplified approach for analytically modeling pitting corrosion deterioration in reinforced concrete bridge columns that can be used in a time-dependent risk assessment framework. The model is validated by comparison with experimental tests.

1. INTRODUCTION

1.1 Corrosion and Time Varying Seismic Risk

Corrosion of reinforcing steel combined with poor concrete durability is a major source of structural deterioration in reinforced concrete infrastructure worldwide including bridges, piers, seawalls, dams, and other structures (Vu and Stewart 2000). Several researchers have investigated the effect of reinforcement corrosion on the time-dependent reliability of reinforced concrete structures subjected largely to dead and live gravity loads (Frangopol et al. 1997; Stewart and Rosowsky 1998; Val et al. 1998; Vu and Stewart 2000). These studies have established that the corrosion of reinforcing steel can lead to significant reductions in the reliability of reinforced concrete members and structural systems over time.

Deterioration due to corrosion has been commonly modeled using phenomenological processes proposed by Tuutti (1982) which segments steel corrosion in reinforced concrete into a series of distinct stages. The first stage involves the initial transport of chlorides through the concrete cover leading to depassivation of the reinforcing steel. This is followed by the formation of oxidation products that cause radial cracking around the steel rebar. Eventually, the oxidation process is accelerated ultimately leading to spalling of the concrete cover. The stages of this phenomenon have been quantified, modeled, and reviewed in part or whole by others (Bentz et al. 1996; Liu and Weyers 1998; Middleton and Hogg 1998; Neville 1995). In the majority of these approaches, the corrosion initiation stages involving transport of the chlorides and corrosives through the cover and initial depassivation have been modeled using Fick's Second Law of Diffusion (Eqn 1).

$$T_{int} = \frac{x^2}{4D_c}\left[\text{erf}^{-1}\left(\frac{C_0 - C_{cr}}{C_0}\right)\right]^{-2} \quad (1)$$

where T_{int} = time to corrosion in years; x = concrete cover depth in mm; D_c = diffusion coefficient in mm^2/yr; C_0 = surface chloride concentration in mg/g; and C_{cr} = threshold chloride concentration for steel depassivation in mg/g.

This is followed by uniform rates of steel corrosion that result in expansive hoop stresses on the concrete cover, exceedence of the tensile strength of the cover, and crack formation and spalling of the cover resulting in unchecked steel corrosion. One such model for uniform corrosion is shown as Equation 2 (Enright and Frangopol 1998).

$$D(t) = D_0 - 0.0203 i_{corr}\,(t - T_{int}) \quad (2)$$

where $D(t)$ = rebar diameter as a function of time in mm; D_o = initial rebar diameter in mm; and i_{corr} = corrosion rate measured as a current density in μA/cm^2.

In recent years, researchers have begun recognizing that the time-dependent decrease in structural reliability due to reinforced concrete corrosion can have a profound effect on the probability of failure of aging reinforced concrete structures exposed to seismic hazards (Choe et al. 2009; Padgett and Ghosh 2009; Kumar et al. 2009). Thus there is demonstrably a dire need for time-varying risk assessment models that can characterize risk due to multi-hazard environments, in this case extreme seismic events and long-term structural deterioration that vary over time.

1.2 Research Motivation

While previous researchers have shown that time-dependent corrosion can have a considerable impact on the probability of failure of structures under seismic loads, the simple method in which corrosion initiation and propagation has been modeled reduces the usefulness of these results for either structural reliability prediction or life cycle cost or impact estimation. Furthermore, neglecting to include the effects of pitting corrosion can lead to a significant underestimation of the actual extent of deterioration and an over-prediction of the residual strength of the structure. This study improves upon previous research by explicitly incorporating the effect of concrete cover cracking in the corrosion phenomenon. The appearance of concrete cracks causes a shift from uniform corrosion along the length of the reinforcement to more severe pitting corrosion at the crack location. Consideration of pitting corrosion represents a significant improvement over the existing models in that the corrosion deterioration process is represented more realistically, thus bringing the time-dependent multi-hazard model closer to actual field conditions over time.

2. CORROSION MODELING

2.1 Model for Multi-Stage Reinforcement Corrosion

Transport of chlorides through the uncracked cover is modeled as a Fickian diffusion process up until time T_{int}, as given by Equation 1 and shown in Figure 1. Time to cracking following depassivation, T_{cr}, is modeled as uniform corrosion using the mechanics-based model of Liu and Weyers (Eqn 3).

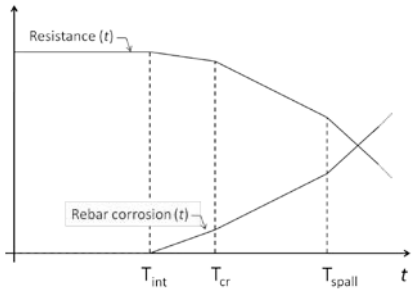

Figure 1 Conceptual multi-stage deterioration process

Time to cracking following depassivation, T_{cr}, is modeled as uniform corrosion using the mechanics-based model of Liu and Weyers (Eqn 3).

$$T_{cr} = \frac{\left[\rho_{rust}\left(\pi\left[\frac{xf_t}{E_{ef}}\left(\frac{a^2+b^2}{b^2-a^2}+\nu_c\right)+d_0\right]D_0+\frac{W_{st}}{\rho_{st}}\right)\right]^2}{\frac{0.208\pi D_0 i_{corr}}{\alpha}} \quad (3)$$

where T_{cr} = time to cover cracking after depassivation in years; ρ_{rust} = density of corrosion products; x = concrete cover depth in mm; f'_t = tensile strength of concrete in MPa; $E_{ef} = E_C/(1+\varphi_C)$; E_C = elastic modulus of concrete in MPa; φ_C = concrete creep coefficient; $a = 0.5(D + 2d_0)$; $b = x + a$; ν_c = Poisson's ratio for concrete; d_0 = thickness of porous band at steel/concrete interface in mm; D_0 = initial diameter of steel reinforcement in mm; W_{st} = mass of corroded steel in mg/mm; ρ_{st} = density of steel; α = molecular weight of steel divided by molecular weight of corrosion products; and i_{corr} = corrosion rate measured as current density in μA/cm^2.

After cracking has occurred, more often than not, instead of a uniform reduction of cross-sectional area, chloride-induced corrosion will lead to localized reductions of rebar cross-sectional area through the formation of pits. Pitting is considered to be more dangerous than uniform corrosion damage. A small, narrow pit with minimal overall metal loss can lead to the failure of an entire reinforced concrete member. Since pitting corrosion is a highly localized phenomenon, it can result in reductions of cross sectional area that are 5 to 10 times greater than that of uniform corrosion given the same corrosion rate (Stewart 2004).

The extent of pitting corrosion has been quantified by others using a pitting factor (Cairns *et al*. 2005; Gonzalez *et al*. 1995; Rodriguez *et al*. 1997; Torres-Acosta and Martínez-Madrid 2003) given as:

$$R = p/P_{av} \quad (4)$$

$$P_{av} = 0.0116 i_{corr}\, t \quad (5)$$

where R = pitting factor; p = maximum pit depth in mm; P_{av} = penetration based on uniform corrosion; i_{corr} = corrosion rate as current density in μA/cm^2.

From Equations 4 and 5 the maximum pit depth along a reinforcing bar is then calculated as

$$p(t) = 0.0116 i_{corr}\, Rt \quad (6)$$

2.2 Reduction of reinforcing steel diameter over time

Given the pit depth as a function of time, Val et al. (1998) suggested that the geometry of the pit can be expressed as a quadrilateral (Figure 2).

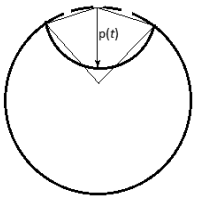

Figure 2 Quadrilateral pit configuration

Therefore, the cross sectional area of steel remaining in an RC component as a function of time is (Stewart and Al-Harthy 2008)

$$A(t) = A_0 - A_{pit}(t) \quad (7)$$

where A = cross sectional area of remaining rebar in mm^2; A_0 = initial cross sectional are of rebar in mm^2; and A_{pit} = cross

sectional area of pit in mm^2 which can be calculated using the equations developed by Val and Melchers (1997).

To facilitate the incorporation of the effects of pitting corrosion in the analytical modeling of the column, a number of simplifications were made on the Val and Melchers model. The mechanical effect of pitting is assumed equivalent to a gross reduction in rebar diameter (Figure 3).

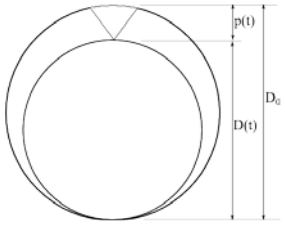

Figure 3 Simplified effect of pitting corrosion on rebar geometry

Combining this with equations 2 and 6, the multi-stage uniform-pitting corrosion model is obtained as

$$D(t) = \begin{cases} D_0, & t \le T_{int} \\ D_0 - 0.0203 i_{corr}\,(t - T_{int}), & T_{int} < t \le T_{int} + T_{cr} \\ D_0 - 0.0116 R i_{corr}\,(t - T_{cr} - T_{int}) & \\ \quad -0.0203 i_{corr}\,(t - T_{int}), & t > T_{int} + T_{cr} \end{cases} \quad (8)$$

where D(t) = diameter of rebar at time t, as shown in Figure 3.

3. STRUCTURAL MODELING

In order to validate the assumptions made in the corrosion model described above, analytical and experimental test results of several reinforced concrete columns were compared. The time-varying nature of the seismic behavior of the columns was accounted for by combining the corrosion model with the finite element structural model in OpenSees. Physical test columns having the same specifications were subjected to different axial loads and varying degrees of accelerated corrosion in an experiment at the State Key Laboratory of Coastal and Offshore Engineering at Dalian University of Technology in China (Li and Gong 2008).

3.1 Tests Used for Validation

The experimental reinforced concrete column test specimens were 1 m tall and had a diameter of 0.26 m. The longitudinal reinforcement consisted of 6x16 mm bars; the distribution of longitudinal bars is shown in the column cross section in Figure 4. The transverse reinforcement consisted of 8 mm stirrups at a spacing of 0.1 m. The concrete cover was 0.03 m. The geometric and structural properties of the test specimens are summarized in Table 1. Table 2 shows the different axial load ratios and corrosion mass loss ratios for the series of tested column specimens.

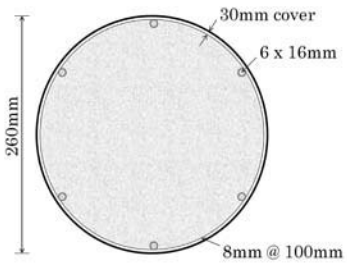

Figure 4 Cross section of the test column specimens (after Li and Gong 2008)

Table 1 Properties of the test column specimens

Height, H	1 m
Diameter, D	0.26 m
Longitudinal Reinforcement Ratio, ρ	2.3%
Longitudinal Rebar Diameter, d_0	16 mm
Transverse Rebar Diameter, d_s	8 mm
Nominal Yield Strength of Steel, f_y	373.2 MPa
Nominal Strength of Concrete, $f_c^{'}$	32.4 MPa

Table 2 Axial load ratios and mass loss ratios for the test specimens (after Li and Gong 2008)

Specimen	A		B		
	A_0	A_{12}	B_0	B_{21}	B_{22}
Mass loss due to corrosion (%)	0.0%	9.4%	0.0%	5.1%	9.4%
Axial Load Ratio	0.15		0.25		

The test columns were subjected to reversed cyclic loading using the triangular waveform shown in Figure 5 and hysteretic and skeleton curves for the columns were obtained. The initial displacement of 2 mm was followed by three full cycles at each subsequent displacement level. Each displacement level was higher than the previous level by 4 mm.

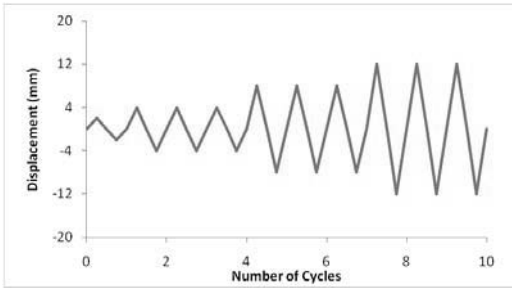

Figure 5 Lateral displacement history (after Li and Gong 2008)

3.2 Analytical Modeling of Test Column

The analytical modeling of the test column was conducted using the Open System for Earthquake Engineering Simulation (OpenSees) software (Mazzoni *et al*. 2009), a finite element method based object oriented software framework for simulating the seismic response of structural systems. The column was modeled as a nonlinear beam-column element, which is a force-based element that considers the spread of plasticity along its length.

The column cross-section was discretized into a number of inelastic fiber segments as shown in Figure 6. The number of elements the cross-section was discretized into was progressively increased starting from a minimal number of elements until a further increase in the number of elements yielded no significant change in the results. This particular discretization was then used for all further analyses.

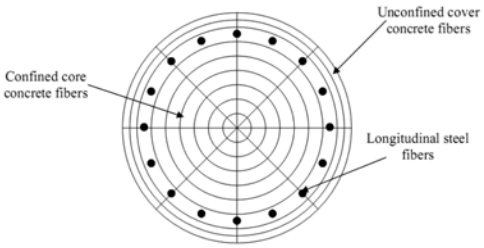

Figure 6 Discretization of cross-section into inelastic fibers

The confined core concrete fibers were modeled using the uniaxial 'Concrete04' material in OpenSees, which uses the Karsan-Jirsa model for unloading and reloading in compression and also provides tensile strength with exponential decay. The unconfined core concrete fibers were modeled using the uniaxial 'Concrete01' material which has no tensile strength. The reinforcement steel was modeled using the uniaxial Giuffre-Menegotto-Pinto 'Steel02' material, which provides isotropic strain hardening.

A zero-length section was introduced at the base of the column to account for the component of the deformation due to bond-slip. The tensile stress-strain model used for the reinforcement was adapted from the modified two-component bond-stress model recommended by Berry and Eberhard (2003).

According to the multi-phase corrosion model described in Equation 8, the diameter of the longitudinal steel bars was reduced as a function of time. While modeling the deterioration due to uniform corrosion, it was assumed that the effects of corrosion are uniform about the perimeter of the column and that all rebars undergo the same reduction in diameter at any given point of time during the service life of the bridge.

For modeling purposes, the reduction in rebar diameter was assumed to be uniform along the height of the column since the formation of cracks due to chloride-induced uniform corrosion is expected to be uniform along the height. Aspects that have not been considered in this study include spalling of the concrete cover, changes in the material properties of steel and concrete due to corrosion and the effect of corrosion on the bond between the rebar steel and concrete. However, as noted by Fang et al. (2004) and Wang and Liu (2004), the effects of corrosion on bonding in well confined concrete are negligible.

3.3 Comparison of analytical and experimental results

The hysteresis curves obtained from the test and the corresponding OpenSees analyses for specimens A_0 and A_{12} are plotted in Figure 7. Similar hysteresis curves were also obtained from the test and the corresponding OpenSees analyses for specimens B_0 and B_{21} and B_{22}, but are not plotted in the figure. Envelope curves are obtained for each of these hysteresis curves by plotting the mean of the absolute values of the three peak forces on either side for each displacement during the revered cyclic load test. The envelope curves obtained from the hysteresis plots are shown in Figure 8.

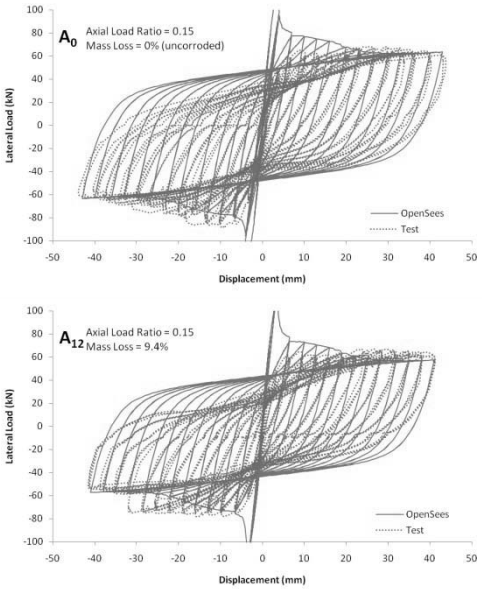

Figure 7 Hysteresis curves from the test (dotted lines) and the OpenSees analysis (solid lines) compared for specimens A_0 (top) and A_{12} (bottom)

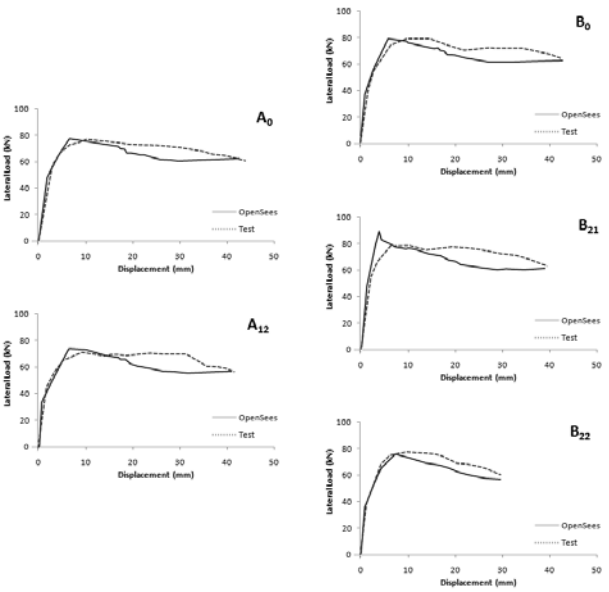

Figure 8 Envelope curves from the test (dashed lines) and the OpenSees analysis (solid lines) compared for the five column specimens

4. DISCUSSION OF RESULTS

Comparing the envelope curves obtained from the test and the analytical model for the uncorroded specimens A_0 and B_0, it can be seen that the nonlinear OpenSees analytical model predicts the envelope or 'backbone' load-displacement response well. Also, the predicted envelope curves for the corroded specimens A_{12}, B_{21} and B_{22} agree well with the test results, indicating that the reinforcing steel deterioration model implemented in OpenSees is able to capture the degradation in the performance of the column due to corrosion sufficiently well at the axial load ratios tested.

Since the objective of the study was to verify that the analytical model can predict the envelope load-displacement response of deteriorating columns, a pinching model was not used to capture the pinching behavior exhibited by reinforced concrete under cyclic loading. This is reflected in the comparison of the hysteresis curves for the test and analytical model. The analytical model under-predicts the energy dissipation during the reversed cyclic loading for all of the specimens. If energy dissipation needs to be predicted, a pinching model such as the 'Pinching4' material in OpenSees could be used.

5. CONCLUSIONS

An improved model for the chloride-induced deterioration of reinforcing steel is presented in this paper that can be used for time-dependent risk assessment of deteriorating structures. The model accounts for the effects of uncracked and cracked concrete covers through the inclusion of pitting corrosion in cracked reinforced concrete. The simplified model used for capturing the deterioration of reinforcement is capable of predicting the envelope load-displacement response of corroded reinforced concrete columns for moderate levels of corrosion, corresponding to less than 10% reinforcement steel mass loss due to corrosion. The improved reinforcing steel deterioration model can thus be used in conjunction with this simplified analytical model to assess the seismic risk of a bridge at various points during its lifetime.

SEISMIC PROPERTIES OF JAPANESE TRADITIONAL WOODEN PAGODAS - STATIC LOADING TEST AND FREE VIBRATION TEST OF A SMALL SCALE MODEL -

Eisuke Nishikawa[1] and Hidekazu Nishizawa[2]

1) Researcher, CUEE, Tokyo Institute of Technology, Japan
2) Professor, Dept. of Architecture, Kansai University, Japan
nishikawa@cuee.titech.ac.jp, sc8h-nszw@asahi-net.or.jp

Abstract: This paper refers to studies on the seismic properties of Japanese traditional wooden pagodas. Because there are few records of collapses of wooden pagodas due to earthquakes available, many researchers have studied this theme, but have done so under the conditions that all pagodas are relatively similar. In reality, pagodas have various scales. In this study, we performed static horizontal loading tests and free vibration tests with a 1/10 model of a three-story pagoda. By changing the weight of the model, we simulated the behavior of pagodas with heights of 18m, 5.4m 1.8m, and examined the effect of the size of the pagoda on its seismic property. The following results have been obtained from these tests. Large pagoda (height: 18m), restoring force is greater and more dissipative than those of small pagodas, and the pagoda bent like a bow, and by an increase in amplitude, the natural frequency tends to be lower, because of the decrease in stiffness. Small pagodas (height: 5.4m, 1.8m), restoring force is smaller than that of the larger one, and these pagodas tilted like a rigid body, and by an increase in amplitude, the natural frequency and damping ratio become small, because of the rocking of the pagoda.

1. INTRODUCTION

1.1 Introduction of Previous Research

This paper refers to studies on the seismic properties of Japanese traditional wooden pagodas. In Japan, many three-story and five-story pagodas have been built, and a great number of these pagodas were built hundreds of years ago. Though in almost all areas of Japan, a big earthquake occurs every hundreds years, there exist few recorded collapses of wooden pagodas due to earthquakes. Therefore, pagodas are believed to have a high seismic performance.

Many researchers have studied this theme, and have often pointed out that the long natural period and high capacity of damping are the keys to the seismic performance of the pagoda.

Microtremor measurements and vibration tests of many pagodas have been performed in the field. According to these tests, the natural frequencies have been observed to range from 0.5～2Hz, the damping factors range from 1～5%, and the natural frequencies are related to the height of the pagoda. But these characteristics relate only to microtremors.

According to tests on a small scaled model, by an increase in amplitude, the natural frequency of vibration and damping ratio become smaller, but the similarity rule between the small model and the full size pagoda is not yet studied. Therefore investigations of the structural characteristics of big amplitude vibrations should be undertaken with consideration of the similarity rule.

1.2 Scope of Model Tests

Pagodas have been built to various scales as shown in Fig.1.1. Depending on the period in which the pagoda was built, the structure varies slightly, but the proportion and the ratio of members are almost the same despite a difference in size. So, from a structural point of view, we can assume that pagodas behave as different-size models with a similar-structure.

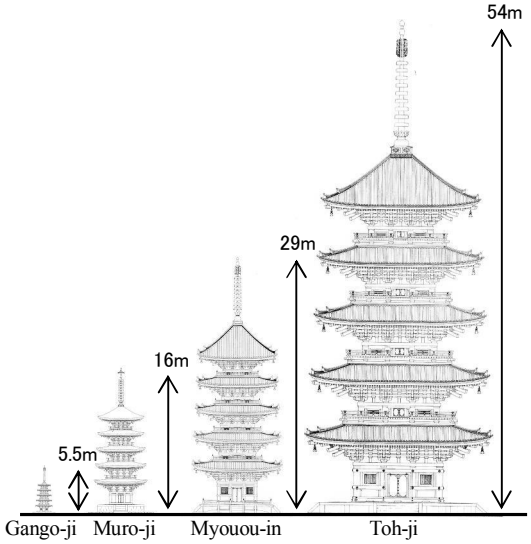

FIGURE 1.1 VARIOUS SCALE PAGODAS

Based on the above, in this study, we performed static horizontal loading tests and free vibration tests with a 1/10 model of a traditional wooden three-story pagoda in order to clarify seismic properties. By changing the weight of the model, we simulated the behavior of three different pagodas with the heights of 18m, 5.4m 1.8m, and we examined the effect of the size of the pagoda on its seismic property.

2. STUDY OF SIMILARITY RULE

2.1 Frame Models of Japanese Traditional Wooden Architectures

As a basic frame of Japanese traditional wooden architectures including the pagoda, we studied the frame models shown in Fig.2.1-① ～ ⑤. Because Japanese traditional wooden buildings are not fixed to their foundation, when they are forced horizontally to some extent, they rock by lifting up the bottom of the frame (Fig.2.1-①) or they slip (Fig.2.1-②). The deformation mechanisms of these frames are as follows:

Frame①: The frame rocks by lifting up its bottom.
Frame②: The frame slips from the foundation.
Frame③: The frame's columns are bent; the joints of the horizontal beam and the columns are rigid.
Frame④: The frame's wooden wall compresses inclined to the column's grain; the joint of the horizontal beam and the columns are pin joints.
Frame⑤: The frame's horizontal beams, which penetrate the columns, compress inclined to the grain of the column's openings.

With the assumption that each of these stress and strain relationships is linear, we studied load deformation relationships of full and small size frames.

2.2 Similarity Ratios of Dimension and Weight

The similarity ratios of dimension and weight of the full and small size frames mentioned above were studied. In this paper, the similarity ratio of dimension is defined by α, that of weight is by β. In Fig.2.1, forces and deformations of the full size frames are expressed by capital letters, and that of the small size frames are expressed by small letters.

2.3 Load Deformation Relationships of Full Size Frames

The load of the full-size frames when the deformation equals X is obtained by Eqs.2.1～2.5. Notations used in the formulas are following.

γ : coefficient of friction
E: Young's modulus of bending deflection
K_s: Young's modulus inclined to the grain

Frame①

$$P_r = \frac{Wg \cdot B_G}{H} \quad \cdots \text{Eq.2.1}$$

Frame②

$$P_s = Wg \cdot \gamma \quad \cdots \text{Eq.2.2}$$

Frame③

$$P_c = \frac{24 \cdot E \cdot I \cdot \delta_c}{H^3}, \quad I = \frac{B^4}{12},$$

$\cdots$Eq.2.10

2.5 Relationship between Similarity Ratios of Dimension and Similarity Ratios of Weight

In order to simulate the structural characteristics of a full-size building composed of the above basic frames, the similarity ratios of load of several frames have to be made the same. According to the above, β has to be made equal to α^2. Table 2.1 shows the similarity ratios of various conditions of a small model in which β is equal to α^2.

TABLE 2.1 SIMILARITY RATIOS OF VARIOUS CONDITIONS

		Full Size	Small Model
Size	m	1	α
Weight	kg	1	α^2
Rotational Inertia	kg.m^2	1	α^4
Load	N	1	α^2
Moment	N.m	1	α^3
Shear Rigidity	N/m	1	α
Rotational Rigidity	N.m/rad	1	α^3
Natural Frequency	Hz	1	$1/\sqrt{\alpha}$
Time	sec.	1	$\sqrt{\alpha}$
Displace	m	1	α
Velocity	m/s	1	$\sqrt{\alpha}$
Accerelation	m/s^2	1	1

2.6 Effect of Similarity Ratio of Weight on Deformation of Small Model of a Pagoda.

Fig.2.2 shows the deformations of the full size pagoda, the small size model in which β is equal to α^2, and the small size model in which β is equal to α^3.

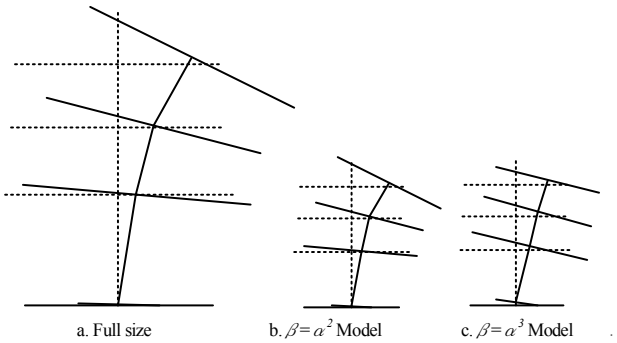

FIGURE 2.2 DEFORMATIONS OF MODELS WITH DIFFERENT WEIGHT

As shown in Fig.2.2, when β is equal to α^2, the deformation of the small size model is similar to that of the full size pagoda. On the other hand, when β is equal to α^3, the small size model rocks by lifting up its bottom more than the full size pagoda.

3. MODEL

3.1 Structure of Model

Fig.3.1 show the 1/10 scale model of the three-story pagoda which was built in Aichi prefecture recently. The model was made like the full size pagoda not only in the proportion but also in detail and was made of Japanese cypress, with height 1.8m. The characteristics of the structure of this model are as follows:

1. The central wooden column (Fig.3.1-A), which is named "shin-bashira", stands on a girder above the first floor, and is independent from surrounding structural frames.
2. The prolonged part of the *shin-bashira* above the roof is covered in bronze ornaments (Fig.3.1-B), which are named "sorin".
3. The frames of each floor are stacked up; the columns (Fig.3.1-C) of the upper floors are erected on the horizontal beams (Fig.3.1-D) which sit on the rafters of the floor below.
4. The columns of the first floor (Fig.3.1-E) are put on base stones (Fig.3.1-F).

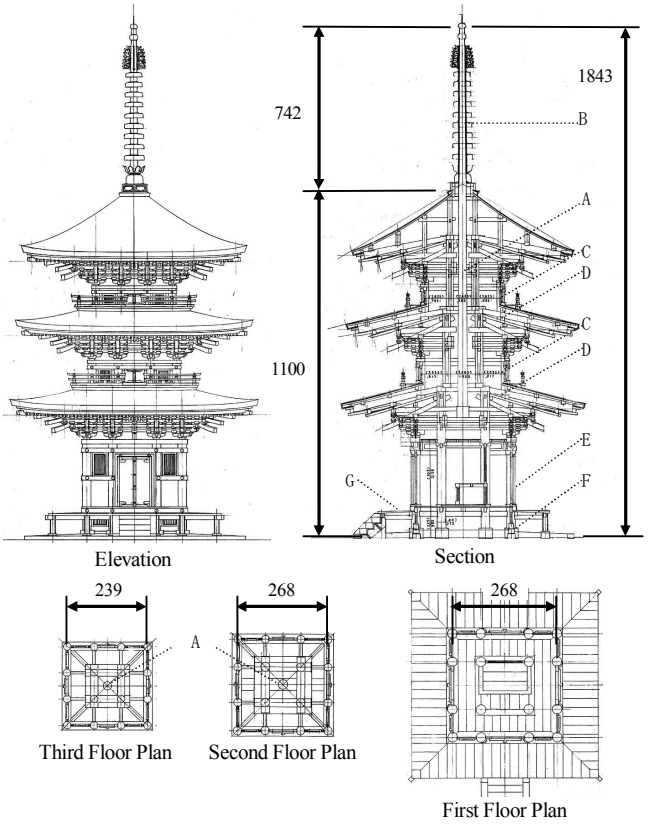

FIGURE 3.1 MODEL OF THREE-STORY PAGODA (unit: mm)

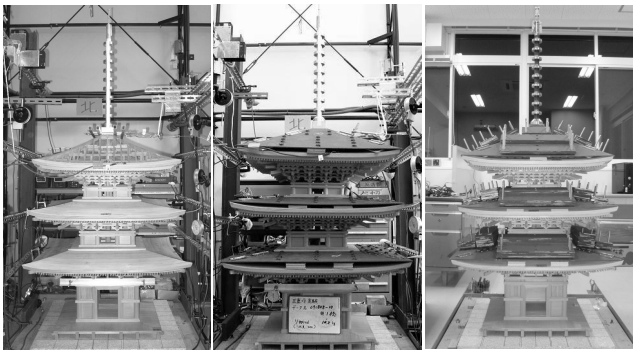
5. The weight of the building and roof covered by thin copper plate of the full size pagoda are 32t and 1.6t respectively. The weight of the roof is 5% of that of the building. So, the former is much smaller than the latter.

3.2 Weight of Model



As shown in Photo.3.1, we performed experiments with the model by adjusting its weight by putting steel plates on the roof of each floor. The patterns of the weight are shown in Tab.3.1, [A]: 30kg, [B]: 83kg, [C]: 319kg.

In order to simulate the weight of the *sorin*, as shown in Fig.3.2, 2 types ([X], [Y]) of *sorin* are modeled on the *sorin* of the full size pagoda, which is composed twelve parts put together. These models are made of aluminum ([X]) and steel ([Y]), their weights being 0.35kg ([X]) and 3.15kg ([Y]). The above Model [A], Model [B] are equipped with [X], Model [C] is equipped with [Y].

3.3 Pagoda Simulation

As mentioned in Chapter 2, β (the similarity ratio of weight) is made to equal α^2 (the similarity size ratio). When α of the 18m high pagoda is 1/10, then β is $1/10^2$. Because the weight of the full size pagoda at 18m is 32t, the weight of the model is equivalent to 320kg. [C] corresponds to the simulation of the 18m pagoda. When α of the 5m pagoda is 1/2.7, the weight of the 5m pagoda is 640kg, so β is $1/2.7^2$, the weight of the model is equivalent to 88kg. [B] corresponds to the simulation of the 5m pagoda approximately. Based on the same way of similitude, [A] corresponds to the simulation of the 1.8m pagoda. The similarity ratios of time γ is $\sqrt{\alpha}$, so γ of each of the patterns are $1/\sqrt{10}$ ([A]), $1/\sqrt{2.7}$ ([B]), 1 ([C]).

Based on the above law of similitude, we can simulate the behavior of pagodas of various sizes by changing the weight of the model in keeping with the similarity rule.

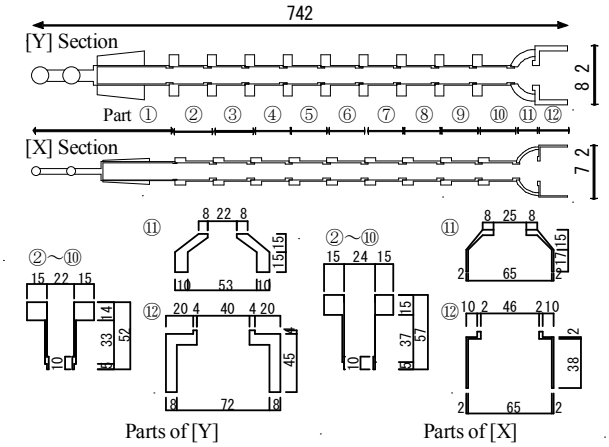

FIGURE 3.2 MODEL OF *SORIN* (unit: mm)

4. HORIZONTAL LOAD TEST

4.1 Test System

Fig.4.1 shows the system of the horizontal loading test. The wires (Fig. 4.1-A) are attached to the base of the *sorin*. The pagoda models were loaded by pulling the wires horizontally with electronic actuators (Fig. 4.1-B) in opposite directions by turns. The targets of the drift angle at the base of the *sorin* are 1/240rad, 1/120rad, 1/90rad, 1/60rad, 1/40rad and, 1/30rad. The loads were measured with load cells (Fig. 4.1-C). The deformations were measured with laser displacement meters (▲) and dial gauges (△).

The horizontal deformations of each floor's eave are noted X1～X4, and the angles of rotation of each floor's eave are obtained by the Eq.4.1.

$$\theta_i = \frac{Y_{i-A} - Y_{i-B}}{l_i} \quad \cdots \text{Eq.4.1}$$

4.2 Comparison of Load Deformation Relationships of Each Model

Fig.4.2 shows the load deformation relationships of each model, and Fig.4.3 shows the +1/30 loops of each model.

The load of Model [A] does not increase when the drift angle is greater than 1/120rad. Similarly, the load of

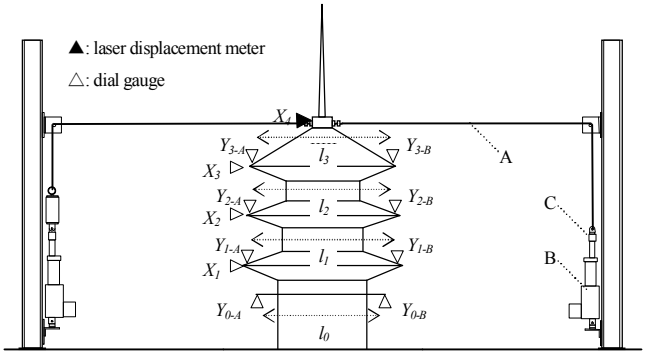

FIGURE 4.1 SYSTEM OF HORIZONTAL LOAD TSET

Model [B] does not increase when the drift angle is bigger than 1/60rad. On the other hand, the load of Model [C] continues to increase until the drift angle equals 1/30rad. The dotted lines in Fig.4.3 are the load deformation of three rigid bodies for comparison. Each body has proportions similar to one of the models. The load deformation of each rigid body is obtained by Eq.4.2.

$$P = W \cdot g \cdot \left(\frac{b}{h_g} - \frac{X_4}{h} \right) \quad \cdots \text{Eq.4.2}$$

P:Load W:Weight

X_4:Displace b:Width of Building(303mm)

h_g:Height of Gravity ([A]:684mm [B]:708mm [C]:684mm)

h:Height of Load Point (1100mm)

In Eq.4.2, the width of the building does not include the width of the first floor veranda, which is called "en" (Fig.3.1-G). The load deformation relationships of Model [A] and [B] are close to that of each rigid body when the deformations are greater than the deformations mentioned above, but the loads of the models exceed slightly those of the rigid bodies. It is thought that the reason for this is that the *en* of each model resists as an outrigger. It is assumed that the load deformation relationships of Model [C] would be close to that of each rigid body when the deformations are bigger than 1/30rad because of rocking by lifting up its bottom.

Table 4.2 shows the restoring force, secant rigidity, absorbed energy, and equivalent damping factor of ±1/30 loop of each model. The highest equivalent damping factor is that of Model [C], the second is that of Model [A] and, the lowest is that of Model [B].

Fig.4.4 shows the relationships between deformation and absorbed energy of each model. The absorbed energy of Model [A] and [B] are smaller than that of Model [C], and slightly increase especially when the deformations are larger than 1/60rad. The absorbed energy of Model [C] largely increases especially when the deformations are larger than 1/240rad.

4.3 Comparison of Deformation of Each Model

Fig.4.5 shows the deformation of each model. In order to clarify the characteristics of deformation, deformations in Fig.4.5 are made 10 times larger than the observed one.

As shown in Fig. 4.5, Models [A] and [B] rock by lifting up their bottom (Photo. 4.1), on the other hand, Model [C] is bent without lifting up its bottom, but the roof of the third floor is lifted up (Photo. 4.2).

5. FREE VIBRATION TEST

5.1 Test System

Fig.5.1 and Photo.5.1 show the system of the free vibration test. The model was loaded by pulling a wire attached to it. The targets of the drift angle at the base of the *sorin* are the same as the horizontal load test. After cutting the wire, free vibration of the model was observed. The vibrations of displacement were measured with 6 laser displacement meters as shown in Fig.5.1 and Photo.5.1-B, C. The frequency of sampling is 200Hz, and the duration of the measurement is 8sec. from an instant before cutting the wire.

A: WHOLE SYSTEM B: LASER DISPLACEMENT C: LASER RECEPTOR

PHOTO. 5.1 SYSTEM OF FREE VIBRATION TEST

5.2 Wave Form

Figs.5.2, 5.3, 5.4, show the observed free vibrations of each drift angle of each model. These figures show the frequencies and damping factors from first to third waves of the third floor and the top of the *sorin* with dotted lines, which are obtained from the peaks of each wave. The waves of the third floor and the top of the *sorin* are assumed to represent the waves of the building and the *shin-bashira*.

Model [C]

As shown in Fig.5.2, the frequencies and phases of the waves of building are different from that of the *shin-bashira*. These differences become smaller with an increase of amplitude, and when the amplitude is small the phases of the *shin-bashira* tend to be later than those of the building.

The damping factors of the first wave of the building in the range of 10～20% are high. But, as shown in Fig. 5.2-A, B, the third wave of the building increases compared to the second one, while, the wave of the *shin-bashira* decreases considerably. In terms of the relationship between the phases of the building and the *shin-bashira*, it is thought that the vibration energy of the *shin-bashira* is transferred to the building by collision after the second wave.

Model [B]

As shown in Fig.5.3, as well as Model [C], when the amplitude is small the phases of the *shin-bashira* tend to be later than that of the building. The damping factors of the first wave of the building which is about 10%, is lower than Model [C]. The wave forms of the *shin-bashira*, in comparison with Model [C], are more similar to a triangle than a sine curve, and these waves are damped considerably

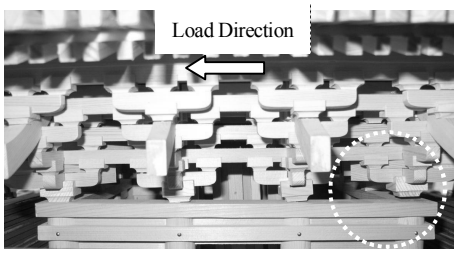

PHOTO 4.2 ROOF OF THIRD FLOOR LIFTED UP (MODEL [C] +1/30)

C: Free Vibration Staring From 1/30rad

FIGURE 5.4 FREE VIBRATION (MODEL [A])

5.3 Relationship between Frequency and Amplitude

Figs.5.5 ～ 5.7 show the relationships between frequency and amplitude of each model obtained from all the experiments.

The frequencies of each of the models are around 2Hz, almost the same when the amplitudes of each model are around 20mm (denoted hereafter as "Big Amp.").

The frequencies of all the models become higher with a decrease in amplitude. The frequencies of each of the models are Model [C]: 2.5Hz, Model [B]: 4Hz, Model [A]: 4.7Hz when the amplitudes of each model are around 3mm (denoted hereafter as "Medium Amp."). The frequencies of all the models become considerably higher with a decrease in amplitude when the amplitude is smaller than the Medium Amplitude. The frequencies of each of the models are Model [C]: 3.8Hz, Model [B]: 5Hz, Model [A]: 7Hz when the amplitudes of each model are around 0.5mm (denoted hereafter as "Small Amp.").

The ratios between the frequencies of the Big Amp. and Small Amp. of each of the models are Model [C]: 1.9, Model [B]: 2.5, Model [A]: 3.5.

The approximate two lines of the relationship between frequency and amplitude of each model, which range from the Small Amp. to the Medium Amp. and from the Medium Amp. to the Big Amp., are noted in Fig.5.5～5.7. As shown in these figures, the increase in ratios of frequency of the range from the Small Amp. to the Medium Amp. of all the models are larger than that of the range from the Medium Amp. to the Big Amp..

The main reason for an increase of frequency by a decrease in amplitude is thought to be a decrease of rigidity of each part of the building in Model [C], and an increase of the rocking angle at the bottom of the building in Models [B] and [A].

5.4 Comparison with Frequency of Small Models and Full Size Buildings

Fig.5.8 shows the relationship between the first natural period and the height of the building obtained by micro tremor measurements from previous research. The 23 pagodas with roofs covered by roof tiles are heavy and are denoted by △, the 12 pagodas with roofs covered by another material and therefore with lighter weight are denoted by ◇. All 35 pagodas are noted in Fig.5.8. The approximate line of the relationship between the first natural period and height, which is noted in Fig.5.8 with the dotted line, is represented in Eq.5.1.

$$T = 0.040H \quad \cdots \text{Eq.5.1}$$

T : 1st Natural Period (sec.)

H : Height (m)

The relationships between the first natural period and height of the 18m pagoda, 5.4m pagoda, and 1.8m pagoda, are obtained from the frequency of Models [A], [B], [C] in the Small Amp. with consideration of the similarity rule, and are denoted in Fig.5.8 by ●. As shown in Fig.5.8, the relationships obtained from the model test are similar to that of the full size buildings.

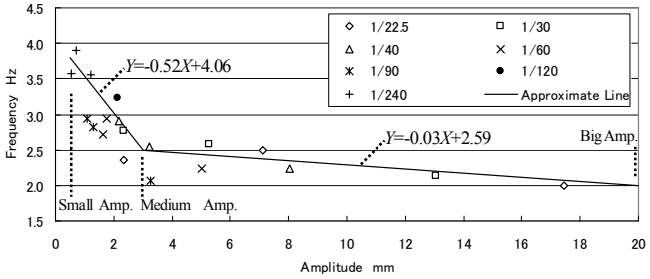

FIGURE 5.5 RELATIONSHIPS BETWEEN FREQUENCY AND AMPLITUDE (MODEL [C])

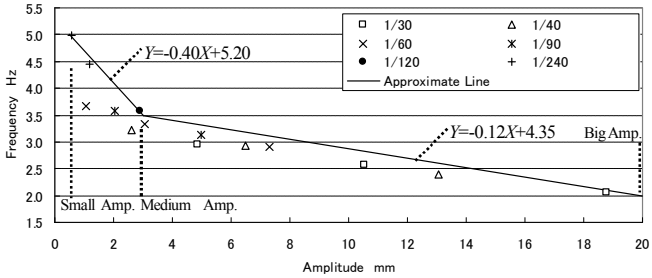

FIGURE 5.6 RELATIONSHIPS BETWEEN FREQUENCY AND AMPLITUDE (MODEL [B])

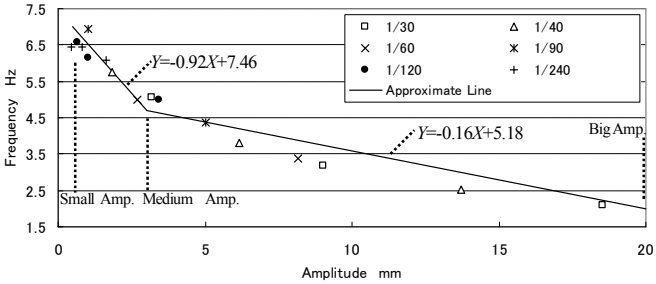

FIGURE 5.7 RELATIONSHIPS BETWEEN FREQUENCY AND AMPLITUDE (MODEL [A])

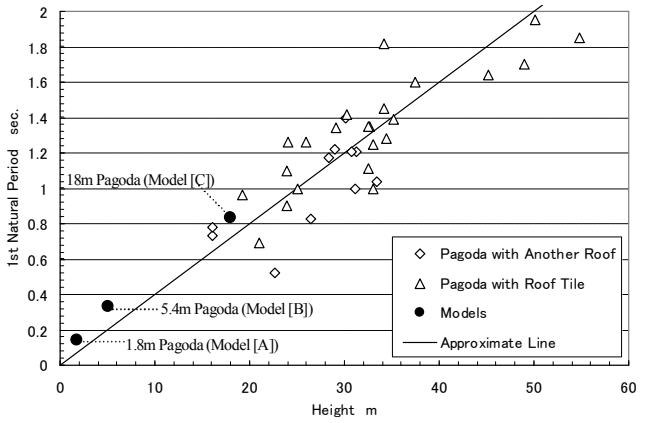

FIGURE 5.8 RELATIONSHIPS BETWEEN 1ST NATURAL PERIOD AND HEIGHT

6. Conclusion

In this study, we performed horizontal load tests and free vibration tests with a 1/10 model of a traditional wooden three-story pagoda. By changing the weight of the model, we simulated the behavior of three different pagodas with heights of 18m, 5.4m and 1.8m. The following results were obtained from these tests:

- When the height of the pagoda is relatively large, the restoring force is greater and more dissipative than that of the smaller one, and the building bends like a bow.
- When the height is small, the restoring force is smaller than that of the above, and the building tilts like a rigid body.
- When the height of the pagoda is relatively large, with an increase of amplitude, frequency of free vibration tends to become smaller, because of a decrease of rigidity.
- When the height is small, with an increase of amplitude, the frequency and damping ratio of free vibration becomes smaller, because of rocking of the building.

Abstract: Light-frame wood construction makes up the majority of the residential building stock in the North America. Wood-frame buildings have performed relatively well under gravity loadings. However, some of the older wood-frame buildings have suffered costly damage and even structural collapse under moderate earthquake events (e.g. 1994 Northridge Earthquake). In light-frame wood buildings, shear walls act as the main lateral load resisting system. This paper presents the key aspects of modeling collapse of wood-frame shear walls under earthquake motions using nonlinear dynamic analysis. In order to predict the wall behavior from small displacement all the wall to the collapse point, a co-rotational formulation and a large displacement theory are utilized in the formulation of the numerical model. The numerical model specifically accounts for (1) bending and axial elongation of the framing members, (2) separation and bearing contact between the framing members, (3) uplift and anchorage effect of the hold-down devices, (4) shear deformation of the sheathing panels, (5) non-linear shear slip response of the sheathing nails, and (6) second order effect due to gravity loads (P-delta). This numerical model has been coded into computer program. Verification of the numerical model was performed using the results of a shake table collapse test on a light-frame wood garage wall. It has been shown that the model can accurately estimate the displacement time history response and the collapse mechanism of the test wall.

1. INTRODUCTION

Light-frame wood construction is the most common form of construction for residential buildings in the North America. The newer light-frame wood buildings, constructed after the implementation of the 1973 *Uniform Building Code*, have performed fairly well under moderate earthquakes. However, past earthquake events, for example, the 1994 Northridge earthquake, have shown that older light-frame wood buildings are prone to costly damage and even structural collapse. The magnitude 6.7 Northridge earthquake, considered to be a moderate intensity event, resulted in more than $20 billion in property damage making it the costliest earthquake disaster in the United States (US) history (USGS 1996). A recent study estimated that one quarter of the existing wood buildings in the San Francisco Bay Area in the Western US would collapse under a magnitude 7.2 earthquake (ATC 2008). However, the exact collapse mechanism of these at-risk wood buildings is not fully understood at this point. This paper presents a state-of-the-art numerical model that is capable of predicting seismic response and collapse mechanism of the main lateral force resisting system in wood buildings, namely the wood shear walls.

2. SHEAR WALL MODEL FORMULATION

A typical engineered wood shear wall consists of four main components: 1) framing members (studs) 2) sheathing panels, 3) fasteners or nails, and 4) anchorage devices (hold-downs or straps). Older wood buildings are commonly built with non-engineered shear walls, i.e. without hold-down devices and thus are prone to structural collapse during earthquakes. Accurate prediction of the deformation responses of wood shear walls requires accurate modeling of the (1) bending and axial elongation of the framing members, (2) separation and bearing contact between the framing members, (3) uplift and anchorage effect of the hold-down devices, (4) shear deformation of the sheathing panels, (5) non-linear shear slip response of the sheathing nails, and (6) second order effect due to gravity loads (P-delta).

A computer program with graphical user interface, M-CASHEW2 (Matlab - Cyclic Analysis of Wood Shear Walls version 2), was developed for collapse analysis of wood shear walls. The M-CASHEW2 program was developed from its predecessor, a Fortran version of the CASHEW program (Folz and Filiatrault 2001). In the

original CASHEW program, the framing members are modeled as pin-ended rigid elements which do not contribute any lateral stiffness and the in-plane wall stiffness is assumed to be provided solely by the panel-to-frame connections (i.e. sheathing nails). In other words, the CASHEW program is based on small deformation theory and only the pure shear deformation is considered. Past shear wall tests (e.g. Johnston et al. 2006) have shown that the end-post uplift and the anchorage condition have a significant influence on the behavior of shear walls. In order to accurately predict the behavior of wood shear walls all the way to the point of collapse, a co-rotational formulation and large deformation theory are utilized in the formulation of M-CASHEW2 program.

2.1 Frame Element

The wood framing members (studs, sill plates and etc.) are modeled with a two-node co-rotational beam element (herein referred as the *frame element*). Each node of the frame element consists of three degrees of freedom (DOFs): two translations and one rotation (Figure 1).

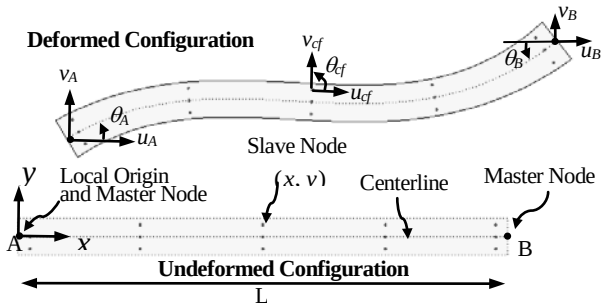

Figure 1: Deformation of a frame element.

The equilibrium of the frame element is given by $\{F_f\}=[K_f]\{D_f\}$ where $\{D_f\}$ is the local element deformation vector and $\{F_f\}$ is the nodal force vector:

$$\{D_f\} = \lfloor u_A \quad v_A \quad \theta_A \quad u_B \quad v_B \quad \theta_B \rfloor^T \tag{1}$$

$$\{F_f\} = \lfloor F_{xA} \quad F_{yA} \quad M_A \quad F_{xB} \quad F_{yB} \quad M_B \rfloor^T \tag{2}$$

The stiffness matrix of the co-rotational beam element, K_f, can be expressed in terms of the summation of the material stiffness matrix, K_e, geometric stiffness matrix, K_g, and initial displacement stiffness matrix, K_d:

$$[K_f] = [K_e] + [K_g] + [K_d] \tag{3}$$

K_e is the well-known elastic stiffness matrix formulated based on the undeformed configuration:

$$K_e = \frac{EI}{L^3}\begin{bmatrix} \frac{AL^2}{I} & 0 & 0 & -\frac{AL^2}{I} & 0 & 0 \\ 0 & 12 & 6L & 0 & -12 & 6L \\ 0 & 6L & 4L^2 & 0 & -6L & 2L^2 \\ -\frac{AL^2}{I} & 0 & 0 & \frac{AL^2}{I} & 0 & 0 \\ 0 & -12 & -6L & 0 & 12 & -6L \\ 0 & 6L & 2L^2 & 0 & -6L & 4L^2 \end{bmatrix} \tag{4}$$

where E, A and I are the elastic modulus, cross-sectional area and moment of inertia, respectively. K_g is the geometric stiffness matrix which accounts for the geometric nonlinearity in the deformed configuration:

$$K_g = \begin{bmatrix} \frac{F_{xB}}{L} & -a_1 & -\frac{M_A}{L} & -\frac{F_{xB}}{L} & a_1 & -\frac{M_B}{L} \\ -a_1 & 2a_2 & a_2 & a_1 & -2a_2 & a_2 \\ -\frac{M_A}{L} & a_2 & a_3 & \frac{M_A}{L} & -a_2 & a_4 \\ -\frac{F_{xB}}{L} & a_1 & -\frac{M_A}{L} & \frac{F_{xB}}{L} & -a_1 & \frac{M_B}{L} \\ a_1 & -2a_2 & -a_2 & -a_1 & 2a_2 & -a_2 \\ -\frac{M_B}{L} & a_2 & a_4 & \frac{M_B}{L} & -a_2 & a_3 \end{bmatrix}$$

$$a_1 = \frac{M_A + M_B}{L^2} \quad , \quad a_2 = \frac{F_{xB}}{10} + \frac{6F_{xB}I}{AL^2} \tag{5}$$

$$a_4 = -\frac{F_{xB}}{30} + \frac{2F_{xB}I}{AL} \quad , \quad a_3 = \frac{2F_{xB}}{15} + \frac{4F_{xB}I}{AL}$$

It should be noted that although the geometric stiffness K_g is formulated based on the deformed configuration, it does not account for the deformed curvature caused by rotations at nodes A and B. Past research have showed that ignoring the deformed curvatures will significantly reduce the accuracy of the analysis when the deformations are large (Zhang and Tong 2008). In this study, the initial displacement matrix, K_d, derived by Zhang and Tong (2008) is employed to account for the effects of the deformed curvature:

$$K_d = \frac{2EI}{L^3}\begin{bmatrix} 0 & 3a_{11} & La_{21} & 0 & -3a_{11} & La_{12} \\ 3a_{11} & 0 & 0 & -3a_{11} & 0 & 0 \\ La_{21} & 0 & 0 & -La_{21} & 0 & 0 \\ 0 & -3a_{11} & -La_{21} & 0 & 3a_{11} & -La_{21} \\ -3a_{11} & 0 & 0 & 3a_{11} & 0 & 0 \\ La_{21} & 0 & 0 & -La_{21} & 0 & 0 \end{bmatrix} + \cdots$$

$$-\frac{EA}{30L}\begin{bmatrix} 0 & 3a_{11} & La_{41} & 0 & -3a_{11} & La_{14} \\ 3a_{11} & 0 & 0 & -3a_{11} & 0 & 0 \\ La_{41} & 0 & 0 & -La_{41} & 0 & 0 \\ 0 & -3a_{11} & -La_{41} & 0 & 3a_{11} & -La_{14} \\ -3a_{11} & 0 & 0 & 3a_{11} & 0 & 0 \\ La_{14} & 0 & 0 & -La_{14} & 0 & 0 \end{bmatrix} \tag{6}$$

$$a_{11} = \theta_A + \theta_B \quad , a_{21} = 2\theta_A + \theta_B \quad , a_{12} = \theta_A + 2\theta_B$$
$$a_{41} = 4\theta_A - \theta_B \quad , a_{14} = 4\theta_B - \theta_A$$

The presented frame element model with co-rotational formulation is suited for nonlinear collapse analysis of shear walls under large deformations.

2.2 Frame Element Shape Functions

The wood shear wall models developed in previous

research (e.g., Folz and Filiatrault 2001, Pei and van de Lindt 2008) utilize centerline modeling approach which ignores the width of the framing members. While the centerline modeling approach is reasonable for most applications, it may not provide accurate estimates of shear wall behavior under large deformations. In M-CASHEW2, a novel geometric model which explicitly considers the actual dimensions of the framing members is employed (Figure 2). Unlike the centerline modeling approach, the geometric model does not allow two frame members to occupy the same space. This modeling capability allows the use of contact element to explicitly model the bearing contact and separation of the framing members as observed in the actual shear wall tests. The contact model will be discussed in a later section.

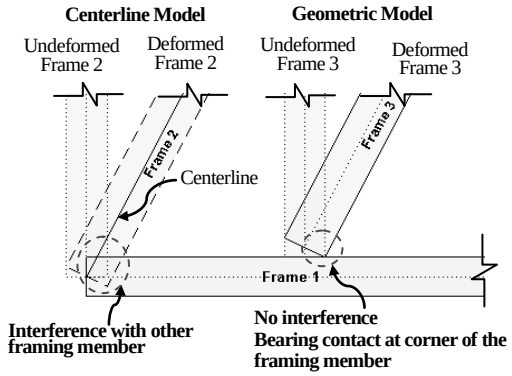

Figure 2: Illustration of centerline and geometric models.

The geometric model is derived using a set of shape functions. Consider the local deformations of a generic point, *slave node*, on a frame with initial local frame coordinates (*x*,*y*) as shown in *Figure 1*. The deformations of the slave node can be expressed in terms of the deformations of the *master nodes* A and B:

$$\{D_{cf}\} = \lfloor N_f \rfloor \{D_f\} \tag{7}$$

where, $D_{cf} = \lfloor u_{cf},\ v_{cf},\ \theta_{cf} \rfloor^T$ is the displacement vector of the slave node on the frame and N_f is the interpolation matrix (i.e. shape functions expressed in a matrix format). Using consistent deformation method, the interpolation matrix considering the width effect is derived and is given in equation (8):

$$N_f = \begin{bmatrix} N_{11}(x) & -N_{32}(x)y & -N_{33}(x)y & N_{14}(x) & -N_{35}(x)y & -N_{36}(x)y \\ 0 & N_{22}(x) & N_{23}(x) & 0 & N_{25}(x) & N_{26}(x) \\ 0 & N_{32}(x) & N_{33}(x) & 0 & N_{35}(x) & N_{36}(x) \end{bmatrix} \tag{8}$$

$$N_{11}(x) = 1 - r \qquad N_{14}(x) = r$$
$$N_{22}(x) = 2r^3 - 3r^2 + 1 \qquad N_{25}(x) = 3r^2 - 2r^3$$
$$N_{23}(x) = (r^2 - 2r + 1)x \qquad N_{26}(x) = (r^2 - r)x$$
$$N_{32}(x) = (r^2 - r)\,6/L \qquad N_{35}(x) = (r - r^2)\,6/L$$
$$N_{33}(x) = 3r^2 - 4r + 1 \qquad N_{36}(x) = 3r^2 - 2r$$

where, $r = x/L$. The use of interpolation matrix allows one to condense the nail DOFs (slave nodes) into just six DOFs (master nodes) regardless of the nail spacing or the total number of nails on a frame thus achieving high computation efficiency.

2.2 Panel Element

The sheathing of shear walls is modeled with a five degrees-of-freedom (DOFs) co-rotational rectangular *panel element*: one rigid body rotation, θ_p, two rigid body translations, u_p and v_p, and two in-plane shear deformations, μ_p and γ_p (*Figure 3*).

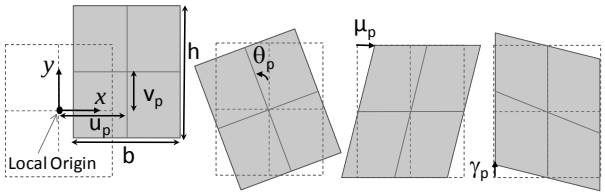

Figure 3: Five DOFs panel elements.

The equilibrium of the panel element is given by $\{F_p\}=[K_p]\{D_p\}$, where$\{D_p\}$ is the local panel deformation vector, $\{F_p\}$ is the local force vector, and K_p, is the stiffness matrix of the panel element:

$$\{D_p\} = \lfloor u_p \quad v_p \quad \mu_p \quad \gamma_p \quad \theta_p \rfloor^T \tag{9}$$

$$\{F_p\} = \lfloor F_{xp} \quad F_{yp} \quad V_{xp} \quad V_{yp} \quad M_p \rfloor^T \tag{10}$$

$$K_p = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \dfrac{2Gbt}{h} & 0 & 0 \\ 0 & 0 & 0 & \dfrac{2Ght}{b} & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \tag{11}$$

G, *b* and *h* are the shear modulus, width and height of the sheathing panel, respectively.

2.3 Panel Element Shape Functions

Similarly, the deformations of a generic connection point (slave node) on the panel can be determined using an interpolation matrix:

$$\{D_{cp}\} = \lfloor N_p \rfloor \{D_p\} \tag{12}$$

where, $D_{cp} = \lfloor u_{cp},\ v_{cp},\ \theta_{cp} \rfloor^T$ is the deformation vector of the connection point on the panel and $\lfloor N_p \rfloor$ is the interpolation matrix (a set of shape functions):

$$N_p = \begin{bmatrix} 1 & 0 & \dfrac{2y}{h} & 0 & -y \\ 0 & 1 & 0 & \dfrac{-2x}{b} & x \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \tag{13}$$

2.4 Connection Elements

Three types of connection elements are employed to model the partial composite action between the shear wall components (i.e. framing members and sheathing panels): panel-to-frame (P2F), frame-to-frame (F2F), and panel-to-panel (P2P) connections (*Figure 4*). The P2F connectors are used for modeling the behavior of the

sheathing nails while the F2F connectors are utilized for modeling the behavior of the framing nails, anchor bolts, hold-down devices, and bearing contact between the framing members. The P2P connectors serve three purposes: (1) to model the bearing contact between the panels, (2) to model the contact between the panel and ground, and (3) to model non-rectangular sheathing panels by connecting multiple rectangular panels together using rigid P2P connections.

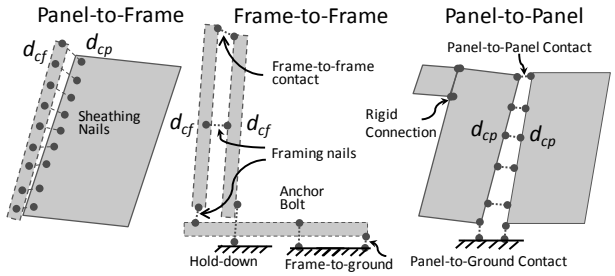

Figure 4: Connection elements.

Each P2F, F2F or P2P connection element is represented by a two-node zero-length element with three uncoupled springs: one rotational and two translational springs (*Figure 5*). Each spring can be assigned with the properties of one of the seven spring models currently available in the M-CASHEW2 program: 1) linear spring, 2) bilinear hysteretic spring, 3) modified Stewart (MSTEW) hysteretic spring (Folz and Filiatrault 2001), 4) evolutionary parameter hysteretic (EPHM) spring (Pang et al. 2007), 5) bearing contact spring, 6) nonlinear hold-down spring (HD1), and 7) nail withdrawal spring (HD2).

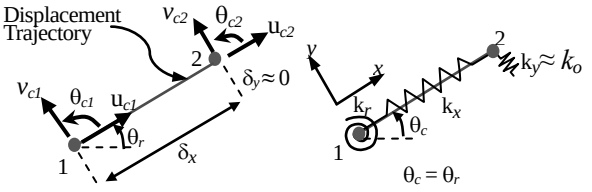

Figure 6: Oriented connection model.

The stiffness matrix of the connector in local coordinate system is:

$$k_c = \begin{bmatrix} k_x & 0 & 0 \\ 0 & k_y & 0 \\ 0 & 0 & k_r \end{bmatrix} \tag{14}$$

where, k_x and k_y are the stiffness of the translational springs, and k_r is the stiffness of the rotational spring.

2.5 Oriented Sheathing Nail Model

The two-node panel-to-frame (P2F) connection is used to model the sheathing nails of wood shear walls. In *Figure 5*, node 1 represents the location of the nail head in the panel and node 2 represents the location of the nail shank in the frame. The rotational spring of a P2F connection is assigned with zero stiffness and the translational springs are assigned with either the MSTEW or EPHM spring. Previous research have shown that the non-oriented P2F spring model tends to overestimate the stiffness and strength of shear walls under reversed cyclic loading (Judd, and Fonseca 2005). Therefore, in M-CASHEW2, an oriented connection model is utilized to model the sheathing nails. The stiffness matrix of the oriented P2F connector in global coordinate system, K_c, is:

$$[K_c] = [R][k_c][R]^T \tag{15}$$

where, R is the transformation (rotation) matrix:

$$R = \begin{bmatrix} \cos\theta_c & -\sin\theta_c & 0 \\ \sin\theta_c & \cos\theta_c & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{16}$$

$\theta_c = \text{atan}(\delta_y/\delta_x)$ is the angle measured from the global x-axis to the displacement trajectory (*Figure 5*). Since the orientation of the connection element, θ_c, is updated after each time step (or increment), the y-spring of the connection does not contribute to the wall stiffness. The y-spring is only for maintaining stability in the transverse direction of the displacement trajectory.

2.6 Contact Spring Model

For modeling the contact (bearing) and separation (gap) phenomena between the shear wall components, a nonlinear hysteretic contact spring element is introduced. This contact element is used to model the interface (1) between the frames, (2) between the sheathing panels, (3) between the frames and foundation, and (4) between the panels and foundation. Figure 6 depicts the force-displacement response of a contact element and its mathematical representation is given in equation(17).

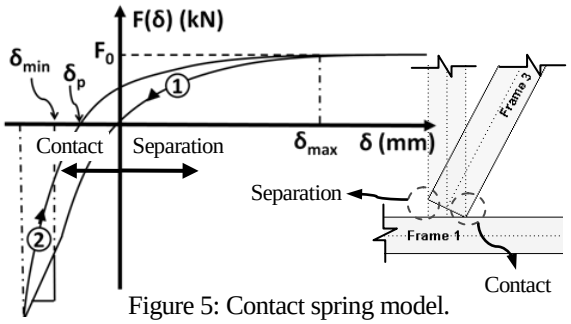

Figure 5: Contact spring model.

$$F(\delta) = \begin{cases} F_o(1-e^{-\frac{\delta_{min}}{\delta_u}}) + k_o e^{-\frac{\delta_{min}}{\delta_u}}(\delta - \delta_p - \delta_{min}) & \delta - \delta_p \le \delta_{min} \\ F_o(1-e^{-\frac{\delta+\delta_p}{\delta_u}}) & \delta_{min} < \delta - \delta_p < \delta_{max} \\ F_o(1-e^{-\frac{\delta_{max}}{\delta_u}}) + k_o e^{-\frac{\delta_{max}}{\delta_u}}(\delta - \delta_p - \delta_{max}) & \delta - \delta_p \ge \delta_{max} \end{cases} \tag{17}$$

The modeling parameters are:

F_o = asymptotic separation force
δ_u = tolerance for contact displacement
δ_{min} = minimum compression displacement
δ_{max} = maximum separation displacement
r_c = permanent bearing deformation ratio

where, $K_o = F_o/\delta_u$ is the initial stiffness and $\delta_p = \min(r_c\delta)$ is a

hysteretic parameter which tracks the permanent bearing deformation (Figure 6). The contact element is formulated such that when gap or separation occurs, the force and stiffness of the element is small enough to be considered zero. In contrary, when contact occurs, the element will respond with a high tangent stiffness to simulate the high reaction force of bearing contact.

2.7 Hold-down Model

A specialized nonlinear hysteretic hold-down spring was developed to model the anchorage effects of hold-down devices (Figure 7). The hold-down spring simulates the uplift force in the hold-down device and uplift deformation of the end studs. This hysteretic model consists of ten parameters:

K_o= initial stiffness,
F_o=asymptotic ultimate tensile force,
F_i = maximum compression force,
δ_u = uplift at maximum tensile force,
r_1 = asymptotic ascending backbone stiffness ratio,
r_d= descending backbone stiffness ratio,
r_u = unloading stiffness ratio,
r_ℓ= reloading stiffness ratio,
r_r = reloading uplift ratio,
r_i= stiffness ratio of line with F_i intercept, $r_i k_o \delta + F_i$

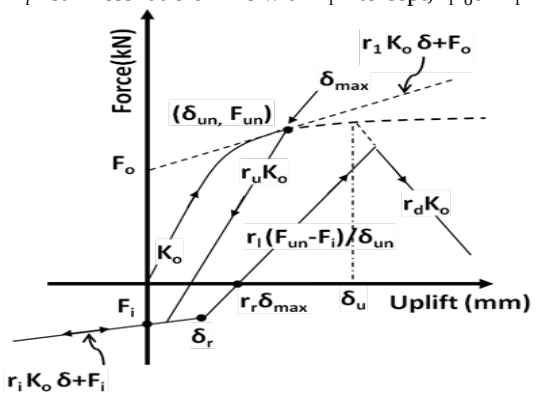

Figure 7: Nonlinear hold-down spring model.

2.8 Nail Withdrawal Model

End nails are commonly used for fastening two framing members together at a 90 degree angle. The end nail connection is an inherently weak connection in withdrawal because the load is applied parallel to the length of the nail. However, it has a good shear resistance under transverse loads. *Figure 8* shows a schematic sketch of an end nail connection modeled using a pair of orthogonal and an translational springs. The withdrawal spring with stiffness k_x in local coordinate is oriented parallel to the length direction of the framing nail (x-spring) and the nonlinear MSTEW or EPHM spring is used to model the shear behavior of the end nail (y-spring). The contact springs are shown at the corners of the stud and are used for modeling the separation and contact between the framing members.

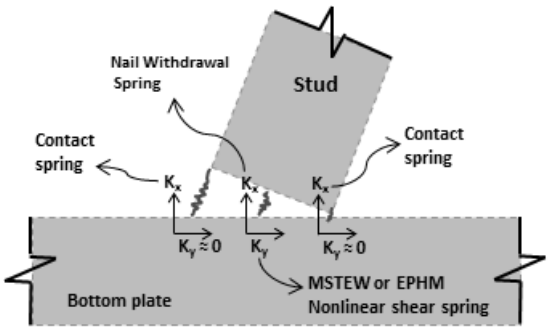

Figure 8: End nail connection model.

3. SHAKE TABLE WALL TEST

The test specimen used to verify the numerical model was a light-frame wood garage wall with a length of 4.52 m, a height of 2.43 m, and an opening width of 3.3 m. Figure 9 shows a sketch of the garage wall. All studs were 2x6 Hem-Fir and sheathing was 12 mm (15/32 inch) thick Oriented Strand Board (OSB). The framing members were assembled using 16d common nails and sheathing nails were 8d common gun-driven nails spaced at 152 mm (6 in.) on the sheathing panel edges and 304 mm (12 in.) on the interior. Two nominally identical specimens were tested simultaneously. The two walls were spaced approximately 2.2 m apart to provide stability and limit accidental torsion since the shake table was uni-axial. Each wall had a tributary seismic weight of 18.2 KN (4.1 kips) at top of the wall. Figure 10 shows the test setup and seismic weight at top of the walls. For safety purpose, the seismic weight was connected to the test setup frames by a set of straps.

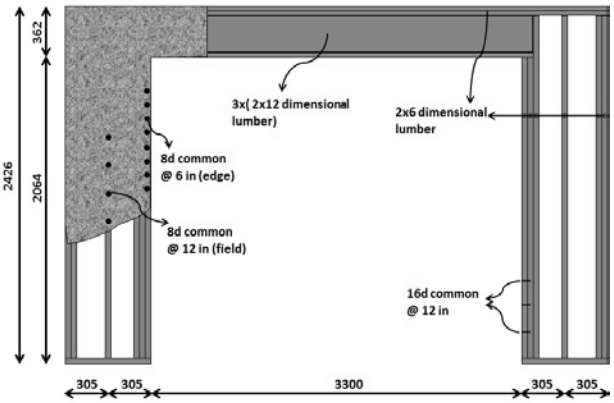

Figure 9: Tested garage shear wall.

Figure 8: Test setup and seismic weight at top

Two historical ground motions that known to collapse wood structures when they occurred were chosen and used during shake table testing of the garage walls. The first ground motion was 100% 1995 Kobe earthquake measured at Akashi station (Test 1), and the second was 85% of the Rinaldi record from the 1994 Northridge earthquake (Test 2). The slight reduction in the seismic intensity to 85% for the Rinaldi record was necessary due to the shake table stroke length limit of 0.5 m. The test started with the Kobe-Akashi ground motion record and this record shook the garage walls to near collapse. At the end of the Kobe-Akashi test, significant damage was observed at the top corners of the garage walls (Figure 11) and sheathing nails were beginning to pull out. With a residual of 0.7%, the walls were still able to support the gravity load. However, they were severely damage and at the verge of incipient collapse.

After the Kobe-Akashi test, the walls were subjected to 85% of Northridge-Rinaldi record. Since the walls were already severely damaged after the first test, collapse occurred almost immediately following the first significant displacement pulse. The failure mechanisms of the specimen were a combined effect of sheathing nail withdrawal, framing nail withdrawal, and damage to sheathing panel near the opening corners.

Figure 11: Damage at the top corner of the garage wall.

4. MODEL VERIFICATION

The M-CASHEW2 was used to model the test wall. Since the test consisted of two nominally identical garage walls, only one wall was modeled numerically. The model consisted of eighteen 6-DOF frame elements and five 5-DOF shear panel elements, resulted in a total of 133 DOFs.

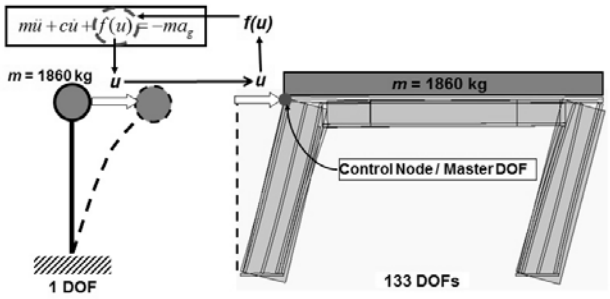

Figure 12: Sub-structuring approach for nonlinear dynamic time history analysis.

A sub-structuring approach was employed in nonlinear dynamic time history analysis to condense the 133 DOFs of the detailed wall model into one master DOF, horizontal displacement at the top of the wall, which can be used to adequately describe the global behavior of the shear wall (Figure 12). Equilibrium in the equation of motion is maintained only for the master DOF. The recorded table accelerations were used as the input ground motion for the dynamic time history analysis.

The 8d common sheathing nails were modeled using the Evolutionary Parameter Hysteretic Model (EPHM) (Pang et al. 2009) (Figure 13) while the Modified Stewart Hysteretic Model (MSTEW) (Folz and Filiatrault 2001) was utilized to describe the shear slip response of the 16d common framing nails. (Figure 14)

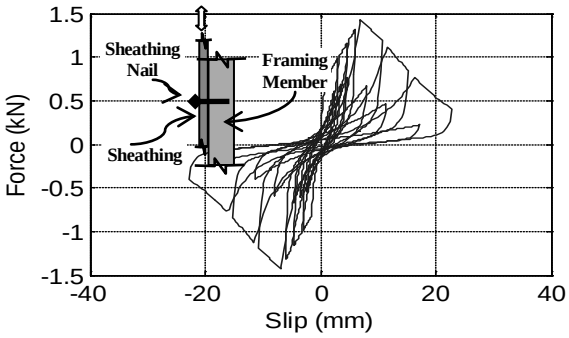

Figure 9: 8d common nails sheathing to framing

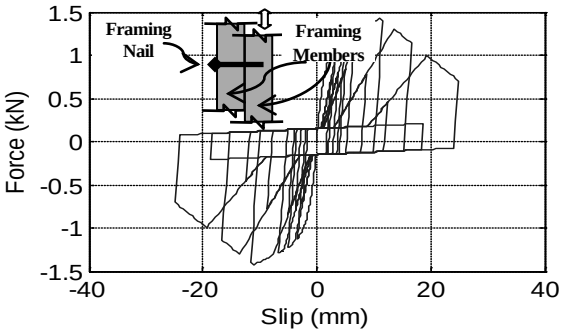

Figure 10: 10d common nails framing to framing.

Two hysteretic elements, a nonlinear hold-down spring (designated as HD1) and a contact element, were utilized to characterize the behavior of each hold-down connection. The HD1 spring was used for describing the uplift response of the hold-down and the contact element was used for modeling the bearing deformation between the end post and the sill plate (Figure 15).

Similarly, the same modeling technique was also employed to model the bearing contact and withdrawal responses of the end nail connections (Figure 16).

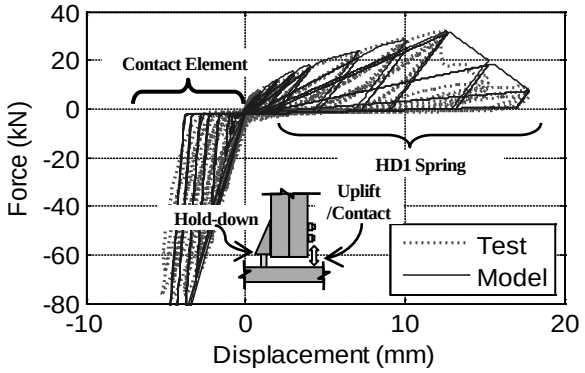

Figure 17: Hysteretic model for hold-down uplift.

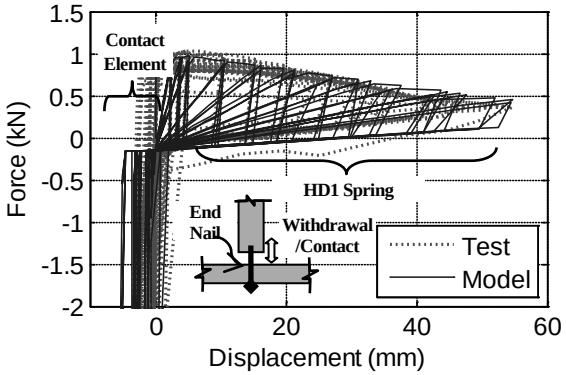

Figure 16: Hysteretic model withdrawal nail.

Bilinear spring elements are utilized to connect two pieces of rectangular panels together (Figure 17). This modeling feature allows the numerical model to capture the moment failure observed at the corner of the sheathing panels of the test walls (Figure 11). Figure 17 shows the model predicted deformed shape at the corner of the garage wall at the end of the dynamic time history analysis. As can be seen, the model was able to reproduce the failure mechanisms observed in the shake table test (i.e. moment failure of the sheathing panels and separation of the framing members).

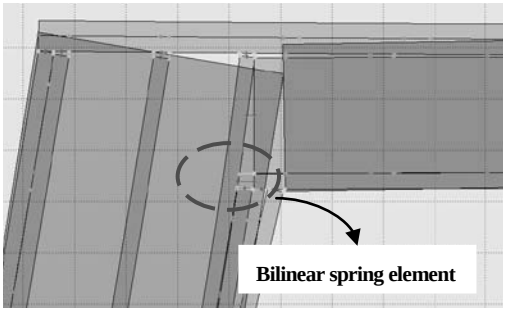

Figure 14: Corner of garage wall (Deformed shape).

5. COMPARISON OF TEST AND MODEL RESULTS

5.2 Hysteresis loops

Figure 18 presents the shake table test and M-CASHEW2 hysteresis loops. The displacements and restoring forces of the model were obtained directly from the M-CASHEW2 program. The forces of the test hysteresis were computed by multiplying the roof accelerations by the tributary seismic weight for one wall. Note that these forces include the restoring forces due to wall deformation in addition to the inherent damping forces. As can be seen, the model is able to reproduce the overall response of the test hysteresis. Clearly it does not reproduce the exact hysteresis, but the overall hysteretic envelopes appear to be well overlaid.

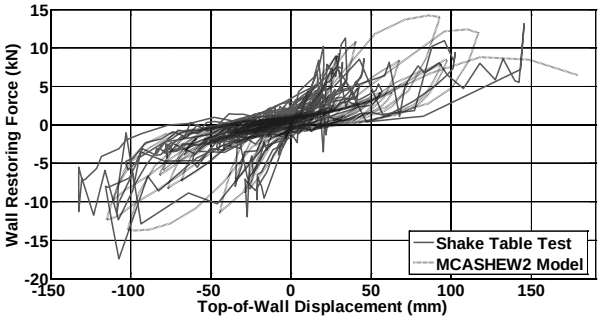

Figure 15: Test and M-CASHEW2 hysteresis loops.

5.1 Displacement Time Histories

Figure 19 shows the inter-story displacement response of the first test with the Kobe-Akashi ground motion. The test displacement time history (Figure 14) shows a residual deformation of about 17 mm (0.7 inches) at the end of the first test. The model predicted peak displacement was 117 mm (4.6 inches), which is close to the test peak displacement 132 mm (5.2 inches) corresponds to 5.5% inter-story drift.

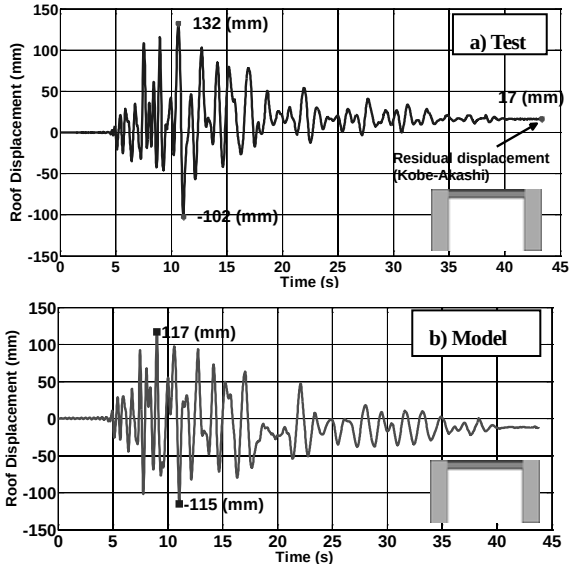

Figure 13: Displacement time histories for test 1 (100% Kobe Akashi) and Model (M-CASHEW2).

5.3 End Post Uplift Time Series

Although hold-downs were installed in the garage walls, significant rocking of wall piers was observed during

the test. Figures 20-23 show the time series of the test and model predicted end post uplifts. The peak test and model uplift responses are identified by square and diamond markers, respectively.

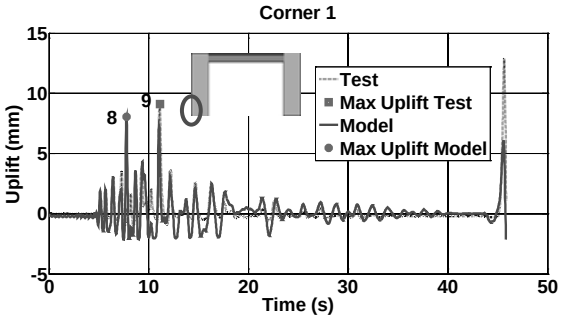

Figure 18: Comparison of test and model uplift

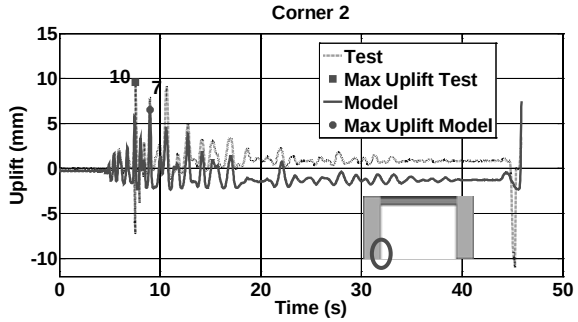

Figure 21: Comparison of test and model uplift

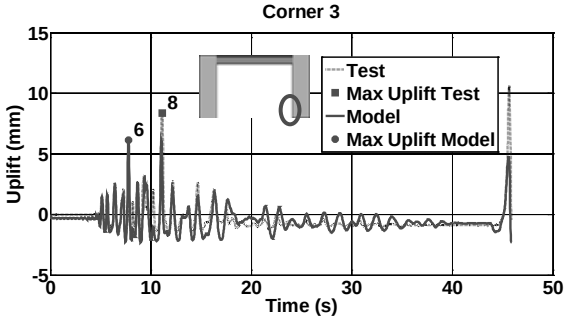

Figure 22: Comparison of test and model uplift

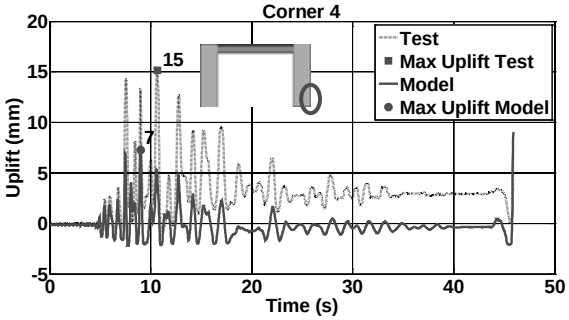

Figure 23 Comparison of test and model uplift

In general, the model was able to reproduce the overall uplift responses of the end posts, especially at corners 1 and 3 with approximately 10 to 20% errors. However, at corner 4, noticeable difference between the test and model predicted uplifts can be seen. The model under predicted the peak uplift at corner 4 by about 50%. This could be attributed to the inherent variability in the uplift resistance or stiffness of the hold-down devices. The model assumed all four hold-downs were identical with the same stiffness and strength. However, examining the uplift time series responses seems to suggest that hold-down at corner 4 was weaker than the other three hold-downs. The test recorded uplift response indicates that there was a gap or slack in hold-down number 4.

6. CONCLUSIONS

The formulation of a detailed mechanistic wood shear wall model which accounts for the non-linear shear slip response of the sheathing nails, bending and axial elongation of the framing members, separation and bearing contact between the framing members, uplift and anchorage effect of the hold-down devices, shear deformation of the sheathing panels, and second order effect due to gravity loads (P-delta) has been developed and coded into a computer program (M-CASHEW2). To verify the numerical model, the M-CASHEW2 program was used to analyze the results of a shake table collapse test of a light-frame wood garage wall. The model predicted peak displacements for Test 1 are within ±15% of the measured values; underpredicting the positive displacement by 11% and overpredicting the negative displacement by 13% and the peak end post uplifts to within +/- 15% (expect for one hold-down). Additionally, it has been shown that the detailed wall model created using M-CASHEW2 is able to predict the failure sequence and mechanism of the wall components all the way to the point of collapse.

According to the analytical and experimental results, the collapse inter-story drift limit for this type of garage walls is more than 6%. The failure mechanisms of the test walls were a combined effect of sheathing nail withdrawal, framing nail withdrawal, and damage to sheathing panel near the opening corners. These governing failure mechanisms observed during the shake table test were also captured by the computer program. Finally, it was observed that variability in the hold-down stiffness has a significant influence on the prediction of the end post uplifts. In order to accurately capture the variability of the shear wall responses, the inherent variability of wood shear wall framing components (frames, panels, nails and etc) should be included in the numerical model. This will be investigated in future studies.

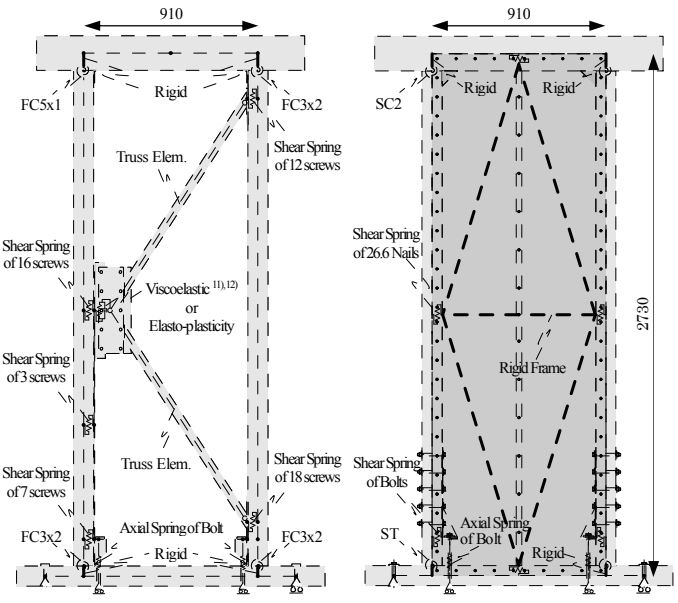
Abstract: This paper proposes an accurate, member-by-member analytical model for timber structures having energy dissipation walls and/or plywood shear walls. Various member joints are modeled by using nonlinear spring elements whose properties derived from numerous test results, and model's schemes are described in detail. The analyses were found to reproduce both local and global responses obtained from cyclic loading tests and shaking table tests of a variety of one-story mult-span timber frames. Moreover, difference between single wall and linked walls, difference of seismic response by variation of damper and nail volume are discussed.

1. INTRODUCTION

It is said that approximately 10 million wooden houses are insufficient for earthquake resistant in Japan, and those houses need to be reinforced immediately. Moreover, to design new wooden houses to be resistant to earthquakes, it is important to investigate rational methods applying the passive control scheme to wooden houses. In order to mitigate the earthquake response and damage of wooden houses, an energy dissipation wall was developed (Kasai and Sakata et al. 2005, Appendix 1) and a lot of experimental studies using the wall were carried out, such as dynamic cyclic loading tests of the energy dissipation walls (Matsuda et al. 2008), shaking table tests of 1-story and 2-story wooden frames (Sakata et al. 2007 and Matsuda et al. 2007), and so on.



However, analytical studies need to be carried out to develop more effective energy dissipation wall and to propose the design method. In particular, a framed analysis is effective to study their local behavior. Therefore the objective of this study is to propose an accurate, member-by-member analytical model for timber structures having energy dissipation walls and/or plywood shear walls.

To make the model, modeling the joint is important extremely. In this study, various member joints are modeled by using nonlinear spring elements whose properties derived from numerous test results, and model's schemes are described in detail. Also the accuracy of the framed analytical model is confirmed by the comparison between the analytical results and many test results. In addition, the difference of seismic response by variation of damper and nail volume are discussed.

2. ANALYTICAL FRAME MODEL

2.1 Outline of Analytical Frame Model

Fig. 1(a) illustrates frame model of the energy dissipation wall and the plywood shear wall. Basically linear beam elements which have same condition to the test members, are arranged in the center of the members. The column and horizontal member are connected by the joint elements which consist of three springs: axial spring, shear

(a) Energy Dissipation Wall (b) Plywood Shear Wall

Fig. 1 Detail of Frame Model

spring and rotational spring (see Fig. 2). The area between the beam edge and the column edge is assumed rigid and the steel pipe brace is set for truss elements. There are reaction springs under the sill (see Fig. 3). Viscoelastic element which was proposed by Kasai et al. (2001, 2002), or elasto-plasticity element are arranged at the point between the intersection of the braces and the steel plate. Basically following equations are used in viscoelastic element.

$$\tau(t) + aD^{\alpha}\tau(t) = G\,[\gamma(t) + bD^{\alpha}\gamma(t)] \qquad (1)$$

$$a = a_{ref}\lambda^{\alpha} \quad , \quad b = b_{ref}\lambda^{\alpha} \qquad (2a,b)$$

$$\lambda = \exp[-p_1(\theta - \theta_{ref})/(p_2 + \theta - \theta_{ref})] \qquad (3)$$

Where D^{α} is operator of fractional derivative, α is order of fractional derivative. a, b and G are parameter to depend on frequency, a_{ref} and b_{ref} are parameter to depend on temperature.

There are two types of joint element: FC3x2, FC5x1 (see Table 1). The L-type metal includes "FC5" and "FC3" which indicate the number of screws on the column. "x1" and "x2" indicate the number of the metals. Detail of setting the each spring will be described in section 3.2. The shear springs between the two nodes are set depending on shear performance of per screw which is set from the test of the joint, because the steel plate is screwed on column by a number of screws. Also the axial springs of bolt are set from the test of joint.

Fig. 1(b) illustrates frame model of the plywood shear wall. Basically constructing method of the exterior frame is same as energy dissipation wall. Therefore linear beam elements which have same condition to the test members, are arranged in the center of the members. Each beam elements are connected by the joint elements which consist of three springs. There are two types of joint element: ST and SC2 (see Table 1). There are shear springs and axial springs of the bolts. The effect of the nails is concentrated to four shear springs using the shear property of a nail and the sheeted wall theory (Murakami et al. 1999).

2.2 Method of Concentrating Nail Spring

Murakami and Inayama have proposed a method to calculate the shear performance of plywood shear wall from relationship between shear force of nail and displacement of nail (Murakami et al. 1999). The method assumes the nail behavior to be able to separate to mode X and mode Y (see Fig. 4). The concentrating method which will be proposed here is based on the same idea.

Considering that the center of Fig.4 (mode X) is separated up and down, the effect of nails of upper side is concentrated to point U in Fig. 5. Similarly the effect of lower side is concentrated to point D. The scale factors of up and down are obtained from equation (4).

$$m_U = \sum y(i_u)^2 / H_U^{\,2} \;,\; m_D = \sum y(i_D)^2 / H_D^{\,2} \qquad (4)$$

Where H_U and H_D are distance of each point to neutral axis, i_U and i_D are number of nail, y is distance of each nail to neutral axis. Similarly considering the mode Y, the scale factors of right and left are obtained from equation (5).

$$m_L = \sum x(i_L)^2 / L_L^{\,2} \;,\; m_R = \sum x(i_R)^2 / L_R^{\,2} \qquad (5)$$

The four scale factors are multiplied by the relationship between shear force of nail and displacement of nail (see Fig.

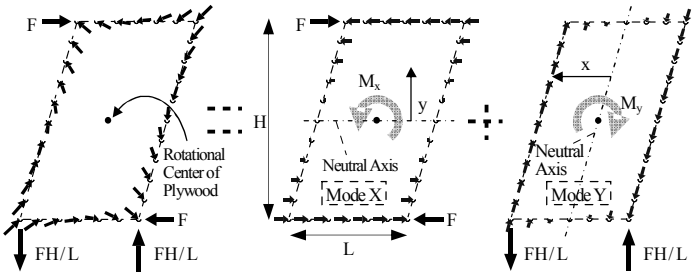

Fig 4 Force Acting on Frame (Elastic)

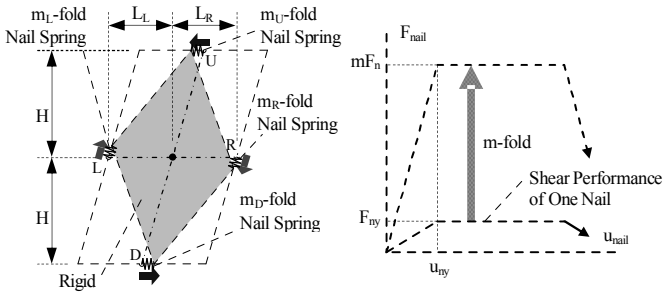

Fig 5 Outline of Concentrating Nail Spring

5), the four springs are connected by the rigid member. It was confirmed that the concentrated model behaves similarly to detailed model and also real structure (Matsuda et al. 2010).

3. CONFIGURATION OF SPRING

3.1 Hysteresis Rule

Fig. 6 illustrates hysteresis rule of Joint. After arriving at the elastic limit, the force increases gradually, and the envelope curve is calculated by Equation (6).

$$P = \frac{(k_0 - k_p)(u - u_a)}{\left(1 + \left|k_0(u - u_a)/P_0\right|^n\right)^{1/n}} + k_p(u - u_a) + P_a \quad (u > u_a) \quad (6)$$

Where P_0 is constant number which is obtained by substituting P_b and u_b into P and u. n is coefficient to decide the shape of the curve.

To duplicate the pinched hysteresis having slippage specific to wooden structure, the hysteresis rule is able to change the slip stiffness depending on maximum displacement (see Fig. 6). This hysteretic rule is applied to the six springs: axial, rotational and shear springs of the joint, and shear springs of the screw, bolt and nail.

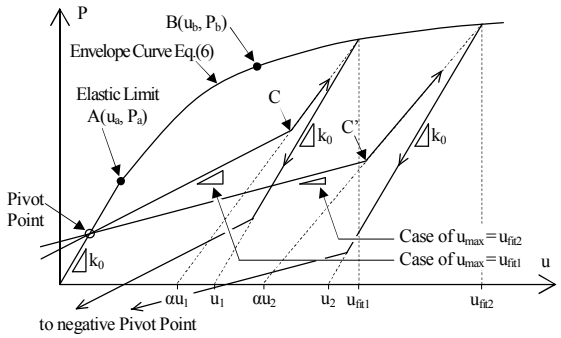

Fig. 6 Hysteresis Rule of Joint

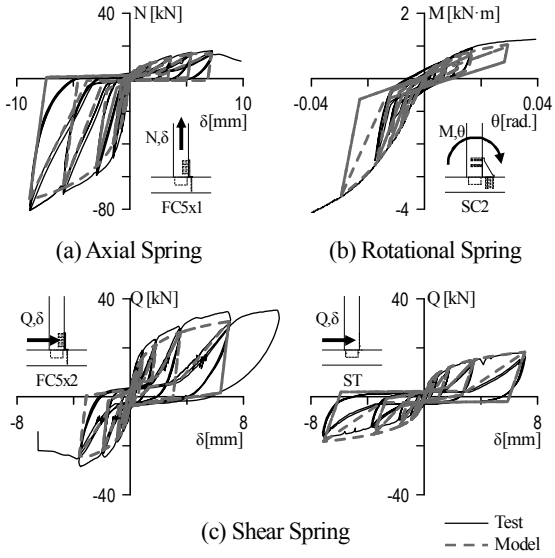
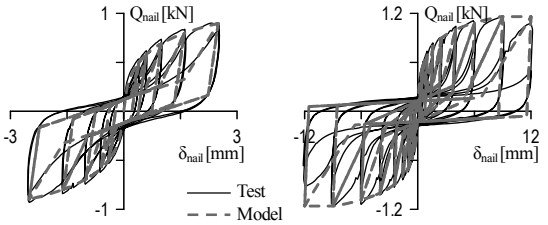


3.2 Joint Spring between Column and Horizontal Member

In order to model the property of the joint spring, a lot of joint test were carried out (Sakata et al. 2009). Fig.7-10 show the modelization of the many kinds of joint. The envelop curves of model are fitted to the average of more than three test results. The models correspond to test results including their cyclic behavior.

4. COMPARISON BETWEEN TEST AND ANARYSIS

4.1 Cyclic Loading Test



As for cyclic loading test of energy dissipation wall and plywood shear wall, Fig. 11 illustrates the comparison of test results (Matsuda et al. 2008) and analytical results. In the case of plywood shear wall, the analysis result duplicates not only strength but also slip behavior. In the case of energy dissipation wall, in both viscoelastic damper and elasto-plasticity damper, system hysteresis and damper

hysteresis, analytical results correspond to test results with high accuracy.

4.2 Shaking Table Test

In order to confirm the accuracy of seismic response, the comparison of shake table test and seismic response analysis will be discussed. Fig. 12 indicates the test specimen. Only center plane of the specimen is substituted to frame model since four-cornered columns hardly have horizontal force. Total seismic mass which the frame model has is 3.64 ton including the weight of specimen. Acceleration record which is measured at the specimen's sill is used.

Fig. 13 and 14 show the comparison of test result and analytical result in both global behavior and local behavior. The specimen's character W means plywood shear wall, V or F mean energy dissipation wall which has viscoelastic damper or friction (elasto-plasticity) damper.

The analytical result is similar to test result in both system and damper hysteresis, and the error in the maximum displacement is within 15%. The rotational angle of local behavior shown in upper stage of Fig. 14 is duplicated with high accuracy. In case of axial displacement shown in center stage of Fig. 14, the analytical displacement of capital part is smaller than the test result. Since the analysis is not able to duplicate axial displacement which the rotation provokes (see Fig. 15). In case of also axial force of bolt shown in lower stage of Fig. 14, the analytical result duplicates the test result nearly. As observed above, the frame model is able to duplicate not only global behavior but also local behavior with a high degree of accuracy.

5. PARAMETORIC STUDY

Using the frame model V, F and W, parametric analysis that the damper quantity and nail quantity are changed will be discussed. Note that each frame models' strengths in case that the model deforms 1/120rad. are from 8.5kN to 8.8kN and they are almost equal. Response spectra of input earthquake waves are showed in Fig. 16. The 6 waves are scaled to target Spa value 1,375cm/s^2 in the case of damping ratio is 2% in the constant area of acceleration.

Fig. 17 shows relationship between story drift and damper quantity. The maximum displacement of model which have viscoelastic damper, V-V, V-W and V-F don't vary among the waves, and it would appear that it is effective for estimating the response. Although the residual displacement of F-F is large, but the residual displacements of F-W and V-F are small. Therefore, adding structural element to friction damper is effective to reduce the residual displacement. The average of displacement of V-F is the smallest, hence combining viscoelastic and friction damper is effective to reduce the maximum displacement.

(Horizontal axis means damper quantity as amount of specimen is 1, and solid line indicates average)

6. CONCLUSION

Accurate, framed analytical models for the wooden energy dissipation wall with damper and plywood shear wall were proposed. In addition, parametric study was carried out using the frame model. Major finding are

- Framed analytical models of energy dissipation wall and/or plywood shear wall were constructed by using many kinds of nonlinear springs whose properties are derived from the test results of the joint. The joint spring between column and horizontal member consists of three types of spring, axial, rotational and shear spring.
- The frame models were able to duplicate not only global behavior but also local behavior with a high degree of accuracy in many kinds of test.
- In the case of the frame which has energy dissipation wall of viscoelastic damper, the maximum displacement doesn't vary among the waves whose response spectra are calibrated equally.
- In the case of the frame which has energy dissipation wall of friction damper, the residual displacement becomes large. But the phenomenon is able to be reduced by combining the friction damper elements with the other structural elements.

Appendix 1: Outline of Energy Dissipation Wall

The feature of K-brace passive control wall is shown below (Fig. A1). When the wall deforms by horizontal force, there is vertical deformation between the brace and the steel plate and the damper is inserted in the place. The wall is classified in to a series of so-called shear link type. In order to reduce the effect of the column's bending, the edge of the brace is fixed near the joint of the column and horizontal member. There are many advantages because the contents of the wall are able to fit in inside of frames. For example it is possible to fix without an attachment of other walls. K-brace is screwed on wooden frames by a lot of screws because of high safety factor.

A stub tenon, L-type metal and bolt (hold-down metal) are allocated in the joint of the column and horizontal member. The square steel pipe is fillet-welded to steel plate B and C (Fig. A1(c)). Energy absorption capacity is increased as much as possible by allocating the bolt closer to the column, and integrating the steel plate C into the hold-down metal.

Abstract: Dynamic properties and seismic responses of timber structure are discussed, with focus on uni-axial stiffness eccentricity of structural walls and horizontal flexibility of floor diaphragm. The stiffness eccentricity factor R_e defined in Japanese building standard law assumes rigid horizontal diaphragm, which can result in considerable error in estimations for torsional properties/responses of timber structures. Simplified formulations for the dynamic properties considering the diaphragm flexibility are given, and are applied to discuss seismic responses of example structures. The stiffness of horizontal diaphragm appears to affect not only the torsional response but also the translational response of the structure.

1. INTRODUCTION

Most wooden houses have stiffness eccentricity because of their eccentric arrangement of shear walls. Since it should be avoided from the point of view of seismic resistance, eccentric ratio R_e is defined in Japanese Building Standard Law. However, R_e assumes rigid horizontal diaphragm, which can result in considerable error in estimations for torsional properties/responses of timber structure. If horizontal diaphragm such as a floor or a roof is flexible, the building becomes vulnerable to torsion because transverse frames are unlikely to resist torsion. In particular, Japanese traditional wooden houses as well as existing old houses are thought to have flexible floor and large stiffness eccentricity.

In allowable stress design for Japanese timber houses, horizontal diaphragm must have enough *floor strength factors* in order to prevent it from breaking out prior to shear walls. As mentioned above, horizontal diaphragm needs to have not only enough strength but also much stiffness. Agawa showed the effect of floor's flexibility of timber structure by shaking table tests and reported that some changes of natural period and deformation mode are observed when stiffness of horizontal diaphragm is lacked.

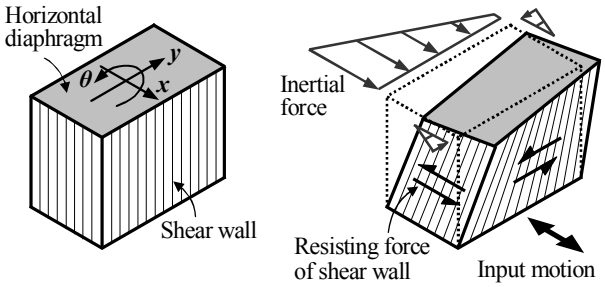
Although much verification of seismic performance of timber house designed on the basis of current seismic standard is carried out in recent days, relationship between stiffness of horizontal diaphragm and dynamic torsional behavior does not appear to be clarified. In this paper, simplified formulations for the dynamic properties considering the diaphragm flexibility are given, and are applied to discuss seismic responses of example structures. We assume that horizontal diaphragm maintains parallelogram after it is deformed in order that degrees of freedom are minimized. As a result, behavior of considering model is simplified compared to that of actual building. However, such a basic study is indispensable in order to clarify its complicated behavior theoretically. In addition, characteristics of shear walls and horizontal diaphragm are assumed to be linear.

2. PRIOR CONDITION

2.1 Single Span Structure Considered in This Paper

As shown in figure 1, single story and single span shear wall structure is considered. Stiffness of *x*- directional shear walls are unbalanced, and center of stiffness is located away in *y*- direction from center of mass. Horizontal diaphragm which means floor of 2nd. story is assumed to behave like a shear panel. Both dead load and live load are thought to be distributed uniformly in the plan.

As shown on the right side of figure 1, when structure is subjected to earthquake in *x*- direction, distribution of inertial force becomes triangular or trapezoidal due to rotation and shear deformation of floor. Figure 2 shows equilibrium between inertial forces and resisting forces of shear walls in three cases ; (a) rigid floor without eccentricity, (b) rigid floor with eccentricity and (c) flexible floor with eccentricity. In this study, we consider the response such as figure 2 (c), and assume that horizontal diaphragm maintains



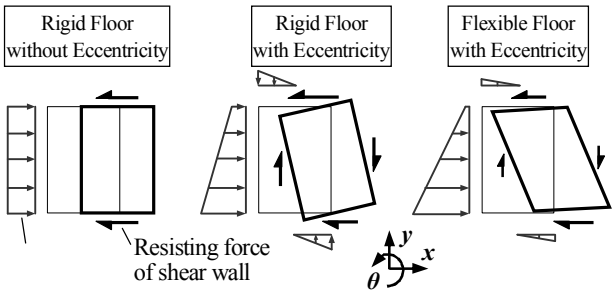


Figure 1 Single Story and Single Span Shear Wall Structure Considered in This Study

(a) Translation (b) (a) and Rotation (c) (b) and Shear deformation

Figure 2 Forces Applied to Horizontal Diaphragm and Deformation of Floor

parallelogram.

3. EQUATION OF MOTION

3.1 In A Case of Rigid Floor

Figure 3 shows structural model considered in this study, and figure 4 shows displacement mode of the structure. In this section, formulation for rigid floor structure is presented. Therefore, displacement mode becomes like a dash line in figure 4, which means horizontal diaphragm maintains rectangle.

k_{xi} and c_{xi} are stiffness and viscosity of i-th structural element in x- direction, respectively. Their distances from center of mass are y_i and y_i'. Similarly, k_{yi} and c_{yi} are stiffness and viscosity of i-th structural element in y-direction. Their distances from center of mass are x_i and x_i'. The origin is set in center of mass. Using above definition, following parameters are obtained.

$$K_x = \sum_i k_{xi}\,, \qquad K_\theta = \sum_i (k_{xi} y_i^{\,2} + k_{yi} x_i^{\,2}) \tag{1a,b}$$

$$C_x = \sum_i c_{xi}\,, \qquad C_\theta = \sum_i (c_{xi} y_i'^{\,2} + c_{yi} x_i'^{\,2}) \tag{2a,b}$$

$$e_y = \sum_i k_{xi} y_i / K_x\,, \qquad e_y' = \sum_i c_{xi} y_i' / C_x \tag{3a,b}$$

Where, K_x and K_θ are total stiffness in x- direction and rotational stiffness around center of mass, respectively. e_y is the distance from center of mass to center of stiffness. Similarly, C_x and C_θ are total viscosity in x- direction and rotational viscosity around center of mass, respectively. e_y' is the distance from center of mass to center of viscosity.

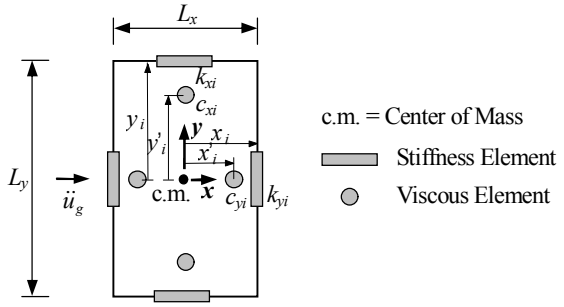

Figure 3 Arrangement of Stiffness and Viscous Element of the Structure

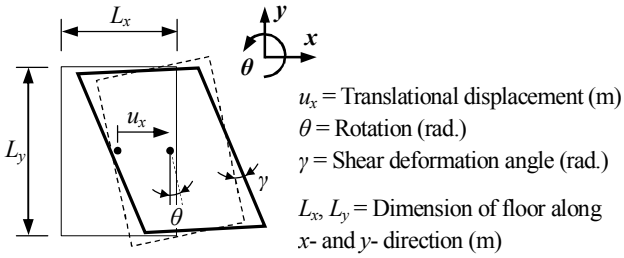

Figure 4 Displacement Mode of the Structure

Using equilibrium of x- directional forces and moment around center of mass, we can obtain the following equation of motion.

$$\begin{bmatrix} m & 0 \\ 0 & I \end{bmatrix} \begin{Bmatrix} \ddot{u}_x \\ \ddot{\theta} \end{Bmatrix} + \begin{bmatrix} C_x & -C_x e_y' \\ -C_x e_y' & C_\theta \end{bmatrix} \begin{Bmatrix} \dot{u}_x \\ \dot{\theta} \end{Bmatrix} + \begin{bmatrix} K_x & -K_x e_y \\ -K_x e_y & K_\theta \end{bmatrix} \begin{Bmatrix} u_x \\ \theta \end{Bmatrix} = -\begin{bmatrix} m & 0 \\ 0 & I \end{bmatrix} \begin{Bmatrix} 1 \\ 0 \end{Bmatrix} \ddot{u}_g \tag{4}$$

Where, m = total mass, I = moment of inertia, $\ddot{u}_g$ = input motion. First entry of displacement vector u_x is translational displacement of center of mass and second entry θ is rotation (rad.) around center of mass, as illustrated in figure 4.

The following parameters are also obtained.

$$\omega_x = \sqrt{K_x / m}\,, \qquad h_x = C_x / (2m\omega_x) \tag{5a,b}$$

$$\omega_\theta = \sqrt{K_\theta / I}\,, \qquad h_\theta = C_\theta / (2I\omega_\theta)\,, \tag{6a,b}$$

$$\bar{e}_y = e_y / r_m\,, \qquad \bar{e}_y' = e_y' / r_m \tag{7a,b}$$

ω_x, h_x are natural circular frequency and damping ratio of the system whose rotation is unfree, and ω_θ, h_θ are those of the system whose translation is unfree, respectively. r_m is radius of gyration. Using r_m, the following transformation is conducted.

$$\Delta u_x = r_m \theta\,, \qquad r_m = \sqrt{I / m} \tag{8a,b}$$

Δu_x is relative displacement from center of mass in the point r_m away in y- direction, which is caused by rotation θ.

Equation (4) can be rewritten using above new parameters as follows.

$$\mathbf{m}\,\ddot{\mathbf{u}} + \mathbf{c}\,\dot{\mathbf{u}} + \mathbf{k}\,\mathbf{u} = -\mathbf{m}\,\{\mathbf{1}\}\,\ddot{u}_g \tag{9}$$

$$\mathbf{m} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad \mathbf{u} = \begin{Bmatrix} u_x \\ \Delta u_x \end{Bmatrix}, \quad \{\mathbf{1}\} = \begin{Bmatrix} 1 \\ 0 \end{Bmatrix}$$
$$\mathbf{c} = 2h_x\omega_x \begin{bmatrix} 1 & -\bar{e}_y' \\ -\bar{e}_y' & \dfrac{h_\theta}{h_x}\dfrac{\omega_\theta}{\omega_x} \end{bmatrix}, \quad \mathbf{k} = \omega_x^2 \begin{bmatrix} 1 & -\bar{e}_y \\ -\bar{e}_y & \dfrac{\omega_\theta^2}{\omega_x^2} \end{bmatrix} \tag{10a-e}$$

Equation (9) is the equation of motion normalized by mass matrix **m**. We can see that the shapes of stiffness matrix **k** and damping matrix **c** are determined by four parameters ; ω_θ / ω_x , $\bar{e}_y$, h_θ / h_x and $\bar{e}_y'$. They are defined as '*torsional properties*' for rigid floor structure.

3.2 In A Case of Flexible Floor

When horizontal diaphragm is flexible, additional degree of freedom, which is shear deformation of floor γ , must be considered as shown in figure 4. It is notable that γ means shear deformation as strain tensor. Therefore, γ is a half of shear deformation angle of horizontal diaphragm.

As shown in figure 5, *x*- and *y*- directional forces produce moment and are balanced through horizontal diaphragm. The moment is replaced with concentric forces Q_x and Q_y applied to floor edge.

$$Q_x L_y = -M^{(x)} - I^{(x)}\left(\ddot{\theta} + \ddot{\gamma}\right), \quad Q_y L_x = M^{(y)} + I^{(y)}\left(\ddot{\theta} - \ddot{\gamma}\right) \tag{11a,b}$$

Equilibrium of moment around center of mass is expressed as follows.

$$Q_x L_y = Q_y L_x \tag{12}$$

$$M^{(x)} + M^{(y)} + I\ddot{\theta} + \left(I^{(x)} - I^{(y)}\right)\ddot{\gamma} = 0 \tag{13}$$

Where, $M^{(x)}$ and $M^{(y)}$ are resisting moment of *x*- and *y*- directional shear walls. $I\ddot{\theta}$ and $\left(I^{(x)} - I^{(y)}\right)\ddot{\gamma}$ are torque when floor rotates θ radian and deforms γ radian, respectively. Their proportional constant I, $I^{(x)}$ and $I^{(y)}$ are calculated by integrating moment by inertial force applied to small body as shown in figure 6.

$$I = \sum_j m_j\left(x_{mj}^2 + y_{mj}^2\right) = I^{(y)} + I^{(x)}\left(= \frac{m}{12}\left(L_x^2 + L_y^2\right)\right), \quad m = \sum_j m_j$$

$$I^{(x)} = \sum_j m_j\, y_{mj}^2\left(= \frac{mL_y^2}{12}\right), \quad I^{(y)} = \sum_j m_j x_{mj}^2\left(= \frac{mL_x^2}{12}\right) \tag{14a-d}$$

Where, m_j is mass of small body, and x_{mj} and y_{mj} are the distances from center of mass in *x*- and *y*- direction, respectively. The last members of equation (14a), (14c) and (14d), which are parenthetic, are realized in the case of uniformly distributed mass.

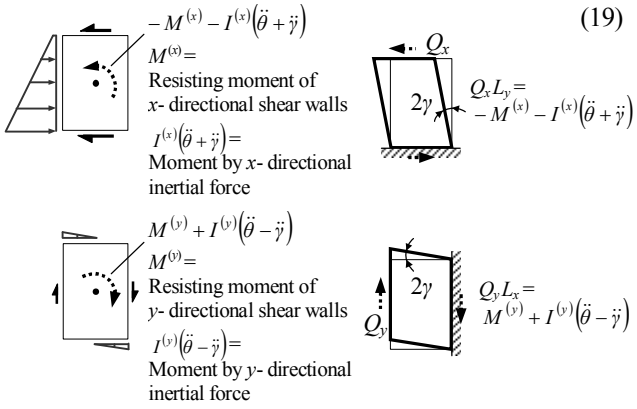
Moreover, horizontal diaphragm is assumed to be a shear panel whose shear modulus is *G*. Its plan dimension is L_x in *x*- direction and L_y in *y*- direction, and thickness is *t*, respectively. Thus, constitutive laws of floor are expressed as follows.

$$Q_x / \left(tL_x\right) = 2G\gamma\,, \qquad Q_y / \left(tL_y\right) = 2G\gamma \tag{15a,b}$$

In addition, by expressing left members of equation (15) using moment applied to floor (figure 5) instead of shear stress,

$$Q_x L_y = 2GV\gamma\,, \qquad Q_y L_x = 2GV\gamma$$
$$V = tL_xL_y \tag{16a-c}$$

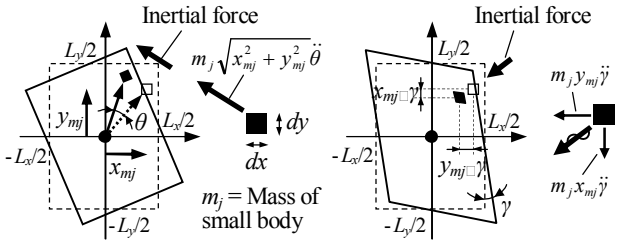
V means volume of the floor. By adding equation (16a) to equation (16b) in both members and substituting equation (11), the following equation of equilibrium is obtained.



$$M^{(x)} - M^{(y)} + \left(I^{(x)} - I^{(y)}\right)\ddot{\theta} + I\,\ddot{\gamma} + 4GV\gamma = 0 \tag{17}$$

Where, $M^{(x)}$ and $M^{(y)}$ are expressed as follows.

$$M^{(x)} = -C_x e_y' \dot{u}_x + C_\theta^{(x)}\left(\dot{\theta} + \dot{\gamma}\right) + -K_x e_y u_x + K_\theta^{(x)}\left(\theta + \gamma\right)$$
$$M^{(y)} = C_\theta^{(y)}\left(\dot{\theta} - \dot{\gamma}\right) + K_\theta^{(y)}\left(\theta - \gamma\right) \tag{18a,b}$$



Thus, equation of motion considering flexibility of floor are obtained as follows.

$$\begin{bmatrix} m & 0 & 0 \\ 0 & I & I^{(x)} - I^{(y)} \\ 0 & I^{(x)} - I^{(y)} & I \end{bmatrix}\begin{Bmatrix} \ddot{u}_x \\ \ddot{\theta} \\ \ddot{\gamma} \end{Bmatrix} + \begin{bmatrix} C_x & -C_x e_y' & -C_x e_y' \\ -C_x e_y' & C_\theta & C_\theta^{(x)} - C_\theta^{(y)} \\ -C_x e_y' & C_\theta^{(x)} - C_\theta^{(y)} & C_\theta \end{bmatrix}\begin{Bmatrix} \dot{u}_x \\ \dot{\theta} \\ \dot{\gamma} \end{Bmatrix}$$
$$+ \begin{bmatrix} K_x & -K_x e_y & -K_x e_y \\ -K_x e_y & K_\theta & K_\theta^{(x)} - K_\theta^{(y)} \\ -K_x e_y & K_\theta^{(x)} - K_\theta^{(y)} & K_\theta + 4GV \end{bmatrix}\begin{Bmatrix} u_x \\ \theta \\ \gamma \end{Bmatrix} = -\begin{bmatrix} m & 0 & 0 \\ 0 & I & I^{(x)} - I^{(y)} \\ 0 & I^{(x)} - I^{(y)} & I \end{bmatrix}\begin{Bmatrix} 1 \\ 0 \\ 0 \end{Bmatrix}\ddot{u}_g \tag{19}$$

(a) Moment Attributed to *x*- and *y*- Directional Forces (b) Equivalent Shear Forces

Figure 5 Forces Applied to Horizontal Diaphragm

(a) Only Rotation (b) Only Shear Deformation

Figure 6 Calculation of Moment of Inertia

Where,

$$K_\theta^{(x)} = \sum_i k_{xi} y_i^{\,2}, \qquad C_\theta^{(x)} = \sum_i c_{xi} y_i'^{\,2} \tag{20a,b}$$

$$K_\theta^{(y)} = \sum_i k_{yi} x_i^{\,2}, \qquad C_\theta^{(y)} = \sum_i c_{yi} x_i'^{\,2} \tag{21a,b}$$

$$K_\theta = K_\theta^{(x)} + K_\theta^{(y)}, \qquad C_\theta = C_\theta^{(x)} + C_\theta^{(y)} \tag{22a,b}$$

$K_\theta^{(x)}$ and $K_\theta^{(y)}$ are contributions of *x*- and *y*- directional shear walls to rotational stiffness K_θ, respectively. Similarly, $C_\theta^{(x)}$ and $C_\theta^{(y)}$ are those of *x*- and *y*- directional shear walls to rotational vicosity C_θ, respectively. The following nondimensional parameters are also defined due to simplified expression.

$$\cos^2\psi_x = K_\theta^{(x)} / K_\theta, \qquad \sin^2\psi_x = K_\theta^{(y)} / K_\theta \tag{23a,b}$$

$$\cos^2\psi_x' = C_\theta^{(x)} / C_\theta, \qquad \sin^2\psi_x' = C_\theta^{(y)} / C_\theta \tag{24a,b}$$

$$\alpha = \left(I^{(x)} - I^{(y)}\right) / I, \qquad \beta = \sqrt{4GV/I} \tag{25a,b}$$

The following transformation is conducted alike equation (8a).

$$\Delta u_x' = r_m \gamma \tag{26}$$

$\Delta u_x'$ is relative displacement from center of mass in the point r_m away in *y*- direction, which is caused by shear deformation angle γ. The difference between Δu_x and $\Delta u_x'$ are shown in figure 7.

Accordingly, **m**, **c** and **k** considering flexibility of floor are expressed as follows.

$$\mathbf{m} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & \alpha \\ 0 & \alpha & 1 \end{bmatrix}, \quad \mathbf{u} = \begin{Bmatrix} u_x \\ \Delta u_x \\ \Delta u_x' \end{Bmatrix}, \quad \{\mathbf{1}\} = \begin{Bmatrix} 1 \\ 0 \\ 0 \end{Bmatrix}$$

$$\mathbf{c} = 2h_x\omega_x \begin{bmatrix} 1 & -\bar{e}_y' & -\bar{e}_y' \\ -\bar{e}_y' & \dfrac{h_\theta}{h_x}\dfrac{\omega_\theta}{\omega_x} & \dfrac{h_\theta}{h_x}\dfrac{\omega_\theta}{\omega_x}\cos 2\psi_x' \\ -\bar{e}_y' & \dfrac{h_\theta}{h_x}\dfrac{\omega_\theta}{\omega_x}\cos 2\psi' & \dfrac{h_\theta}{h_x}\dfrac{\omega_\theta}{\omega_x} \end{bmatrix} \tag{27a-e}$$

$$\mathbf{k} = \omega_x^{\,2} \begin{bmatrix} 1 & -\bar{e}_y & -\bar{e}_y \\ -\bar{e}_y & \dfrac{\omega_\theta^2}{\omega_x^2} & \dfrac{\omega_\theta^2}{\omega_x^2}\cos 2\psi_x \\ -\bar{e}_y & \dfrac{\omega_\theta^2}{\omega_x^2}\cos 2\psi_x & \dfrac{\omega_\theta^2}{\omega_x^2}\left(1+\dfrac{\beta^2}{\omega_\theta^2}\right) \end{bmatrix}$$

We can see that there are eight '*torsional properties*' for flexible floor structure ; α, $\cos 2\psi_x$, $\cos 2\psi_x'$ and β/ω_θ added to those for rigid floor structure. α, $\cos 2\psi_x$ and $\cos 2\psi_x'$ represent influence of arrangement of mass, stiffness and viscosity upon floor deformation, respectively. β/ω_θ means the ratio of floor shear stiffness to rotational natural circular frequency, which is explained for details in the next chapter.

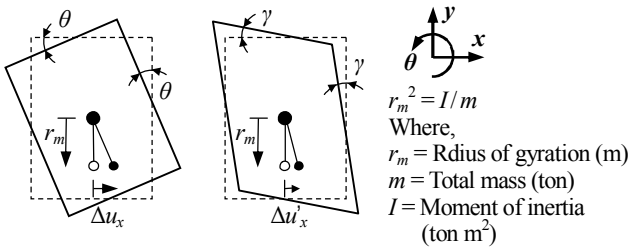


Figure 7 Definition of Δu_x and $\Delta u'_x$

4. DYNAMIC PROPERTIES

4.1 Supposed Range of Torsional Properties

In this section, some example structures are shown and their torsional properties are examined. Figure 8 shows structure model considered. The length of black rectangle expresses stiffness of each shear walls. Viscous elements are neglected. Constant proportional *a*, *b* and *c* are used ; *a* = the ratio of stiffness of two *x*- directional shear walls, *b* = the ratio of total stiffness of *y*- directional shear walls to that of *x*- direction and *c* = aspect ratio of floor.

Torsional properties calculated using above *a*, *b* and *c* are shown in table 1. *a* is changed from 0.5 to 0. *x*-directional eccentric ratio R_{ex} is also shown in the table. In the current Japanese design code for timber houses, R_{ex} must not exceed 0.3. Note that $\bar{e}_y = \bar{e}_y'$, $\omega_\theta/\omega_x = h_\theta/h_x$ and $\cos 2\psi_x = \cos 2\psi_x'$ are assumed because damping matrix **c** is typically considered to be proportional to stiffness matrix **k**.

Furthermore, physical meaning of β/ω_θ is explained here. By replacing β/ω_θ with equations (6a) and (25b),

$$\left(\beta/\omega_\theta\right)^2 = 4GV/K_\theta \tag{28}$$

It is found that β/ω_θ represents the ratio of floor shear stiffness to rotational stiffness of structure.

In Japan, floor strength factor is defined for each floor specification, which are based on experimental results. It is convenient to think that floor strength factor are decided by its strength in 1/150 rad. and means the shear stiffness of floor. Let α_f be floor strength factor, and GV is expressed as follows.

$$GV = 1.96\times 150\,\alpha_f L_x L_y \tag{29}$$

1.96 (kN/m) means standard strength value corresponding to α_f = 1. Similarly, let α_x (m/m^2) be wall length, which means summation of product of bracing unit multipliers and length of shear walls per unit area. Bracing unit multipliers is the strength of shear walls per unit length, and appears to means its stiffness. As a result, K_θ is expressed as follows.

$$K_\theta = \frac{1.96\times 150\,\alpha_x L_x L_y\left(b+c^2\right)}{h}\left(\frac{L_x}{2}\right)^2 \tag{30}$$

Where, *h* is floor height. By substituting equation (29) and (30) into equation (28),

$$(\beta/\omega_\theta)^2 = \frac{16\alpha_f h}{\alpha_x L_y^2\left(1+b/c^2\right)} \tag{31}$$

It is found that β/ω_θ has the following characteristics. β/ω_θ is proportional to α_f and inversely proportional to α_x, which means stiff floor is needed on the basis of the amount of shear walls. β/ω_θ is affected by other parameters ; b/c^2 and h/L_y^2. b/c^2 means the contribution of transverse walls to rotational stiffness. h/L_y^2 does three-dimensional shape of building.

Table 2 shows corresponding values of floor strength factor when the other parameters are given. $L_x = L_y =$ 5.46m (c = 1), α_x = 0.15, 0.3, 0.45m/m^2, b = 0.5, 1, 2 and β/ω_θ = 0.5, 1, 1.5, 2, 3 are considered in this table (Appendix A). $\beta/\omega_\theta = 0$ and infinity (Rigid floor) are also examined in a later chapter.

4.2 Dynamic Properties of the Structure

Natural circular frequency ω_i and eigen vector $\boldsymbol{\varphi_i}$ with respect to i-th mode are obtained by solving the following real eigen equation.

$$(-\omega_i^2 \mathbf{m} + \mathbf{k})\,\boldsymbol{\varphi_i} = \mathbf{0} \tag{32}$$

Higher mode response can be neglected because timber houses are likely to have short natural period. Therefore, characteristics of natural circular frequency ω_1 and eigen vector $\boldsymbol{\varphi_1} = \{\varphi_{11}, \varphi_{21}, \varphi_{31}\}^{\mathbf{T}}$ are discussed in this section. As shown in figure 9, φ_{j1} represents j-th degree of freedom based on 1st. mode ; j = 1(translation), = 2 (rotation) and =3 (shear deformation). Figure 10 shows ω_1/ω_x, $(\varphi_{21} + \varphi_{31})/\varphi_{11}$ and $\varphi_{31}/\varphi_{11}$.

In the case of a = 0.5 (without eccentricity), ω_1/ω_x becomes 1 regardless of either b or β/ω_θ. Reduced a leads to decreasing of ω_1/ω_x, which is more remarkable in the case of smaller β/ω_θ. In addition, β/ω_θ more affects the reduction of ω_1/ω_x when b is larger.

$(\varphi_{21} + \varphi_{31})/\varphi_{11}$, which means torsion between two x-directional walls, becomes large when β/ω_θ is small. If b is larger, β/ω_θ more affects the increase of $(\varphi_{21} + \varphi_{31})/\varphi_{11}$.

A few previous researches led to the fact that $\varphi_{31}/\varphi_{11}$ is not changed when a is constant. However, we can find that $\varphi_{31}/\varphi_{11}$ has some relation to a, as shown on the right side of figure 10. It is because the former researches considered static concentric forces applied to center of mass.

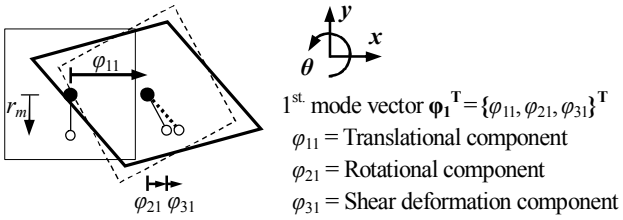

Figure 9 1st. Mode Shape of the Structure

4.3 Equivalent Eccentric Ratio Considering Floor Flexibility

Deformation of floor leads to reduced deformation of transverse walls as shown on the left side of figure 11. It can be replaced with reduced stiffness of transverse walls of rigid floor model as shown on the right side of figure 11. The two models are described as '*Flexible floor model*' and '*Equivalent rigid floor model*', respectively. In this section, influence of flexible floor is quantitatively presented using these two models.

The reduction ratio of transverse walls' stiffness of equivalent rigid floor model is defined as '*Effective transverse walls' stiffness coefficient k*'. This reduction results in decreasing of ω_θ/ω_x. Let $\overline{\omega}_\theta/\omega_x$ be that of equivalent rigid floor model. Its natural circular frequency of 1st. mode $\overline{\omega}_1$ is obtained by solving equation (10) and (32).

$$\overline{\omega}_1^2 = \frac{\omega_x^2}{2}\left[1 + \frac{\overline{\omega}_\theta^2}{\omega_x^2} - \sqrt{\left(1+\frac{\overline{\omega}_\theta^2}{\omega_x^2}\right)^2 - 4\left(\frac{\overline{\omega}_\theta^2}{\omega_x^2} - \bar{e}_y^2\right)}\right] \tag{33}$$

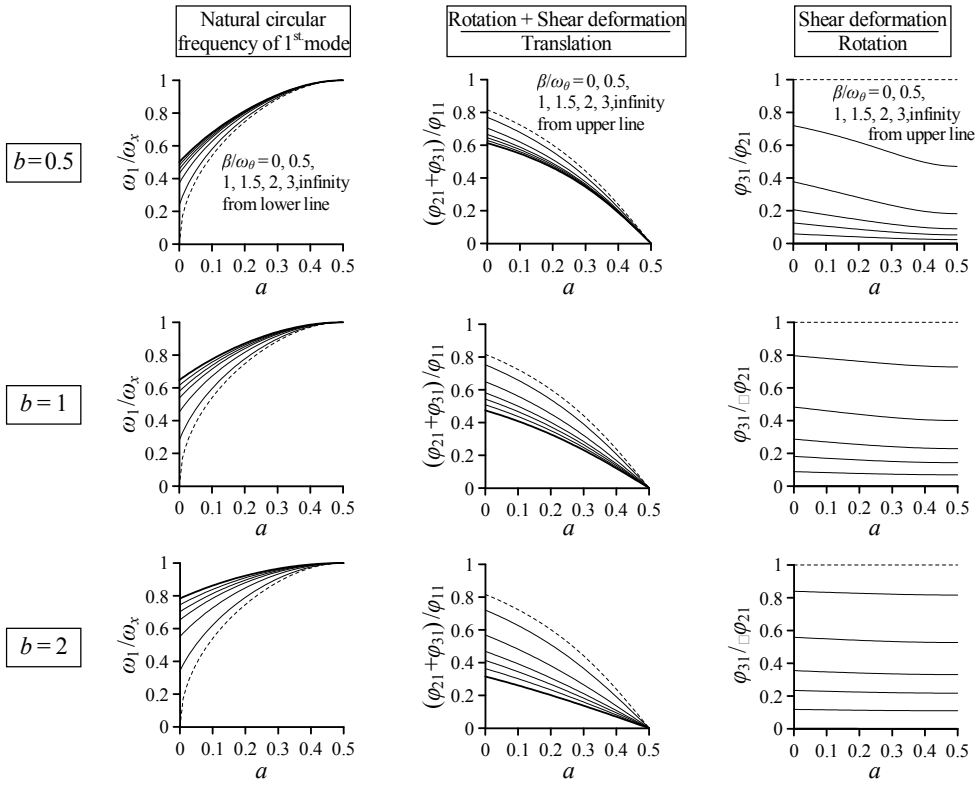

Figure 10 Relationship between β/ω_θ and Dynamic Properties of the System ($\beta/\omega_\theta = 0$ (Dash lines), 0.5, 1, 1.5, 2, 3 and infinity (Bold lines), $c = 1$)

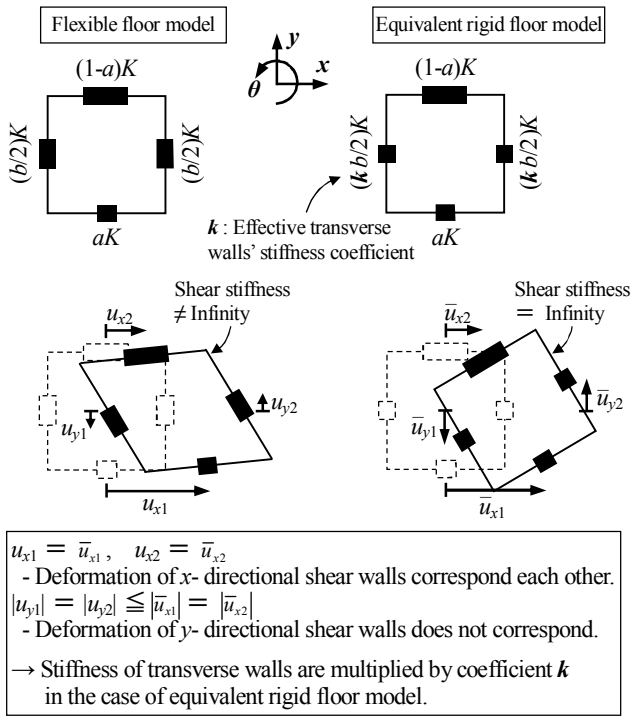

Figure 11 Flexible Floor Model and Equivalent Rigid Floor Model

By solving equation (33) for $\overline{\omega}_\theta / \omega_x$,

$$\frac{\overline{\omega}_\theta}{\omega_x} = \sqrt{\frac{\overline{\omega}_1^2}{\omega_x^2} + \frac{\overline{e}_y^2}{1 - \overline{\omega}_1^2 / \omega_x^2}} \tag{34}$$

By substituting ω_1, which is natural circular frequency of flexible floor model, into $\overline{\omega}_1$, we can obtain k as well as $\overline{\omega}_\theta / \omega_x$. As a result, natural circular frequencies and displacement modes of x- directional walls of both models agree exactly with respect to one another (Appendix B). Moreover, eccentric ratio of equivalent rigid floor model is calculated using above k. This is defined as '*Equivalent eccentric ratio considering floor flexibility* R'_{ex}'.

Figure 12 shows k and R'_{ex}. Other parameters are the same as those of figure 10. Reduced a leads to decreasing of k, which is more remarkable in the case of smaller β/ω_θ. In addition, the larger b is, the smaller k becomes if a and β/ω_θ are fixed. Right side of figure 12 shows relationship between R_{ex} and R'_{ex}. R_{ex} corresponds to R'_{ex} exactly when β/ω_θ is infinity. R'_{ex} nearly equals to R_{ex} in the case of b = 0.5. However, R'_{ex} obviously becomes larger than R_{ex} in the case of b = 1 or 2.

According to above discussion, flexible floor apparently leads to decreasing of stiffness of transverse walls or increasing of eccentric ratio. The influence is demonstrated theoretically.

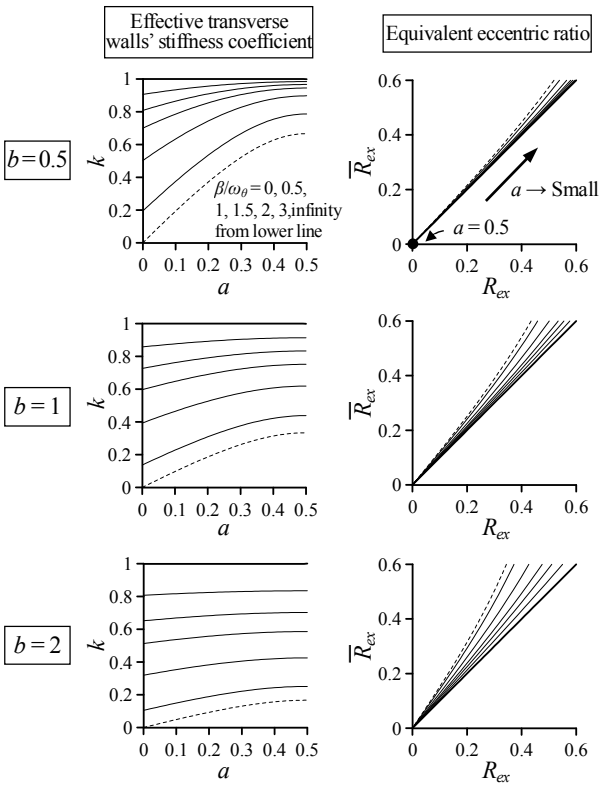

Figure 12 Effective Transverse Walls' Stiffness Coefficient k and Equivalent Eccentric Ratio $\overline{R}_{ex}$ (β/ω_θ = 0 (Dash lines), 0.5, 1, 1.5, 2, 3 and infinity (Bold lines), c = 1)

5. SEISMIC RESPONSE ANALISIS

5.1 Maximum Displacement of the System Subjected to Earthquake Characterized by Constant Acceleration Spectrum

In this chapter, basic characteristics of earthquake response of flexible floor structure are examined. For simplified discussion, input motion is characterized by its pseudo acceleration spectrum. In addition, the response derived from only 1st. mode is considered.

Modal participation factor β_1 is obtained as follows.

$$\beta_1 = \boldsymbol{\varphi}_1^{\mathrm{T}}\mathbf{m}\{\mathbf{1}\}/\boldsymbol{\varphi}_1^{\mathrm{T}}\mathbf{m}\boldsymbol{\varphi}_1 \tag{35}$$

Let $S_{pa}(h_0=0.05)$ be constant pseudo acceleration spectrum for damping ratio $h_0 = 0.05$. $S_{pa}(h_0 = 0.05)$ = 196cm/s^2 is used, which shows that base shear coefficient C_0 = 0.2 is assumed. Note that natural period of 1st. mode T_1 (= $2\pi/\omega_1$) is located in the spectrum constant area.

Maximum displacement vector $\mathbf{u_{max}}$ is calculated as follows.

$$\mathbf{u_{max}} = \beta_1 \boldsymbol{\varphi}_1 S_{pa}(h_0 = 0.05)/\omega_1^2 \tag{36}$$

Damping ratio of 1st. mode is assumed to be 0.05 in all cases, so that response reduction by damping is not considered.

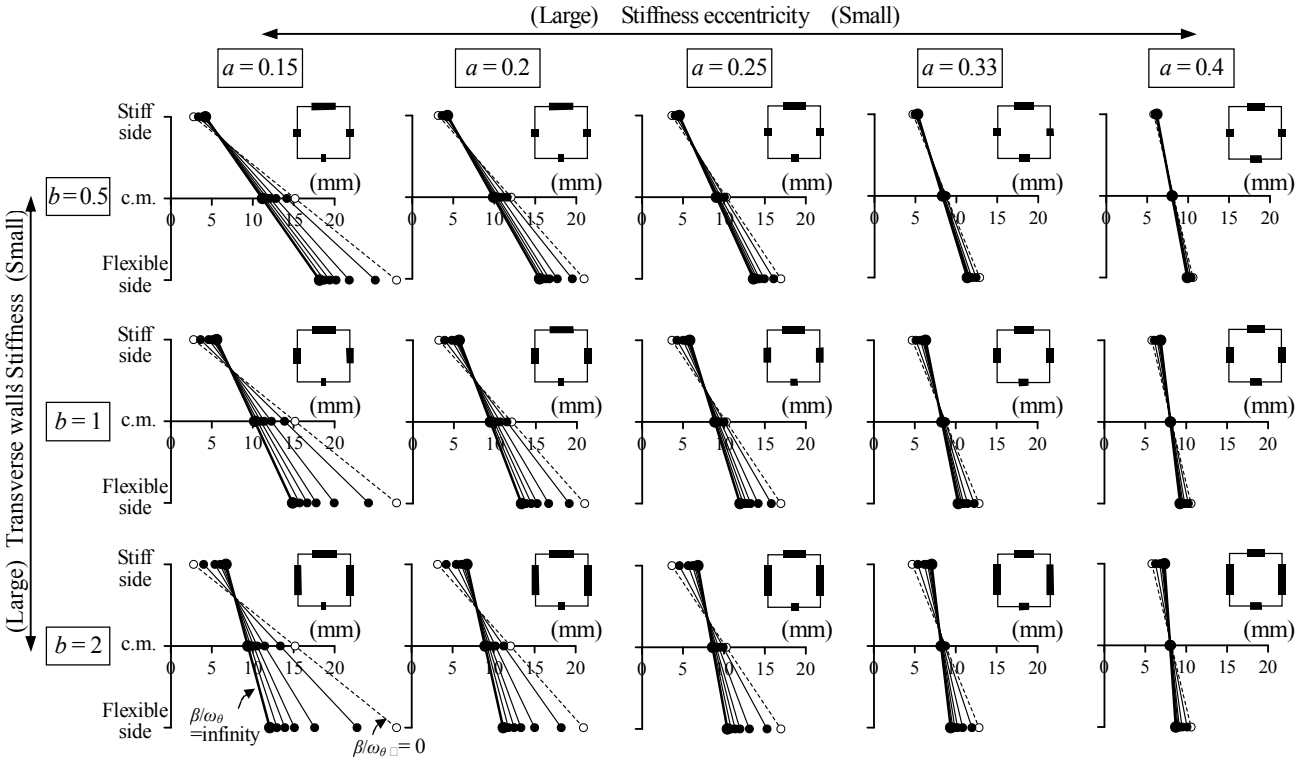
5.2 Distribution of Maximum Displacement

Maximum displacement in three points are compared ; center of mass (c.m.), flexible side wall and stiff side wall in x- direction. a = 0.15, 0.2, 0.25, 0.33, 0.4 and β/ω_θ = 0, 0.5, 1, 1.5, 2, 3, infinity are examined. T_x (= $2\pi/\omega_x$) = 0.4 second is assumed.

At first, c = 1 is assumed, and three cases of b (= 0.5, 1 and 2) are shown in figure 13(a). In the case of small a, structure becomes more vulnerable to torsion according as β/ω_θ is reduced. In other words, the smaller β/ω_θ becomes, the larger maximum displacement in flexible side wall becomes. In addition, It is particularly notable that translational displacement in c.m. is also increased when β/ω_θ is small, compared to β/ω_θ = infinity especially in the case of small a. This certainly results from reduced ω_1 attributed to small β/ω_θ. Since timber houses have short natural period T_1 as mentioned above, maximum displacement is likely to be proportional to square of T_1.

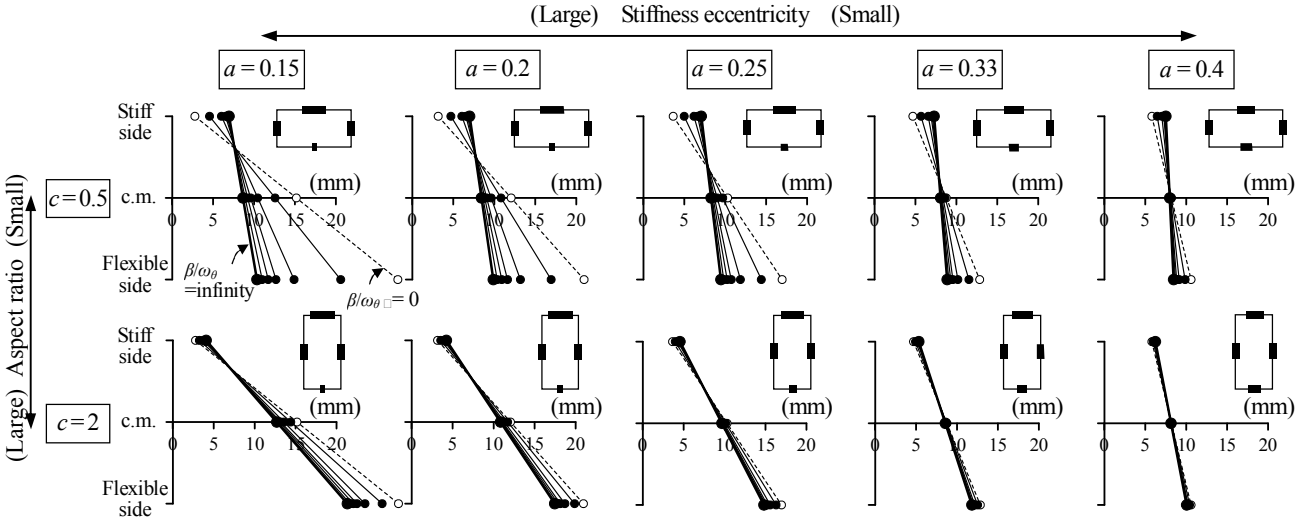
In figure 13(b), b = 1 is assumed, and two cases of c (= 0.5 and 2) are shown. In the case of c = 2, the response is unlikely to be greatly affected by reduced β/ω_θ because transverse walls are not effective to resist torsion due to its plan shape. In other words, reduced floor stiffness especially affects the maximum responses of stiffness eccentric buildings which rely on transverse walls for their rotational stiffness.

Finally, we try to set the condition that horizontal diaphragm can be assumed to be rigid. Judging from figure 10 and 13, β/ω_θ > 1.5 can be the criteria of rigid floor apparently. In other words, dynamic properties/responses when β/ω_θ is larger than 1.5 are about the same as those of structure with rigid floor. Thus, we can solve equation (31) for α_f using β/ω_θ = 1.5 and h = 2.73m.



$$\alpha_f = 0.052\left(1+b/c^2\right)\alpha_x L_y^2 \approx \frac{L_y\left(1+b/c^2\right)}{9.7}\frac{\alpha_x}{2}L_y \tag{37}$$

Equation (37) means minimum floor strength factor for rigid floor assumption derived from structural dynamics. However, more close investigation should be required regarding the criteria of β/ω_θ.



6. CONCLUSIONS

In this paper, evaluation method for dynamic properties of timber structure with flexible floor and uni-axial eccentricity is proposed. Based on the method, estimation of earthquake response is also demonstrated. The following are findings obtained.

1) Flexibility of horizontal diaphragm is represented by β/ω_θ derived from equation of motion for simplified model. β/ω_θ has two interpretations ; one is the ratio of floor shear stiffness to rotational stiffness of the structure (equation (28)), and another is the value determined by wall length, stiffness balance of x- and y-directional walls and the dimension of the building as well as floor strength factor (equation (31)).

(a) Influence of Stiffness Eccentricity a and Transverse walls' Stiffness b (c = 1 = Constant)

(b) Influence of Stiffness Eccentricity a and Aspect Ratio c (b = 1 = Constant)

Figure 13 Maximum Displacement of the System Subjected to Earthquake Characterized by Constant Acceleration Spectrum (β/ω_θ = 0 (Dash lines), 0.5, 1, 1.5, 2, 3 and infinity (Bold lines))

2) Relationship between floor flexibility and dynamic properties is obtained by solving eigen equation (equation (32)) as shown in figure 10.
3) Shear Deformation of floor leads to reduced deformation of transverse walls. It is replaced with reduced stiffness of transverse walls, and equivalent eccentric ratio considering floor stiffness is evaluated (figure 12).
4) Reduced stiffness of floor results in not only increasing of torsion but also increasing of translational displacement in center of mass.
5) Dynamic properties/responses are about the same as those of structure with rigid floor when β/ω_θ is larger than 1.5. Therefore, minimum floor strength factor for rigid floor assumption is expressed by equation (37).
6) Reduced floor stiffness remarkably affects the maximum responses of stiffness eccentric buildings which rely on transverse walls for their rotational stiffness.

A. Wall Length Considered in This Paper

In wall length method which is the most popular design method for timber houses provided by Japanese building standard law, timber houses are categorized into heavy buildings or light buildings. Demand length of wall depends on such a building type and the number of story etc.. In this study, wall length α_x = 0.15, 0.3 and 0.45m/m^2 are demonstrated, and it is determined by referring to the amount provided by the law.

B. Relationship between Flexible Floor Model and Equivalent Rigid Floor Model

In section 4.3, we made a condition that natural circular frequencies of two models, flexible floor model and equivalent rigid floor model, agree with respect to one another. Eigen vector and participation factor of two models are also presented here.

Eigen equation of 1$^{st.}$ mode is expressed as follows.

$$(-\omega_1^2\,\mathbf{m}+\mathbf{k})\,\boldsymbol{\varphi}_1 = 0 \tag{B1}$$

By expanding above matrix and vector into three equations, we can obtain the following relation from the fist row.

$$\frac{\varphi_{21}+\varphi_{31}}{\varphi_{11}} = \frac{1-\omega_1^2/\omega_x^2}{\bar{e}_y}, \qquad \beta_1 = \frac{\varphi_{11}}{\varphi_{11}^2+\varphi_{21}^2+\varphi_{31}^2+2\alpha\varphi_{21}\varphi_{31}} \tag{B2a,b}$$

Let $\bar{\boldsymbol{\varphi}}_1 = \{\,\bar{\varphi}_{11}, \bar{\varphi}_{21}\,\}^{\mathrm{T}}$ and $\bar{\beta}_1$ be eigen vector and participation factor of equivalent rigid floor model, respectively. They are obtained as follows.

$$\frac{\bar{\varphi}_{21}}{\bar{\varphi}_{11}} = \frac{1-\omega_1^2/\omega_x^2}{\bar{e}_y}, \qquad \bar{\beta}_1 = \frac{\varphi_{11}}{\varphi_{11}^2+\varphi_{21}^2} \tag{B3a,b}$$

We can see that $\bar{\varphi}_{21}/\bar{\varphi}_{11}$ agrees to $(\varphi_{21}+\varphi_{31})/\varphi_{11}$ exactly, which means displacement modes of *x*- directional walls of two models are similar. In addition, participation factors also agree in the case of $\alpha = 1$.

Abstract: The seismic collapse potential of a multi-story building with Magneto-Rheological (MR) dampers is investigated by performing incremental dynamic analyses (IDAs) to develop fragility curves for collapse. The building is designed with MR dampers to achieve a performance objective of 1.5% story drift and 3.0% story drift under the design basis earthquake (DBE) and maximum consider earthquake (MCE), respectively. Nonlinear time history analyses are conducted using OpenSees as a tool for the IDAs. A set of 22 recorded far-field ground motion pairs provided in the Applied Technology Council (ATC) Project 63 are used for the IDAs. A phenomenological based deterioration model for beam-to-column connections calibrated from experimental data is incorporated into OpenSees to enable strength degradation in the lateral load resisting system to be modeled, along with the Maxwell Nonlinear Slider (MNS) MR damper model. The MR dampers are controlled either in passive or semi-active mode, where five different semi-active control strategies are considered for the MR dampers. The collapse fragility curves for the various control strategies are obtained along with the case where the building is designed as a conventional MRF without MR dampers. Collapse fragilities and the collapse margin ratio are compared for each case in order to assess the effectiveness of semi-active and passive dampers in reducing seismic collapse.

1. INTRODUCTION

In earthquake engineering, collapse implies that a structural system, or a part of it, is incapable of maintaining gravity load carrying capacity in the presence of seismic effects (Ibarra and Krawinkler 2005). When a building is subjected to large story drifts, it is vulnerable to dynamic instability due to P-Δ effects and deterioration in strength and stiffness of its structural components, subsequently, resulting in collapse of the system. Protection against collapse has always been a major concern in the design of structures. The recently developed FEMA P695 (ATC 2009) document provides a methodology for seismic collapse assessment of structures.

While several studies have been conducted to assess the performance of supplemental damping systems and their effectiveness in mitigating the seismic hazard of structures under the design basis earthquake (DBE) and maximum considered earthquake (MCE), the collapse resistance of buildings with Magneto-Rheological (MR) dampers has not been investigated. The seismic collapse potential of structures with passive supplemental damping systems has been investigated by a few researchers using the incremental dynamic analysis (IDA) method (Solberg et al. 2007; Marshall and Charney 2010; Miyamoto et al. 2010). In this paper, the collapse resistance capacity of a 3-story building with MRFs and braced frames with MR dampers designed for seismic performance under the DBE and MCE is assessed for seismic collapse using the procedure given in FEMA P695. The nonlinear time history analyses used in the IDA method are conducted using OpenSees (2009). A phenomenological-based model developed by Ibarra and Krawinkler (2005) and modified by Lignos (2008) for modeling deterioration in beam plastic hinge regions in MRFs is incorporated into OpenSees. The IDA are performed on the building using five different controllers (Chae 2011), including: i) passive control; ii) linear quadratic regulator (LQR); iii) sliding mode control (SMC); iv) decentralized bang-bang control (DBB); and v) phase angle control (PAC). Collapse fragility curves are obtained using the ensemble of 22 recorded far-field ground motion pairs (i.e., 44 far-field ground motions) provided in FEMA P695. The collapse fragility curves for the various control strategies are compared in order to assess the performance of the MR damper control strategies in mitigating structural collapse under extreme earthquake ground motions.

2. BEAM PLASTIC HINGE DETERIORATION MODEL

The P-Δ effect and the strength and stiffness deterioration of structural components are considered to be

the major contributors to the collapse of a structural system under seismic loading. The P-Δ effect is well-understood and mathematical models have been formulated for use in linear and nonlinear structural analysis, while the modeling of strength and stiffness deterioration under seismic loading is an on-going research topic. For the accurate evaluation of the collapse of a structure, it is necessary to construct a model that is capable of capturing the strength and stiffness deterioration of structural components under seismic loading. In this section, recently developed deterioration models are introduced. The models are used for the IDA presented later in this paper.

Ibarra and Krawinkler (2005) developed a hysteretic inelastic deterioration model to describe the moment-rotation behavior in the plastic hinge region of a steel or concrete beam. The model is based on a backbone curve that defines a reference skeleton behavior of a non-deteriorated system. A set of rules are used to define the basic characteristics of the hysteretic behavior between the bounds defined by the backbone curve as well as deterioration in strength and stiffness with respect to the backbone curve.

Lignos (2008) modified the Ibarra-Krawinkler model based on observations from data from several hundred tests that had been conducted on steel and reinforced concrete beams. Lignos modified the backbone curve and the cyclic deterioration modeling in the original Ibarra-Krawinkler model, where the new backbone curve proposed by Lignos is shown in Figure 1. In Figure 1, δ_c is the cap deformation (deformation associated with capacity F_c for monotonic loading); F_y is the effective yield strength; δ_y is the effective yield deformation (=F_y/K_e); K_e is the effective elastic stiffness; F_r is the residual strength capacity; δ_r is the deformation at residual strength; δ_u is the ultimate deformation capacity; δ_p is the plastic deformation capacity associated with monotonic loading; δ_{pc} is the post-capping deformation capacity associated with monotonic loading; F_{yp} is the predicted effective yield strength; F_{yn} is the nominal effective yield strength; and κ is the residual strength ratio (=F_r/F_y). The capacity F_c mentioned above is the strength cap associated with the maximum strength incorporating average strain hardening. The strain hardening ratio α_s and the post-capping stiffness ratio α_c are defined as $\alpha_s = K_s/K_e = [(F_c/F_y)/\delta_p]/K_e$ and $\alpha_c = K_{pc}/K_e = (F_c/\delta_{pc})/K_e$, respectively. The reference energy dissipation capacity E_t, which is used to describe the cyclic deterioration, is defined by using the parameter δ_p in the normalization of the reference energy dissipation capacity, i.e., $E_t = \Lambda\delta_p$, where Λ denotes the reference cumulative deformation capacity.

3. MODELING OF 3-STORY BUILDING

The 3-story building shown in plan and elevation in Figures 2 and 3, respectively, was used for the study. The building has two perimeter MRFs along each of its sides and braced internal bays with MR dampers (called *damped brace frames* (DBFs)) at the 2nd and 3rd floors. The structure was designed using the simplified design procedure developed by Chae et al. (2011) to achieve a performance objective of 1.5% story drift and 3.0% story drift under the DBE and MCE, respectively. The 3-story building was scaled down using a scale factor of 0.6 for the study since a reduced scale model of the building will be constructed and tested in the laboratory in future research. The members of the MRF are proportioned using a weak beam-strong column design. Yielding is expected to occur predominately at the ends of the MRF beams and at the base of the columns in the first story of the MRF and DBF. The beams and diagonal bracing members in the DBF have pin-ended connections. The beams are axially restrained in the DBF by the floor diaphragm (which is assumed to be rigid in-plane) at each floor level and expected to remain elastic. The diagonal bracing is expected to remain elastic up to 135% story drift (Chae 2011). Tables 1 and 2 summarize the member sizes for the 0.6-scale building. The OpenSees model for the scaled building is shown in Figure 4. Symmetry in the floor plan and ground motions along only one principal axis of the building were considered in the analysis. Hence, only one-quarter of the building was modeled consisting of one MRF, one DBF, and the gravity frames that are within the tributary area of the MRF and DBF.

Each beam of the MRF in the model consists of three elements: two inelastic deterioration elements with zero length at the column faces based on the modified Ibarra-Krawinkler model; and one linear elastic element between the deterioration elements. The parameters for the deterioration element are summarized in Table 3, where M_y, θ_p and θ_{pc} denote the yield moment, plastic rotation capacity and the post-capping rotation capacity, respectively. The values of these parameters are based on Lignos and Krawinkler (2009) for the beam sections used in the MRF.

The columns of the MRF and DBF are modeled using a nonlinear distributed plasticity force-based beam-column element. Each fiber is modeled with a bilinear stress-strain relationship with a post-yielding stiffness that is 0.01 times the elastic stiffness. The columns extend below the ground level in the model to the base, where they are pinned. The beam-to-column joints in the MRF are modeled using a nonlinear panel zone element, where shear and symmetric column bending deformation modes are considered (Seo et al. 2009). Doubler plates in the panel zones of the MRF are included in the model. The beams and braces of the DBF are modeled using linear elastic truss elements. The gravity frames are idealized using the concept of a lean-on column, where an elastic beam-column element with geometric stiffness is used to model the lean-on column. The section properties of the lean-on column are obtained by taking the sum of the section properties of each column of the gravity frames within the tributary area (i.e., one quarter of the floor plan) of the MRF and the DBF.

The structural model in Figure 4 has two major structural components that can lead to dynamic instability under extreme earthquake ground motions: (1) negative stiffness induced by the gravity loads acting on the lean-on

column (the P-Δ effect); and (2) strength deterioration in the inelastic deterioration elements in the beams of the MRF. The columns of the MRF and DBF are assumed to have sufficient strength and compactness of their cross-sections such that no deterioration in strength or stiffness of the columns is expected to occur.

To model a rigid floor diaphragm at each floor level the top node of each panel zone element in the MRF and the beam-column joint in the DBF are horizontally constrained together with the node of the lean-on column, while the vertical and rotational DOFs are released. The MR damper is assumed to be located between the top of the diagonal bracing and beam-to-column joint of the DBF. The variable current MNS model developed by (Chae 2011) is used to model the MR dampers for the nonlinear time history analysis.

Large-scale MR dampers were used for the study which can generate a 200kN damper force at a velocity of 0.1m/sec. (Chae et al. 2010). The damper has a stroke limit of ±279mm. The story height of the 3-story building is 2.286m, implying that the dampers will reach their stroke limit at 12.2% story drift. Since large story drifts can be expected in a collapse simulation, the MR damper may bottom out with respect to their stroke limit under extreme earthquake ground motions. In this case, a gap or the hook element should be included in the model to account for the dynamic behavior associated with reaching the stroke limit, as suggested by Miyamoto et al. (2010). The MR dampers in this study are assumed to have sufficient stroke limit to accommodate the large story drifts during a collapse simulation since no experimental data exists that can be used to model the effect of bottoming out of the dampers.

4. GROUND MOTIONS

As noted previously, the far-field ground motion record set provided in FEMA P695 (ATC 2009) was selected as ground motions for the IDA. These ground motions were selected from the PEER-NGA data base to permit evaluation of the record-to-record (RTR) variability of the structural response and calculation of the median of the intensity of spectral acceleration at which collapse occurs. Among the 22 earthquakes, 14 occurred in the United States and 7 in other countries. Event magnitudes range from M6.5 to M7.6, with an average magnitude of M7.0. Each earthquake has two horizontal components so that a total of 44 ground motions are used for the IDA.

FEMA P695 recommends the use of spectral acceleration at the fundamental period of a structure, S_{aT_1}, as the intensity measure (IM). The ground motions are scaled up (or down) based on the spectral acceleration at the fundamental period of the structure. The MR damper stiffness depends on its displacement amplitude (Chae 2011). Hence, the effective fundamental period of the structure is dependent on the amplitude of the damper displacements, which is a function of the intensity of ground motion. In this paper, the fundamental period of the structure without MR dampers is used to determine the spectral acceleration corresponding to the IM, rather than using the effective fundamental period of the structure with the dampers. The fundamental period without the MR dampers is 0.94 sec. (Chae 2011), and the scaling of ground motions is performed based on the spectral acceleration at this period.

5. CONTROLLERS

As noted previously, five different control strategies for MR dampers are used in this study, namely: i) passive control; ii) linear quadratic regulator (LQR); iii) sliding mode control (SMC); iv) decentralized bang-bang control (DBB); and v) phase angle control (PAC). More details on these controllers can be found in Chae (2011). A constant current with I=2.5A is supplied to the MR dampers for passive control, while either I=0.0A or 2.5A is used for the semi-active controllers.

6. INCREMENTAL DYNAMIC ANALYSES

The incremental dynamic analysis (IDA) curves are a set of plots that correlate a damage measure (DM) with the IM that characterizes the applied scaled accelerograms (Vamvatsikos and Cornell 2002). The roof drift ratio of the building structure, θ_{roof}, is selected as the DM for this study. A ground motion is scaled up until dynamic instability occurs, where an IDA curve becomes a flat line, i.e., at collapse. Each selected ground motion is gradually scaled up until θ_{roof} reaches 17% or collapse occurs. For the 44 ground motions in the ensemble, the IDA curves all became flat indicating collapse before θ_{roof} reached 17%. The median roof drift when the IDA curves become flat was approximately 14%.

Figures 5 through 10 show the IDA curves for the structure with various control strategies. These results are for the 44 ground motions. The collapse margin ratio (CMR) was determined for each case, where the CMR is defined by FEMA P695 (ATC 2009) as the ratio of the median value for the collapse spectral acceleration, $\hat{S}_{CT}$, to the spectral acceleration of the MCE, S_{MT}, at the fundamental period of the structural system:

$$\text{CMR} = \frac{\hat{S}_{CT}}{S_{MT}} \tag{1}$$

$\hat{S}_{CT}$ for each control case is calculated from the IDA curves and marked in Figures 5 through 10 along with the S_{MT}. Table 4 shows the CMR values for each control strategy. Since the purpose is to evaluate the collapse capacity of a structure with MR dampers with various control strategies, the further adjustment of the CMR values based on the spectral shape factor (SSF) (ATC 2009) is not considered in this study. The results in Table 4 show that when passive control is used that the CMR value increases by about 26% compared to the no damper case, demonstrating the benefit of using MR dampers. The overall performance of each semi-active controller is similar to that of the passive control case, except for the LQR controller.

The LQR controller shows the highest CMR value, but the improvement over passive control is about 7%.

7. COLLAPSE FRAGILITY CURVES

A collapse fragility curve is the cumulative distribution function (CDF) which relates the intensity of ground motion to the probability of collapse, and is constructed utilizing the results of the IDAs (ATC 2009). For a prescribed level of spectral acceleration S_{aT_1} the number of cases, N_{SaT1}, where collapse occurs for a spectral acceleration equal to or less than this value of S_{aT_1} among the IDA curves for the various ground motions is counted. The probability of collapse associated with this value of S_{aT_1} is N_{SaT1}/N_{tot}, where N_{tot} is the total number of IDA curves (i.e., ground motions). The probability of collapse typically follows a lognormal distribution. A set of collapse data points can then be fitted using the lognormal distribution to construct the collapse fragility curve. The fitted lognormal distribution is defined by two parameters, namely, the median collapse spectral acceleration ($\hat{S}_{CT}$), and the standard deviation of the natural logarithm of the collapse spectral accelerations (ζ). The CDF with a lognormal distribution, $F(x)$, is mathematically expressed as

$$F(x) = \int_0^x \frac{1}{s\zeta\sqrt{2\pi}} \exp\left[-\frac{(\ln s-\lambda)^2}{2\zeta^2}\right] ds = \Phi\left(\frac{\ln x-\lambda}{\zeta}\right) \quad (2)$$

where, Φ is the cumulative distribution function of the standard normal distribution and $\lambda = \ln \hat{S}_{CT}$. Figure 11 compares the collapse fragility curves for passive control with the no damper case. The fragility curve for passive control is located to the right of the fragility curve for the no damper case, which means the collapse potential of the structure with passive control is lower than that for the structure with no dampers. This result is also illustrated in Table 4 by a comparison of the CMR values, where passive control has a higher CMR value. The collapse fragility curve for various semi-active control strategies are compared to the collapse fragility curve for passive control in Figures 12 through 15. The collapse fragility curves for the semi-active control strategies are shown to be similar to passive control, except for the LQR controller. The collapse fragility curve for the building with the LQR controller is more notably to the right of that for the passive control case (Figure 12) than for the other comparisons, indicating a lower probability of collapse compared to passive control, and consistent with having a higher CMR value in Table 4.

8. COLLAPSE MODE

The collapse mode of the building structure studied is characterized by the formation of plastic hinges in the beams and columns leading to a collapse mechanism. A soft story mechanism, where both ends of all columns at a particular story level develop plastic hinges, did not occur in any of the cases. The design methodology based on a strong column-weak beam design appears to have helped avoid a soft story collapse mechanism.

Figure 16 shows the deformed shape of the building with passively controlled MR dampers at the time of maximum drift under the 1994 Northridge earthquake (Canyon country, 000 component), where the ground motion was scaled to a spectral acceleration of S_{aT_1} =2.25g. Collapse for this ground motion occurs when S_{aT_1}=2.27g. Both ends of each beam in the 1st through 3rd floors in the MRF and the ground level of the 1st story columns for both the MRF and DBF form plastic hinges during the earthquake.

9. CONCLUSIONS

In this paper, the collapse potential of a 3-story steel frame building with MR dampers controlled by various control strategies was investigated. A model of the structure was developed using OpenSees that included strength and stiffness deterioration along with the P-Δ effect. Incremental dynamic analyses based on nonlinear time history earthquake simulations were performed to obtain the statistical response and collapse margin ratios (CMRs) for the structure. Five different control strategies for the MR dampers were used, and the collapse potential for each case was compared. The passive control of MR dampers with a 2.5A constant current input improved the CMR value by about 26% compared to the structure without MR dampers. The collapse fragility curves for sliding mode control, decentralized bang-bang control, and phase angle control resulted in almost the same collapse potential as passive control, while the LQR controller provided a reduction in the collapse potential. The CMR is about 7% greater for the structure with an LQR controller compared to passive control.

The LQR and SMC controllers require control gains to be specified. To reach more general conclusions about the seismic collapse potential of buildings with semi-active controlled MR dampers it is recommended that the effect of the control gains on the collapse potential be further investigated. In addition, other semi-active controllers and various structural geometries (e.g. the height of the building) should be included. The effect of a damper bottoming out on the collapse potential of structures with MR dampers also needs to be investigated.

Abstract: Building of new Generation III+ passively safe nuclear power plants (NPPs) and commercial development of Generation IV advanced reactor concepts has started. There are strong indications that NPP vendors are considering seismic response modification through base isolation and modular construction to achieve greater economy while maintaining or improving safety of the new plant designs. Seismic isolation has been used for conventional buildings and non-building structures for more than forty years. Advances in this technology (new materials, development of new motion isolation and damping devices, advances in combating aging, and improved analysis methods) support deployment of base isolation systems for nuclear facility structures. Modular construction using sandwich steel/concrete (S/C) composite walls, featuring steel plates that function as a stay-in-place form for concrete and reinforce it, has shown great promise for factory pre-fabrication, shipping and installation of large NPP modules simultaneously reducing construction time and increasing quality. Aspects of the risk-informed performance-based design codes and regulatory frameworks needed to successfully design and license NPPs featuring seismic isolation and S/C composite walls are discussed.

1. INTRODUCTION

Advanced technologies for structural design and construction have the potential for major impact not only on nuclear power plant construction time and cost, but also on the design process and on the safety, security and reliability of next generation of nuclear power plants. In future next-generation reactors structural and seismic design should be much more closely integrated with the design of nuclear and industrial safety systems, physical security systems, and international safeguards systems. Overall reliability will be increased through the use of replaceable and modular equipment, and through design to facilitate on-line monitoring, in-service inspection, maintenance, replacement, and decommissioning. Economics will also receive high design priority, through integrated engineering efforts to optimize building arrangements to minimize building heights and footprints. Finally, the licensing approach will be transformed by becoming increasingly performance based and technology neutral, using best-estimate simulation methods with uncertainty and margin quantification.

In this context, two structural engineering technologies, seismic base isolation and modular steel-plate/concrete (S/C) composite structural wall, are discussed. These technologies have major potential to 1) enable standardized reactor designs to be deployed across a wider range of sites; 2) reduce the impact of uncertainties related to site-specific seismic conditions; and 3) alleviate reactor equipment qualification requirements. Two principal hazards, the seismic hazard and the hazard of deliberate aircraft impact, must be considered. Aspects of the risk-informed performance-based design codes and regulatory frameworks needed to successfully design and license NPPs featuring seismic isolation and S/C composite walls are discussed.

2. SEISMIC ISOLATION

Seismic isolation is a civil/structural technology that enables engineered modification of the seismic response of a seismically isolated structure. Such response modification is accomplished by placing a seismic isolation system between the superstructure and its substructure. A seismic isolation system typically comprises seismic isolator units, structural elements that transfer forces to and from the isolator units, and their connections. Seismic isolator units are horizontally flexible structural elements designed to enable large lateral deformations of the isolation system under seismic loads. They may also be used as a part of the vertical load supporting system of the structure. Seismic isolation system may also include a wind load resisting system, a system of energy dissipation devices, and/or a displacement restraint system. Because the seismic isolator units are usually (but not necessarily) installed at the base of a structure, seismic isolation is often referred to as base isolation.

Seismic isolation changes the dynamics of the structure such that the dynamic response of the isolated

superstructures to seismic excitation is decoupled from that of its substructure (Naeim and Kelly, 1999). The decoupling is accomplished using one or a combination of the following two horizontal deformation mechanisms: shear deformation of a flexible device; and sliding on friction-controlled surfaces (Kelly, 1993). The flexible device mechanism works by introducing an additional natural vibration mode shape of the isolated structural system: this mode shape is orthogonal to the vibration mode shapes of the superstructure and thus works as a filter that minimizes the vibration of the isolated superstructure. The sliding mechanism limits the force to the level of friction generated between the sliding surfaces: it allows the isolated structure to move when inertia of the isolated superstructure exceeds the friction.

While the initiation of motion is different, both horizontal deformation mechanisms perform in a similar manner once the isolated superstructure is moving. They modify the dynamic response of the structure by making the fundamental horizontal-direction vibration period of the isolated structural system significantly longer than that of the original fixed-base (non-isolated) structure. This leads to significant reductions in the horizontal accelerations and inertial forces transmitted to the isolated superstructure during an earthquake compared to the traditional fixed-base structure. Making use of a typical seismic design spectrum and the fact that horizontal acceleration are roughly inversely proportional to the fundamental vibration period of the structure in the range of interest, it is evident that elongation of the fundamental vibration period achieved by seismic isolation is a very effective method of reducing inertial forces experienced by the isolated superstructure. Reduction of seismic loads in the superstructure offers another benefit: the superstructure can easily be engineered to be sufficiently strong and stiff to control its deformation and acceleration to acceptably small levels and thus protect its integrity and the integrity of the systems and components it contains. At the same time, the seismic isolation devices undergo large horizontal deformations: they are engineered to safely sustain such motions and thus protect the isolated superstructure.

2.1 Benefits of Seismic Isolation

A properly engineered seismically isolated superstructure will, with high confidence, be decoupled from the earthquake-induced motion of its foundation and experience significantly smaller inertial forces than if that same structure was fixed to its base in the same earthquake shaking event. The reduced forces make it easier to design the superstructure to remain essentially elastic: this, in turn, ensures that the deformations of the structure will remain small and in the acceptable range, improving its seismic performance and protecting the internal systems and components. The mechanical properties of seismic isolator units vary among different units produced in a series and change with time, but to a significantly lesser extent than the mechanical properties of other structural elements. Taken together, reduction in inertial forces and deformations experienced by the superstructure achieved by the seismic isolation system, and the repeatable performance of seismic isolator units, can substantially reduce the contribution of seismic hazard to the total probability of large radiation does release. This directly increases the safety margins of seismically isolated nuclear facilities. Seismic isolation can be custom-engineered to specific nuclear facility site characteristics, both with respect to site seismic hazard exposure and to local soil conditions and configurations. Engineering the substructure and the seismic isolation system provides an opportunity to engineer the isolated superstructure for essentially the same level of seismic demand regardless of the site characteristics. This, in turn, facilitates standardization of nuclear facility design and makes the seismic behavior of the isolated superstructure more predictable, leading to increased reliability of isolated nuclear facilities. Equally important, standardization facilitates regulatory review and design certification of seismically isolated nuclear facilities.

While seismic isolation adds a structural system between the substructure and superstructure, the added cost and complexity is very likely to be compensated for by the savings realized through the increase of safety margins despite the smaller strength, size and complexity of the superstructure. However, a significantly larger economy can be derived from simplified, standardized designs made to suite modular construction methodology. Today, modular construction is being implemented at the level of components and systems: use of seismic isolation enables expansion of the modular concept to the entire isolated superstructure and provides the all-important cost driver for use of seismic isolation in new nuclear power plants.

2.2 Challenges of Seismic Isolation

Use of seismic isolation systems brings about a number of challenges. Seismic hazard analysis for seismically isolated structures must consider the long fundamental vibration period of such structures, typically 2 seconds or longer. Thus, ground motion records must be filtered differently to provide reliable data in this long-period (low-frequency) range, ground motion attenuation relations must be developed accordingly, and design spectra and ground motion selection procedures must be modified. Maximum horizontal deformation of the isolator units occurs under combined effects of the horizontal components of ground motion and the relative eccentricity of the isolated superstructure with respect to the isolation system. Effect of the vertical motion of the isolated superstructure on the isolator units must be accounted for, regardless of the cause: overturning moment in the superstructure, ground motion in the vertical direction, or the rotational (rolling) components of the ground motions. Therefore, ground motion selection and scaling must account for all components of ground motion. Modeling of the response of seismically isolated structures must directly account for the three-dimensional non-linear behavior of seismic isolators under both design-basis and beyond-design-basis earthquake ground motions. This is particularly challenging for the traditional

frequency-domain methods used to evaluate the effects of soil-structure interaction on the structural demands and floor spectra. To overcome this challenge, it is imperative to develop effective time-domain non-linear modeling and analysis methods to account for soil-structure interaction between the foundation, the seismic isolation system, and the isolated superstructure, and to develop validated and verified models of the isolator units.

Non-redundancy of the seismic isolation system is a profound challenge. The seismic isolation system comprises a large number of essentially identical seismic isolation units that act in parallel. The performance of the seismic isolation system will not be significantly affected by failure of a one or even a few seismic isolation units or components. However, the seismic isolation layer connects the isolated superstructure to the substructure forming a series system. As such, the seismic isolation layer is not redundant. Therefore, engineering measures must be taken to prevent simultaneous or cascading failure of many seismic isolation units due to exceeding their deformation or force capacities. Such engineering measures include fail-safe system such as deformation limiters achieved by physical (bumpers, stoppers, walls) or mechanical (increasing isolator unit stiffness, slider breaks) means, and additional passive or semi-active dampers. These measures, when engaged, may result in impact and/or gradual increase in forces transmitted to the isolated superstructure. The engineering objective is to provide sufficient space for the isolation system to move without obstacles and for graceful degradation of the seismic isolation layer in extreme situations: a cliff-edge sudden seizure of its isolation function must be avoided.

This engineering objective is particularly challenging when another important beyond-design basis load is considered: aircraft impact. The U.S. Nuclear Regulatory Commission issued a final rule that requires new reactor applicants to assess the ability of their reactor designs to avoid or mitigate the effects of a large commercial aircraft impact (USNRC, 2009). The specific aircraft attributes the USNRC requires applicants to consider are considered to be "safeguarded" information and are restricted from public disclosure. To adequately represent the full range of possible impacts now and over a typical 60 to 100 year lifetime of a nuclear power plant, two airplanes are considered: the Boeing 747-400 and the Boeing 737-900. The Boeing 747 is one of the heaviest and fastest commercial airliners currently in use. While significant further evolution of aviation technology will occur over the typical 60 to 80 year lifetime of new nuclear power plants, the 747 provides a reasonable example for a very severe aircraft crash. Conversely, the 737 is one of the lighter commercial airliners in use, providing a reasonable lower bound for commercial aircraft collision loading. The loading functions for these two aircraft, developed using a method developed by Riera (1968) using the available data on the length, weight and possible impact velocity of the aircraft, are shown in Figure 1.

The deformation of the base isolation system when an aircraft impacts a seismically isolated nuclear facility structures depends on the ratio of the masses of the aircraft and the balance of the facility above the isolation layer. This is because the duration of the impact (about 0.3 sec) and the time when the structure attains peak acceleration is significantly shorter than the isolated period of the structure (about 2.0 sec), making the impulse momentum balance the primary determinant of peak post-impact isolation system displacement. Therefore, given that the mass of the model aircraft is constant, the displacement of the isolation system will be inversely proportional to the weight of the balance of the plant above isolation layer. In contrast, deformation of the isolation system under seismic loading depends on the fundamental period of the isolated system, making it, in general, directly proportional to the weight of the balance of the plant above the isolation layer. Therefore, deformation of the seismic isolation layer of a relatively light plant may be controlled by aircraft impact, while that of a relatively heavy plant is likely to be controlled by seismic demands. This situation is further complicated by the different seismicity in the West and the Central and Eastern US, and different estimates of the magnitude of beyond-design basis seismic demand.

3. STEEL/CONCRETE MODULAR WALLS

Conventional, fixed-base, nuclear power plant structures are constructed using the reinforced concrete structural shear wall elements to form the primary gravity and lateral load structural systems. In addition to their load-carrying ability, such walls offer good radiation protection, provide a satisfactory pressure barrier, and offer good fire resistance. The isolated superstructure and the foundations of seismically isolated nuclear power plants may also be constructed using this conventional technology.

The structural reinforced concrete shear walls are erected using the cast-in-place construction method. The forms for such walls are erected first. The reinforcement is placed into the forms, usually using pre-assembled reinforcement cages. Finally, the concrete is poured into the forms, vibrated into place, and left to cure to a strength that allows for removal of forms. While there is ample experience with such construction method in the industry, three obstacles still remain. One is the design of the forms to sustain the weight of the flowing concrete: this limits the height of the pouring lifts, thus constraining the speed of construction. Second is the time needed for concrete to cure to the level where forms can be removed to advance construction. Use of slip-forming for cylindrical walls can accelerate construction. And third is the need to completely remove the forms such that, over time, wood debris left behind does not cause unwanted corrosion. Liner corrosion problems have been observed at existing U.S. nuclear plants due to wood debris left during construction.

The solution for these construction problems is to use so called "stay-in-place" forms. Such forms are, by themselves, structural elements that are capable of sustaining the load of flowing concrete and additional formwork above the pour level. In addition, they can be composited with the poured

concrete to become part of the larger structural element. Stay-in-place forms can, furthermore, be pre-fabricated and pre-assembled into large modules, enabling significant speedup in construction.

Stay-in-place forms have been made using a variety of materials. It is not uncommon to use thin reinforced concrete plate elements, or plates made of fiber-reinforced mortars or polymer composites to form structural walls and leave them in place. However, the most common material used for stay-in-place forms is steel plate. Steel plates forms can be pre-fabricated as modules of significant size, lifted and assembled into place, and welded at the contacting seams before additional reinforcement is placed into them (if needed). The concrete pour is then the same as in conventionally-formed walls.

3.1 Benefits of S/C Modular Construction

The principal advantage of steel stay-in-place forms is that the form steel can be composited with the interior concrete to form a composite steel-concrete structural element. Steel studs, steel through-bars and/or light steel frames can be used to achieve the composite action between steel and concrete. In addition, stiffeners are used to stiffen the steel plates such that they can sustain the hydrostatic pressure of flowing concrete and maintain their form. Steel-concrete composite construction is regulated by structural design code documents: ASCE 7-05 for design of composite structural systems, and ANSI/AISC 360-05 and ANSI/AISC 341-05 for design of composite structural elements for non-seismic and seismic applications, respectively. However, the existing US design provisions do not cover composite steel plate shear walls where structural concrete is encased by steel plates and the bond between steel and concrete is maintained to ensure composite load carrying action. Research to support the provisions proposed for the next edition of the AISC code is ongoing.

Additional advantage of stay-in-place steel forms is the ability to pre-fabricate large and complex modules. Using ship-building techniques, modules comprising a variety of structural openings, corners and attachments can be pre-fabricated in a controlled factory environment and shipped to the construction site. The only limit is the shipping and lift-and-place capability. Such modules can pre inspected at the construction yard and match-assembled to ensure easy installation and welding on site (a technique long-used in long-span bridge construction).

The final advantage of S/C modular walls is their ability to resist penetration of missiles and parts of aircraft engine better than conventionally reinforced walls.

3.2 Challenges of S/C Modular Construction

Steel-plate/concrete construction has been identified as a very promising technology for construction of new nuclear power plants (Schlaseman, 2004). However, while earlier experience exists with BWRs, this technology still entails significant challenges.

The first group of challenges concerns the design and modeling of steel-plate/concrete walls. The experimental data available for such walls has been obtained by testing scaled-down specimens, with overall thickness between 100mm and 300mm and steel plate thickness between 2mm and 6mm. The prototype wall thicknesses are larger than 1,000mm while the plate thicknesses remain between 6mm and 12mm. Recognizing that full-scale test may not be possible using the existing structural laboratories, more tests on correctly scaled specimens are needed to establish the benchmarks for calibrating computer models for thick steel-plate/concrete walls. That said, the existing computer models for composite steel concrete structures need to be validated for situations where structural shapes are used to tie the two plates together, to carry the bi-axial shears, and where studs are provided to prevent the thin liner plates from debonding during pouring or unexpected internal out-gassing pressures. For limitation of buckling the studs also play a useful role because only a small amount of support is needed to prevent buckling from occuring.

The second group of challenges concerns construction of steel/plate composite walls. While construction of the wall itself is made much easier, implementation of the wall-to-floor connections is challenging. Design and construction of structural connections between steel-plate/concrete and conventional reinforced concrete elements has not been extensively studied. Finally, implementation and anchoring of piping and equipment attachments to the steel skin of steel-plate/concrete walls remains an important design issue.

The third group of challenges concerns inspection and service of steel/plate composite walls over the life of the nuclear power plant. It is universally recognized that the composite walls offer superior resistance to extreme loading conditions, such as aircraft impact and earthquake loading. Under impact, the steel skin increases the resistance of the wall to local perforation, scabbing and penetration (shear cone punching) compared to conventional reinforced concrete walls. Under earthquake loading, properly designed steel-plate/concrete walls (with details to delay elephant-foot buckling and formation of buckled compression diagonals) should be significantly more ductile than the correspondingly reinforced conventional reinforced concrete walls. However, long-term degradation of steel-plate/concrete walls is not fully understood, although experience exists with steel liners commonly used on the internal surfaces of reactor containments. The exposed steel plates may need to be protected against corrosion. Inspection methods to establish the conditions of inaccessible portions of the walls have not been evaluated, particularly concerning the state of bond between steel plates and concrete. Behavior of such walls under elevated temperatures during accidents and fires has not been studied at the size and scale used in nuclear power plants.

Finally, the forth group of challenges concerns decommissioning of nuclear power plants after the end of their service life. Methods for effective deconstruction of the steel-plate/concrete walls have not been investigated. In particular, it is not clear how to deal with portions of such walls that may be irradiated or otherwise contaminated

during the regular service life of a nuclear power plant.

4. PERFORMANCE-BASED DESIGN AND EVALUATION FRAMEWORK

A framework, a consistent set of requirements and guidelines for design and regulatory approval, is needed to successfully design seismically isolated nuclear power plant structures. The framework proposed in this paper builds on the design framework for conventional seismically isolated structures defined in Chapter 17 of ASCE 7-10 (ASCE 2010), on the design objectives for nuclear facility structures contained in ASCE 43-05 (ASCE, 2006), and on design provisions proposed for the upcoming ASCE 4-11 (ASCE 2011) standard.

The proposed framework is performance-based, and applies to both seismic isolation and composite steel/concrete wall construction. It comprises the following phases: 1) setting the performance objectives; 2) preliminary design for seismic and aircraft impact loads; 3) design, manufacturing and prototype testing consistent with the requirements for prototype testing for conventional facilities; 4) detailed modeling of the NPP structure; 5) evaluation of the design-basis and beyond-design-basis performance of the structure under seismic and aircraft impact loads; 6) specification of quality acceptance and quality control for manufacturing and installation; and 7) specification of in-service monitoring procedures and alert levels.

4.1 Performance Objectives

ASCE 43-05 defines five Seismic Design Categories (SDC). Categories 3, 4 and 5 are associated with nuclear facility structures, systems and components through ANSI/ANS 2.26. ASCE 43-05 defines four Limit States based on structural deformations to describe levels of acceptable structural damage. These damage states range from significant damage with a structure close to collapse (state A) to no significant damage with a structure in operational condition (state D). The performance objective for a seismically isolated nuclear power plant structure is SDC5-D. ASCE 43-05 also defines the Design Basis Earthquake (DBE) using a Probabilistic Seismic Hazard Assessment (PSHA) to derive a Uniform (or Equal) Hazard Response Spectrum (UHRS) for the site and modifies it further using a Design Factor. The Design Factor is calibrated to achieve a mean annual seismic core damage frequency of 10-6 considering the failure probabilities inherent to current design codes and the design goal proposed in ASCE 43-05 (Kennedy, 2007). The design goal for structural components not explicitly covered in ASCE 43-05 is to *reasonably* achieve both of the following design objectives (Section 2.0 of ASCE 43-05):

1. Less than 1% probability of unacceptable performance for the DBE ground motion (defined in).
2. Less than 10% probability of unacceptable performance for 150% of the DBE ground motion (defined in Section 2.0 of ASCE 43-05).

Acceptable performance for structural framing such as concrete shear walls and moment frames typically found in nuclear power plant structures is described as "essentially elastic behavior." This performance objective can be extended to S/C modular walls. In addition, the response of the S/C walls in beyond-design-base load cases should not exhibit a cliff-edge effect, i.e. the response should be ductile and degrade gracefully without sudden local fractures or instabilities that induce significant redistributions of the applied load among the S/C wall resistance mechanisms. A principal method for achieving such behavior is the provision of sufficient connectivity between the steel skin plates. Ongoing research is addressing this issue starting from the minimum transverse reinforcement requirements for conventional reinforced concrete walls.

Acceptable performance of the seismically isolated structure is defined through acceptable behavior of its components. The foundation and the seismically isolated superstructure are expected to remain in ASCE 43-05 state D, i.e. "essentially elastic". The structures, systems and components are expected to remain operational in case of impact generated by failure of the seismic isolation system. The seismic isolation system is expected to also develop no significant damage and remain in operational condition (state D). This means that the structural elements framing the seismic isolation system (the foundation and the isolation diaphragms) must remain "essentially elastic" and capable of distributing and transferring the gravity and ordinary lateral loads even if some of the seismic isolator units fail. Unacceptable performance of the seismic isolator units under seismic and aircraft impact loads is defined as:

1. Permanent damage to the seismic isolator unit, such as tearing, buckling or disassembly, that prevents it from functioning as intended;
2. Excedance of the design displacement limit of the seismic isolator unit.

It is important to note that ASCE 43-05 is calibrated to the mean annual frequency. US NRC requires a design to achieve high confidence of low probability of failure (HCLPF).

4.2 Preliminary Design

A preliminary assessment of seismically isolated nuclear structures for design basis and beyond-design basis ground motions at three different sites has recently been conducted by Huang, Whittaker, Kennedy and Mayes (Huang et.al, 2009). The main outcome of this study is a triplet of performance statements aimed at achieving the two ASCE 43-05 probability-based design goals. Namely:

1. Individual isolators shall suffer no damage in DBE shaking.
2. The probability of the isolated nuclear structure impacting the surrounding structure (moat) for 100% (150%) DBE shaking is 1% (10%) or less.
3. Individual isolators shall sustain gravity and earthquake-induced axial loads at 90th percentile lateral displacements consistent with 150% DBE shaking.

These performance statements, derived for seismic loading, are extended to aircraft impact loading by

considering it as beyond-design basis event in the same category as the 150% DBE event. Preliminary design of the seismic isolator units can be conducted using the following procedure. A target isolation system horizontal fundamental vibration period can be at least 4 times longer than the fundamental vibration period of the isolated superstructure, and outside any regions where UHRS has an unusual amplification. Typical values are between 2 and 4 seconds. A target characteristic horizontal strength of the isolation system may be between 3% and 9% of the weight of the isolated superstructure. These values are based on the ranges of parameters considered in (Huang et.al, 2009). A target effective damping may be between 15% and 20% of critical damping (Naeim and Kelly, 1999).

Performance statements 1 and 2 can be utilized for preliminary assessment of the design displacement of the seismic isolator unit. To do this, a stick model representing the principal mass and stiffness characteristics of the isolated superstructure should be combined with a model of the seismic isolator unit capable of representing the force-deformation response of the unit in two horizontal directions. Best-estimate values for mechanical properties of the units should be used at this stage. Huang et.al (2009) find that the seismic displacement with a 10% exceedance probability in 150% DBE shaking governs the design. Using their Approach I, select or generate 11 seed three-component ground motions to appropriately represent the site conditions and the controlling hazard, spectrally match these motions to the DBE spectra, perform 11 non-linear response history analyses, compute the vector-sum maximum displacement of the seismic isolator units in each analysis and then find the median value of these maxima. Multiply this median value by 3 to determine the seismic design displacement of the isolator unit. The aircraft impact displacement can be computed using the same computer model of the facility used for preliminary seismic analysis and the aircraft impact load models including the USNRC aircraft impact model. The obtained aircraft impact displacements are expected to represent the mean and HCLPF displacements, respectively. The mean aircraft impact and the mean seismic displacements of the isolation system should be compared to determine the governing displacement for the next design phase. A procedure suggested in (Naeim and Kelly, 1999) or in (Buckle, 2006) can be used to compute the remaining properties of the seismic isolator unit and to design the unit. Using a procedure suggested in (Naeim and Kelly, 1999), a manufacturer should be selected and a proof-test isolator unit should be manufactured. The proof-test should be conducted using a test procedure suggested in (Buckle, 2006).

Preliminary design of S/C modular walls should be conducted using the minimum design provisions for conventional reinforced concrete structures and the current design provisions for composite steel/concrete structures. These provisions will provide the designer with the fundamental estimates of the thickness of the steel plates and the amount of steel needed to connect the steel plates and resist the seismic and aircraft impact shear. The thickness of the S/C wall will be governed by aircraft impact demands and by the demands to transfer the forces at the connections between the S/C and conventional R/C walls and/or foundations. US code provisions for verification of such designs are under development.

4.3 Modeling and Evaluation

Design of the seismic isolation system may also include design of supplemental dampers intended to further reduce design displacements, vertical restraint or isolation devices, and fail-safe devices intended to reduce or eliminate adverse consequence of superstructure impact on the surrounding soil or structure. A detailed model of the seismically isolated nuclear power plant can then be made. This model should be used to evaluate the response of the nuclear power plant structure under design and beyond-design basis earthquake shaking and aircraft impact. The limit states associated with the seismic isolation system include (but are not limited to): 1) failure of isolator units due to exceedance of design displacement; 2) failure due to tearing or instability such as buckling, rollout or disassembly; 3) impact of the isolated superstructure against the isolation mote; 4) vertical motion and uplift due to ground motion, and overturning or rocking due to aircraft impact; 5) local failure of the S/C walls due to in-plane bending or out-of-plane shear forces; 6) failure of connections between S/C walls and other conventional structural elements; 7) local penetration failure of the S/C wall; and 8) global or partial collapse of the S/C wall due to aircraft impact.

The challenge posed by seismic isolation response modification technology is that the seismic isolator units are expected, and relied upon in design, to behave in a non-linear manner during design-basis and beyond-design-basis earthquake shaking. Even though the isolated superstructure is expected to remain essentially elastic (and can be modeled assuming it remains within its elastic response range), and the soil and the foundation may behave in a manner such that they can be modeled using equivalent elastic properties, the seismic isolator units must be modeled as non-linear using a model capable of accurately computing the isolator force-deformation response under bi-directional horizontal excitation. Even such relatively simple non-linear models cannot be linearized with sufficient accuracy to represent the response of the seismically isolated structure over the range of excitations of interest. Yet, it is likely that more sophisticated models of seismic isolators and other devices, such as dampers and displacement restrainers if used in design, will be needed to demonstrate satisfactory performance of the seismically isolated structure with the high confidence required by licensing regulators.

Development of verified and validated tools for time-domain non-linear analysis of seismically isolated S/C modular structures and soil is on the critical path for successful design and licensing of new seismically isolated nuclear power plants. Such tools should include sophisticated 3-directional interaction models of seismic isolators, models of contact, uplift and impact, non-linear models of S/C walls, and non-linear models of soil. Ideally,

such models should enable propagation of seismic wave excitation from the source (or rock layer), eliminating the need for additional software. Finally, these tools should enable non-linear modeling of the response of the isolated superstructure capable of capturing its response in higher vibration modes, propagation of horizontal and vertical excitation through the isolation system and into the structure, and the corresponding floor response spectra to enable coupling to equipment fragility evaluation. The time scales of the response quantities of interest span approximately three orders of magnitude (0.1Hz to 10 Hz). The dimensions of the model elements also span roughly four orders of magnitude (0.1m to 100m). Even without non-linear behavior, the time and length scales present a significant challenge for development and implementation of efficient and accurate solution algorithms. Nevertheless, some of solid finite element software package used by industry today can handle such complex problems. But, then need to be verified and validate for use for seismically isolated structures, and sped-up, simplified and hardened for use in design practice.

5. CONCLUSIONS

Seismic isolation response modification and compsite steel/concrete modular structural wall technologies are mature and ready for application in safety critical nuclear power plants. The benefits of using these technologies (improved safety, reliability and economy) clearly outweigh the challenges. Three major issues are on the critical path for adoption of these new technologies in nuclear engineering practice and regulation. The first is the development of the regulatory guidelines to define the way seismically isolated and S/C modular nuclear power plant license applications are going to be evaluated. Work in this direction is ongoing. The second is the development of practical non-linear seismic and aircraft impact soil-structure interaction response analysis of the seismically isolated S/C modular nuclear power plants. Research in this direction is starting. Third is the work by vendors to develop seismically isolated S/C modular nuclear power plant designs and the willingness of the utilities to support the licensing process of the first such license application. The risk for such first movers is significant, but taking this risk on is essential.

Abstract: In this study a damper called three-pin steel damper was developed. The experimental results showed that the energy dissipation mechanism was stable with a large area of hysteresis loops while it can eliminate the defects of the X type and the triangular type steel damper called ADAS. A 14-story RC building structure was designed and installed with the damper. The nonlinear dynamic responses of the designed RC structures were conducted to investigate the effectiveness of the developed damper using the earthquake records of Taipei Basin and SAP 2000. The results demonstrated that the use of developed dampers is effective in reducing the seismic responses. From the results obtained for all the cases investigated, the maximum reduction in story ductility ratio is 70% and that in story drift ratio is 54%.

1. INTRODUCTION

Different measures have been proposed over the last years to reduce the responses of the structures subjected to earthquakes and one of them is to use energy dissipation device called damper which is developed by exploiting the stable hysteretic behavior of the selected material. The main philosophy of using dampers is to dissipate the input energy by dampers not by the inelastic behavior of the primary structural members.

Among many types of energy dissipation device proposed is the type called steel plate damper which uses the steel's stable hysteretic behavior to dissipate the input energy. Added Damping and Stiffness device (ADAS) is a mechanical device made of steel plates with X or triangular shape and assembled with bolts and/or welds to end blocks, the top of which is connected to girder while the end block is attached to the brace members. Investigations (Su, 1992; Chen, 1994; Juang et al., 2001) have demonstrated that ADAS can provide initial stiffness and stable and large hysteretic energy dissipation capability, leading to the effective reduction in structural responses. Other types of steel damper such as shear-panel damper (Masayoshi and Satoshi, 1994; Masatoshi et al., 1995) and damper with honeycomb-shapes opening (Naoki, et al., 1989) also showed the effectiveness of steel plate dampers.

For the previous steel dampers, they must be installed on bracing members within a panel. In this paper a new device called three-pin steel damper is developed which can be installed on a separated wall within a panel/.

2. THREE-PIN STEEL DAMPER

2.1 Geometrical Shape

Figure 1 shows the sketch of the developed three-pin steel damper. When the three-pin steel dampers are used, they are always in pairs and connected using pins at locations A, B and C. As compared with the previous steel dampers, such hinge-type connections lead to easy manufacture and avoidance of effect of welding quality. In the figure, b is the width of any cross section between the cross sections AA and BB and h is the distance of this cross section to the pin at the end pin on the same side. The width b varies with the distance h such that $bh^{-0.5}$ remains constant. Two types of three-pin steel damper were initially developed on the basis of predicted location of breakage. Type A damper is designed to ensure that the steel damper remains elastic behavior at the location of pin connections and the breakage occurs at some distance from the center pin as shown in Figure 2. Type B damper, on the other hand, is designed to let the plastic zone be developed near the center pin and the breakage extends from the edge of the steel damper to the center pin as shown in Figure 3.

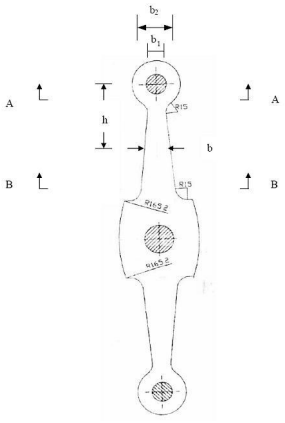

Figure 1 Sketch of three-pin steel damper

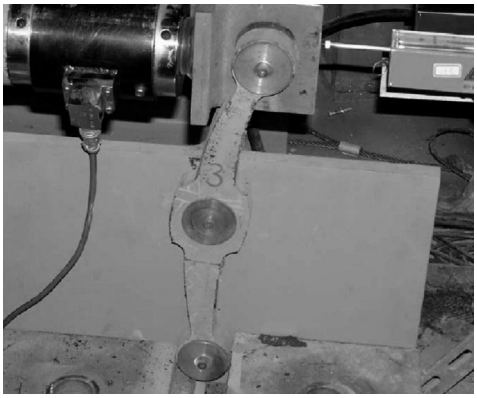

Figure 2 Failure of Type A damper

Figure 3 Failure of Type B damper

2.2 Experimental Results and Numerical Simulations

For type A damper, the experiments were conducted for a pair only as shown in Figure 4. The displacement-control cyclic tests were performed for displacements of 20mm, 30mm, 40mm, 50mm and 60mm, respectively. Figure 5 shows the number of cycles before failure. It can be seen that the number of cycles leading to failure decreases with increasing displacement. Since the code requires that the number of cycles before the failure must be greater than 5, we took the 50mm as the ultimate displacement for the developed steel damper.

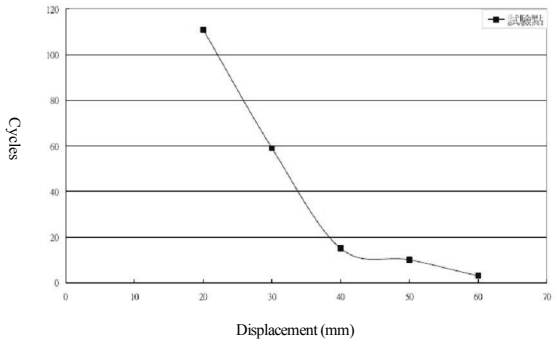

Figure 5 Cycles of loading before failure

For type B damper the experiments were conducted for 10 dampers (5 pairs) as shown in Figure 6. The displacement-control cyclic tests were performed for displacements of 12.5mm, 25m, 37.5mm and 50mm respectively. The results shown in Figure 7 show the stable hysteretic loop and no signs of decrease in strength.

Since the effectiveness of the three-pin steel damper on the reduction of seismic responses of structures will be investigated using SAP2000, a constitutive relation for numerical analysis must be developed for the three-pin steel damper. In this study the three-pin steel damper is modeled as a link member with bilinear constitutive relation and to fully describe the hysteretic behavior, the parameters required are initial stiffness (K), yield strength (P_y), post yield ratio (R) and yielding exponent (E) which is the curvature at the junction of bilinear model. The SAP2000

was used to determine these parameters. For type B damper, the parametric values obtained are P_y=490.5 kN, K=882.9kN/mm, R=0.005 and E=2. Figure 8 compares the experimental results and numerical simulations (smooth curves) for the type B damper. Since the arrangement of the dampers are in parallel, the parametric values for each pair of damper are P_y=98.1kN, K=176.58kN/mm, R=0.005 and E=2. These values were used for the study on the effectiveness of the three-pin steel damper on the reduction of seismic responses of structures.

3. DISCUSSIONS OF ANALYSIS RESULTS

To investigate the effectiveness of three-pin steel damper, a 14-story reinforced concrete building was designed according to the design code of Taiwan and the design spectrum of Zone III of Taipei basin. The building has three bays in each direction and each bay has a length of 8m. The height of first story is 5.4m and all the other floors have the same height of 3.4m with a total building height of 49.l6m. Detailed information about this building can be found in (Tang, 2010). To install the three-pin steel dampers, within a panel a wall-type column is constructed between the beams at the top and the bottom and cut into two parts with a distance of 500mm apart vertically which is used for the installation. The thickness of the wall is 300mm the horizontal length is 1300mm in this study. In this study the three-pin steel damper consists of 7 pairs at each location and is installed up to 11th floor.

The analyses were conducted by simplifying the building as a stick model where each story is modeled as a link member as shown in Figure 9. The pushover analysis was performed to obtain the relation between the story shear and the story displacement. With this relation and the selection of Takeda model, the hysteresis relation was set up by the SAP 2000 which was then used for the seismic analyses of reinforced concrete building. For three-pin steel damper, it was models as a link with P_y=2774kN, K=4944.24kN/mm, R=0.005 and E=2.

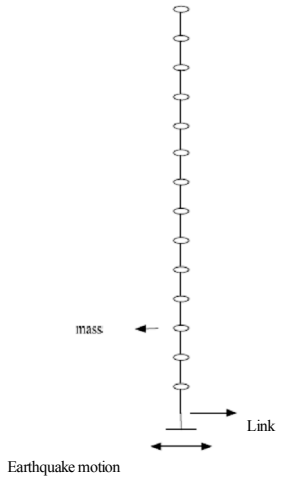

Figure 9 Building model for analysis

The ChiChi earthquake recorded in Taipei basin denoted as TAP013, TAP014, TAP090 and TAP100 were adopted for the analyses. Both the peak ground velocity (PGV) of the NS and EW components of the selected records were normalized to have PGV= 250mm/sec (PGV25), 500mm/sec (PGV50) and 750mm/sec (PGV75). However, in the following discussions only the results using TAP090, located in zone III of Taipei basin, as input will be presented.

Figures 10 and 11 show the story ductility ratios for each component of earthquake motion, respectively. Shown in Figures 12 and 13 are the story drift ratios for each component of earthquake motion, respectively. It can be seen that the use of three-pin steel damper can lead to the reduction in both story ductility ratios and the story drift ratios. The amount of reduction increases with increasing PGV with maximum of reduction of 63% for story ductility ratio and of 53.1% for story drift ratio.

4. CONCLUSIONS

In this study a damper called three-pin steel damper was developed. The experimental results showed that the energy dissipation mechanism was stable with a large area of hysteresis loops while it can eliminate the defects of the X type and the triangular type steel damper called ADAS. 14-story RC building structures were designed with or without installing the damper. The nonlinear dynamic responses of the designed RC structures were conducted to investigate the effectiveness of the developed damper using the earthquake records of Taipei Basin and SAP 2000. The results demonstrated that the use of developed dampers is effective in reducing the seismic responses. From the results obtained for all the cases investigated, the maximum reduction in story ductility ratio is 70% and that in story drift ratio is 54%.

Abstract: During the 2008 Wenchuan earthquake China, a 6-story RC frame structure located in Dujiangyan city sustained serious damage at the bottom story, which served as a parking area, whereas the upper stories were almost undamaged. To retrofit the structure, the seismic isolation technology was applied. The bottom columns were restored and strengthened, and lead rubber bearings were installed at the top of these columns. The soft story of the structure was replaced to an isolation story, and the function of the bottom story was recovered. This paper reviews the state-of-the-practice of Chinese design of seismic isolation and presents the retrofit of the 6-story structure as an example. Major conclusions obtained in this study are as follows: (1) Chinese design of seismic isolation is getting mature; (2) seismic isolation technology is effective in the retrofit of the soft story structures damaged in the earthquakes.

1. INTRODUCTION

A strong earthquake with a magnitude of 8.0 hit Wenchuan of Sichuan province, China in 2008. A huge number of buildings were damaged in the earthquake, leading heavy casualties and property losses. Post-earthquake investigation showed that serious damages at the bottom story were quite common for reinforced concrete frames as shown in Fig. 1 (Lin et al. 2009). This is mainly because that the bottom story, commonly used as a sales area or parking, has less infill wall, leading the story essentially a weak story. Thanks to the damage of the bottom story, which played a role as an isolated story, the upper stories were "protected".

Figure 1 Serious Damage at Bottom Soft Story

To retrofit the structures, the stiffness and strength of the bottom story will be significantly increased if using conventional methods, such as adding shear walls or enlarger the columns, commonly cost much, and also affect the functionality of the original structure. On the other hand, a large number of regions affected in the Wenchuan earthquake increase their earthquake fortification intensity, meaning that the seismic forces considered in these regions are enlarged after the earthquake. The damaged structure should be retrofitted according to the new earthquake fortification intensity, and the "protected" upper stories should also be strengthened if using the conventional retrofit methods. Strengthening these upper stories costs even more.

Seismic isolation technology was considered for the retrofit of the structures. Specifically, the bottom story columns were restored and strengthened, seismic isolators were installed on the tops of the columns, and the bottom story was changed to a seismic isolation story. Compared to the conventional retrofit methods, the retrofit method using seismic isolation has significant advantages: (1) it enhances the earthquake resistant capability of the entire structures without strengthening the upper stories; (2) it maintains the functionality of the bottom story as parking or sales areas; (3) it provides better protection to the contents of the structures in addition to the structures themselves; (4) it cost much less than the conventional retrofit methods. (National Standard of China, 2001)

The seismic isolation has been applied to the retrofit of building structure for many years in some oversea countries. The earliest case is the Salt Lake Mansion in USA, which was built in 1894, suffered partial failure in an earthquake in 1934, and was retrofitted in 1989 (Xu et al. 2001). However, retrofit using seismic isolation is still rather rare in China. This paper mainly briefs Chinese design practise of seismic isolation buildings and explains a specific design of a building that sustains soft story damage in the Wenchuan earthquake as an example.

2. CHINESE DESIGN PRACTICE FOR SEISMIC ISOLATED BUILDING

2.1 Performance targets

Three levels of earthquakes are considered in Chinese structure design practice, i.e. frequent earthquake, local fortification intensity earthquake, and rare earthquake. The three levels of earthquakes have return periods of about 50, 475, and 2000 years, respectively, corresponding to the three levels of earthquakes, the seismic fortification targets of buildings are as follows: (1) When subjected to frequent earthquakes, the buildings should sustain no damage or only slight damage, and be serviceable without repair. (2) When subjected to local fortification intensity earthquakes, the buildings are allowed for some damage but should be serviceable after ordinary repair or without repair. (3) When subjected to rare earthquake, the buildings shall neither collapse nor suffer severe damage that can endanger human lives.

To achieve the design targets, two stages of design are conducted: (1) First stage design is to ensure the seismic performance of buildings under frequent earthquakes. Essentially a Load and Resistance Factor Design method is applied in this stage. Structure members are designed, and story drifts are checked. (2) Second stage design is to ensure the seismic performance of buildings under rare earthquakes. Detailing design and story drift control under rare earthquakes are considered in this stage.

According to Chinese seismic design code issued in 2001, the seismic isolation structures under the frequent, fortification and rare earthquakes shall meet the requirements higher than conventional structures. Such provisions imply enhanced performance requirements for base-isolation compared to the general design of structures in China. In the release of 2008 Chinese seismic design code, the provision is removed, meaning that the seismic isolation structures do not have to use higher performance standard. This is particularly to promote the application of seismic isolation after the Wenchuan earthquake.

2.2 Ground Motions

In Chinese design practise, nonlinear time history analyses are recommended for seismic isolation structures. According to the seismic design code, at least 2 sets of real ground motions and 1 set of synthetic ground motion shall be selected based on the design spectra. Their average seismic response spectra shall be in conformity with the seismic spectra given in the code. The peak ground accelerations (PGAs) for the ground motions are adjusted according to the values given in Table 1. The linear elastic time-history analyses should be applied to justify the selection of the ground motion before the nonlinear analyses. The structure base shear obtained from each ground motion shall not be less than 65% of that from the response spectrum method, and the average value from the three ground motions shall not be less than 80% of that from the response spectrum method.

Table 1 Peak ground accelerations (PGAs) for time-history analysis (cm/s^2)

Seismic Fortification Intensity	6	7	7.5	8	8.5	9
Frequently earthquake	18	35	55	70	110	140
Rare earthquake	-	220	310	400	510	620

2.3 Common Design Procedure

As shown in Fig. 2, the design of seismic isolation structure mainly commonly adopts the following four steps, i.e. design of super-structure, design of base-isolation layer, validation of superstructure design, and design of base structure and foundation, with step 1 to 3 conducted in an iterative manner.

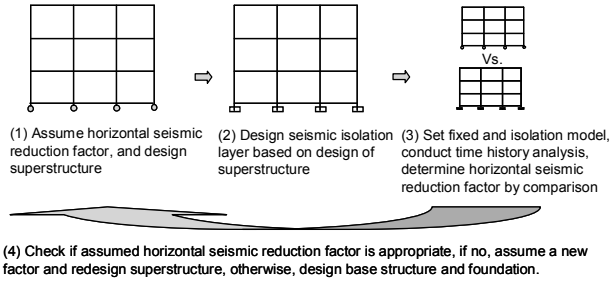

Figure 2 Flow chart for design of seismic isolation buildings

(1) The superstructure is first to be designed. In Chinese design practise, the seismic forces of the superstructure adopt the multiplication of the seismic force for the non seismic isolation structure and the seismic reduction factor. The seismic reduction factor is assumed to be a specific value, e.g. 0.5, in the beginning. Once the seismic forces are determined, the superstructure can be designed by following the design method for conventional structures.

(2) The base-isolation layer is then designed. For the design of seismic isolation layer, the following major issues are considered: the ratio of the fixed-base period to the base-isolated period of the structure is recommended to be greater than three to achieve an effective reduction of the earthquake demands. The isolator configuration is determined by the gravitational loads. The vertical average stress of the isolators is set to be about 10 to 15N/mm2. The number of dampers is assessed in order to obtain an equivalent damping for rare earthquake of about 15% to 20% to control the maximum lateral deformation of seismic isolation layer. Hysteretic dampers, if used, are designed to resist the frequent lateral loads in the elastic domain. The common yield threshold of the hysteretic dampers is commonly in the range of 3% to 5% of the weight of the structure. The maximum displacement of the isolation layer for rare earthquake should not exceed the limit, which is specified as the maximum of 0.55 times diameter and 3.0 times total rubber thickness of the rubber bearings.

(3) The seismic reduction factor assumed in Step (1) need to be validated after the superstructure and base-isolation layer are determined. Two models, i.e. seismic isolation and non seismic isolation models are established, and time history analyses are conducted. The seismic reduced factor is determined according to Table 2 and depends upon the maximum ratio of isolated story shear forces to non-isolated story shears forces, in of all stories. The horizontal seismic reduction factor shall not be smaller than 0.25. The difference between horizontal seismic reduction factor and maximum ratio of story shear forces is considered as the safety margin. If the seismic reduction factor obtained in this step is larger or too much smaller than that assumed in Step (1), the superstructure and the base-isolation layer need to be redesigned.

(4) The design of base structure and foundation is preceded after the design of the superstructure and seismic isolation layer is completed. The design is similar to conventional structures, but the vertical force, horizontal force and moment of force at the bottom of the isolators under rare earthquake, which are transferred from the superstructure, should be considered.

Table 2 Relation of the maximum ratio of story shear force and the horizontal seismic reduced factor

Maximum ratio of story shear force	0.53	0.35	0.26	0. 18
Horizontal seismic-reduced factor	0.75	0.50	0.38	0.25

3. APPLICATION EXAMPLE

3.1 Structure Brief

As shown in Fig. 3, the example building is a 6-story RC-frame structure located in Dujiangyan City, with a height of 21.22m and a floor area of 5400m2. The first floor is used as a parking place thus having no infill walls and its upper stories are apartments with both horizontal and vertical infill walls. Concrete C30 is used in this frame, and HRB335 is used in longitudinal reinforcement. Cross-sections of the column are ranged from 650mm × 450mm to 400mm × 400mm along the height; and those of the beams are 720mm × 250mm in short direction, and 620mm × 200mm in long direction. The thickness of slab is 120mm, and 240mm of wall.

During the Wenchuan earthquake, the bottom story was seriously damaged (refer to Fig. 4). The plastic hinges occurred at the ends of columns, and the maximum residual displacement was over 200mm corresponding to a story drift angle of 1/15. However, the upper stories were almost untouched. In addition, the earthquake intensity of Dujiangyan City was increased from intensity 7 to 8. Accordingly, the design spectra of the city got doubled. The maximum value of the design spectra was changed from 0.04g to 0.08g for frequent earthquake, and from 0.08g to 0.16g for rare earthquake. The seismic design group of the city, which represents the distance from the epicenter of possible earthquake, is changed from Group 1 to Group 2. The site class for the building, which is determined according to the equivalent shear-wave velocity and the overlaying depth of soil profile, is Site Class 2. The design characteristic period of the ground motions for this building is 0.4s.

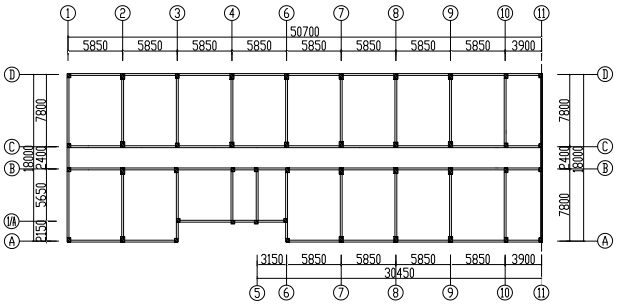

Figure 3 Structure plane

Figure 4 Damages of bottom columns

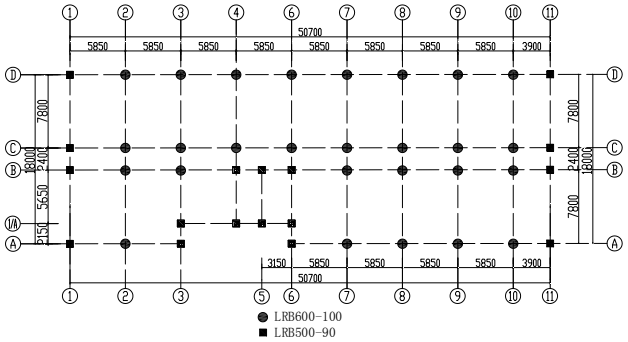

Figure 5 Arrangement of seismic isolator

3.2 Retrofit Using Seismic Isolation

Seismic-isolation technology is applied to the retrofit of this building. The retrofit procedure is considered as follows: (1) enlarge the columns of the bottom story; (2) jack the superstructure above the second floor, and cut the columns of bottom story at the top; (3) install slide bearings, and restore the structure to the original position; (4) replace the slide bearings with rubber bearings. As shown in Fig. 5, two types of lead rubber bearings are adopted in this project, i.e. LRB500-90 and LRB600-100. The rubber bearings are carefully arranged so that the stiffness and the mass centres match well.

The equivalent damping ratios at 100% horizontal deformation are 23.9% and 21.9%, respectively. The second shape factors are 5.00 for both two types of rubber bearings. The rubber bearings are set at the top of columns at the first story. The compressive stresses when subjected to 1.0 times

Dead Load plus 1.0 times Live Load are less than 12MPa, the limit for allowable long term compressive forces.

3.3 Computational Model

In this project, a structure analysis program called SAP2000 is used for the time history analyses. As shown in Fig. 6, two models are built: one is for the original structure. It uses a mass-spring model, in which each story is represented by a mass and a spring. The other is for the building after seismic isolation. In this model, a nonlinear LINK element, provided by SAP2000, is used to represent the rubber bearings. The isolation layer is modelled in detail, and the eccentricities of the superstructure are also carefully modelled, so that the torsion effect on the displacement of the seismic isolation layer can be taken into account.

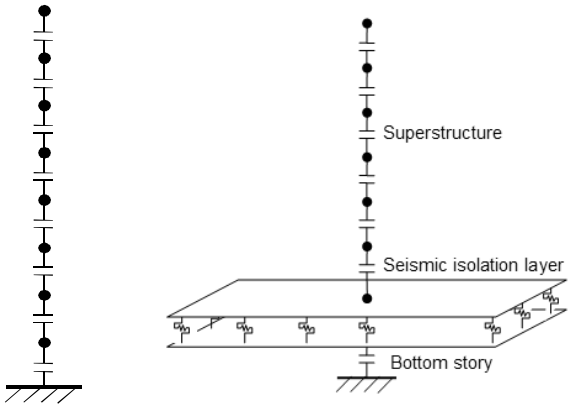

Figure 6 Computational models of structure (a) Model 1 Original structure, (b) Model 2 Seismic isolation structure

3.4 Ground Motions

According to the Chinese seismic design code, 2 sets of real ground motions (El Centro(NS) and Taft(NS)) and 1 set of synthetic ground motion were selected based on the site class. The acceleration histories and the associated spectra are given in Fig. 7. The maximum accelerations of ground motions are adjusted to 70gal for frequent earthquake, 200gal for local fortification intensity earthquake, and 400gal for rare earthquake.

3.5. Modal Analysis

Modal analyses are conducted and the results are given in Table 3. According to the modal analysis results of the original structure and seismic isolation structure models, it is found that after seismic isolation the period of the first mode extends from 0.609s to 2.281s in X direction, and from 0.569s to 2.267s in Y direction. Note that the modal analysis for the seismic isolation structure uses the stiffness of rubber bearing corresponding to 100% shear strain. The first vibration mode is characterized by the translation in X direction, the second vibration mode is characterized by the translation in Y direction, and the third vibration mode is a torsion mode around Z direction.

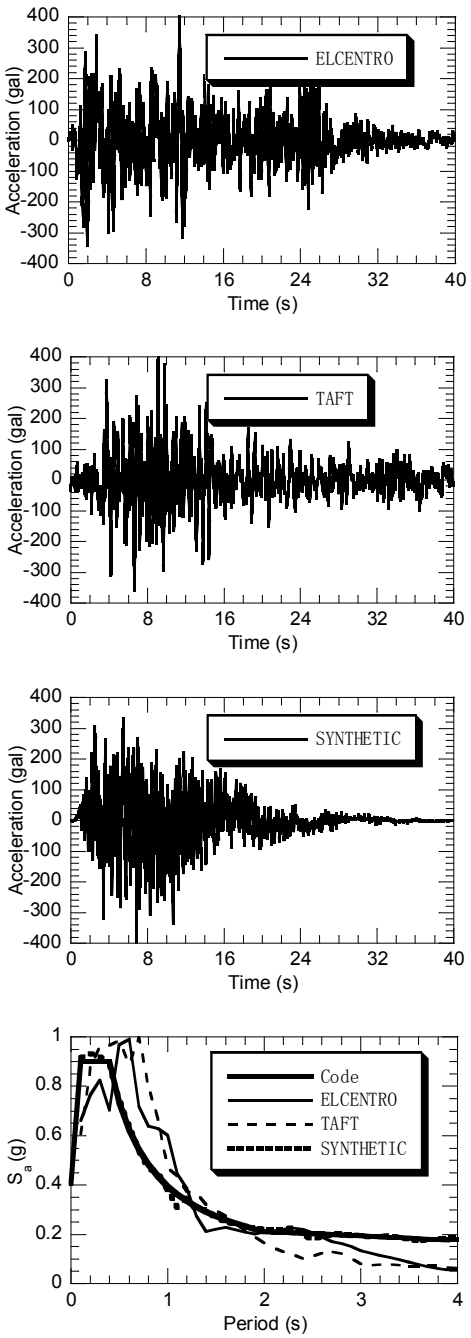

Figure 7 Time history and spectra for rare earthquake

Table 3 Natural period of the first three modes and quality participation coefficient

Mode	Time/s	UX	UY	RZ
1	2.281	0.938	0.003	0.115
2	2.267	0.003	0.975	0.668
3	2.075	0.037	0.000	0.200

3.6 Maximum Story Shear of Superstructure

Time history analyses are conducted, and average of the maximum story shears of the superstructure when subjected to three ground motions for intensities 7 and 8 are obtained

(refer to Fig. 8). Analysis results show that after seismic isolation the story shear is decreased to no more than 40% of the original non seismic isolated structure, and the story shears of the seismic isolation model for Intensity 8 are smaller than those of the original structure model for Intensity 7, suggesting that the after seismic isolation the superstructure satisfies the requirement of new intensity without strengthening.

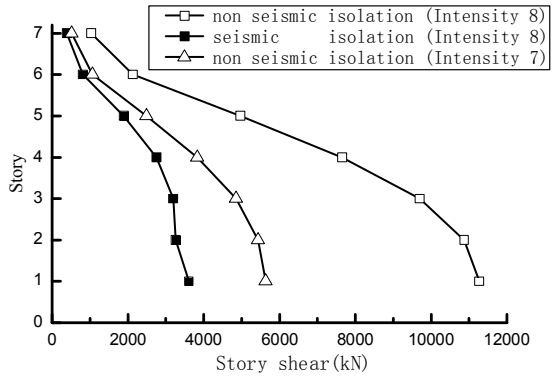

Figure 8 Story shear of superstructure

3.7 Maximum Displacement of Isolation Layer for Rare Earthquake

As shown in Table 4, the maximum displacement of the isolation layer under rare earthquake is investigated. In the table, the data for the cases including and not including torsion effects are given separately. It can be observed that the maximum displacements are all smaller than the limit values, which are specified as the maximum of 0.55 times diameter and 3.0 times total rubber thickness of the rubber bearings. The results also suggest that no significant torsion effects can be observed in the isolation layer. This is mainly thanks to the well arrangement of the LRBs so that the mass and the stiffness centres match.

Table 4 The maximum horizontal displacement of the isolation layer under rare earthquake (mm)

Without/with consideration of torsion effect				
Direction of the seismic wave	ELNS	TAFT	SYNTHETIC	AVERAGE
X direction	118/119	122/123	158/161	132.7/133.7
Y direction	117/117	123/123	157/158	132.3/132.7

3.8. Design of Bottom Column and Foundation

The design of the bottom columns and foundation is similar to the design of conventional structures. However, the following issues were considered: (1) the shear forces, axial forces, and moments transferred from the superstructure under the rare earthquakes are exerted as external load at the top of the columns. (2) The performance of the bottom columns is set to be elastic under rare earthquake (Xu et al. 2001).

4. CONCLUSIONS

This paper mainly presents the design methodology and engineering application of seismic isolation. The seismic isolation design of a building damaged in the Wenchuan earthquake in soft bottom story mode and retrofitted after the earthquake is outlined. Major conclusions obtained in this study are as follows:

(1) Chinese design of seismic isolation is getting mature.

(2) The retrofit solutions using the mid-story isolation technology effectively improve the seismic performance of the structure.

Abstract: Seismic base isolation is effective to control the seismic responses of building structures. However, compared with conventional seismic systems, the robustness of the base-isolated buildings is generally considered lower and thus the selection of input ground motions becomes a more crucial issue in assessing the seismic safety of base-isolated buildings. Extensive incremental dynamic analysis (IDA) is carried out to evaluate the ultimate state of base isolated buildings in terms of the fragility curves. The ground motion record set in FEMA P695 is adopted for analysis. The influences of the stiffness of isolation layer, the height of rubber bearings, clearance and hysteretic behavior of the retaining walls as well as the strength of the superstructures are examined. Based on the analysis results, the following can be concluded:(1) increasing the clearance of retaining walls is the most effective manner to enhance the seismic safety of base isolated buildings; (2) the seismic safety margin of base-isolated buildings might be significantly increased with stronger superstructures only if the retaining wall is appropriately proportioned so that the yielding of retaining wall is prior to that of the superstructure.

1. INTRODUCTION

The deformation pattern of base-isolated structures is clearly defined by employing a soft isolation layer at the bottom of the building, which is usually composed of both isolators and energy dissipating devices. Under earthquakes, most deformations and energy dissipations are expected to concentrate in the isolation layer so that the superstructure suffers only slight damage. But on the other hand, the robustness of isolated structures subjected to unexpected violent earthquakes remains questionable (Kikuchi *et al*, 1995). Shaking table test reveals that reinforced concrete walls in the superstructure of isolated structures are likely to suffer severe damage if hardening of the rubber bearing in the isolation layer occurs (Kitamura *et al*, 2009).

In order to assess the seismic safety of base-isolated structures under unexpected earthquakes, the incremental dynamic analysis proposed by Vamvatsikos *et al* (2002) is employed and the collapse margin ratios (CMR) of base-isolated structures with various parameters are evaluated in accordance with the framework in FEAM P695 (2009). The following ultimate states are considered in this study: (1) hardening and fracture of rubber bearing; (2) collision of the superstructure with surrounding retaining walls; (3) excessive damage in the superstructures. The failure of dampers is not considered.

2. ANALYSIS MODEL

The base-isolated structure is modeled by a 2-DOF system as shown in Figure 1. The weight of superstructure and isolation layer is 150,000kN and 40,000kN, respectively. Hysteretic behavior of each component is introduced below.

2.1 Superstructure

The superstructure is modeled by a SDOF system with tri-linear degrading hysteresis (Takeda *et al*, 1970) as shown in Figure 1(a). Yield strength Q_y is set to be base shear coefficient C_0 times the superstructure weight W_S (150,000kN). Cracking strength is $0.3Q_y$ and the secant stiffness at yielding point is 0.3 times the initial stiffness. Post-yielding tangent stiffness is 0.001 times the initial stiffness. Unloading stiffness ratio β=0.4. Damping of the superstructure is assumed proportional to the tangent stiffness with a 2% damping ratio at the fixed-base period. For non-isolated structure, 3% damping ratio is assumed to consider the damping induced by soil-structure interaction.

In this study, C_0 varies from 0.15 to 0.40 with an increment of 0.05. The initial stiffness is assumed to be proportional with C_0 value. In the case of C_0=0.3, which is a common practice in Japan, the fundamental period of fixed-base structure is assumed to be 0.3s, and the

corresponding initial stiffness is 6,709❹$10^3$kN/m.

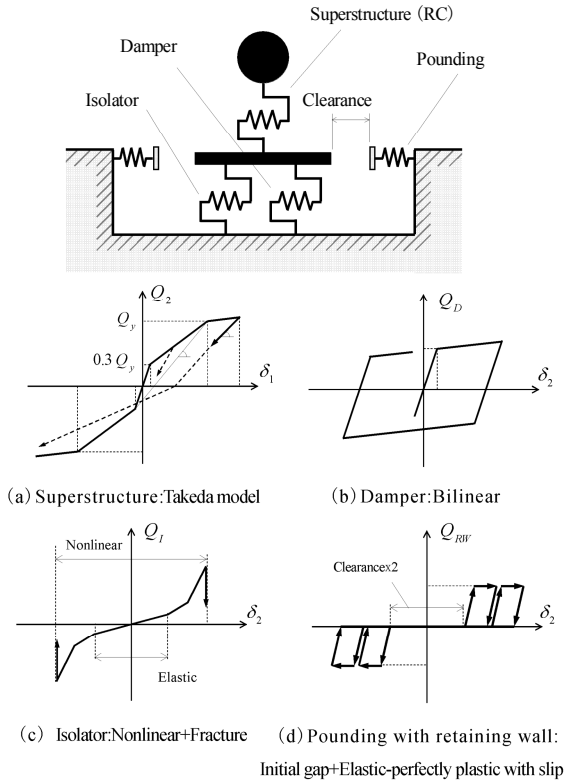

Figure 1 Analysis model and the hysteretic behavior

2.2 Damper

It is assumed that the damper have adequate deformation capacity up to the collapse of the structure. Bilinear hysteretic behavior with an initial stiffness of 240.0❹$10^3$kN/m and a post-yielding stiffness ratio of 1/60 is assumed for the damper (Figure 1b). The damper yield strength is 7,600kN, which is 0.04 times the total weight of the whole structure.

2.3 Isolator

It is assumed that natural rubber bearing is used as seismic isolator. Nonlinear elastic behavior with deformation limit as shown in Figure 1(c) is assumed. The initial stiffness k_{i1} is determined by tuning the isolation period T_f (Equation 1) to 4.0s, 5.0s and 6.0s. The corresponding k_{i1} is 47800, 30600 and 21300kN/m, respectively.

$$T_f = 2\pi\sqrt{M/k_{i1}} \quad (1)$$

where M is the total weight of the structure.

It is assumed that the tangent stiffness of the isolator increases to $k_{i2}=2k_{i1}$ in the shear strain range of 250%~350%, and $k_{i3}=7.0k_{i1}$ in the range of 350%~450%. Shear strain of 450% defines the ultimate deformation of the isolator. These assumptions are made based on the test results reported in previous studies (Takayama, 1995; Yabana *et al*, 1996; Uryu *et al*, 1996; JSI, 1995). The isolator fracture deformation can be adjusted by varying the total rubber thickness nt_R. In this study, nt_R varies from 160mm, 200mm to 240mm. The corresponding fracture deformations of the isolator are 720mm, 900mm to 1080mm, respectively.

Beyond 450% shear strain, the isolator fractures and the restoring force is replaced by the friction between the isolation layer and its foundation. This is modeled by an elastic-perfectly plastic behavior with an elastic stiffness of 1600~3600 times the isolator stiffness and a strength of 0.4 times the total weight of the structure. The fall down of the isolation layer due to isolator fracture is not considered.

2.4 Pounding with retaining wall

An elastic-perfectly plastic spring with slip and initial gap is used to model the retaining wall and the clearance to the superstructure (Figure 1d). The same retaining wall as used by Kashiwa *et al* (2005) is assumed. Elastic stiffness is 57.5❹$10^3$kN/m and the yield strength is 34,500kN. The clearance varies from 500mm, 800mm to infinity (no pounding).

3. GROUND MOTIONS

A set of strong ground motions representing an earthquake scenario is required when evaluating the seismic performance using the incremental dynamic analysis. In this study, the selection of ground motion records is based on the Far-Field set in FEMA P695 (2009). Among the 22 records in the Far-Filed set, 8 components from 6 records are considered not appropriate for evaluating the seismic performance of seismic isolated buildings in this study since their lowest usable frequencies are no less than 0.167Hz, which indicates the long period contents with period longer than 6.0s are not reliable. For this reason, these 6 records are removed from the record set and only the remaining 16 records are used in this study.

3.1 Normalization of ground motion records

In order to remove the unwarranted variability in the ground motions, the selected records should be appropriately normalized. In FEMA P695, the records are normalized by the geometric mean of the peak ground velocities (PGV) of the two horizontal components. This method is dependent on the direction of observation.

In this study, each record is first rotated to the direction where the maximum PGV occurs. The ground acceleration in this direction is denoted as GA_{MV}, where the subscript MV stands for "Maximum Velocity". The normalization factor is then calculated by Equation 2.

$$NM_i = \text{median}\left(PGV_{MV,i}\right)/PGV_{MV,i} \quad (2)$$

where PGV_{MV} is the PGV of GA_{MV}, the subscript i denotes the record number.

3.2 Scaling of record set

In an incremental dynamic analysis, the intensity of the scenario earthquake represented by the ground motion record set needs to be scaled incrementally until the ultimate

failure of the structure is achieved. Before doing so, some intensity measure (IM) needs to be defined. In FEMA P695, the median of the 5% damping spectral accelerations at the fundamental period $S_a(T_1, 5\%)$ of the record set is used as the IM. However, as recommended by Akiyama (1980), the equivalent velocity at the isolation period $V_E(T_f)$ can better represent the seismic response of base-isolated structures, which usually have long natural periods of vibration. T_f is given in Equation 1. The equivalent velocity V_E is a representation of the earthquake input energy with the unit of velocity. It is calculated by Equation 3.

$$V_E(T) = \sqrt{2E_I(T,10\%)/M} \quad (3)$$

where T is the natural period, $E_I(T, 10\%)$ is the input energy for a SDOF system with a period of T and 10% damping. M is the total mass of the system.

In this study, the median $V_E(T_f)$ of the normalized records is chosen to be the IM in the incremental dynamic analysis for base-isolated structure. For conventional non-isolated structures, the median $S_a(T_1)$ of the normalized records is used as the IM following FEMA P695. Note that the method of normalizing the records for both isolated and non-isolated structures is the same.

Since the IM for based-isolated and non-isolated structures are different, the intensity ratio (IR) defined as the ratio of the currently-used IM and design level IM is used to interpret the incremental dynamic analysis results (Equation 4).

$$\mathrm{IR} = \mathrm{IM}/\mathrm{IM}_D \quad (4)$$

IM_D is the design equivalent velocity $V_S(T_f)$ for base-isolated structures, and the design spectral acceleration $S_a(T_1)$ for non-isolated structures. $V_S(T_f)$ and $S_a(T_1)$ at the engineering bedrock recommended by BCJ (2005) are adopted. They can be easily transformed to those at other site conditions by multiplying the surface geology factor $G_s(T)$ recommended by BCJ (2005).

Figure 2 shows the equivalent velocity of the 16 ground motion records after being normalized and scaled to IR=1.0 for isolated structures with a period of 4.0s. Details of the selected ground motions are given in the appendix.

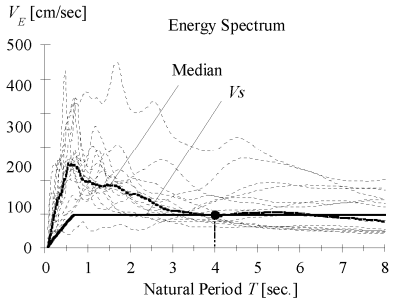

Figure 2 Equivalent velocity spectrum of normalized records when IR=1.0

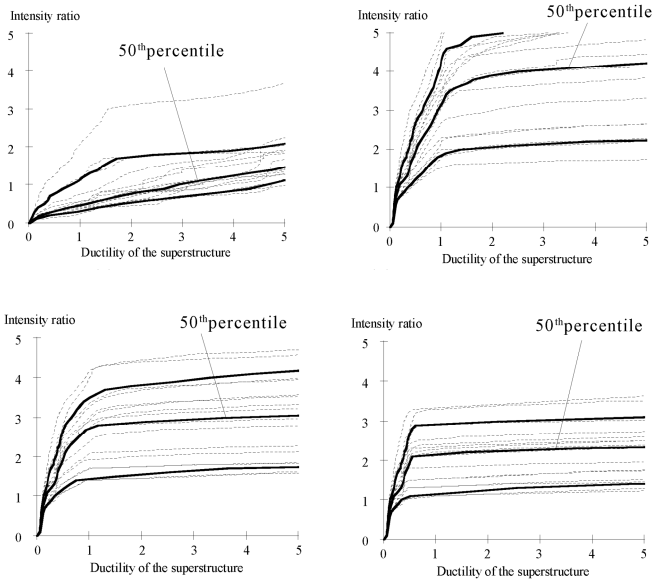
4. INCREMENTAL DYNAMIC ANALYSIS

The IDA curves of the based-isolated structures with T_f=4.0s and C_0=0.3 as well as the corresponding non-isolated conventional structure are compared in Figure 3. In the IDA curves, the ductility of the superstructure defined as the ratio of the maximum and the yield deformation is chosen as the damage measure (DM).

For the based-isolated structure, 3 models denoted as Model A, B and C are used to examine the effect on the seismic performance of isolator fracture and pounding against the retaining wall. The 3 models are:



Model A. Ideal isolation. The isolator is assumed linearly elastic and no retaining wall is modeled (or the clearance is infinite).

Model B. The total rubber thickness of the isolator nt_R is 200mm and the hardening and fracture of the isolator as described above is considered. Still, no retaining wall is modeled.

Model C. Linearly elastic retaining wall with a 500mm clearance to the structure is modeled. All the other parameters are the same as in Model B.

Figure 3 gives the IDA curves for the non-isolated and the 3 models of the isolated structure. Dotted lines are the IDA curves for individual ground motions and bold solid lines mark the 16th, 50th (median) and 84th percentile of the IDA curves.

In terms of the median IDA curve, damages to the non-isolated structure increases gradually with the increase of intensity ratio (Figure 3a). No obvious softening of the median IDA curve can be observed since neither strength deterioration nor P-Δ effect are considered in the modeling, i.e. the structure does not exhibit negative stiffness.

(c) Model B: Isolator fracture (d) Model C: Pounding

Figure 3 IDA curves of non-isolated and based-isolated structure

In contrast, the damage of the superstructure in the isolated building is limited to a very low level (say the ductility is below 1.0) prior to a certain limit of earthquake intensity. Beyond the limit, significant softening occurs even if the *P-Δ* effect is not considered. The superstructure ductility grows rapidly with slight increase of earthquake intensity.

From Figure 3(b)-(d), it is evident that the nonlinearity of the isolator and the pounding with the retaining wall significantly deteriorates the seismic performance of base-isolated structure. The value of IR when median IDA curve softens is about 4 for ideally isolated structure (Model A, Figure 3b). It is reduced to about 3 when nonlinearity of the isolator is considered (Model B, Figure 3c) and is further reduced to only about 2 if pounding occurs (Model C, Figure 3d).

It is also worth noting that the dispersions of IDA curves of isolated structures that can be visually identified by the range between 16th and 84th percentile in Figure 3(b)-(d) are also significantly reduced if the isolator's nonlinearity and the pounding are considered.

5. COLLAPSE MARGIN RATIOS

It is assumed herein that the structure or the superstructure in an isolated building collapses at the ductility of 4.0. The corresponding intensity ratios (IR) under individual ground motion input are collected from the IDA curves. By assuming a lognormal distribution, fragility curves as demonstrated in Figure 4 can be produced, where the vertical axis is the probability of collapse, i.e. the ductility equals or exceeds 4.0, and the horizontal axis is the intensity ratio (IR). Figure 4 gives an example of fragility curves of the above mentioned Model A, B and C for isolated structures. The IR corresponding to the 50% probability of collapse is taken as the collapse margin ratio (CMR). It is obvious from Figure 4 that CMR decreases significantly from Model A (ideal isolation) to B and C.

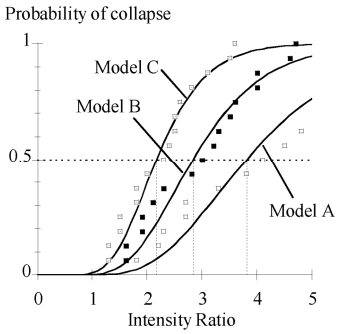


Figure 4 An example of fragility curves of isolated structure

The influences of various parameters on the CMRs of base-isolated structures are discussed. In order to help identifying the sequence of isolator fracture and retaining wall pounding, characteristic deformations (i.e. hardening limit and fracture limit) of the isolator with various total rubber thicknesses nt_R are compared with the size of clearance in Figure 5. For example, if the total rubber thick is 160mm and the clearance is 800mm, the isolator will fracture prior to the pounding. In other words, pounding is not likely to occur in this case.

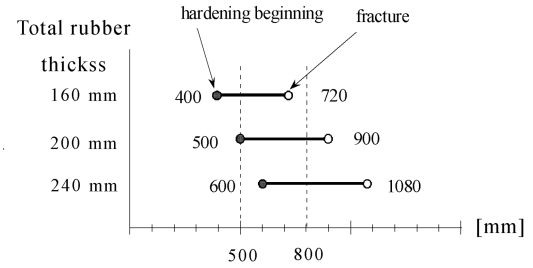

Figure 5 Characteristic deformations of the isolator compared with the size of clearance

Figure 6 summaries the CMRs of the base-isolated structures with various superstructure strengths, total rubber thicknesses, isolation periods, retaining wall properties and sizes of clearance.

For 500mm clearance, as indicated by Figure 5, pounding with the retaining wall occurs prior to the fracture of the isolator and hence dominates the ultimate behavior of the isolated structure no matter the total rubber thickness is 160mm, 200mm or 240mm. In this case, the superstructure strength has only marginal effect on the CMRs, regardless of the total rubber thickness and the isolation period (Figure 6a).

If the retaining wall behaves in an elastic-plastic manner, as shown in Figure 6(b), CMR can be increased considerably with larger superstructure strength, especially when superstructure strength is large enough to resist the shear force in the isolation layer when the retaining wall yields. Meanwhile, larger fracture deformation of the isolator (i.e. larger total rubber thickness) can increase the CMR. Table 1 lists the shear coefficient of the isolation layer when the retaining wall yields in various cases.

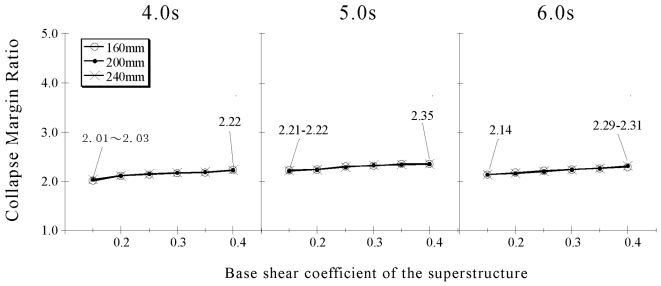

Table 1 Shear coefficient of isolation layer when retaining wall yields

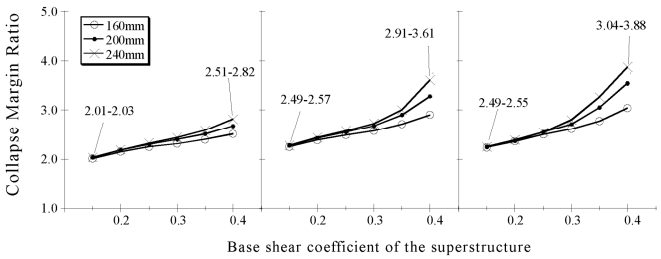
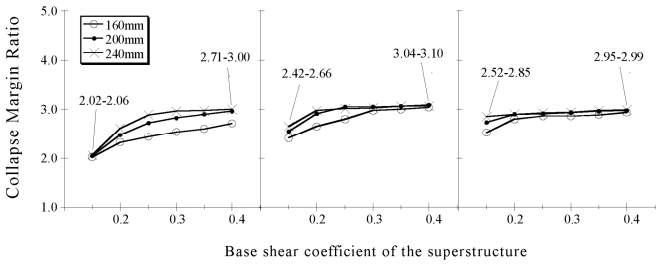
Clearance (mm)	Isolation period T_I (s)	Total rubber thickness (mm)		
		160	200	240
500	4.0	0.41	0.39	0.37
	5.0	0.35	0.33	0.32
	6.0	0.31	0.30	0.29
800	4.0	No pounding	0.75	0.52
	5.0		0.56	0.42
	6.0		0.46	0.36

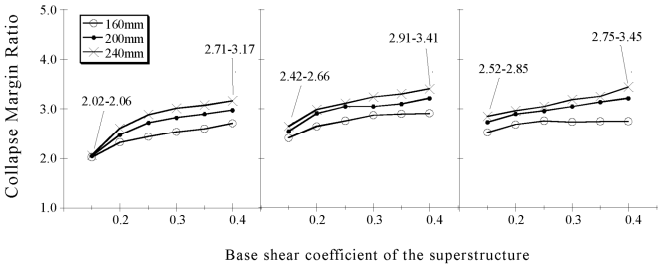


On the other hand, if the clearance of the retaining wall is increased to 800mm, the pounding is not likely to occur since the isolator fractures prematurely if the rubber thickness is only 160mm (See Figure 5). In this case, it makes no difference whether the retaining wall is elastic or elastic-plastic (see Figure 6c and 6d). Otherwise, when the total rubber thickness is 200mm or 240mm, pounding occurs

during the hardening range of the isolator. In these cases, yielding of the retaining wall will permit the isolator to develop larger deformation up to its fracture. As a result, CMR is increased with larger fracture deformation of the isolator (Figure 6d).



It's also worth noting that the CMRs with 800mm clearance are generally larger than those with 500mm clearance.



(a) Elastic retaining wall with 500mm clearance

(b) Elastic-plastic retaining wall with 500mm clearance

(c) Elastic retaining wall with 800mm clearance

(d) Elastic-plastic retaining wall with 800mm clearance

Figure 6 Influence of various parameters on CMR of base-isolated structures

Figure 7 shows the variations of CMRs of the isolated structure with 5.0s isolation period and 200mm total rubber thickness. If the structure is ideally isolated (i.e. neither pounding nor isolator's nonlinearity is considered), CMR is large and increases dramatically with higher superstructure strength. But this is not realistic. If the clearance is not adequate (say 500mm) and the retaining wall is very strong, CMRs become much smaller and keeps almost constant regardless of the superstructure strength. Yielding of the retaining wall in this case will increase the CMR with the assistance of stronger superstructure. On the other hand, the CMR can be significantly increased if the clearance is enlarged from 500mm to 800mm.

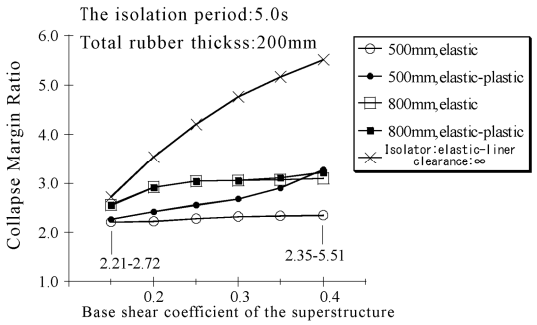


Figure 7 Influence of retaining wall behavior, superstructure strength and clearance size

6. CONCLUSIONS

As a fundamental study on the ultimate state of seismic isolated structure subjected to unexpected strong earthquakes, the seismic performance of base-isolated structures is assessed by incremental dynamic analysis of a 2DOF model with one directional ground motion input. Collapse margin ratios of the models with various influencing parameters are evaluated. From the above discussions, the following conclusions can be drawn:

(1) The seismic safety margin of the base-isolated structures can be significantly increased by increasing the clearance to the retaining walls.

(2) Increasing the strength of superstructure has marginal effect on the overall seismic safety of the base-isolated structure if pounding with the retaining wall occurs and the retaining wall would not yield.

(3) If the retaining wall is appropriately proportioned so that the yielding of retaining wall is prior to that of the superstructure, the seismic safety of base-isolated buildings can be considerable enhanced.

Note that these conclusions are based on the many assumptions made in this study. They should be carefully interpreted in cases where, for example, the higher modes of the superstructure, the vertical failure of the isolator, or the bi-directional ground motion input needs to be considers. These outline the scope of the future study.

Appendix: Ground motion record set used in the study

Table A1 lists the details of all the 16 ground motion records that are used in this study. These ground motion data are obtain from the PEER/NGA database and the data in Table A1 are also from the database with the exception of the last 3 columns. In these columns, the PGV_{MV} defined in this study and the rotating angles where the PGV_{MV} occurs are listed. These angles are with respect to the 1st component of the original record. In the last column, the normalization factors in accordance with the normalization method in this study are given.

SEISMIC DESIGN FOR A RESILIENT AND SUSTAINABLE SOCIETY

Victor Zayas

President, Earthquake Protection Systems, California, USA
Victor@EarthquakeProtection.com

Abstract: A seismic resistant construction method is presented that reduces initial construction costs, and reliably avoids seismic damage to structures, non-structural components, and building contents. Avoiding seismic damage to structures, non-structural components and contents of a building is necessary if we are to avoid the devastating economic losses and disruption that major earthquakes cause urban regions. New buildings are typically designed to comply with only the minimum seismic safety requirements of the building codes. Building codes do not require avoiding damage to structures, non-structural components, or building contents during severe earthquakes. Sustainable construction does however require structures that are not damaged. Moreover, resilient construction requires that contents and non-structural components maintain their ability to function after a severe earthquake. Example applications are presented for major buildings, bridges, and industrial facilities, that avoid seismic damage and have lower initial construction costs as compared to ductility based design methods. A design method for Triple Pendulum seismic isolation is presented that achieves 98% reliably of maintaining function of the non-structural components, contents, and structure, for an earthquake having only a 2% chance of being exceeded in 50 years. The Triple Pendulum is a multi-stage seismic isolation bearing. Each bearing has three independent isolation mechanisms that can be optimized to protect contents, non-structural components and structures from damage. With their compact size and lower bearing costs, Triple Pendulum bearings can actually lower construction costs as compared to traditional ductility design methods.

SEISMIC DESIGN BACKGROUND

Modern building codes have saved the lives of hundreds of thousands of people. Building engineers worldwide have achieved seismic safety and construction cost savings by designing structures to comply with modern codes at the lowest construction cost. Yet every year, major earthquakes cause devastating economic losses and disruption to the urban areas they affect. Facility owners and occupants are always very surprised when code compliant facilities suffer extensive damage, loss of use, and disruption as a result of earthquakes. Government-reported loss data from the Kobe and Northridge earthquakes shows that total economic losses including loss of use and disruption were ten times greater than the direct costs for repairing damaged structures. In modern code compliant buildings, the loss of use and costs of damage to nonstructural elements and contents can be substantial even for moderate seismic events. Today, the public expects engineers to protect them from the economic losses and disruption caused by earthquakes.

Although it is possible to design buildings strong enough to remain elastic during earthquakes, these structures are expensive, and the increase in structure strength causes higher in-structure accelerations, and results in greater damage to nonstructural components and contents.

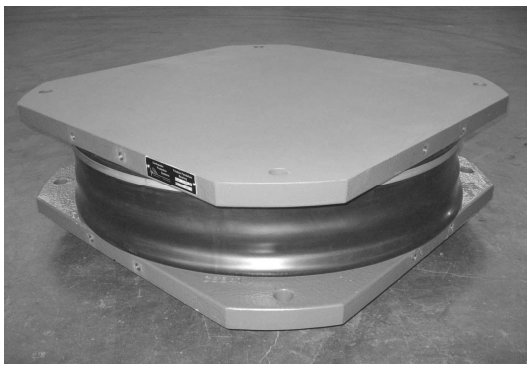

Figure 1: Triple Pendulum Bearing

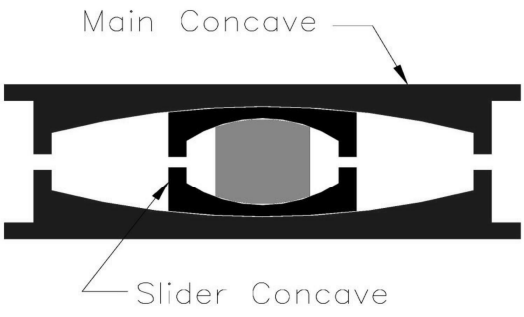

Figure 2: Three Internal Sliders in Triple Pendulum

Figures 3 to 7 show newer code compliant buildings that could not function after moderate earthquake shaking because of non-structural and content damage. Figures 7 to 14 show the severe non-structural and content damage observed in code compliant buildings that had no structural damage. California's Olive View Hospital experienced only modest ground shaking during the 1994 Northridge Earthquake (Fig. 6), but had to be evacuated because of the extensive damage to nonstructural components. Consequently, this hospital was not available at the time when it was needed the most.

The intent of modern seismic codes has been to achieve life-safe buildings at the minimum construction cost. Triple Pendulum seismic isolation (Figs. 1 and 2) can avoid seismic damage to structures, non-structural components, and contents, and in many cases at a lower initial construction costs as compared to ductility designs. To achieve a resilient and sustainable society, avoiding seismic damage should become the performance objective of building codes.

Examples of Friction Pendulum Seismic Isolation

Friction Pendulum technology (Ref. 1 to 4) has been used to avoid seismic damage and reduce construction costs for over 20 years. Over US $ 40 Billion in constructed value of important facilities in over 20 countries rely on Friction Pendulum bearings for seismic protection. In 1991, the retrofit of the US Federal Court building in San Francisco was designed to avoid seismic damage, with Friction Pendulum bearings saving 25% of the construction costs as compared to using rubber bearings (Fig. 15). Four major hospitals in California have been designed using Triple Pendulum bearings for continued functionality following a major earthquake (Fig. 16). The Cathedral of Christ in Oakland California is an example of elegant architecture, designed for no seismic damage, and constructed at a 50% reduction in cost as compared to the alternative strength and ductility design (Figs. 17 and 18). Triple Pendulum bearings (Refs. 3 and 4) have made significant advances in both reducing construction costs, and protecting structures, non-structural components, and contents from seismic damage. The three pendulum stages are three independent degrees of freedom that can be optimized for the different performance requirements needed to protect contents, non-structural components and structures. The 200,000 square meter Sabiha Gokcen Airport building in Turkey was built using Triple Pendulum bearings to avoid seismic damage, and was constructed at approximately the same cost as a minimum code design (Figs. 19 and 20). The San Francisco Airport International Terminal was designed to avoid damage to the architectural glass façade, with Friction Pendulum bearings saving 3% of the construction costs as compared to using rubber bearings (Fig. 21). Many government buildings in California have been seismically isolated to maintain function after a seismic event (Figs. 22 and 23).

Three major Offshore Oil Platforms have been designed using Friction Pendulum bearings to minimize the disruption and lost production that would result from damage to the equipment and facilities on the platform deck (Fig 24).

Eight large LNG Tanks, containing over 1.2 billion liters of liquid natural gas, have used Friction Pendulum bearings to avoid seismic damage to the concrete tanks. Two LNG Tanks at Quintero Chile, using 520 Triple Pendulum bearings, had no disruption to operations after the 2010 Magnitude 8.8 earthquake (Fig 25). Over 30 bridges have used Friction Pendulum bearings to avoid seismic damage, and were constructed at an average 15% lower construction cost as compared to typical minimum code ductility designs (Figs. 26 to 30).

Design Methodology for 98% Reliability of Avoiding Seismic Damage for a 50 Year Design Life

Using Triple Pendulum seismic isolation, 98 % reliability in 50 years is achievable, quantifiable, and surprisingly cost-effective for a wide range of structures. Triple Pendulum Bearings provide the opportunity to tune the different stages of the seismic isolation system to accommodate the multiple performance objectives for the structure, architectural components, and contents. Achieving 98 % reliability in 50 years requires the facility design to be such that the structure, non-structural components, and contents can withstand an earthquake with a 2500-year return period without damage. Although this level of seismic hazard is higher than required for minimum code compliance, it is consistent with society's expectations that new structures should not have seismic damage. By designing to protect against damage, instead of just minimum code requirements, the structural engineer can help achieve a sustainable and resilient society that can avoid the widespread damage and disruption that is seen every time a major earthquake occurs in a metropolitan area.

Design Method for 98% Reliability of Avoiding Damage to Building Structures, Non-Structural Components, and Contents Damage for a 50 Year Design Life

1) Design for an earthquake strength that has less than a 2% chance of being exceeded in 50 years (2500 year return period). Design the structure and isolation system to reliably avoid structure damage, non-structural damage, and content damage for the 2500 year earthquake hazard.
2) Design the structure to be reliably elastic during seismic events. Use a seismic reduction factor Rw = 1.0, and standard member capacity factors, and a seismic load factor = 1.0. This avoids damage caused by typical structure irregularities, asymmetries, construction imperfections, structure modeling limitations, and design errors.
3) Limit story drifts to 0.5% maximum. This avoids

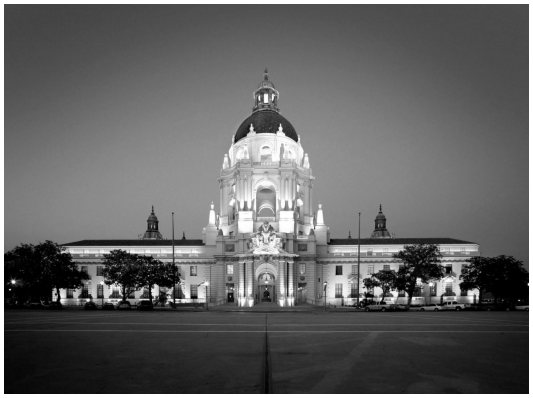

Figure 23: Pasadena City Hall, California

Figure 24:Shell Offshore Platform, Russia

Figure 25: Chile LNG Tank after 8.8 mag. EQ

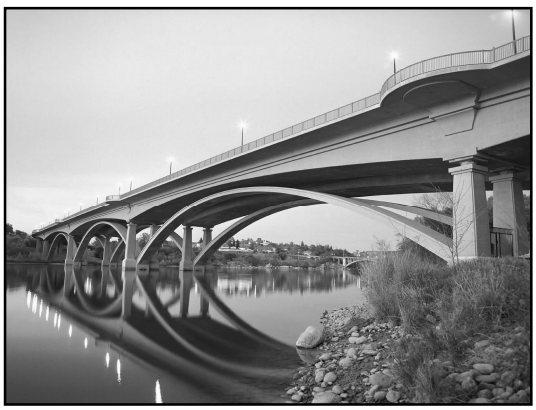

Figure 26: America River Bridge, California

significant damage to most nonstructural components and contents that are drift sensitive.

4) Limit the in-structure floor accelerations to less than 0.4g, and in-structure velocities to less than 180 cm/sec. This avoids serious damage to most ordinary contents and non-structural components.

A design example for avoiding seismic damage is provided for an ordinary concentric braced frame (Fig. 31), at a site having the 2% in 50 year spectra as shown in Figure 32. Triple Pendulum bearings are used having the multi-stage force-displacement properties shown in Figure 34. Also evaluated are the responses of an isolated ordinary moment frame, and code compliant conventional fixed base structures including a special ductile moment frame, and a special ductile concentric braced frame. The building responses for the 2% in 50 year earthquake are provided in Figure 33, together with estimated structural frame construction costs (including isolation bearings), and expected seismic losses as a percentage of the total value of the building, content, and use, and expected loss of use days for the facility.

The fixed base ductile moment frame has in-structure velocities of 274 cm/second, and a structure drift of 3.5%, which is a near collapse condition, and results in an estimated 100% economic loss for the building, contents, and function.

The fixed base ductile braced frame has a structure drift of 1.5%, which would cause major damage to the structure, and moderate damage to non-structural components; and in-structure accelerations of 1.7g, and in-structure velocities of 400 cm/second, which would cause major damage for contents and non-structural components; and which results in an estimated 70% economic loss of the total value of the building, contents, and function.

The isolated moment frame has a calculated structure drift of 1.1%, 0.2g in-structure accelerations, and in-structure velocities of 137 cm/second. Using special details for the interior partitions and non-structural components for a 1% drift would result in modest damage to non-structural components, with an estimated 3% economic loss for nonstructural components and function.

The Triple Pendulum isolated braced frame has a calculated structure drift of 0.3%, 0.3g in-structure accelerations, and in-structure velocities of 130 cm/second, and with no special details for the interior partitions would result in an estimated 0.1% economic loss due to minor disruption to non-structural components and function. The analysis results show that Triple Pendulum bearings with an ordinary concentric braced frame, provides the lowest estimated seismic damage and loss of use days.

Triple Pendulum bearings with a concentric braced frame also had the lowest structure cost of $422/square meter. The fixed base moment and braced frames had structures costs of $600 and $516/square meter, and the isolated moment frame had a cost of $613/square meter.

Fig. 33. Structure Response, Structure Costs, Expected Losses, and Expected Loss of Use for the 2% in 50 Year Earthquake

The ordinary concentric braced frame had the lowest structural frame costs because of the savings from avoiding ductility detailing for the concentric braced frame, and the relatively low cost of the Triple Pendulum bearings. The structure with the best seismic performance and most reliable fully elastic behavior also has the lowest initial construction cost. Thus, the Triple Pendulum has improved the seismic performance, increased the design reliability, and reduced the cost of construction to design for avoiding seismic damage.

The first application of Triple Pendulum bearings in Japan was for the Todaiji Temple Exhibit Museum (Figs. 35 to 38). Ancient Japanese cultural artifacts are displayed on a concrete exhibit floor that is seismically isolated with Triple Pendulum bearings. During the museum design phase, shake table tests of the Todaiji bearings were performed by Obayashi Corporation to demonstrate the effectiveness of the Triple Pendulum bearings to protect these historic cultural artifacts. Triple Pendulum bearings designed to avoid non-structural and content damage will again be tested at Japan's E-Defense Laboratory in August of 2011. A five story full scale building outfitted with non-structural components and building contents will be tested subject to the most extreme earthquake shaking motions considered possible to occur in Japan. An opening ceremony for the Todaiji Exhibit Museum will be held during September 2011.

The sliding mechanisms of Triple Pendulum bearings are compared to single stage Friction Pendulum bearings in Fig. 39. Triple Pendulum bearings allow explicit control of the various aspects of a seismic response that affects the structure, non-structural components, and contents. The period, damping, and displacement capacity of each of the three pendulum mechanisms can be selected independently. There are nine bearing design parameters that can be selected to optimize the isolation system for the desired response of the structure, nonstructural components, and contents. The period and damping for the first pendulum stage are selected specifically to limit the in-structure accelerations to 0.4g. The period and damping for the second pendulum mechanism are selected to limit the structure drifts to ½ %. The period and damping for the third pendulum mechanism are selected to keep the structure response reliably elastic, and the isolator displacements within the available seismic gap.

The inside of a Triple Pendulum bearing is shown in Figure 40. The upper and lower slider concaves are seen attached together with an ethylene propylene seal, concealing the inner slider. The three sliders, having three different friction coefficients, achieve three independent single pendulum mechanisms in one bearing. The concept of a single stage sliding pendulum is shown in Figure 41. For all Friction Pendulum bearings the dynamic properties are verified through testing at the bearing's natural period, and the full design loads and displacements (Fig. 42), providing high very reliability for the bearing properties as used in dynamic analyses.

With Comparison of Bearing Sizes

CONCLUSIONS

1) The three stages of Triple Pendulum bearings can be optimized for the seismic protection of structures, non-structural components, and building contents.

2) The initial construction costs of an ordinary concentric braced frame with Triple Pendulum bearings can be less than for traditional moment and braced frames designed for minimum code requirements.

3) Multi-stage Triple Pendulum bearings can significantly reduce structure drifts, in-structure accelerations, and in-structure velocities, sufficient to avoid significant damage to non-structural components and contents.

4) Owners and occupants expect newer code compliant buildings to resist earthquakes with very little or no damage to structures, non-structural components, and contents.

5) Using multi-stage seismic isolation technology, engineers can help achieve a resilient and sustainable society by designing buildings, bridges, and industrial facilities to withstand earthquakes without damage.

Abstract: Key issues related to repair of RC buildings using dampers are discussed, based on actual repair work performed in China and extensive full-scale experiments for dampers conducted in Japan. This Part 1 paper describes the 7-story RC building damaged due to the 2008 Wenchuan Earthquake, actual repair work performed, detailed full-scale damper tests, and hypothetical repair and analysis using the damper test results.

1. INTRODUCTION

1.1 General

As a apart of Strategic China-Japan Cooperative Program on Science and Technology organized by the National Natural Science Foundation of China (NSFC) and Japan Science and Technology Agency (JST), the joint research on the seismic evaluation and mitigation technologies is being conducted by the researchers in Tongji University, China and in Tokyo Institute of Technology (Tokyo Tech.) and Hokkaido University, Japan.

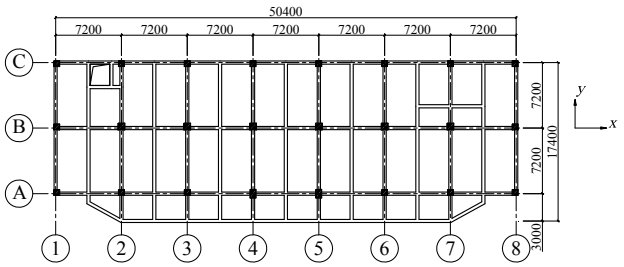
The first stage of the research focuses on the use of seismic energy dissipaters, hereby called as "dampers", for seismic repair or upgrade of the existing reinforced concrete (RC) buildings. The dampers have been extensively utilized to steel buildings, since connecting the dampers to the steel frames is convenient and simple. However, there exist many RC buildings with a variety of serious problems in terms of seismic vulnerability, and extended use of the dampers to such buildings is of strong interest not only to China and Japan, but also to many other countries of high seismic activity.

1.2 Scope and Objectives

Accordingly, the present paper and the companion paper (Kasai et al. 2011) discuss key issues related to repair and retrofit of RC buildings using dampers, based on actual repair work performed in China and extensive full-scale experiments for dampers conducted in Japan. The present paper, designated as Part 1, describes the 7-story RC building damaged due to the 2008 Wenchuan Earthquake, actual repair work performed, detailed full-scale damper tests, and hypothetical repair and analysis using the damper test results.

2. 7-STORY RC-BUILDING DAMGED DURING THE 2008 WENCHUAN EARTHQUAKE

The 7-story RC building is an office building of a Power Gas Company in Dujiangyan, Sichuan Province. It is a reinforced concrete (RC) frame structure. The structure was originally designed based on a seismic intensity of 7 in 1997, the plan layout and elevation are shown in Figure 1 and Figure 2. The structure has a plan dimension of 50.4m by 17.4m. There are seven stories with a story height of 4.6m, 4.2m, 3×3.6m, 4.2m and 3.6m from Story 1 to 7, respectively. The total height of the structure is 27.4m. RC frame structural system is applied to undertake the gravity loads and lateral forces. The cross sections of frame beams are 350 mm by 600 mm and those of columns changed along the structural height from 800 mm by 800 mm to 500 mm by 500 mm. The thickness of the slab is 100 mm. All concrete design grades are C30



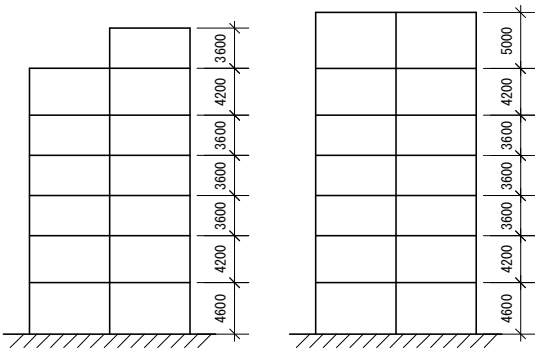


Figure 1 Plan layout of the building

(a) Before retrofit (b) After retrofit

Figure 2 Elevation of the building

Figure 4 Damage at beam and column ends

Figure 3 Horizontal cracks of infilled walls

that has a compressive strength of 14.3 MPa. The infilled wall is made by hole brick with a thickness of 200mm. The total mass of the building is about 6456 t.

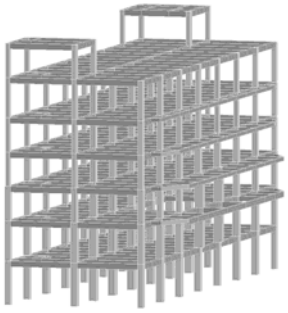

Figure 5 Building analytical model (before retrofit)

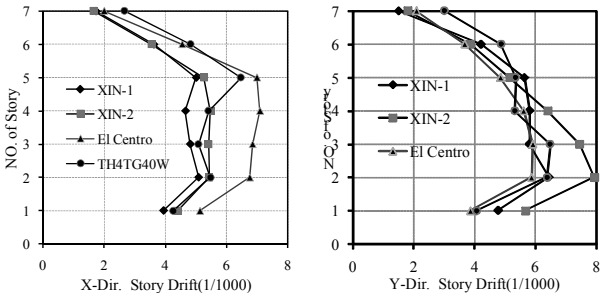

Figure 6 Inter-story drift in *X* and *Y* direction

During the time when the building was designed and constructed, the seismic protection intensity in that area is 7 with a basic peak ground acceleration (PGA) of 0.1g, and the design code was the version of 1989 in which lower requirements and structural detailing were suggested compared to the current one.

The building was damaged during the 2008 Wenchuan Earthquake. Most visible damages are the horizontal infilled wall cracks in the longitudinal direction (Figure 3). Cracks with a width of 0.1 mm to 3 mm were observed at the structural beam ends in longitudinal direction. In Story 3 and 4, minor cracks (0.1 mm~0.5 mm) were also observed at the ends of the columns (Figure 4). Because of the limited structural elements damage found, the structure was evaluated as "minor damage" grade by the seismic evaluation team although the earthquake intensity in that area was evaluated by China Earthquake Administration as 9 that is substantially larger than expected. Therefore soon after the Wenchuan earthquake, the seismic design intensity in Dujiangyan city is increased to 8 with a basic PGA of 0.2g.

An analytical structural model is built up by PKPM2008 to investigate the seismic response, as shown in Figure 5. Four sets of time histories, including two strong earthquake records and two artificial accelerograms, are applied to obtain the dynamic responses of the structure. The peak ground acceleration in the time-history analysis is taken as 0.3g to accommodate the seismic intensity 8 in Dujiangyan area. The maximum inter-story drifts under four ground motions are shown in Figure 6.

One can easily find that the structural inter-story drifts in both directions are just beyond the code limitation of 1/200 under basic earthquake of intensity 8.5. The minor damage characteristic is in accordance with the results of analysis. Therefore strengthening of this building is required by Building Regulations and Codes to control the structural responses and to meet the code provisions because the building is lifeline structure.

3. REPAIR PERFORMED TO THE BUILING

The common practice to strengthen earthquake damaged buildings in China is to strengthen damaged members and joints with concrete or steel jacketing and to increase the size of most structural members so as to meet the new design requirements. This practice is suitable for most of the strengthening applications. However, it needs to demolish all the decorations of undamaged members, which is a time-consuming process, and the site construction may pollute the environment. Considering the above disadvantages and the importance of the building, a comprehensive strengthening scheme with less labor work was selected as follows. First, to strengthen the damaged joints with steel jacketing and to inject epoxy resin into the cracks. And then to use viscous damper and steel bracing to increase the overall stiffness of the structure while to reduce the seismic force to the structure. Detailed and optimal analysis was done to select steel jacketing, dampers and their locations. Figures 7 and 8 show the photos of steel jacketing for the damaged joint and damper and steel bracing in construction site.

On the selection of dampers in preliminary design phase, the added stiffness to the frame provided by viscous dampers and braces is approximately neglected, so as to easily estimate the required supplementary damping ratio of the structure, and therefore viscous dampers can be designed according to the required equivalent damping ratio. Typically, for RC frames which are mainly of shearing deformation, its required damping ratio can be estimated based on Chinese Code Response Spectrum (GB 50011-2010), as given in Eq. (1):

$$\Delta_{\max} / \Delta_T = \alpha_{0.05} / \alpha_{(\zeta_r + 0.05)} \tag{1}$$

Where $\Delta_{\max}$ is the maximum value of story drift in the structure (obtained under moderate earthquake), Δ_T is the corresponding target value of story drift, ζ_r is the required equivalent damping ratio, $\alpha_{0.05}$ is seismic influence coefficient for the damping ratio of 5%, while $\alpha_{(\zeta_r+0.05)}$ is for the damping ratio of $(\zeta_r+0.05)$ (based on GB 50011-2010).

Moreover, the Code requires that the final damping ratio shall not exceed 25% in general, whereas it should be counted to 25% once exceeds, which also means that the primary frame shall be further strengthened in this case.

Figure 7 Photo of steel jacketing

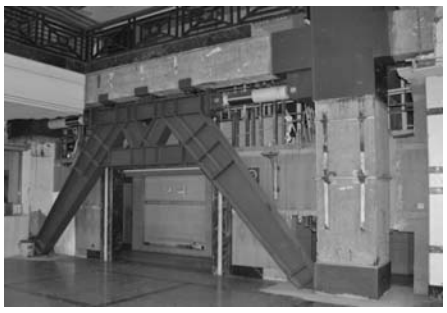

Figure 8 Photo of damper and bracing

According to the calculated required damping ratio, the expected designed damping force can be obtained by the following equations (2) ~ (6):

$$F_{di} = \zeta_r \cdot \beta \cdot Q_i \tag{2}$$

$$\beta = \left[\pi \sum_{j=1}^{N} \Delta_j Q_j \right] \Big/ \left[2 \sum_{i=j_1}^{N_1} \Delta_i Q_i (1 - \mu_i) \right] \tag{3}$$

$$\mu_i = \Delta_{di} / \Delta_i \tag{4}$$

Where F_{di} is the expected damping force on the i-th floor, β is the design coefficient related to story damping force and shear force, Q_i is the story shear force on the i-th floor under moderate earthquake, N is the total number of floors for calculation, N_1 is the total number of floors equipped with viscous dampers, j_1 is the initial number of floor equipped with viscous dampers, μ_i is the ratio of yield displacement of viscous damper and peak value of story drift on the i-th floor, Δ_{di} is the yield displacement of viscous damper on the ith floor.

Specially, to achieve the best damping effect of supplementary viscous dampers, an optimizing coefficient is introduced to modify the designed damping forces given by Eq. (2), which conducted as follows:

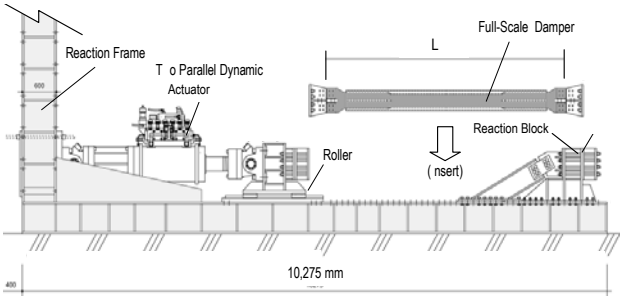
$$F_{(di)m} = \Omega_i \cdot F_{di} \tag{5}$$

$$\Omega_i = \Delta_i \Big/ \left(\sum_{j=1}^{N} \Delta_j / N \right) \tag{6}$$

Where: $F_{(di)m}$ is the modified designed damping force on the ith floor, Ω_i is the optimizing coefficient on the ith floor. However, it is noteworthy that the optimizing process of designed damping forces here is advisory but not compulsory step, and therefore the final designed damping forces are usually interpolated in the value range between the designed damping forces given by Eq. (2) and the modified damping forces given by Eq. (5) with the combination of the allowable story drift rotation for buildings in China's seismic design code (i.e. GB 50011-2010).

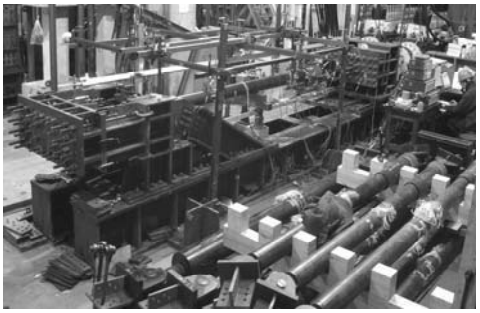
Based on above steps of design and distribution of expected damping force on certain floor, it is concluded that the expected supplementary damping forces of the existing frame are designed on the basis of story shear forces, and optimized in the light of story drifts. Nonlinear viscous dampers manufactured in China were installed, and they will be named as Type 1 nonlinear viscous damper from now on. Properties of the Type 1 damper will be given in Sec. 6.

4. FULL-SCALE TEST OF VISCOUS DAMPERS



4.1 Damper Test Scheme

In addition to the Type 1 damper used in the actual repair project explained above, the present study will also consider Type 2 damper. Twelve full-scale nonlinear viscous dampers of Type 2 are tested at Tokyo Tech. They were the dampers in the full-scale 5-story building tested using the world's largest shake-table, "E-Defense" (Kasai et al. 2007, 2009, 2010), and were produced by a manufacturer in the United States. Steel, oil, and visco-elastic dampers produced by Japanese manufacturers were also tested at E-Defense and Tokyo Tech., but they are not included in the present study.



The purpose of the Tokyo Tech. test is to confirm accuracy of load monitoring gages that were attached on the damper and used during the E-Defense tests, and to compare effects of boundary conditions for the two tests. Note that Tokyo Tech. tests consider the typical boundary conditions used for proof tests of manufactured dampers, and the comparison will be important for evaluating on-going practical test method.

As shown by Figure 9, the test set-up utilizes two parallel dynamic actuators whose maximum possible stroke, velocity, and load are 400 mm, 500 mm/s, and 2000kN, respectively. Deformations of various components of the damper-brace assembly are measured (Figure 10a), and Figure 10b are used to estimate properties of the analysis models.

The material used in the damper is polymer liquid, and its resistance against flow produces the damper force (JSSI Manual 2005, 2007, Chinese Translation 2008). Damper-brace assemblies are categorized into three types according to load capacity of 1700, 850, and 425 kN, respectively. The load capacities are defined as the damper force at stroke speed of 300 mm/s. Table 1

$u_c = u_{c1} + u_{c2} + u_{c3} + u_{c4}$

(b) Model for Deformation Components

Figure 10 Deformation Measurement Scheme for Viscous Dampers

indicates dimensions of the three types, where the diameters of the cylinders vary from 286 to 152 mm, and those of the braces 236 to 140 mm. The damper-brace assemblies of the same type had difference only in the length of the extenders, and average value of the total length L is specified in Table 1. In the order of types 1 to 3, the number of assemblies tested is two, six, and four, and variations of test results within each type are found insignificant.

Sinusoidal deformation tests are performed. As indicated in Table 2, one damper from each type is selected for detailed tests using seven different peak

Table 1. Dimensions and dynamic properties determined for three damper-brace assembly types tested at E-Defense and Tokyo Tech.

Type	F_d [1] (kN)	L [2] (mm)	Brace Dimension			Damper Dimension			Damper Properties [3]		
			L_b (mm)	A_b (mm^2)	D_b (mm)	L_d (mm)	A_d (mm^2)	D_d (mm)	C_d (kN/(mm/ses)$^\alpha$)	K_d (kN/mm)	α
1 (2 dampers)	1700	4238.8	1932	15323	236	689	28124	285.8	181 (196)	547 (∞)	0.39 (0.38)

3 (4 dampers)	425	4024.5	2429	9121	140	535	8034	152.4	48 (49)	146 (∞)	0.34 (0.38)

Notes: 1) F_d = Nominal damper force at stroke velocity of 300 mm/s.
2) L = Average length of the same type damper-brace assembly.
3) Parenthesis indicates the catalogue value provided by the manufacturer.

Table 2. Damper stroke velocities (mm/s) under different frequency and stroke

Maximum Displacement	Excitation Frequency							
	0.1 Hz	0.5 Hz	1.0 Hz	2.0 Hz	3.0 Hz	6.0 Hz	10 Hz	15 Hz
0.5 mm	0.3	1.6	3.1	6.3	9.4	(18.9)	(31.4)	(47.1)
1.0 mm	0.6	3.1	6.3	12.6	18.9	(37.7)	(62.8)	(94.3)
3.0 mm	1.9	9.4	18.9	37.7	56.6	(113.1)	(188.5)	(282.7)
6.0 mm	3.8	18.9	37.7	75.4	113.1	(226.2)	(377.0)	—
12.0 mm	7.5	37.7	75.4	150.8	226.3	(452.4)	—	—
24.0 mm	15.1	75.4	150.8	301.6	452.4	—	—	—
36.0 mm	22.6	113.1	226.2	452.4	—	—	—	—

Note: The velocity in parenthesis was applied to only one damper per type.

displacements (0.5, 1, 3, 6, 12, 24, and 36 mm) and eight frequencies (0.1, 0.5, 1, 2, 3, 6, 10, and 15Hz). By eliminating cases exceeding the stroke velocity limit of 500 mm/s aforementioned (Table 2), total of forty-one cases are tested. All other dampers are tested for the same peak displacements, but for a smaller range of frequency 0.1 to 3 Hz (Table 1).

Random deformation tests are also performed at Tokyo Tech. The input for each damper is its deformation history recorded at the E-Defense test, where the damper was connected to the 5-story building. The building was subjected to varied levels of JR Takatori ground motion, one of the strongest recorded during the 1995 Kobe earthquake. The Tokyo Tech. test utilizes the damper deformation histories at 15, 50, and 100% JR Takatori motions, respectively.

4.2 Deformation Measurements

As shown in Figure 10a, the deformation of the damper-brace assembly u_a is broken down to those of three portions defined as damper, brace, and connection deformations, u_m, u_b, and u_c, respectively, i.e.,

$$u_a = u_m + u_b + u_c \tag{7}$$

where deformation of each portion is subdivided further, as will be explained below (Figure 10a):

First, damper deformation (stroke) u_m is subdivided as:

$$u_m = u_d + u'_d \tag{8}$$

where u_d , u'_d = deformations of nonlinear dashpot and spring representing the elastic flexibility of the viscous fluid (Figure 10b).

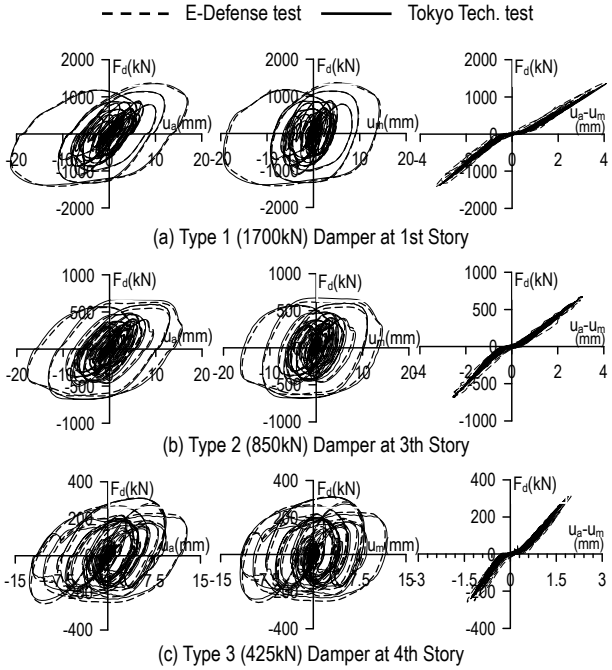

Figure 11. Comparison between E-Defense test results and Tokyo Tech. test results for Type 2 dampers of different size and orientation

Second, brace deformation u_b is expressed as:

$$u_b = u_{b1} + u_{b2} + u_{b3} + u_{b4} \tag{9}$$

where u_{b1} , u_{b2} , u_{b3} , u_{b4} = deformations of left splice, damper cylinder, extender (typical brace), and right splice, respectively (Figure 10a).

Third, connection deformation u_c is expressed as:

$$u_c = u_{c1} + u_{c2} + u_{c3} + u_{c4} \tag{10}$$

where u_{c1} , u_{c2} , u_{c3} , u_{c4} = play of left pin, deformation of screw joint between cylinder and extender, deformation of screw joint between extender and right clevis, and play of right pin, respectively (Figure 10a).

4.3 Tests Results

Figure 11 compares responses of the same viscous damper tested at E-Defense and Tokyo Tech., respectively. In spite of very different boundary conditions of the two tests, the results are almost the same. This suggests appropriateness of the typical damper tests performed under idealized boundary conditions like the Tokyo Tech. test.

Damper force F_d is plotted against damper deformation (stroke) u_m, total deformation of the damper-brace assembly or added component u_a , and race and connection deformations $u_b + u_c$ (= u_a - u_m) , see Eq. (7). Note that $u_b + u_c$ is about 15% of u_a and cannot be neglected. Because of such deformation, the hysteresis becomes inclined, leading to increased elastic stiffness and reduced damping.

Note also from F_d vs. (u_a - u_m) that the stiffness of the brace and connection is smaller when the force is tension, indicating influence of some of the screw joints more flexible in tension. The flat curves at F_d = 0 are due to slackness and play of the pins, and cannot be neglected at small amplitude shaking.

5. ANALYTICAL MODELING FOR DAMPERS

5.1 Determination of Three Parameters

The basic equations for the force and deformation are as follows:

$$F_d = C_d |\dot{u}_d|^{\alpha} \mathrm{sgn}(\dot{u}_d) \quad , \qquad u_m = u_d + F_d / K_d \tag{11a,b}$$

where C_d and K_d are nonlinear viscous coefficient and elastic spring stiffness of the Maxwell model, and α is the fraction to determine the power (Eq. (11a)).

Using Eq. (11) and $u_d = u_m - F_d/K_d$ from Figure 10b, the constants C_d , K_d , and α are determined by the least square method minimizing the following error:

$$R = \sum_i [F_d^{(i)} \mp C_d |\dot{u}_m^{(i)} - \dot{F}_d^{(i)} / K_d|^{\alpha}] \tag{12}$$

where i = step number for data $F_d^{(i)}$ and $u_m^{(i)}$. The negative and positive signs in Eq. (12) are used, when

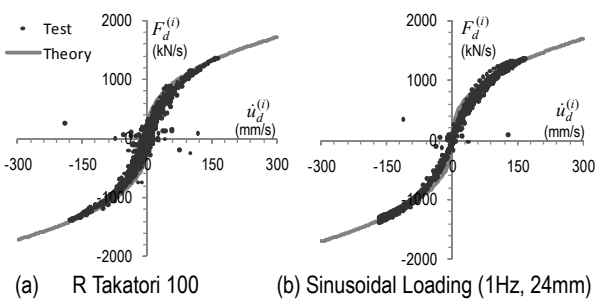

Figure 12. Plots of experimental damper force $F_d^{(i)}$ and estimated dashpot velocity $\dot{u}_d^{(i)}$ (see Sec.5.1) compared with model curve

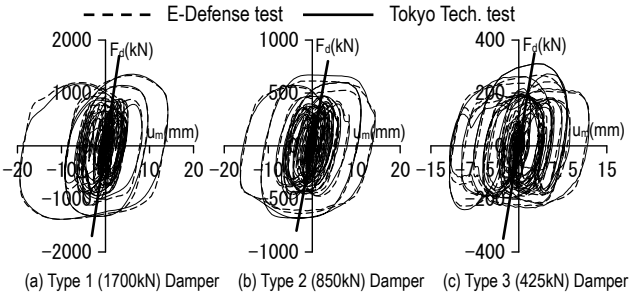

Figure 13. Comparison between test and analysis results (JR Takatori 100%)

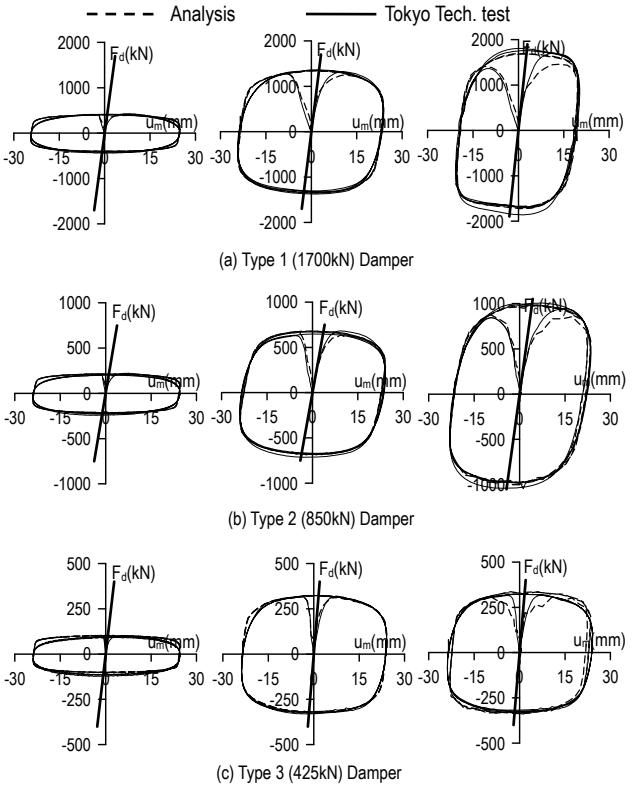

Figure 14. Comparison between test and analysis results (sinusoidal loading, 0.1, 1, and 3 Hz from left)

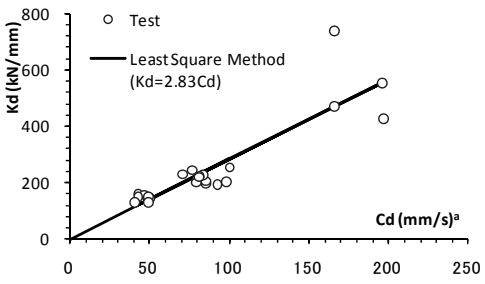

Figure 15. C_d vs. K_d obtained from Type 2 damper test and linear regression

the content in the absolute value bracket is positive and negative, respectively.

In Figure 12, force $F_d^{(i)}$ is plotted against estimated dashpot velocity $\dot{u}_d^{(i)}(=\dot{u}_m^{(i)}-\dot{F}_d^{(i)}/K_d)$, and is compared with the model curve given by Eq. (11a). The curve agrees well with the test data, except for the small velocity range. Because it was difficult to fit the curve in this range, Eq. 12 is applied to $\dot{u}_m^{(i)}$ whose absolute value larger than 50 mm/s.

In the above manner, C_d , K_d , and α values are obtained from each damper and each test applying deformation that corresponds to either 50% or 100% Takatori input. The values are alternatively determined from many other tests applying various sinusoidal deformations to the dampers.

The values of the three parameters thus-determined appear to be very similar for the same damper type, regardless of loading.

5.2 Damper Model and Accuracy

Figure 13 comparers the load-deformation curves obtained from the experiments with those predicted by the analytical model (Figure 10b). The dampers and their loading histories at Tokyo Tech. are the same as those in Figure 11. The analytical model agrees well with the experiment for the random loading.

The straight inclined line shows the value of K_d in the models, and indicates that it determines inclination of the hysteresis, which can be easily proved by Eq. 11. Modeling K_d as infinity was advised by the damper manufacturer (Table 1), but such an idealization is unreasonable for the cases shown in Figure 13.

Figure 14 shows comparison for cases of sinusoidal deformations, and again confirms accuracy of the analytical model for the loading.

The values C_d , K_d , and α values are then averaged over dampers of the same type and the two Takatori input cases, and the results are indicated in Table 1.

Like the Type 1 dampers adopted for the actual retrofit (Sec. 3 and Sec. 6), the Type 2 dampers tested in this study produce hysteresis loops of combined ellipse and rectangle. However, $\alpha = 0.2$ for the Type 1 dampers, and $\alpha = 0.34$ to 0.39 (Table 1) for the Type 2 dampers, making hysteresis curve of the latter more round.

Figure 15 shows values of C_d vs. K_d obtained for the twelve dampers (Table 1) and the two Takatori input cases. Because of strong linear relationship as Kasai et al. indicated for other viscous dampers (Kasai et al. 2007, JSSI Manual 2005, 2007), the following relationship is considered from now on:

$$K_d = \beta C_d \tag{7}$$

where $\beta = 2.83$ mm$^{\alpha-1}$/s$^{\alpha}$, if the length unit of mm is used.

As Figures 13 and 14 indicate, the inclination of damper force-stroke curve produces equivalent stiffness, less phase angle between the force and stroke, and less energy dissipation compared with the case of infinite K_d (Kasai et al. 2007). Likewise, if a flexible brace is attached in series with the damper (Figure 10b), the trends will be more prominent.

6. REDESIGN AND ANALYSIS

For comparative research, the Type 1 damper used in the repair project of actual RC building in China and the Type 2 dampers experimented in the present study are considered. They are now analytically used to achieve the aforementioned retrofitting objective on the premise that the design and distribution of these two dampers are equal expected damping forces under moderate earthquake. Thus, three different structural states (ST0, ST1 and ST2) are denoted in the comparative analysis, here ST0 is the primary frame (after repairing and story-adding transformation), ST1 is the damped frame using Type 1 dampers, and ST2 is the damped frame using Type 2 dampers.

Firstly, the finite element modeling and analysis are performed by PKPM2008 and SAP2000 software, and the corresponding structural properties of ST0 under seismic protection intensity 8 are shown in Table 3. It is noted that the X-direction here is the longitudinal direction (i.e. along West-East direction), and the Y-direction is the transverse direction (i.e. along North-South direction). Moreover, after primary analysis, 2 sets of strong earthquake records and 2 sets of artificial acceleration time-histories are adopted to the later time-history analysis.

Based on the simplified retrofitting design procedure introduced in Sec. 3, design and distribution of expected damping forces of ST1 and ST2 are conducted respectively. Therefore, with the consideration of retrofitting objective and architecture function of the existing frame, 4 buckling-restrained-braces (BRB) are installed on the ground floor, and 48 viscous dampers (with 24 chevron braces) are installed on the 2nd to 7th floor, as listed in Table 4. Here it is noteworthy that the total numbers of BRB and viscous dampers, as well as their locations are the same in ST1 and ST2, while the only difference is the damper categories and their design mechanical properties, as shown in Table 5.

As to Table 5, where α is the velocity exponent, C_d is the damping coefficient, and K_d is the interior stiffness of the viscous damper. Here K_d is obtained by the E-Defense test for Type 2 dampers, and assigned by 70% of C_d for Type 1 dampers. In minor earthquake response analysis, the all K_d are assigned by ∞ for ST1 and ST2. Besides, it is also noted that the damper category *A*, *B*, *C*, *D* of Type 1 dampers are expected to provide the designed damping forces of 600, 360, 240, and 120 kN, respectively, at the expected velocity of 80 mm/s under the moderate earthquake. Likewise, the damper category *A*', *B*', *C*' of Type 2 dampers are expected to provide the design damping forces of 1040, 520, and 260 kN, respectively, in the same condition.

Table 3 Structural properties of ST0 under earthquake intensity 8

Floor	Height (*m*)	Storey mass (*t*)	X-direction			Y-direction		
			Stiffness (*kN/mm*)	Shear force (*kN*)	Drift Angle (*rad*)	Stiffness (*kN/mm*)	Shear force (*kN*)	Drift Angle (*rad*)

K_d	175	105	70	35	526	220	146

Note: Unit of C_d is kN/(mm/s)$^{\alpha}$, and unit of K_d is kN/mm.

Accordingly, comparative analysis of ST1, ST2 and ST0 are conducted through time-history analysis method with the aforementioned ground accelerations, which refer to the comparison of the envelops of the inter-story drifts and story shear forces under minor earthquake, moderate earthquake and major earthquake respectively, as shown in Figures 16 and 17.

Here it is noted that the story shear forces are obtained from section forces of frame columns (without damper-braces). Moreover, for analysis cases under minor earthquake, the installation errors may have heavy influence on damping effect of the viscous damper due to its relatively small stroke, thus the interior stiffness of viscous damper is artificially modified to a larger value; while for analysis case under strong earthquake, the elastic modulus of concrete decrease with the structure going into plastic state, therefore the lateral stiffness of story is approximately reduced by a discount factor of $1/\mu$ (where μ is the displacement ductility coefficient, here in this frame it is assigned to 2) for simplified calculation.

In addition, from above figures, it is easily seen that both ST1 and ST2 have excellent structural performances and remarkable control effect compared to ST0, which means that both Type 1 and Type 2 dampers can be appropriately designed to control seismic behavior of non-ductile structures. With the equal expected damping forces provided by supplemental viscous damper (and BRB) under moderate earthquake, performances of ST1 are apparently superior to that of ST2 under minor earthquake, as shown in the left columns of Figures 16 and 17. However, these two damping scheme acquire similar control effect of story drifts and story shear forces, as shown in the middle columns of Figures 16 and 17. Whereas, performances of ST2 are relatively better than that of ST1 under strong earthquake, as shown in the right columns of Figures 16 and 17, which may partly derive from a larger velocity exponent of the Type 2 dampers, as compared to the Type 1 dampers.

7. CONCLUSIONS

This paper has described a 7-story RC building damaged due to the 2008 Wenchuan Earthquake, actual repair work performed, detailed full-scale damper tests, comparison of using two distinct types of nonlinear viscous dampers, herein called as Type 1 and 2 dampers, in the analysis of retrofit design.

Compared with Type 1 damper, Type 2 damper has higher velocity exponent and interior stiffness. Regardless of their differences in mechanical properties, it is concluded that when designed and distributed according to the simplified procedure proposed in this paper, both types have excellent damping effect and evidently can be used to achieve the structural retrofitting objective to increase one grade of seismic protection intensity without heavy strengthening work.

As to the application in seismic retrofit of the damaged frame, when Type 1 and Type 2 dampers are designed with the equal expected damping forces under moderate earthquake, it is apparent that Type 2 can provide relatively larger damping forces at a higher velocity, and consequently it has better control effects of story drifts and story shear forces under strong earthquake. Likewise, Type 1 can provide relatively large damping forces at a lower velocity due to its smaller velocity exponent. It is thus proved to have better damping effect under minor earthquake.

Abstract: Following the companion paper (Part 1) that described the 7-story RC building damage, actual repair work and analyses, and full-scale damper test, the present paper (Part 2) proposes a design method to determine the required capacity of viscous damper and its story-by-story distribution for RC building structure whose hysteresis is modeled as a stiffness-degrading type. The design method maintains the story drift uniformly at the target value. Its accuracy is verified by example damper design and time history analyses of the 7-story RC building.

1. INTRODUCTION

1.1 RC building repair using dampers

Use of dampers for seismic repair and retrofit of reinforced-concrete (RC) buildings is an attractive option. The cracking and spalling of concrete that can require extensive repair will be reduced significantly, if the dampers are attached to the building in a manner to efficiently absorb seismic energy.

The companion paper (Lu et. al. 2011) has described the 7-story RC building damaged due to the 2008 Wenchuan Earthquake, actual repair work performed by using nonlinear viscous dampers, detailed full-scale damper tests, and hypothetical repair and analysis using the damper test results. In the studies, the viscous dampers have been sized through design iterations utilizing time history analyses.

1.2 Damper distribution rule

RC frame shows complex hysteretic characteristics of degrading stiffness, and nonlinear viscous damper depends on not only velocity but also displacement. Because of these, the aforementioned design iterations based on trial and errors require significant effort.

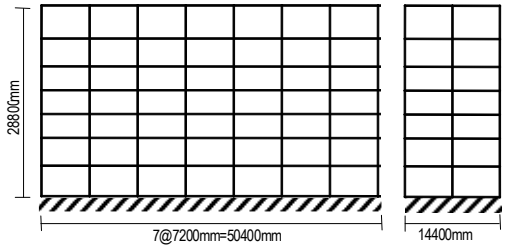
Thus, it is highly desirable to develop a comprehensive design rule that clearly indicates effects as well as necessary capacities of the dampers for the target performance of nonlinear RC frames. This paper proposes such a rule, by extending the writers' earlier design method for the elastic frame and nonlinear viscous dampers (Kasai et al. 2003b, 2007, JSSI Manual 2005, 2007, Chinese Translation 2008).

Like typical performance-based design, it is considered that the design earthquake level and corresponding limit for the story drift are given. The design rule then determines the distribution of required damper capacities throughout the building height, so as to maintain the story drift uniformly at the target value, thereby avoiding damage concentration to a particular story.

The sample RC building discussed in Part 1 (Lu et al. 2011) is briefly introduced, and the target performance for its repair design is explained in Section 2. Modeling scheme for the original RC building is proposed in Section 3. The damper distribution rule and specific steps are described in Section 4. Accuracy of the rule and design will be demonstrated in Section 5, where the design example will consider Type 2 dampers discussed in Part 1 (Lu et al. 2011).

2. SEISMIC DESIGN CRITERIA FOR REPAIR

2.1 Description of RC Building



The existing building under investigation was originally a 6-story RC frame (with partial 7-story extruded) constructed in 1997, and it was damaged by the Wenchuan earthquake in 2008. After earthquake, the building was strengthened by adding steel columns, and reconstructed into a 7-story building. All analysis of this study will be based on the existing 7-story building. Figure 1 shows the front view of the building damaged by the earthquake, as well as the elevation of the building frame. The companion paper (Lu et al. 2011) describes more details.

2.2 Design criteria based on Chinese spectrum

The writers consider the same design criteria as used for the actual repair project (Lu et al. 2011). In order to

(a) Building damaged by earthquake

(b) Elevation of 7-sotry building (X and Y- direction)

Figure 1. RC building damaged by the 2008 Wenchuan earthquake and its elevation after repair and strengthening

meet the increased requirement of Chinese code after the quake (GB50011-2010), and to provide redundant load carrying capacity of structure, the target story drift angles of the building are set as 1/800, 1/300 and 1/100, at minor, moderate, and major earthquakes, respectively.

A suit of four ground acceleration histories are used to examine the structural performance, of which two are artificial and two others are recorded ones. According to the China seismic code, the peak ground acceleration (PGA) for seismic intensity 8 should be 70, 200, and 400 cm/s^2 for minor, moderate, and major earthquakes, respectively. However, as described previously (Lu et al. 2011, Weng et al. 2009, 2011), in order to consider the contribution of partition walls to the stiffness of the building, the PGA is amplified by 22%, and 85.4, 244, and 488 cm/s^2 will be used, respectively. Figure 2 shows four acceleration histories thus-amplified to PGA = 488 cm/s^2, and corresponding pseudo-acceleration spectra with 5% damping ratio.

3. RC FRAME NONLINEAR MODEL

3.1 Static push-over analysis of 7-story RC frame

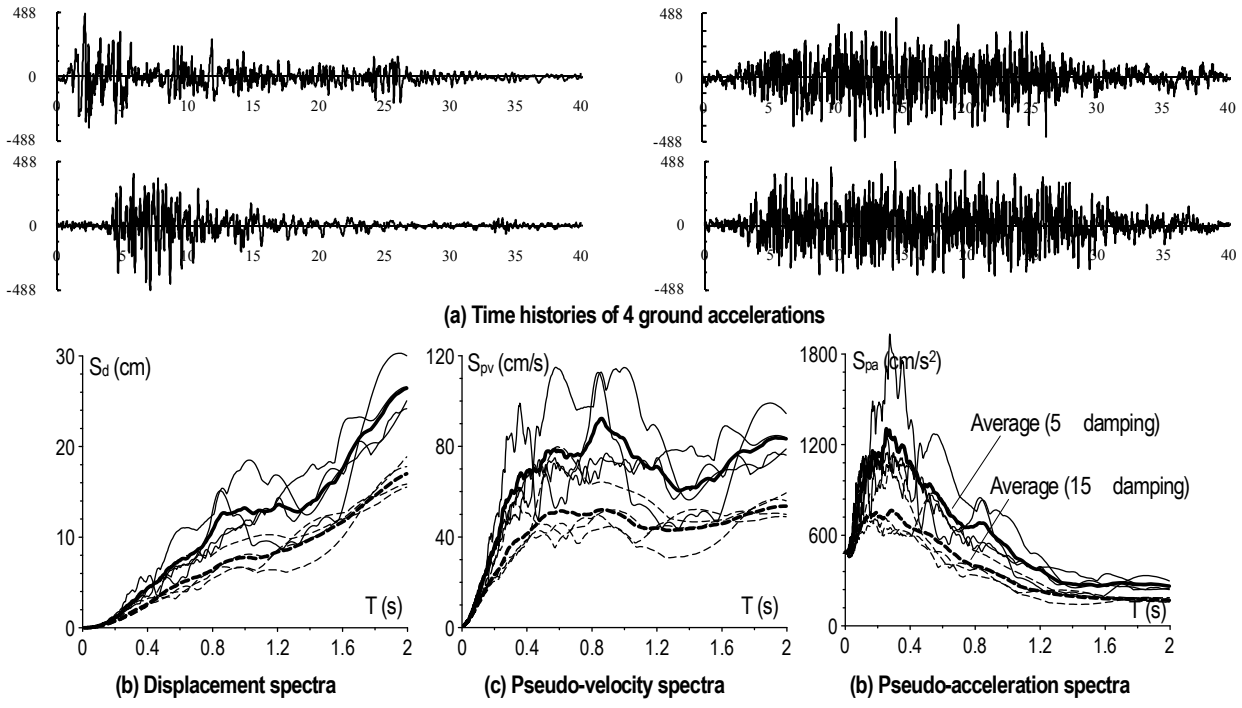
The RC frame was modeled in the actual repair project by using the nonlinear member-to-member model, hereby defined as "frame model". The Chinese computer program PKPM2008 is used to analyze the model.

Figures 3a and b show results of static push-over analyses in X- and Y-directions, respectively. Relationship of story shear Q_i vs. story drift $h_i\theta_i$ at i-th story level is shown, where h_i and θ_i = story height and story drift angle at i-th story level, respectively. The lateral load distribution corresponds to the story shear distribution calculated from Chinese code (GB50011-2010).

The frame tends to show highly non-uniform deformation, with larger story drifts at the 2nd and 3rd story levels.

3.2 Story-by-story idealization of cyclic behavior

For the rule to estimate required damper capacities, hysteretic characteristics of the RC frame must be known beforehand. Instead of time-consuming analysis applying



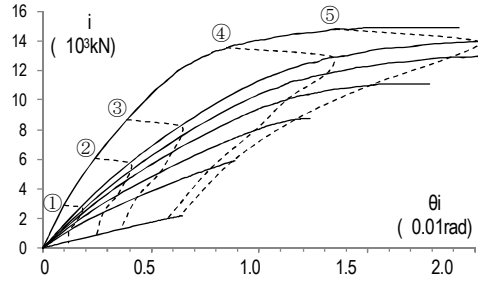


Figure 2. Time histories of 4 ground accelerations and their response spectra with different damping ratios (Solid line =5% damping ratio, broken line = 15% damping ratio)

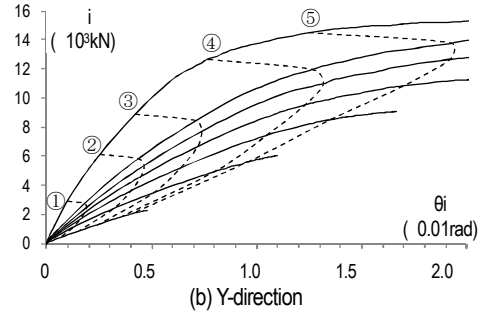

Figure 3. Static pushover analysis results for the frame model (Average drift angle = 1/800, 1/300, 1/200, 1/100, 1/75 in the order of ①~⑤)

cyclic load to the nonlinear member-to-member model (Sec. 3.1), such characteristics will be idealized story-by-story using the stiffness degrading model called "Takeda model" (Takeda et al. 1970) as follows.

In the model, hysteresis depends on experienced maximum story drift angle θ_i, where i = story level. The model is elastic at $\theta_i<\theta_{ci}$, where θ_{ci}= cracking drift angle defined by micro-cracking of the concrete material. Figure 4a shows the model at $\theta_{ci}<\theta_i<\theta_{yi}$, where θ_{yi}= yield drift angle when the steel reinforcing bars yield significantly and plastic hinge formed at the member. Figure 4b shows the model at $\theta_{ci}<\theta_{yi}<\theta_i$.

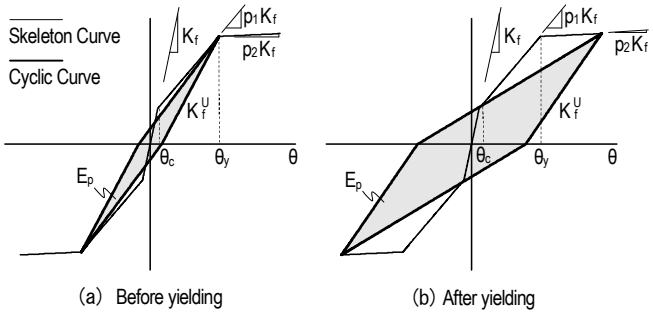

Figure 4 Idealized hysteresis (Takeda) model for RC frame (Note: subscript "i" to denote story level is not indicated)

Accordingly, Takeda model has tri-linear skeleton curve, and the first, second, and third lines represent elastic stiffness K_{fi}, post-crack stiffness $p_{1i}K_{fi}$, and post-yield stiffness $p_{2i}K_{fi}$ against the story drift $h_i\theta_i$, respectively.

The most significant characteristics that differentiate Takeda model with other models are the loading and unloading rules. The stiffness K_{fi}^U when unloading from skeleton curve depends on θ_i experienced, and is given as:

$$\theta_i \le \theta_{ci}: \quad K_{fi}^U = K_{fi} \tag{1a}$$

$$\theta_{ci} < \theta_i \le \theta_{yi}: \quad K_{fi}^U = K_{fi}\frac{2\theta_{ci} + p_{1i}(\theta_i - \theta_{ci})}{\theta_i + \theta_{ci}} \tag{1b}$$

$$\theta_{yi} < \theta_i: \quad K_{fi}^U = K_{fi}\frac{2\theta_{ci} + p_{1i}(\theta_{yi} - \theta_{ci})}{(\theta_{yi} + \theta_{ci})(\theta_i/\theta_{yi})^{0.4}} \tag{1c}$$

After one or more loading cycles have occurred, the loading curve can be constructed by connecting the point at zero load to the point reached in the previous cycle, if that point lies on the skeleton curve or on a line aimed at a point on the skeleton curve. The more details about loading and unloading rules can be found in Takeda et al. (1970).

In order to perform analysis using Takeda hysteretic model, tri-linear skeleton curves are constructed to substitute the continuous nonlinear curves, as depicted by Figure 5. After the initial stiffness K_{fi} is specified from the pushover curve (step 1 in Figure 5), the third segment of skeleton curve crossing the original nonlinear curve at drift angle of

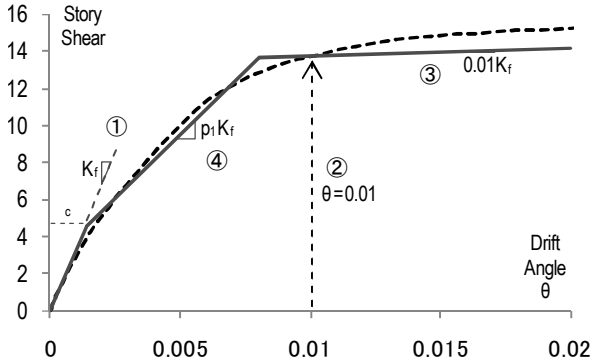

Figure 5. Tri-linear approximation of frame pushover curve

4	10221	3600	366	245	3.7	0.24	0.94	3139	9419	348	212	3.5	0.22	0.95	2804	8414
3	10427	3600	395	280	4.0	0.24	0.93	3467	10400	395	249	4.0	0.22	0.94	3194	9584
2	9369	4200	382	259	3.8	0.24	0.92	3776	11328	400	232	4.0	0.21	0.94	3560	10681
1	11152	4600	658	329	6.6	0.16	0.77	4686	14059	726	298	7.3	0.14	0.81	4580	13740

1/100 (step 2) with the post-yield stiffness $p_{2i}K_{fi} = 0.01K_{fi}$ is drawn (step 3). Further, post-crack stiffness $p_{1i}K_{fi}$ is drawn (step 4) on the basis of energy equivalence and condition that the force at cracking is 1/3 of the yield force. (Figure 5)

In this manner, for the *i*-th story level, all parameters K_{fi}, p_{1i}, p_{2i}, θ_{ci}, and θ_{yi} to construct Takeda model are evaluated, and the values are listed in Table 1. Additionally, for the stories where drift angle could not reach 1/100 in pushover analysis, the maximum drift angle can be used instead of 1/100 in step 2 mentioned above. The tri-linear skeleton curve obtained for the 7-story RC building agrees reasonably well with the push-over curve in both X- and Y-directions, see Figure 6.

3.3 Accuracy of story-by-story idealization

In order to check appropriateness of the story-by-story idealization explained above, a stick model having the idealized hysteresis (Figure 4) of the 7-story RC frame is produced. Seismic responses of the stick model and the original frame model (Sec. 3.1) are compared using four different ground acceleration histories and three different levels explained in Sec. 2.2.

Figure 7 shows average of story drifts due to the four acceleration histories at each excitation level. For the minor and moderate excitation levels, the stick model shows excellent match with the frame model. For the major level, the former shows more deformation at the 2nd and 3rd story levels, indicating sensitivity of responses against plastic stiffness of each story. Thus, as a conservative and simplified approach for the stories developing large deformations, the idealized hysteresis will be considered throughout the present paper.

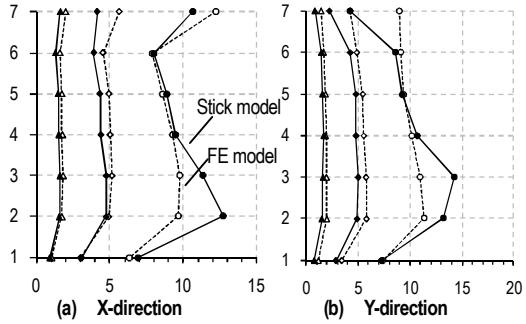

Figure 7. Comparison of analysis results obtained by finite element model and a stick model with idealized hysteresis

The 7-story multi-degree-of-freedom (MDOF) stick model without dampers will be called as the "*MDOF system*", and the system combining it with dampers story-by-story will be called as the "*damped MDOF system*" from now on. Further, for the single-degree-of-freedom system to be discussed, the "*SDOF system*" and the "*damped SDOF system*" are defined.

3.4 Energies produced from idealized frame hysteresis

The present rule aims to produce uniform story drift angle of the target value θ_t. Using idealization depicted by Figure 4, Secs. 3.2 and 3.3, stored and dissipated energies E_{si}, E_{di} at *i*-th story of the MDOF system developing the target drift angle θ_t uniformly are given as:

$$E_{si}=\beta_i K_{fi}(h_i\theta_t)^2/2 \quad , \quad E_{pi}=\zeta_i K_{fi}(h_i\theta_t)^2 \tag{2a,b}$$

where β_i and ζ_i are used to compare energies E_{si}, E_{di} with the stored energy of an elastic MDOF system, and they depend on the magnitude of θ_t, *i.e.*,

$$\theta_t \le \theta_{ci}: \quad \beta_i=1 \quad , \quad \zeta_i=0 \tag{3a,b}$$

$$\theta_{ci}<\theta_t \le \theta_{yi}: \quad \beta_i=p_{1i}+(1-p_{1i})\frac{\theta_{ci}}{\theta_t} \tag{4a}$$

$$\zeta_i=\frac{2(1-p_{1i}(1-\theta_{ci}/\theta_t)\{p_{1i}+(1-p_{1i}\theta_{ci}/\theta_t)\}}{2+p_{1i}(\theta_t/\theta_{ci}-1)} \tag{4b}$$

$$\theta_{yi}<\theta_t: \quad \beta_i=-p_{2i}+(1-p_{1i})\frac{\theta_{ci}}{\theta_t}+(p_{1i}-p_{2i})\frac{\theta_{yi}}{\theta_t} \tag{5a}$$

$$\zeta_i=2\beta_i-\frac{\beta_i^2(1+\theta_{ci})(\theta_t/\theta_{yi})^{0.4}}{2\theta_{ci}+p_{1i}(1-\theta_{ci})} \tag{5b}$$

The above equations will be used in the next sections.

4. SEISMIC CONTROL DESIGN

The present rule finds damper distributions to achieve uniform story drift angle θ_t, even for frames of irregularly distributed structural parameters (Sec. 1.2). Considering the MDOF system with idealized hysteresis (Secs. 3.2 and 3.4), damper design for the given earthquakes and target performance is outlined below:

Step 1: The MDOF system is converted to a SDOF system, such that stored and dissipated energies of both

systems are equal at the target θ_t (Sec. 4.1).

Step 2: For the above SDOF system, required capacity of a viscous damper to be added to satisfy θ_t is found by time history analyses (Sec. 4.2).

Step 3: The required damper capacity found in step 2 for the SDOF system is converted and distributed story-by-story to the MDOF system (Sec. 4.3).

The following sections describe each step:

4.1 Conversion from MDOF system to SDOF system

The first step converts the MDOF system to an equivalent SDOF system. By imposing uniform deformation to the MDOF system and equating its stored and dissipated energies to those of the SDOF system,

$$E_s = \frac{1}{2}\beta K_f (H_{eff}\theta_t)^2 = \sum_{i=1,N} E_{si} \tag{6a}$$

$$E_p = \zeta K_f (H_{eff}\theta_t)^2 = \sum_{i=1,N} E_{pi} \tag{6b}$$

where E_s, E_p = stored and dissipated energies of the SDOF system, β, ζ = factors to determine E_s and E_p, respectively, and H_{eff} = effective height of the RC building estimated by assuming uniform deformation (e.g., Kasai et al. 1998, 2010b, Kasai and Pu 2010a, JSSI Manual 2005, 2007) as follows:

$$H_{eff} = \sum_{i=1,N} m_i H_i^2 / \sum_{i=1,N} m_i H_i \tag{7a,b}$$

Using Eq. 6 and other conditions set for the elastic range, post-crack range, and post-yield range, respectively. parameters defining hysteresis of the SDOF system will be determined as follows:

Elastic stiffness K_f is obtained by substituting $\beta = 1$ into Eq. (6a). Other parameters characterizing the hysteresis loops are named as p_1, p_2, θ_c, and θ_y (Figure 4), like those in the MDOF system. They are obtained in the following two ways:

If $\theta_t < \theta_{yi}$ in all stories of the MDOF system, the SDOF system is considered to be at either elastic or post-crack state, and only p_1 and θ_c are needed to define its hysteresis. After obtaining β_i and ζ_i from Eq. (3) or (4) and estimating the energies of the MDOF system by Eq. (2), the β and ζ of the SDOF system are calculated using Eq. (6). Then, p_1 and θ_c are obtained by solving the following equations:

$$\beta = p_1 + (1-p_1)\frac{\theta_c}{\theta_t} \tag{8a}$$

$$\zeta = \frac{2(1-p_1)(1-\theta_c/\theta_t)\{p_1 + (1-p_1)\theta_c/\theta_t\}}{2 + p_1(\theta_t/\theta_c - 1)} \tag{8b}$$

Note that the same hysteresis type as that of the MDOF system is considered, thus, Eq. (8) is similar to Eq. (4).

If $\theta_t > \theta_{yi}$ in at least one story of the MDOF system, the SDOF system is considered to be at post-yield state. Thus, all parameters p_1, p_2, θ_c, and θ_y must be obtained. Like the post-crack state discussed above, equations similar to Eqs. (5a) and (5b) can be used to solve for the two of the four unknowns. In the present study, p_2 and θ_c are considered less important than p_1 and θ_y, and they are simply estimated as average of the values at all stories of the MDOF system. Thus, p_1 and θ_y are obtained by solving Eqs. (9a,b) below:

$$\beta = -p_2 + (1-p_1)\frac{\theta_c}{\theta_t} + (p_1 - p_2)\frac{\theta_y}{\theta_t} \tag{9a}$$

$$\zeta = 2\beta - \frac{\beta^2 (1+\theta_c)(\theta_t/\theta_y)^{0.4}}{2\theta_c + p_1(1-\theta_c)} \tag{9b}$$

$$p_2 = \sum_{i=1,N} p_{2i}/N \quad , \quad \theta_c = \sum_{i=1,N} \theta_{ci}/N \tag{9c,d}$$

Figure 8 plots an example for hysteresis curves of the MDOF system at drift angle of ± 1/100 rad , from which different extent of plastification and degradation can be recognized story-by-story. Figure 8 also shows the hysteresis curve of the equivalent SDOF system determined by the above method.

Like the actual repair project (Lu et al. 2011), the above conversion was performed for two principle directions of the building, with the target story drift angle θ_t = 1/300 against the moderate earthquake (Sec. 2.2). After designing the dampers, the performance of the damped MDOF will be checked by considering the minor and major earthquakes (Sec. 2.2) and their drift limits 1/800 and 1/100, respectively.

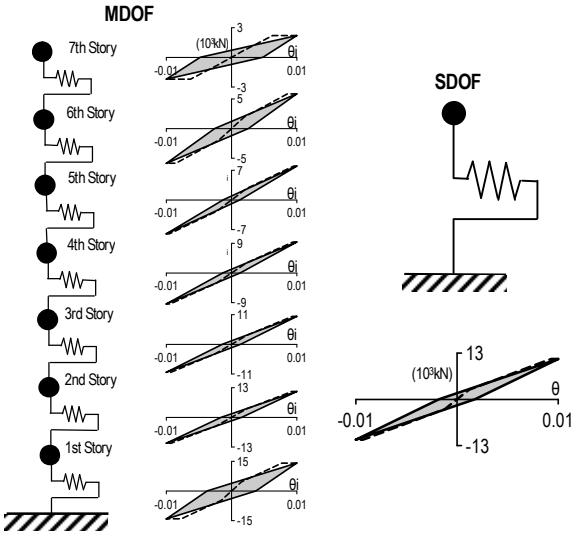

Figure 8 Conversion of MDOF system to SDOF system without damper (X-direction)

4.2 Damper Design for SDOF system

A system combining the SDOF system and a nonlinear viscous damper element with assigned values of C_d, K_d, and α is created, and it will be named as the damped SDOF system. Type 2 damper will be considered (Sec. 1.2).

As shown in Figure 9, an "added component" consists of a series combination of the nonlinear dashpot of with the viscosity coefficient of C_d, the spring simulating damper internal stiffness K_d, and the spring simulating the stiffness of support brace and connections K_b. In the present study, K_d is considered to be much smaller than K_b, thus only the

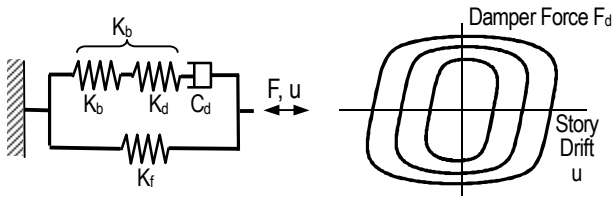

Figure 9. Damper force vs. story drift curve for equivalent damped SDOF system under different target drifts

value of K_d is used to simulate the flexibility of the spring.

The time history responses of the damped SDOF system are obtained for the set of earthquakes (Sec. 2.2.). Note that the method to create the analytical model requires some caution due to nonlinearity of viscous damper, and details are explained in Appendix-I.

Figure 10 shows such analyses using one of the artificial earthquakes. The value of C_d is increased from 0, and analysis repeated only a few times until the maximum displacement of the damped SDOF system is about equal to the target θ_t. Based on full-scale tests (Lu et al. 2011), α = 0.38 and K_d= 2.83C_d are considered, with units kN/mm and kN/(mm/s)$^{0.38}$ for K_d and C_d, respectively.

The example in Figure 10 considers the moderate earthquake (one of the artificial earthquakes) and target θ_t= 1/300, as explained in Sec. 4.1. The undamped SDOF system 1 develops the drift angle 1/232, but the damped SDOF system 2 has reduced it to 1/300 rad. The values are based on the assumption of uniform drift angle, and may be viewed as the indicator of an average drift angles throughout the building. Note also that the curve indicating peak base shear vs. peak deformation of the damped SDOF system follow the profile of the frame skeleton curve, with added force produced by the nonlinear viscous damper (Figure 10).

In the present design, the required C_d value is found such that the average of the drift angles of the SDOF system due to the four moderate earthquakes reaches the target θ_t= 1/300. Using the values of C_d, K_d, and $u_{d,\max}$ thus-obtained, as well as β from either Eq. (8a) or (9a), effective circular

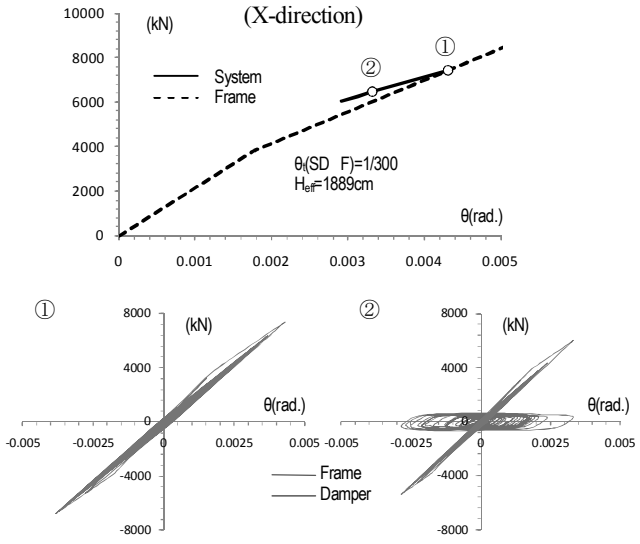

Figure 10 Time history analysis of SDOF system with damper

frequency ω_{eq} is obtained from Eq. (10a) with a few iterations, *i.e.*,

$$\omega_{eq}=\sqrt{\frac{K'_a(\omega_{eq})+\beta K_f}{M_{eff}}} \quad , \quad M_{eff}=\frac{\sum_{i=1,N}(m_i H_i)^2}{\sum_{i=1,N} m_i H_i^2}$$

$$K'_a=\frac{\lambda^{1+\alpha}}{1+\lambda^{1+\alpha}}K_b^* \quad , \quad \lambda=\frac{C_d \omega_{eq}^{\alpha} u_{d,\max}^{\alpha-1}}{K_b^*} \qquad \text{(10a-d)}$$

where M_{eff} = effective modal mass estimated by assuming a straight-line mode shape, $K'_a(\omega_{eq})$ = storage stiffness of the added component, K_b^* = equivalent brace stiffness combining effects of K_b and K_d (Figure 9), approximately equal to K_d in the present study, as mentioned above. Eqs. (10c,d) were derived previously (Kasai et al. 2003b, 2007, JSSI Manual 2005, 2007, Chinese Translation, 2008).

After obtaining ω_{eq} , the supplemental equivalent damping ratio ξ_{eq} is calculated as follows:

$$\xi_{eq}=\frac{E_p+E_v}{2\pi(K'_a(\omega_{eq})+\beta K_f)(H_{eff}\theta_t)^2} \qquad (11)$$

where E_p is already known from Eq. (6a), and E_v is the energy dissipated by the viscous damper. Using the formulas derived earlier (Kasai et al. 2003b, 2007), E_v is expressed as follows:

$$E_v=4\left(\frac{1+\lambda^{1+\alpha}}{e^{0.24}}\right)^{\alpha} C_d \omega_{eq}^{\alpha} u_{d,\max}^{\alpha-1}(H_{eff}\theta_t)^2 \qquad (12)$$

The calculated values for θ_t = 1/300 are as follows: Compared with the x- and y-direction elastic vibration periods 1.41 and 1.43 seconds, the effective periods ($2\pi/\omega_{eq}$) has changed to 1.59 and 1.55 seconds, due to softening of the frame and stiffening by the damper. Supplemental effective damping ratios ξ_{eq}'s are somewhat small and 0.034 and 0.031, respectively, where E_p is about 2 times the E_v .

The values of ω_{eq} and ξ_{eq} of the damped SDOF system will be utilized for design of the damped MDOF system in the next section.

4.3 Damper distribution rule for MDOF system

The required damper capacity for the damped SDOF mentioned above will be distributed story-by-story to the MDOF system, satisfying the constraining conditions below:

(1) The equivalent damping ratios of the damped SDOF system and damped MDOF systems are equal.
(2) Equivalent story stiffness of the damped MDOF system at a uniform target drift angle θ_t is proportional to the design story shear force.

The design story shear force distribution is calculated based on the Chinese seismic code. The writers derived distribution rules for many combinations of the dampers and frames (e.g., Kasai et al. 1998, 2005-2008). Based on the previous work, the distribution rule for the required damper force $F_{di,\max}$ is proposed below:

$$F_{di,\max}=\left(\frac{1+\lambda^{1+\alpha}}{\lambda^2}\right)^{\alpha/2}\left\{\frac{\sum_{i=1,N}(A\beta_i-\zeta_i)K_{fi}h_i^2}{A\sum_{i=1,N}Q_ih_i-2\pi\xi_{eq}}\frac{Q_i}{h_i}-K_{fi}\beta_i\right\}h_i\theta_t$$

$$u_{di,\max}=\frac{h_i\theta_t}{(1+\lambda^{1+\alpha})^{1-0.5\alpha}}\quad,\quad A=\frac{4e^{-0.24\alpha}}{\lambda^{\alpha}(1+\lambda^{1+\alpha})^{1-\alpha}} \qquad (13a\text{-}c)$$

where α = 0.38, Q_i = design story shear force, and $u_{di,\max}$= expected maximum deformation of the dashpot (Figure 9) at i-th story of the damped MDOF system.

Eq. (13) assumes the dampers are oriented horizontally, following the actual project (Lu et al. 2011). A negative value of $F_{di,\max}$ means that the frame at the i-th story is stronger than necessary, and no damper is assigned to such a story. Detailed derivation of Eq. (13) will be given elsewhere.

Note that Eq. (13b) indicates effectiveness of the damper: It clarifies how much damper deforms relative to the maximum story drift $h_i\theta_t$, and depends largely on the "support deformation ratio" λ (Eq. (10d)), a ratio between the maximum deformations of the spring of equivalent brace stiffness K_b^* and the nonlinear dashpot (Figure 9). Larger λ means larger spring deformation, and consequently less damper deformation and energy dissipation.

In the present formulation, λ is assumed constant, thus, approximate proportioning K_b^* to C_d is required at each story. This is automatically satisfied in the present study, since K_b^* is approximately set to K_d which is also proportional to C_d (Sec. 4.2). However, if K_b happens to be small, it should be adjusted to satisfy the above assumption.

Since the nonlinear viscous damper force is proportional to fractional power of velocity, the required viscosity coefficient C_{di} is obtained from:

$$C_{di}=\frac{F_{di,\max}}{(\omega_{eq}u_{di,\max})^{\alpha}} \qquad (14)$$

Table 2. MDOF design results for viscous dampers (α=0.38)

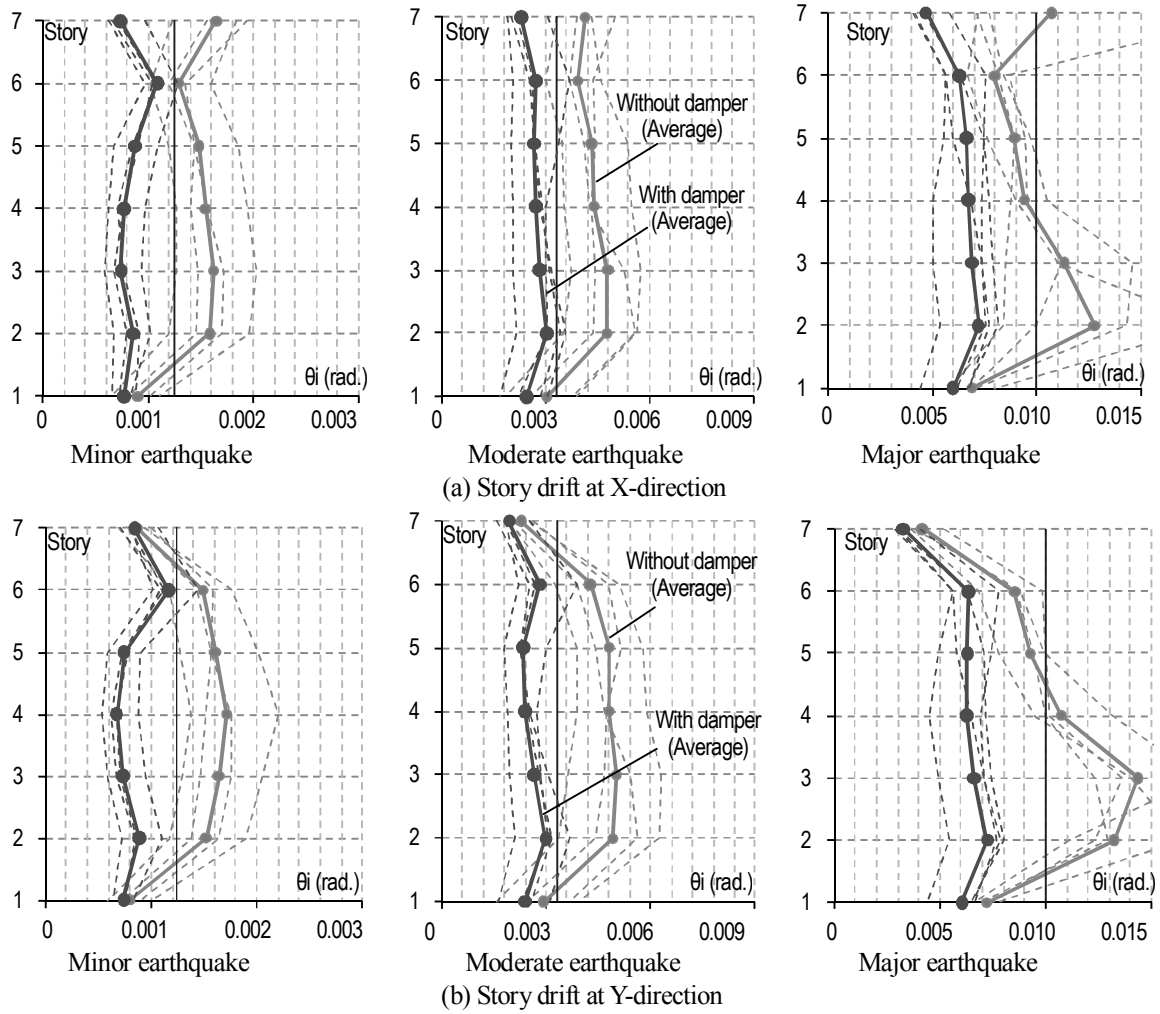

Figure 11. Drift angles of RC building with and without dampers (dampers designed for the moderate earthquake)

and $K_{di} = 2.83 C_{di}$ with the unit kN/mm (Sec. 4.2).

Table 2 lists required damper capacities for the moderate earthquake and target θ_t = 1/300 in X- and Y-directions, respectively. In order to obtain equivalent stiffness distribution proportional to story shear force (Sec. 4.3), the dampers are distributed to relatively weak stories but not all stories based on their stiffness. Namely, the added components compensate the stiffness of frame, while dissipating earthquake energy as required by the rule.

The dynamic analysis on existing undamped frame building (Sec. 3, Figure 7) showed relatively small responses in 1st and 6th stories of X-direction, and 1st and 7th stories of Y-direction. Eq. (13) using the static load captures this dynamic trend, and requires no dampers in these stories for the moderate earthquakes considered.

5. ANALYTICAL VALIDATION AND COMMENTS

5.1 Validation by Dynamic Analyses

As commented earlier, repair design of the 7-story RC building is completed for the moderate earthquakes with the target story drift angle θ_t = 1/300. It is then checked against the minor and major earthquakes and the corresponding drift limits 1/800 and 1/100, respectively.

Broken lines in Figure 11 show drift angles of the (undamped) MDOF system as well as damped MDOF system against the four minor earthquakes, the four design (moderate) earthquakes, and the four major earthquakes, respectively. The thick solid line shows the average of the responses over the four earthquakes, and vertical and thin solid straight line indicates the design limit for each earthquake level.

Story drift angles of the damped MDOF system under the design (moderate) earthquakes match well with the target angle θ_t = 1/300 with some conservatism, indicating appropriateness of the proposed damper distribution rule. Also, those under the minor and major earthquakes are below the design limits, respectively, and the system designed for the moderate earthquake appears to be adequate for the other levels of earthquakes as well.

As an example, responses due to a major earthquake are shown in Figure 12, where hysteretic curves show story shear and story drift angle relationship for every story of the 7-story undamped system (Figure 12 left) and damped system (Figure 12 right), respectively. The former shows considerable deformations and stiffness degradation in the 2nd and 3rd stories, whereas the latter using the dampers mitigates such a problem. Figure 12 right also shows the frame of the latter responds almost elastically, by virtue of the dampers sharing story shear and dissipating energy. The damper distribution rule achieving uniform deformation at the design level (Figure 11) appears to be reasonably effective at the major earthquake level as well. The stories where the rule indicated no need for dampers has performed satisfactorily without dampers (Figure 12 right).

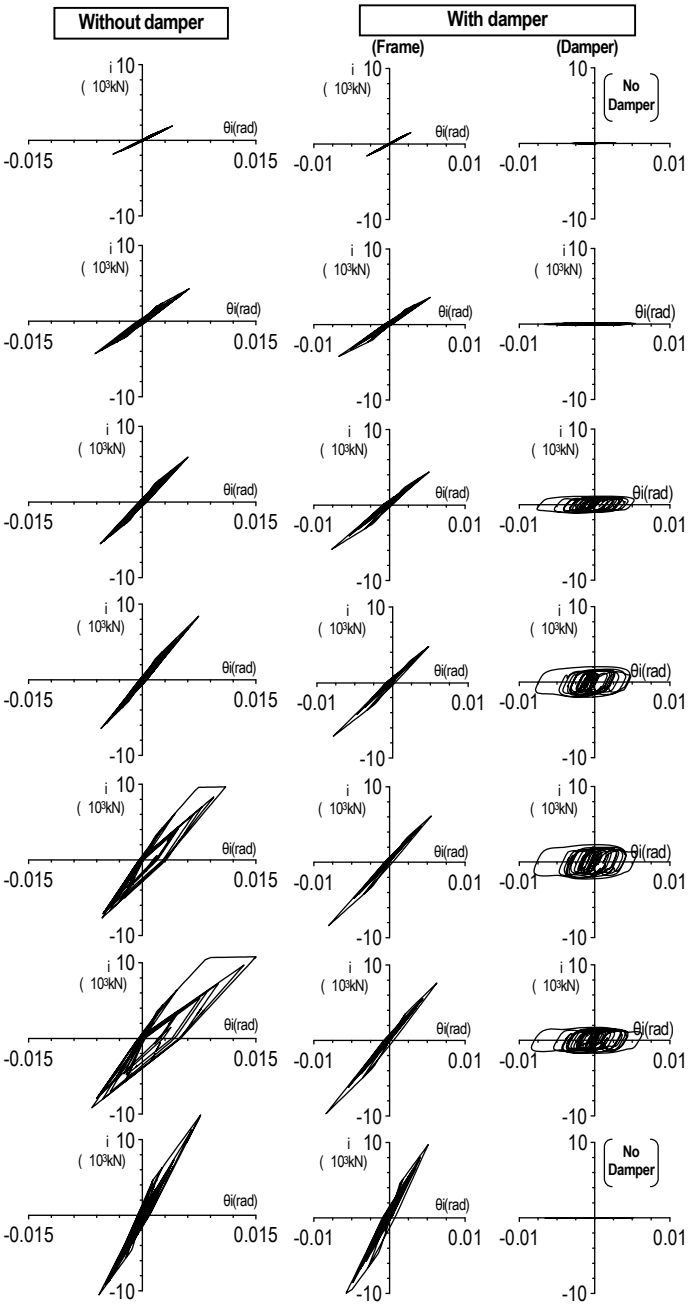

Figure 12. Hysteresis example for design against major earthquake (Y-direction)

5.2 Important Comments

It is interesting to compare the present damper design with the previous design performed on a trial basis assuming the same damper type (Type 2), as discussed in the companion paper. Both designs consider the same moderate earthquakes and target θ_t.

From Tables 4 and 5 of the companion paper (Lu et al. 2011), the sum of required C_{di}'s (i = 1 to 7) of the Type 2 dampers was 1,960 kN/(mm/s)$^{0.38}$ in each of X- and Y-directions. Whereas, from Table 2 of the present paper, the values are 1,108 and 1,319 kN/(mm/s)$^{0.38}$ in X- and Y-directions, respectively. They are 0.57 and 0.67 times that of the previous design, which is significant difference, even considering that the previous design was limited by

commercially available C_{di}-values and thus over-sizing of damper was inevitable.

The main reason for such difference of the two designs is that the present distribution rule can optimize the damper capacity story-by-story, thereby requiring less capacities. As discussed in Sec. 4.3, dampers were not used in 1st and 6th stories for X-direction, and 1st and 7th stories for Y-direction. Further, in contrast to the previous design increasing the damper capacity gradually from upper to lower stories, the present design provides larger amount of damper wherever necessary.

However, it is also noted that, due to nonlinearity of the frame and dampers, optimum damper capacities and distributions vary, depending on the level of the earthquake and target performance. Thus, once design is complete at one level, its adequacy must be confirmed at other stipulated levels. In Sec. 5.1, the design was confirmed in such a manner (Figure 11).

Comparing the earthquake levels and corresponding drift limits, which level governs the design is almost obvious in the present building case. However, if it were not the case, or if preliminary estimate for required damper capacity were necessary, the check using the SDOF system (Sec. 4.2) would be simple and useful. By this check, one can find the earthquake level requiring the most control, hence the largest damper quantity, and corresponding dynamic properties such as effective period and damping ratio. The result of this SDOF check will also be directly utilized to the damper distribution rule for the MDOF system.

Accordingly, the writers are currently developing a simplified tool to perform the same SDOF check. Considering a graphical approach as one of the practical methods to solve nonlinear problem, the writers developed various "performance curves" expressing response reduction in term of the amount of linear or nonlinear dampers and linear or nonlinear frame properties (Kasai et al. 1998, 2005-2009, 2010a and b, JSSI Manual 2005, 2007, Chinese Translation 2008.) The curves are being extended to include nonlinear viscous dampers and stiffness-degrading frames discussed in the present paper.

6. CONCLUSION

This paper has proposed a design method to determine the required capacity of viscous damper and its story-by-story distribution for RC building structure whose hysteresis is of stiffness-degrading type. The design method maintains the story drift uniformly at the target value. Its accuracy is verified by example damper design and time history analyses of an existing 7-story RC building damaged during the 2008 Wenchuan Earthquake and repaired using nonlinear viscous dampers of different type (Lu et al. 2011).

Compared with the trial-based design reported in Part 1, the present design method requires considerably less damper capacities, by optimizing the damper capacity story-by-story. The optimized solution is hardly obtained by trial-based design, and it is significant advantage for the economy of dampers, connections, surrounding frame members, and foundations transmitting the damper forces.

The initial step for the design method using the SDOF system and its time history analyses is unique, and provides many significant information for the passive control design. On the other hand, it will be replaced by a simplified graphic approach in order to simplify the whole design procedure.

ACKNOWLEDGEMENTS

APPENDIX-I

The undamped MDOF system is firstly converted to an equivalent SDOF with equivalent height estimated by Eq. (7a). Time history analysis on SDOF system with increased damper is repeated until the target drift angle is achieved. Figure A1 shows two analysis models used for the SDOF system. In model A, the damper is added at the equivalent height H_{eff}=1889cm together with the spring denoting the stiffness of frame K_f. Obviously, the damper in SDOF system will experience deformation much larger than the actual deformation of dampers in MDOF system.

Due to the nonlinear viscosity, the damper obtained in such a way may not reflect the correct relationship between damper and frame. Therefore, a substituted Model B is used, where the frame stiffness and damper are added to a typical story height H_0 (360cm used in this study) of the original MDOF system, so that damper in the SDOF system experiences approximately the same deformation and velocity as those in the MDOF system at target drift angle θ_t (Figure A1).

It is noted that the displacement of spring of frame in Model B is reduced to be H_0/H_{eff} times, the force of SDOF frame is accordingly scaled up by multiplying it by H_{eff}/H_0. Namely, the stiffness of frame in Model B is set as Eq. (A1), while the equivalent periods of two systems without dampers remain equal.

$$K'_f = K_f (H_{eff}/H_0)^2 = M_{eff}\omega_{eq}^2 (H_{eff}/H_0)^2 \qquad \text{(A1)}$$

After the required values of C'_d, K'_d in Model B are determined by repeated time history analyses, the values of the equivalent C_d, K_d in Model A are estimated by Eq.(A2a) and (A2b), while $u_{d,max}$ keeps unchanged (Eq. (A2c)).

$$C_d = C'_d (H_{eff}/H_0)^2 \ , \ K_d = K'_d (H_{eff}/H_0)^2 \ ,$$

$$u_{d,\max} = u'_{d,\max} \qquad \text{(A2a-b)}$$

The obtained values of C_d, K_d, $u_{d,max}$ will be used in Eqs. (10) and (11). In the time history analysis, tangent stiffness proportional damping is used for the spring to simulate the frame, with damping ratio set to 5% at elastic state. Vibration period is 1.4 sec. These are consistent with the analysis of the MDOF system.

Abstract: According to the shake table test results of a complex high-rising building with large local space, the dynamic characteristics of such structure are complex and the torsional mode becomes the first mode, while the torsional responses under earthquake excitation, especially of the floor just above the large local space, are very remarkable. Special measures are required for such structural system for maintaining its seismic safety. The bidirectional Tuned Mass Damper (TMD) is employed for reducing the torsional vibration of the high-rising building with large local space. The optimization of the TMD parameters, such as natural frequency, damping ratios and mass ratio, is performed. The time history analysis results indicate that the proposed bidirectional TMD is very effective in torsional vibration control.

1. INTRODUCTION

For some high-rising buildings, large local space is very useful for the special function needs, such as conference hall and hotel lobby. The high-rising structures with large local space obviously belong to complex irregular structural system which may suffer serious damages induced by the torsional vibration under earthquake condition. A shake table test on such structural system has been performed by Zhao et al. (2007) that indicate the dynamic characteristics are complex and the torsional mode has become the first mode of the structure. The torsional responses under earthquake excitation, especially of the floor just above the large local space, are quite remarkable and special measures are required for such structural system for maintaining its seismic safety.

During the past 30 years, several innovative passive and active control devices have been developed and constructed for reducing vibrations in structures caused by wind loads and earthquakes (Housner et al. 1997, Lu and Zhao 2003). Tuned Mass Damper (TMD) is an example of such devices, and their design has been a subject of much interest to researchers all over the world, with a wealth of theoretical and experimental work in the literature (Ankireddi and Yang 2000). A simple unidirectional TMD consists of a single mass m, connected to the structure by a viscous dashpot c and a linear spring k. The mass is constrained to move in one direction alone, and is usually most effective when the response of the structure is predominantly in the direction in which the damper can move. However, if the structural response is such that there is a very small component of its motion along the path of the damper, or a quite large component perpendicular to the path of the damper, or the structure is suffered large torsional responses, then the unidirectional TMD may not be very effective. For reducing the seismic responses of the complex building structures, such as the high-rising building structure with large local space, a bidirectional TMD system which is shown as Figure 1 may be applied.

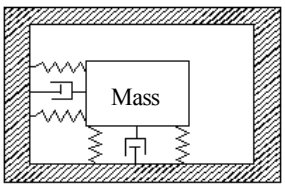

Figure1 Schematic diagram of the bidirectional TMD

In this paper, the seismic behavior and the torsional responses of a complex high-rising building with large local space are studied. A simple multi-floor building model is established and the bidirectional TMD system is employed to reduce the torsional responses of the structure under seismic condition. The numerical results indicate that the well-designed bidirectional TMD system is effective in reducing the torsional responses of the whole structure as well as the top of the large local space.

2. FORMULATION OF BUILDING WITH TMD

2.1 Mechanical Model of the Building

A sample multi-floor model of a building, shown as

Figure 2, is considered in this research. The mass of the structure is concentrated at the floors, which are linked by massless springs to represent horizontal and rotation stiffness of the walls and columns. Each floor has a mass center and a stiffness center, and the story has three degrees of freedom - the horizontal orthogonal translations along the x- and y-directions and the rotation.

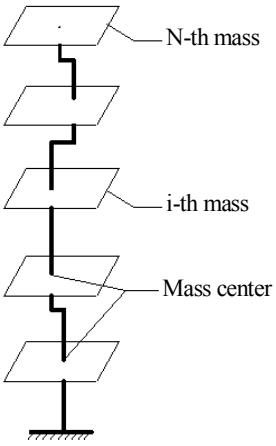

Figure 2 Schematic diagram of the building model

2.2 Equations of Motion of the Building with TMD

The equations of motion of the building in the presence of seismic forces is

$$[M]\{\ddot{D}\}+[C]\{\dot{D}\}+[K]\{D\}=-[M]\{\ddot{D}_g(t)\}+[H]\{U(t)\} \quad (1)$$

and the equation of motion of the TMD system is

$$[M_0]\{\ddot{D}_0\}+[C_0]\{\dot{\gamma}\}+[K_0]\{\gamma\}=-[M_0]\{\ddot{D}_g(t)\} \quad (2)$$

while the control forces can be expressed as

$$\begin{aligned}\{U(t)\} &= -[M_0](\{\ddot{D}_0\}+\{\ddot{D}_g(t)\}) \\ &= [K_0](\{D_0\}-\{D_i\})+[C_0](\{\dot{D}_0\}-\{\dot{D}_i\})\end{aligned} \quad (3)$$

where,

$$\{\gamma\}=\{D_0\}-\{D_i\},\{\dot{\gamma}\}=\{\dot{D}_0\}-\{\dot{D}_i\}$$

$$[K]=\begin{bmatrix}[K_{xx}] & [0] & [K_{x\varphi}]\\ [0] & [K_{yy}] & [K_{y\varphi}]\\ [K_{\varphi x}] & [K_{\varphi y}] & [K_{\varphi\varphi}]\end{bmatrix}_{3n\times 3n}$$

$$[C]=\begin{bmatrix}[C_{xx}] & [0] & [C_{x\varphi}]\\ [0] & [C_{yy}] & [C_{y\varphi}]\\ [C_{\varphi x}] & [C_{\varphi y}] & [C_{\varphi\varphi}]\end{bmatrix}_{3n\times 3n}$$

$$[M]=diag[[m]\ \ [m]\ \ [J]]$$

$$[C]=a[M]+b[K]$$

$$[C_0]=\begin{bmatrix}c_{dx} & \\ & c_{dy}\end{bmatrix},[K_0]=\begin{bmatrix}k_{dx} & \\ & k_{dy}\end{bmatrix},$$

$$c_{dx}=2m_0w_{dx}\xi_d,k_{dx}=m_0w_{dx}^2,$$

$$c_{dy}=2m_0w_{dy}\xi_d,k_{dy}=m_0w_{dy}^2$$

$[H]$ is the matrix defining the location of TMD, when TMD is setup on the i-th floor,

$$[H]=\begin{bmatrix}0 & \cdots 1 & \cdots\cdots 0 & \cdots l_y\cdots & 0\\ 0 & \cdots 0 & \cdots\cdots 1 & \cdots -l_x\cdots & 0\end{bmatrix}^T_{2\times 3n}$$

$$\begin{matrix}\vdots & \vdots & \vdots\\ i & n+i & 2n+i\end{matrix}$$

$[D_0]$ is displacement vector of the TMD,

$$[D_0]=\{x_0,y_0\}^T$$

$[D_i]$ is the displacements of i-th floor,

$$[D_i]=\{x_i+l_y\cdot\varphi_i,y_i-l_x\cdot\varphi_i\}^T$$

where, l_x and l_y indicate the distances between the floor mass center and the TMD in x and y directions.

Then, the general equations of motion of the building with TMD can be expressed as

$$[M^*]\{\ddot{D}^*\}+[C^*]\{\dot{D}^*\}+[K^*]\{D^*\}=-[M^*]\{\ddot{D}_g^*(t)\} \quad (4)$$

where, $[M^*]$, $[K^*]$ and $[C^*]$ are the combined mass, stiffness and damping matrixes, and $[D^*]$ is the combined displacement vector.

$$[M^*]=diag[[m]\ \ [m]\ \ [J]\ \ \ [M_0]]$$

$$[K^*]=\begin{bmatrix}[K^*_{xx}] & [0] & [K^*_{x\varphi}] & \\ [0] & [K^*_{yy}] & [K^*_{y\varphi}] & [K_{c\infty}]\\ [K^*_{\varphi x}] & [K^*_{\varphi y}] & [K^*_{\varphi\varphi}] & \\ & [K_{c\infty}]^T & & [K_0]\end{bmatrix}_{(3n+2)\times(3n+2)}$$

$$[K_{c\infty}]=-[H][K_0]$$

In which $[K^*_{xx}]$ and $[K^*_{yy}]$ are turn out from $[K_{xx}]$ and $[K_{yy}]$ by adding k_{dx} and k_{dy} to their i-th diagonal element, respectively. $[K^*_{\varphi\varphi}]$ is turn out from $[K_{\varphi\varphi}]$ by adding $(l_y^2k_{dx}+l_x^2k_{dy})$ to its i-th diagonal element. $[K^*_{x\varphi}]$ and $[K^*_{y\varphi}]$ are turn out from $[K_{x\varphi}]$ and $[K_{y\varphi}]$ by adding $l_y\cdot k_{dx}$ and $-l_x\cdot k_{dy}$ to their i-th diagonal element, respectively. Take $[K^*_{\varphi\varphi}]$ as an example, its formation procedure is shown as

$$\left[K^*_{\varphi\varphi}\right]=\begin{bmatrix} k_{\varphi 11} & -k_{\varphi 12} & & & & & \\ -k_{\varphi 21} & k_{\varphi 22} & -k_{\varphi 23} & & & & \\ & \ddots & \ddots & & & & \\ & & -k_{\varphi i(i-1)} & k_{\varphi ii}+(l_y^2k_{dx}+l_x^2k_{dy}) & -k_{\varphi i(i+1)} & & \\ & & \ddots & \ddots & \ddots & & \\ & & & -k_{\varphi(n-1)(n-2)} & k_{\varphi(n-1)(n-1)} & -k_{\varphi(n-1)n} & \\ & & & & -k_{\varphi n(n-1)} & k_{\varphi nn} & \end{bmatrix}$$

The combined damping matrix $[C^*]$ follows the same formation of the matrix $[K^*]$.

In the state space, Eq. 4 becomes

$$\dot{Z}(t)=AZ(t)+B\ddot{D}^*_g(t) \tag{5}$$

where

$$Z(t)=\begin{bmatrix} D^*(t) \\ \dot{D}^*(t)\end{bmatrix}_{1\times 2(3n+r)}$$

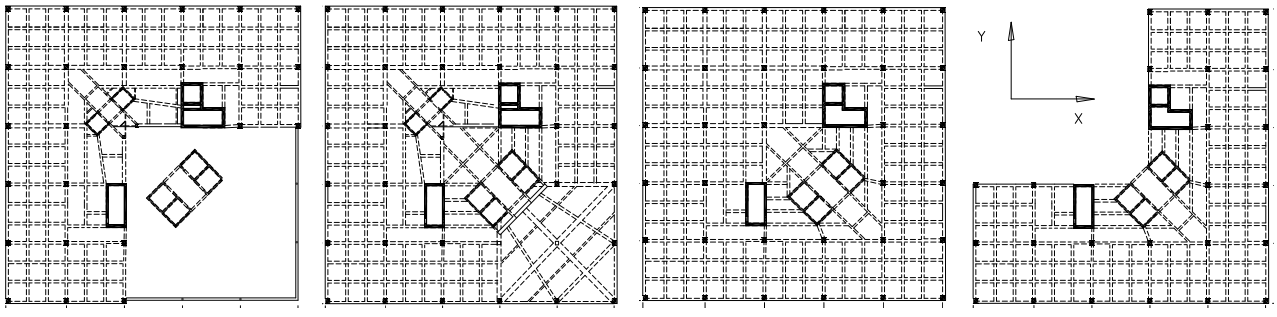
$$A=\begin{bmatrix} 0 & I_{3n+r} \\ -\left[M^*\right]^{-1}\left[K^*\right] & -\left[M^*\right]^{-1}\left[C^*\right]\end{bmatrix}_{2(3n+r)\times 2(3n+r)}$$

$$B=\begin{bmatrix} 0 \\ -E\end{bmatrix}_{2(3n+r)\times(3n+r)}$$

$$E=\begin{bmatrix} I_{n\times 1} & 0 & 0_{n\times 1} & 1 & 0 \\ 0 & I_{n\times 1} & 0_{n\times 1} & 0 & 1\end{bmatrix}^T$$

$$\ddot{D}^*_g=\begin{bmatrix}\ddot{d}_{gx} \\ \ddot{d}_{gy}\end{bmatrix}$$

3. MODELING OF A HIGH-RISING STRUCTURE WITH LARGE LOCAL SPACE



A typical high-rising building with large local space (Zhao et al. 2007) is used for verification of the strategy of using bidirectional TMD system to reduce the torsional responses of the structure under seismic excitation. The prototype is a 18-story building with totally height of 98 m, while the height of the first, fourth, ninth and tenth story reach 8.4 m, the height of the top story is 5.8 m and the other story with height of 4.2 m. The plan size of the structure is 44 m × 44 m, through deleting some columns of the lowest 4 stories, a 26.3 m × 26.3 m large hall is turn out at a corner of the building. Above the tenth floor, some opposite columns are also deleted which forms a series of L- type floors. The general plan layout of the structure is given in Figure 3. Obviously, the mass and stiffness center of lower and higher part of the structure are far away from the vertical axis.

The multi-floor model of the building can be achieved through a response spectrum analysis on its 3-D structural model (He 2008). All the parameters of the established multi-floor model are listed in Table 1 (Gao 2010).

The mode analysis is carried out and the period, direction factor and mass participation factor of the first 6 modes are listed in Table 2. The pattern of the first mode is rotation which is exactly in accordance with the test result (Zhao et al. 2007). One can also find that the rotation component is very remarkable and the rotation factors of mode number 3, 4, 5 and 6 are equal to or greater than 30%. Under earthquake condition, the structure will suffer large torsional displacements.

4. DESIGN OF THE BIDIRECTIONAL TMD

According to the plan layout of the building, there are three options to setup the bidirectional TMD system: (1) To hang the TMD at the top of the large local hall - fourth floor; (2) To put the TMD at the vertical layout changing location – ninth floor; or (3) to put the TMD on the top floor of the structure – eighteenth floor. Physically, it is more convenience to choose option (2) and (3), both the tenth floor and eighteenth floor can provide ideal space holding the TMD. From the original objective of reducing the torsion responses of the structure, mainly the torsion responses at the top of the large local hall, option (2) has been chosen and the TMD is set up on the ninth floor.

Table 2 Mode analysis result of the established model

Mode No.	Period (s)	Direction factor			Mass participation factor		
		X	Y	Rotation	X	Y	Rotation
1	2.71	25.5%	23.9%	50.6%	17.9%	15.9%	39.0%
2	2.38	27.4%	68.8%	3.8%	20.1%	50.8%	3.0%
3	2.10	47.4%	7.8%	44.8%	36.8%	6.4%	32.9%
4	0.98	11.7%	58.3%	30.0%	1.3%	9.2%	6.8%
5	0.96	25.9%	41.2%	33.0%	3.3%	7.8%	4.6%
6	0.87	62.7%	0.9%	36.4%	10.1%	0.2%	4.0%

Generally, the frequency of the TMD system should be set to the main frequency of the controlled structure (Zhang 2007). For such complex structure, according to the mode analysis result which is listed in Table 2 and the objective of torsion response control, the frequency in x-direction of the TMD system is defined as 0.48 Hz (the frequency of Mode No. 3) while the frequency in y-direction is defined as 0.37 Hz (the frequency of Mode No. 1).

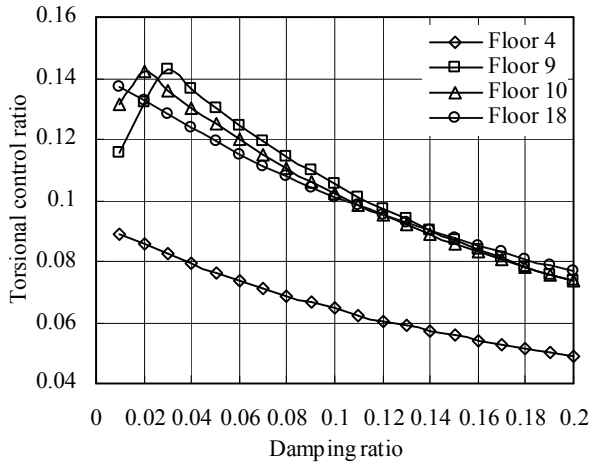
5. NUMERICAL ANALYSIS

Based on the equation of motion of the building with TMD of the Eq. 5, a program is developed to assess the effect of the bidirectional TMD system on torsion responses reduction of the seismically excited structure.

5.1 Assessment Index

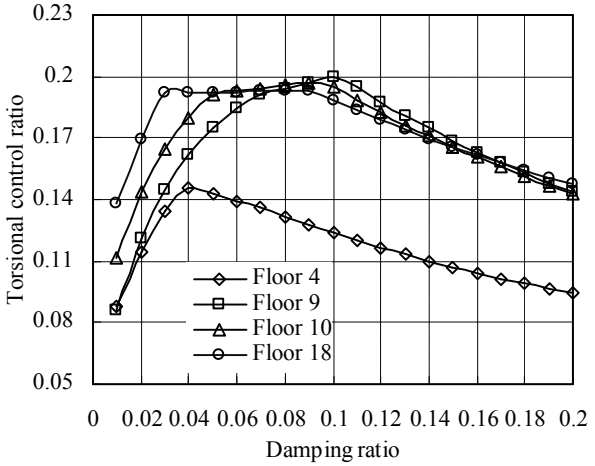
In order to consider the overall effect of the torsion response reduction under different earthquake waves, a common control ratio is defined as

$$\eta = \sum_{i=1}^{i=n} \eta_i / n \,, \quad \eta_i = (U_i^o - U_i^c)/U_i^o$$



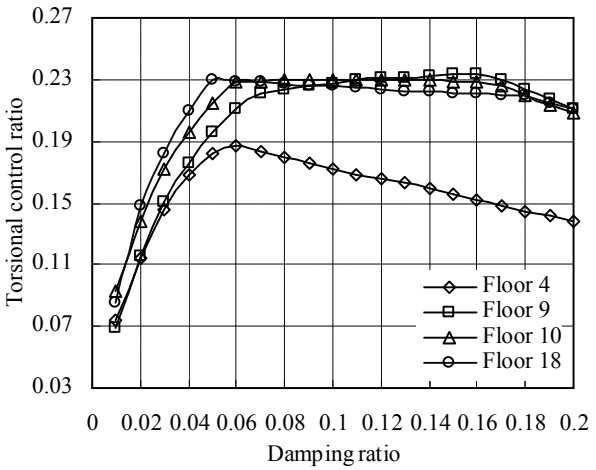
where, U_i^o is the maximum response of the un-controlled structure under i-th earthquake wave and U_i^c is the maximum response of the structure with TMD system.

5.2 Numerical Result

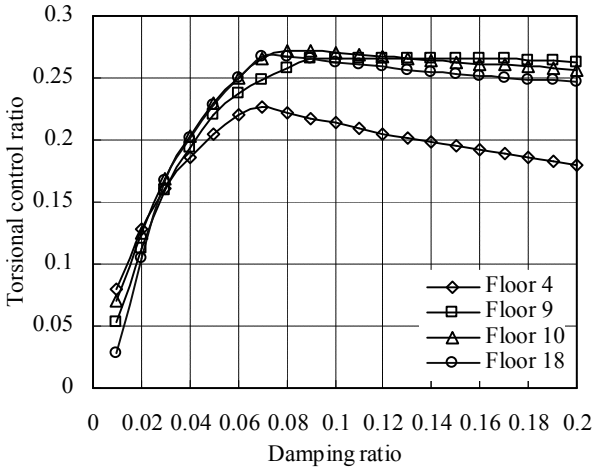


The widely used El Centrol and Talf earthquake records and an artificial earthquake wave are chosen as the input ground accelerations for the numerical analyses. The peak accelerations of the waves are adjusted to 0.2 g. The relationship of the rotation control ratios and the TMD damping ratios with different TMD mass ratio of 0.005, 0.01, 0.015, 0.02, 0.025 and 0.03 are given as Figure 4. From these diagrams, it is easy to find that the rotation control ratios increase as the TMD mass ratio increase from 0.005 to 0.03. But when the mass ratio is greater than 0.01, the rotation control ratio increase is only about 4% as mass ratio increase of each 0.005. The optimal damping ratio increase as the mass ratio becomes large, and the control effect

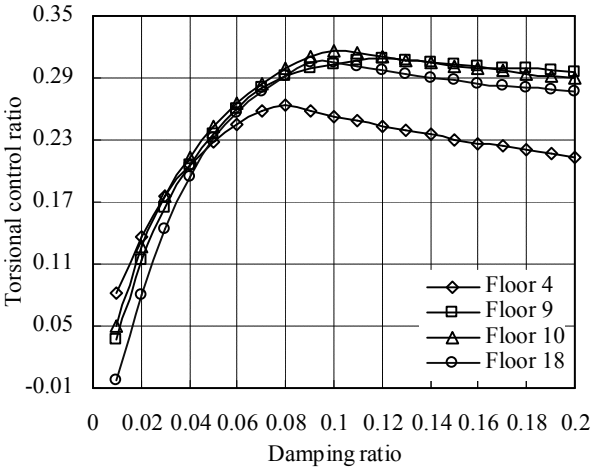
changes gently when the damping ratio greater than the optimal damping ratio.



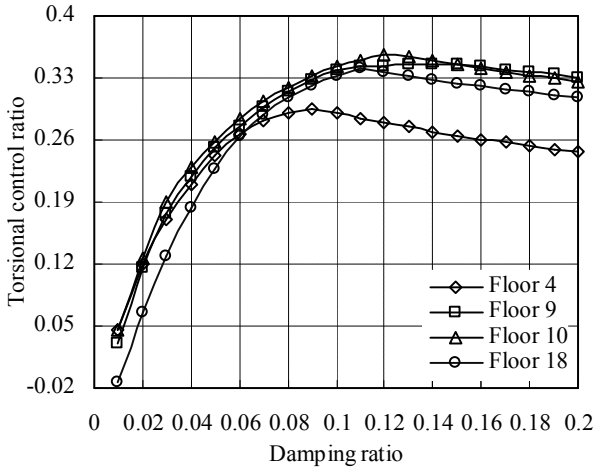
As mentioned before, the sample way for determining the TMD parameters is to set its frequencies in both x- and y-direction equaling the first frequency of the structure. The relationship of the rotation control ratios and the TMD damping ratios with different TMD mass ratio of 0.01 and 0.02 are given as Figure 5. Comparing Figure 5 with Figure 4 (b) and (d), one can find the above two modes control strategy is more effective than this first mode strategy.



(a) TMD mass ratio=0.005

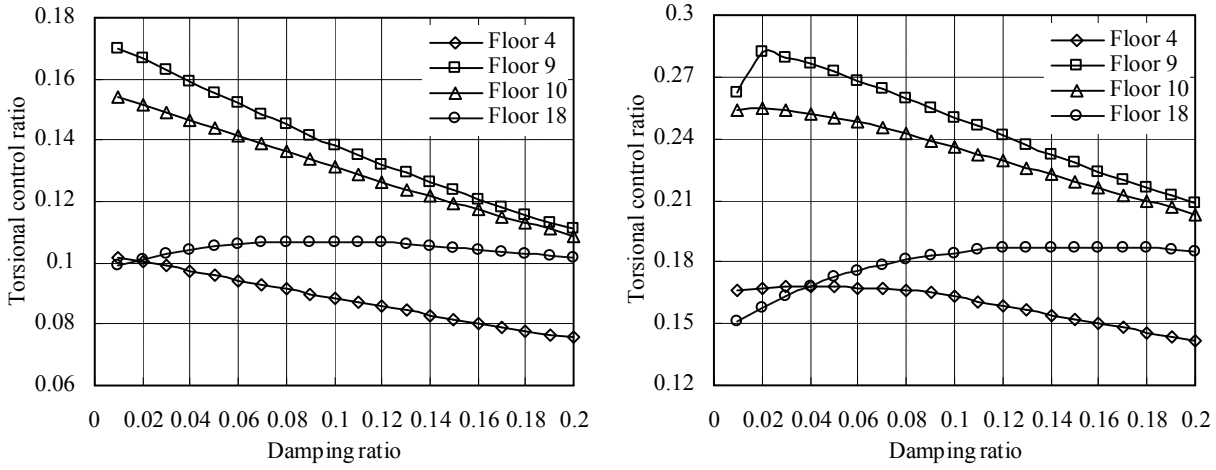


(b) TMD mass ratio=0.01



(c) TMD mass ratio=0.015

(d) TMD mass ratio=0.02



(e) TMD mass ratio=0.025

(f) TMD mass ratio=0.03

Figure 4 Relationship between torsional control ratio and damping ratio

(a) TMD mass ratio=0.01

(b) TMD mass ratio=0.02

Figure 5 Relationship between torsional control ratio and damping ratio

6. CONCLUSIONS

In this research, the seismic behavior, mainly the torsional responses and its control strategy, of a complex high-rising building with large local space are studied. The simple multi-floor building model is established and the bidirectional TMD system is applied to reduce the torsional responses of the structure under seismic condition. The numeric analyses indicate that:

(1) A well-designed bidirectional TMD system is very effective in reducing the torsional responses of the whole structure as well as the tope of the large local space.

(2) As the complex of the dynamic property of the highly irregular structure like high-rising building with large local space, different dynamic mode should be considered in the TMD parameter design, and an optimal combination of structural modes is more effective than the first mode control strategy.

Abstract: The design of tall buildings in Japan have recently incorporated seismic isolation systems as a means of providing enhances seismic protection. Whereas seismic isolation has traditionally been applied to short, stiff structures, several successful projects have demonstrated the viability of seismic isolation for tall buildings. However, a general methodology describing an approach for selecting appropriate isolation system parameters given a range of superstructural characteristics has yet to be developed. In this paper, a procedure for generating an equivalent viscoelastic system to describe a tall isolated building is described. In this procedure, the problem of a significant non-proportionally damped multi-DOF structure is overcome by introducing an assumption of steady-state vibration combined with a correction to account for the difference in peak velocity compared to peak pseudo-velocity. Analysis of a wide range of isolated building models indicates excellent agreement between response prediction from response history analysis of the non-proportionally damped model and the proposed spectrum-based equivalent viscoelastic analysis. A methodology is proposed to select optimal isolation system period and damping given a superstructure height, seismic intensity, and acceptance criteria for drift and isolator displacement.

1. INTRODUCTION

Recent trends in urban planning have led to the development of high-density residential and commercial areas. Due to limitations in available space, tall buildings must be constructed to accommodate such high-density areas. Given the large number of occupants in these tall buildings, combined with the financial significance of organizations which inhabit them, the consequences of damage due to a seismic event must be carefully assessed. In the past 25 years, seismic isolation has been applied worldwide to achieve enhanced seismic performance in structures subjected to earthquakes. There have been recent applications of seismic isolation technology to tall, flexible building in Japan [Ariga, et al. 2006, Kani 2009, Miyazaki 2009]. Given this trend, there has been recent research dedicated to examining the behavior of tall buildings with seismic isolation systems [Takewaki 2007, Takewaki and Fujita 2009.]

Traditionally, base isolation has been seen as applicable only to short, stiff structures. For tall, flexible structures, the period is already longer than the predominant period of most ground motions. Therefore, it is assumed that the addition of an isolation system is ineffective for the enhancement of seismic performance. However, the addition of an isolation layer can alter the mode shape such that a significant portion of the deformation response is concentrated in the isolations system rather than the supported structure. Since there is very little information about the behavior of tall or flexible structures on isolation systems, it is necessary to develop robust design methodologies to target desired levels of performance.

2. DEFINITION OF PARAMETERS

To develop equations of motion for generic 2-DOF isolated structures, a coordinate system must be chosen. Since relative deformations of the superstructure and isolation system are of primary interest, equations of motion are expressed using relative deformations. Relative to some fixed reference frame, let the ground displacement, isolation level displacement, and structural displacement be u_g, x_b, and x_s, respectively. Here we define the isolator displacement as $u_b = x_b - u_g$ and the structural displacement as $u_s = x_s - x_b$. We also define the mass at the isolator and structure level as m_b and m_s, respectively. Between the ground and base mass, the isolation system is represented as a Kelvin element having spring stiffness k_b and linear viscous damping coefficient c_b. Between the base mass and superstructure mass, a second Kelvin element with spring stiffness k_s and linear viscous damping coefficient c_s is defined to represent the superstructure. The 2-DOF structure with the above parameters is depicted in Figure 1.

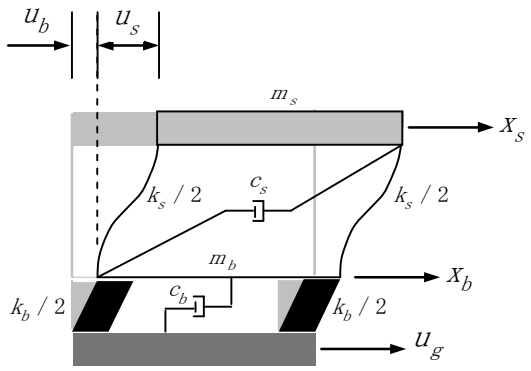

Figure 1: Definition of parameters for 2-DOF isolated structure

With these definitions, it is possible to develop the equations of motion for this system subjected to some ground acceleration $\ddot{u}_g$. First, it is convenient to define a mass ratio $\gamma = m_s / (m_s + m_b)$, which tends to unity at the superstructure mass becomes very large compared to the base mass. Additionally, it is useful to define the natural frequencies of the isolation system and the superstructure. The squares of the natural frequencies of the isolation system and superstructure, ω_b^2 and ω_s^2 are defined as

$$\omega_b^2 = \frac{k_b}{m_s + m_b}, \quad \omega_s^2 = \frac{k_s}{m_s} \tag{1}$$

Notice that ω_b is the natural frequency of the isolated structure assuming the superstructure is infinitely rigid. This definition follows that of modern building codes (e.g. ASCE-7, 2005.) Similarly, we can define critical viscous damping ratios for the isolation system and superstructure as

$$\zeta_b = \frac{c_b}{2(m_s + m_b)\omega_b}, \quad \zeta_s = \frac{c_s}{2m_s\omega_s} \tag{2}$$

3. VISCOELASTIC REPRESENTATION

In order to develop an equivalent SDOF system which may be used to estimate the response of the previously-described 2DOF structure, a steady-state response approach is taken. For tall isolated buildings, the superstructure mass will be much larger than the base mass, which implies that γ approaches unity. If the superstructure mass m_s is assumed to be much larger than the base mass m_b (i.e. $\gamma \to 1$), the isolated structure may be represented by a viscoelastic (VE) system subjected to some forcing function f, as shown in Figure 2. All other definitions remain as defined above, except the damping ratio of the superstructure, ζ_s, is assumed negligible compared to that of the isolation system, and is therefore assumed to be zero.

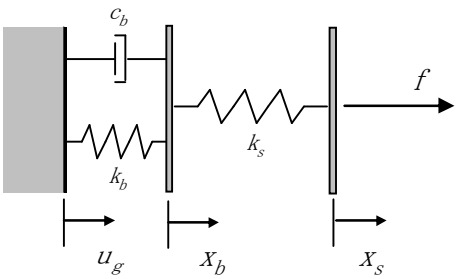

Figure 2: Viscoelastic representation of isolated 2DOF structure

We define the displacement of the equivalent system as $u = x_s - u_g$, which could be expressed equivalently as $u = u_b + u_s$. Suppose that the response of the equivalent system is described by

$$u = u_0 \sin \omega_{eq} t \tag{3}$$

Where u_0 is the maximum displacement response and ω_{eq} is some frequency of excitation of the equivalent VE system. With no loss of generality, we assume the mass of the equivalent VE system is equal to unity. As a result, the total mass-normalized force f acting on the system can be described by either the isolation system force f_b as

$$f = f_b = \omega_b^2 u_b + 2\zeta_b \omega_b \dot{u}_b \tag{4}$$

or the superstructure force f_s as

$$f = f_s = \omega_s^2 u_s \tag{5}$$

The individual component deformations may be expressed as

$$u_b = \frac{f - 2\zeta_b \omega_b \dot{u}_b}{\omega_b^2}, \quad u_s = \frac{f}{\omega_s^2} \tag{6}$$

Applying the relations $u = u_b + u_s$ and $\dot{u} = \dot{u}_b + \dot{u}_s$, the deformation u is given by

$$u = \frac{f - 2\zeta_b \omega_b (\dot{u} - \dot{u}_s)}{\omega_b^2} + \frac{f}{\omega_s^2} \tag{7}$$

Substituting $u = u_0 \sin \bar{\omega} t$, $\dot{f} = \omega_s^2 \dot{u}_s$, and applying algebraic manipulation leads to the following first-order differential equation

$$f\left(\frac{\omega_b^2 + \omega_s^2}{\omega_b^2 \omega_s^2}\right) + \dot{f}\left(\frac{2\zeta_b}{\omega_b \omega_s^2}\right) = u_0 \sin \omega_{eq} t + u_0 \omega_{eq} \left(\frac{2\zeta_b}{\omega_b}\right) \cos \omega_{eq} t \tag{8}$$

It can be shown that the solution to this differential equation is given by

$$f = \left(\frac{\omega_s^2 \omega_b^2}{\omega_b^2 + \frac{\omega_s^2}{\Gamma}} \right) u_0 \sin \omega_{eq} t + \left\{ \frac{\omega_s^2 \omega_b^2 \eta_b}{\left(\omega_b^2 + \frac{\omega_s^2}{\Gamma} \right) \left[1 + \frac{\omega_b^2}{\omega_s^2} \left(1 + \eta_b \right)^2 \right]} \right\} u_0 \cos \omega_{eq} t \tag{9}$$

Where the loss factor $\eta_b = 2\zeta_b$ and the non-dimensional parameter Γ is defined as

$$\Gamma = 1 + \frac{\omega_s^2 \eta_b^2}{\omega_s^2 + \omega_b^2} \tag{10}$$

In general, the total force in the equivalent VE system undergoing stead-state vibration can be described as

$$f = k'_{eq} u_0 \left(\sin \omega_{eq} t + \eta_{eq} \cos \omega_{eq} t \right) \tag{11}$$

where k'_{eq} is the storage stiffness and η_{eq} is the loss factor. Here, we introduce a term to account for the inexact assumption of steady state response for a system subjected to earthquake excitation. Under steady-state response, the peak velocity of the system can be computed through differentiation as

$$\dot{u}_0 = \max \left[\dot{u}(t) \right] = \omega_{eq} u_0 \tag{12}$$

This definition follows that of the peak pseudo-velocity (Chopra, 2007) where u_0 is the peak earthquake displacement response of an SDOF oscillator having natural frequency ω_{eq}. However, the damping force is related to the actual velocity, whose peak is generally not equal to the peak pseudo-velocity. For some ground motion excitation, we define a correction term

$$\alpha_v = \frac{\dot{u}_0}{\omega_{eq} u_0} \tag{13}$$

where u_0 and $\dot{u}_0$ are the peak displacement and velocity at frequency ω_{eq}, respectively. The correction term α_v is generally a function of frequency and damping, and varies depending on the ground motion under consideration. Using the relationship $\dot{u}_0 = \alpha_v \omega_{eq} u_0$, the corrected force in the VE system is described by

$$f = k'_{eq} u_0 \left(\sin \omega_{eq} t + \eta_{eq} \alpha_v \cos \omega_{eq} t \right) \tag{14}$$

An important observation is that the maximum force in the VE system can be expressed as

$$f_{\max} = k'_{eq} u_0 \sqrt{1 + \eta_{eq}^2 \alpha_v^2} \tag{15}$$

The derived force from Eq. (9) can be expressed in the same form as Eq. (15) where

$$k'_{eq} = \frac{\omega_s^2 \omega_b^2}{\omega_b^2 + \frac{\omega_s^2}{\Gamma}}, \quad \eta_{eq} = \frac{\eta_b}{\left[1 + \frac{\omega_b^2}{\omega_s^2} \left(1 + \eta_b \right)^2 \right]} \tag{16}$$

Therefore, the equivalent VE representation of the 2DOF isolated structure undergoing steady-state vibration is described by the parameters k'_{eq} and η_{eq}. From this we can conclude that the natural frequency of the equivalent system is given by $\omega_{eq} = \sqrt{k'_{eq}}$, or

$$\omega_{eq} = \sqrt{\frac{\omega_b^2 \omega_s^2}{\omega_b^2 + \frac{\omega_s^2}{\Gamma}}} \tag{17}$$

Similarly, the viscous damping ratio of the equivalent system can be computed by recognizing that the critical damping $\zeta_{eq} = \eta_{eq} / 2$, or

$$\zeta_{eq} = \frac{\zeta_b}{1 + \left[\frac{\omega_b}{\omega_s} \left(1 + 2\zeta_b \right) \right]^2} \tag{18}$$

The relationship of the equivalent period $T_{eq} = 2\pi / \omega_{eq}$ and the equivalent damping ζ_{eq} to the isolation period T_b for various fixed-base periods T_s and isolation damping ζ_b is shown below in Figure 3.

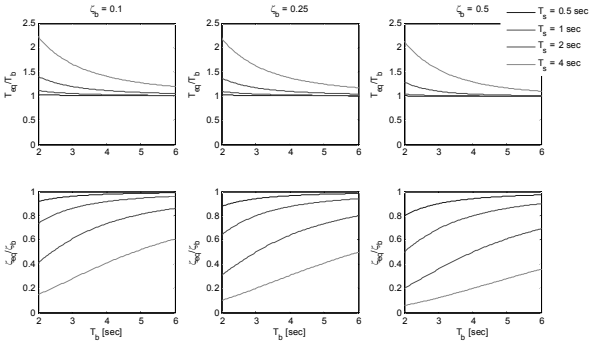

Figure 3: Equivalent period T_{eq} and equivalent damping ζ_{eq} as a function of isolation period T_b

With these definitions, it is possible to analyze an equivalent SDOF system subject to earthquake ground motion, and obtain an estimate for the maximum displacement response u_0. However, it is important that the individual displacements of the isolation system and superstructure are captured from this equivalent analysis. Therefore, a procedure is needed to extract u_{b0} and u_{s0} from the computed u_0. Suppose the steady-state isolator displacement is described by $u_b = u_{b0} \sin \omega_{eq} t$. Substituting u_b and its derivative into Eq. (4), the maximum force developed in the isolation system is

$$f_{b\max} = u_{b0} \sqrt{\omega_b^4 + 4\alpha_v^2 \zeta_b^2 \omega_b^2 \omega_{eq}^2} \tag{19}$$

Noting $f_{b\max} = f_{\max}$ and solving for u_{b0} gives

$$u_{b0} = u_0 \frac{\omega_{eq}^2}{\omega_b^2} \sqrt{\frac{1+4\alpha_v^2\zeta_{eq}^2}{1+4\alpha_v^2\zeta_b^2\left(\frac{\omega_{eq}^2}{\omega_b^2}\right)}} \tag{20}$$

Similarly, we let $u_s = u_{s0}\sin\omega_{eq}t$ and substitute $f_{s\max} = f_{\max}$ from Eq. (15) into Eq. (19) to obtain

$$u_{s0} = u_0 \frac{\omega_{eq}^2}{\omega_s^2}\sqrt{1+4\alpha_v^2\zeta_{eq}^2} \tag{21}$$

With these definitions, it is straight-forward to estimate the peak deformation in both the isolator and superstructure based on a ground motion displacement spectrum developed for a damping level of ζ_{eq}.

4. TRANSFORMATION OF NDOF TO 2DOF

To conduct realistic analytical simulations, a procedure is needed to convert a generic *N*-story building to an idealized 2DOF structure. The necessary properties for the 2DOF system are: number of stories *N*, superstructure period T_s, superstructure damping ratio ζ_s, isolation period T_b, isolation damping ratio ζ_b, and mass ratio γ. It is necessary to make some assumption regarding T_s based on *N*, so the well-known approximation $T_s = 0.1N$ is made here. Therefore, assuming equal floor weights, the mass ratio γ can be expressed as $\gamma = (N-1)/N$. This idealization is described below in Figure 4.

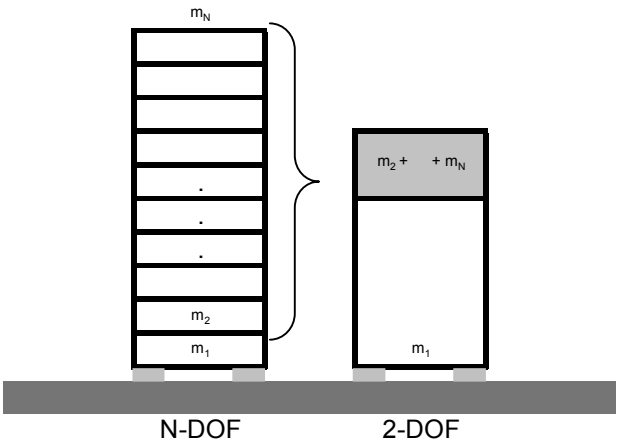

Figure 4: Description of the idealization of N-story building to a 2DOF structure

Given the assumptions of T_s, ζ_s, T_b, and ζ_b, we can define the properties of the 2DOF system, shown in detail in Figure 1, as follows. For the superstructure, the spring stiffness k_s and damping coefficient c_s are computed as

$$k_s = \left(\frac{2\pi}{T_s}\right)^2 \sum_{i=2}^{N} m_i, \quad c_s = 2\zeta_s\left(\frac{2\pi}{T_s}\right)\sum_{i=2}^{N} m_i \tag{22}$$

Similarly, for the isolation level, the spring stiffness k_b and damping coefficient c_b are computed as

$$k_b = \left(\frac{2\pi}{T_b}\right)^2 \sum_{i=1}^{N} m_i, \quad c_b = 2\zeta_b\left(\frac{2\pi}{T_b}\right)\sum_{i=1}^{N} m_i \tag{23}$$

These parameters are sufficient to characterize the 2DOF system for response history analysis.

5. GROUND MOTIONS

To both facilitate the development of statistical descriptions of demand and to consider a variety of seismic characteristics, an ensemble of ground motions is selected to represent possible realizations of ground motion at a site. As part of the SAC Steel Project, several ensembles of ground motions were developed for the Los Angeles basin. Since the objectives of these studies is to identify demand parameter sensitivities to inputs having multiple frequencies of occurrence, three ground motions ensembles were selected. Each of the three ensembles contains 20 acceleration records, and were developed for return periods of 72-years, 475-years, and 2475-years. For further details of the development of the SAC ground motions, see Somerville et al. [1997.]

Figure 5 through Figure 7: Elastic response spectra for 2475-yr records (median shown bold) show the elastic response spectra for each ground motion for the 72-yr, 475-yr, and 2475-yr ensembles, respectively. Figure 8 shows a comparison of the median spectra for all three return periods, including an overlay of the USGS prescriptive spectra with best fit parameters. Best-fit parameters are determined by selecting S_{DS} and S_{D1} such that the error between the median spectrum and the USGS spectrum is minimized for both constant acceleration and constant velocity regions, for all three return periods.

A key ingredient of the VE analysis procedure described previously is a relationship that describes the ratio between peak velocity and peak pseudo-velocity, defines as α_v. While estimates of this ratio are available in the literature for the period range $0.1\,\text{sec} \le T \le 3\,\text{sec}$ (Kasai et al., 2009,) there is little information regarding its characteristics at long-periods of vibration, which are important for isolated tall buildings. For the purpose of estimating this parameter, linear least-squares regression analysis was performed using the SAC suite of ground motions and the following 6-parameter linear model for α_v:

$$\begin{aligned}\alpha_v(T,\zeta) &= \frac{\dot{u}_0}{\omega_{eq}u_0} \\ &= \beta_0 + \beta_1 T + \beta_2 T^2 + \beta_3\zeta + \beta_4\zeta^2 + \beta_5 T\zeta\end{aligned} \tag{24}$$

Where the input factors T and ζ are the period and damping of an SDOF oscillator. From this analysis, the following least-squares estimates were determined for each regression coefficient:

$$\begin{aligned}&\hat{\beta}_0 = 0.7062,\ \hat{\beta}_1 = 0.1186,\ \hat{\beta}_2 = 0.0265, \\ &\hat{\beta}_3 = 1.5101,\ \hat{\beta}_4 = -1.1248,\ \hat{\beta}_5 = 0.0334\end{aligned} \tag{25}$$

This equation defines the assumed relationship for $\alpha_y(T,\zeta)$ used in subsequent analyses, and is valid for the period range $2\,\text{sec} \le T \le 10\,\text{sec}$ and a damping range $0.02 \le \zeta \le 0.40$.

6. LINEAR 2DOF STUDIES

To study the accuracy of the equivalent VE analysis method presented previously, a comparison of displacement demands based on response spectrum and explicit response history analysis (RHA) is made. In the case of response history analysis, the 2DOF system with non-classical damping behavior is analyzed exactly through numerical integration using input earthquake acceleration records. The peak isolator displacement $\max\left[u_b(t)\right]$ and peak structural displacement $\max\left[u_s(t)\right]$ is computed for each of the 60 ground motions described. These peak deformations of the isolation system and superstructure are compared to those estimated by Eq. (20) and (21) based on the VE approximation and individual ground motion response spectra.

Figure 9 describes the response of a 2DOF structure having $T_b = 4$ sec, $T_s = 1$ sec (i.e. $N = 10$ stories.) It appears that, for both levels of isolation system damping ζ_b considered (10% and 25%) there is very close agreement between the 2DOF RHA and the equivalent SDOF analysis, with very little observable bias and dispersion.

Figure 10 through Figure 12 present similar response comparison data for 2DOF and SDOF analyses, but for superstructure periods $T_s = 2$, 3, and 4 sec ($N = 20$, 30, and 40 stories) respectively. It is clear that, as the superstructure period becomes longer, there is similar variation in the estimate of isolator displacement u_b and structural displacement u_s, with negligible bias and dispersion. The results presented here demonstrate that an accurate, response spectrum-based method of estimating isolator displacements and superstructural drift is feasible for tall, isolated buildings with a range of period and damping characteristics.

To investigate the accuracy of the proposed method for *all* SDOF systems studied, the statistical relationship between the exact and the estimated displacement response is described. Here we assume some linear relationship $u_{RHA} = \lambda u_{VE}$ where u_{RHA} is the exact displacement response computed from response history analysis and u_{VE}

is the same displacement response estimated from the proposed equivalent viscoelastic method. The slope parameter λ may be estimated using least-squares regression from the computed data for all 60 ground motion records. If we define $\hat{\lambda}$ as the least-squares estimate of the true slope $\lambda = u_{RHA} / u_{VE}$, then $\hat{\lambda} > 1$ indicates unconservative bias, $\hat{\lambda} < 1$ indicates conservative bias, and $\hat{\lambda} = 1$ indicates a lack of bias. The estimated slope parameters for both isolator and structural displacement are summarized for ζ_b = 10% and 25% in Table 1 and Table 2, respectively. This data demonstrates that the proposed method gives reliable estimates of both isolator displacement and superstructure drift for buildings having natural periods between 1 and 4 seconds (number of stories between 10 and 40) and isolation systems between 2 and 4 seconds for both levels of isolation system damping considered (ζ_b = 10% and 25%.) The estimates for isolator displacement show negligible unconservative bias ($\hat{\lambda} < 1.014$) and those for structural drift show low unconservative bias ($\hat{\lambda} < 1.070$.)

6. DESIGN METHODOLOGY

The preceding development of a simplified approach to estimating seismic demands on tall base isolated buildings can be extended to form a robust design methodology. Consider the task of selecting an isolation system for a tall building, subject to some limitations on seismic demand for one or several levels of ground shaking intensity. For a given level of seismic intensity, defined simply by the displacement spectrum, we can estimate the roof displacement of the fixed-base tall building. Additionally, from the same displacement spectrum adjusted to account for the effective damping computed by Equation (18), we can estimate both the displacement of the isolation layer and the roof displacement of the building relative to the isolation layer (the drift in the superstructure), from Equations (20) and (21), respectively. This is indicated graphically below in Figure 13. This corresponds to a 40 story building with an isolation system having a 4 second natural period, and 40% equivalent viscous damping. From this figure, it is clear how the introduction of an isolation layer, even where very little period shift is attained, leads to a significant reduction of story drift demand in the supported tall structure.

With these derived closed-form expressions for both peak interstory drift and peak isolator displacement, it is possible to map contours of each demand parameter as a function of two basic isolation system parameters: natural period T_b and viscous damping ratio ζ_b. Figure 14 shows how these contour plots may be constructed such that a permissible region of isolation system period and damping, (T_b, ζ_b), is defined for a given building height and particular earthquake return period. Such a tool is useful for preliminary design, with the performance of the final combination of structure and isolation system verified through nonlinear response history analysis.

3. CONCLUSIONS AND FUTURE STUDIES

This study focuses on the response of isolated tall buildings subjected to seismic excitation. A methodology is described to convert a generic *N*-story isolated structure to an idealized 2DOF system using basic natural parameters such as isolation system period and damping, and superstructure period and damping. An equivalent viscoelastic SDOF system is derived in such a away to allow closed-form expressions for isolator and structure displacements given some earthquake response spectrum. This development is made tractable by letting the

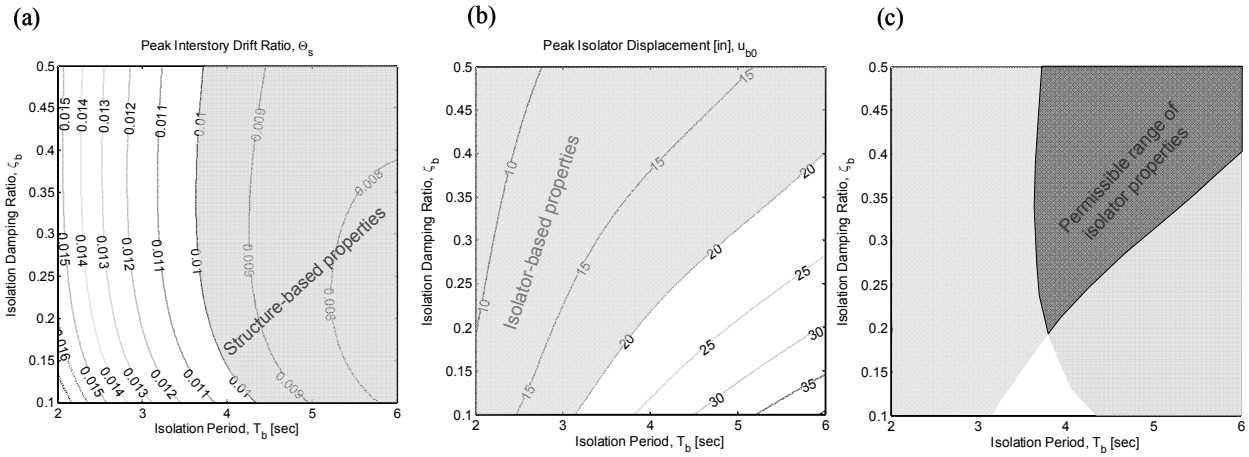

Figure 14: For a 40-story building subjected to DBE, permissible range of isolator properties based on (a) peak interstory drift ratio $\Theta_s \leq 0.01$, (b) peak isolator displacement $\underline{u_{bo}} \leq 20$ in. and (c) combination of drift criteria in (a) and isolator displacement criteria in (b)

superstructure mass become large relative to the base mass, which is a reasonable assumption for tall isolated buildings. The described approach leads to accurate estimates of peak isolator displacement and peak structural drift through the simple use of a response spectrum. The proposed method gives accurate results even in cases of long isolation period and high isolation system damping, both of which give are characterized by highly non-proportional damping.

Future work includes:

1. Development of spectrum-based design procedures that give estimates of displacement *and* acceleration demand
2. Investigation of the relationship between linear and nonlinear response for isolated tall buildings considering MDOF representations
3. Quantification of the relative reliability of isolated tall buildings compared to conventional tall buildings in terms of probabilistic hazard analysis.

Abstract: Different seismic control and isolation techniques with inherent advantages and disadvantages have been developed to manage the amount of seismic energy that is input into a building as well as its dissipation. Their ultimate purpose is to reduce the demands on the primary structural elements and, thus, improve the global performance of the structure. The authors have combined the positive aspects of some of these techniques while eliminating their negative side-effects to create a novel seismic isolation/control system that has the potential to outperform technically and economically the currently available control and isolation strategies. This paper introduces the ideated system and presents the initial analytical steps that will be taken for its complete development.

1. INTRODUCTION

Earthquakes have caused the death of millions of people as well as wide-spread infrastructure destruction (USGS 2009). Although earthquake engineering has advanced quickly, major seismic events continue to show us that we are still vulnerable to them. Many of the advancements are in the area of seismic control whose strategies use a variety of damper and shock-absorbing technologies. These strategies have been proven to reduce the structural demands, improve the structural performance and, in cases, make up for the additional cost of installing them by allowing lighter structural designs. In general, however, the control techniques are expensive, need regular inspection, maintenance and component replacement after major earthquakes. They also have limited applicability, interfere with architectural features, require special mountings and reinforcements in the places where dampers/actuators are installed, etc. Base Isolation, on the other side, is effective in reducing interstory drifts and floor accelerations; however, its use has been limited by the isolating technologies as well as by the prevention of the mechanisms that would jeopardize the safety of the base-isolated structure.

This project attempts to use the virtues of some seismic control/isolation tools and combine them into a new, but simple earthquake resistant product that has the potential to outperform through the isolation of the floor masses from the seismic accelerations, the currently available seismic control and isolation strategies. Since the ideated system is simple and most of its components have already been approved for their application, the implementation of the concept should follow directly after a small amount of studies have been carried out. The proposers also believe that their concept of mass isolation is easy to implement in new buildings and with retrofitting purposes.

2. BACKGROUND

Recent structural design philosophies require the provision of sufficiently ductile structural elements in buildings to cope with and limit the seismic input energy of an earthquake. By providing ductility, structural materials will dissipate energy by incursions in their nonlinear range; however, inelastic deformations cause structural and non-structural damage which has to be kept within acceptable limits.

Alternatively, innovative concepts for the seismic protection of structures that consist in the incorporation of energy dissipating devices and/or the modification of dynamic characteristics of the structures have been

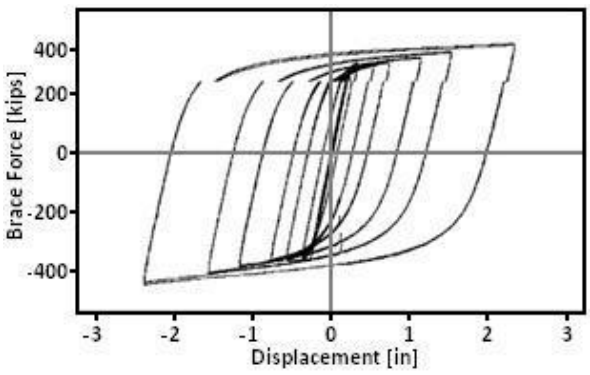

Figure 1 Force displacement plot of buckling-restrained braces (Sabelli, Mahin et al. 2003)

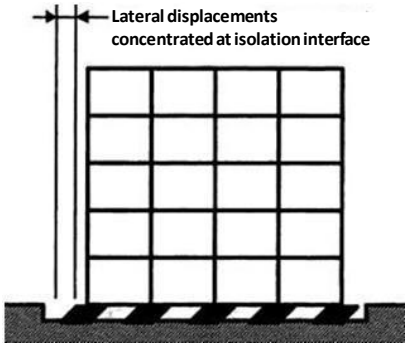

Figure 2 Base Isolation (ASCE 2004)

engineered with the objective of reducing the energy dissipation demand (and damage) in the primary structural members. The intention of including energy dissipating devices in buildings is that they perform most of the task of energy dissipation instead of the building's structural elements, one example of such devices are buckling-restrained braces (Figure 1). Since now damage is concentrated in these elements, they have to be inspected and/or replaced after a number of earthquakes or immediately after major ones to guarantee the safety of the building, which can be expensive and time consuming (PDL 2009).

Another technique of earthquake protection that has proven to be very effective and surprisingly simple (Naeim and Kelly 1999) is Base Isolation; it consists in providing a relatively flexible (isolating) layer between the structure and its foundation. This layer "detaches" the building from the ground, making the former less susceptible to the accelerations of the latter (Figure 2). Implementation of Base Isolation modifies the inherent dynamic properties of a structure in a way that promotes the predominance of the first mode of vibration in its seismic response. Also, like yielding or friction energy dissipaters do, Base Isolation lengthens the fundamental period of the building, thus, reducing the input of seismic energy. However, the flexibility and dependence of the good functioning of the system on the single-mode behavior of the system makes it vulnerable and susceptible to problems derived from these conditions. These include the possibility of resonance and excessive lateral displacements (Komodromos, Polycarpou et al. 2007); therefore, special considerations are necessary to accommodate this side-effects. These include, among others, the provision of a seismic moat and the inconvenient installation of additional springs and/or energy dissipaters at the base-level of the building (Kelly 1999; ASCE 2004).

The existence of a moat makes pounding a possibility. Pounding is a very serious problem in Base Isolation because it causes a sudden and important excitation of higher response modes which, first of all, eliminates the advantages that are inherent to the "first-mode" structural behavior. But more important is that pounding can result in an unexpected structural behavior for which the building might not have been designed. Therefore, pounding can raise the structural response parameters to critical levels (Komodromos, Polycarpou et al. 2007) which translates into severe structural and non-structural damage. Since the issue of large lateral displacements at the base and the associated danger of pounding constitute major concerns, design codes need to specify conservative general provisions that minimize their occurrence and/or their effects, but that reduce the effectiveness and benefits of Base Isolation (Pan and Cui 1998; Kelly 1999).

Different approaches have been proposed to alleviate the problem of pounding and, in general, the one of large displacements of base-isolated structures. One of them consists in the installation of additional springs and/or energy dissipaters at the base level; however, as Kelly (1999) demonstrated, this is detrimental to the performance of the Base Isolation technique, since it reduces the level of isolation and allows the participation of higher modes of vibration. In a more radical way, Pan and other researchers (Pan, Ling et al. 1995; Pan and Cui 1998; Earl and Ryan 2006; Komodromos, Polycarpou et al. 2007) have attempted to solve the problem by studying variations to the concept of Base Isolation. Pan et al. (1995; 1998) have proposed to insert isolation layers at various levels of a building (including the base) to reduce the magnitude of the lateral displacements throughout the height of the building, but mainly at the base (Figure 3). Their analyses show that with their idea, significant reductions of the base displacements can be achieved while the characteristic outstanding interstory and acceleration performance of Base Isolation is kept.

Another shortcoming of Base Isolation arises from the limited vertical-load resistance of the isolating devices (isolators). Apart from the issue with the displacements, this has also limited the use of Base Isolation to low-rise structures. The elevated forces necessary to test at full-scale and develop current and new isolating technologies for heavier (taller) structures cannot be achieved in laboratories (ASCE 2004). This adds to the difficulties of developing and, hence, accepting new isolating technologies and code provisions related to their implementation.

Finally, the interaction of the large displacements of the isolators with the large vertical forces imposed on them by the building generates stability problems due to the p-delta effect that is induced (Figure 4). This issue has already been the subject of several research studies (Haringx 1948;

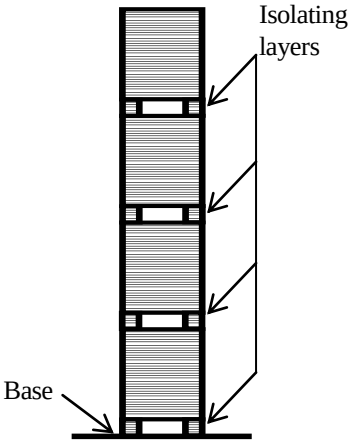

Figure 3 Segmental building concept (Pan and Cui 1998)

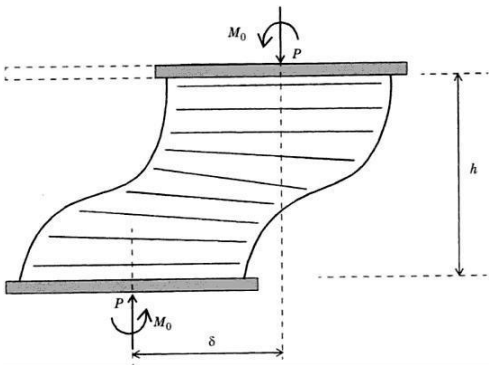

Figure 4 P-delta in rubber isolator (Naeim and Kelly 1999)

Gent and Lindley 1959; Gent 1964; Kircher, Delfosse et al. 1979); however, it is still and will inevitably always be a concern in the development of isolators and the design of base isolated systems.

From the economical point of view, although the isolation of the base of a new building is technically simple, it becomes expensive and complicated in retrofit applications, since it requires excavations, temporary load transfer and sometimes the removal from service of the structure during certain stages of the isolation process (Earl and Ryan 2006).

3. MASS ISOLATION

3.1 Principles

Conventional buildings have their bases attached to the ground through their foundations and, in practical terms, fully experience the accelerations imposed by earthquakes when they take place. The concept of structural isolation attempts to detach the structure from the source of the excitation so that the induction of forces is reduced. An example of this is the case of Base Isolation explained before where a whole building is "separated" from the ground through the use of low-stiffness isolators. It is not necessary to separate the whole bulky and heavy structure from its foundation to achieve its isolation, the isolation of only the individual mass concentrations produces in theory the same effect.

Buildings are designed and built to resist gravity and lateral loads; this requires two different structural sub-systems, one that provides resistance to the vertical loads and another one that resists forces in the horizontal planes. In practice, both sub-systems are built into a single system in which they work in a coupled manner.

The masses in buildings are considered lumped at the floor slabs, which are part of the gravity system and are linked to the ground by the lateral resisting sub-system. The general concept of mass isolation is based on introducing a discontinuity between the floor masses (gravity sub-system) and the lateral sub-system to reduce or, ideally, eliminate the interaction between the two. By placing an isolating gap between the two systems, the masses are automatically "detached" from the ground and, consequently, their participation and ease of excitation by earthquake accelerations decreases (Figure 5). Lower excitations of the masses translate into reduced demands on the lateral sub-system, which ultimately results in better structural performance and the need for lighter (more economical) designs.

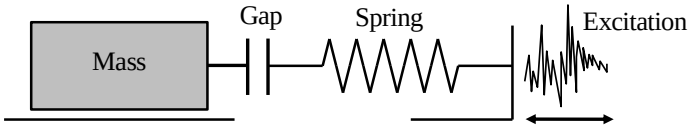

Figure 5 Mass isolation (Ziyaeifar 2002)

The "elimination" of the physical links between the masses and the lateral springs leaves a loose gravity system that undergoes large velocities and displacements relative to the stiffness system when it is subjected to earthquake excitations. While they may look as an inconvenient at first, the increased relative velocities and displacements can actually be used to dissipate the input seismic energy through velocity-dependent or displacement-dependent energy dissipaters to further improve the performance of the already less demanded mass-isolated system.

3.2 Current state of knowledge

A certain number of researchers have already worked with ideas that are in some form associated to the concept of mass isolation. In Japan, for example, Niiya et al. (1992) and Sakamoto et al. (2000) describe structural systems in which auxiliary masses or the actual masses of the floors are used as vibration absorbers to reduce the seismic response of buildings (Figure 6). An example of this is the case of the Active-Passive Composite Tuned-Mass Damper presented in (Sakamoto, Koshika et al. 2000).

Other approaches to seismic isolation that are more similar to what has been described as mass isolation have been proposed by Pan et al. (1995; 1998), Ziyaeifar and Noguchi (1998), Villaverde (1998), Villaverde and Mosqueda (1999), Ziyaeifar (2000; 2002), Villaverde et al. (2005), Pourmohammad et al. (2006), Earl and Ryan (2006), and Phocas and Pamboris (2009). As described earlier, Pan and his co-researchers proposed an extension of the concept of Base Isolation to other levels of the building, which consists in introducing isolation layers between various segments of a building (Figure 3). They showed that reduced displacements, especially at the base, can be achieved with

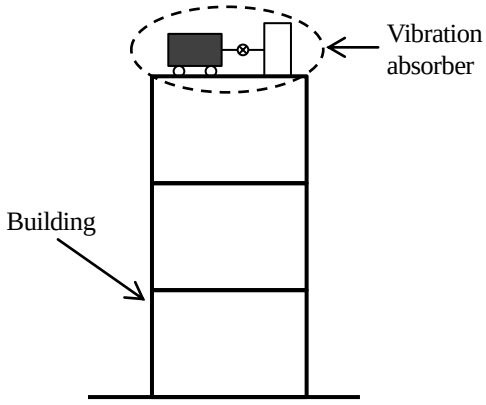

Figure 6 Building with active vibration absorber (Sakamoto, Koshika et al. 2000)

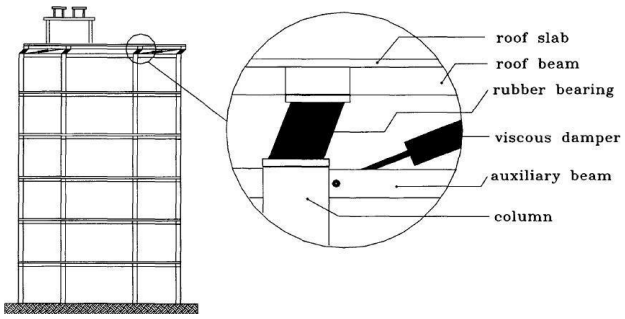

Figure 7 Typical building with roof isolation (Villaverde 1998)

their system. On the other hand, Villaverde and his co-researchers have focused on isolating only the mass of the building roof in a way similar to the method of Base Isolation, but rather approached their idea as that of turning the roof into a vibration absorber (Figure 7). Villaverde recognized that a very large roof mass is needed for an effective implementation of his idea and, also, that the very large displacements of the roof that result require special care. However, his studies, both analytical and experimental, demonstrated that the appropriate isolation of part of the total mass of a structure leads to significant reductions in the seismic demands of the lateral-force resisting system. For retrofitting works, he pointed out that the isolation of the roof should be less disruptive for the service of the building than the implementation of Base Isolation.

Ziyaeifar (1998; 2000; 2002) carefully explained the concept of mass isolation and proposed mass-isolated structural systems that agree with the definition of the mass isolation concept in this document. His systems isolate the mass subsystem from the ground by diverse methods (Figure 8). He supported his ideas with limited analytical testing whose outcomes clearly show technical benefits of isolating the main mass concentrations in buildings from the lateral system and, thus, the ground. Pourmohammad and his colleagues (2006) proposed to isolate each floor of a building in the way Villaverde proposed to isolate the roof; that is, by introducing (rubber) isolators between the floor slabs and the beams that support them (Figure 8a).

Earl and Ryan (2006) deepened the concept of segmental isolation that was initially developed by Pan et al. (1995) and compared the effectiveness of placing various isolating layers at different levels of a building. They point out the technical benefits of placing the isolation layer(s) above the ground instead of placing it at the base level like in Base Isolation. These include the achievement of a level of reductions of the dynamic response of the structure of the same order as those achieved when Base Isolation is used, but eliminating the risk of pounding and the necessity for provisions for the accommodation of large displacements at the base.

Mass isolation is an appealing and simple concept with proved potential; however, to date only limited research related to its development has been done. The technical, architectural and economic benefits (or disadvantages) that could be drawn from this system are far from having been

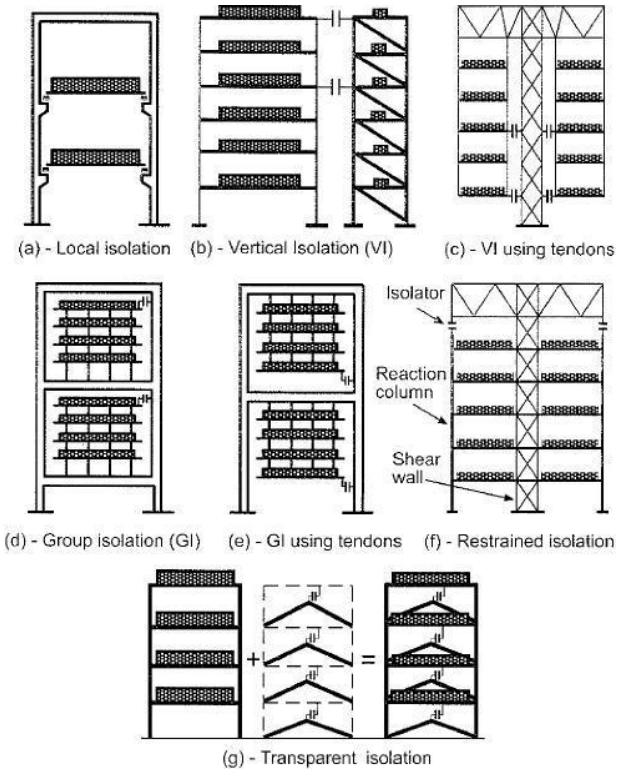

Figure 8 Some methods of mass isolation (Ziyaeifar 2002)

accurately addressed; in fact, the studies on the concept that have been carried out, have many times served to only introduce the concept.

4. STABILITY-DEPENDENT MASS-ISOLATION

4.1 System description

The system proposed for the application of mass isolation in buildings, depicted in Figures 9 and 10, has the following characteristics:

- The concept is intended to be applied to steel buildings where hinged end-conditions of the structural elements can be produced more naturally. The building does not show major physical differences compared to a typical "fixed-base" building, only that the mass sub-system is built detached from the lateral system; that is, there are no primary structural links between the two structural sub-systems.
- All connections in the mass system are pinned, including possibly those at both ends of the columns joining adjacent floor levels, so that free relative motion of a floor slab with respect to the adjacent ones is intentionally allowed.
- The lateral-load-resisting system can consist of any system currently used in practice, namely, shear walls, moment frames, concentrically and eccentrically braced frames, or variations thereof.
- Since the mass sub-system is detached from the lateral system it is inherently unstable. In order to provide it with stability, linear (nodal) springs are placed at each floor level between the slabs and the lateral system.

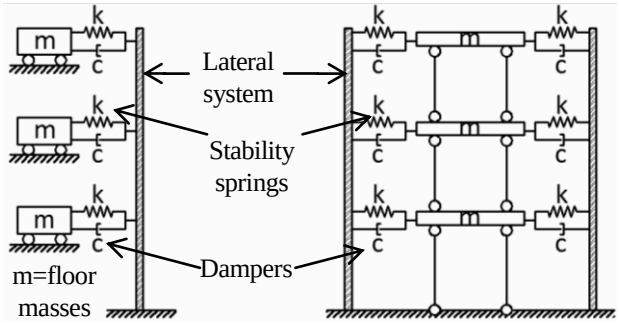

Figure 9 Equivalent sketches of proposed method of SDMI

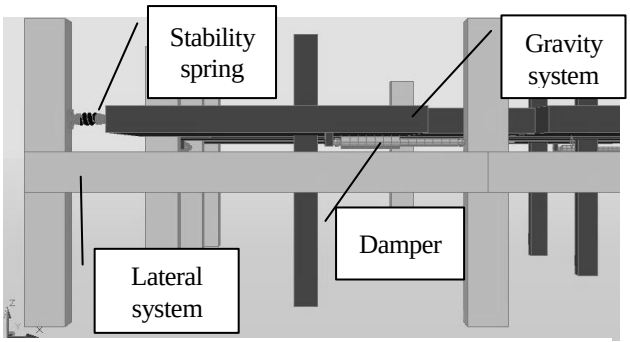

Figure 10 Scheme of proposed SDMI

These springs are referred to as stability springs. Their provision will couple the mass and lateral systems to some extent; that is why, to minimize the coupling of the two systems and, thus, maximize the level of isolation, the stiffness of the stability springs has to be the minimum that guarantees the safety and full restoration of the mass sub-system after the action of an earthquake.

- Since the stiffness of the stability spring springs is relatively low, they act as low-stiffness isolators. The flexibility of these links joining the two sub-systems allow large velocities of the floor masses during seismic excitations which are used for energy dissipation through the use of velocity-dependent energy dissipaters.

Since the level of isolation of the floor masses of the building is limited by the stability requirements of the mass sub-system, the concept is named Stability-Dependent Mass Isolation (SDMI). Some of its advantages compared to typical fixed-base, base-isolated buildings and the other isolation systems mentioned before are:

- As an isolated structure it possesses the associated advantages of reduced floor accelerations and interstory drifts.
- It incorporates the concept of segmental and/or interstory isolation which eliminates the disadvantages and d angers of Base-Isolation (high displacements and associated risk of pounding); in fact, in the case of SDMI there will be no lateral displacements at the base at all.
- The length of the stability springs can be designed to accommodate the maximum relative displacements between the mass and lateral (stiffness) sub-systems. Since adjacent floor levels are not linked with each other in the horizontal direction, the displacements throughout the height of the building are not cumulative.
- Since there are no interstory springs in the mass system, the excitation of higher modes of response and the associated increase in floor accelerations and interstory drifts is kept within certain limits.
- The incorporation of viscous dampers at various levels of the building allows greater energy dissipation than in the case of Base Isolation, Segmental Isolation, Roof Isolation, etc., or than by system damping only and ductile deformations.
- Since it does not use rubber isolators the concept can be applied to high rise structures.
- Since there are actually no complex elements or mechanisms in this system, its cost should be low compared to that of other isolation or control systems. Even in the case of retrofit problems, the implementation of this concept should cause minimal or no disruptions to the service of a building.
- Any additional cost derived from the installation of the energy dissipaters should be compensated with the reduced cost of a lighter lateral system. Moreover, once built, the structural performance of the building during earthquakes will be significantly improved and the damage to primary structural members will be reduced considerably. This will also result in a lower life-cycle cost of the building and a greater probability that the structure will be available for service even after major seismic events.
- The way SDMI is outlined allows the resistance to wind excitations in practically the same way it is achieved in typical fixed-base buildings; i.e., the wind forces will hit the surface of the building which is directly supported by the lateral system.

4.2 Description of requirements for stability springs and dampers

The provision of stability to the mass sub-system is a fundamental requirement. However, for the SDMI system to function as intended, there are issues that have to be considered in the selection/design of the stability springs in order to comply with the stability requirements without compromising the effectiveness of the isolation of the mass sub-system.

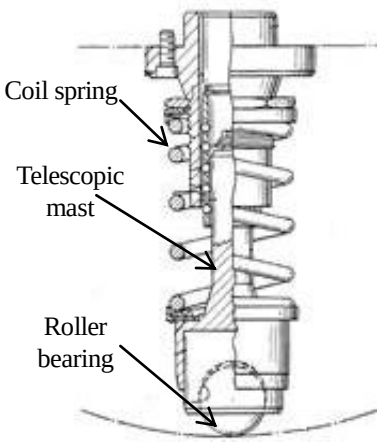

Figure 11 Earthquake isolating support (Yaghoubian 1988)

The fact that the motion of the floor slabs in the building is a three-dimensional phenomenon, it is important that the stability springs do not couple the displacement of the floors with that of the lateral system in any direction, since this would preclude the proper isolation of the floor masses. Yet, at the same time, restoration forces have to be provided in all directions of movement. To achieve this dual purpose, it is necessary to use supports of the form of the U.S. patented seismic isolation support by Yaghoubian (1988) (Figure 11). This support consists of a coil spring mounted around a telescopic mast with a roller bearing, thus, it resists axial forces while allowing lateral motions. These springs would be placed at all floor levels and bearing against all the sides of the slabs. It is also necessary that these springs remain always elastic so that the original positions of the floors can be fully restored.

In the same way, the selection of the type of the energy dissipaters that should be used in conjunction with the stability springs has to be made considering the need for a full restoration of the undisturbed (original) position of the building. Of the many commercially available energy dissipaters, fluid viscous dampers are likely best suited to perform this job. Yielding dampers, for example, would not let the stability springs bring the floor masses to their original position after an earthquake since, once they yield, they adopt a new equilibrium position. Practically the same happens with friction dampers, which would require the stability springs to provide restoring forces greater than the friction forces of the dampers to return the slabs to their initial positions. Viscous dampers allow the stability springs perform the restoration of the system until it is completed. Moreover, the fluid viscous damper technology is already sufficiently developed and tested to provide with the energy dissipation needs for this project (TDI 2009).

5. OBJECTIVES

An analytical study has been designed with the following objectives:

- The construction of computer models using available powerful computational tools for the nonlinear dynamic analysis of SDMI buildings,
- The determination of the appropriate configuration of the stability springs and dampers,
- The establishment of the dynamic properties of the SDMI buildings,
- The analysis of the computer models using standardized methodologies, tools and criteria to identify and assess key design parameters influencing the response of SDMI buildings,
- The generation of optimized designs of SDMI buildings,
- The assessment of dynamic response quantities of interest such as accelerations and interstory drifts, among others, to determine the technical advantages and disadvantages of the SDMI system,
- The proposal of design guidelines for SDMI buildings, and
- The eventual design of experimental models to calibrate and corroborate the analytical results and design guidelines.

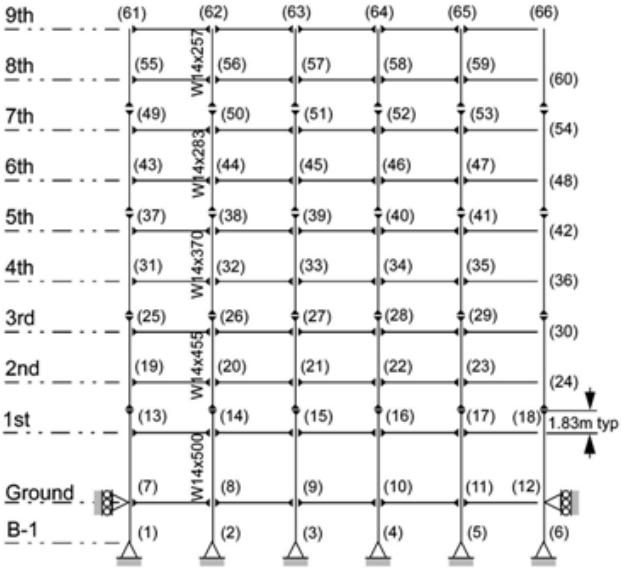

Figure 12 9-Story benchmark building (Ohtori, Spencer Jr et al. 2004)

6. PRELIMINARY STUDIES

6.1 Seismic response of a SDMI building compared to that of a fixed-base building

Preliminary nonlinear dynamic analyses of a 9-story SDMI frame were carried out to determine very roughly the potential reductions in the structural response that can be achieved when a possible form of a SDMI is implemented. For this purpose, the 9-story benchmark building (Figure 12) (Ohtori, Spencer Jr et al. 2004) designed for the SAC Steel Project was selected and the SDMI concept was applied to it. The modeling and analysis of the frame were carried out with the commercial computer program SAP2000 (CSI 2007). It is important mentioning that, in these preliminary studies, none of the design parameters like damper

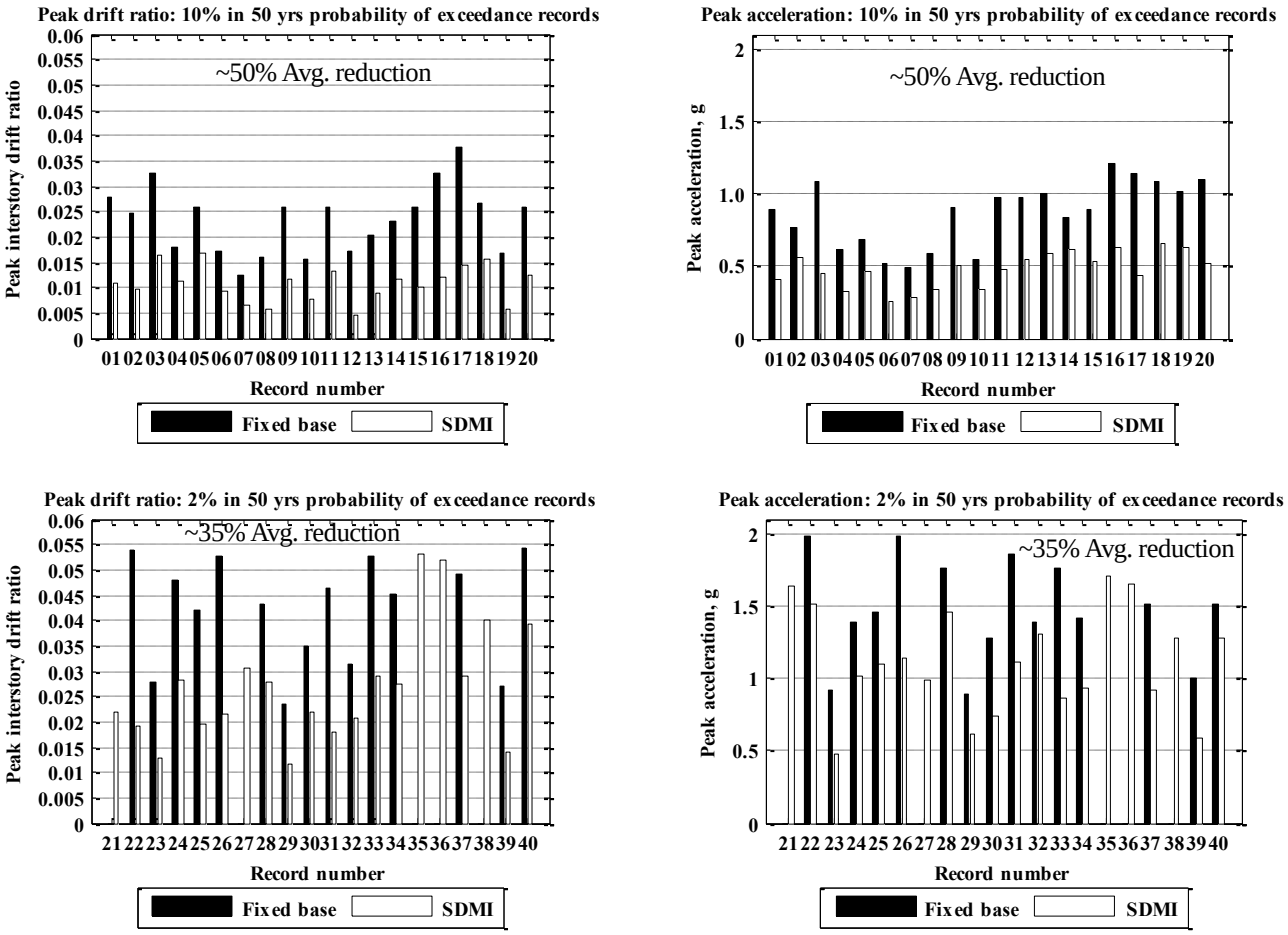

Figure 13 Comparative peak dynamic response of SDMI building vs. fixed-base building

configuration, damper properties, spring properties, etc. in the SDMI building model was optimized to yield the minimum response, which means that the performance of the structure can be further improved if optimal values for these parameters are specified.

The fixed-base and SDMI models were subjected to 40 earthquake records consistent with the location of the building (Los Angeles, CA), 20 having a probability of exceedance of 10% in 50 years (records 01-20) and 20 having a probability of exceedance of 2% in 50 years (records 21-40). The ground acceleration histories that were used are the ones developed by Somerville (1997) for the SAC Steel Project (FEMA 1994). The results provided in Figure 13 show the impressive performance of the SDMI building compared to the original fixed-base building even without optimization. It is also worth mentioning that the fixed-base structure collapsed under records 21, 27, 35, 36 and 38 (no bars are shown on charts for these cases), but the SDMI building was able to resist them.

6.2 Determination of damper configuration

For the generation of the optimized designs of the SDMI buildings, extensive use will be made of genetic algorithms (Haupt 2004). The design optimization process begins with the determination of the most convenient configuration for the dampers based on the configuration

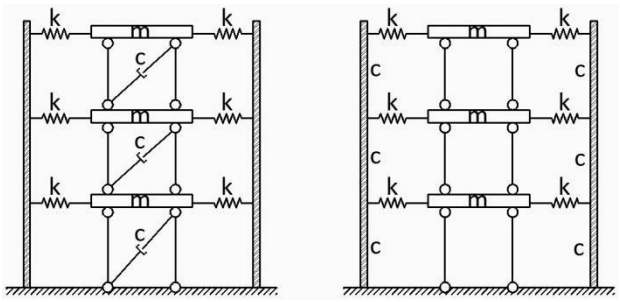

Figure 14 a) SDMI with dampers within gravity sub-system, b) SDMI with dampers within the lateral sub-system

that will minimize particular structural response parameters. For this and for now, the objective function is preliminarily selected to be the interstory drift ratio in the lateral sub-system. Three main damper configurations are considered:

1. Dampers are joining the lateral sub-system with the gravity sub-system as depicted in Figure 9,
2. Dampers are within the gravity sub-system joining adjacent floor levels (Figure 14a), and
3. Dampers are within the lateral sub-system joining adjacent floor levels (Figure 14b).

In order to find which of the three options is technically most convenient, a genetic algorithm based on the blend crossover method (Haupt 2004) is applied to all damper

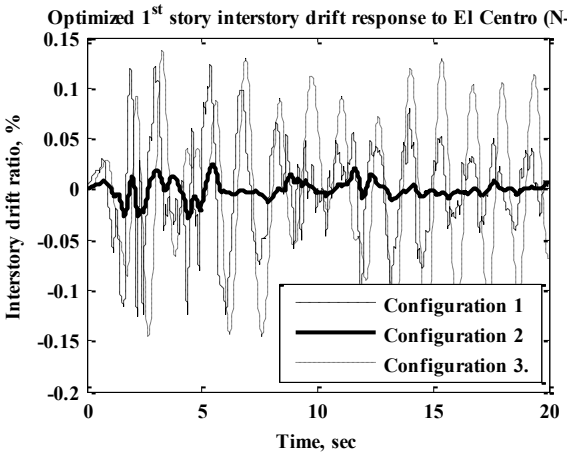

Figure 15 Interstory drift ratio time histories for the different configurations considered subjected to El Centro (N-S)

configurations to find optimal values for the stiffness of the stability springs and damping coefficients for the dampers. The 3-story benchmark building (Ohtori, Spencer Jr et al. 2004) is modeled using Matlab (TheMathWorks 2008), where the gravity sub-system is modeled as a triple pendulum attached through the stability springs to the lateral subsystem. The model is subjected to the north-south component of *El Centro* as part of the optimization process. The genetic algorithm that is used already includes a subroutine that will check that the values found for the stiffness of the springs are sufficient to provide static stability to the gravity system; compliance with dynamic stability requirements is implicit in the process of minimizing the structural response.

Results of the genetic algorithm show that the best way to place the dampers is within the gravity sub-system joining adjacent floor levels (Figure 14a) and not in the configuration used in Figure 9 and in the preliminary analyses of the SDMI system (Figure 15). This outcome makes sense, since placing the dampers joining the two structural sub-systems enables additional coupling of the two, thus, the isolation of the floor masses is lowered and, therefore, the benefits of SDMI are also reduced.

7. CONCLUSIONS

The development of the proposed concept of seismic mass isolation will constitute an important advancement in the field of seismic isolation of buildings which, at present, has practically been limited to the case of Base Isolation. Although attempts have already been made to diversify the strategy and generalize the concept of isolation, until now, these have been discrete and have fallen short in the scope that is necessary for a newly developed system to be considered for practical applications.

The proposed study intends to address every analytical aspect necessary to take SDMI to a level that permits its practical implementation. With the already available and encouraging results provided by Base Isolation and the preliminary analyses carried out on the SDMI concept, the authors believe that SDMI promises technical and economic advantages and, therefore, has the potential to become a wide-spread strategy for improving the seismic performance of buildings in the future. At the same time, it should open an important amount of new possibilities for earthquake protection.

RESPONSE BEHAVIOUR OF ISOLATED BUILDINGS TO EARTHQUAKE EXCITATIONS CONSIDERING SOIL FLEXIBILITY

Sayed Mahmoud[1], and Per-Erik Austrell[2]

1) Postdoctoral Research Fellow, Division of Structural Mechanics, Lund University, Lund, Sweden
2) Assistant Professor, Division of Structural Mechanics, Lund University, Lund, Sweden
elseedy@hotmail.com, per_erik.austrell@construction.lth.se

Abstract: Seismic response time history analysis of isolated-base buildings considering and ignoring supporting soil flexibility is investigated. In the analysis, a large number of parametric studies in which different earthquake excitations, and building natural periods has been performed. Moreover, several values of shear wave velocities have been considered. The action of the underlying soil has been modelled through a lumped parameter model with swaying and rocking spring-dashpot system. Compared are certain aspects of the response with and without soil-structure interaction (SSI) effect leading to the following conclusions. (1) Soil flexibility significantly affects the rigid superstructure response and slightly influences the response of the flexible base bearing. (2) The peak response of the SSI system with a nonlinear bearing is shown to be larger than those obtained with the SSI system having a linear base particularly for moderate and high earthquake actions. (3) Although the peak response is highly affected by the inclusion of soil flexibility; it appears insensitive to the variation of soil velocity. (4) As the building natural periods become larger, a decrease trend in the effect of SSI on the obtained response has been observed for all the considered ground motions, base isolations, and shear waves.

1. INTRODUCTION

Seismic isolation is a strategy to reduce the response and the seismic forces to or near the structure elastic capacity. Isolation systems applied in base-isolated buildings are generally effective due to their flexibility and energy dissipation characteristics. Flexibility in the horizontal direction will lower the fundamental frequency of the building below the range of frequencies which dominate general earthquake input. Providing means of energy dissipation reduce the seismic energy transmitted to the system during earthquakes so that the structural response will be reduced.

A number of base isolation systems has been proposed and their effects on the dynamic behaviour of structures have been accurately reviewed by many authors (Buckle and Mayes 1990, Jangid and Datta 1995, Chopra 1995, Kelly 1997, Kelly 1998, Kelly 1999). Two of the most commonly used isolation systems consist of laminated rubber bearings (LRBs) and high damping rubber bearings (HDRBs). LRBs are often used with passive dampers for the purpose of controlling the excessive base displacements. On the other hand, the application of HDRBs is considered as one of the most promising among several methods of seismic isolation. However, most of the research works investigating the performance of seismically isolated buildings have been focused on the dynamic behaviour of sliding structures based on the PF system subjected to harmonic support motion (Mostaghel et al. 1983, Westermo and Udwadia 1983, Jangid 1997, Calio et al. 1998), to earthquake excitations (Toki et al. 1981, Constantinou and Kneifati 1987, Liaw et al. 1997, Ryan 2004) and to randomly moving foundation (Constantiou and Tadjbakhsh 1983, Constantiou and Tadjbakhsh 1984). A review of the above cited papers indicates that the conducted analyses ignore the influence of soil-structure interaction (SSI) on the dynamic response of a structure. Moreover, the isolated bases of the analysed structures were usually modelled as PF base isolation systems.

Ignoring the SSI effects may lead to incorrect structural response assessment since it has been recognized that it may have a significant impact on the dynamic system response. Two general methods are available for rationally incorporating SSI effects into structural analysis (Wolf 1994). The first one is a direct method in which the structure and a portion of the base soil are both incorporated into a finite element mesh. In the second method, known as a substructure method, the structure and the soil are analyzed separately. A simplified model, which is typically composed of one or more springs or spring-damper combinations to approximate the behaviour of the soil, is coupled with the structural model at its base. The most common analytical model is the one in which the soil domain is considered to be a homogeneous elastic half-space. For the dynamic SSI problems, several studies proposed lumped-parameter models (Wolf and Somaini 1986, De Barros and Luco 1990,

Wolf 1994, Wolf 1997, Wu and Chen 2001, Wu and Lee 2002, Wu and Lee 2004) to simulate unbounded soil so that these models can be used directly in the time domain analysis.

Quite extensive research works have been conducted in order to investigate the impact of considering SSI effects on the response of isolated bridge structures (Zheng and Takeda 1995, Vlassis and Spyrakos 2001, Tonganokar and Jangid 2003, Jangid 2004, Kunde and Jangid 2006). However, very limited research works have been carried out for the response of seismically isolated buildings with SSI effects (Spyrakos et al. 2009a, Spyrakos et al. 2009b).

The aim of this paper is to evaluate the effect of SSI on the seismic response behaviour of isolated buildings. A large number of simulations using isolated building model with different natural periods subjected to three different ground motion records has been performed. The response and peak responses in the mean of accelerations, velocities and displacements with and without SSI effects have been analyzed. Also, the sensitivity of the response has been investigated for a variety of shear wave velocities.

2. MODELLING AND IDEALIZATION

2.1 Isolated Building Model

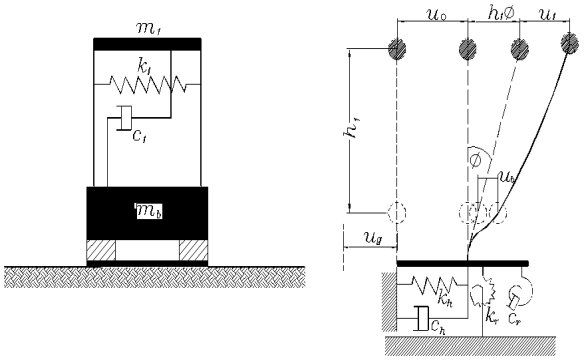

Figure 1 Idealized SDOF Mathematical Model

Figure 1 shows the idealized SDOF mathematical model for the isolated one-storey building of height h_1. A rigid deck of mass m_1 is connected to a rigid mat of mass m_b through massless columns of stiffness k_1 and damping coefficient c_1. The values of structural stiffness and damping coefficients can be calculated from the formulas (Harris and Piersol 2002):

$$k_1 = \frac{4\pi^2 m_1}{T_1^2}; \qquad c_1 = 2\xi_1\sqrt{k_1 m_1} \tag{1}$$

where T_1 and ξ_1 denote the natural structural vibration period and structural damping, respectively.

2.2. Isolation Base Model

Laminated rubber bearing (LRB) is one type of elastomeric bearings. It exhibits the parallel action of linear spring and damper. The restoring force developed in the LRB can be written as:

$$F_b = k_b u_b + c_b \dot{u}_b \tag{2}$$

where k_b, c_b, u_b and $\dot{u}_b$ are the stiffness, damping coefficient, displacement and velocity of the LRB system, respectively.

The isolation time-period T_b in terms of the stiffness, damping coefficient and the total mass M_t of the base-isolated building (including the base mass) can be written as:

$$T_b = 2\pi\sqrt{\frac{M_t}{k_b}} \tag{3}$$

On the other hand, the damping ratio ξ_b can be related to the damping coefficient, total mass and the isolation base frequency ω_b by the formula:

$$\xi_b = \frac{c_b}{2M_t\omega_b} \tag{4}$$

2.3. Soil Modelling

The considered building model rests on a half-space elastic flexible soil with no slippage between the base and the soil. The soil flexibility allows for horizontal translation and rocking at the structure's base making a system with four degree-of-freedom for the one-storey building and six degree-of-freedom for the three-storey building models. For a foundation of length L and width B, the spring stiffness and damping coefficients of swaying and rocking effects, which represent the SSI, are computed using the following expressions (Whitman and Richart 1967):

$$\begin{aligned} k_h &= 2(1-\nu)G\beta_x\sqrt{BL}, \\ c_h &= 0.576k_h r_h\sqrt{\frac{\gamma}{gG}} \\ k_r &= \frac{G}{1-\nu}\beta_\phi BL^2 \\ c_r &= \frac{0.3}{1+\beta_\phi}k_r r_r\sqrt{\frac{\gamma}{gG}} \end{aligned} \tag{5}$$

where k_h, and c_h are stiffness and damping coefficients of swaying spring, k_r and c_r are stiffness and damping coefficients of rocking spring, ν is the Poisson's ratio of soil, β_x and β_ϕ are the constants of swaying and rocking springs (depending on the ratio L/B), r_h and r_r denotes the equivalent radii of isolated foundation for swaying and rocking springs, respectively; γ is the density of soil, g refers to the acceleration of gravity and G is the shear modulus which depends on of the shear wave velocity, V_s, and can be calculated as (Whitman and Richart 1967):

$$G = \frac{\gamma(V_s)^2}{g} \tag{6}$$

2.4. Earthquake Modelling

The effects of SSI on the response time history of the considered building models have been studied under three different ground motions. The analysis has been carried out under the El Centro earthquake (18.05.1940, PGA=0.34*g*), the N. Palm Springs earthquake (08.07.1986, PGA=0.59*g*) and the The Chi-Chi (Taiwan) earthquake (20.09.1999, PGA=1.13*g*). .

3. EQUATION OF MOTION

The equation of motion for the superstructure and base of the isolated system incorporating the horizontal and rotation motions of the soil at the structure's base can be written as:

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{C}\dot{\mathbf{U}} + \mathbf{K}\mathbf{U} + \mathbf{F_b} = -\mathbf{M}\mathbf{R}\ddot{\mathbf{U}}_\mathbf{g} \qquad (7)$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ is the mass, damping and stiffness matrix, respectively; $\mathbf{R}$ is an influence matrix; $\ddot{\mathbf{U}}$, $\dot{\mathbf{U}}$, and $\mathbf{U}$ represent the acceleration, velocity and displacement vectors, respectively; $\ddot{\mathbf{U}}_\mathbf{g}$ is the ground acceleration vector and $\mathbf{F_b}$ denotes vector containing the forces mobilized in the isolation bearing. Details of the matrices and vectors can be defined as

$$\mathbf{M} = \begin{pmatrix} m_1 & 0 & m_1 & m_1 h_1 \\ 0 & m_b & m_b & 0 \\ m_1 & m_b & m_1 + m_b & m_1 h_1 \\ m_1 h_1 & 0 & m_1 h_1 & m_1 h_1^2 \end{pmatrix}, \quad \mathbf{C} = \begin{pmatrix} c_1 & -c_1 & 0 & 0 \\ -c_1 & c_1 & 0 & 0 \\ 0 & 0 & c_h & 0 \\ 0 & 0 & 0 & c_r \end{pmatrix}, \quad \mathbf{K} = \begin{pmatrix} k_1 & -k_1 & 0 & 0 \\ -k_1 & k_1 & 0 & 0 \\ 0 & 0 & k_h & 0 \\ 0 & 0 & 0 & k_r \end{pmatrix}$$

$$\mathbf{R} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1/h_1 \end{pmatrix}, \ddot{\mathbf{U}} = \begin{pmatrix} \ddot{u}_1 \\ \ddot{u}_b \\ \ddot{u}_0 \\ \ddot{\phi} \end{pmatrix}, \quad \dot{\mathbf{U}} = \begin{pmatrix} \dot{u}_1 \\ \dot{u}_2 \\ \dot{u}_0 \\ \dot{\phi} \end{pmatrix}, \quad \mathbf{U} = \begin{pmatrix} u_1 \\ u_b \\ u_0 \\ \phi \end{pmatrix}, \quad \mathbf{F_b} = \begin{pmatrix} 0 \\ f_b \\ 0 \\ 0 \end{pmatrix}$$

where u_1 and u_b is the displacement of the superstructure and the isolation bearing, respectively; u_0 and ϕ describe the soil horizontal translation and rocking movements. The corresponding velocities and accelerations are represented with dots (derivatives with respect to time).

4. RESPONSE ANALYSIS

Extensive numerical simulations have been conducted to investigate the effects of soil flexibility on the response of single and multi-storey base-isolated buildings having different natural periods. In the analysis, different sandy soil types (Wei et al. 1996) and earthquake motions have been used. Due to the paper length limitation, representative results for one sandy soil type with different shear wave velocities at depth of 15 m are presented. The soil properties characterized by the shear wave velocities and densities are shown in Table 1. The isolated buildings have been excited by a suit of ground motion records. The records are intended to encompass low, moderate and high PGA levels to better understand the effect of SSI under different earthquake excitations. Numerical study has been carried out using lumped mass models of the base-isolated building under consideration for calculation of response quantities of interest in terms of displacements, velocities and accelerations.

Table 1 Sandy Soil type with Different Densities and Shear Wave Velocities at Depth of 15 m.

Soil density γ (kg/m^3)	Shear wave velocity V_s (m/sec)
1.89×10^3	196
1.94×10^3	220
2.00×10^3	255
2.07×10^3	275

The building superstructure fundamental period, damping ratio and mass are: $T_n = 1$ s, $\xi = 0.05$ and $m_1 = 30\times10^3$ kg. The storey height is $h = 3.5$ m. For the isolation system, the natural period and the viscous damping ratio of LRBs system are $T_b = 2$ s and $\xi_b = 0.1$. The base mass is $m_b = 90\times10^3$ kg. The stiffness of swaying and rocking springs and the damping coefficients of dashpots have been evaluated using the formula given by Eq. (1). The soil mass density and Poisson's ratio are: $\gamma = 1.89\times10^3$ kg/m^3 and $\nu = 0.3$. The shear wave velocity is given by $V_s = 196$ m/sec. The radii of equivalent circular foundation for swaying and rocking have been estimated and found to be of equal values $r_h = r_r = 4$ m (Takewaki 2005).

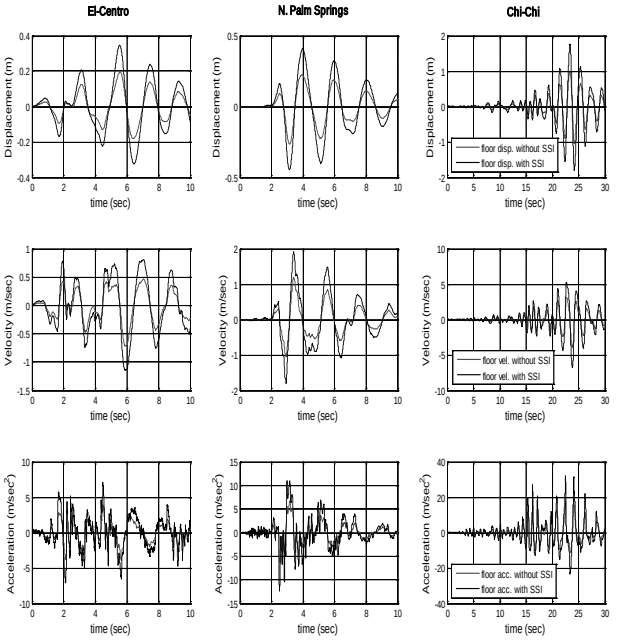

Figure 2 Displacement, Velocity and Acceleration Time Histories with and without SSI under The El Centro, N. Palm Springs and Chi-Chi Earthquakes

Figure 2 shows the storey displacement, velocity and acceleration time histories of one-storey building isolated by the LRB system with and without SSI under the El Centro earthquake, N. Palm Springs earthquake and Chi-Chi (Taiwan) earthquake. The plot indicates that the displacement, velocity and acceleration are higher when SSI is considered. The peak values of storey acceleration of 4.835, 8.684 and 20.156 m/sec^2 without SSI is increased upto 7.045, 12.404 and 32.119 m/sec^2 under the El Centro earthquake, N. Palm Springs and Chi-Chi (Taiwan) earthquake, respectively. However, the capacity demand for the superstructure increases due to increased superstructure accelerations with soil flexibility consideration.

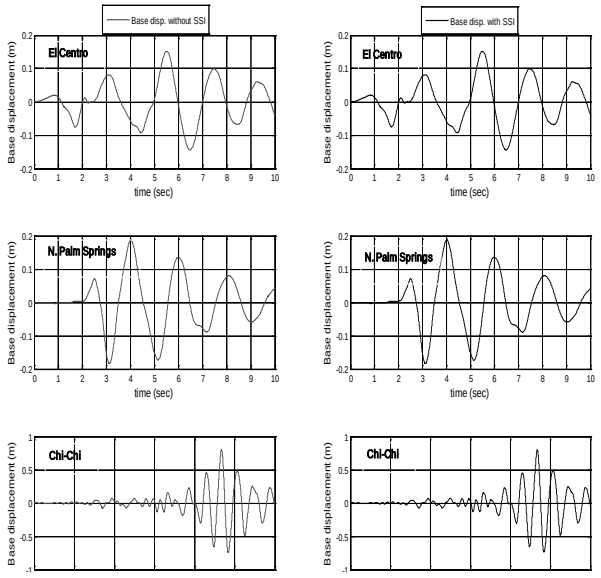

Figure 3 Displacement Ttime Histories at The Base of The Seismically Isolated Building under Different Earthquakes with Three PGA Llevels for The Case without and with SSI

Displacement time histories at the base of the seismically isolated building under different earthquakes with three PGA levels considered in the study are shown in Figure 3 for the case without and with SSI. It can be observed that the differences between the two plots are very difficult to be identified. Only a slight increase in the peak values due to incorporation of soil flexibility is detected. This implies that considering the flexibility of soil does not affect the response of the flexible base-isolation system. It has also been found that the peak base displacements obtained by ignoring the effect of underlying soil are of 0.1519, 0.1882 and 0.8033 m while for the case of considering the SSI effect the corresponding values have been recorded to be of 0.1524, 0.1883 and 0.8040 m for the El Centro, N. Palm Springs and Chi-Chi earthquake, respectively. This confirms the fact that the flexibility of soil significantly affects the rigid superstructure response and unables to influence the behaviour of the flexible base-isolation system. Similarly, velocity and acceleration time histories at the base of the seismically isolated building under different earthquakes with three PGA levels considered in the study confirm the previous results for displacement time histories with and without SSI.

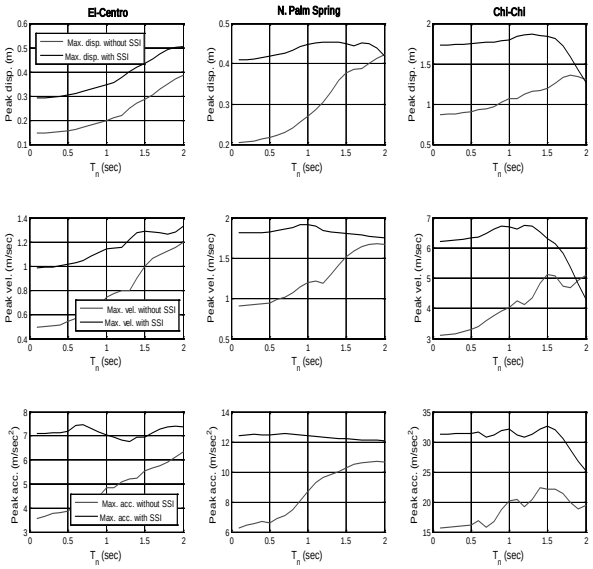

Figure 4 Peak displacement, velocity and acceleration responses for the SDOF system with different natural periods and LRBs as an isolation system with and without SSI effects under different earthquakes

Figure 4 shows the peak displacement, velocity and acceleration responses for of the linear isolation system with LRBs for different natural structural periods with and without SSI effects under different earthquakes. It can be observed from the figure that as the building period increases, the peak response of the isolated building, ignoring SSI effects, increases as well. Similar trends can be observed for the system with the incorporation of soil flexibility. For the earthquakes with higher PGA with the increase in the building natural period a slight increase trend can be observed for the peak response curves with SSI effects and with further increase in the natural period a sharp decrease trend occurs.

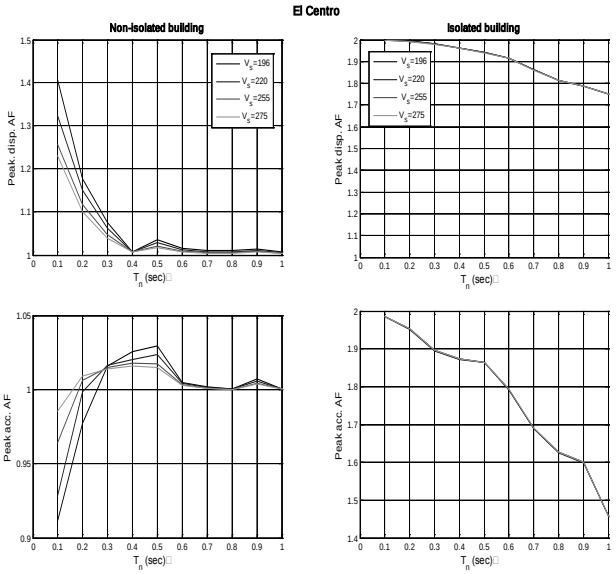

Figure 5 Peak Displacement and Acceleration Amplification Factors for the Non-isolated and Isolated Buildings with Respect to the Structural Natural Period under the El Centro Earthquake for Different Shear Wave Velocities

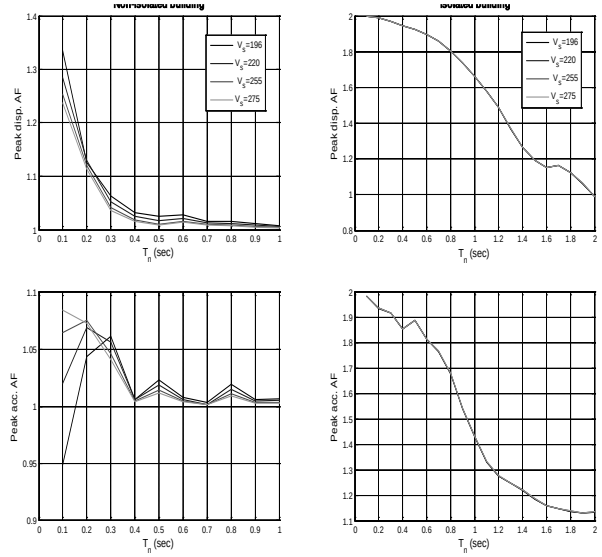

Figure 6 Peak Displacement and Acceleration Amplification Factors for the Non-isolated and Isolated Buildings with Respect to the Structural Natural Period under the N. Palm Springs earthquake for different Shear Wave Velocities

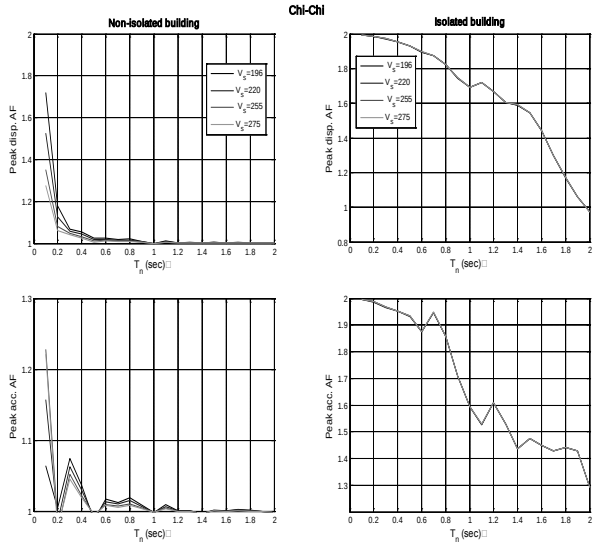

Figure 7 Peak Displacement and Acceleration Amplification Factors for the Non-isolated and Isolated Buildings with Respect to the Structural Natural Period under the Chi-Chi Earthquake for Different Shear Wave velocities

Figures 5-7 show the peak displacement and acceleration amplification factors (AF) for the non-isolated and isolated buildings with respect to the structural natural period under the El Centro, N. Palm Springs and Chi-Chi earthquakes with different shear wave velocities in the soil specified in Table 1. It can be seen from the figures that, for the non-isolated building, variations in shear wave velocities significantly change the values obtained for the peak response AF, especially for low structural natural periods. Moreover, as the soil condition becomes soft, i.e. shear wave velocity decreases, the corresponding peak displacement AF increases, while the peak AF for the acceleration decreases. It is also worth noting that the PGA levels have been found to be important in affecting the peak acceleration. Figure 5 shows that, for the El Centro earthquake with PGA=0.34*g*, the peak acceleration AF appears to be below the unity for lower shear wave velocities and slightly above the unity for higher velocity values. For the N. Palm Springs earthquake (see Figure 6), which has PGA level greater than the PGA level of the El Centro earthquake, the values for the peak acceleration AF exceed the unity, except for the lowest shear wave velocity. On the other hand, for high PGA levels represented by Chi-Chi earthquake (see Figure 7) the peak acceleration AF is higher than the unity for all considered shear wave velocities in the soil.

Figures 5-7 also show that the response of the base-isolated building is not altered by the shear wave velocity variations, although it is highly affected by the soil flexibility. The simulation results indicate that as the natural period of the building decreases the peak displacement and acceleration AF significantly increase. For all the considered shear wave velocities in the soil, the peak response of the isolated building is uniformly amplified. Similar trends have been observed for all the earthquakes considered.

5. CONCLUSIONS

The present paper has been focused on the seismic response behaviour of single-storey buildings isolated by LRB system with and without SSI effects under different earthquakes. In the analysis, the records of the 1940 El Centro, 1986 N. Palm Springs and 1999 Chi-Chi earthquakes have been used, as examples of ground motions with different PGA. The seismically isolated building has been considered to have different natural periods as well as resting on soils with different densities and shear wave velocities. From the results of present study, the following conclusions can be drawn:

Numerical simulations demonstrate that soil flexibility has a significant influence on the earthquake-induced response of base-isolated buildings.

Considering the flexibility of soil significantly affect the rigid superstructure response and unable to influence the behaviour of the flexible base-isolation system.

The influence of the SSI effects on the response of base-isolated buildings is more significant for structures with longer natural period, particularly in the case of earthquakes with high PGA.

The response of non-isolated buildings has been found to be sensitive to the variations in shear wave velocity in the soil, especially for low structural natural periods. On the other hand, the response of isolated buildings seems to be insensitive to the shear wave velocity variations.

Abstract: Previous studies have shown that pounding of seismically isolated buildings during earthquakes could significantly affect the performance of these buildings. In this paper analysis of seismic pounding of a typical 4-story base-isolated reinforced concrete (RC) building with retaining walls at the isolation level is presented. A modified Kelvin-Voigt impact force model, which does not have the limitations of the conventional model, is used to simulate impact. Geometric and material nonlinearities are considered in the analysis. The effect of seismic pounding on the performance of the building is evaluated based on drift demands and damage indices. The findings of the study are expected to assist design and evaluation of typical mid-rise base-isolated RC buildings.

1. INTRODUCTION

Seismic pounding refers to collision between adjacent structures during earthquakes. It occurs when structures with different dynamic characteristics, having insufficient separation between them vibrate out of phase. Earthquake reconnaissance surveys have reported that seismic pounding of *fixed-base buildings* may lead to severe damage and even result in complete collapse (Rosenblueth and Meli 1986, Kasai and Maison 1997). At least one case of seismic pounding of *base-isolated buildings* has been reported viz. the Fire Command and Control (FCC) building in Los Angeles experienced one-sided pounding with the entry bridge during the 1994 Northridge earthquake. Increased story shear, drift and acceleration demands on the steel structure were evident due to pounding (Nagarajaiah and Sun 2001). Although seismic pounding of fixed-base buildings has been studied extensively (Maison and Kasai 1992, Pant et al. 2010) for two decades, it is only recently that the seismic pounding of base-isolated buildings has drawn the attention of researchers (see for example Matsagar and Jangid 2003, Polycarpou and Komodromos 2010). All previous studies related to seismic pounding of base-isolated buildings have been carried out where the buildings were modeled as elastic or elastoplastic shear beams or elastic multi-degree-of-freedom lumped mass systems. However, these simplified models cannot incorporate characteristics of the realistic building materials such as reinforced concrete (RC). Therefore, the response of a base-isolated RC building considering seismic pounding is not well understood. Owing to the increasing use of base isolation technology for seismic protection of mid-rise RC buildings around the world, it is important to study the seismic pounding response of such buildings.

In this study, seismic pounding of a typical mid-rise base-isolated RC building with retaining walls at the base is studied. The effect of seismic pounding on the performance of the building is assessed using three-dimensional nonlinear finite element (FE) analysis.

2. IMPACT SIMULATION

The contact element approach is widely used for the simulation of impact between structures, due to its clear physical meaning and simple algorithm. The appropriate force-deformation relationship of the contact element is one of the important issues in pounding simulations. Hence, there have been numerous efforts to develop various impact force models for these contact elements. Although nonlinear impact force models are also available, the linear impact force models provide a good balance between simplicity and accuracy. The Kelvin-Voigt (KV) model, which can be represented by the combination of a spring and a dashpot in parallel, is the most widely used impact force model. In this model, the impact force F between the impacting bodies is,

$$F = \begin{cases} k_l \delta + c\dot{\delta} & \delta > 0, \\ 0 & \delta \le 0, \end{cases} \tag{1}$$

where k_l is stiffness of spring element, c is damping coefficient and indentation δ and relative velocity of impact $\dot{\delta}$ are given by,

$$\delta = u_i - u_j - d_g, \qquad \dot{\delta} = \dot{u}_i - \dot{u}_j, \tag{2}$$

where u_i and u_j are displacements and $\dot{u}_i$ and $\dot{u}_j$ are velocities of impacting nodes *i* and *j*, respectively and d_g is at-rest gap distance between the impacting nodes. The damping coefficient c in Eq. (1) can be expressed in terms of the coefficient of restitution r, which is defined as the ratio of the relative velocity after impact to the relative velocity before impact. The expression for the damping coefficient in the KV model is (Anagnostopoulos 2004),

$$c = 2\xi\sqrt{\left(k_l m_{eff}\right)}, \tag{3}$$

where the stiffness k_l in the absence of experimental studies is determined based on the axial stiffness of colliding bodies and the effective mass m_{eff} and damping ratio ξ are given by,

$$m_{eff} = \frac{m_1 m_2}{m_1 + m_2}, \quad \xi = -\frac{\ln(r)}{\sqrt{\pi^2 + (\ln(r))^2}}, \tag{4}$$

where m_1 and m_2 are masses of the colliding bodies. Although the model is attractive due to its simplicity, the limitations are:

(i) Due to a constant damping coefficient, it shows a sudden jump in the impact force at the beginning of impact, which is not reasonable for concrete-to-concrete impact (Fig. 1(a)). This sudden jump in the force induces unrealistic high accelerations in the impacting bodies.

(ii) Due to the dashpot being activated even in the restitution phase, the colliding bodies exert tension on each other just before the separation (Fig. 1(a)), which has no physical meaning.

Hence, a modification to the KV model referred to as the Modified Kelvin-Voigt (MKV) model was proposed by Pant et al. 2010. The MKV model is based on the assumption that most of the energy during impact is dissipated in the compression phase. Hence, the energy dissipated in the restitution phase can be neglected. This assumption allows for the removal of the dashpot from the spring-dashpot assembly in the restitution phase. The impact force F between the impacting bodies can be expressed as,

$$F = \begin{cases} k_l\delta + c\dot{\delta} & \delta > 0 \text{ and } \dot{\delta} > 0, \\ k_l\delta & \delta > 0 \text{ and } \dot{\delta} \le 0, \\ 0 & \delta \le 0. \end{cases} \tag{5}$$

In order to avoid a sudden jump in the impact force at the beginning of impact, the damping coefficient c is taken to be directly proportional to the indentation δ as,

$$c = \xi\delta. \tag{6}$$

This leads to a new relationship between ξ and r as,

$$\xi = \frac{3k_l\left(1 - r^2\right)}{2r^2\dot{\delta}_0}, \tag{7}$$

where $\dot{\delta}_0$ is relative velocity before impact. The relationship between impact force and indentation for the MKV model is shown schematically in Fig. 1(b). It is clear from Fig. 1(b) that the sudden jump in impact force at the beginning of impact and the tensile impact force just before the separation of the KV model are no longer present. Thus, all the major limitations of the KV model are eliminated in the MKV model, while maintaining the simplicity and clear physical meaning of the KV model. Furthermore, the model is implemented in FE program OpenSees 2010 in the form of a uniaxial material and is used to simulate seismic pounding of a base-isolated building in subsequent sections.

It is noted that other researchers have also proposed different modifications to the KV model. However, a comparison of these models with the MKV model has shown that the MKV model is more rational for seismic pounding simulation of multi-story buildings (Pant 2010).

To verify the correctness of the derived formula (Eq. (7)) and its proper implementation in OpenSees, numerical verification is conducted by simulating the first instance of impact between a spherical ball and a stationary rigid surface. A ball of mass $m = 1.0\ kg$ is dropped freely from a height $h = 0.5\ m$ on a stationary rigid surface (Fig. 2(a)). Different values of coefficient of restitution r_{pre} are specified, pounding simulations are performed and the coefficient of restitution from the simulation r_{post} are obtained and compared with the pre-specified values. In OpenSees, the simulation is conducted using two-dimensional FE method. The FE model of the problem is shown in Fig. 2(b). The stationary rigid surface and the spherical ball are modeled as node 1 and node 2, respectively. Node 1 is fixed and node 2 is free to move

0.90	0.902	0.2
1.00	1.000	0.0

only in the vertical direction. A contact element needs to be placed between the nodes to simulate the pounding phenomenon. Here, a so called zero-length element available in OpenSees is chosen. With the zero-length element, end nodes of the element can have same coordinates. Particular choice of zero-length element as contact element becomes very advantageous while performing a large number of numerical simulations of seismic pounding between structures with various at-rest gap distances. The nodal coordinates of the adjacent structures need not to be revised for each gap case; rather the gap parameter in the associated uniaxial material only needs to be changed. For the present simulation, the MKV model is assigned to the aforementioned contact element. The stiffness of spring element k_1 is set to 2.0×10^7 N/m. In the free fall condition, node 2 has a constant acceleration of g in downward direction. Hence, a uniform acceleration loading is applied at node 2. To be consistent with the seismic pounding simulations going to be discussed in forthcoming sections, the applied acceleration is treated from the viewpoint of *uniform ground acceleration.* The resulting system of nonlinear equations is solved using Newmark's method of constant acceleration ($\beta = 0.25$, γ=0.5), where Modified Newton-Raphson method is used for iterative solution. The analyses are performed for 0.35 sec with a time step of 1×10^{-7} sec. The values of r_{post} obtained from pounding simulation are compared with r_{pre} and relative error is computed as $\left|r_{pre}-r_{post}\right|/r_{pre}$. The comparison is shown in Table 1. The relative error reduces with increasing r. The coefficient of restitution used to simulate structural pounding ranges from 0.5 to 0.75 (Jankowski 2005). It is clear from Table 1 that the relative error is small for the values of coefficient of restitution in this range. This shows that the relationship between ξ and r given by Eq. (7) is correct and hence can be used for rational simulation of structural pounding.

3. SEISMIC POUNDING CASES

A 4-story, 2-bay by 2-bay base-isolated RC building is considered to investigate the effect of pounding on the response of a typical mid-rise structure. The bay widths and story heights are 6 m and 3.6 m, respectively. The building is supposed to be used as an elementary school such that substantial hazard to human life is expected in case of failure. The building is assumed to be located at a stiff soil site. Two cases of seismic pounding of this building are examined:

(i) Pounding with the retaining wall on one side (Fig. 3(a)),
(ii) Pounding with the retaining walls on both sides (Fig. 3(b)).

The retaining wall extends from ground level up to the isolation level (Fig. 3). The building was designed following the 2009 International Building Code (ICC 2009). According to the code, an equivalent lateral force procedure was used for the design of this building. ACI 318-08 (ACI 2008) was followed for the design of the structural concrete. Compressive strength, unit weight and modulus of elasticity of concrete are taken as 28 MPa, 22.76 kN/m^3 and 2.5×10^4 MPa, respectively. The yield strength of main steel reinforcement bars and ties are taken as 420 MPa and 300 MPa, respectively. The unit weight and modulus of elasticity of steel are assumed to be

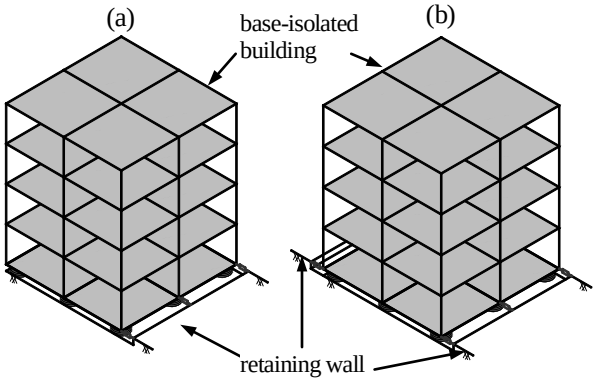

Fig. 3. The base isolated building with: (a) retaining wall on one side; (b) retaining walls on both sides.

76.97 kN/m^3 and 1.99×10^5 MPa, respectively. Live loads on floors and roofs are assumed to be 4.79 kN/m^2 and 0.96 kN/m^2, respectively. Total wall thickness is taken as 113 mm with a unit weight of approximately 15.0 kN/m^3. The slab thickness is 200 mm. For the floor finish, a 10 mm thick porcelain tile with a unit weight of 23.57 kN/m^3 is taken. Seismic force-resisting system of the building is chosen as special moment-resisting frame (SMRF). The lead rubber bearing (LRB) isolation system is selected for the building. Bearings are designed for gravity and earthquake loads using SAP2000 (2009) and Microsoft Excel spreadsheets. Identical circular bearings of 750 mm diameter and 572 mm height are provided under each of the 9 column bases. A total of 30 layers of rubber with a layer thickness of 15 mm are used. Steel shim thickness is taken as 2 mm. The design displacement D_D and total maximum displacement D_{TM} of the isolation system are 225 mm and 462 mm, respectively. Figure 4 shows the cross-section of the bearing.

In order to investigate the influence of separation, the structures are assumed to be separated by different at-rest gap distances d_g in both of the pounding cases. It is considered that the gap between buildings can be as small as half of the design displacement D_D. Therefore, ratio of at-rest gap distance to the design displacement is taken as 1.0, 0.9, 0.8, 0.7, 0.6 and 0.5.

For performance evaluation, four earthquake ground motions are selected from 1968 Hachinohe, 1940 El Centro, 1995 Kobe and 1994 Northridge earthquakes (see Table 2 for details of ground motions). The earthquake ground motions are matched to the design response spectrum at 5% damping using wavelet adjustments. The program RspMatch2005 (Hancock et al. 2006) is used to match the ground motions simultaneously to the design acceleration response spectrum (Fig. 5) and the design displacement response spectrum for natural periods up to 6 sec.

4. NUMERICAL MODELING AND ANALYSIS

A macromodel-based approach is adopted for three-dimensional modeling of seismic pounding of the base-isolated building in OpenSees. There are three

modeling issues to be addressed viz. modeling of structural members which are beams, columns, lead rubber bearings and slabs, modeling of retaining walls and modeling of impact. Reinforced concrete beams and columns are modeled using force-based, fiber beam-column elements, which are considered as most accurate and robust distributed plasticity elements. In fiber beam-column elements, the element response is evaluated at certain number of integration points i.e. sections along the length of the element and each section is discretized into unconfined concrete, confined concrete and steel fibers (Fig. 6, 7). Uniaxial materials with nonlinear constitutive relationship are assigned to these fibers. Section constitutive relationship is derived from the integration of constitutive relationship of fibers. There are several material models to describe nonlinear constitutive relationship of concrete and steel under monotonic as well as cyclic loading. In this study the modified Kent and Park model (Park et al. 1982) is used for the response of concrete in compression. In tension, a linear elastic branch is followed by a linear softening branch up to zero stress (Fig. 8(a)). For reinforcing steel, the constitutive model of Menegotto and Pinto (Menegotto and Pinto 1973) is used (Fig. 8(b)). Lead rubber bearings are modeled using elastomeric bearing elements. A bilinear hysteretic model (Fig. 8(c)) is used to describe shear force-deformation relationship of these elements. Floor and roof slabs are not modeled explicitly; rather their restraining effect is accounted for by assuming an in-plane rigid diaphragm response. Retaining walls are modeled as rigid objects. Backfill soil-structure

interaction is considered outside the scope of this study. Impact is modeled using zero length elements, which are used as contact elements between structures at floor levels (Fig. 3). The material property of the contact elements is based on the MKV model. The coefficient of restitution r is taken as 0.65 and stiffness of spring element k_i is assessed based on the axial stiffness of a slab.

Nonlinear time-history analyses are performed. Time integration of equations of motion is accomplished using Newmark's method of constant acceleration. A time step of 0.005 sec is used for all the cases. The nonlinearity of the problem demands an iterative solution procedure. At the beginning of each time step modified Newton-Raphson method is employed for the iterative solution and the method is changed if the convergence is not achieved in the time step. There are many alternatives to modified Newton-Raphson method in OpenSees such as Newton with line search or Broyden method. The convergence of the solution is based on energy increment. For damping in the building, stiffness proportional damping is applied to the superstructure only. A damping ratio of 5% is used for the first mode of the isolated structure.

The accuracies of impact force model and FE modeling have been validated using an available impact experiment and a shake table test of a base-isolated RC building, respectively. Details of the validation are shown elsewhere (Pant 2010).

5. RESULTS AND DISCUSSION

Inter-story drift ratio and overall damage index (ODI) based on Park and Ang damage index (Park et al. 1985) are presented to illustrate the influence of pounding on the structural performance of the base-isolated building.

Table 3. Values of inter-story drift ratios and overall damage indices for performance evaluation of RC buildings.

Degree of damage	Physical appearance	Inter-story drift ratio (%)	ODI
No damage	Minor localized cracking	drift ratio $<$ 0.5	ODI $<$ 0.1
Minor to moderate damage	Light cracking throghout to extensive cracking and localized spalling of concrete	0.5 $\leq$ drift ratio $<$ 1.5	0.1 $\leq$ ODI $<$ 0.4
Severe damage	Extensive crushing of concrete and exposure of buckled reinforcement	1.5 $\leq$ drift ratio $<$ 3.0	0.4 $\leq$ ODI $<$ 1.0
Total collapse	Complete loss of load carrying capacity	drift ratio $\geq$ 3.0	ODI $\geq$ 1.0

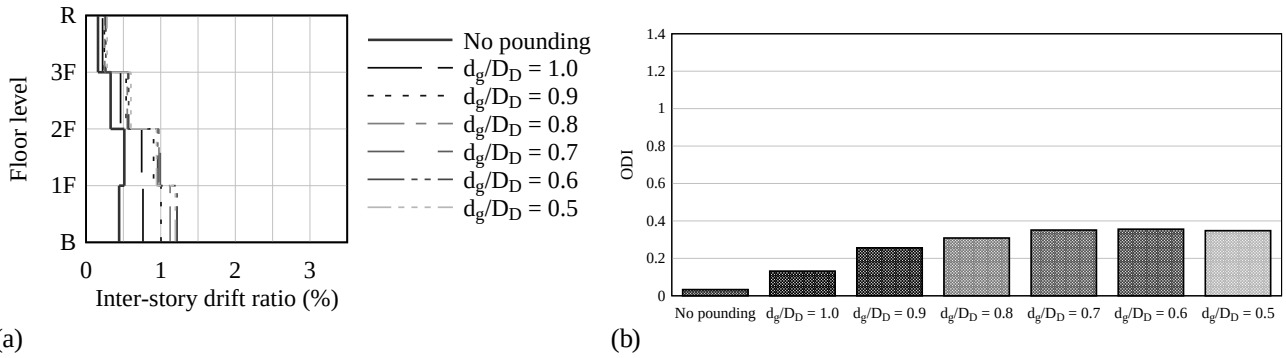

Fig. 9. Response of the base-isolated building considering pounding with the retaining wall on one side: (a) peak inter-story drifts; (b) overall damage indices.

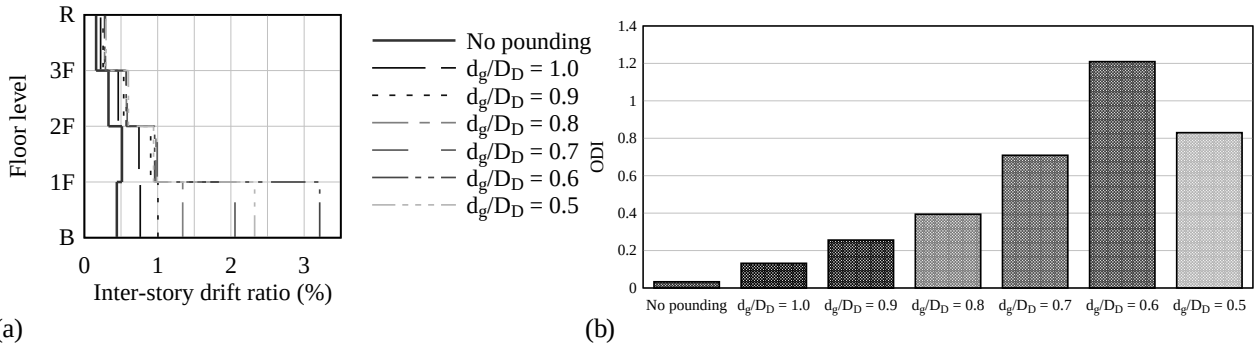

Fig. 10. Response of the base-isolated building considering pounding with retaining walls on both sides: (a) peak inter-story drifts; (b) overall damage indices.

The damage can be classified as no damage, minor to moderate damage, severe damage and total collapse based on inter-story drift ratio and ODI as shown in Table 3. Note that to highlight the trends in the response, the results presented represent maximum responses generated due to all four earthquake excitations.

When the pounding of the base-isolated building is considered with the retaining wall on one side, the peak inter-story drift ratio, which is less than 0.5% at the first story when there is no pounding, becomes more than 1.2% due to pounding (Fig. 9(a)). This implies that the base-isolated building experiencing no damage without any interaction with adjacent structures undergoes minor to moderate damage due to pounding. In general, the inter-story drift demand increases with reduction in the gap. In addition, the maximum inter-story drift occurs at the first story and gradually reduces at upper stories. The minor to moderate damage to the building is also evident from Fig. 9(b), where ODI remains less than 0.4. A clear pattern of overall damage is also observed from Fig. 9(b). Overall damage index increases rapidly for the gaps up to 70% of the design displacement and becomes nearly constant for further reduction in the gap.

Significant increase in the demands is observed in case

of pounding with the retaining walls on both sides compared to one-sided pounding (Fig. 10(a)). The peak inter-story drift demand at the first story clearly exceeds 1.5% for the gaps smaller than 80% of design displacement, denoting severe damage to the story. Imminent collapse of the story is evident at a gap equal to 60% of the design displacement. The influence of pounding is less severe at upper stories. Fig. 10(b) shows clear trend in the overall damage to the building for various gaps. With decreasing gap, the ODI first increases and then reduces with further reduction of the gap. This implies that there exists a critical at-rest gap distance causing maximum damage to the base-isolated building.

6. CONCLUDING REMARKS

This study investigates the performance of a typical mid-rise base-isolated RC building considering seismic pounding. It is found through series of numerical analyses that the seismic pounding has detrimental effects on the response of a base-isolated RC building. While one-sided pounding with a retaining wall at the base causes minor to moderate damage to the base-isolated building, two-sided pounding with retaining walls at the base could even lead to its collapse, depending upon the clear space maintained around the building.

The present study only focuses on the evaluation structural damage to the building due to pounding. Evaluation of the non-structural damage, which requires accurate estimation of floor accelerations in the building, could be studied in the future. Furthermore, the present study is only focused on the seismic performance evaluation of base-isolated buildings. The mitigating measures against pounding should also be studied in the future.

Abstract: Designed according to modern seismic provisions, base isolated structures are required to develop sufficient strength such that they remain essentially elastic in the expected Design Basis Earthquake (DBE). Additionally, a sufficient seismic separation distance (or moat) must be provided to accommodate expected displacement in a Maximum Considered Earthquake (MCE). However, little consideration is given to the effect of inelastic superstructural behavior on the seismic performance given the occurrence of an event greater than the DBE. This study investigates parametrically the effect of superstructure yield strength and seismic separation on the ultimate behavior of base isolated structures. Nonlinear response history analysis including pounding is then utilized to examine the tradeoffs between providing a weaker superstructure and a smaller seismic gap. Results indicate that a decrease in superstructural strength significantly increases ductility demand but the likelihood of pounding reduces. In contrast, an increase in gap size does not assure a decrease in ductility.

1. INTRODUCTION

Base isolation is an approach to mitigate earthquake damage that has been used over the past 25 years. The concept is to reduce seismic demand by adding horizontally flexible elements called isolators between the structure above and its base, thereby isolating the building from the horizontal components of ground motion. However, large deformation is expected at the isolation interface, and as a result, sufficient separation between the structure and surrounding moat walls must be provided to prevent pounding.

Following modern US building code provisions, a separation gap between the isolation level and surrounding walls is required to accomodate the displacement in a Maximum Considered Earthquake (MCE), an event having a 2475-year return period. Moreover, the superstructure is expected to remain elastic for the expected Design Basis Earthquake (DBE), an event whose response spectrum is 2/3 of the MCE. Figure 1(a) schematically shows the behavior of the isolated structure implied by the code, whereby pounding is avoided and yielding in the superstructure is prevented. Previous studies on base isolated structures have primarily focused on this case.

On the other hand, for an earthquake greater than DBE level, yielding is expected to occur, as shown in Figure 1(b). Also, insufficient seismic gap may cause pounding, as shown in Figure 1(c), which can significantly increase the building acceleration and force (Kasai et al. 1990), and may cause much damage to the structure. Additionally, a combination of pounding and yielding may occur, as indicated in Figure 1(d). Although yielding causes structural damage, it impedes the base from moving further and reduces the possibility of pounding. Therefore, selecting an appropriate combination of superstrucutural strength and separation distance is a potentially useful approach to

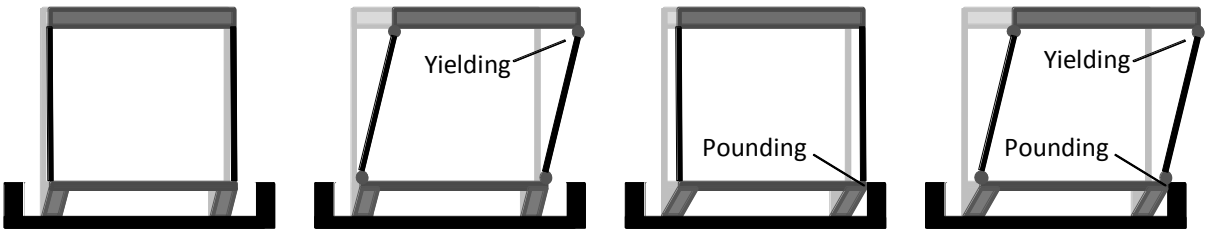

Figure 1 Possible modes of behavior for base isolated buildings

achieve the desired performance of the structure. This study investigates parametrically the combined effects of superstructure yield strength and seismic separation.

2. MODELING ASSUMPTIONS

As depicted in Figure 2, the base isolated structure is modelled as a 2 degree-of-freedom (2DOF) system. Assuming equal floor masses, the superstructure mass to total mass ratio can be calculated as $\gamma = (N-1)/N$ where N represents number of stories of the structure. Letting $m_s + m_b = 1$, we can compute $m_s = \gamma$, and $m_b = 1-\gamma$. During earthquake excitation, the isolation system is assumed to behave linearly with stiffness k_b and damping coefficient c_b, while the superstructure behaves elasto-perfectly-plastically with superstructural stiffness k_s, damping coefficient c_s, and ratio of superstructure yield strength f_{ys} to superstructural weight $m_s g$, namely $\overline{f}_{ys}$ ($=f_{ys}/m_s g$). Pounding is assumed to occur at the isolation level, the most common case of impact for base isolated buildings. Contact elements are simulated using a linear elastic spring with stiffness k_w arbitrarily taken as 10 times the superstructure stiffness k_s, following the general assumption of previous researchers (Tsai 1997, Komodromos 2008). This contact element is located a separation distance, s, away from both sides of the base structure. Energy dissipation due to pounding is not considered based on previous studies (Tsai 1997).

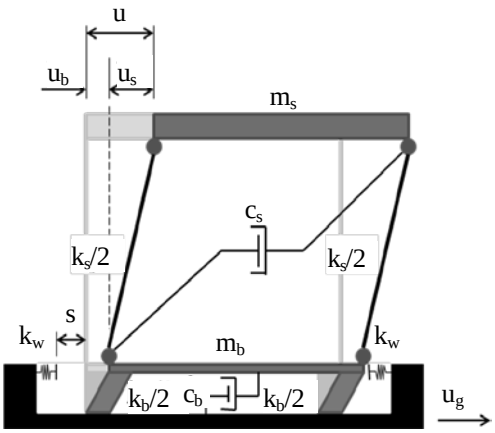

Figure 2 Analysis model

3. GROUND MOTIONS

The SAC suite of ground motions with 2% possibility of exceedance in 50 years for the Los Angeles area, LA21-LA40, are used in this study (Somerville et al. 1998). These ground motions were developed to represent the MCE for downtown Los Angeles. Figure 3 shows response spectra of these 20 ground motions, including a comparison of the median acceleration spectrum with the code-prescribed DBE and MCE for the site. Previous researchers have indicated that ground motion parameters are lognormally distributed (Mcguire 2004), and as a result, the geometric mean provides a good measure of central tendency of a sample and is used here to estimate the median.

4. PARAMETRIC STUDIES

The superstructure vibration period is defined as $T_s = 0.1N$. Base and superstructural masses and stiffnesses are selected to obtain the desired isolation system and superstructural periods and damping ratios from the following equations:

$$T_s = 2\pi\sqrt{\frac{m_s}{k_s}}, \quad T_b = 2\pi\sqrt{\frac{m_s + m_b}{k_b}} \qquad \text{(1a,b)}$$

$$\zeta_s = \frac{c_s T_s}{4\pi m_s}, \quad \zeta_b = \frac{c_b T_b}{4\pi(m_s + m_b)} \qquad \text{(2a,b)}$$

From the parameters above, "Elastic No-Pounding (ENP) Response" for a particular ground motion with given T_s, ζ_s, T_b and ζ_b can be obtained. For the selected strength reduction factor R and separation ratio β, superstructure

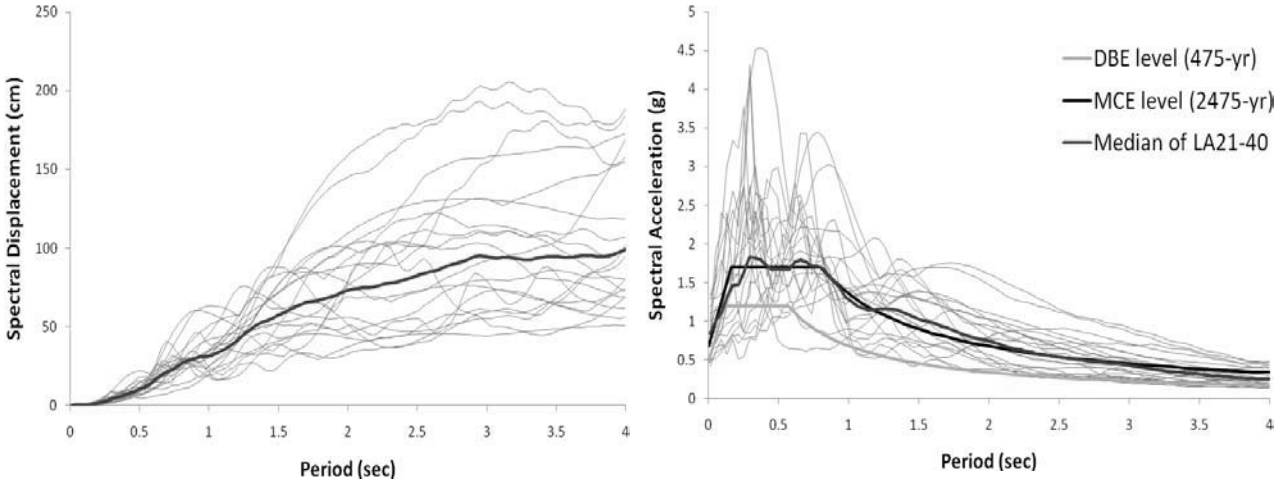

Figure 3 Response spectra of SAC LA21-40 ground motions and comparison with code spectra

yield strength f_{ys} and separation distance s for the simulation can be computed based on the definitions as follows:

$$R = f_{s0}^{ENP} / f_{ys}, \quad \beta = s / u_{b0}^{ENP} \qquad (3a,b)$$

where f_{s0}^{ENP} is the maximum superstructural force for the ENP case and u_{b0}^{ENP} is the maximum displacement of the isolator relative to the ground for the ENP case.

This study focuses on the case of a 5-story building, so T_s = 0.5 sec. is assumed and superstructure damping is taken as ζ_s = 0.02. Six isolation systems are considered, with period T_b = 2, 3, and 4 sec., and damping ζ_b = 0.10 and 0.30. R is varied from 0.1 to 1.0 with increments of 0.1 and from 1.5 to 4.0 with increments of 0.5. β is varied from 0.0 to 1.0 with increments of 0.2. The result for each combination of system parameters are discussed using median response from the suite of 20 ground motions.

5. EXAMPLE RESPONSE HISTORIES

5.1 Four cases of pounding / no-pounding histories

As an example, four cases of dynamic response of a structure with T_s = 0.5 sec., ζ_s = 0.02, T_b = 2 sec., and ζ_b = 0.10 subjected to the LA29 excitation is discussed. Peak ground acceleration of the LA29 record is 0.81g. The maximum superstructural force normalized by superstructural weight, $\overline{f}_{s0}^{ENP}$, for this ground motion is 0.32. Case 1, presented as thick solid lines in Figure 4 for which R = 1.0 and β = 1.0, corresponds to the ENP case (as shown in Figure 1(a)). Case 2, presented as thick dotted lines, describes the response when R is increased to 1.5 which represents yielding with no-pounding case (Figure 1(b)). Case 3, shown as thin solid lines, corresponds to Figure 1(c) which is pounding with elastic response of the superstructure. The separation ratio is reduced to 0.4 while R is reduced to 0.3. Case 4, shown as thin dotted lines, has the same separation distance of 0.4, but R is increased to 1.5, resulting in a combination of yielding and pounding as in Figure 1(d).

5.2 Observations

Figure 4(a) shows the superstructure displacement relative to the base, u_s (as shown in Figure 2). The first case, which represents the ENP response, shows elastic behavior with the maximum superstructure displacement u_{s0}^{ENP} = 2 cm. When R is increased for Case 2, a single yield excursion occurs at around 12.3 sec., resulting in the largest residual structural displacement among the four cases shown. In Cases 3 and 4 where the gap size is reduced, pounding first occurs at approximately 11.4 seconds and results in a sudden displacement increase in the superstructure. However, the responses are different due to the difference in superstructural strength.

Figure 4(b) represents superstructure ductility demand $\mu_s = u_s / u_{ys}$ where u_{ys} is the superstructure yield displacement computed from $u_{ys} = f_{ys} / k_s$ and f_{ys} is the superstructure yield strength obtained from Eq. (3a). Ductility demand of the ENP case is in the range of -1.0 to 1.0, meaning yielding does not occur. Case 2 shows significant yielding when R is increased as described above, resulting in the largest ductility demand (μ_s = 8.54) among all cases. Due to the increased strength, large displacements caused by pounding in Case 3 do not exceed the yield displacement and therefore the superstructure responds elastically. This can be seen by observing that μ_s is in the range between -1.0 to 1.0. Considering Case 4, which has the same strength as Case 1 but with the gap size reduced to 0.4, the response due to pounding causes yielding of the superstructure, and the ductility demand is increased to 5 relative to Case 1 in which no pounding occurs. The occurrence of both pounding and yielding in Case 4 results in a residual displacement smaller than that obtained from Case 2, but this may not be a general trend for all ground motions.

Base displacement u_b normalized by the maximum base displacement of the ENP case u_{b0}^{ENP} is shown in Figure 4(c). For this example, u_{b0}^{ENP} is 29 cm. Using this number as the normalizing value, u_b / u_{b0}^{ENP} of Case 1 reaches the maximum of -1.0 at 12.5 sec. In Case 2, yielding of the superstructure reduces the base displacement, implying that a weaker structure decreases the possibility of pounding. In Cases 3 and 4, pounding limits the base displacement so that the peaks and troughs of both cases are flattened at 0.4 which correspond to the separation ratio (Eq.(3b)) provided. Differences in superstructural strength causes yielding that affect response at the base. Pounding occurs five times between 11 to 14 seconds in Case 3 while occuring only three times in Case 4 and another two times between 16-17 seconds.

Figure 4(d) describes the total superstructure acceleration $\ddot{u}_{s,tot} = \ddot{u}_s + \ddot{u}_b + \ddot{u}_g$. In Cases 1, 2 and 4 where superstructural strengths are limited, the effect of pounding to superstructural acceleration is not significant because yielding prevents the impact force from propagating to the above structure (Tsai 1997). But when R=0.3 in Case 3, the superstructure behave elastically and pounding causes high acceleration that even larger than the peak ground acceleration of the excitation. This agrees with previous studies (Tsai 1997, Komodromos 2008).

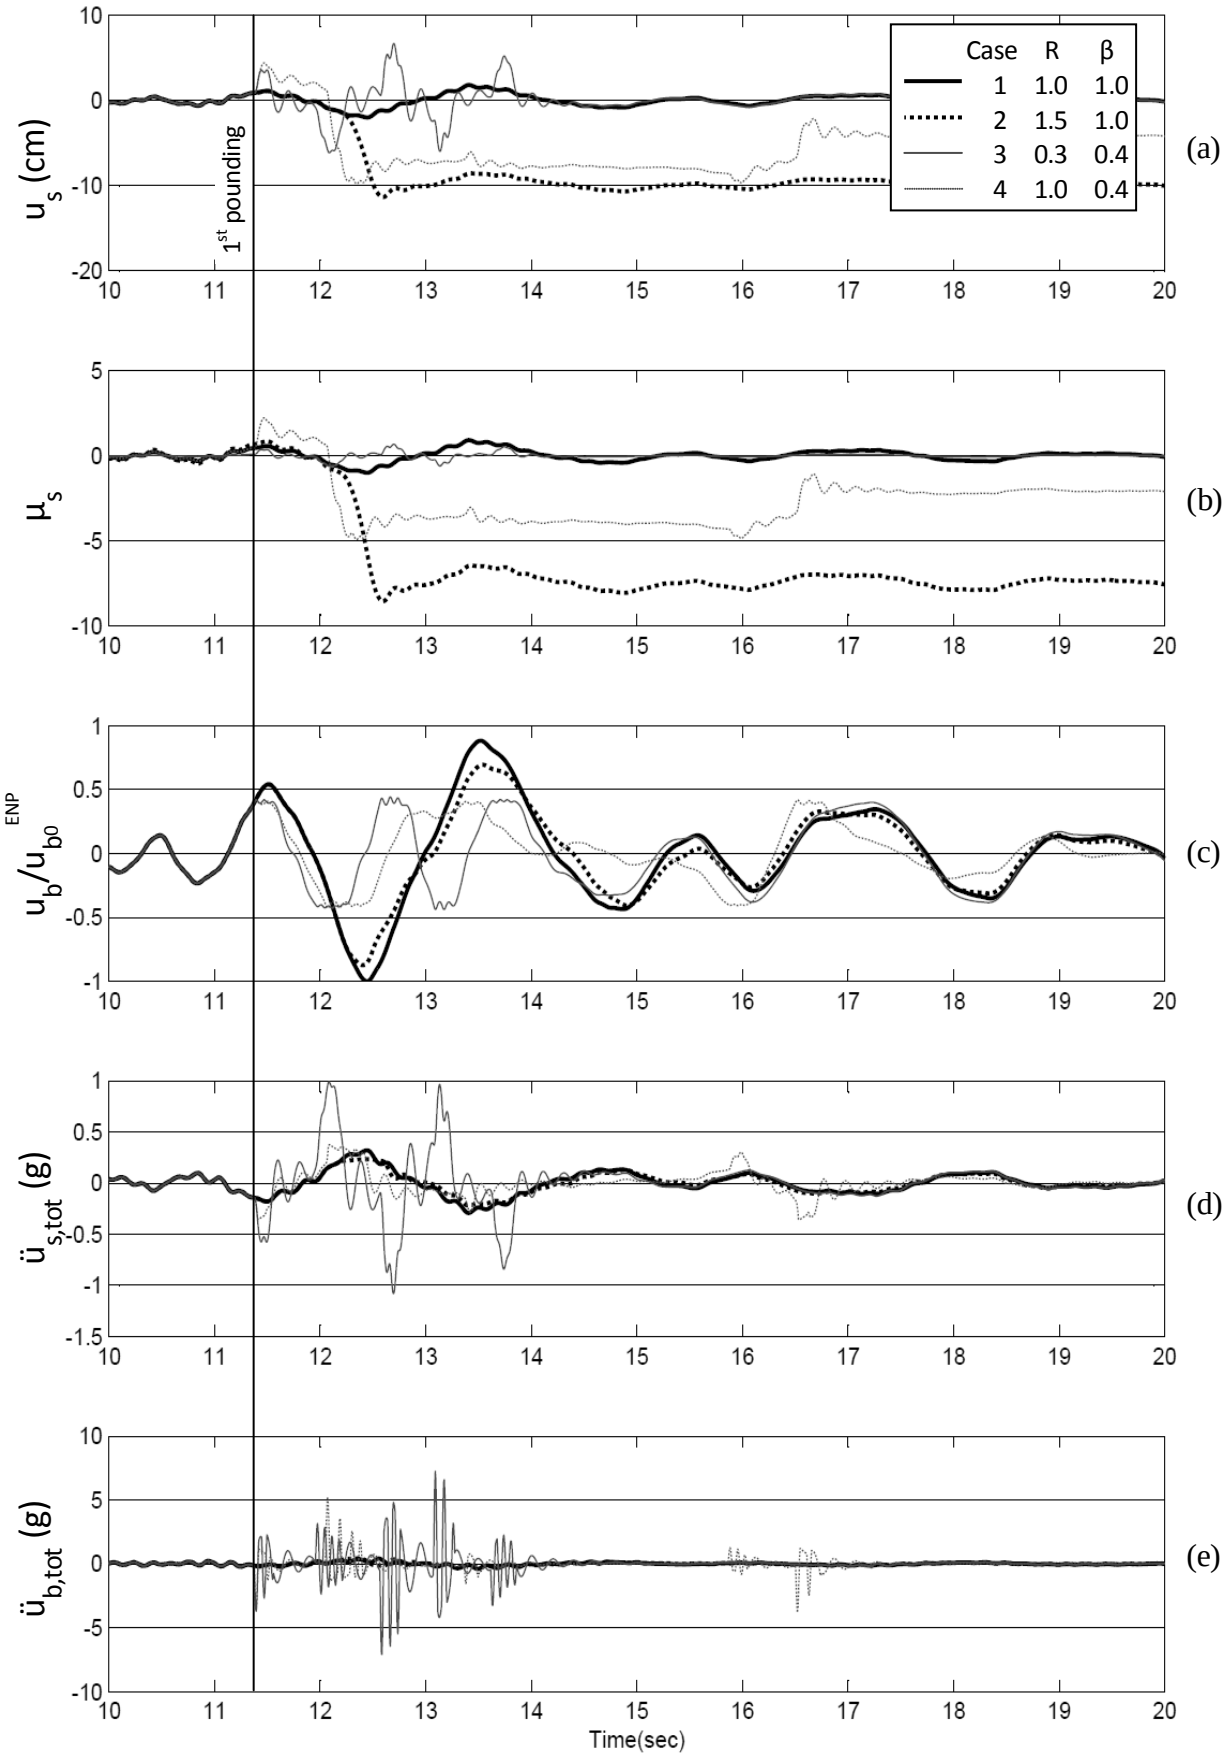
Base acceleration $\ddot{u}_{b,tot} = \ddot{u}_b + \ddot{u}_g$ is presented in Figure 4(e). For the first 2 cases without pounding, the response is very smooth. However, the occurrence of pounding excites large acceleration spikes at the isolation system level. This agrees with previous research findings (Kasai et al. 1990, Ye et al. 2009).

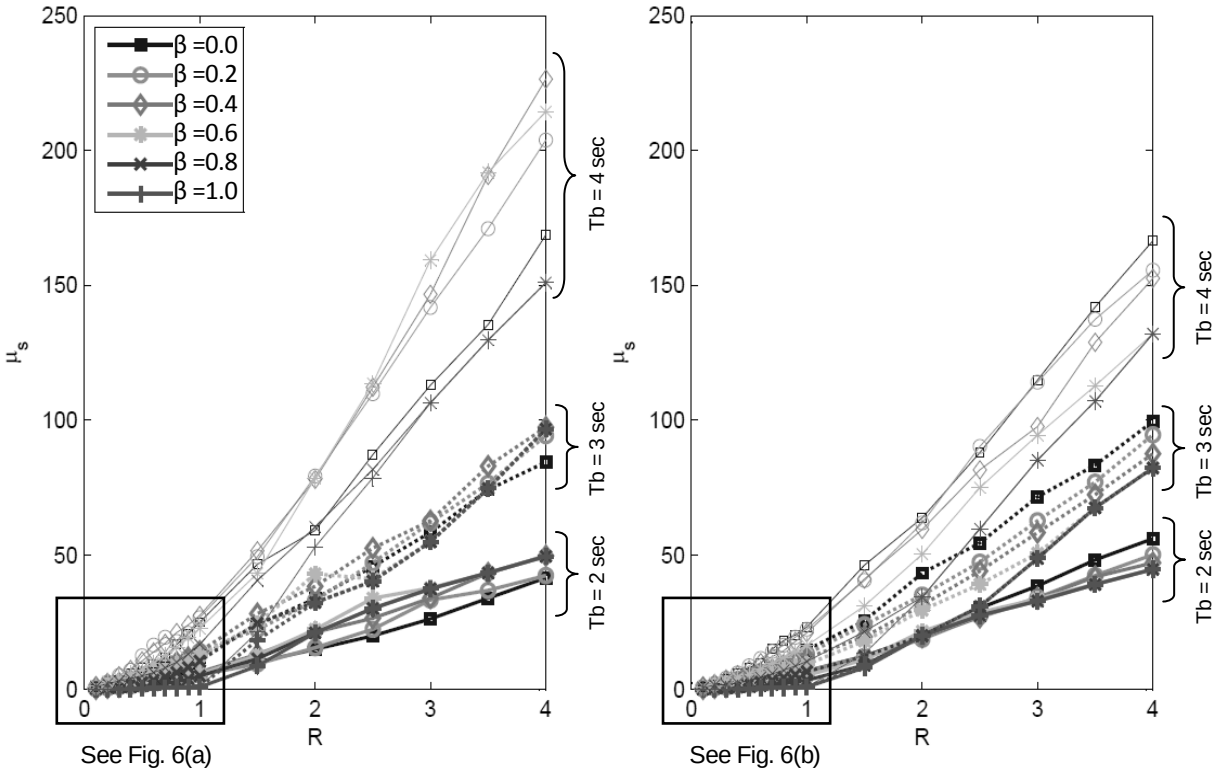
Because acceleration response is highly sensitive to the characteristic of the wall, effect of superstructure strength and separation distance on the acceleration response should be a subject of further study. However, the subsequent chapter focuses only on ductility demand, μ_s.

6. RESULTS OF PARAMETRIC STUDIES

6.1 Superstructural yield strength f_{ys}

The strength reduction factor R is varied from 0.1 to 4.0 to study the ductility demand resulting from a specified





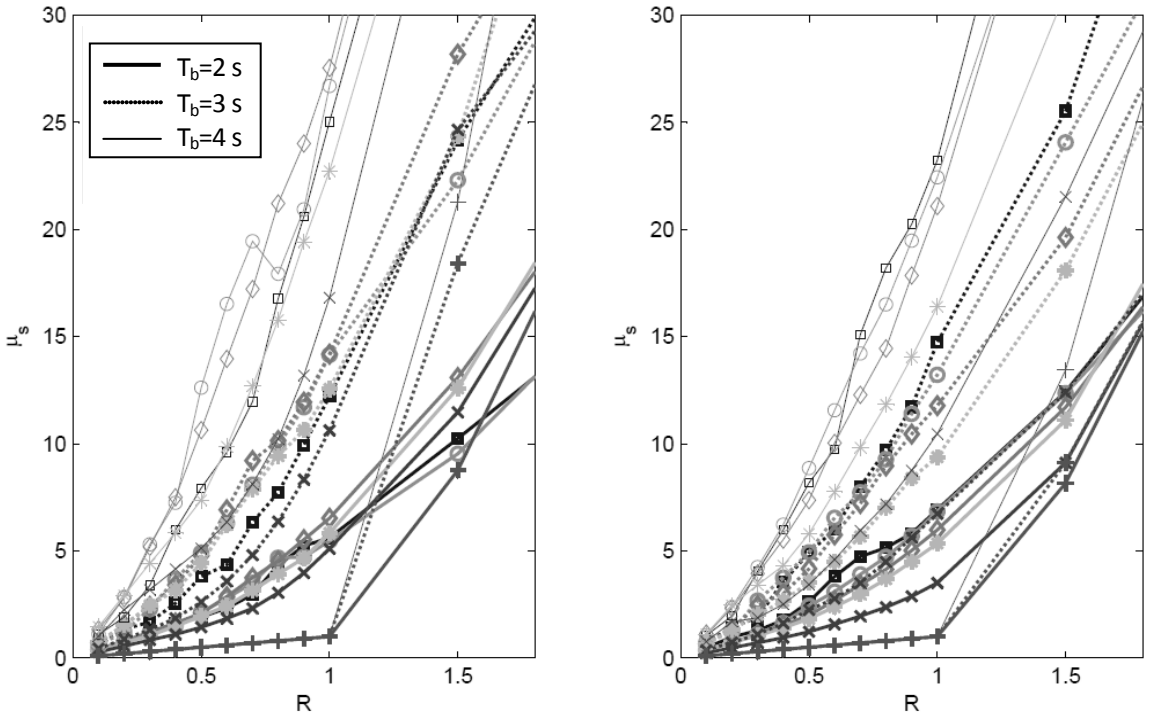


Figure 4 Response history results of a T_b = 2 sec., ζ_b = 0.1 structure subjected to LA29 excitation

(b) $\zeta_b = 0.1$ (b) $\zeta_b = 0.3$

Figure 5 Effect of superstructural yield strength on median ductility demand for given separation distance

(a) $\zeta_b = 0.1$ (b) $\zeta_b = 0.3$

Figure 6 Effect of superstructural strength on ductility demand when the strength reduction factor $R \leq 1$

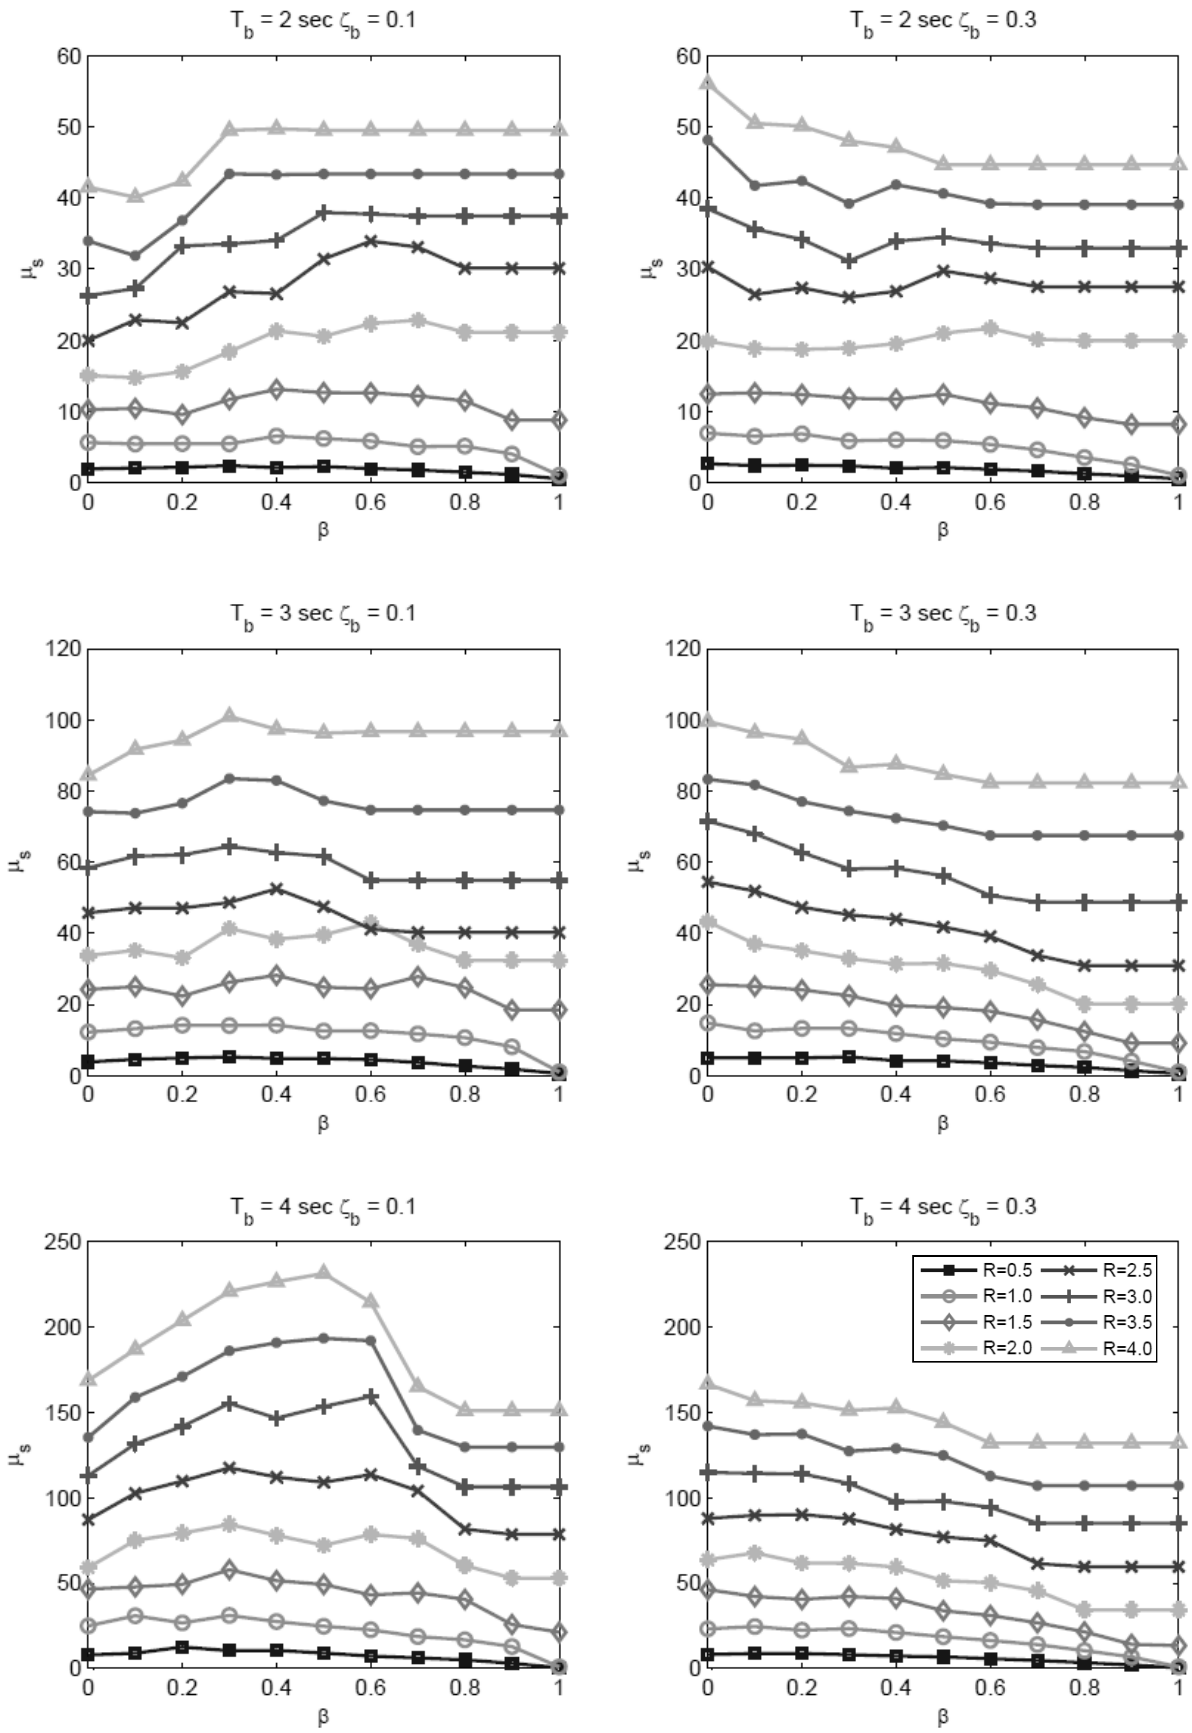

Figure 7 Effect of separation distance on median ductility demand for given superstructural yield strengths

superstructural strength for base isolated structures. Results indicate that yield strength has a significant effect on resulting ductility demand in the superstructure. Each graph in Figure 5 describes the median ductility demand as a function of strength reduction factor R, from the suite of ground motions for each isolation system damping ratio ζ_b considered. Each line in the graph corresponds to a distinct isolation system period T_b and separation distance s. The square data points shows the case that β is equal to 0 (similar to a fixed base building) while the '+' data points represent β = 1.0 (no pounding). Figure 6 is enlarged from Figure 5 to present the response when R less than 1. From this figure, when β = 1.0, the ductility damand is equal to strength reduction factor R. Moreover, ductility demand is exactly 1.0 when β = 1.0 and R = 1.0 for every isolation period and damping ratio. These indicate the ENP cases for which no yielding or pounding occurs. Note that the same R gives different values of superstructure yield strength for different combinations of T_s, ζ_s, T_b, ζ_b and earthquake ground motion, depending on the ENP response. For larger R and other value of β, as the superstructural strength decreases, ductility demand of the superstructure increases dramatically for all gap sizes.

6.2 Separation ratio β

The separation ratio β is varied from 0.0 to 1.0 to study the effect of separation distance on ductility demand.

In Figure 7, the median ductility demand is presented as a function of separation ratio β. Each graph in the figure corresponds to a distinct isolation period T_b and damping ratio ζ_b. For $R \leq 1.0$, the ductility demand is equal to R when β = 1.0, and increases as β decreases due to yielding of superstructure that caused by the high impact forces resulted from pounding.

When $R > 1.0$, the lines become flat as β is increased to 1.0, meaning that the resulting ductility demand eventually becomes insensitive to the seismic separation after some threshold gap size. This can be seen also in Figure 5, since for large cases of β the results are converging to a single line. The ductility demands observed when β is small result from yielding that results from pounding. However, when the gap size is sufficiently large such that the superstructure yields before pounding occurs, the base ceases to move further and an increased gap size no longer provides any benefit. The resulting ductility demand is due to yielding alone, not pounding. Therefore, a decrease in gap size does not significantly affect the ductility demand so long as the gap size provided is large enough to accommodate the isolation level displacement which results in a shear causing yielding of the superstructure.

6.3 Isolation period T_b and damping ratio ζ_b

Base isolated structures with isolation system period T_b = 2, 3, and 4 sec. and isolation system damping ratio ζ_b = 0.10 and 0.30 have been considered in this study. Figure 5 clearly indicates that, for a given R, median ductility demand increases with isolation system period. An increase in isolation damping results in minor reductions in ductility demand, particularly for the long period cases. From Figure 7, for high damping isolation systems, the ductility demand decreases more significantly as the gap size increase. However, for the low damping cases, an increase in gap size does not necessarily lead to a decrease in ductility demand.

7. CONCLUSIONS

Parametric studies of the response of base isolated structures considering yielding of the superstructure and pounding of the isolation level against the surrounding moat wall have been described. Results indicate that a decrease in superstructural strength significantly increases ductility demand but the likelihood of pounding reduces. Separation gap size does not significantly affect the ductility demand compared with superstructure strength, and an increase in gap size does not assure a decrease in ductility demand. For a particular yield strength, a specific gap size exists beyond which further increase has no effect on structural behaviour. Moreover, for a given superstructure strength, an increase in isolation period leads to an increase in ductility demand.

In future studies, various parameters such as number of stories, and multiple classes of contact elements will be considered. In addition to ductility demand of superstructure, acceleration response will be investigated.

Abstract: An analytical model is derived for the simulation of the free vibration motion of hybrid base-isolation systems. The high damping rubber bearing component of the isolation system is modeled by a bi-linear spring while the low friction sliding bearing component is modeled by a linear Coulomb friction damper. After the formulation of the equation of motion of the combined system, an analytical solution is provided. A numerical application is then presented where the behavior of each component of the model is analyzed. The solution of the inverse problem is then considered whereby the system parameters must be evaluated given the acceleration response of the system being released after an initially imposed displacement. An evolution strategy has been used to solve a mathematically formulated inverse problem by using an imperfect model and a perfect one, demonstrating the importance of appropriate models in dynamic structural identification. Finally the model has been used for the identification of a hybrid base-isolation system in a real building, from acceleration records obtained in full scale free vibration tests on the building. The paper ends with a comparison of the results obtained by two different Coulomb friction models (constant and linear) and by quantifying the amount of energy dissipation in the various components of the system.

1. INTRODUCTION

At the beginning of the last decade two reinforced concrete buildings, originally not designed to withstand earthquake action, were seismically retrofitted by Hybrid Base Isolation Systems (HBIS) in Solarino, a small town in eastern Sicily. Some details of the buildings considered and of the base-isolation systems adopted are provided in the papers by Oliveto et al. (2004) and by Oliveto and Marletta (2005). The retrofitting works were completed in the summer of 2004 and in July of the same year several free vibration tests were performed on one of the retrofitted buildings upon static application and sudden release of a displacement of the same order of magnitude as the design one. A description of the testing apparatus and some of the results obtained were presented by Oliveto et al. at the 10th Anniversary Symposium of the JSSI held at Yokohama (2004).

Much of the work by the senior author and his research associates in the following years was devoted to the interpretation of the experimental results with the goal of extracting from them as much information as possible. Earlier work, based on elementary dynamics, provided basic results presented by Oliveto and Scalia at the 8NCEE-EERI (2006). Among the results derived in the work above are the dependence of the vibration period on the displacement amplitude and the separation of the equivalent damping in a fraction due to friction in the Low Friction Sliding Bearings (LFSB) and the complementary fraction concerning the High Damping Rubber Bearings (HDRB). These results are shown graphically and analytically by the same couple of authors in a following paper presented at the ANIDIS conference (2007).

The following studies were devoted to dynamic identification of the Solarino base isolation system. As was shown by N. D. Oliveto et al. (2008), identification in the frequency domain is not well suited for base isolation systems and the results were not encouraging. However those studies provided the setting for further identification work in the time domain, N. D. Oliveto et al. (2010). The hybrid base isolation system typical of the Solarino buildings was described by two models working in parallel; one describing the HDRB system and the other the LFSB one. The model describing the HDRB system is composed by a bilinear (elastic-plastic) spring in parallel with a viscous damper while the one describing the LFSB system consists of a Coulomb friction system. The matching between the experimentally measured acceleration and the simulated one was much better in the present case than in the previous identification studies performed in the frequency domain.

Most relevant in the dynamic identification work is that all the system parameters are identified and that these can be compared with the corresponding ones obtained by performing mechanical tests on individual components. In fact the field experimental tests combined with the system identification can serve as an assessment of the design and construction work. The results of the identification process can be used for building certification purposes.

In the case of the Solarino building an identification procedure based on the least squares method was formulated ad hoc and used. The procedure was preliminarily tested against a mathematically generated solution and it was shown that the given solution could be approximated to any required degree of accuracy. However, when the procedure was applied to experimental data, the degree of accuracy, although acceptable for engineering purposes, was not comparable with the one obtained for the test problem. The diminished accuracy with the experimental data may be due as usual to measurement noise and/or to model consistency. Two different models were used in the already quoted study by N. D. Oliveto et al. (2010) differing by whether or not a viscous damper was used in parallel with a bilinear spring to model the HDRB isolators. Recent work to be published elsewhere shows that the model including the viscous damper provides a better fitting between experimental and simulated results and the identified physical parameters from several tests performed show a smaller dispersion than with the other model.

2. THE PHYSICAL MODEL

The physical model is composed of two independent systems acting in parallel as shown in Fig. 1. The first one models the HDRB isolators and is composed by a bilinear spring acting in parallel with a linear viscous dashpot; the second one models the LFSB isolators and is represented in the figure by a friction slider. Both systems are connected to the same mass. The resulting model is a single degree of freedom system and its suitability for the simulation of the dynamic behavior of base isolation systems has been explained in the literature, see for instance Furukawa et al. (2005) and N. D. Oliveto et al. (2010).

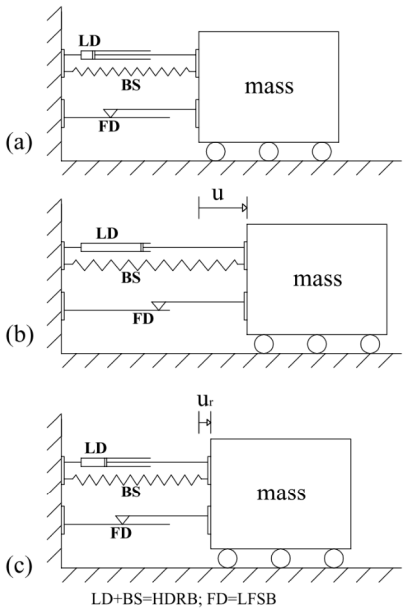

Figure 1 The physical model: (a) Initial configuration, (b) Deformed configuration during the dynamic test, and (c) Rest configuration after the dynamic test

As shown in Fig. 2, the constitutive behavior of the bilinear spring is described by only three parameters which, for coherence with previous work, are chosen to be the elastic stiffness k_0, the post-yielding stiffness k_1 and the first yielding displacement u_y.

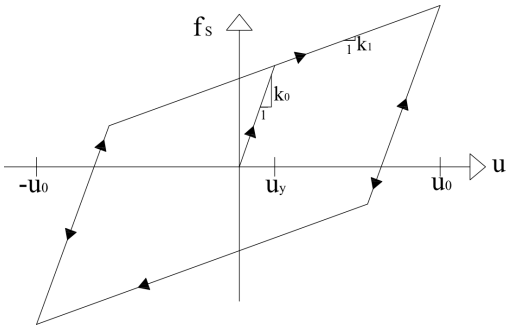

Figure 2 Bi-linear spring constitutive behavior

The present work departs from the previous one for the constitutive behavior of the friction damper which is shown in Fig. 3.

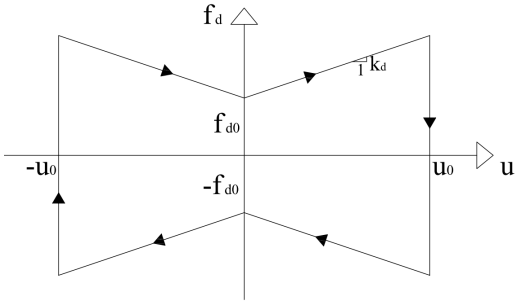

Figure 3 Friction force-displacement relationship

In a standard Coulomb model the friction force is independent of the amplitude of motion and opposes the velocity. The model itself is characterized by a single parameter which is the amplitude of the friction force or equivalently the friction coefficient. The present model differs from a standard Coulomb model because the friction force (or friction coefficient) is no longer constant but a linear function of the displacement amplitude. The constitutive equation for this model is described by only two parameters that are chosen as the friction force at zero displacement f_{d0} and the slope k_d of the force-displacement linear relationship.

3. EQUATION OF MOTION

The equation of motion for the model considered may be written in the following form:

$$m\ddot{u} + c\dot{u} + f_s(u,\dot{u}) + f_d(u,\dot{u}) = 0 \qquad (1)$$

It is easy to recognize that the inertia forces in the

equation above are balanced by the resisting force in the viscous damper (dashpot), the restoring force in the bilinear spring and by the friction force in the slider. The restoring force in the bilinear spring takes different forms according to whether the system experiences an elastic phase of motion or a plastic or yielding one. When the system, after yielding, enters an elastic phase with displacement u_i, the restoring force in the bilinear spring takes the following expression:

$$f_s(u,\dot{u}) = k_0[u - u_i - u_y sign(\dot{u})] + \\ +k_1[u_i + u_y sign(\dot{u})] \tag{2}$$

During a yielding phase the restoring force in the bilinear spring may be written as:

$$f_s(u,\dot{u}) = k_0 u_y sign(\dot{u}) + k_1[u - u_y sign(\dot{u})] \tag{3}$$

Independently of the phase of motion, the resisting force in the slider always takes the expression:

$$f_d(u,\dot{u}) = (f_{d0} + k_d \mid u \mid) sign(\dot{u}) \tag{4}$$

It may be worthwhile to notice at this point that the model considered can reach a position of static equilibrium different from the original unstrained one, satisfying the following equation:

$$f_s(u_r,0) + \tilde{f}_d(u_r,0) = 0 \tag{5}$$

where u_r is the residual displacement, Fig. 1(c), and

$$-\left|f_d(u_r,0)\right| \le \tilde{f}_d(u_r,0) \le \left|f_d(u_r,0)\right| \tag{6}$$

4. ANALYTICAL SOLUTION

In the following an analytical solution is provided for the equation of motion (1) under the initial conditions:

$$u(0) = u_0;\ \dot{u}(0) = 0 \tag{7}$$

Three different phases of motion need to be considered which are: 1) elastic behavior after yielding, 2) yielding behavior and 3) purely elastic behavior. A phase of pure elastic behavior is one which is not followed by a yielding phase, but instead is followed by static equilibrium, that is rest. A phase of pure elastic equilibrium ends with the system satisfying equation (5). In the following an analytical solution will be provided for each of the phases listed.

4.1 Elastic Behavior after Yielding

After using equations (2) and (4), performing some algebraic manipulations and making appropriate settings, the equation of motion (1) takes the following form:

$$\ddot{u} + 2\zeta_0\omega_0\,\dot{u} + \tilde{\omega}_0^2 u = \tilde{\omega}_0^2 u_p \tag{8}$$

where

$$\omega_0 = \sqrt{\frac{k_0}{m}};\ \zeta_0 = \frac{c}{2m\omega_0};\ \omega_{0D} = \omega_0\sqrt{1-\zeta_0^2} \tag{9}$$

$$r_{d0} = \frac{k_d}{k_0};\ \rho_0 = \sqrt{1 + r_{d0} sign(u) sign(\dot{u})} \tag{10}$$

$$\tilde{\omega}_0 = \rho_0\omega_0;\ \tilde{\omega}_{0D} = \omega_0\sqrt{\rho_0^2 - \zeta_0^2} \tag{11}$$

$$u_p = \frac{-u_{d0} sign(\dot{u}) + \left(1 - \dfrac{\omega_1^2}{\omega_0^2}\right)\left[u_i + u_y sign(\dot{u})\right]}{\rho_0^2} \tag{12}$$

The analytical expressions obtained for displacement, velocity and acceleration are given by equations (13)-(15).

$$u(t) - u_p = u_a e^{-\zeta_0\omega_0(t-t_i)}\cos[\tilde{\omega}_{0D}(t-t_i) - \theta_0] \tag{13}$$

$$\dot{u}(t) = -\dot{u}_a e^{-\zeta_0\omega_0(t-t_i)}\sin\tilde{\omega}_{0D}(t-t_i) \tag{14}$$

$$\ddot{u}(t) = -\ddot{u}_a e^{-\zeta_0\omega_0(t-t_i)}\cos[\tilde{\omega}_{0D}(t-t_i) + \theta_0] \tag{15}$$

where t_i is the starting time for the present phase, $t \ge t_i$ and

$$\sin\theta_0 = \frac{\zeta_0}{\rho_0};\ \cos\theta_0 = \frac{\sqrt{\rho_0^2 - \zeta_0^2}}{\rho_0} \tag{16}$$

$$u_a = (u_i - u_p)\frac{\rho_0}{\sqrt{\rho_0^2 - \zeta_0^2}} \tag{17}$$

$$\dot{u}_a = \tilde{\omega}_0 u_a;\ \ddot{u}_a = \tilde{\omega}_0\dot{u}_a = \tilde{\omega}_0^2 u_a \tag{18}$$

4.2 Yielding Behavior

After yielding occurs, the equation of motion (1) takes the following form:

$$\ddot{u} + 2\zeta_1\omega_1\,\dot{u} + \tilde{\omega}_1^2 u = \tilde{\omega}_1^2 u_p \tag{19}$$

where:

$$\omega_1 = \sqrt{\frac{k_1}{m}};\ \zeta_1 = \frac{c}{2m\omega_1};\ \omega_{1D} = \omega_1\sqrt{1-\zeta_1^2} \quad (20)$$

$$r_{d1} = \frac{k_d}{k_1};\ \rho_1 = \sqrt{1 + r_{d1} sign(u) sign(\dot{u})} \quad (21)$$

$$\tilde{\omega}_1 = \rho_1\omega_1;\ \tilde{\omega}_{1D} = \omega_1\sqrt{\rho_1^2 - \zeta_1^2} \quad (22)$$

$$u_p = -\frac{\left[\frac{\omega_0^2}{\omega_1^2}u_{d0} + \left(\frac{\omega_0^2}{\omega_1^2} - 1\right)u_y\right] sign(\dot{u})}{\rho_1^2} \quad (23)$$

The analytical solution is given by equations (24)-(26).

$$u(t) - u_p = u_a e^{-\zeta_1\omega_1(t-t_j)}\cos[\tilde{\omega}_{1D}(t-t_j) - \theta_1] \quad (24)$$

$$\dot{u}(t) = -\dot{u}_a e^{-\zeta_1\omega_1(t-t_j)}\sin[\tilde{\omega}_{1D}(t-t_j) - \theta_1 + \theta_2] \quad (25)$$

$$\ddot{u}(t) = -\ddot{u}_a e^{-\zeta_1\omega_1(t-t_j)}\cos[\tilde{\omega}_{1D}(t-t_j) - \theta_1 + 2\theta_2] \quad (26)$$

where t_j is the starting time for this phase, $t \geq t_j$ and

$$u_a = \sqrt{(u_j - u_p)^2 + \left[\frac{\dot{u}_j + \zeta_1\omega_1(u_j - u_p)}{\tilde{\omega}_{1D}}\right]^2} \quad (27)$$

$$\dot{u}_a = \tilde{\omega}_1 u_a;\ \ddot{u}_a = \tilde{\omega}_1\dot{u}_a = \tilde{\omega}_1^2 u_a \quad (28)$$

$$\sin\theta_1 = \frac{\dot{u}_j + \zeta_1\omega_1(u_j - u_p)}{u_a\tilde{\omega}_{1D}};\ \cos\theta_1 = \frac{u_j - u_p}{u_a} \quad (29)$$

$$\sin\theta_2 = \frac{\zeta_1}{\rho_1};\cos\theta_2 = \frac{\sqrt{\rho_1^2 - \zeta_1^2}}{\rho_1} \quad (30)$$

4.3 Purely Elastic Behavior

The same equations hold as in the elastic phase, with

$$u_p = \frac{-u_{d0} sign(\dot{u}) + \left(1 - \frac{\omega_1^2}{\omega_0^2}\right)\left[u_i + u_y sign(\dot{u}_i)\right]}{\rho_0^2} \quad (31)$$

Here u_i is the displacement at the end of the last yielding phase, $sign(\dot{u}_i)$ is the velocity sign in the following phase of elastic recovery and $sign(\dot{u})$ is the velocity sign in the considered phase.

4.4 Rest Conditions

In a free vibration test or in a phase of free vibration following a forced vibration motion, equation (5) is satisfied when the system finally comes to rest. However, for the system to come to rest and equation (5) to be satisfied the following relationships must hold

$$|\ddot{u}| \leq 2\frac{|f_d(u_r, 0)|}{m} \quad (32)$$

$$sign(\ddot{u}_) = -sign(\dot{u}_) \quad (33)$$

The suffix _ in equation (33) indicates that the condition must be satisfied just before the system comes to rest.

5. NUMERICAL APPLICATION

A numerical application will be presented in the following in order to show in graphical form the dynamic response of the system considered following its release after a statically imposed initial displacement. The parameters that characterize the system are collected in a vector S_0 that for later reference shall be called system parameter vector, Oliveto et. al. (2010). For convenience the imposed initial displacement u_0 shall be enclosed as the first component of this vector, Tab.1. The remaining components have all been defined in the previous section 2 and are listed in the following order: the yield displacement u_y, the friction displacement u_{d0}, the elastic frequency ω_0, the yielding frequency ω_1, the stiffness ratio r_{d0} and the damping ratio ζ_0. The values given to the considered parameters were chosen in order to produce results similar to the recorded experimental ones and to those used earlier in the literature, Oliveto et. al. (2010).

Table 1 System parameter vector S_0

u_0 (m)	u_y (m)	u_{d0} (m)	$\omega_0/2\pi$ (s^{-1})	$\omega_1/2\pi$ (s^{-1})	r_{d0}	ζ_0
0.12	0.02	0.003	0.50	0.40	0.10	0.01

The graph of the evaluated displacement function is shown in Fig. 4. It can be seen that the motion stops after 5.539 s and the residual displacement is -1.22 mm. Due to the presence of the friction damper and of the bi-linear spring the system completes only two full cycles of motion and stops during the third one.

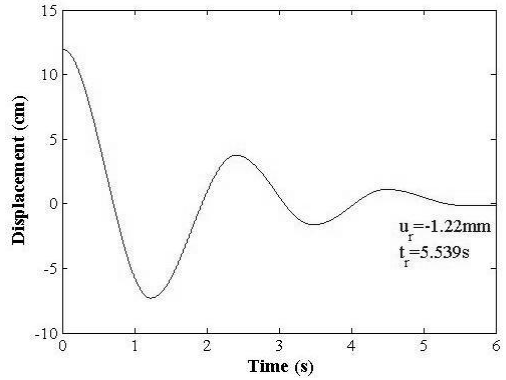

Figure 4 Displacement time history corresponding to the set of system parameters S_0 specified in Table 1

The graph of the velocity function is shown in Fig. 5. It is easy to see when the motion stops because the velocity remains equal to zero ever after. Another point that can be noticed in the velocity graph is the presence of a discrete number of slope discontinuities which correspond to velocity sign changes and jump discontinuities in the friction force.

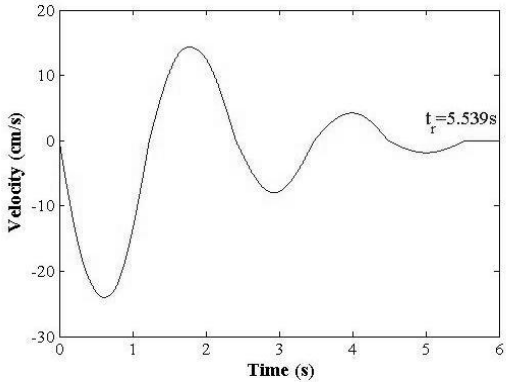

Figure 5 Velocity time history corresponding to S_0

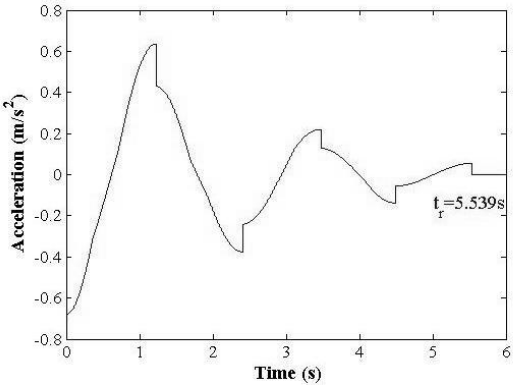

Figure 6 Acceleration time history corresponding to S_0

The acceleration graph is shown in Fig. 6. A number of function discontinuities corresponding to changes of sign in the velocity and the friction force are clearly visible. Due to the particular friction model being used the jumps are larger in the early stages of the motion, when the displacement is larger, and become smaller as the amplitude of the displacement decays. The significant decay in the amplitude of the acceleration jumps is due to the relatively large value of the stifness ratio r_{d0}. Should this have been smaller the decay would have been barely visible.

In order to complete the picture of the behavior of the system considered it is useful to present the force-displacement relationship for the restoring force in the bi-linear spring and of the resisting force in the friction damper. To evaluate these forces in dimensional form another system parameter is required. By assuming this to be the mass m and setting its value to 1200 kNs^2/m, the graph of force-displacement relationship in the bi-linear spring is shown in Fig.7. It may be useful to realize that the initial value of the restoring force is 994.85 kN while the value when the motion stops, with a residual displacement u_r=-1.22 mm, is -30.40 kN.

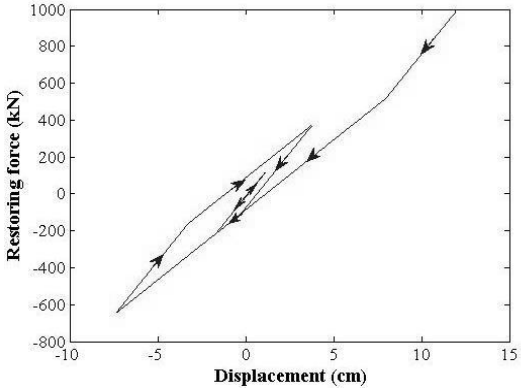

Figure 7 Restoring force-displacement relationship corresponding to the system parameter vector S_0

The force-displacement relationship for the friction damper is shown in Fig. 8. It may be worth noticing that the initial value of the friction force is -177.65 kN while the value at rest is -30.40 kN, exactly balancing the force in the bi-linear spring.

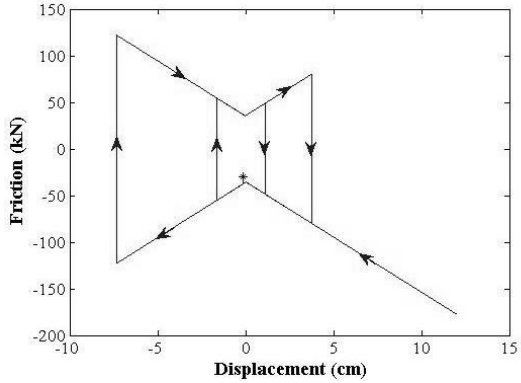

Figure 8 Friction force-displacement relationship corresponding to the system parameter vector S_0

6. INVERSE PROBLEM

The problem that we are going to address now is that of

finding the system parameters as given in the system parameter vector S_0, for example the values shown in Tab.1, once the acceleration record shown in Fig. 6 is known in sampled form. The sample is given by N acceleration values calculated at N discrete times $t_n=n\cdot\Delta t$ with $n=1,....N$. The sampling frequency shall be given by $f_s=\Delta t^{-1}$. At the present the sample is generated mathematically by using the equations developed in section 4. In real applications the data sample could be generated by dynamic testing. In doing this we are following the lead in Oliveto et al. (2010). However we want to gain some additional insight in the solution of inverse problems by using a different model from that which was used to generate the data sample. In real life applications we may collect accurate data, but we may not have a sufficiently accurate model as to match the experimental data exactly. Just to show what happens in such a case we shall use an inaccurate model to solve the inverse problem, namely the classical Coulomb friction model which in our case amounts to set r_{d0} in all our equations. In a geometrical description the stiffness k_d in the graph of Fig.3 shall be set equal to zero.

6.1 Solution Strategies

In previous work by the senior author and his research associates, Oliveto et al. (2010), the least squares method was used in the solution of the inverse problem. A suitable error function was defined in order to measure the distance between any trial solution and the given data set. In the present work we generate the error function in exactly the same way, taking care of the matching of both acceleration and corresponding time. More details about the error function used can be obtained from the reference quoted above.

An ongoing research cooperation with researchers from the School of Computing Science of the University of Birmingham (UK), has shifted our interest from the use of in house developed optimization methods based on least squares to evolution strategies, Hansen and Ostermeier (2001). Details on the performance of evolution strategies in the solution of inverse problems deriving from dynamic structural identification shall be reported elsewhere in the specialized literature. Here the focus shall be on the model rather than on the identification method.

6.2 Constant Coulomb Friction Model

We cannot expect to obtain an exact solution of the inverse problem because the model we are using is not consistent with the model that was used to generate the data. In real life applications this is equivalent to not having a sufficiently accurate model to describe the problem considered. One problem with evolution strategies is that at each run the algorithm considered may provide a different solution. Having fixed the number of fitness (error) evaluations for each run of the algorithm and the number algorithm runs, one usually chooses the solution with maximum fitness (minimum error). The best solution found in the present case is shown in Tab.2 where the estimated system parameters are compared to the real ones. Of course the parameter r_{d0} is equal to zero in the classical Coulomb friction model and so it was not identifiable. The matching between the data function and the identified one is shown in Fig. 9. The main discrepancy between the given function and the identified one appears to be in the size of the acceleration jumps. As it should have been expected the system parameter with the largest error (63%) is u_d because it is affected by the fact that the model used does not allow for the friction force to be dependent on the displacement amplitude. Viscous damping is the other parameter that shows a considerable error while all the others show an error smaller than 10%. The most important aspect of the present application is that the errors measured are all model errors and not identification errors as it will be shown in the next paragraph.

Table 2 Identified system parameter vector using the Constant Coulomb Friction Model (CCFM)

u_0 (m)	u_y (m)	u_{d0} (m)	$\omega_0/2\pi$ (s^{-1})	$\omega_1/2\pi$ (s^{-1})	r_{d0}	ζ_0
Real system parameter vector						
0.1200	0.0200	0.0030	0.5000	0.4000	0.10	0.0100
Identified system parameter vector

Error regarding the system parameters (%)						
9	0	63	2	2	-	24
Overall error: $e^2 = 8.5222\cdot10^{-3}$						

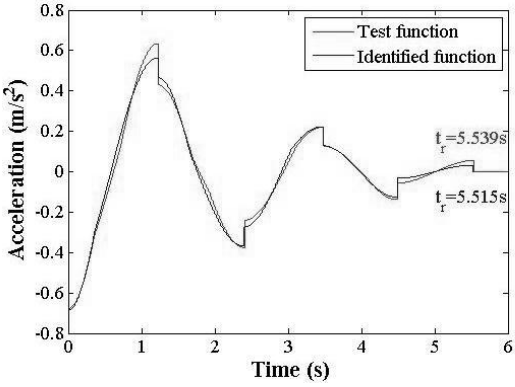

Figure 9 Test and identified function using the CCFM

6.3 Linear Coulomb Friction Model

The data function used for the system identification was generated by the linear Coulomb friction model. Therefore it is expected that the system parameters should be evaluated very accurately. In the present application the tolerated error or optimal fitness was set equal to 10^{-10} and the algorithm used successfully completed the search in just one run. All the system parameters were identified to all significant digits. This confirms what anticipated in the previous paragraph when asserting that the measured errors were all model errors rather than identification errors.

7. APPLICATION TO REAL SYSTEMS

The present model will now be applied to data obtained from free vibration tests performed on a real base-isolated building and the model parameters will be identified. Of course the parameters obtained shall be only as good as the model is. This is the reason why the application in section 6.2 was performed. We should recognize that the parameters obtained shall be the best ones to fit our model into the experimental data, but it does not mean that the present model is the best that could be conceived. The results shall be compared to those obtained by using the constant Coulomb friction model to see if any improvement is achieved, and then some conclusions shall be drawn.

7.1 Results from Test 3

The identification procedure described in section 6 for a mathematically generated data set is applied to the acceleration record obtained from test 3 performed on the Solarino building, Oliveto et al. (2004). The matching shown in Fig. 10 is obtained using the constant Coulomb friction model (CCFM) while that shown in Fig. 11 is obtained using the linear Coulomb friction model (LCFM). The two models produce two very close acceleration functions and, in fact, differences are barely visible at first sight, as may be seen from the superimposed graphs of Fig. 12. The identified system parameters are shown in Tab.3 along with the resulting error, or solution fitness in computer science jargon. Although the error appears to be roughly the same for both models, careful comparison shows an improvement in the solution fitness of more than 5%.

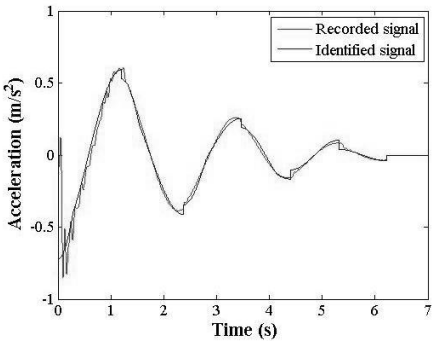

Figure 10 Recorded and identified signal for the CCFM

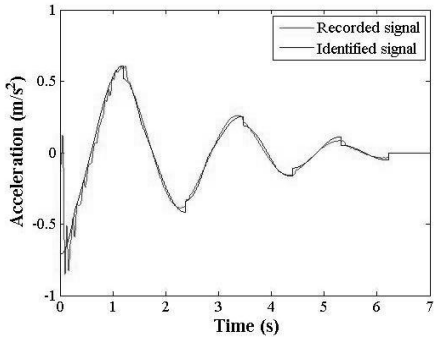

Figure 11 Recorded and identified signal for the LCFM

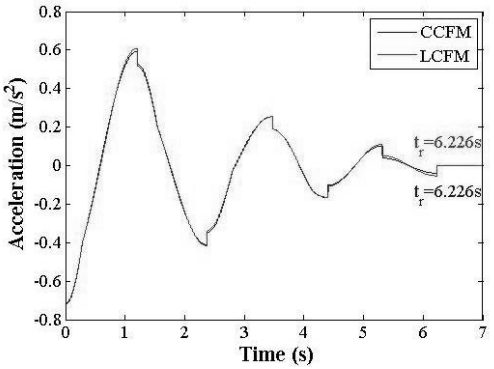

Figure 12 Comparison of the identified signals using the two friction models

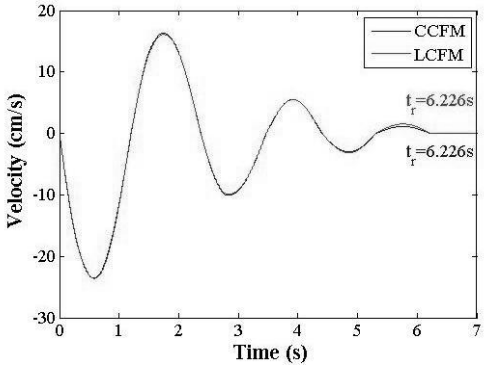

Figure 13 Velocity time histories for the two friction models

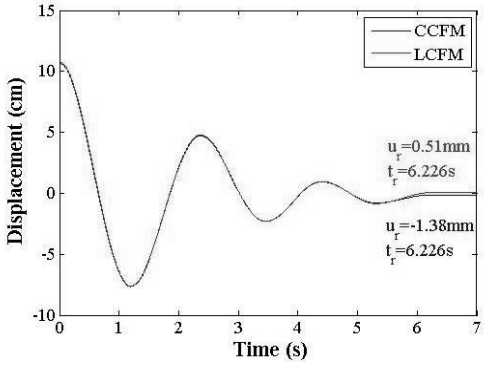

Figure 14 Displacement time histories for the two friction models

Table 3 Identified system parameter vector using the Constant Coulomb Friction Model (CCFM) and the Linear Friction Model (LCFM)

u_0 (m)	u_y (m)	u_{d0} (m)	$\omega_0/2\pi$ (s^{-1})	$\omega_1/2\pi$ (s^{-1})	r_{d0}	ζ_0
CCFM [Overall error: e^2= 1.4730·10^{-2}]						
0.1068	0.0136	0.0027	0.5490	0.4008	0.000	10^{-10}
LCFM [Overall error: e^2=1.3948·10^{-2}]						
0.1079	0.0132	0.0022	0.5528	0.4035	0.0211	10^{-10}

Another interesting aspect is that viscous damping is predicted as vanishingly small by both models so that energy dissipation is accounted almost entirely by the bi-linear spring and by the friction damper. The constant friction force in the CCFM can be compared to the minimum friction force in the LCFM and obviously the former turns out to be larger, see third column in Tab.3. The bi-linear spring yield displacement is slightly larger for the CCFM while the initial imposed displacement is predicted a little larger by the LCFM. As shown in the literature, Oliveto et al. (2004) and Oliveto et al. (2010), the nominal initial displacement is 11.48 cm; however, due to preliminary tests performed prior to the considered one (at least 2) and not having recorded the history of the residual displacement after each test, the precise value of the imposed displacement is unknown and the actual value is a part of the identification process. The predicted values are 10.68 cm according to the CCFM, 10.79 cm according to the LCFM, see first column of Tab.3, and 11.08 cm according to the identification performed by Oliveto et al. (2010) using the CCFM and a least squares based identification procedure. It may be interesting to notice that the residual displacement predicted by the present identifications from test 3 is rather small: 0.51mm using the LCFM and -1.38 mm using the CCFM.

7.2 Mass Identification

For the identification of the physical parameters of the models considered, a preliminary estimate of the system mass is required. This can be done via a formula derived by Oliveto et al. (2010) based on the results of the static test preceding the dynamic one:

$$m = \frac{f_0 - f_{ds}}{\omega_0^2 u_y + \omega_1^2 (u_0 - u_y)} \tag{34}$$

All the terms in the denominator of equation (34) are obtained as a result of the dynamic identification procedure and can be read from Tab. 3. The two forces on the nominator are the externally applied force needed to impose the initial displacement and the static force in the friction damper f_{ds} which balances the external force f_0 before the system starts to move. By using the minimum estimate for the static friction force f_{ds}=100 kN and the measured value of the external force f_0=1027.04 kN, Oliveto et al. (2004) and Oliveto et al. (2010), the estimates for the system mass and for the other physical parameters of the model considered are shown in Tab. 4.

Table 4 Identified physical parameters

Model	m (kNs^2/m)	k_0 (kN/m)	k_1 (kN/m)	k_d (kN/m)	f_{sy} (kN)	f_{d0} (kN)
CCFM	1231	14651	7807	0	199	39
LCFM	1207	14561	7758	307	193	32

7.3 Force-Displacement Relationships

The knowledge of the values of the physical parameters of the system from Tab. 4 enables the construction of the force-displacement relationships using the expressions given by equations (2), (3) and (4). The force-displacement relationship for the bi-linear spring is shown in Fig. 15 for the CCFM and in Fig.16 for the LCFM. For the friction damper the corresponding relationships are given in Fig. 17 and in Fig.18.

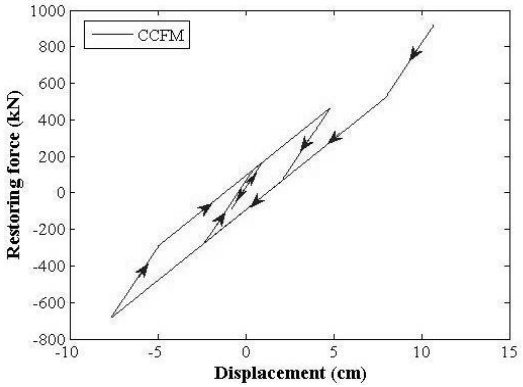

Figure 15 Restoring force-displacement relationship for the CCFM

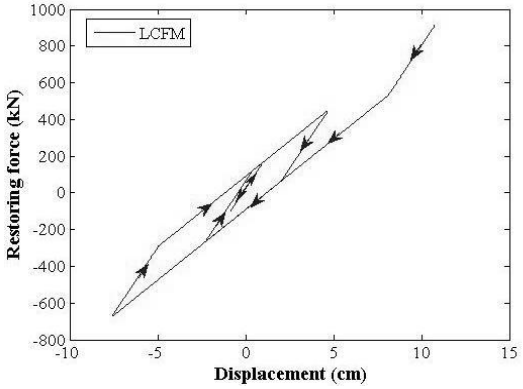

Figure 16 Restoring force-displacement relationship for the LCFM

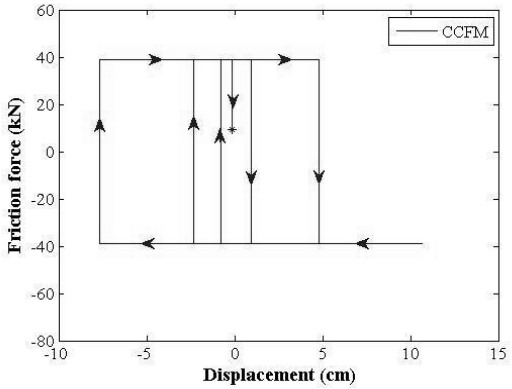

Figure 17 Friction force-displacement relationship for the CCFM

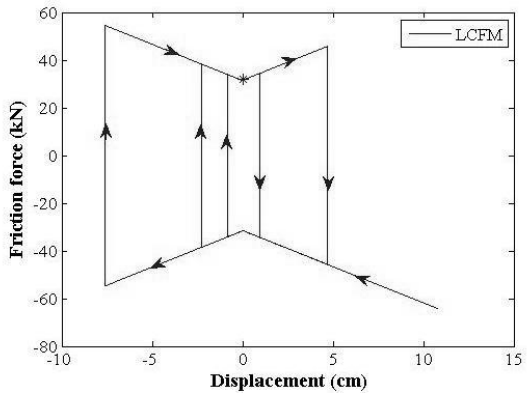

Figure 18 Friction force-displacement relationship for the LCFM

7.4 Energy Balance

The energy balance for the system considered can be formulated in terms of the following equation:

$$E_K(t) + W_{VD}(t) + W_{BS}(t) + W_{FD}(t) = 0 \tag{35}$$

where the first term is the kinetic energy of the system and the remaining terms represent the work performed by the forces in the viscous damper, in the friction damper and in the bi-linear spring over the time interval *(0,t)*. Equation (35) can be rearranged in a more expressive form as follows:

$$\begin{aligned} &E_K(t) + E_S(t) + \\ &+E_{VD}(t) + E_{BSD}(t) + E_{FD}(t) = E_S(0) \end{aligned} \tag{36}$$

where the energy terms referring to the viscous damper and to the friction damper coincide with the corresponding work terms in equation (35) while the energy dissipated in the bilinear spring may be calculated by using the following expression:

$$E_{BSD}(t) = W_{BS}(t) + E_S(0) - E_S(t) \tag{37}$$

For completeness the expressions used for the calculation of each term in the balance equations (35) and (36) are given below.

$$E_K(t) = \frac{1}{2} m \cdot \dot{u}^2(t) \tag{38}$$

$$W_{VD}(t) = \int_0^t c \cdot \dot{u}^2(\tau) \cdot d\tau \tag{39}$$

$$W_{BS}(t) = \int_0^t f_s(u,\dot{u}) \cdot \dot{u}(\tau) d\tau \tag{40}$$

$$W_{FD}(t) = \int_0^t f_d(u,\dot{u}) \cdot \dot{u}(\tau) d\tau \tag{41}$$

The calculation of the strain energy $E_s(t)$ which concurs in the definition of the energy dissipated in the bi-linear spring $E_{BSD}(t)$ can be carried out by means of the following formula, Sivaselvan et al. (2009):

$$E_S(t) = \frac{1}{2} \frac{f_s^2(u,\dot{u},t)}{k_e} + \frac{1}{2} \frac{f_h^2(u,\dot{u},t)}{k_h} \tag{42}$$

where the meaning of the newly introduced symbols is given below:

$$k_e = k_0;\ k_h = \frac{k_0 \cdot k_1}{k_0 - k_1};\ f_{sy} = k_0 \cdot u_y \tag{43}$$

$$f_h(u,\dot{u},t) = f_s(u,\dot{u},t) - f_{sy} \cdot sign(\dot{u}) \tag{44}$$

in the yielding phases, and

$$f_h(u,\dot{u},t) = f_h(u_i,\dot{u}_i,t_i) \tag{45}$$

in the elastic phases, with the suffix "*i*" indicating the value of the variables at the end of the previous yielding phase.

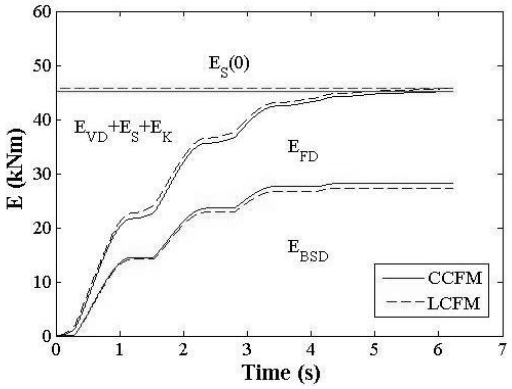

Figure 19 Energy dissipation by friction damper and bilinear spring

The contribution to energy dissipation by the viscous damper turns out to be negligible in both models (CCFM and LCFM). As it should have been expected the contribution of the bi-linear spring to energy dissipation is larger than that of the friction damper with the former accounting for about 60% of the total energy dissipated and the latter for about 40%, Fig. 19. However the LCFM results in a larger energy dissipation in the friction damper compared to the CCFM. By assuming that the former model is more accurate than the latter, this means that the CCFM underestimates the energy dissipation by the LFSB. This underestimation, approximately 8% of the final value, is not excessive but also not negligible.

8. CONCLUSIONS

An improved model for the dynamic identification of hybrid base isolation systems has been presented. The model is the evolution of a previous one already available in the literature, Oliveto et al. (2010). In the previous model a bi-linear spring was used to characterize the HDRB component of the system, while a constant Coulomb friction damper was used to describe the LFSB component. The present model differs from the previous one in that it replaces the constant Coulomb friction model with a linear one characterized by two parameters instead of just one. The response of the system to the sudden release of a statically imposed displacement is provided in closed form. The response provided by the system has been shown graphically in terms of displacement, velocity, acceleration and resisting forces in the bi-linear spring and in the friction damper.

The analytical solution provided has then been used to solve an inverse problem whereby the acceleration response is assumed to be known while the system parameters and the initial displacement are assumed to be unknown. An evolution strategy is used to provide a solution to the inverse problem but this will be discussed elsewhere. Here the importance of the suitability of the model for structural dynamical identification is addressed instead. An acceleration response produced using a LCFM is used as experimental data. When the CCFM is used for the system identification, the error of the optimal solution is of the order of 10^{-2} which, in computer jargon, says that the solution fitness is rather poor. This is demonstrated also by the errors in the individual system parameters which in some cases appear to be exceedingly large. On the other hand, when the LCFM is used for the identification, given enough time, the error can be made as little as desired, meaning that the real solution can be found.

The next step has been that of applying the newly developed model solution to the identification of a real hybrid isolation system, that existing in a base-isolated building in the little Sicilian town of Solarino. An improvement of the order of 5% in the fitness of the solution obtained was observed as compared to previous results obtained by using the CCFM. Interestingly enough both models showed that viscous damping did not play a role in the identification suggesting that the viscous damper could be removed from the physical model without affecting the final results.

An interesting feature of the identification procedure presented is the possibility of identifying the initial and residual displacements besides the system parameters. While the identified initial displacements differ by only about a unit per cent from one model to the other, the residual displacements differ by a large amount. It is therefore evident that the reliability of the model shall be relevant if one wants to predict the residual displacement accurately.

An additional feature of the present work which had not yet been expounded in the existing literature is the evolution of the energy balance during the test. The initial input provided in the form of stored elastic strain energy is split in various components and their evolution with time is depicted. Confirming what had already emerged, the contribution of the viscous damper to energy dissipation is negligible. The contribution of the bilinear spring to energy dissipation is discontinuous and limited to the yielding phases which are interrupted by elastic recovery phases that become permanent sometime before the motion stops. On the contrary the contribution of the friction damper to energy dissipation is continuous. The LCFM leads to a larger energy dissipation than the CCFM. The difference is of about 8%, which is not excessive but negligible either.

Finally it is interesting to observe how in a hybrid base isolation system, like the one in the Solarino building, the LFSB component only accounts for about 4% of the base shear force while contributing to nearly 1/3 of the overall energy dissipation, the remaining 2/3 being dissipated by the HDRB component.

Abstract: This paper investigates numerically the effect of seismic isolation on the response of tall reinforced concrete cantilever wall buildings subjected to strong pulse-type near-fault ground motions. Five 20-story reinforced concrete cantilever wall buildings are considered. Two building designs are fixed-base and three use seismic isolation. The first fixed-base design allows the formation of a plastic hinge only at the base of the wall, with the wall above the plastic hinge region detailed to remain elastic. In the second fixed-base design plasticity is allowed to spread anywhere along the height of the wall. The three designs using seismic isolation vary in the location and number of isolation planes. The isolation plane consists of low-damping laminated rubber bearings, and is either only at the base, only at mid-height, or at both base and mid-height. The buildings are subjected to seven strong near-fault ground motions. The nonlinear dynamic time history analysis of the buildings shows a significant reduction in the engineering response parameters of the base isolated building in comparison with those of the fixed-base buildings. Using two seismic isolation planes further reduces, in comparison with the base isolation building, bending moments, inelastic section curvatures, and inter-story drifts. The building with a single isolation plane at its mid-height is not effective in reducing response parameters.

1. INTRODUCTION

Construction of tall buildings worldwide is increasing at an exponential pace due to the rapid growth of cities and their dense inner cores in the U.S. and around the world. Not only are super tall buildings—100 or more stories—continuing at a rapid pace, but construction of 20- to 80-story tall buildings has also increased significantly (CTBUH 2011). This trend has been slower in regions of high seismicity, but numerous tall buildings are being planned or designed in regions vulnerable to earthquakes. Currently, two hundred buildings taller than 120 m (394 ft) are proposed or under construction in U.S. with 21 of them in highly seismic regions: 7 in Los Angeles, 8 in San Francisco, and 6 in Seattle (CTBUH 2011).

Many tall buildings in highly seismic regions are now designed with reinforced concrete core walls as the main lateral force resisting system. Currently, RC core-wall buildings are designed to develop nonlinear deformations in regions defined as plastic hinges located at the base of the walls (LA 2005, SEAONC 2007, TBI 2010). Numerical studies have shown, however, that tall cantilever wall buildings undergoing strong ground shaking experience high acceleration and force demands along their entire height with significant contribution from the higher modes of response (Moehle 2007, Panagiotou and Restrepo 2009, Panagiotou et al. 2009). For walls designed to develop significant inelastic response at a single plastic hinge at their base, studies have shown that large bending moment demands develop around their mid-height (Panagiotou and Restrepo 2009, Panagiotou et al. 2009). If these regions have to remain elastic, a large amount of longitudinal reinforcement is required. On the other had if plasticity is allowed to develop anywhere along the height of the wall then special detailing is required over the entire wall height in order for these regions to be able to accommodate inelastic deformations. In this study the effect of seismic isolation is investigated to reduce the acceleration, force, and inelastic deformation demands along the height of the walls of such buildings, to reduce their post-earthquake damage and thus to enhance their seismic performance.

Seismic isolation is a well-established approach for improving the seismic performance of structures (Kelly 1999). Hundreds of applications of seismic isolation have been made around the world over the last 40 years. Traditionally seismic isolation has been considered effective for relatively short and stiff structures by elongating their fundamental period, and thus reducing the accelerations and forces they develop. In tall buildings the main goal of seismic isolation is not to increase the already long fundamental period, but to reduce forces and accelerations by controlling the response of a few robust regions while the rest of the building is designed to remain elastic, reducing post-earthquake structural damage. Several applications of base isolation to tall buildings have been made, primarily in Japan (Komuro 2005, Kani 2009). Most of these buildings have a single seismic isolation plane at their base, while cases where this plane is located on the upper part of the building have been reported. (Sueoka 2004, Tsuneki et al. 2009). One third of all recorded isolated buildings in Japan

are over 40-m tall, with the tallest being 50 stories (Kani 2009).

This study investigates the effect of seismic isolation on the performance of tall reinforced concrete core-wall buildings and compares their performance with that of buildings designed according to current building codes. The effectiveness of three seismic isolation designs which differ in the number (one or two) of the seismic isolation planes and the location (base and/or mid-height) of these planes is also investigated.

2. BUILDING AND ISOLATION PLANE DESIGN

2.1 Building Design

Five buildings are considered, two of them fixed-base, and three – seismically isolated. Figure 1 shows the common floor plan view of the buildings considered. A reinforced concrete core-wall provides all the lateral force resistance in the fixed-base buildings. Table 1 lists the main characteristics of the buildings, including the main building and core-wall geometrical properties, floor height h, the seismic weight per floor w, the axial load per floor ΔP, acting on the wall, and the axial stress ratio at the wall base. The axial load ratios are based on a specified concrete compressive strength of $f_c^{'}$ = 50 MPa (8 ksi).

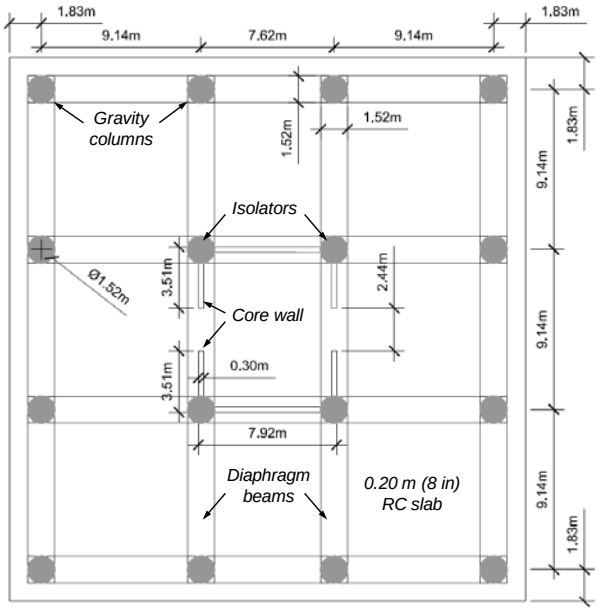

Figure 1. Floor plan view of the studied 20-story RC core-wall buildings showing the isolation plane.

The fixed-base buildings are designed according to ASCE 7-05 (2006) seismic provisions. The mean of seven ground motions, described in section 3.2 below, and a response modification factor R = 5 were used for design with the modal response spectrum analysis (MRSA) method. For the fixed-base buildings, described below, the bending moment, shear force, and axial force capacity along the height of the walls exceeds the design demands.

The first considered fixed-base design is referred to as single plastic hinge (SPH) and is designed to form a single flexural plastic hinge extending over the bottom two stories [see Figure 2]. The reinforcing steel ratio in the plastic hinge region is equal to ρ_b = 0.7%. Above the plastic hinge region the wall is modeled with a high longitudinal steel ratio ρ_E = 3.0%, sufficient to ensure nearly elastic response of this part of the wall. The SPH design follows the methodologies of the EC8 code (2004), which advocates that all plasticity be restrained to a single plastic hinge region at the base of the wall with all other regions designed to remain elastic. The expected flexural strength at the base of the wall, $M_{y,b}$, is computed with moment -curvature analysis using the provided reinforcement and axial loads, and is 1.13 times the moment at which the outer steel yields. The expected flexural strength, $M_{y,b}$, and the corresponding curvature, $\varphi_{y,b}$, are presented in Table 1.

Table 1. Main characteristics of studied buildings.

Floor height h, m (ft)	3.35 (11)
Building height H, m (ft)	67.1 (220)
Floor plan view dimension L_o, m (ft)	31.1 (102)
Base axial load ratio $P / (f'_c A_g)$	0.15
Seismic weight / floor w, kN (kip)	5502 (1237)
Length of core L_w, m (ft)	7.9 (26)
Core thickness t_w, m (ft)	0.3 (1.0)
Expected base flexural strength $M_{y,b}$, kN·m (kip·ft)	504100 (371840)
Curvature at expected base flexural strength $\varphi_{y,b}$, rad/m (rad/in)	$5.5 \cdot 10^{-4}$ ($1.4 \cdot 10^{-5}$)

In the second fixed-base building, referred to as extended plasticity (EP), plasticity is allowed to develop in any region along the height of the wall. Steel reinforcement is curtailed at thirds of the height of the wall with longitudinal steel ratios ρ_l = 0.7%, 0.6%, 0.5% at the base, middle, and top third of the wall height, respectively.

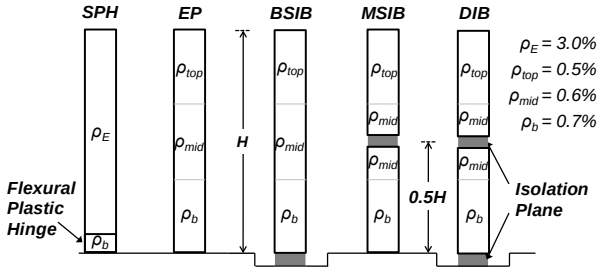

Figure 2. Schematic view of the five building designs including location of isolation planes and longitudinal reinforcement ratio along the height of the walls.

The core walls of the three seismically isolated buildings have the same details as the wall of the EP building. These buildings are seismically isolated using one

or two isolation planes at the base, mid-height, or at both base and mid-height. Building height, *H*, is defined as the height above the ground surface. For the isolated buildings with an isolation plane at their base, base is defined the base of the levels below ground. The system with a single plane of isolation at the base is referred to as BSIB, while that with the isolation plane at mid-height as MSIB. The system with two isolation planes, at base and at mid-height is termed DIB.

Diaphragm beams are utilized at the mid-height isolation plane to distribute the isolators over the entire floor plan and minimize tension demand in the bearings. These beams are installed at the top of the story below the isolators to allow full use of that story, and above the isolators, below the floor slab of the above story.

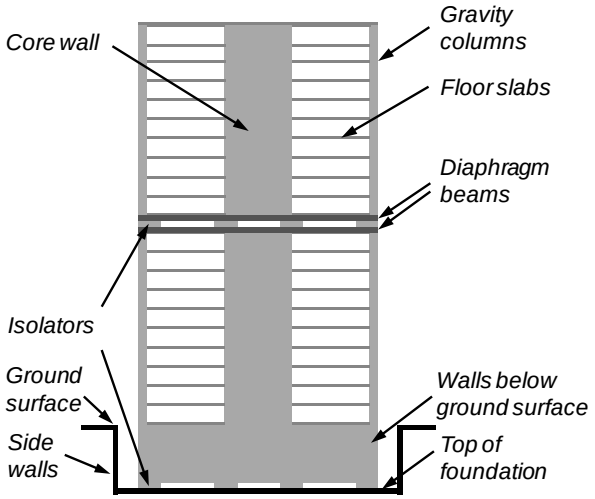

Figure 3. Elevation showing the location of isolation levels at building base and mid-height.

2.2 Seismic Isolator Design

Low-damping laminated rubber bearings were used for all isolated buildings. The main objective of the isolated buildings was to reduce acceleration and force demands and achieve a nearly elastic response of the walls. This could be accomplished by controlling the force that is transferred through the isolation plane at a target displacement of the isolation plane. For this target peak displacement the stability of the bearings under the combined axial and shear force has to be ensured (Kelly and Takhirov 2006). The target peak shear strain was 200% while the maximum tensile strain was 1%. The peak allowable ratio of peak vertical load to critical buckling load, P/P_{cr}, was considered equal to 0.3 (Kelly 1999). For the BSIB the target peak shear force was 0.15W at 0.75 m (30 in) target isolator displacement. Iterations, including preliminary numerical time history analyses, were performed to arrive at the design described in this study.

The base isolation plane of the BSIB, and DIB buildings were identical as they were the mid-height isolation planes of the DIB, and MSIB buildings, respectively. The ratio of the mid-height to the base isolation plane stiffness determines the difference in the response of the DIB in comparison with the BSIB. In order for this system to be effective, the stiffness of the mid-height isolation plane should be selected to reduce the force transmitted through it without the isolators exceeding a specific level of deformation. By preliminary analysis, a ratio of base to mid-height isolation plane stiffness of 0.7 was selected. Table 2 summarizes the main characteristics of the isolators. Sixteen isolators were used at both the base and the mid-height isolation planes. The diameters of the isolators used at the base and mid-height isolation planes were 1524 mm (60 in) and 1270 mm (50 in), respectively. All other design parameters for the isolators were identical.

Table 2. Main characteristics of seismic isolators.

Isolation Level	Base	Mid-height
Number of bearings	16	16
Outer diameter, mm (in)	1524 (60)	1270 (50)
Total rubber thickness t_r, mm (in)	635 (25)	635 (25)
Individual plane rubber thickness t, mm (in)	12.7 (0.5)	12.7 (0.5)
Steel plate thickness t_s, mm (in)	3.18 (0.125)	3.18 (0.125)
Individual bearing lateral stiffness K_h, kN/m (kip/in)	1386 (7.92)	963 (5.50)
Individual bearing vertical stiffness in compression, $K_{v,c}$, kN/m (kip/in)	3741000 (21375)	1804000 (10308)

2.3 Numerical Modeling of the Buildings

The Open System for Earthquake Engineering Simulation (OpenSees) software was used in this numerical study. Nonlinear beam-column elements with fiber sections were utilized to model the RC walls. An initial concrete modulus E_c = 33.8 GPa (4900 ksi) was used. Linear vertical, horizontal, and rotational zero-length springs were used to model the force-displacement behavior of each isolator at the corresponding direction. The vertical force, shear force, and bending moment interaction (Kelly and Takhirov 2004, Ryan et al. 2005) was not modeled. The vertical stiffness of the isolators in tension was modeled five times smaller than the compressive one (Fujita 1991, Kato 2003), however the isolators did not undergo tension in this numerical study. Rubber with shear modulus G = 483 KPa (70 psi) was assumed for the isolators. At each isolation plane "rigid" beam-column elements were used to model the diaphragm beams [see Figure 4]. The axial effect of the gravity columns was ignored. Vertical mass equal to half the lateral mass was modeled. Rayleigh damping with 2% damping in the first and the sixth mode was used.

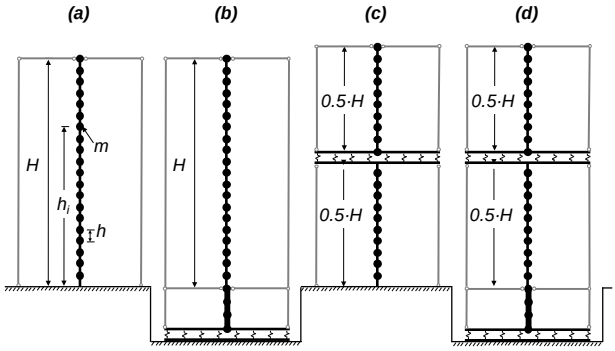

Figure 4. Elevation of numerical models showing lumped masses, diaphragm beams, and isolator springs.

3. NUMERICAL ANALYSIS RESULTS

3.1 Modal Analysis

The modal periods of the five buildings are presented in Table 3. The periods of the modes of lateral vibration elongate at least 120% for the isolated buildings. Compared with EP, the fundamental vertical periods of BSIB, MSIB, and DIB are 8%, 11%, and 18% longer, respectively.

Table 3. First three lateral ($T_{L,i}$) and first vertical ($T_{V,1}$) modal periods of the studied buildings.

Period (sec)	SPH	EP	BSIB	MSIB	DIB
$T_{L,1}$	1.91	1.99	5.17	4.42	6.13
$T_{L,2}$	0.30	0.31	1.35	0.67	2.62
$T_{L,3}$	0.11	0.11	0.26	0.30	0.66
$T_{V,1}$	0.13	0.14	0.15	0.16	0.17

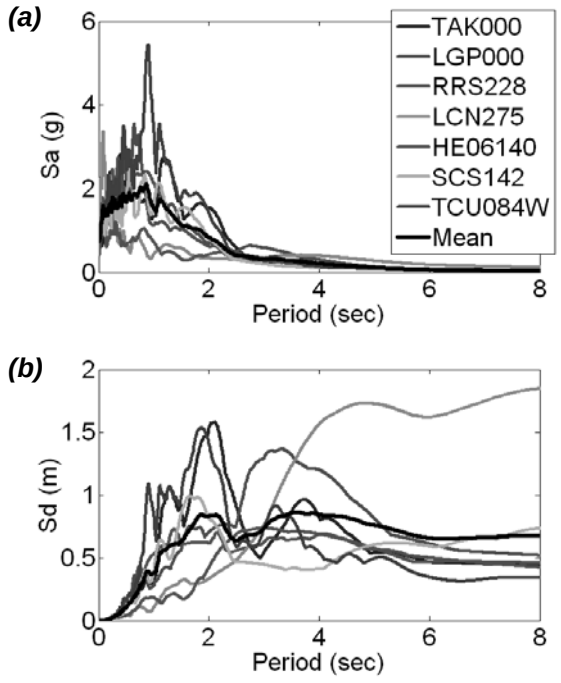

Figure 5. Total acceleration and relative displacement spectra of the 7 considered ground motions, 2% damping.

3.2 Ground Motions

Seven strong pulse-type near-fault ground motions from the Imperial Valley (1979), Loma Prieta (1989), Landers (1992), Northridge (1994), Kobe (1995), and Chi-Chi (1999) earthquakes were used in this study. Their spectral total acceleration and relative displacement spectra for 2% damping are presented in Figure 5. The ground motions were selected to have different predominant frequency content.

3.3 Comparison of Mean Results

Mean computed response envelopes, for the seven strong ground motions are shown in Figure 6 for six response quantities. The following six response quantities are considered: bending moment M normalized by the expected flexural strength at the base of the wall $M_{y,b}$, curvature ductility μ_φ defined as the measured curvature divided by $\varphi_{y,b}$, shear force V normalized by the total corresponding building weight W_t, total acceleration A normalized by the mean peak ground acceleration PGA, relative displacement D, and interstory drift ID.

BSIB, in comparison with the fixed base buildings reduces significantly accelerations, forces, interstory drifts and inelastic curvatures. In comparison with the EP building, BSIB reduces mid-height bending moment, base shear force, average floor acceleration along the building's height, and average interstory drift along the building's height by 28%, 74%, 65%, and 34%, respectively. In comparison with the SPH building, which has the largest mid-height bending moment, due to the "elastic" design of this building above the bottom plastic hinge and the significant contribution of the second mode to the response, the BSIB reduces mid-height bending moment by 56%.

The mean base curvature ductility demand μ_φ for the BSIB is equal to 4.1, which is 60% and 64% smaller than the corresponding values of the SPH and EP buildings. The mean curvature ductility at the base for BSIB is heavily influenced by the high value of μ_φ =15.3 recorded for LCN275 ground motion, which was the motion with the highest Sd for periods larger than 3.6 sec. The mean curvature ductility at the base for BSIB for the remaining six ground motions, omitting LCN275, is μ_φ = 2.2. Above the bottom three stories the BSIB remains elastic in comparison with the EP building which reaches a mean μ_φ = 3.2 at 45% of the height.

In comparison with the BSIB, the DIB reduces base bending moment and average interstory drifts along the height by 19% and 36%, respectively. The DIB building remains nearly elastic with a mean curvature ductility μ_φ = 1.9.

Similar mean roof displacements were computed for all buildings [see Figure 6(e)] since for most of the ground motions the spectral displacement for periods larger than 2.5 sec do not vary significantly, see Figure 5.

The MSIB develops forces and acceleration closer to those of the fixed-base buildings while it develops highly

inelastic response at its base, higher than the corresponding response of the fixed-base buildings. This occurs because the isolation plane at the mid-height of the structure controls the force that can be transferred through it while the forces that develop below this plane are bounded only by inelastic response of the wall in flexure. The bending moment and shear force envelopes of the MSIB are similar to those of the EP building. The above observations indicate the inefficiency of the MSIB design with the specific characteristics described in this paper.

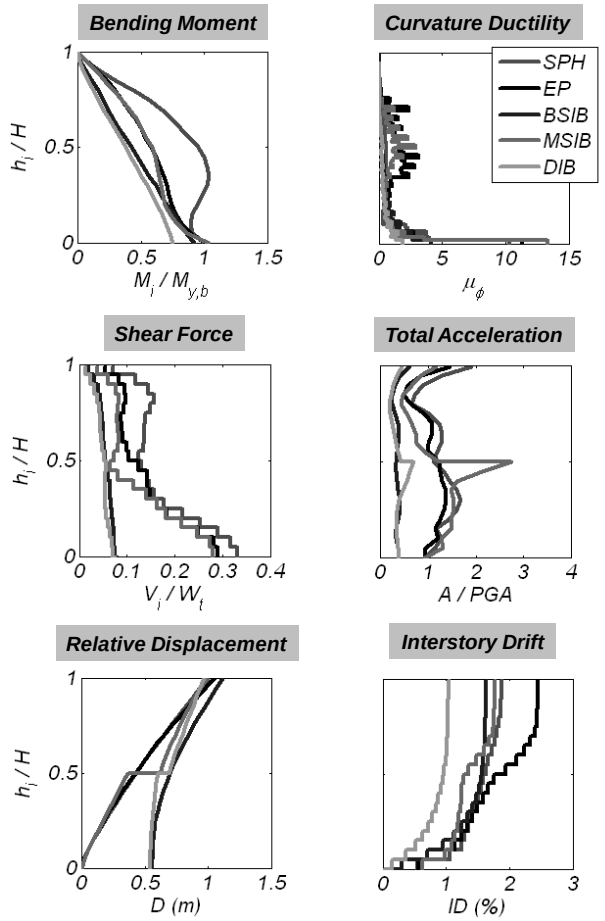

Figure 6. Mean response envelopes based on numerical analysis with seven strong near-fault records.

Response quantities of the bearings are summarized in Tables 4 and 5. The mean displacements of the bearings did not exceed 50% of their diameter *D*, while the peak was equal to 0.63*D* at the base for BSIB and 0.57*D* at mid-height for DIB. These peak displacements correspond to a shear strain of 147% and 111%, respectively. The peak compressive stress of 7.0 MPa (1.12 ksi) and 9.6 MPa (1.53 ksi) was reached for the isolators in the base plane of BSIB and in the mid-height plane of the DIB, respectively, corresponding to peak axial load ratio P / Pcr = 0.27 and 0.23.

Table 4. Mean of 7 near-fault ground motions, and peak (in parenthesis) displacements of the bearings (meters).

Isolation Plane	Base	Mid-height
BSIB	0.56 (0.95)	-
MSIB	-	0.54 (0.66)
DIB	0.54 (0.73)	0.51 (0.72)

Table 5. Mean of 7 near-fault ground motions, and peak (in parenthesis) isolator compressive strains (percent).

Isolation Plane	Base	Mid-height
BSIB	0.30 (0.33)	-
MSIB	-	0.30 (0.32)
DIB	0.26 (0.32)	0.25 (0.30)

3.4 Response to Individual Ground Motions

The response envelopes to each of the seven ground motions are presented in Figure 7. Less variability in the shear force and bending moment envelopes is observed for the BSIB compared with the fixed-base buildings. The bending moment envelopes of BSIB have a nearly linear profile along the building height.

For the LCN275 record, which has the largest spectral displacement demands for periods larger than 3.6 sec, the response of BSIB and DIB was highly inelastic at their base. To accommodate these high demands, the longitudinal reinforcement has to be increased along the height of the wall to remain elastic. For the isolated buildings the relative displacements for the LCN275 record are much higher in comparison to the other records. This record had significantly larger spectral displacements for T larger than 4.5 sec which was the fundamental period range of the isolated buildings.

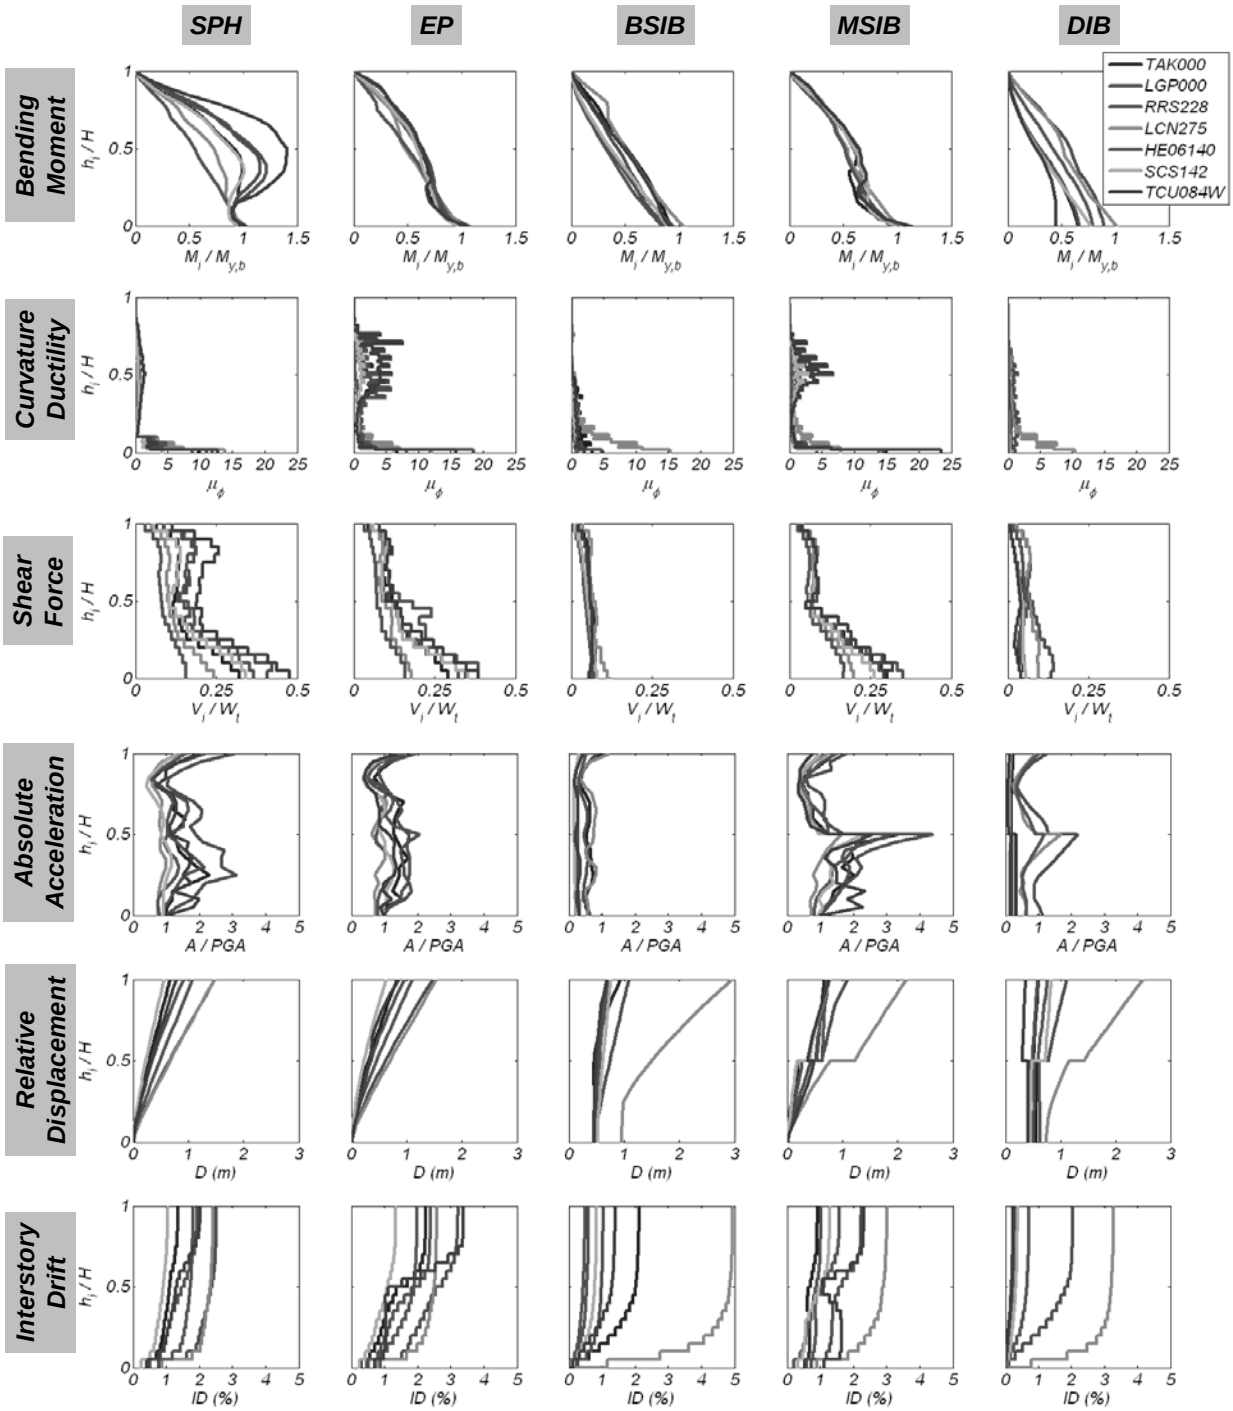

Figure 7. Response envelopes to individual ground motions of the five studied buildings.

4. CONCLUSIONS

This study investigated numerically the effect of seismic isolation on the response of 20-story tall reinforced-concrete core-wall buildings. The response of three seismic-isolated buildings was compared with this of two fixed-base buildings. The seismic isolation designs, differed in terms of number and location of the isolation planes. The buildings were subjected to seven strong pulse-type near-fault ground motions. The following conclusions are drawn:

- Base isolation reduced mid-height bending moment, base curvature ductility, base shear force, average along the height floor acceleration, and average along the height interstory drift demands in the fixed-base building by 28%, 64%, 74%, 65%, and 34%, respectively.
- Using and isolation plane at mid-height of the building in addition to the base, in comparison with using the isolation plane only at the base, resulted in a decrease of base bending moment, and average interstory drift along the wall height equal to 19% and 36%, respectively.
- The building with an isolation plane only at its mid-height was ineffective, and resulted in acceleration

and force demands closer to those of the fixed-base buildings, while its response was highly inelastic at the base.

- Base isolation, in comparison with the fixed base buildings, resulted in smaller sensitivity of the computed shear force and bending moment envelopes to the ground motion characteristics.

Abstract: Natural periods of isolation buildings in stiff construction sites were usually much larger than sites' characteristic period. But the two kinds of periods may be close to each other for isolation buildings and soft sites, this may cause resonance easily. In the paper, the resonance of a base isolation model under long-period seismic wave was studied by means of shaking table test, and the variations of acceleration, displacements and bearings' hysteretic curve were analyzed. The results showed that the resonant base isolation structure had distinctive feature which was different from non-resonant structure. The acceleration amplification factors, relative displacements and interstory drift of the super-structure in resonant isolation buildings were large, and deformations of bearings, with their hysteretic curves being pinched and hardened obviously, were super-large. As the seismic energy was accumulated, displacement of isolation storey would increase continuously, and it was very easy to cause damage or instability of the isolators even the isolation storey.

1. INTRODUCTION

The main objective of seismic isolation is to introduce horizontally flexible but vertically stiff isolation storey at the base of a building to substantially uncouple the superstructure from earthquake motion. By means of large deformation, the isolation storey can absorb most of the seismic energy transmitting to the building, and finally bring down seismic reactions of the structure. Fixed-based structures usually have large interstory drift and strong acceleration response under earthquake ground motion which tend to cause damage for structural members and non-structural components. However, the superstructure which has very small acceleration and interstory drift is almost rigid body motion and basically intact with deformations and hysteretic energy mainly occurring in the isolation storey.

The primary reason why isolation buildings could mitigate seismic reaction is that the stiffness of isolation story is very small which can lengthen the natural vibration period greatly. The period of isolation building is usually far from predominant period of construction site and is in the descending stage of seismic reaction. Furthermore, isolation bearings have excellent characteristics of large deformation, big damping ratio and good energy dissipation, and they can absorb most seismic energy which would be transmitted to the super-structure in fixed based building.

The relation between isolation structure's natural period and site's predominant period has great influence on efficacy of absorption of energy. Only if building's natural period is much greater than site's period, could the structure get good isolation efficacy. But when the natural period is close to the predominant period, the building may cause violent resonant reaction.

In the test, the model of a isolation building with small height-width ratio in soft site (e.g. 4 class or softer) is excited by high frequency and long period ground motions respectively, and the model gives rise to two kinds of responses, namely non-resonant and resonant reactions. After comparative study of these two kinds of phenomena, the resonant characteristics of base isolation building is known clearly.

2. MODEL TEST

2.1 General Situation of Model

The real structure is a large 6-story isolation building with small height-width ratio, and the plane dimension of the building is 105m×105m. There is a 4-story high, 40m × 40m sized atrium in the middle of the building, and the atrium's roof is 40m length long span trusses. The six storey test model is made in accordance with 1/30 similar ratio, and the plane size is 3.5m×3.5m. Total height of the super-structure, isolation storey and sensors under the bearings is 1.86m, and the super-structure is 1.178m high. The atrium's top roof truss is installed on the 4th floor column cap, and two storeys are suspended under the truss. The shaking table test model is shown in Figure 1.

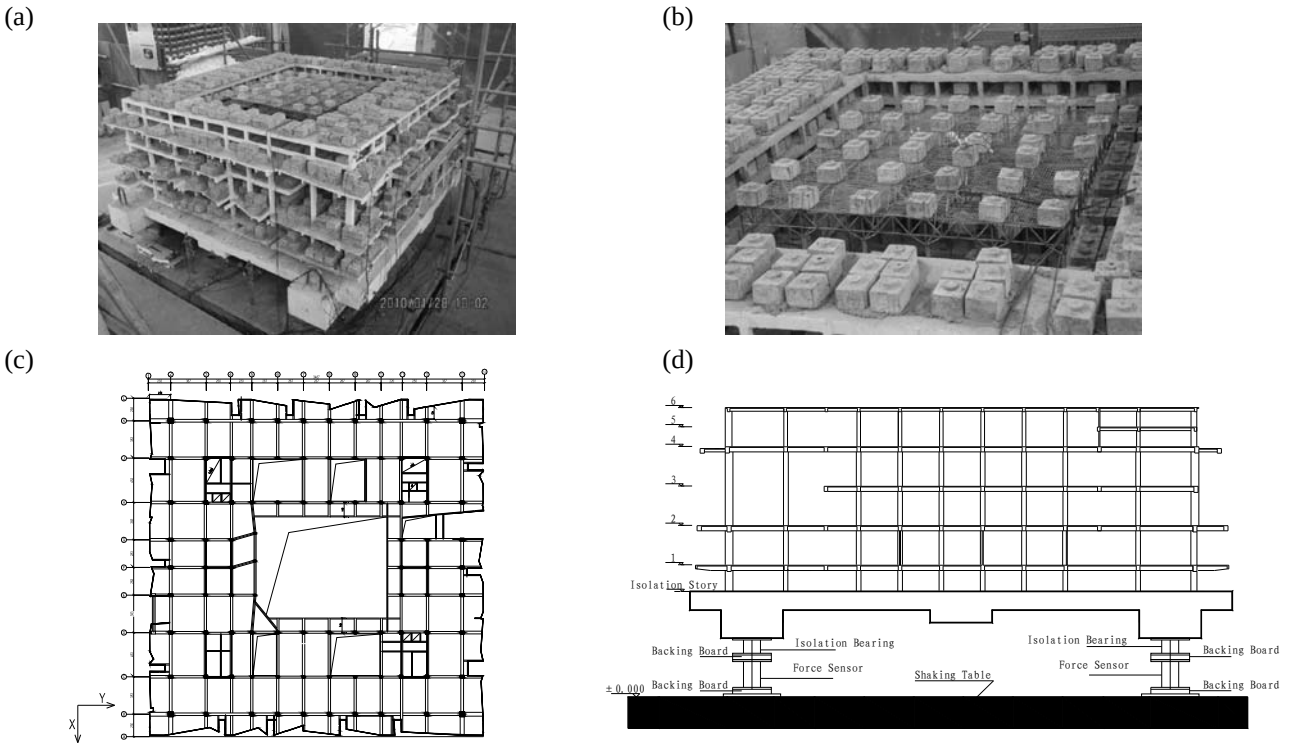

Figure 1 Shaking Table Test Model: (a) Shaking Table Test Model, (b) Truss on The Top Floor,(c) Plan Layout of Typical Storey, and (d) Typical Elevation of The Test Model

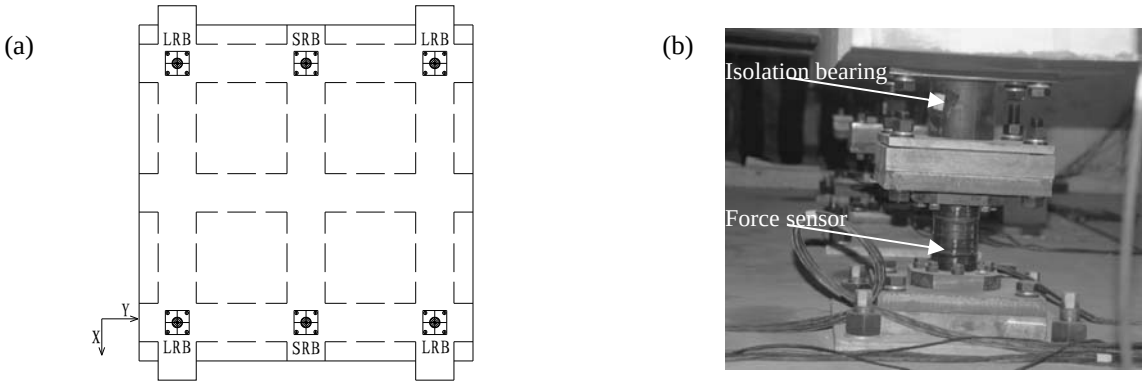

Figure 2 Isolated Bearings:(a)Locations of Isolation Bearings, and (b) Arrangement and detail of Isolation Bearing

The isolators' locations and arrangement detail of a typical LRB are shown in Fig 2, and there are 6 isolators in the isolation storey. 4 of them are lead rubber bearings (LRB) which located in the corners, the others are polysaccharide sliding rubber bearing（SRB）which located in the mid of two sides. According to similarity theory, the acceleration similar ratio is 1.888, and time similar ratio is 0.2.

2.2 Earthquake Records And Features

In the previous test, the isolation test model is not resonant under earthquake wave records of stiff sites such as El-Centro waves, Tanjin waves, Taft waves and LWD waves, and it has excellent ability of seismic reduction. The acceleration record of North-South direction of El-Centro waves (e.g. El-NS) is shown in Fig 3, and response spectrums of 3 direction acceleration of El-Centro records are shown in Fig 4. It shows that predominant periods of El-Centro wave records are less than 0.6s, while isolation buildings' natural periods are usually larger than 2s which is much greater than the predominant period of the wave records. Accordingly, El-Centro waves which can reduce reactions in the isolation structure can be representative of typical non-resonant earthquake waves in stiff sites..

Wenchuan earthquake (which happened in Sichuan province, China) wave records were recorded by State Key Laboratory of Disaster Reduction in Civil Engineering, Tongji University, in may 12, 2008. The duration of the wave records was 200s long, and the velocity was 3.2km/s. The acceleration peak values of south-north direction record (WC-SN), east-west direction record (WC-EW), and vertical direction record (WC-VER) are 2.32cm/ s^2, 1.96cm/s^2 and 1.17cm/s^2

respectively, and East-west direction record (WC-EW) is selected as the long-period resonant wave in the test. The acceleration record is shown in Fig5, and Fig 6 shows acceleration spectrums of the 3 records.

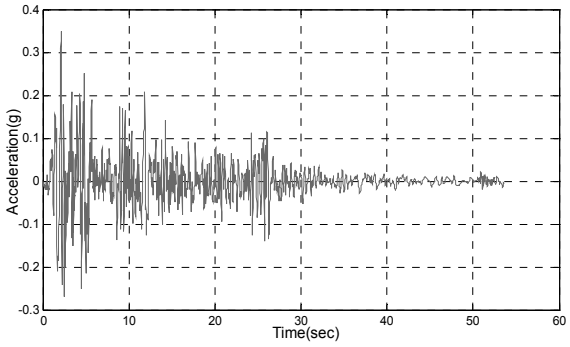

Figure 3 El-Centro(NS) earthquake wave record

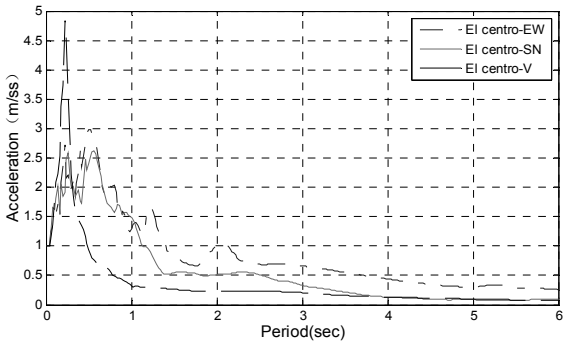

Figure 4 Acceleration response spectrum of El-Centro wave records

Fig 6 shows that predominant periods of WC-EW, WC-SN and WC-VER wave records are 2.4s, 2.6s and 2.3s respectively. Wenchuan waves' predominant periods are close to the natural period of high-rise, isolated and other long-period buildings, and these buildings would have violent reactions under long-period ground motions.

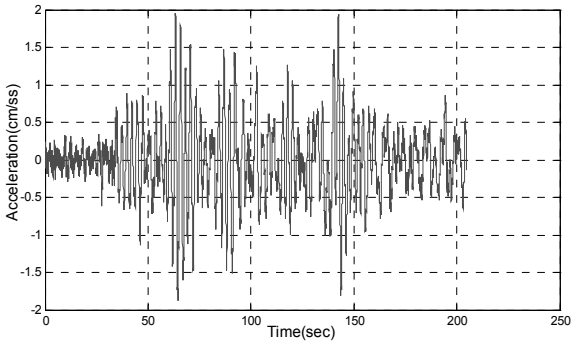

Figure 5 WC-EW Wave Record of Wenchuan Earthquake

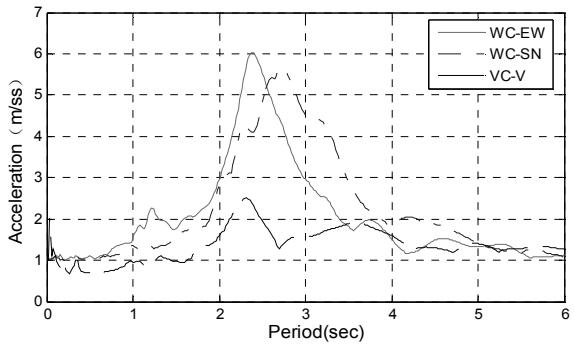

Figure 6 Acceleration Response Spectrum of WC Wave Records

2.3 Test Conditions

The test consists of two stages: base isolation structure's typical non-resonant reactions are verified in the first stage, and base isolation structure's resonant reactions are did in the second stage. In order to get dynamic properties, white noise is inputted before and after each stage, and base isolation model's shaking table test conditions is shown in table 1. Note that, the peak values of white noises in condition 1 and 4 are 0.1g, and the peak value in condition 7 after test of stage 2 is 0.05g so as to avoid further damage in superstructure especially in isolation layer,

Table 1 Test Conditions of Base Isolation Model

NO.	Earthquake Records	X	Y	Z	Notes	
1	White noise	0.100g	0.100g	0.100g	Sweep	Test of the first stage
2	El(NS)-x	0.100g	--	--	Frequent	
3	El(NS+EW+V)-xyz	0.200g	0.123g	0.121g	Design	
4	El(NS+EW+V)-xyz	0.400g	0.246g	0.242g	Rare	
5	White noise	0.100g	0.100g	0.100g	Sweep	Test of the Second stage
6	WC-EW	0.400g	--	--	Rare	
7	White noise	0.050g	0.050g	0.050g	Sweep	

In the test, the peak value of really inputing X direction acceleration of El-Centro wave is 0.393g in condition 4, and real peak value of X direction WC-EW wave is 0.317g in condition 6. These two peak values are similar, so they can be compared effectively.

3. EXPERIMENTAL PHENOMENA AND DYNAMIC CHARACTERISTICS

3.1 Experimental Phenomena

After white noise was inputted, the isolation storey has obvious vibration, but no overlarge displacement.

In the tests of first stage, the isolation storey has obvious displacement respectively under degree frequent wave, design wave and rare earthquake wave. The super-structure is nearly rigid body motion, and it almost has no torsion reaction and no obvious deformation. There are no new cracks in beams and columns, and at the same time, roof truss, suspended members and other components are well with the prism brick on isolation storey vibrating small. The test shows that normal base isolation buildings can reduce the earthquake reactions.

(a)

(b)

Figure 7 Bearing Deformation:(a)Small Deformation, and(b) Large Deformation

(a)

(b)

Figure 8 Typical Cracks on Super-structure's Beam and Column

7 degree rare WC-EW earthquake wave is inputted in the second stage. Because the acceleration amplitude is small in the first 15s, the isolation storey has no large deformation. As the wave is inputted, isolation story's deformation becomes obvious, larger and larger, and finally, the deformation is much larger than the deformation limit. Fig 6 shows the change of bearing deformation, (a) is bearing's small deformation, and (b) is bearing's super large deformation. At the moment of super large deformation, lead rubber bearings' appearance is well, but the inner lead may be destroyed and one slider has slide out from the Teflon slide type rubber bearing. The responses of super-structure are violent: the interstory drift is large with more and more concrete members cracking and many of cracks becoming wider, the diagonal bracings and the suspended members' bending deformation becomes aggravated, and the prism on isolation storey is overturned. Fig 8 shows the typical cracks on column and beam. The second stage test implies that the model has 'resonant' phenomena which are completely different from the first stage, and resonance has great influence on isolation storey and super-structure. After the super-large displacement, to avoid serious damage in bearings and the model, the test is stopped.

3.2 Dynamic Properties of Model

Table 2 shows variation of model's dynamic characteristics. Natural frequencies of model's Y direction and X direction were 1.712Hz and 1.953Hz respectively before tests. During tests of the first stage, model's natural frequency and vibration mode did not change, implying that the earquake waves had no influence on non-resonant isolation structure, and the model is basically intact. Model's X direction natural period was 0.512s before the second stage tests, while predominant period of the wave inputted in second stage was 0.48s which is 7 percent lesser than structural. According to structural dynamics, the predominant period was in structural resonance zone, and the model was liable to be resonant for the WC-EW wave record.

In table 2, it is known that model's X direction nominal natural frequency has no change under 0.05g white noise after stage 2. In fact, model's X direction frequency should be less than 1.953HZ under 0.1g white noise and has decreased, and the damping ratio is greater than the before. Furthermore, Y direction is model's first vibration mode before stage 2, but X direction becomes model's first vibration mode after stage 2, so it shows that isolation bearings are destroyed in large deformation, and this affects model's Vibration Characteristics.

4. ANALYSIS OF TEST RESULTS

4.1 Acceleration Reaction of Model

Fig 9 shows comparisons of X direction acceleration time history between isolation storey, 6th floor and shaking table under El-Centro 3 direction wave records. When the peak value of shaking table acceleration time history is 0.394g, peak value of 6th floor in super-structure is only 0.18g and isolation story's peak value is only 0.134g, so isolation model could reduce acceleration response effectively under El-Centro wave records. The tests also shows that the acceleration is larger, the isolation system mitigate the acceleration

reaction better.

Table 2 Model's Dynamic Characteristics

Sweep	Frequency(HZ)	Period(sec)	Damping Ratio	Vibration Mode
Before First Stage(0.1g)	1.712	0.584	0.372	Y direction motion
	1.953	0.512	0.374	X direction motion
Before Second Stage(0.1g)	1.709	0.585	0.374	Y direction motion
	1.953	0.512	0.375	X direction motion
After Second Stage(0.05g)	1.953	0.512	0.427	X direction motion
	2.197	0.455	0.283	Y direction motion

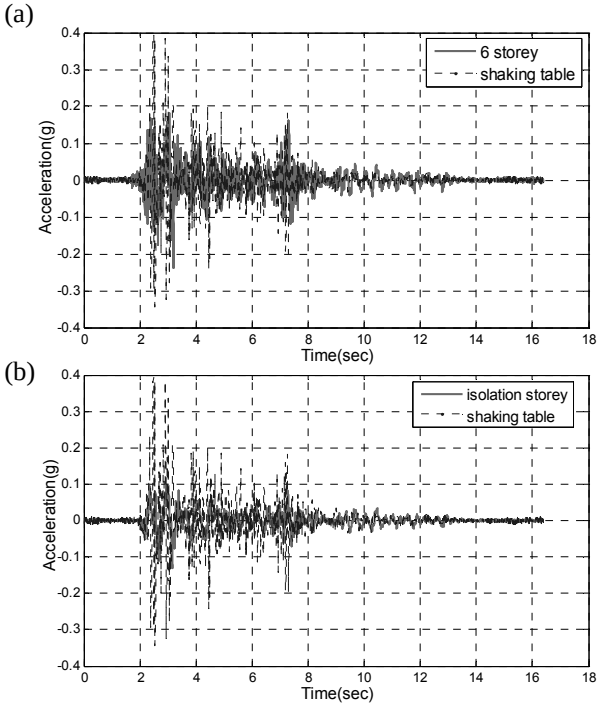

Figure 9 Comparison of Model's X Direction Acceleration Time History of El-Centro Wave: (a) 6th Floor and Shaking Table, and (b) Isolation Storey and

Fig 10 shows comparisons of X direction acceleration time history between isolation storey, 6th floor and table under WC-EW wave. The model amplifies acceleration response greatly under WC-EW wave: when the peak value of acceleration of table is 0.32g, the 6th floor's peak value of time history is as large as 0.76g, and isolation story's peak value is 0.69g. As the energy is accumulated, the model amplifies the acceleration reaction much greater. For example, at 27th second, the peak value of inputting acceleration is 0.21g, but the maximum acceleration is 0.76g in 6 floor and 0.69g in isolation storey. The result indicates that base isolation building can not mitigate acceleration when resonant.

Maximum accelerations of each floor under El-Centro and WC-EW waves are shown in Fig 11, and Fig 12 shows acceleration amplification factors of each floor. When El-Centro wave is inputted, maximum acceleration of each floor is much smaller than the table value: when maximum acceleration of table is 0.393g, peak values of the isolation storey and super-structure are between 0.132g and 0.238g respectively, and the acceleration amplification factors are between 0.34 and 0.61, so base isolation structure could mitigate each floor's acceleration obviously. However, when WC-EW wave is inputted, each story's acceleration is much larger than the table value: when the inputted acceleration is 0.318g, while the maximum accelerations of super-structure vary from 0.635g to 0.916g, and the acceleration amplification factors are between 2.06 and 2.88. Base isolation structure amplifies acceleration reaction of each floor obviously when resonant.

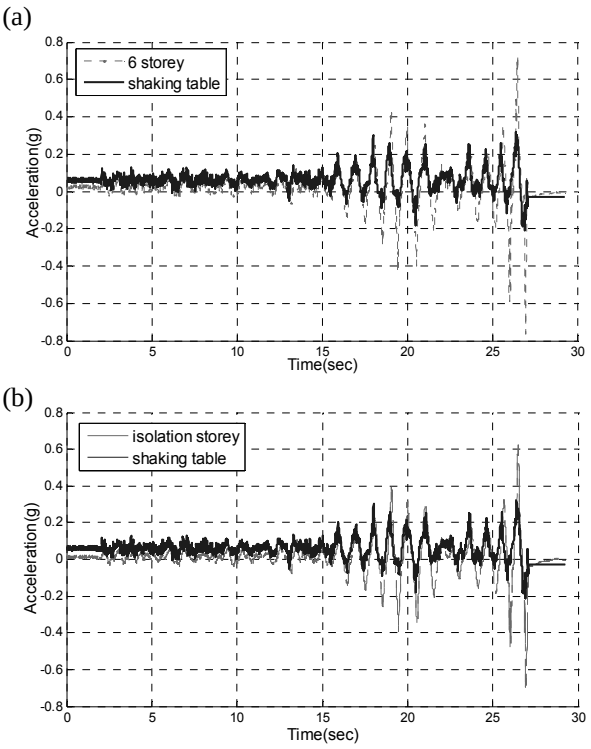

Figure 10 Model's X Direction Acceleration Time History of WC-EW Wave: (a) 6th Floor and Shaking Table, and (b) Isolation Storey and Shaking Table

As the numbers of storey increase, each floor's maximum acceleration is similar and change gently in non-resonant base isolation building rough the horizontal stiffness changed greatly. However, story's maximum

acceleration became larger as the numbers of storey increase in resonant condition, and the floor acceleration changed greatly when the horizontal stiffness varied. The accelerations are sensitive to the storey horizontal stiffness, for example, 3rd floor acceleration changed greatly along with the change of the horizontal stiffness. In brief, non-resonant base isolation building reduces the acceleration reaction greatly, but resonant isolation building amplifies the acceleration seriously and the acceleration is more sensitive to the variation of horizontal stiffness.

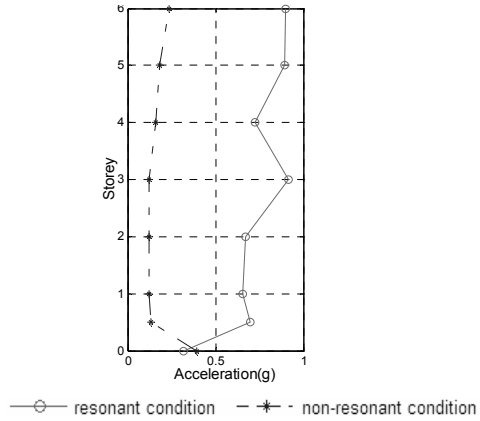

Figure 11 Maximum Acceleration For Different Storey

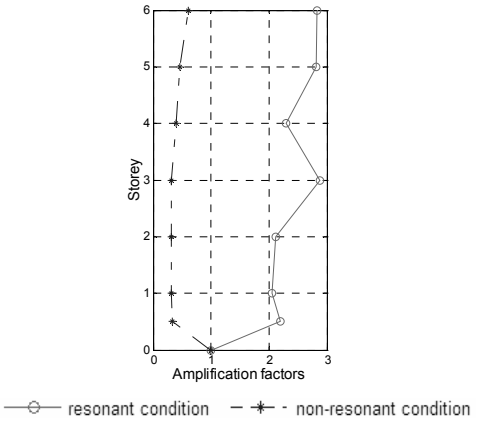

Figure 12 Maximum Acceleration Amplification Factors for Different Storey

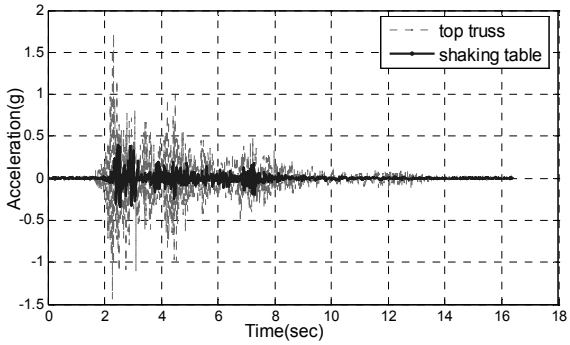

Figure 13 Acceleration Time-history of Truss and Shaking Table Under El-Centro Wave

Acceleration time histories of roof truss under El-Centro wave and WC-EW wave are shown in Fig13 and Fig 14 respectively. The truss acceleration is large under both two waves, and the acceleration amplification factors are larger than 4 which are much greater than the main structure's. Therefore resonance has little influence on the truss, but truss' response is still serious.

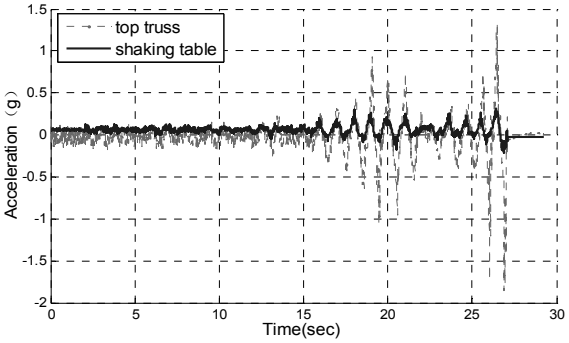

Figure 14 Acceleration Time-history of Truss and Shaking Table Under WC-EW Wave

4.2 Displacement Reaction of Model

The comparison of displacement time history of shaking table and isolation storey under El-Centro earthquake waves is shown in Fig 15. The isolation storey displacement is a little larger than the table, and displacement of isolation storey do not increase obviously as the earthquake wave inputted continuously. Fig 16 shows the comparison of displacement time histories of shaking table and isolation storey under WC-EW ground motion. Displacement of the isolation storey is larger than the table, and the displacement of isolation storey amplifies greatly as the earthquake wave is inputted continuously.

The relative displacement of isolation storey under El-Centro wave is shown in Fig 17, and the peak displacement is 5.34mm (LRB shear deformation 37.4%), implying that the isolation storey has "small" displacement. Fig 18 shows the relative displacement of isolation storey under WC-EW wave. As the wave is inputted and energy is accumulated, the isolation storey displacement increases continuously (this also can be seen from Fig 16). The largest relative displacement of isolation storey reached 59.9mm (LRB shear deformation 419%), and bearings' stability is very bad and may be destroyed easily.

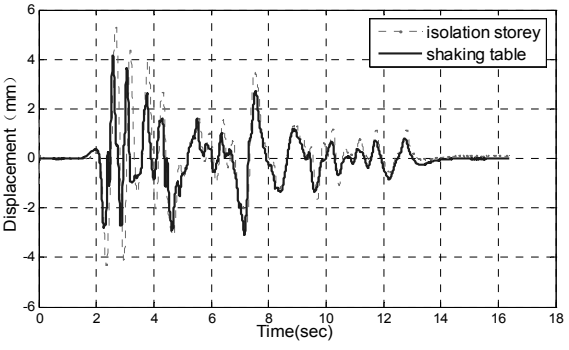

Figure 15 Displacement Time History of El-Centro wave

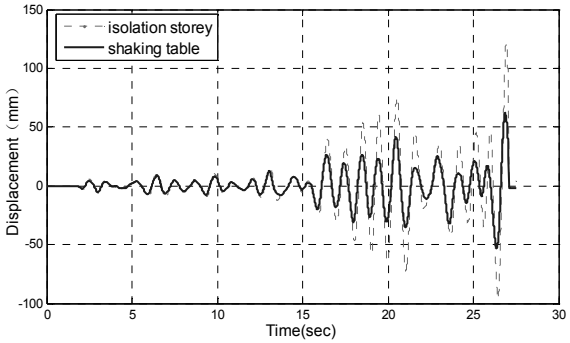

Figure 16 Displacement Time History of WC-EW Wave

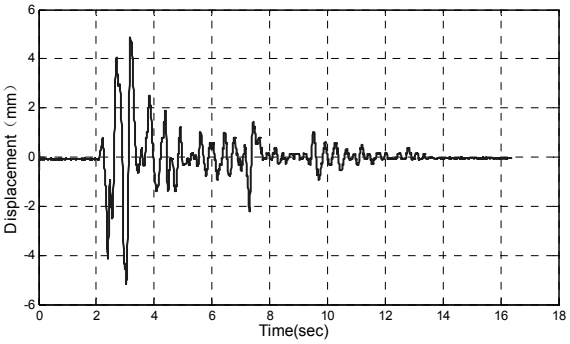

Figure 17 Relative Displacement Time History of Isolation Storey Under El-Centro Wave

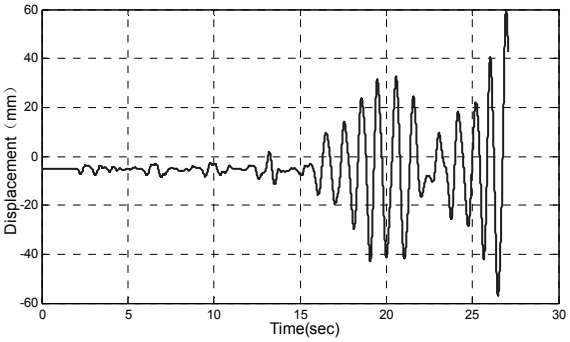

Figure 18 Relative Displacement Time History of Isolation Storey Under WC-EW Wave

Fig 19 shows peak displacements of isolation storey and super-structure under El-Centro and WC-EW waves. Under El-Centro wave, displacement of isolation storey is very small (5.34mm), and super-structure displacement is nearly "rigid body motion", namely displacement of each floor in super-structure is almost the same. But when WC-EW wave is inputted, both isolation storey deformation and floor relative displacements in super-structure are very large, and the model is not "rigid body motion" any more.

Displacement reaction of each floor in super-structure is shown in Fig 20. The peak value of interstory drift is only 0.22mm under El-Centro wave, and the largest drift angle is 1/1151. But in resonant condition, the relative displacement between 6th floor and isolation storey is 13.98mm. Interstory drift between 1st and 2nd floor is 4.5mm with drift angle 1/58, and storey drift between 4th and 6th floor is 6.8 mm with the drift angle 1/38. The storey relative displacement, interstory drift and drift angle in superstructure exceed the non-resonant condition greatly.

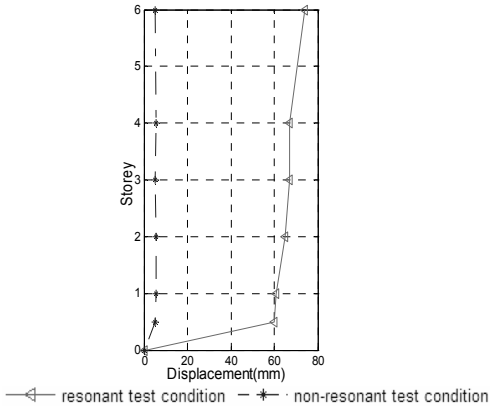

Figure 19 Model Absolute Displacement

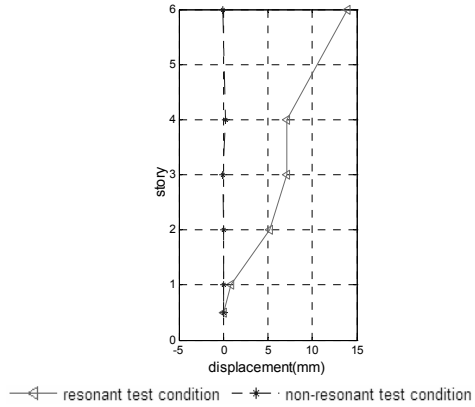

Figure 20 Superstructure Relative Displacement

According to "Technical Specification For Seismic-isolation With Laminated Rubber Bearing Isolators(CECS126:2001, Chinese)", isolation bearing's largest displacement should satisfy the following expressions :

$$u_{\max} \le 0.55d \quad (1)$$

$$u_{\max} \le 3t_r \quad (2)$$

Where,

$u_{\max}$ is bearing's largest horizontal displacement, and 59.9mm in the test.

d is diameter of the isolation bearing, and 100mm in the test.

t_r is total thickness of bearing's rubber layers, and 14.3mm in the test.

However, in the test,

$$u_{\max} = 59.9mm = 0.6d > 0.55d = 55mm$$

&

$$u_{\max} = 59.9mm = 4.2t_r > 3t_r = 42.9mm$$

the relative displacement of isolation storey is super large, and it would cause instability and damage in isolation bearings.

According to "Code For Seismic Design of Building

(GB50011-2010, china)", the allowable value of storey drift angle of earthquake resistant structure should be less than 1/50, and the storey drift angle limit in "CECS126" is 1/100, so interstory drift and storey drift angle of the superstructure exceed the limits of codes seriously.

4.3 Hysteretic Characteristics of Isolation Bearings

Hysteretic curve of typical lead rubber bearing under El-Centro wave is shown in Fig 21. The hysteretic curve is plump, elliptical and spindle shape with good energy dissipation, and its biggest horizontal force and displacement are 4.2Kn and 5.2mm respectively.

Fig 22 shows hysteretic curve of the same bearing under WC-EW wave. The curve has very large horizontal force (30kn) and displacement (59.9mm),which are 7.14 times and 11.54 times of non-resonant structure respectively, therefore the resonant hysteretic curve is much larger than the non-resonant curve.

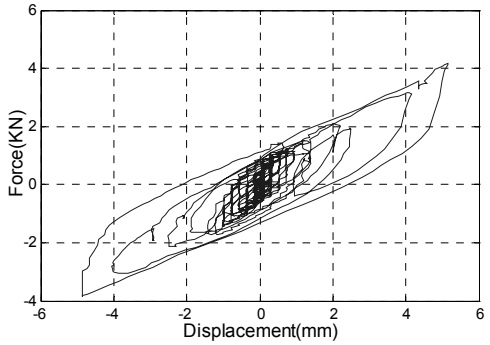

Figure 21 LRB Hysteretic Loop of El-Centro Wave

For resonant condition, when the bearing's displacement is small, such as 28mm (about 200% shear deformation), the hysteretic curve is plump, elliptical and spindle, and the bearing has good capacity of energy dissipation. As the displacement increases, the hysteretic loop becomes larger with more energy is absorbed, but the hysteretic loop began to be pinched. When bearings displacement is less than 40mm (about 300% shear deformation), it still is stable and possesses good capability of energy consumption rough the curve begins to be pinched. When the displacement is larger than 40mm, the hysteretic loop becomes larger while the displacement increases sharply. For large deformation, The lead rubber bearings are pinched seriously, and bearing's horizontal stiffness is hardened obviously. Bearing's characteristics have changed greatly, and it is not stable. So the largest shear deformation of bearing must be less than 300%, the limit is same to formula (2), and the suggesting peak value should not be larger than 200% for base isolation building in soft site.

Hysteretic curve of typical sliding rubber bearing under El-Centro wave is shown in Fig 23. The hysteretic curve is plump and the capability of energy consumption is stable and good.

Fig 24 shows the bearing's hysteretic curve under WC-EW wave. When the displacement is larger than 40mm, the hysteretic curve increase greatly and is pinched, not stable.

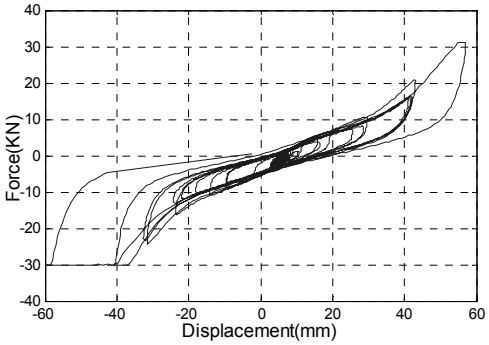

Figure 22 LRB Hysteretic Loop of WC-EW Wave

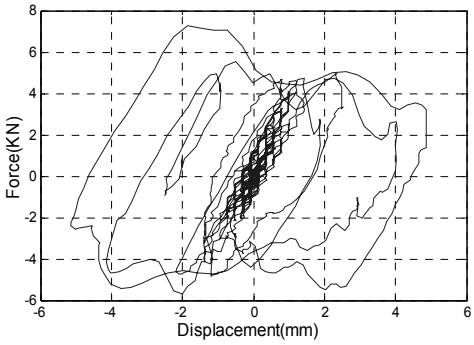

Figure 23 Sliding Bearing Hysteretic Loop of El-Centro Wave

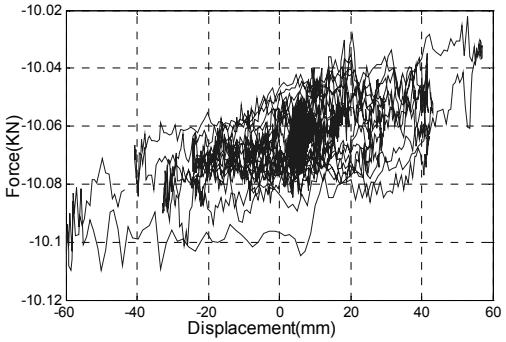

Figure 24 Sliding Bearing Hysteretic Loop of WC-EW Wave

5 CONCLUSIONS

According to resonance in shaking table test, the isolation buildings in soft sites are liable to be resonant if the natural period is close to site's predominant period. And the following main conclusions could be drawn.

(a) Horizontal relative displacement of isolation storey increase continuously in resonant base isolation buildings. The peak value can reach 59.9mm(4tr, 400% shear deformation, and this would lead to damage of bearings in isolation layer.

(b) When deformation of LRB is less than $2.0t_r$, the hysteretic curve with good energy consumption is plump and spindle. when deformation is larger than $2.0t_r$, the curve begins to be pinched and the lead core begins to be hardened. When the deformation is larger than $3.0t_r$, the hysteretic curve increases sharply and is pinched

seriously. The lead core is hardened obviously in large deformation and the bearings are not stable. To ensure some Safety Margin, the largest deformation of LRB in soft site should be less than 2.5 t_r, and must be smaller than 3.0t_r.

(c) The acceleration amplification factor of each floor in resonant isolation building is larger than 2, and both isolation storey and superstructure amplify shaking table's (also ground's) acceleration greatly. With storey numbers increasing, floor amplification factor becomes larger.

(d) Super-structure in resonant base-isolation building is not "rigid body motion" any more. The peak interstory drift angle is 1/37 in test, and it is much larger than the allowable limit. Many concrete members crack, and some steel members are bended and largely deformed. When the storey horizontal stiffness changed, the acceleration and displacement varied greatly, and seismic reactions of resonant building are more sensitive to the variation of horizontal stiffness.

(e) When a base-isolation building is resonant, not only it can't mitigate the seismic reaction, but also its isolation storey and super-structure are liable to be destroyed. Accordingly, if a base isolation building is built in soft site, structure's resonance should be avoided, and the limit of bearing's largest deformation should be more strict.

Abstract: This paper proposed a passive control design method for reinforced concrete (RC) structures with visco-elastic dampers. The dynamic properties of the passive system are described, and the variation of equivalent parameters of system is discussed. The performance curves for reinforced concrete structures, which describe the interaction between dampers, structural component, and seismic input intuitively, are developed, and a damper distribution method for MDOF RC building structure is proposed. The time history analysis over a wide range of system parameters and input earthquakes shows good accuracy of the proposed method.

1. INTRODUCTION

Energy dissipation technology for seismic protection of building structures has got significant advance and active practice in recent years. As one of the major types of energy dissipation device, visco-elastic (VE) damper is being widely used both in new construction and in retrofitting of various types of strucutres, including reinforced concreted (RC) building structures. Compared with other velocity-dependent dampers, VE damper has the spring element in addition to the damping element, which functions to restore the objective structure to the original position after deformation. On the other hand, VE dampers have some characteristics such as the frequency dependency, temperature dependency, which lead to the necessity of careful consideration of environment where the VE damper is installed during the design.

Due to the complex mechanical behavior of RC materials and VE dampers, it is highly desirable to develop a comprehensive design rule that clearly indicates effects as well as necessary capacities of the dampers for the target performance of RC buildings. The writers have extended earlier design method (JSSI 2005, 2007) for the elastic frame and VE dampers to nonlinear behavior frames including steel frame and timber frame (Kasai and Pu 2010, Kasai et al. 2010). This study will propose a design method for RC building structure by extending the previous method.

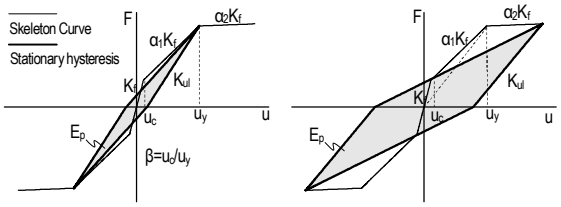
The aim of the present design method is to provide an optimum distribution of VE damper for multi-story RC building so that each story develops same story drift prescribed beforehand. That will be realized by tuning the equivalent stiffness of the system, as will be described in the next sections.

2. DYNAMIC PROPERTIES OF SYSTEM

2.1 Degrading stiffness model for RC frame

The degrading Takeda model is used for the hysteresis rule of RC building. In the model, hysteresis depends on experienced maximum deformation $u_{\max}$. The model is elastic at $u_{\max}<u_c$, where u_c= cracking deformation defined by micro-cracking of the concrete material. Figure 1a shows the model at $u_c<u_{\max}<u_y$, where u_y= yield deformation when the steel reinforcing bars yield significantly and plastic hinge formed at the member. Figure 1b shows the hysteresis at $u_c<u_y<u_{\max}$.

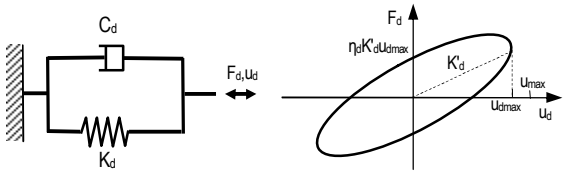
Accordingly, Takeda model has tri-linear skeleton curve, and the first, second, and third lines represent elastic stiffness K_f, post-crack stiffness $\alpha_1 K_f$, and post-yield stiffness $\alpha_2 K_f$ against the displacement $u_{\max}$, respectively. From now on, ductility ratio μ and normalized cracking displacement μ_c will be used, where



$$\mu = u_{\max}/u_y , \quad \mu_c = u_c/u_y \tag{1a,b}$$

The most significant characteristics that differentiate Takeda model with other models are the loading and unloading rules. The stiffness K_f^U when unloading from skeleton curve depends on μ experienced, and is given as:

$$\mu_c<\mu\le 1: \quad K_f^U = K_f \frac{2\mu_c+\alpha_1(\mu-\mu_c)}{\mu+\mu_c} \tag{2a}$$



$$1<\mu: \quad K_f^U = K_f \frac{2\mu_c+\alpha_1(1-\mu_c)}{(1+\mu_c)\mu^{0.4}} \tag{2b}$$

After one or more loading cycles have occurred, the loading curve can be constructed by connecting the point at zero load to the point reached in the previous cycle, if that point lies on the skeleton curve or on a line aimed at a point

(a) Hysteresis before yielding (b) Hysteresis after yielding

Figure 1. Hysteresis loop of stiffness degrading model

(a) Kelvin Model for VE damper (b) Typical hysteresis loop of VE Damper

Figure 2. Typical hysteresis loop of VE Damper

on the skeleton curve. The more details about loading and unloading rules can be found in Takeda et al. (1970).

The equivalent stiffness at maximum displacement is given by Eq. (3),

$$K_{f,eq}=K_f p \tag{3}$$

where p is ratio of equivalent stiffness to initial stiffness of frame and given as Eq. (4).

$$\mu_c<\mu\le 1: \quad p=[\mu_c+\alpha_1(\mu-\mu_c)]/\mu \tag{4a}$$

$$1<\mu: \quad p=[\mu_c+\alpha_1(1-\mu_c)+\alpha_2(\mu-1)]/\mu \tag{4b}$$

2.2 Model for VE damper

Figure 2 shows the typical stationary-state hysteresis for visco-elastic damper. The VE damper produces the elastic force and viscous force proportional to the deformation and velocity, respectively, so VE damper develops hysteresis loop of an inclined ellipse. The secant stiffness at maximum deformation is defined as storage stiffness K'_d, and loss stiffness K''_d is defined as the force at deformation u=0 divided by maximum deformation u_{dmax}. Loss factor $\eta_d = K''_d/K'_d$ is used to denote the ratio of loss stiffness to storage stiffness (Fu and Kasai 1998).

2.2 Dynamic properties of system

Figure 3 shows the constitution of RC frame and VE damper system. The damper is connected to elastic brace in series, and the damper-brace assembly is called as "added component". The added component is connected to main frame in parallel to form the passive control system. Obviously, damper and brace experience the same force, added component and frame experience the same deformation.

Given the stiffness of brace K_b, storage stiffness of damper K'_d, and loss factor of damper η_d, the storage stiffness K'_a and loss factor η_a for added component can be easily obtained as following.

$$K'_a=\frac{K'_d}{1/\Gamma_d+K'_d/K_b}, \quad \Gamma_d=1+\frac{\eta_d^2}{1+K_b/K'_d} \tag{5a-c}$$

$$\eta_a=\frac{\eta_d}{1+(1+\eta_d^2)K'_d/K_b}$$

Similarly, storage stiffness of system K' and loss factor η are expressed by

$$K'=K_f+K'_a, \quad \eta=\eta_a\frac{K'_a}{K_f+K'_a} \tag{6a,b}$$

Let T_f, h_f denote the initial period and damping ratio of frame, the natural period T_0, damping ratio h_0 of the elastic system with added component can be easily obtained.

$$T_0=T_f\sqrt{K_f/(K_f+K'_a)}, \quad h_0=h_f+0.9\frac{\eta}{2} \tag{7a,b}$$

where the factor 0.9 in Eq. (3b) serves to modify the damping effect of system in random response when damping factor estimated from stationary response is used (Kasai & Okuma 2004).

For elasto-plastic system, using the equivalent stiffness of frame defined by Eq. (3), the equivalent period of system at maximum displacement can be calculated by Eq. (8).

$$T_{eq}=T_f\sqrt{1/(p+K'_a/K_f)} \tag{8}$$

Based on the previous definitions for frame and damper, the dissipated energies of damper and frame at maximum deformation u_{max} are given as Eq. (9).

$$E_v=\pi\eta_a K'_a u_{\max}^2, \quad E_p=qK_f u_{\max}^2 \tag{9a,b}$$

where q in Eq. (9b) is given as,

$$\mu\le\mu: \quad q=0$$

$$\mu_c<\mu\le 1: \quad q=2\beta(1-\beta)/\{1+(1-\beta)\mu/\mu_c\} \tag{10a-d}$$

$$\beta=(1-\alpha_1)\{1-(\mu_c/\mu)\}$$

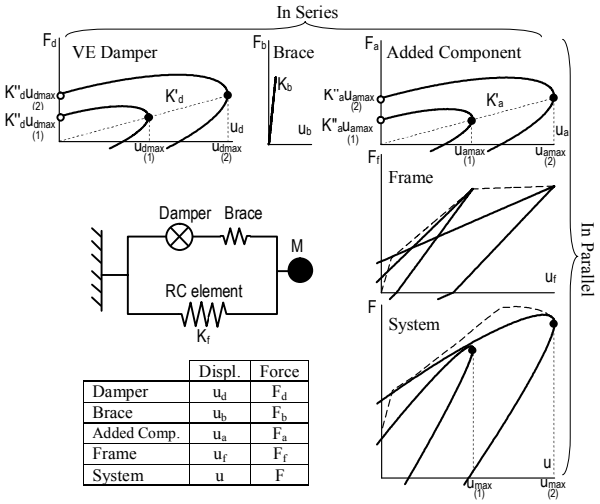


Figure 3. Force and displacement relationship of structural components of SDOF system.

$1<\mu$: $q=2p[1-p\mu^{0.4}(1+\mu_c)/\{2\mu_c+\alpha_1(1-\mu_c)\}]$

The stored energy of system can be easily estimated by

$$E_s=(pK_f+K'_a)\cdot u_{\max}^2/2 \tag{11}$$

The damping ratio of system is estimated by Eq. (12).

$$h_{eq}=h_{eq,v}+h_{eq,p}=\frac{E_p+E_v}{4\pi E_s} \tag{12}$$

$$h_{eq,v}=\frac{E_v}{4\pi E_s},\quad h_{eq,p}=\frac{E_p}{4\pi E_s} \tag{13a,b}$$

When building frame subjected to random excitation, it develops different hysteresis loops because loading stiffness depends on the maximum deformation experienced by frame. The ductility ratio of frame varies from 0 to maximum randomly. In order to include this effect in the analysis, the average damping method proposed by Newmark & Rosenbluth (1971) is used in this study. The average damping ratio of system was estimated by Eq. (14).

$$h_{eq,ave}=\frac{1}{\mu}\int_0^{\mu}h_{eq}(\mu')d\mu' \tag{14}$$

3 DAMPER DESIGN BASED ON PERFORMANCE CURVE

3.1 Response reduction of VE system

The evaluation method of response reduction of passive control building has been proposed based on the elastic response spectrum previously. In this section, the design method for RC structure added with VE damper is constructed by extending the previous method. The displacement spectrum, pseudo-velocity spectrum, pseudo-acceleration spectrum are defined as S_d, S_{pv} and S_{pa}, respectively. From any one of the three spectra, the other two spectra can be calculated in terms of Eq. (15).

$$S_d(T_f,h_f)=\frac{T_f}{2\pi}S_{pv}(T_f,h_f)=\left(\frac{T_f}{2\pi}\right)^2 S_{pa}(T_f,h_f) \tag{15}$$

The response reduction is the combination effect of decreased vibration period and increased damping effect by adding VE damper into structure. We define the ratios of the displacement u, force F of passive system to the displacement and force of original elastic frame u_{el}, F_{el} as displacement reduction ratio R_d, pseudo-acceleration reduction ratio R_{pa}, respectively.

$$R_d=\frac{S_d(T_{eq},h_{eq})}{S_d(T_f,h_f)}=D_h\frac{T_{eq}}{T_f}\frac{\bar{S}_{pv}(T_{eq},h_f)}{S_{pv}(T_f,h_f)} \tag{16a}$$

$$R_{pa}=\frac{S_{pa}(T_{eq},h_{eq})}{S_{pa}(T_f,h_f)}=D_h\frac{T_f}{T_{eq}}\frac{\bar{S}_{pv}(T_{eq},h_f)}{S_{pv}(T_f,h_f)} \tag{16b}$$

where $\bar{S}_{pv(T_{eq},h_f)}$ is the average pseudo-velocity spectrum over period range from T_0 to T_{eq} (Kasai et al. 2005, 2009). The reason to use averaged pseudo-velocity spectrum is in that the spectrum is smoothed and the possible difference between the spectrum value at T_f and T_{eq} can be reduced in such a way.

Assume the pseudo-acceleration spectrum in short-period and pseudo-velocity spectrum in medium- to long-period are identical, respectively, the response reductions of structure can be rewritten as

$$R_d=D_h\frac{T_{eq}(T_{eq}+T_0)}{2T_f^2},\ R_{pa}=R_d\left(\frac{T_f}{T_{eq}}\right)^2\quad(S_{pa}=\text{Const.}) \tag{17a,b}$$

$$R_d=D_h\frac{T_{eq}}{T_f},\qquad R_{pa}=R_d\left(\frac{T_f}{T_{eq}}\right)^2\quad(S_{pv}=\text{Const.}) \tag{18a,b}$$

where D_h is called as damping effect factor, it describes the response reduction ratio due to increase of damping of system. Equation (19) is used for calculating D_h, where a=25 in case of real earthquake motions, and other different values will be used if artificial earthquake motions are used. (Kasai et al. 2003).

$$D_h=\sqrt{(1+\alpha h_f)/(1+\alpha h_{eq})} \tag{19}$$

Given the loss factor η_d and storage stiffness ratio K''_d/K_f, calculate T_0/T_f, T_{eq}/T_f, and h_{eq}, and then obtain R_d and R_{pa} by using Eqs. (17) and (18). The plot for R_d-R_{pa} estimated for varied parameters is defined as "performance curve".

Assume K_b/K_f =3, μ_c = 0.1, α_1 = 0.22, α_2 = 0.01 and h_f = 0.02, the performance curves for μ = 0.75 and μ=1.5 are plotted in Fig. 4 and Fig. 5, respectively. Fig. 4(a) and Fig. 5(a) are based on constant pseudo-acceleration spectrum S_{pa}, Fig. (4b) and Fig. (5b) are based constant pseudo-acceleration spectrum S_{pa}. For comparison, the performance curves for elastic system with μ=1 are plotted in broken line in each figure.

The performance curves as plotted in Figs. 4 and 5 show the ratios of the displacement and acceleration responses of VE system to those of initial elastic frame. Using the performance curves, the responses of elasto-plastic VE system can be easily obtained after the elastic response of initial system is calculated. The necessary damper quantity for achieving a target response level can also be easily determined bases on such performance curves.

3.2 Passive control design based on performance curve

The already-known include the initial period T_f, initial damping factor h_f, all structural parameters for RC frame, brace stiffness ratio K_b/K_f, target ductility ratio μ. Based on the performance curve, the passive control design to determine the quantity of damper can be performed as following.

(1). Make performance curves for target ductility ratio μ.
(2). Calculate responses of elastic frame u_{el}, F_{el}.
(3). Calculate the response reductions R_d, R_{pa}.
(4). Determine the storage stiffness ratio K''_d/K_f, with an assumed loss factor η_d.
(5). Get the pseudo-acceleration reduction R_{pa}, and subsequently get maximum shear force of system.

If both the target maximum force and maximum displacement are satisfied, the design is finished.

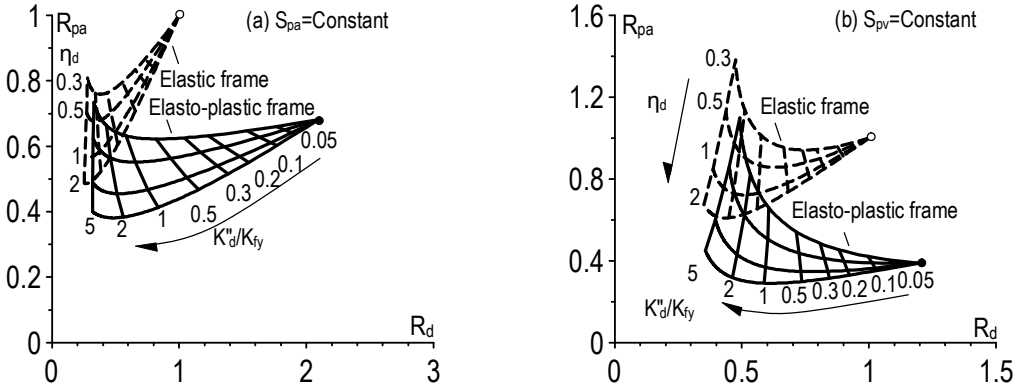

Figure 4 Performance curve (μ=0.75, K_b/K_f=3, μ_c=0.1, α_1 = 0.22, α_2 = 0.01)

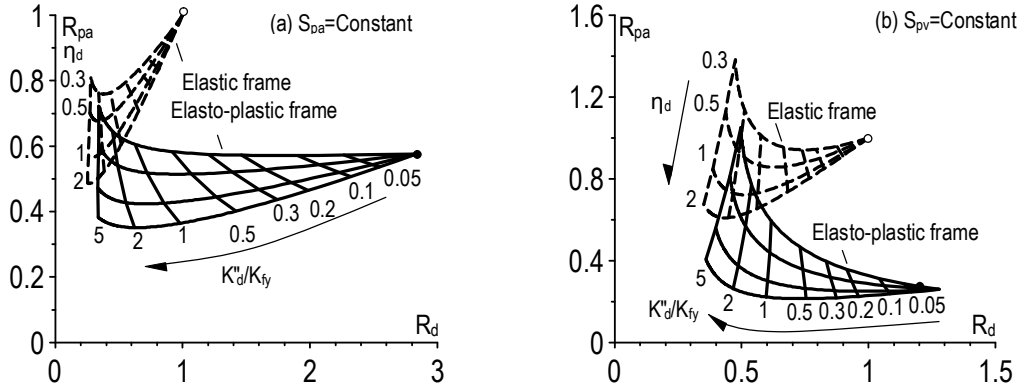

Figure 5. Performance curve (μ=1.5, K_b/K_f=3, μ_c=0.1, α_1 = 0.22, α_2 = 0.01)

4. DAMPER DISTRIBUTION RULE FOR MDOF SYSTEM

4.1 Design procedure

As outlined in Sec. 1, the present design method contains a rule to optimize damper distributions so as to produce uniform story drift angle that matches with the target value even for frames of irregularly distributed structural parameters.

The writers developed a series of design methods for elastic and elasto-plastic frames with various types of dampers, and validated them by extensive numerical tests considering arbitrary parametric distributions. The present study for the first time extends the previous methods to RC building typically having complex hysteretic properties.

The general design procedure is shown as follows.

Step 1. Establish the required basic design data, including mass m_i and story height h_i of each story of building, and specify the target drift angle, design spectrum and earthquake motions for dynamic analysis.

Step 2. Establish the constitutive model for each story based on the pushover analysis, and construct a MDOF shear beam model for building.

Step 3. Reduce the degree of freedoms to get an equivalent SDOF model at target displacement level.

Step 4. Determine the necessary damper quantity for SDOF system through performance curves.

Step 5. Distribute damper into each story of MDOF system (Section 4.3).

Step 6. Examine the performance of passive control building by time history analysis.

4.2 Conversion of MDOF frame to SDOF frame

The conversion of MDOF structural frame into an equivalent SDOF frame is divided into three cases according to the target drift angle θ_t. Firstly, the elastic stiffness of the equivalent SDOF system is estimated by,

$$K_f=\sum_{i=1}^{N}K_{fi}h_i^2/H_{eff}^2\,,\quad H_{eff}=\sum_{i=1}^{N}m_iH_i^2/\sum_{i=1}^{N}m_iH_i \qquad (20a,b)$$

where H_{eff} is the effective height of the RC building, and straight-line mode giving uniform story drift angle is assumed, as often considered by the writers (Kasai et al. 2006, 2010).

The storage and dissipated energies are respectively assumed equal between equivalent SDOF system and MDOF system, namely,

$$\frac{1}{2}pK_f(H_{eff}\theta_t)^2=\sum_{i=1}^{N}E_{si}\,,\quad qK_f(H_{eff}\theta_t)^2=\sum_{i=1}^{N}E_{pi} \qquad (21a,b)$$

In case of μ_i>1, namely, yielding happens in one or more stories at target drift angle θ, it is assumed similarly that μ>1 holds true for SDOF system. In addition to the previous two constraint conditions, μ_c and α_2 of SDOF system are assumed to be the average value of μ_{ci} , α_{2i} of each story level of MDOF frame (Eq. (22)). v

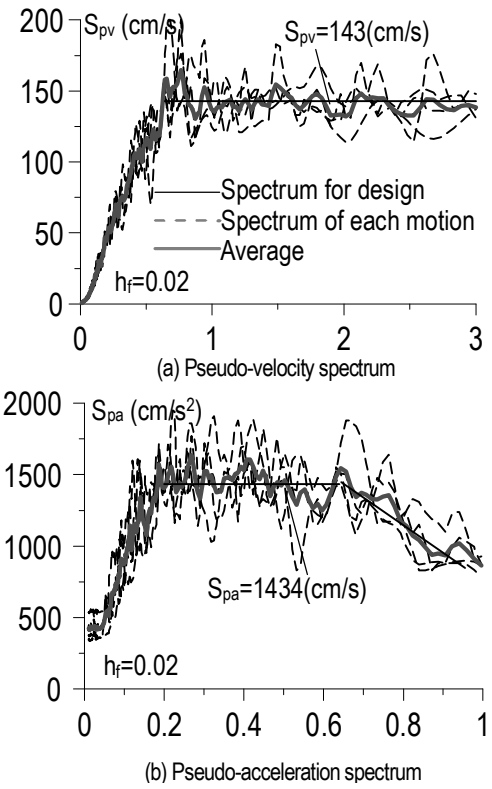

Figure 6 Response spectra of ground accelerations

$$\alpha_2=\frac{1}{N}\sum_{i=1}^{N}\alpha_{2i}\ ,\quad \mu_c=\frac{1}{N}\sum_{i=1}^{N}\mu_{ci} \tag{22a,b}$$

In this way, an equivalent SDOF system is determined. It is noted that the equivalent SDOF system depends on the target displacement level, because the equivalent SDOF is made based on the equivalence of damping and period SDOF and MDOF systems at specified performance level.

4.3 Damper distribution rule for MDOF system

The damper quantity obtained for equivalent SDOF system is distributed to each story of MDOF system by using the following two constraint conditions.

(a) The equivalent damping factors of SDOF and MDOF passive control systems are equal.

(b) The equivalent stiffness of passive control MDOF system at target drift angle is proportional to the story shear force Q_i acting on each story.

Equations (23) and (24) are constructed based on the above conditions.

$$\frac{E_v+E_p}{2\pi(K'_a+K_{eq,f})(H_{eff}\theta)^2}=\frac{\pi\sum_{i=1}^{N}\eta_{ai}K'_{ai}(h_i\theta_t)^2+\sum_{i=1}^{N}E_{pi}}{2\pi\sum_{i=1}^{N}\{(K'_{ai}+K_{eq,fi})(h_i\theta)^2\}} \tag{23}$$

$$\frac{Q_i}{\{K_{fi}p_i+K'_{ai}\}h_i}=\frac{\sum Q_i}{\sum\{K_{fi}p_i+K'_{ai}\}h_i} \tag{24}$$

The storage stiffness of viscous damper distributed to i-th story K''_{di} is obtained as Eq. (25).

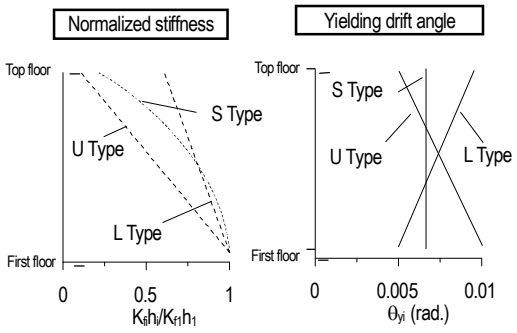

Figure 7. Stiffness and yielding drift distributions

$$K'_{di}=\left[\frac{\sum E_{pi}/\pi\theta^2-\eta_a\sum K_{fi}p_ih_i^2}{(2h^m-\eta_a)\sum Q_ih_i}\cdot\frac{Q_i}{h_i}-K_{fi}p_i\right]\cdot\left(\frac{K'_d}{K_b}+\frac{1}{\Gamma_d}\right) \tag{25}$$

5. ACCURACY VERIFICATION

Time history analysis is performed to verify the accuracy of present design method. A suit of 6 artificial earthquake motions are used. The motions are scaled so that the averaged S_{pa} between 0.16s and 0.64s equal to 1434cm/s^2, and averaged S_{pv} over 0.64s equal to 143cm/s. Figure 6 shows the pseudo-velocity and pseudo-acceleration spectrum for each earthquake motion and their average.

10-story RC building structures are considered. The building has height of 42m and elastic period of 1.26s. Three distribution patterns of initial stiffness are considered, which include S-type where stiffness is proportional to the shear force Q_i, and L-type and U-type where the lower stories and upper stories, respectively, are relatively weak compared to S pattern. Three yield drift angle distribution patterns are considered. S-type has identical yielding drift angle of 1/150 in each story. L-type, U-type have linear distribution of θ_{yi} between 1/200 and 1/100 over the height (Fig.7). The target drift angle is set to be 1/150 and 1/100, respectively. Accordingly, 9 frames designed to 2 types of target drift angle and 6 earthquake motions, a total of 108 cases are investigated.

Figure 8 shows the accuracy of the present damper design methods per frame stiffness distribution type. The broken line denotes the averaged story drift of frame of 3 types of yielding drift angle distribution pattern, for each earthquake motion. The solid line shows the averaged story drift of passively controlled system designed by the present method, the story drift is averaged over three types of yielding drift distribution pattern and 6 earthquake motions. One can see that the present method shows good accuracy.

6. CONCLUSIONS

This paper proposed a passive control design method for RC structure added with elasto-plastic damper. The dynamic properties of the system constituted by the main frame and the added component in parallel are discussed, the variation of equivalent period and damping with respect to system's parameters were described.

The dampers are designed by tuning the equivalent stiffness of the system so that an optimum equivalent

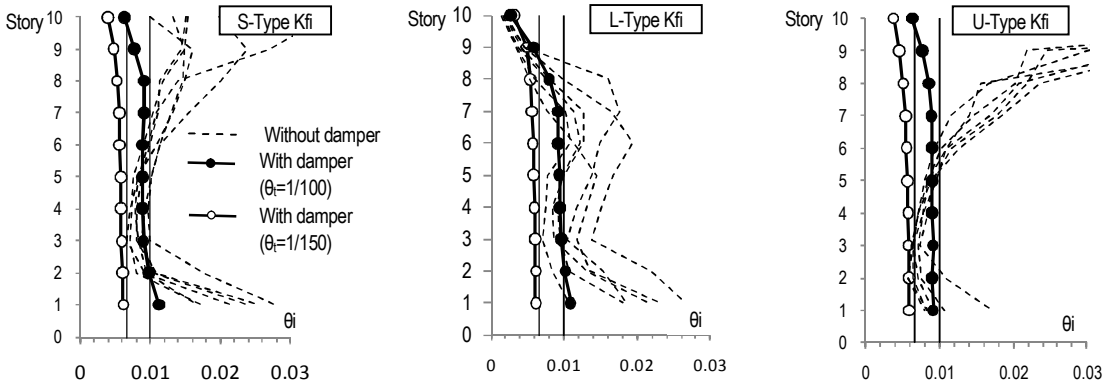

Figure 8. Comparison of story drift between structures with and without damper

stiffness distribution can be achieved at target drift by adding VE dampers, while the earthquake energies are dissipated by VE dampers as well. The time history analysis on structures with irregular distribution of structural parameters was performed, the good accuracy of the proposed method was verified.

Abstract: This paper presents a new vibration control system using the viscoelastic dampers. In the proposed devices, the vibration energy is absorbed through shear deformation of viscoelastic material. The system is based on a quasi-linear motion mechanism. Consequently, bracing members are subjected only to tensile force. This can eliminate the brace-buckling problem and the rod members can be employed as bracing. The seismic response analysis is conducted for steel moment frames with the proposed vibration control system. Energy dissipation characteristics are examined using time-history response results of energy. Maximum story drift angle distributions and time-history response results of displacement show that the proposed device can reduce the seismic response of the frames effectively.

1. INTRODUCTION

Recent research has developed various devices for vibration control systems to reduce earthquake damage to structures. Passive dampers, one type of vibration control device, absorb seismic energy and enhance the seismic performance of structures by reducing drift, velocity, and acceleration demands of structures.

Viscoelastic dampers have been investigated extensively as passive dampers. The damper comprises some layers of viscoelastic material bonded with steel plates. The energy input to structures is absorbed through shear deformation of the viscoelastic material. For velocity-dependent dampers such as viscoelastic dampers, numerous mechanical models and damper devices have been developed (Ibrahim et al. 2007). Ooki et al. (2009) proposed application of viscoelastic dampers to light-gage steel frames having tension braces. Kasaki et al. (2005) investigated the dynamic behavior of a wood frame with a shear link passive control mechanism involving a K-brace. Natsubori et al. (2005) proposed a wall-type viscoelastic damper using styrene-olefin material.

Steel dampers have also been developed. They dissipate seismic energy through the yield deformation of steel dampers, which are inexpensive and which require minimal maintenance. Therefore they have been widely adopted to reduce the seismic response of structures. Steel dampers are classifiable into three types by their yield deformation: axial-yield type such as buckling-restrained braces (Sabelli et al. 2003); shear-yield type such as shear panels (Chan et al. 2009); and bending-yield type such as U-shaped steel dampers (Gao and Tagawa 2009).

This study investigates passive energy dissipation devices using viscoelastic dampers based on a quasi-linear motion mechanism. In the proposed device, only tension force is generated in bracing members and brace buckling need not be considered. In this paper, seismic response analysis is conducted for steel moment frames considering the proposed vibration control system. Energy dissipation characteristics are examined using time-history response results of energy. Maximum story drift angle distributions and time-history response results of displacement show that the proposed device can reduce the seismic response of the frames effectively.

2. OUTLINE OF ENERGY DISSIPATION DEVICE

2.1 Quasi-Linear Motion Mechanism

Figure 1 portrays the Chebyshev linkage, which realizes a quasi-linear motion mechanism. While hinges C and D move rightward and leftward, middle point E moves on the approximate straight line g. Figure 2 portrays the proposed energy dissipation system. Figure 3 portrays the proposed energy dissipation scheme. As presented in Figure 3(a), a connection member is pin-supported and viscoelastic dampers are installed under the connection member. Two rods intersect from the edge of the connection member. As presented in Figure 3(b), when the frame deforms under a lateral load, the viscoelastic materials in the damper exhibit shear deformation. Tensile axial force is generated in the rods, but compression axial force is not generated. When the direction of the lateral load reverses, tensile axial force is generated immediately in an opposite rod. This behavior is based on characteristics of the quasi-linear motion mechanism.

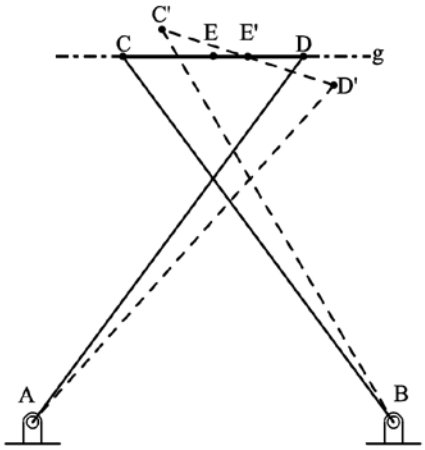

Figure 1 Quasi-Linear Motion Mechanism

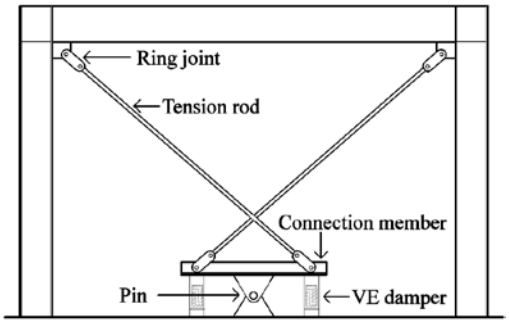

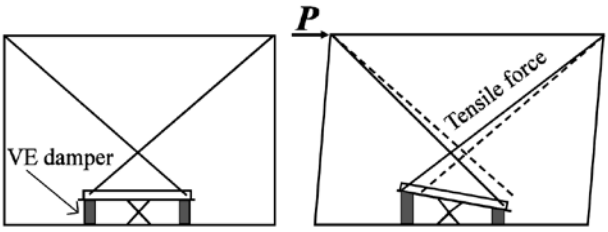

Figure 2 Proposed Energy Dissipation System

(a) Before Deformation (b) After Deformation

Figure 3 Energy Dissipation Scheme

2.2 Viscoelastic Damper

Viscoelastic (VE) materials usually consist of polymers or glassy substances and have the property of dissipating energy in the form of heat when subjected to deformation (Ou et al. 2007). The VE materials in dampers show a complicated behavior that is dependent on the vibration frequency, velocity and temperature. Reportedly, the VE material of styrene-olefin can reduce the influence of temperature variation(Natsubori et al. 2005).

The overall behavior of typical VE dampers can be represented using a spring and a dashpot in parallel such as a Kelvin model. Styrene-olefin material can be represented using a four-element model, as shown in Figure 4, where dynamic characteristics K_1, C_1, and C_2 depend on shear strain. K_2 is the elasto-plastic spring. The VE materials damping modulus and stiffness decrease when the shear strain of the VE material increases.

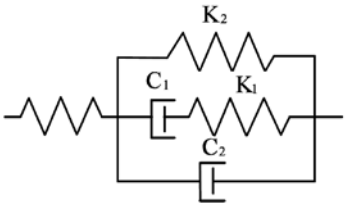

Figure 4 Four-Element Model

3. DESIGN OF ANALYSIS STRUCTURES

3.1 Design of the Moment Frame

Figure 5 shows the steel moment frame without dampers that consist of three bays of 6.0 m and the story heights of 4.0 m. The steel sections of H-350×350×12×19 for columns and H-450×200×9×14 for beams are used in the Model frame, and the yield strength of the steel material are assumed to be 259 N/mm^2. The mass of each story is set as 87 tons. The story shear coefficient in the first story at the final stage of the nonlinear static pushover analysis was obtained as C_B=0.432. The eigenvalue analysis provided the fundamental natural period as 0.845 s. Stiffness-proportional damping is considered with a 2% damping ratio for the first mode throughout this paper.

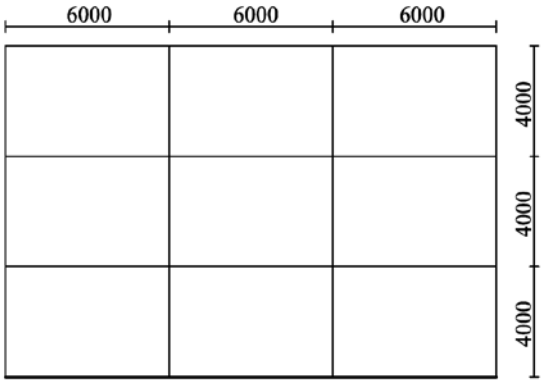

Figure 5 Steel Moment Frame (Model-A)

3.2 Design of the Damping Device

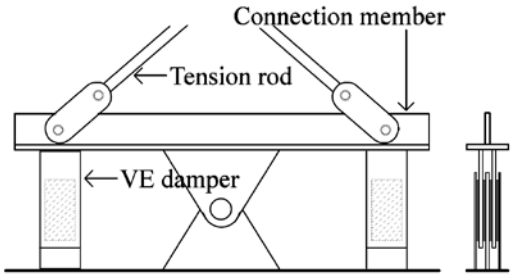

Figure 6(a) portrays the damping device detail that composes of VE dampers, tension rods, and pin-supported connection member. Figure 6(b) shows the analysis model in which some rigid truss member form both the connection member and the pin-support. The bracing members were 52 mm diameter tension rods. Table 1 presents values of VE damper parameters.

3.3 Description of Analysis Structures

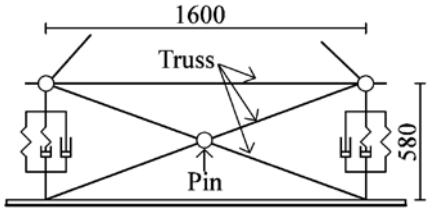

Figure 7 shows analysis models. Model A is the moment frame without dampers described in Section 3.1. Models B, C, and D have the proposed dampers. For Models B and C, one damping device is located on the ground level. For Model B, tension rods are connected to the top story at the center bay. For Model C, tension rods are connected to the top story at the outside bay. For Model D, damping devices are located at all stories.

4. SEISMIC RESPONSE ANALYSIS

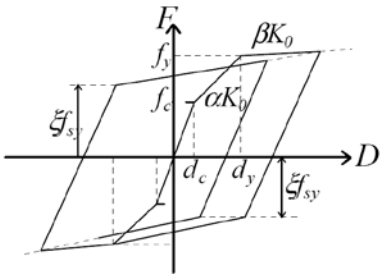
This section presents results of nonlinear dynamic analysis for moment frames with and without proposed devices. The characteristics and advantages of the proposed device are examined through comparison of analysis results.

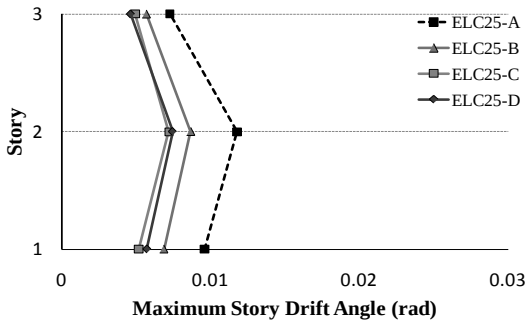
4.1 Analysis Models and Conditions

The nonlinear dynamic analysis program SNAP ver. 5 was adopted for this study. The beams and columns were modeled using beams and columns elements. The rods were molded using the elastic spring element "EL1". The VE material was modeled using the VE damper element "VET".

Figure 8 shows hysteresis loops of member ends in beams and columns. The following values are assumed: f_y=644.9 kN·m, α=0.99, β=0.001, and ξ=0.7 for columns, and f_y =426.53kN·m, α=0.99, β=0.001, and ξ=0.7 for beams. Tension rods were assumed to be elastic and modeled using spring elements.

The 1940 El Centro earthquake record, the 1952 Taft earthquake record, the 1968 Hachinohe earthquake record, and the 1995 Japan Meteorological Agency (JMA) Kobe record were used for input ground motions. The seismic duration of 30 s was considered for all motions. Acceleration records used in the analysis were scaled so that the maximum velocity was equal to 25 and 50 cm/s. Table 2 shows the maximum velocity (Max. *V*) and maximum acceleration (Max. Acc.) of the scaled motions. The scaled ground motions of Max. *V*=50 cm/s represent severe earthquakes considering the fact that the dynamic design practices of high-rise buildings in Japan often use the scaled motions of Max. *V*=50 cm/s as severe earthquakes.





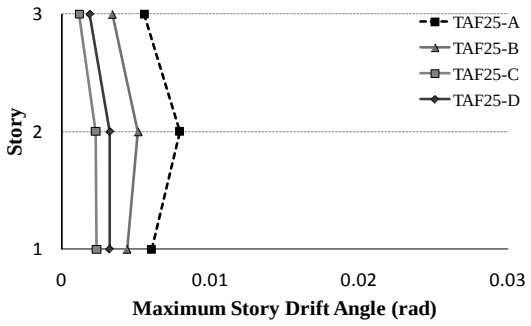


Figure 8 Hysteresis Loops

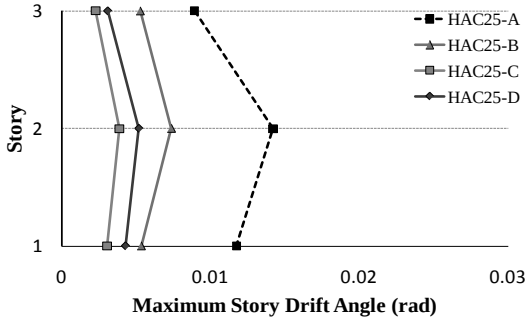
Table 2 Seismic Ground Motions Used for Analysis



Input motion	Max *V*	Max. Acc.	Duration
El Centro	25 cm/s	255.4 cm/s^2	30 s

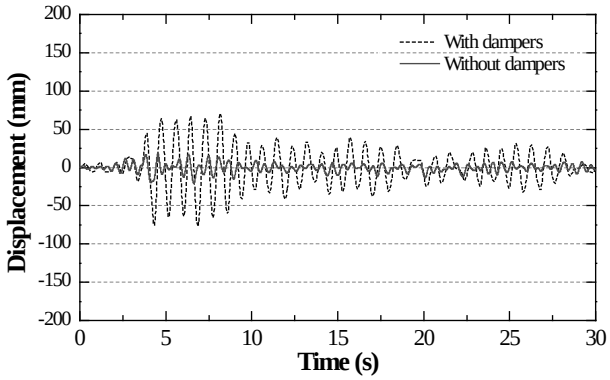
4.2 Analysis Results

Figures 9 and 10 depict the maximum story drift angle distributions for the cases of Max. V=25 cm/s and 50 cm/s, respectively. For Max. V=25 cm/s, the maximum story drift angle in the models with dampers is smaller than 0.01 rad. Model C exhibits the lowest story drift.



For Max. V=50 cm/s, in all cases except for Kobe 50 of Model B, the maximum story drift angle distributions were reduced by locating the proposed damping device. Models C and D show similar amounts of story drift angle reduction. It can be described that Model C is more effective because only one damping device is used.

Figures 11 and 12 show time-history responses of displacement for Max. V=25 cm/s and 50 cm/s. From these figures, the performance of the proposed device can be examined by comparing cases with and without the proposed devices. Displacement is reduced by implementing the proposed device. Table 3 presents maximum displacement and the rate of the value with the device to that without the device. The rate for the cases of Max. V=25 cm/s is lower than that of Max. V=50 cm/s for each input ground motion.

Table 3 Maximum Displacement (mm)

Input motion		Without Device	With Device	Rate
El Centro	25 cm/s	113.84	66.745	0.59
	50 cm/s	145.49	136.49	0.94
Taft	25 cm/s	136.72	35.67	0.26
	50 cm/s	165.22	92.332	0.56

Figures 13 and 14 depict the time-history response of energy for Max. V=50 cm/s in Models A and C, respectively. The performance of the proposed device can be examined by comparing the results for Model A and Model C. In the figures, Ei, Ek, Es, Ed, and Ev represent the total input energy, kinetic energy, strain energy, damping energy, and viscoelastic energy. As Figure 14 shows, the strain energy is reduced dramatically, but the viscoelastic energy increases, which indicates that a large amount of input energy is dissipated in the proposed damping device.

Figure 15 portrays the location of plastic hinges and indicates their yield ratio at the final stage of seismic response analysis for Taft earthquake of Max. V=50 cm/s. In Model A, the plastic hinges form at all beam-ends, except for the top beams and at the column-base in the first story. For Model B, the number of forming plastic hinges did not decrease, although the yield ratios decreased. For Models C and D, both the number of plastic hinges and their yield ratios decreased. Especially for Model C, the deformations were reduced dramatically, implying that the location method of the proposed damping device for Model C is best if the bracing members are permitted to connect the ground level damping device directly to the top story beams in the other bay.

5. Conclusions

This paper presented the seismic response analysis of the steel building frames to investigate the effectiveness of

the proposed vibration control system with VE dampers. The system is based on the quasi-linear motion mechanism. Consequently, the brace buckling problem is eliminated. For that reason, the steel rod members are applicable as the bracing member.

To confirm the applicability of the proposed device, seismic response analyses were conducted for three-story frame models with and without the proposed device. The maximum story rotation angle distributions, the time-history responses of top displacement and energy and plastic hinge formations were examined. The results of analyses demonstrated that the proposed device can reduce the seismic response of the frames. The location method of the damping device influenced the damping effect. The analysis model in which the bracing members connect the damping device at the ground level directly to the top story beams in the other bay exhibited the greatest reduction of deformation.

Abstract: Passive energy dissipation technology has been proven to be thoroughly reliable and robust through numbers of practical applications, hence various supplemental dampers have been applied to the building structure for acquiring better performance when it is subjected to earthquakes, severe windstorm, bomb blast and other transient disturbances. The focus of this paper is on a simplified design method for energy-dissipated building structure with viscous dampers. The analytical model of viscous damping structure is researched, and the specific process scheme and content frame are proposed, with the thought of designing the main structure and energy-dissipating components respectively. Besides, the related calculating equations about performance parameter design of energy-dissipating components are also listed. In the end, with the combination of a practical milt-story reinforced concrete frame which is retrofitted by energy dissipation devices, the corresponding analysis and demonstration are conducted. It is concluded that this simplified design method is feasible and effective, and can be well applied to energy-dissipated structure with viscous dampers, so as to satisfy various demands of structural performance objectives under different earthquake risk levels.

1. INTRODUCTION

In the past several decades, a variety of energy dissipation devices have been developed, such as oil dampers, viscous dampers, visco-elastic dampers, metallic dampers, friction dampers, etc. However, for the control target of simultaneous stress and deflection reduction in the structure subjected to a transient, maybe viscous damper is a better option among above dampers, due to its pure viscous behavior of having an out-of-phase relationship between the column restoring force and damper force (Symans and Constantinou, 1998). Fluid viscous dampers, which are initially used in the military and aerospace industry, typically consist of a piston head with orifices contained in a cylinder filled with a highly viscous fluid, and dissipate the external energy by transferring it into heat (Housner et al., 1997; Hanson and Soong, 2001). Since viscous dampers have such characteristic, they are regarded as a more effective approach for structural vibration control and consequently applied to seismic protective design of many new constructions or retrofitting buildings after the cold war in 1990. The projects of new constructions using viscous dampers mainly refer to Dubai Racetrack Stadium (Dubai/United Arab Emirates, 2009), Hydra Waves (Mazatlan/Mexico, 2009), T.F.Green Airport Parking Garage (Providence/USA, 2009), Meguro Gajoen Extension Project (Tokyo/Japan, 2010), etc. And the projects of retrofitting buildings equipped with viscous dampers contain 865 Market Street – San Francisco Centre (San Francisco/USA, 2009), Nagoya-Port Government Office Main Building (Nagoya/Japan, 2009), ASE I – Mihai Eminescu Project (Bucharest/Romania, 2009), Gas Company Building (Sichuan/China, 2009), Dujiangyan Middle School Buildings (Sichuan/China, 2010), etc.

With the extensive application of passive energy dissipation technologies in the industry and the civil construction field, researches on practicable and feasible design methods, as well as rational analytical model, become hot topic and key issues recently (Martinez-Rodrigo and Remero, 2003; Uetani et al., 2003; Kasai and Kibayashi, 2004; Sorace and Terenzi, 2008). As to energy-dissipated structures with viscous dampers, the corresponding design process and analysis methods are given by various standards from different countries, such as ATC-33 (Applied Technology Council, 1997), FEMA-273/274 (Federal Emergency Management Agency, 1997), NEHRP 2000 Provision (National Earthquake Hazards Reduction Program, 2000), FEMA-368, NEHRP 2003: Chapter 15 – Structures with Damping Systems, EC 8: Design of Structures for Earthquake Resistance – Part 1 (Eurocode 8, 2003), ASCE 7-05: Seismic Provisions (American Society of Civil Engineering, 2005), JSSI Manual: Design and Construction Manual for Passively Controlled Buildings (Japan Society of Seismic Isolation, 2003/2005/2007), Technical Specification for Building with Energy Dissipation Devices (People's Republic of China Profession standard, 2011), etc.

Although the proposed design procedures for viscous damping structures vary with different standards, their philosophies are essentially based on the response spectrum

modal analysis method. And besides, it is probably no exaggeration to say that, among above standards, only JSSI Manual provides instructions and specific steps for design of viscous dampers in passive control system at present. Pursuant to this Manual, the main design process of passive control system with viscous dampers can be depicted as follows (Kasai and Kibayashi, 2004): Firstly, given an earthquake input of a smooth response spectrum, the peak displacement and base shear of the frame prior to damper installment can be predicted easily from the response spectrum. Then, the target reduction ratios of displacement and base shear can be estimated based on the required performance. Finally, considering the target reduction ratios and the performance curve, the necessary stiffness of viscous dampers and braces can be determined, while optimum design solution to control both displacement and force can also be found from the performance curve. Moreover, it is noteworthy that the performance curves model buildings as an equivalent SDOF system, and therefore design of viscous dampers in the multistory case can be conducted by modeling the MDOF frame to an equivalent SDOF system.

In this case, for optimum design of energy-dissipated structure with viscous dampers in Japan, adopting the design method in JSSI Manual and performing time-history analysis (using appropriately selected ground motions) to confirm or make modification in design may be a good option. However, as to the building constructions using passive control technology in China, it is difficult to directly apply the JSSI Manual method to practical design, because of the limitations in performance curves caused by different response spectrum. Furthermore, several controversial points in JSSI Manual method are still needed to be think over: (a) the validity of SDOF system correspond to MDOF system; (b) determination of the target DRR (displacement reduction ratio), especially for the design of existing MDOF system with different DRR on each storey; (c) distribution of total viscous dampers is conducted based on their loss stiffness (which is defined as the force at zero displacement divided by the peak deformation in steady-state responses of the viscous damper, JSSI Manual) proportioning to storey stiffness of MDOF system, while the influences of weak floors are not taken into account. Pursuant to this, improving the JSSI Manual method to suit China's current seismic design codes, or exploring a new simplified design procedure for energy-dissipated structures with viscous dampers will definitely be helpful for the application of viscous dampers to seismic design in China, and which is also the focus and purpose of this paper.

2. VISCOUS DAMPING PRINCIPLE

Regardless of new constructions or existing buildings need to be damped, the added viscous dampers (usually with required braces or support members) are deemed as supplemental system to main structure, hence the design of viscous dampers-braces and design of frame can be conducted respectively (it is particularly easy to understand for seismic retrofit of existing buildings). Based on this idea, the analytical model of viscous damping frame structures can be divided into the model of main frame and the model of viscous dampers-braces (VDB), as shown in Figure 1.

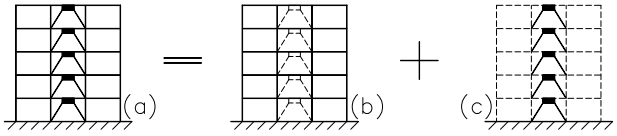

Figure 1 Analytical Model of Viscous Damping Structure: (a)damping model, (b)model of frame, and (c)model of VDB

Based on Dynamics of Structure, it is assumed that the actual damping in structures can be idealized satisfactorily by a linear viscous damper or dashpot with a equivalent viscous damping, hence for the frame structure without dampers, the equation of motion is:

$$[M]\{\ddot{u}(t)\}+[C]\{\dot{u}(t)\}+[K]\{u(t)\}=-[M]\{\ddot{u}_g(t)\} \quad (1)$$

Where [*M*], [*C*], [*K*] are the mass matrix, the damping matrix, the stiffness matrix of the frame structure respectively; $u(t)$, $\dot{u}(t)$, $\ddot{u}(t)$ are its displacement vector, velocity vector, acceleration vector respectively; and $\ddot{u}_g(t)$ is the ground acceleration vector.

For viscous damping structures, the effect from added viscous dampers and required braces should be taken into account and represented by the Γ operator. Generally speaking, the Γ operator has the comprehensive force provided by added mass, added damping and added stiffness, the equation of motion for such system becomes:

$$[M]\{\ddot{u}(t)\}+[C]\{\dot{u}(t)\}+[K]\{u(t)\}+\Gamma = -([M]+[M_a])\{\ddot{u}_g(t)\} \quad (2)$$

$$\Gamma=[M_a]\{\ddot{u}(t)\}+[C_a]\{\dot{u}(t)\}+[K_a]\{u(t)\} \quad (3)$$

Where [M_a], [C_a], [K_a] are the added mass matrix, the added damping matrix, the added stiffness matrix provided by viscous dampers and required braces respectively.

However, for practical design and analysis, the added mass of viscous dampers and required braces is far less than the whole structural mass, and the added stiffness of required braces closely depend on braces stiffness, damping constant and load frequency (Fu and Kasai, 1998). Thus, to simplify calculations in preliminary design phase, usually assuming [M_a] = 0, and approximately neglecting the added stiffness (i.e. [K_a] = 0, only for handily estimate the required added damping in preliminary design), thus, the Γ operator can be consequently expressed by the pure viscous damping force:

$$\Gamma=\{F_d(\dot{u}(t))\}=\left\{C_d\cdot Sgn(\dot{u}(t))\cdot|\dot{u}(t)|^{\alpha}\right\} \quad (4)$$

Where $F_d(\dot{u}(t))$ is the viscous damping force, which directly depends on the relative velocity across the damper; *Sgn* denotes the symbolic function, C_d is the damping

coefficient, α is the velocity exponent ($0 \le \alpha \le 1$). Apparently, equation (4) signify linear viscous damper when α=1, and friction damper when α=0.

Besides, it is noted that whether the viscous dampers are linear or nonlinear, the damping force can be approximately converted into an equivalent linear expression under the equal dissipated energy, hence we get:

$$\Gamma = \left\{ F_d \left(\dot{u}(t) \right) \right\} = [C_0] \left\{ \dot{u}(t) \right\} \tag{5}$$

Where $[C_0]$ is the matrix of added equivalent linear damping (while α=1 in this case).

Substituting equations (3), (4) and (5) in Eq. (2) gives:

$$[M] \left\{ \ddot{u}(t) \right\} + ([C] + [C_0]) \left\{ \dot{u}(t) \right\} + [K] \left\{ u(t) \right\} = -[M] \left\{ \ddot{u}_g(t) \right\} \tag{6}$$

Equation (6) can be solved by the Implicit Newmark Iterative method or the Discrete Fourier Transform method (Soong and Dargush, 1997), it is noteworthy that the added viscous dampers can be preliminarily designed according to the added equivalent damping ratio to the main frame structure (here the impact of added stiffness provided by viscous dampers and braces doesn't take into account, but it actually has on the structure).

3. SIMPLIFIED DESIGN PROCESS

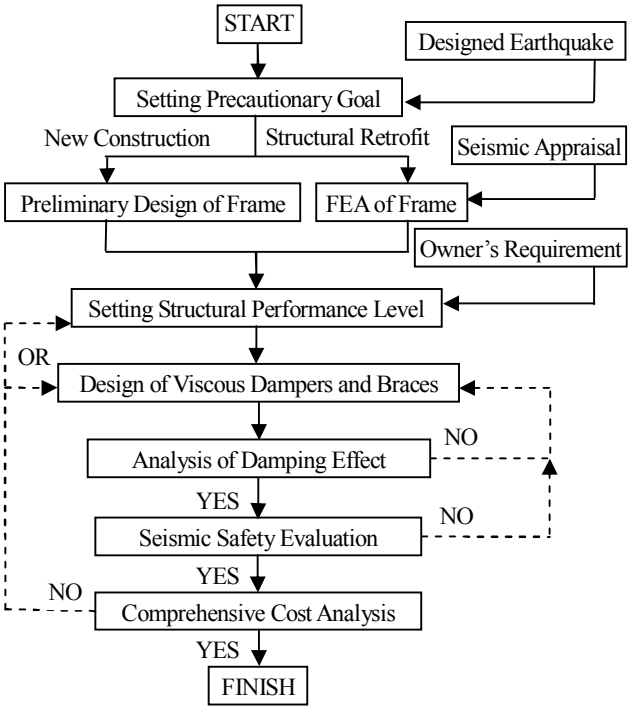

Figure 2 Process of Simplified Design Method for Viscous Damping Structures

Based on above viscous damping principle and design philosophy, a simplified design method for energy dissipated frame structure using viscous dampers (and required braces) is presented in this paper, and its design process and contents are briefly introduced, as shown in Figure 2, It is seen that the simplified design process has the following steps:

Step (1): Setting precautionary goal. According to certain seismic precautionary grade and seismic protection classification of the structure, given by Code for seismic design of buildings (GB 50011-2010) and Standard for classification of seismic protection of building constructions (GB 50023-2008), the seismic precautionary goal shall be determined under designed earthquake.

Step (2): Design and analysis of the frame structure. Design of viscous dampers used in new constructions is surely different with that used in retrofitting buildings, thus work in this step has the following two cases: (a) for seismic retrofit of existing buildings, three-dimensional finite element model of the primary structure shall be established to estimate its present seismic performances, with the combination of seismic appraisal results (while sometimes a simplified model under the hypothesis of lumped mass is used for fast design). However, (b) for damping design of new constructions, the preliminary design of the frame shall be conducted based on the requirements which are half grade or one grade lower than those of the precautionary goal preset in step (1), and then the design of supplemental system shall be conducted in the light of designed performances of the frame.

Step (3): Setting structural performance level. For energy dissipated structure, its performance level shall be set in conformity with the owner's requirements and the seismic precautionary goal determined in Step (1). To be specific, the seismic precautionary goal of structure closely associates with Code's requirements, hence the limit values of storey drift rotation of structures, which can be taken as the representative of structural performance level, vary with different Codes in different countries (e.g.: the three-level design objective of China's current codes, the classified performance levels from SEAOC, etc.).

Step (4): Design of viscous dampers and braces. As presented by Weng (Weng et al., 2011), the damping forces given by viscous dampers can be calculated according to the required added damping ratio (obtained by structural performances set in Step (3)) for certain design objective. Thus, as to the calculated damping forces, location of added viscous dampers and pattern of required braces (e.g.: diagonal brace and chevron brace) shall be firstly determined in the light of architecture function and structural arrangement, and then distribution of added viscous dampers corresponding to different storey shall be conducted, as well as the design of component parameters, such as damping coefficient and velocity exponent of viscous dampers, stiffness of required braces, etc.

Step (5): Analysis of damping effect. Since viscous dampers are of nonlinear characteristic, time-history method shall be adopted to analyze the viscous damping structure in practical design. Combining the philosophy of performance-based design under moderate earthquake and the reference to load-based design under minor earthquake (in China's seismic design code), the damping effect

provided by added viscous dampers (and required braces) is verified based on the control of structural dynamic behavior under minor earthquake and moderate earthquake. Specially, the main contents in this step include the calculation of added equivalent damping ratio, the comparison of storey shear forces, storey drifts (or storey drift rotation) between primary frame and damped frame, the check of damped frame's performances, etc (Weng et al., 2011). Whereas, if the damping effect to the frame structure is unsatisfactory, then the design process must return to Step (4) and design of viscous dampers and braces must be readjusted until acquiring desirable damping effect.

Step (6): Seismic safety evaluation. After acquiring satisfactory damping effect in Step (5), seismic safety evaluation to the whole structure shall be conducted subsequently, it is mainly comprised of the elastoplastic deformation check, the safety assessment of added system and the verification of seismic design details. Likewise, if the results of seismic safety evaluation in this step are unsatisfactory, the design process shall also return to Step (4) for a new circular iterative calculation.

Step (7): Comprehensive cost analysis. As to adopting a new strategy (e.g.: using viscous dampers), an estimate of its total cost shall be required in contrast to traditional strategies. It is noteworthy that this cost analysis shall be conducted with taking various factors into account, such as the construction cost of supplemental system, its maintenance charge for operation, the reduced losses of damped frame under new seismic hazard (and the inherent value of primary building only for structural retrofit), etc. A key task for designers is to seek the optimal safety-cost ratio for seismic design of the structure, which means to give reasonable seismic safety at significantly lower cost. Thus, if the owner dissent from the cost of current damping scheme, the design process shall be back to Step (4) or Step (3) for a redesign.

4. DAMPER PARAMETER DESIGN

For viscous damping structures, viscous damper is an indispensable part of supplemental system to dissipate seismic energy, however sometimes the brace or support member (for diagonal brace-damper) and also the lead rubber bearing (LRB, for chevron brace-damper) are required, as shown in Figures 3~4.

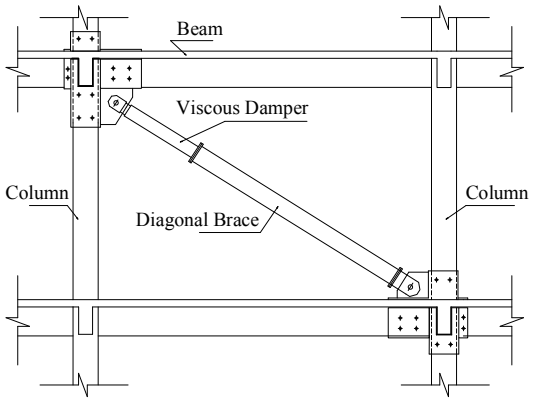

Figure 3 Diagonal Brace-Dampers

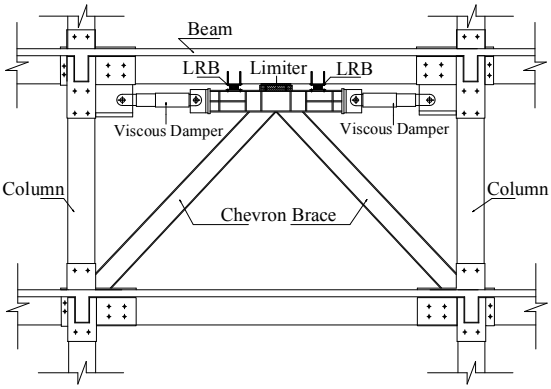

Figure 4 Chevron Brace-Dampers

4.1 Estimate of Required Equivalent Damping Ratio

Based on the viscous damping principle mentioned above, for simplified analysis in preliminary design phase, the added stiffness to the frame provided by viscous dampers and braces is approximately neglected, so as to handily estimate the required added damping ratio of the structure, and therefore viscous dampers can be designed according to the required equivalent damping ratio.

Under this circumstance, rational estimate of the required damping ratio seems to be crucial for the whole design process. And usually, for RC frames which are mainly of shearing deformation, its required damping ratio can be estimated based on energy concept (Uang and Bertero, 1988), or Code Response Spectrum (e.g.: GB 50011-2010):

$$\Delta_{\max} / \Delta_T = \alpha_{0.05} / \alpha_{(\zeta_r+0.05)} \tag{7}$$

Where Δ_{max} is the maximum value of storey drift in the structure (obtained under moderate earthquake), Δ_T is the corresponding target value of storey drift, ζ_r is the required equivalent damping ratio, $\alpha_{0.05}$ is seismic influence coefficient for the damping ratio of 5%, while $\alpha_{(\zeta_r+0.05)}$ is for the damping ratio of $(\zeta_r+0.05)$ (based on GB 50011-2010).

Moreover, it is noteworthy that the final required damping ratio shall not exceed 25% in general, whereas it should be counted according to 25% once exceeds, and which also means that the primary frame shall be further strengthened in this case.

4.2 Calculation of Expected Damping Force

According to the calculated required damping ratio, the expected designed damping force can be obtained by the following equations (14) ~ (18):

$$F_{di} = \zeta_r \cdot \beta \cdot Q_i \tag{8}$$

$$\beta = \left[\pi \sum_{j=1}^{N} \Delta_j Q_j \right] \Big/ \left[2 \sum_{i=j_1}^{N_1} \Delta_i Q_i (1 - \mu_i) \right] \tag{9}$$

$$\mu_i = \Delta_{di} / \Delta_i \tag{10}$$

Where F_{di} is the expected damping force on the i^{th} floor, β is the design coefficient related to storey damping force and shear force, Q_i is the storey shear force on the i^{th} floor under moderate earthquake, N is the total number of floors for calculation, N_1 is the total number of floors equipped with viscous dampers, j_1 is the initial number of floor equipped with viscous dampers, μ_i is the ratio of yield displacement of viscous damper and peak value of storey drift on the i^{th} floor, Δ_{di} is the yield displacement of viscous damper on the i^{th} floor.

Specially, to achieve the best damping effect of added viscous dampers, an optimizing coefficient is introduced to modify the designed damping forces given by Eq. (8), which conducted as follows:

$$F_{(di)m} = \Omega_i \cdot F_{di} \tag{11}$$

$$\Omega_i = \Delta_i \Big/ \left(\sum_{j=1}^{N} \Delta_j / N \right) \tag{12}$$

Where: $F_{(di)m}$ is the modified designed damping force on the i^{th} floor, Ω_i is the optimizing coefficient on the i^{th} floor. However, it is noteworthy that the optimizing process of designed damping forces here is advisory but not compulsory step, and therefore the final designed damping forces are usually interpolated in the value range between the designed damping forces given by Eq. (8) and the modified damping forces given by Eq. (11) with the combination of the allowable storey drift rotation for buildings in China's seismic design code (i.e. GB 50011-2010).

Based on above equations in this section, it is concluded that the expected added damping forces in the frame are designed based on storey shear forces, and optimized in the light of storey drifts.

4.3 Design of Brace Stiffness and LRB

As to the system of viscous dampers and required braces, the brace stiffness definitely affects the energy-dissipated capability of viscous dampers (Weng and Lu, 2004), and therefore the brace stiffness related to viscous dampers is recommended as:

$$K_b \geq \left(6\pi / T_1\right) \cdot C_v \qquad \text{(Linear VD)} \tag{13}$$

$$K_b \geq 3K_c = F_{d,\max} / u_{d,\max} \qquad \text{(Nonlinear VD)} \tag{14}$$

Where K_b is the stiffness of the brace used to support the viscous damper in the frame structure; T_1 is the fundamental vibration period of the damped frame structure; C_v is the linear damping factor of the linear viscous damper (VD), which corresponds to T_1 and is usually determined by testing; K_c is the loss stiffness of the nonlinear VD (while in practical design it may be approximately replaced by elastic stiffness for simplicity); $F_{d,\max}$, $u_{d,\max}$ are the maximum designed damping force and the maximum relative displacement of the nonlinear VD under moderate earthquake respectively.

Besides, when the chevron brace is used to install the viscous dampers, a lead rubber bearing (LRB) corresponds to a viscous damper is used to prevent the out-of-plane instability of supplemental system, and also to improve the seismic performance of damped frame, especially for the structure with inadequate lateral stiffness. In practical design, analysis of LRB is typically conducted by using Bouc-Wen plastic model or bilinear model.

4.4 Examination of Equivalent Damping Ratio

Since the added viscous dampers are designed based on the estimate of required damping ratio (in section 4.1), thus the real equivalent damping ratio provided by designed viscous dampers shall be examined in contrast to the predicted required damping ratio. As to the damped frame structure (mainly exhibit shearing deformation), when the torsion effect is not taken into consideration, its total strain energy and energy dissipated by viscous dampers can be estimated by the following equations (15) ~ (18):

$$\zeta_a = W_c / (4\pi \cdot W_s) \tag{15}$$

$$W_c = \sum_{i=1}^{m} W_{ci} \tag{16}$$

$$W_{ci} = \sum_{j=1}^{d_i} E_{d(ij),\max} = 4 \sum_{j=1}^{d_i} \gamma \cdot \left| F_{d(ij)}(t) \cdot \Delta_{d(ij)}(t) \right|_{\max} \tag{17}$$

$$W_s = \frac{1}{2} \sum (F_i \cdot u_i) = \frac{1}{2} \sum_{j=1}^{n} (M_j \cdot \left| \ddot{u}_j(t) \cdot u_j(t) \right|_{\max}) \tag{18}$$

Where ζ_a is the equivalent damping ratio added by the viscous dampers; W_c is the energy dissipated by all added viscous dampers in one cycle under expected displacement of the structure; W_s is the total strain energy of the damped structure under expected displacement; W_{ci} is the energy dissipated by viscous dampers on the i^{th} floor in one cycle under expected displacement of the structure; $E_{d(ij),\max}$ is the peak energy in one cycle dissipated by the j^{th} damper on the i^{th} floor; γ is the discount coefficient of hysteresis hoop area of dampers; $E_{d(ij)}(t)$ is the damping force of the j^{th} damper on the i^{th} floor at the fixed time t; $\Delta_{d(ij)}(t)$ is the stroke of the j^{th} damper on the i^{th} floor at the fixed time t; F_i is the horizontal seismic action characteristic value of the i^{th} mass, and u_i is the displacement of the i^{th} mass correspond to aforementioned F_i; M_j is the lumped mass of the j^{th} floor; $u_j(t)$ is the peak displacement of the center of mass on the j^{th} floor at the fixed time t, $\ddot{u}_j(t)$ is the peak acceleration of the center of mass on the j^{th} floor at the fixed time t.

5. CASE STUDY

The engineering case used for this paper is an existing RC frame in Sichuan, China, which was constructed in 2007 and performed well in 2008 Wenchuan earthquake. The

frame was originally designed based on seismic precautionary intensity 7, measure grade 3-rd, design earthquake group 1-st and the response spectra characteristic period 0.35 *s* (design parameters in China's code). However, after Wenchuan earthquake, the precautionary grade of the frame is increased to seismic precautionary intensity 8, and therefore the corresponding design parameters are upgraded to measure grade 2-nd, design earthquake group 2-nd and the response spectra characteristic period 0.4 *s*.

Since the present seismic capability of the frame under original design is obviously insufficient to resist the new precautionary earthquake, as seen in Table 1, the frame was retrofitted by using viscous dampers (with braces and/or LRB in necessary) after earthquake, and therefore it can be used to demonstrate the feasibility and reliability of the simplified design method proposed in this paper for energy-dissipated frame structure with viscous dampers.

Table 1 Structural Information under Intensity 8

Floor	Height (*m*)	Storey mass (*t*)	X-direction			Y-direction		
			Stiffness (*kN/mm*)	Shear force (*kN*)	Rotation (*rad*)	Stiffness (*kN/mm*)	Shear force (*kN*)	Rotation (*rad*)
5	3.6	1122	776	4844	1/1560	472	4894	1/966
4	3.6	1294	1066	9474	1/1213	718	9284	1/809
3	3.6	1232	1088	12690	1/896	758	11852	1/629
2	3.6	1232	1062	15224	1/716	760	13186	1/520
1	4.4	1270	654	16864	1/476	564	14826	1/422

Noted: here the storey shear forces of the frame structure are obtained under moderate earthquake.

For comparative research, two approaches are used to distribute viscous dampers to the multistory frame, one is the simplified method (i.e. Designed based on storey shear forces and optimized by storey drifts), and the other is the JSSI Manual method (i.e. Distributed by dampers' loss stiffness in proportion to storey stiffness). It is also noted that the total designed horizontal forces provided by added viscous dampers under moderate earthquake (i.e. total viscous coefficient in horizontal direction) in these two approaches are expected to be equal and obtained by the simplified method. Pursuant to this, three different structural states (ST0, ST1 and ST2) are denoted in the comparative analysis, and here ST0 is the primary frame, ST1 is the damped frame using the JSSI Manual method, ST2 is the damped frame using the simplified method.

Table 2 Designed Damping Force of ST2 (*kN*)

Floor	X-direction		Y-direction

Total horizontal damping forces			X: 20800 *kN*, Y: 19200 *kN*	

Table 2 shows the design of expected damping forces provided by added viscous dampers of ST2, as explained in Section 4.2, the final designed damping forces are usually interpolated in the value range between the originally designed damping forces (i.e. based on storey shear forces) and the optimal damping forces (i.e. based on storey drifts), and it is also noted that the actual damping forces may be partly different with the aforementioned final designed damping forces, due to the limitation of damper categories.

According to the actual damping forces in Table 2, distribution of added viscous dampers (with required braces) in ST1 and ST2 can be conducted, as listed in Table 3, here the DB signifies Diagonal Brace to the damper, while the other dampers default to the brace pattern of Chevron Brace. Moreover, for cost saving, viscous dampers of a Chinese product are used in this engineering case, and the corresponding design mechanics properties of which are assigned to: α=0.18, and C_v=150, 200, 300, 450 $kN/(mm/s)^{\alpha}$ for the categories of ***A***, ***B***, ***C*** and ***D*** respectively (as listed in Table 3), where α is the velocity exponent, C_v is the damping coefficient. Besides, damper category ***A***, ***B***, ***C***, ***D*** are expected to provide the designed damping forces of 300 *kN*, 400 *kN*, 600 *kN*, 900 *kN* respectively at the expected velocity of 150 *mm/s*, here it is also noted that the peak damping force of the viscous damper shall be no less than 120% of the designed damping force.

Table 3 Distribution of Added Viscous Dampers

Floor	ST1		ST2	
	X-direction Dampers (N×category)	Y-direction Dampers (N×category)	X-direction Dampers (N×category)	Y-direction Dampers (N×category)
4	8×***D*** (DB)	8×***C***	8×***C*** (DB)	4×***B*** +4×***A***
3	8×***D*** (DB)	8×***C***	8×***C*** (DB)	4×***C***+4×***B***
2	16×***A***	8×***C***	16×***B***	4×***D*** +4×***C***
1	16×***A***	8×***C***	8×***C*** +8×***A***	8×***C*** +4×***B***
total damping forces	20400 *kN*	19200 *kN*	20800 *kN*	19200 *kN*

Noted: the horizontal damping force of the viscous damper with DB pattern shall be reduced by a discount coefficient of 0.75, and here the minor deviation of total horizontal damping forces along X direction between ST1 and ST2 is neglected.

The installed location of viscous dampers and braces in this engineering case are shown in Figures 5~6, which are installed on the 1st to 4th Floor. Here it is also noted that VD: DB signifies viscous damper with diagonal brace, and VD: CB signifies viscous damper with chevron brace.

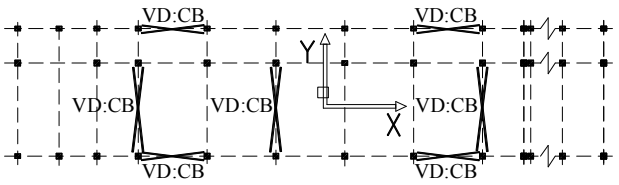

Figure 5 Schematic Diagrams of Installed Location for Viscous Dampers and Braces on the 1st ~2nd Floor

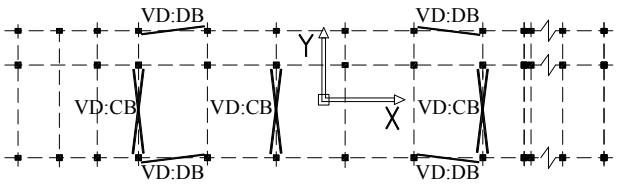

Figure 6 Schematic Diagrams of Installed Location for Viscous Dampers and Braces on the 3rd ~4th Floor

Comparative analysis of these three structural states under minor earthquake (Mi-E), moderate earthquake (Mo-E) are conducted through time-history analysis method, the corresponding analytical results are shown in Figures 7~14, and the elasto-plastic analysis results of ST0 and ST1 are obtained through static elasto-plastic analysis (pushover) method, as listed in Table 4.

Table 4 Comparison of Elasto-Plastic Analysis of ST0 and ST2

Seismic action direction	ST0		ST2		Comparison	
	Base shear $Q1(kN)$	Drift rotation $R1(rad)$	Base shear $Q2(kN)$	Drift rotation $R2(rad)$	$\frac{Q2-Q1}{Q1}$	$\frac{R2-R1}{R1}$
X-dir.	16616	1/108	13762	1/143	-17.2%	-24.5%
Y-dir.	14574	1/94	12260	1/123	-15.9%	-23.6%

Noted: here the pushover analysis is conducted based on Chinese design response spectrum (GB 50011-2010).

As to Figures 7~10, it is noted that the Shear Forces on each storey here are obtained from section cut forces of frame columns (without damper-braces), and Shear Capacity is represented by the calculated bearing shear force of floors in primary frame (i.e. according to the original design under seismic precautionary intensity 7), which can be obtained through PKPM2008 software and be surely below the actual bearing shear force of Floors in the light of real reinforcing bars. Thus, it is concluded that demonstration and comparison of storey shear forces conducted here is still conservative and safe to some degree.

In addition, from above Figures, it is easily seen that both ST1 and ST2 have excellent structural performances and remarkable control effect compared to ST0, which means the viscous dampers can be appropriately designed to control seismic behavior of non-ductile structures. Performance of ST2 is deemed to be more rational and well-distributed than that of ST1, which indicates that the principle of distributing viscous dampers by their loss stiffness in proportion to storey stiffness of the frame in JSSI Manual method sometimes may be inappropriate, especially for multistory frame structures with weak floors, seismic behavior of some weak floors may not be effectively controlled in such method. Whereas, as addressed in the simplified design method in this paper, viscous damping forces to multistory frame structure are firstly designed by storey shear forces and consequently optimized by storey drifts, which is demonstrated to have good control effect of the whole structure compared to the distribute principle of only in proportion to storey stiffness in the JSSI Manual method.

Table 4 shows the comparative elasto-plastic analysis results of ST0 and ST2, it can be seen that the storey drift of ST2 is reduced by about 24% than that of ST0, and the base shear force is reduced by about 15%, which also indicates that the simplified design method proposed in this paper can be used to control and improve the structural seismic behavior under strong earthquake.

6. CONCLUSIONS

For any simplified design methods proposed for energy-dissipated structures, the demonstration of its validity and reliability shall be absolutely required, and always conducted with comprehensive considerations, such as the damping effect analysis and seismic safety evaluation of the damped structure (designed in this simplified method), the cost analysis and comparison of the selected damping strategy with other control strategies (to seek the optimal safety-cost ratio for seismic design).

In preliminary design phase, the required added damping ratio, which can be given based on Code Response Spectrum or energy concept, is usually estimated under the assumption of neglecting the added stiffness provided by viscous dampers and braces (but it actually has on the structure), and therefore obtain the expected damping forces.

In JSSI Manual method, the viscous dampers to multistory structure are distributed based on their loss stiffness being in proportion to storey stiffness, which sometimes may be inappropriate in practical design, especially for multistory structures with weak floors, the control effect of the whole structure is always unsatisfactory. Whereas, in the simplified method proposed in this paper, viscous damping forces are firstly designed by storey shear forces and consequently optimized by storey drifts, which is proved to have better control effect and well-distributed performance of the whole structure.

With the combination of case study, it is concluded that the simplified design method proposed in this paper can evidently decrease complex iterative steps of computational analysis, but still be accurate enough for practical design; furthermore, since the required damping ratio for structural seismic design can be flexibly adjusted, this simplified design method can well conform with China's current design codes, and also can be well applied to engineering design for satisfying various demands proposed by owners or achieving structural performance objectives under different earthquake risk levels.

Abstract: The behavior of a self-centering moment resisting frame (SC-MRF) is characterized by connection gap opening and closing at beam-to-column interfaces under earthquake loading. An SC-MRF uses high strength post-tensioning (PT) strands to precompress the beams to the columns and to close the gaps that develop under earthquake loading, returning the frame to its initial position (i.e. the frame is "self-centering"). In this study, a beam web friction device (WFD) is included in each beam-to-column connection to dissipate energy under seismic loading. Unlike a special steel moment-resisting frame with welded connections (W-SMRF), an SC-MRF can be designed to survive the design basis earthquake (DBE) without structural damage, providing the potential for immediate occupancy (IO) performance, and to suffer only modest damage under the maximum considered earthquake (MCE), providing collapse prevention (CP) performance. A 7-bay, 4-story SC-MRF prototype building located in the Los Angeles area was designed using a performance-based design procedure. A 0.6-scale model of two bays of the SC-MRF building was developed and subjected to simulated earthquakes using the hybrid simulation method. This paper focuses on the MCE-level performance of the SC-MRF. Results from MCE hybrid simulations and quasi-static pushover tests are presented. A special PT strand fuse was developed and installed in the SC-MRF. The behavior of the SC-MRF with the fuses in a quasi-static pushover test is also presented.

1. INTRODUCTION

Conventional steel moment resisting frames (MRFs) are often used in building systems to resist earthquake loading. Under the maximum considered earthquake (MCE), conventional MRFs are designed to develop plastic deformation and significant damage in main structure members, resulting in buildings with large residual drift and the potential for being near collapse. To avoid large residual drift, post-tensioned (PT) beam-to-column connections for self-centering MRFs (SC-MRFs) were developed by Ricles et al. (2001). These connections are designed to develop gap opening at the beam-to-column interface rather than permanent plastic deformation in the beams. PT forces close the gap and enable the connections to self-center upon unloading. Energy is dissipated by special devices located in the connection regions.

This paper presents the seismic response of a 0.6-scale 2-bay 4-story SC-MRF test frame. This SC-MRF uses beam web friction devices (WFDs) at beam-to-column connections to dissipate energy. WFDs are attached to the columns and located on the beam webs to avoid interference with the floor slab. PT strands are used to provide self-centering forces. The floor diaphragm is attached to only one bay of the SC-MRF to avoid restraining the gap opening behavior at the connections. The SC-MRF is designed using a performance based design (PBD) approach and associated design criteria to achieve immediate occupancy (IO) performance under the design basis earthquake (DBE) and collapse prevention (CP) performance under the MCE. The details of the SC-MRF prototype frame, the test frame, the simulated floor diaphragm in the experiments, DBE simulation results, and the IO performance evaluation are given by Lin et al. (2009) and Ricles et al. (2010). This paper focuses on the MCE performance. MCE-level design criteria, results from MCE simulations and quasi-static tests, and a CP performance evaluation are presented and discussed in this paper. A fuse that helps to control the force in the PT strands under the MCE is also presented in this paper.

2. SC-WFD CONNECTION

2.1 Connection Details

Figure 1(a) schematically shows an SC-MRF with self-centering WFD (SC-WFD) beam-to-column connections. The PT strands run parallel to the beams across multiple bays. The WFD (Figure 1(b)) includes two channel sections (denoted friction channels) welded to the column flange. Brass plates are sandwiched between the webs of the friction channels and the beam web to enable reliable

friction at the interface. The channels are clamped to the beam web by friction bolts shown in Figure 1(b) which produce normal force on the friction surface. The friction channels are welded to the column flange after the friction bolts are tightened. The shape of the friction channels reduces the tendency for weld shrinkage to pry the friction channels away from the friction surface. Slotted holes in the beam web shown in Figure 1(c) accommodate the travel of the friction bolts during connection gap opening and closing. Shim plates shown in Figure 1(b) are welded to the column flange to provide good contact surfaces for the beam flanges. Reinforcing plates are welded to the outside surfaces of the beam flanges to avoid excessive yielding in the beam flanges. Reinforcing plates are also welded to the inside surfaces of the column flanges to avoid excessive yielding around the holes for the PT strands.

2.2 Moment-Rotation Behavior

The moment M in the SC-WFD connection is controlled by the axial force in the beam (P) and friction force resultant in the WFD (F_f) as follows:

$$M = Pd_2 + F_f r \quad (1)$$

Where d_2 = distance from the beam section centroid to the center of rotation (COR) and r = distance from the WFD friction force resultant to the COR. The COR is at the point of contact of the beam compression flange with the column. The product $F_f r$ is the friction moment denoted M_{Ff}. F_f is calculated as:

$$F_f = 2\mu N_b n_b \quad (2)$$

where μ = friction coefficient, N_b = normal force produced by one friction bolt, n_b = total number of friction bolts in a WFD, and the factor 2 accounts for the two friction surfaces in the WFD, one for each friction channel. μ=0.4 is used for design. P includes the PT force, T, and an axial force from inertial force transferred by the floor diaphragm P_{fd} as follows:

$$P = P_{fd} + T \quad (3)$$

where T can be estimated as follows:

$$T = T_o + \bar{\theta}_r [2 d_2 k_b k_s / (k_b + k_s)] \quad (4)$$

where T_o = initial PT force; k_b and k_s = axial stiffness of the beam and axial stiffness of the PT strands within one bay, respectively; and $\bar{\theta}_r$ = average relative rotation of the connections over one floor level.

The imminent gap opening moment (M_{IGO}) is calculated from Eq. (1) using $P=T_o$. The effective energy dissipation ratio β_E for a connection can be estimated as follows:

$$\beta_E = M_{Ff}/M_{IGO} \quad (5)$$

Studies by Seo and Sause (2005) show that as β_E is increased, the lateral drift demand for an SC system is reduced. The theoretical maximum value of β_E for an SC system is 50%. Based on results from Seo and Sause (2005), 25% is selected as the lower bound design value for β_E.

3 PERFORMANCE-BASED DESIGN

3.2 Design Objectives

Performance-based design (PBD) objectives for SC-MRFs (Figure 2) were modified from previous work by Garlock et al. (2007). The DBE and MCE are the two seismic input levels considered. The MCE is a ground motion intensity with a 2% probability of exceedance in 50 years (BSSC 2003). The DBE is a ground motion intensity that is two-thirds that of the MCE (BSSC 2003), with an approximate return period of several hundred years. Immediate occupancy (IO) and collapse prevention (CP) are the target performance at the DBE and MCE level, respectively. IO performance requires essentially no structural damage, and as shown later, does not require the SC-MRF to be unusually strong. Gap opening and minimal yielding (e.g., column base yielding and beam flange yielding with the strain less than twice the yield strain ($2\varepsilon_y$)) are permitted for IO performance. Panel zone yielding, beam web yielding, and beam flange yielding with the strain greater than $2\varepsilon_y$ are permitted for CP performance. PT strand yielding, which can lead to strand fracture, and beam web buckling, which can lead to loss of beam axial and flexural resistance, are not permitted for CP performance.

3.2 MCE Design Criteria

This paper focuses on MCE-level performance. To avoid beam web buckling and PT strand yielding under the MCE. The following design criteria are used:

(i) Beam web compactness criterion: SC-MRF beams should satisfy the compactness criterion of the AISC Seismic Provision (2005):

$$(h/t_w) / \lambda_{ps,MCE} \leq 1.0 \quad (6)$$

where h/t_w = beam web width-thickness ratio, and $\lambda_{PS,MCE}$ = limiting width-thickness ratio calculated as follows:

$$\lambda_{PS,MCE} = \max\{1.12(2.33 - C_a)\sqrt{E/\sigma_y}, 1.49\sqrt{E/\sigma_y}\} \quad (7)$$

where E = Young's modulus, σ_y = nominal yield stress, and $C_a = P_{MCE}/0.9P_y$. P_{MCE} = beam axial force demand under the MCE P_{MCE}. P_y = nominal beam axial yield strength.

(ii) Strand yield criterion: the total PT strand force under the MCE (T_{MCE}) should not exceed 90% of the total PT strand design yield force ($0.9T_{y,des}$) as follows:

$$T_{MCE} / 0.9T_{y,des} \leq 1.0 \quad (8)$$

where $T_{y,des}=0.9T_{u,n}$ and $T_{u,n}$ = total PT strand nominal

ultimate force capacity.

4 EXPERIMENTAL PROGRAM

4.1 Experimental Setup

A 7x7-bay prototype office building shown in Figure 3(a) was designed using the above PBD objectives. The building has four stories above ground level and one basement story. The building is assumed to be located on a stiff soil site in Van Nuys, California in the Los Angeles area. Each perimeter frame has two 2-bay steel SC-MRFs with SC-WFD connections. The SC-MRF design demands (Lin et al. 2009; Ricles at el. 2010) are summarized in Table 1. $\theta_{rf,DBE}$ and $\theta_{rf,MCE}$ are the roof drift demands, $\theta_{s,DBE}$ and $\theta_{s,MCE}$ are the story drift demands, $\overline{\theta}_{r,DBE}$ and $\overline{\theta}_{r,MCE}$ are the demands for the average relative rotation demands under the DBE and the MCE, respectively. The MCE demand-capacity ratios from Eq. (6) and (8) are listed in Table 2. In each SC-MRF, the floor diaphragm (FD) is attached to the beam in one bay (labeled "FD bay" in Figure 3). The beam in the other bay (labeled "sliding bay" in Figure 3) and the columns are free to move horizontally relative to the floor diaphragm to avoid restraining gap opening of the SC-WFD connections.

Considering the symmetry of the building plan, the earthquake response of one quarter of the building was simulated at the NEES Real-Time Multi-Directional (RTMD) earthquake simulation facility at Lehigh University. The hybrid simulation method was used. One 2-bay SC-MRF acting in one direction of the building was simulated by the SC-MRF test frame (Figure 3(b)) as an experimental substructure, and the remainder of one quarter of the building was simulated as an analytical substructure. The SC-MRF test frame is a 0.6-scale model of one 2-bay SC-MRF in the prototype building (Lin 2011). The gravity load bearing system, associated gravity loads, and seismic mass tributary to one SC-MRF, as well as the damping were included in the analytical substructure. Rayleigh damping was used with 2% and 5% damping in the 1st and 3rd modes. The equations of motion were solved using the CR integration algorithm (Chen and Ricles, 2009).

4.2 Floor Diaphragm

During the experiments, the lateral force (i.e., the simulated diaphragm force acting on the SC-MRF test frame) at each level is applied by a hydraulic actuator through a simulated floor diaphragm (Lin 2011). The floor diaphragm is connected to the test frame with steel diaphragm plates, which are fillet welded to the middle of the north-bay beam to simulate the FD bay in the prototype structure.

As shown in Figure 4, when the SC-MRF test frame is subjected to a lateral force at the x^{th} floor (F_x) toward the north (Figure 4(b)), the maximum beam axial force is at the north end of the north-bay beam (denoted NN) and can be estimated as follows:

$$P_{N,x}^{NN} = T_x + (1/4)F_x \quad (9)$$

When F_x is toward the south (Figure 4(c)), the maximum beam axial force is at the south end of the north-bay beam (denoted NS) and can be estimated as follows:

$$P_{S,x}^{NS} = T_x + (3/4)F_x \quad (10)$$

Therefore, the maximum strain in beam flange will occur in the bottom flanges at the NN and NS connections.

4.3 Matrix of Experiments

This paper focuses on the MCE-level performance. The MCE-level experiments (Table 3) included two earthquake hybrid simulations (MCE-1 and MCE-2) and three quasi-static tests (PH, TU, and FU). The spectral acceleration S_a of the ground motion records for the MCE-1 and MCE-2 simulations (Figure 5) are compared with the USGS uniform hazard spectrum (denoted USGS-UHS) for ground motions with a 2% probability of exceedance in 50 years and the ASCE7 (2005) (denoted ASCE7-05) MCE design spectrum. The scaling of the ground motion records is similar to that given in Lin et al. (2009) and Ricles et al. (2010) for DBE ground motions. The S_a values at the test frame fundamental period (T_1=1.26 sec), denoted $S_a(T_1)$, are 0.55g for the USGS-UHS and the ASCE7-05 MCE spectra. For MCE-1 $S_a(T_1)$=0.67g, and for MCE-2 $S_a(T_1)$=0.65g.

The floor displacement profiles used for the quasi-static pushover tests are shown in Figure 6, where a positive floor displacement indicates a displacement to the north. The PH and TU tests were conducted to evaluate the beam buckling and PT strand yield strengths, respectively. The FU test was conducted to evaluate the behavior of the SC-MRF test frame when PT strand fuses were installed at the 3rd floor.

5. EXPERIMENTAL RESPONSES

5.1 MCE-1 and MCE-2 Simulation Results

The floor displacement time histories from the MCE-1 and MCE-2 simulations are shown in Figure 7. The residual story drifts (obtained by dividing the difference in residual displacements of adjacent floors by the story height) are listed in Table 4. The largest residual drift is 0.18% rad from the MCE-2 simulation in the 1st story. These results demonstrate the self-centering behavior of the SC-MRF under the MCE. Table 4 also gives the maximum roof drift $\theta_{rf,max}$, the maximum story drift $\theta_{s,max}$, the maximum of average relative rotation $\overline{\theta}_{r,max}$, the maximum total PT force T_{max}, the loss of PT force after the simulation ΔT normalized by $T_{u,n}$, and the estimated β_E. The average relative rotation $\overline{\theta}_r$ for each floor is taken over four connections, and a positive value corresponds to a north floor displacement. ΔT is the difference in the PT force before the simulation (T_i) and after the simulation (T_{end}). The estimated β_E is based on Eq. (5). $\theta_{rf,max}$=3.2% and 4.6%

rad respectively for MCE-1 and MCE-2, which are smaller and larger values than the design demand $\theta_{rf,MCE}$ =3.9% rad (Table 1). The largest $\theta_{s,max}$=5.8% and 7.2% rad respectively in the 4th story for MCE-1 and MCE-2, which are smaller and larger values than the design demand $\theta_{s,MCE}$=5.9% rad (Table 1). The largest $\overline{\theta}_{r,max}$=5.4% and 6.7% rad for MCE-1 and MCE-2, respectively, which are both larger than the design demand $\overline{\theta}_{r,MCE}$=4.7% rad (Table 1).

The largest $T_{max}=0.81T_{u,n}$ at the 3rd floor from MCE-2, which equals $0.9T_{y,des}$ in Eq. (8). However, yielding did not occur in the PT strands. The measured total PT force T_{exp} (normalized by $T_{u,n}$) vs. measured $\overline{\theta}_{r}$ from MCE-2 simulation is shown in Figure 8, where T_{exp} is compared with the theoretically predicted total PT force T_{th} (calculated from Eq. (4) using the measured T_o, $\overline{\theta}_{r}$, and d_2, as well as the nominal k_s and k_b). The measured $\overline{\theta}_{r}$ is the average of the measured θ_r for the four connections in one floor. θ_r varies for connections at the same floor, and $\overline{\theta}_{r}$ in Eq. (4) accounts for the variation. T_{th} and T_{exp} have good correlation. The difference is within 3% of $T_{u,n}$. T_{exp} decreased during the simulation due to seating of the PT anchorages, and the largest ΔT was 2.5% of $T_{u,n}$ at the 3rd floor during MCE-2 (Table 4).

The typical measured connection moment M_{exp} (normalized by the nominal plastic moment $M_{p,n}$) vs. the measured relative rotation θ_r for each connection in the south bay from the MCE-2 simulation are shown in Figure 9. The positive moment and positive θ_r are when the beam top flange is in compression. θ_r returns to zero upon unloading, which demonstrates self-centering behavior. M_{exp} is compared to theoretical connection moment M_{th} in Figure 9. M_{th} is calculated from Eq. (1) using the measured P, d_2, r, and estimated F_f (using Eq. (2) with N_b=12 kip, which is the design normal force). Good agreement between M_{exp} and M_{th} is shown in Figure 9. M_{exp} is larger than M_{th} while θ_r is larger due to the friction bolt bearing against the longitudinal edge of the beam web slots. Each connection has different post gap opening M-θ_r stiffness for positive and negative θ_r. The stiffness is higher when the inertial force from the floor diaphragm generates a compression force in the beam (Figure 4(c)). The compression force increases the beam axial force P in Eq. (1) and therefore increases the moment M. The estimated β_E from the MCE simulations (Table 4) ranges from 27% to 38%, which is larger than the target β_E as shown in Figure 3(b) due to the friction bolt bearing.

During the MCE simulations, beam flanges yielded at the end of the reinforcing plates. The maximum beam flange strain at the end of reinforcing plates $\varepsilon_{rp,max}=8.65\varepsilon_y$ (MCE-1) and $9.02\varepsilon_y$ (MCE-2) in the bottom flange of the south end of the north-bay beam in the 4th floor (denoted 4FNS). Figure 10 shows the beam yielding and flange distortion from the MCE-2 simulation, but beam web buckling did not occur.

Beam flange strain larger than $2\varepsilon_y$ is expected under the MCE. No the PT strand yielding and no beam web buckling occurred during the MCE simulations, which demonstrated the SC-MRF achieved the CP performance under the MCE.

5.2 PH and TU Quasi-Static Pushover Results

As described earlier, the PH and TU quasi-static pushover tests were conducted to evaluate the beam buckling and PT strand yield strength, respectively. The largest $\theta_{s,max}$=8.4% and 11.1% rad in the 4th story for the PH and TU tests, respectively, which are larger than the design demand $\theta_{s,MCE}$=5.9% rad (Table 1). The largest $\overline{\theta}_{r,max}$=6.8% and 7.9% rad for the PH and TU tests, which are larger than the design demand $\overline{\theta}_{r,MCE}$ =4.7% rad (Table 1).

During the PH test, the largest $\overline{\theta}_{r,max}$=6.8% rad is at the 4th floor, but the largest $T_{max}=0.81T_{u,n}$ is at the 3rd floor, because the nominal value of $d_2k_bk_s/(k_b+k_s)$ in Eq. (4) at the 3rd floor is larger than that at the 4th floor. During the TU test, the largest $T_{max}=0.82T_{u,n}$ at the 4th floor. Although the largest T_{max} from PH and TU tests respectively equals and exceeds 90% the PT strand design yield strength, $0.81T_{u,n}$, yielding did not occur in the PT strands.

The beam bottom flange and web buckled at the south end of the north-bay beam (NS) at the 4th floor during the PH test (Figure 11(a)) and at north end of the north-bay beam (NN) during the TU test (Figure 11(b)). The beam buckled as $\overline{\theta}_{r,max}$=6.8% and 7.9% rad (Table 5) during the PH and TU tests, respectively, which are larger than the design demand $\overline{\theta}_{r,MCE}$=4.7% rad (Table 1). The beam buckling at NS in the PH test occurred at a smaller $\overline{\theta}_{r,max}$ than at NN in the TU test due to the larger beam axial force (compare Eq. (9) and (10)). The largest $\Delta T=0.014T_{u,n}$ and $\Delta T=0.058T_{u,n}$ from the TU and PH tests (Table 5) due to the beam buckling and seating of the PT anchorages.

Figure 12 shows the total PT force (normalized by $T_{u,n}$) vs. $\overline{\theta}_{r}$ at the 4th floor from the TU test. From Points A to B, the beam buckling shortened the beam and caused a loss of the PT force, $\Delta T_{AB}=0.04T_{u,n}$. From Points B to C, the total PT force increased due to the increase of $\overline{\theta}_{r}$. At point C, the PT force decreased due to unloading of $\overline{\theta}_{r}$.

6. PT Strand Fuses

Based on the PBD objectives as shown in Figure 2, under the MCE, the SC-MRF should achieve CP performance by avoiding beam web buckling and PT strand yielding. To prevent beam web buckling under the MCE, beam sizes can be selected to satisfy the beam web compactness criterion (Eq. (6)). Alternatively, beam web longitudinal stiffeners (Kim and Christopoulos, 2008) can be used to avoid beam web buckling. To prevent PT strand yielding, one approach is to increase the number of PT strands, so the stress in each strand remains low under the MCE. However, additional PT strands require larger holes or more holes in the column flanges, which can lead to low cycle fatigue from net section yielding in the flanges. Another approach is to use better anchorages and wedges so PT strands have ductile behavior before fracture (Walsh and

Kurama, 2010). The approach proposed in this paper is using a PT strand "*fuse*", which yields at a specific load to limit the force developed in the PT strands. The developed PT fuse is shown in Figure 13. In the SC-MRF test frame, the fuses were installed at the 3rd floor (Figure 13(a)). Each fuse is aligned with the PT strand, and the PT strand passes through the center of the fuse. Each fuse is supported by the column flange at one end and supports the PT anchorage at the other end. Therefore, each fuse carries the same force as developed in the PT strand.

The typical fuse (Figure 13) is composed of an annealed A513 steel tube and wood (poplar) discs as shown in Figure 13(c) and (d). The typical steel tube has a length of 4 in. and four 3/16 in. diameter holes drilled around the wall at quarter length locations. The purpose of the wood and the holes is to provide controllable inelastic buckling of the tube. The typical normalized force-deformation response of the fuse from a uniaxial test is shown in Figure 14(a), where p_{fs} is the compression force in the fuse, $t_{u,n}$ is the nominal force capacity of a single PT strand used at the 3rd floor of the SC-MRF test frame, $L_{o,fs}$ is the length of the steel tube (i.e. 4 in.), and Δ_{fs} is the fuse axial deformation. The fuse buckled sequently at Points 1 and 2 with $p_{fs}/t_{u,n}$=0.7 and 0.76, respectively, which are less than the value of $0.9T_{y,des}/T_{u,n}$=0.81 given in Eq. (8). The typical deformed fuse from a uniaxial test is shown in Figure 14(b), where the buckling forms uniformly around the circumference of the steel tube wall. The buckling formed at the ends is corresponding Point 1 bucking, and the buckling formed at the mid length is corresponding to Point 2 buckling.

The fuses were installed for each PT strand at the 3rd floor of the SC-MRF test frame, and the FU quasi-static pushover test was conducted to evaluate the response of the SC-MRF test frame with the fuses. Table 5 shows that at the 3rd floor in, T_{max}=0.64$T_{u,n}$ from the FU test is smaller than T_{max}=0.81$T_{u,n}$ from the PH test while $\overline{\theta}_{r,max}$=6.7% rad from FU test is larger than $\overline{\theta}_{r,max}$=6.3% rad from PH test. This result demonstrates that the fuses controlled the force developed in the PT strands, preventing PT strands from yielding. The total PT force (normalized by $T_{u,n}$) vs. $\overline{\theta}_r$ at the 3rd floor from FU test is shown in Figure 15. All fuses started buckle at Point a, which caused a decrease in the total PT force. Then, the total PT force remained constant until unloading at Point b. The response from Point a to Point b shows the ductile behavior of the PT strands with the fuses. The deformed fuses after the FU test are shown in Figure 16. The largest $T/T_{u,n}$=0.64 at Point a, which is less than $p_{fs}/t_{u,n}$=0.7 at Point 1 in Figure 14(a) because the buckling of the fuses did not form uniformly around the steel tube circumferences as observed in the uniaxial test. The permanent buckling of the fuses caused ΔT=0.2$T_{u,n}$ at the end of the FU test. As a result, the fuses need to be replaced after they deform permanently during a severe ground motion.

6. SUMMARY AND CONCLUSIONS

This paper focuses on MCE performance evaluation of an SC-MRF. Performance-based design (PBD) objectives were described, and MCE design criteria used for a SC-MRF to achieve CP performance were given. A 0.6-scale 2-bay 4-story SC-MRF test frame was developed and tested. Two MCE-level ground motions were imposed to the test frame using the hybrid simulation method. Three quasi-static pushover tests were conducted to investigate beam buckling, PT strand yielding strengths, and behavior of PT strands with special fuses, respectively.

The MCE hybrid simulations produced essentially no residual drift, which demonstrates the self-centering behavior of the SC-MRF. The SC-WFD connections provided reasonable energy dissipation for the SC-MRF. β_E was found to be larger than the design due to the friction bolt bearing against the longitudinal edges of the beam web slots. During the MCE hybrid simulations, beam flanges yielded with the largest strain larger than $2\varepsilon_y$ as expected in the PBD approach. Beam web buckling did not occur in the SC-MRF test frame. The largest total PT force reached 90% of the strand design yield strength $0.9T_{y,des}=0.81T_{u,n}$, but yielding did not occur in the PT strands. Therefore, beam web buckling and PT strand yielding in the SC-MRF did not occur during the MCE hybrid simulations, showing that the SC-MRF satisfied the PBD objectives under the MCE and achieved CP performance.

Test results from the PH and TU quasi-static pushover tests showed that the north-bay beam at the 4th floor buckled in the webs and bottom flanges when the largest $\overline{\theta}_{r,max}$ exceeded the design demand for $\overline{\theta}_{r,,MCE.}$ Therefore, the beam web compactness criterion gave the SC-MRF beams sufficient web buckling strength under the MCE. The beam always buckled in the bottom flange, so full plastic hinges do not form in the beam as in a conventional MRF. The largest total PT force exceeded $0.9T_{y,des}=0.81T_{u,n}$ by $0.01T_{u,n}$, but strand yielding did not occur. The strand yield criterion helped prevent PT strands from yielding under the MCE.

To avoid PT strands from yielding under the MCE, a special fuse was developed for the PT strands. The fuses were installed at the 3rd floor of the SC-MRF test frame. The FU quasi-static pushover test was conducted to study the behavior of the PT strands with the fuses. Test results showed that the fuses limited the force developed in the PT strands successfully and helped prevent PT strand yielding. The PT strands with the fuses had ductile behavior. Therefore, using the fuses to protect PT strands from yielding is an option for a SC-MRF to achieve CP performance.

Abstract: An energy dispersion mechanism called "Sacrificial Bonds and Hidden Length" found in some biological systems, such as abalone shells and bones, is the inspiration for new mechanisms for structural control. Sacrificial bonds and hidden length can substantially increase the stiffness and enhance energy dissipation in the constituent molecules of abalone shells and bone. This paper presents a fundamental method for designing and optimizing bio-inspired passive actuators for structural control. A simple optimization method utilizing the Force-Displacement-Velocity (FDV) plots and a statistic approach of linear regression are adopted in this research to find the initial values of the desired parameters for the bio-inspired passive actuator. The illustrative examples, conducted by numerical simulation with experimental validation, suggest that the bio-inspired passive actuator based on sacrificial bonds and hidden length may be comparable in performance to state-of-the-art semi-active actuators, and can also be adaptive to different earthquakes.

1. INTRODUCTION

Abalone shell is 3,000 times more fracture resistant than crystalline calcium carbonate even though it is composed of 97% crystalline calcium carbonate (Jackson, Vincent et al. 1988). Part of the secret is the amazing mechanical performance of the other 3%, which is organic, primarily proteins (Smith, Schaffer et al. 1999), working together with the structural geometry (Fritz, Belcher et al. 1994; Zaremba, Belcher et al. 1996; Schaffer, IonescuZanetti et al. 1997; Evans, Suo et al. 2001). In bone as well, a small percentage by weight of non-collagenous proteins, such as osteopontin, contributes significantly to the fracture resistance (Thompson, Kindt et al. 2001; Hansma, Fantner et al. 2005; Fantner, Rabinovych et al. 2006; Fantner, Adams et al. 2007).

The key points in both abalone shells and bones are: 1) the work that must be done against entropy to stretch the hidden length is of order 30 times greater than the work to break strong bonds, and 2) sacrificial bonds can reform and the work done against entropy is non-destructive (Thurner, Erickson et al. 2006; Thurner, Erickson et al. 2007). This is the goal of this research: to find new ways to dissipate energy from threats such as earthquakes, winds, impacts, or even blasts to civil and mechanical infrastructures, flutter of aircraft wings, bridges, cooling towers, and more.

What can be learned from abalone shell and bone that could help move the field of structural control forward? One lesson that can be learned is how to develop bio-inspired autonomous passive actuators. Both abalone shells and bones have distributed passive actuators that use the mechanism of sacrificial bonds and hidden length. Figure 1 shows a Scanning Electron Microscope image of bone being fractured: the molecules with sacrificial bonds and hidden length can be seen resisting the start of the fracture (Smith, Schaffer et al. 1999; Fantner, Hassenkam et al. 2005; Fantner, Oroudjev et al. 2006). The biological system with sacrificial bonds and hidden length mechanism can dissipate energy from threats. A schematic drawing of the basic principle of the sacrificial bond and hidden length mechanism is shown in figure 2. Before the sacrificial bond is broken, only the solid length of the molecule contributes to the entropic spring and therefore to the force with which the molecule resists the stretching. The dotted length of the molecule is hidden from the applied force by the sacrificial bond. When the bond breaking force is reached, only a small amount of energy is required to break the sacrificial bond. After that, the whole length (solid plus dotted) contributes to the entropy of the molecule. This mechanism is very different from the mechanisms of dashpots and springs used in conventional engineered actuators.

Various state-of–the-art semi-active devices have been proposed and developed for civil infrastructural applications. For example, Dyke et al (1996) and Spencer et al (1997) have proposed the magnetorheological (MR) dampers for seismic response reduction. Scruggs and Iwan (2003) have proposed another semi-active electrical machine for civil structural control. Chen and Chen (2004) have designed and tested the semi-active piezoelectric friction dampers on a quarter-scale building model.

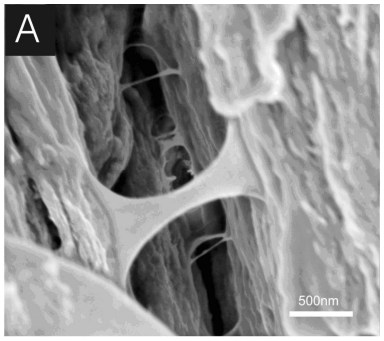

Figure 1 The molecules with sacrificial bonds and hidden length in the Scanning Electron Microscope Image of bone being fractured (Smith, Schaffer et al. 1999; Fantner, Hassenkam et al. 2005; Fantner, Oroudjev et al. 2006).

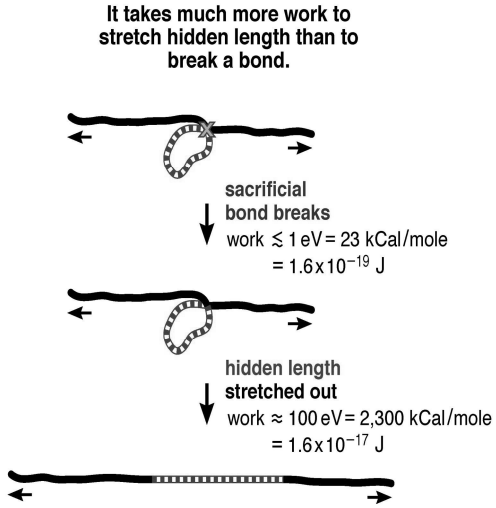

Figure 2 Schematic drawing of the sacrificial bond – hidden length mechanism (Fantner, Oroudjev et al. 2006).

In order to illustrate and prove the concept of using the inspiration from sacrificial bonds and hidden length to design bio-inspired and bio-autonomous actuators for structural control applications, a building structural model is chosen as an example with earthquake as the threatening force. The primary reason for using building response to earthquake excitation as the present model is because of the high level of work done in the field: it will be possible to compare the present results to the state-of-the-art examples which have already been developed. Additionally, structural models similar to those already constructed (Spencer Jr, Dyke et al. 1998) can be tailor built to experimentally test the usefulness and effectiveness of the bio-inspired passive actuators invented in this study.

In this research, the authors test the biologically inspired passive actuators on a three-story model building similar to that proposed by Dyke et al (1996). This research is done by numerical simulation with experimental validation. The control performance of the proposed bio-inspired passive actuator is compared with the well developed semi-active actuators using the same structural control example. Within the illustrative examples shown here, it is found that the current bio-inspired passive control devices can achieve comparable performance to the state-of-the-art semi-active devices.

2. OPTIMAL PASSIVE ACTUATOR

The force vs. displacement and velocity for the sacrificial bond–hidden length mechanism is very different from that of conventional passive actuators. A new type of plot, the Force-Displacement-Velocity plot (FDV plot), is presented in this study to facilitate the optimization of passive actuator systems to each structural system.

Considering a seismically excited structure with actuators on given floors, the equation of motion can be written as

$$\mathbf{M}_s\ddot{x} + \mathbf{C}_s\dot{x} + \mathbf{K}_s x = \Gamma f - \mathbf{M}_s \Lambda \ddot{x}_g \tag{1}$$

where x is a vector of the displacements of each floor, $\ddot{x}_g$ is, for simplicity, a one-dimensional ground acceleration, f is the control force applied by the actuator installed on the structure, $\mathbf{\Gamma}$ and $\mathbf{\Lambda}$ are the location matrices, and Ms, Cs and Ks are the mass, damping and stiffness matrices of the linear system, respectively. Equation (1) can be written in state-space representation as

$$\dot{z} = \mathbf{A}z + \mathbf{B}f + \mathbf{E}\ddot{x}_g \tag{2}$$

where z is the state vector. The measurement equation is given by

$$y = \mathbf{C}z + \mathbf{D}f + v \tag{3}$$

where y is the vector of measured outputs, v is the noise vector in measurement, and A, B, C, D and E are the state-space matrices, which are the same as those defined in (Dyke, Spencer Jr et al. 1996) and given by

$$\mathbf{A} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M_s}^{-1}\mathbf{K_s} & -\mathbf{M_s}^{-1}\mathbf{C_s} \end{bmatrix} \quad \mathbf{B} = \begin{bmatrix} \mathbf{0} \\ \mathbf{M_s}^{-1}\mathbf{\Gamma} \end{bmatrix} \quad \mathbf{E} = -\begin{bmatrix} \mathbf{0} \\ \mathbf{\Lambda} \end{bmatrix} \tag{4}$$

and

$$\mathbf{C} = \begin{bmatrix} -\mathbf{M_s}^{-1}\mathbf{K_s} & -\mathbf{M_s}^{-1}\mathbf{C_s} \\ 1\ 0\ 0 & 0\ 0\ 0 \end{bmatrix} \quad \mathbf{D} = \begin{bmatrix} \mathbf{M_s}^{-1}\mathbf{\Gamma} \\ \mathbf{0} \end{bmatrix} \tag{5}$$

The FDV plot presented here is a contour plot of the control force applied on a structure as a function of the displacement and velocity under a specific excitation. Figure 3 shows two kinds of typical passive control forces at the first floor of the three-story structural model considered by Dyke et al (1996) for 1,250 sets of values of displacement (x_1) and velocity (v_1) over the first 5 seconds, with Δt=0.004 seconds, while excited by the N-S acceleration components of the scaled 1940 El Centro Earthquake.

With the aid of FDV plots, the bio-inspired passive actuators in model structures can be optimized. First, for example, the linear-quadratic regulator (LQR) optimization (Kwakernaak and Sivan 1972) is used to find the ideal FDV plot (shown in figure 4) of an active actuator during a simulated earthquake. The objective of using a LQR optimization is to minimize a cost function of

$$J = \lim_{t\to\infty} \int_{-\infty}^{t} \left(y^T \mathbf{Q} y + f^T \mathbf{R} f \right) dt \qquad (6)$$

where Q and R are the weighting matrices and can be defined according to the mechanical dynamics of the system under consideration.

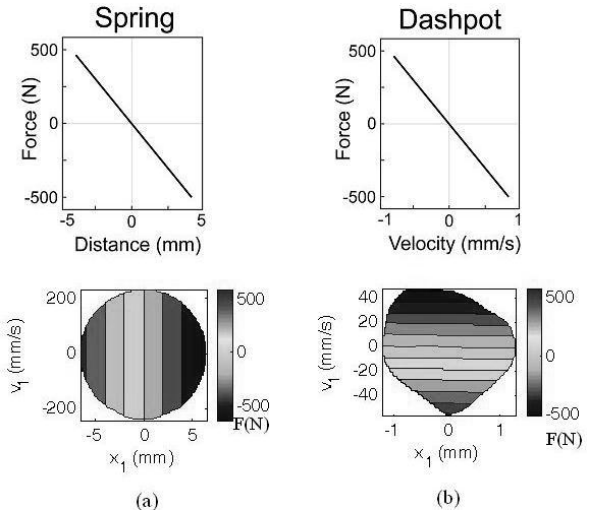

Figure 3 FDV plots of two kinds of passive control forces at the first floor of the model considered by Dyke et al (1996) for 1,250 sets of values of displacement x_1 and velocity v_1 over the first 5 seconds, with Δt=0.004 seconds, of N-S acceleration components of the scaled 1940 El Centro Earthquake: (a) spring constant = 1,000 (N/cm); (b) damping coefficient = 110 (N s/cm).

Efforts are then made to try to replicate this Force-Displacement-Velocity plot of an active actuator with a combination of components from the current bio-inspired pallet of passive actuators. By choosing the appropriate parameters of the bio-inspired passive actuator, it is possible to construct the optimal passive actuator to control the structure during a specific earthquake.

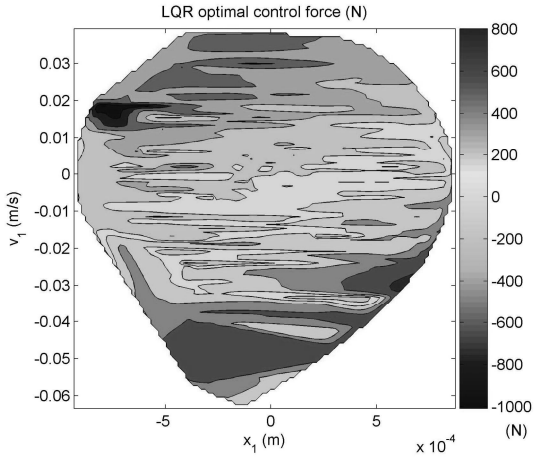

Figure 4 FDV plot calculated on the model considered by Dyke et al (1996) over the N-S acceleration components of the scaled 1940 El Centro Earthquake with LQR optimal control force. The LQR is based on the minimization of cost function:

$$J = \lim_{t\to\infty} \int_{-\infty}^{t} \left(1.83\times10^{6}\, \ddot{x}_3^2 + 7.2\times10^{12}\, x_1^2 + 1.0 f_1^2 \right) dt \,.$$

3. DESIGN OF BIO-INSPIRED ACTUATOR

For the three-story model structure considered by Dyke et al (1996), the Force-Displacement-Velocity plot cannot be simulated using a linear combination of conventional dampers and springs. In fact what is needed is the addition of a component to tilt the Force-Displacement-Velocity plot of a damper the opposite way from adding a conventional spring. From biology, the authors are inspired to evolve a device that will optimize Force-Displacement-Velocity plot and hence optimize the control of structural vibrations. The simple mechanical model of the bio-inspired system is shown in Figure 6, which formed the basis for the numerical simulation model and for the construction of the passive actuators used in this research. The applied force f predicted by the model is given by

$$f = \mathrm{BIO}(x, \dot{x}) + C_0 \dot{x} \qquad (7)$$

where $\mathrm{BIO}(x, \dot{x})$ is the force generated by the bio-inspired mechanism, and C_0 is the damping coefficient.

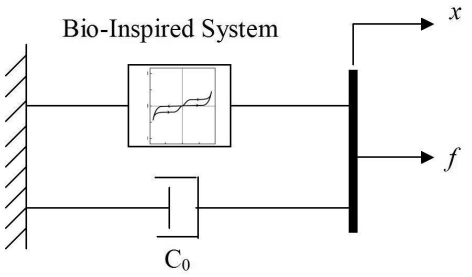

Figure 5 Simple mechanical model of the bio-inspired system as the basis for the numerical simulation and the construction of passive actuators.

In this study, the function $\mathrm{BIO}(x,\dot{x})$ is defined by

$$\mathrm{BIO}(x,\dot{x}) = \begin{cases} f_{\max} & if \quad x \geq 0 \ \ and \ \dot{x} \leq 0 \\ -f_{\max} & if \quad x \leq 0 \ \ and \ \dot{x} \geq 0 \\ 0 & if \quad x \cdot \dot{x} > 0 \end{cases} \tag{8}$$

where f_{max} is the maximum force assumed in the sacrificial bond-hidden length mechanism.

A statistic approach is utilized in this study to determine the parameters of the optimal passive actuator. Since the FDV plot of LQR control over a specific earthquake (Figure 4) is desired, the linear regression is used to fit every point on the FDV plot:

$$F = \beta_{spring} \times x_1 + \beta_{damping} \times v_1 + \beta_{bio} \times BIO \tag{9}$$

where F is the desired control force from LQR control, and x_1 and v_1 are the displacement and velocity of the controlled floor, respectively. BIO is the force generated by the bio-inspired mechanism based on the negative sacrificial bonds and hidden length with f_{max} = 1 N. The coefficients on the independent variables, x_1, v_1, and BIO, are β_{spring}, $\beta_{damping}$, and β_{bio}, respectively. The values of β_{spring} and $\beta_{damping}$ are equivalent to the stiffness coefficient, K_0, and the damping coefficient, C_0, respectively. The value of β_{bio} is equivalent to f_{max} in the $\mathrm{BIO}(x,\dot{x})$ function.

The spring coefficient in (9) is used to show the idea of negative spring, which is similar to the negative sacrificial-bond/hidden-length mechanism and is not included in Figure 5. The optimal control parameters of the bio-inspired passive controller defined in (9) can be obtained by linearly regressing (9) to the ideal FDV plot (Figure 4). These values can be used as the initial values when optimizing the parameters of the control device.

4. EXAMPLES

4.1 Numerical Example

In order to prove the concept and to demonstrate the applicability and performance of the proposed bio-inspired passive actuator, a three-story numerical structure model is considered in this study. The equation of motion of the structure is given in Equation (1), where $x = [x_1\ x_2\ x_3]^T$ is the vector of displacements of the three floors. Since the bio-inspired actuator is installed on the first floor, the variable x in (7) and (8) is equal to x_1. The system matrices are the same as those documented in (Dyke, Spencer Jr et al. 1996) and given by

$$\mathbf{M_s} = \begin{bmatrix} 98.3 & 0 & 0 \\ 0 & 98.3 & 0 \\ 0 & 0 & 98.3 \end{bmatrix} \text{kg}$$

$$\mathbf{C_s} = \begin{bmatrix} 175 & -50 & 0 \\ -50 & 100 & -50 \\ 0 & -50 & 50 \end{bmatrix} \frac{\text{N s}}{\text{m}}$$

$$\mathbf{K_s} = 10^5 \begin{bmatrix} 12.0 & -6.84 & 0 \\ -6.84 & 13.7 & -6.84 \\ 0 & -6.84 & 6.84 \end{bmatrix} \frac{\text{N}}{\text{m}}$$

$$\mathbf{\Gamma} = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \qquad \mathbf{\Lambda} = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}.$$

To account for the model scale and to compare with the simulating results by Dyke et al. (1996), the N-S acceleration components of the 1940 El Centro Earthquake is time-scaled by a factor of 5 and used as the excitation to the structure model in the proposed simulation. Due to the passive nature of the proposed bio-inspired actuator, there is no need to design a control strategy such as those usually used by active or semi-active control devices. In this example, the cost function of the LQR control is chosen in a way to minimize the third floor acceleration, the first floor displacement, and the applied control force. The cost function then is defined by

$$\begin{aligned} J &= \lim_{t\to\infty} \int_0^t \left(y^T \mathbf{Q} y + f^T \mathbf{R} f \right) dt \\ &= \lim_{t\to\infty} \int_0^t \left(Q(3,3)\ddot{x}_3^2 + Q(4,4)x_1^2 + R(1,1)f_1^2 \right) dt \end{aligned} \tag{10}$$

where $\ddot{x}_3$ is the acceleration measured on the third floor of the structure model, x1 and f1 are the displacement and control force on the first floor, respectively. In this research, Q(3,3), Q(4,4), and R(1,1) are chosen to be 1.83×10^6, 7.20×10^{12}, and 1.0, respectively, to minimize the largest floor-to-floor drift, while the maximum control force is set to be 941 N to be the same as in the work done by Dyke et al. (1996). This choice is different from those chosen by Scruggs and Iwan (2003), which can also successfully reduce the structural response. However, the results of control performance are close to each other. The LQR optimal control force based on (10) is used to derive the parameters of the bio-inspired passive controller defined in (9).

For example, if only the combination of damping and negative sacrificial-bond/hidden-length mechanism are considered, the result of the regression shows the damping coefficient to be 104.5 N s/cm and the f_{max} of negative sacrificial bond – hidden length to be 133.8 N with an R-squared value of 0.81. These two coefficients are both significant at 95% confidence level.

If only the stiffness and damping coefficients are considered, the regression suggests a negative spring constant of -2,139 N/cm and a damping coefficient of 126.1 N s/cm. The negative spring constant means the structure is too stiff and can be softened to reduce the structural response. The R-squared value of the regression is 0.83, and both coefficients are significant at 95% confidence level.

If all three variables are considered, the regression suggests a negative spring constant of -1,795.5 N/cm, a damping coefficient of 120.6 N s/cm, and f_{max} of 34.8 N. The R-squared value of the regression is 0.83. All

coefficients are significant at 95% confidence level.

The statistic approach based on linear regression can provide a good estimation of the parameters of the passive actuator. A better control performance can be achieved by tuning the parameters starting from the estimated values.

In this study, the value of C_0 and f_{max} are chosen to be 70 (N s/cm) and 350 (N), respectively, to improve the performance. The simulation comparison of the bio-inspired passive actuator to the MR damper proposed by Dyke et al (1996) due to a 2.5 Hz sinusoid excitation with an amplitude of 1.5 cm is shown in Figure 6. The Force-Displacement-Velocity plot of this passive actuator is then calculated and shown in Figure 7. It is noticed that the FDV plot here is tilted in the same way as the FDV plot based on LQR optimal control force (Figure 4).

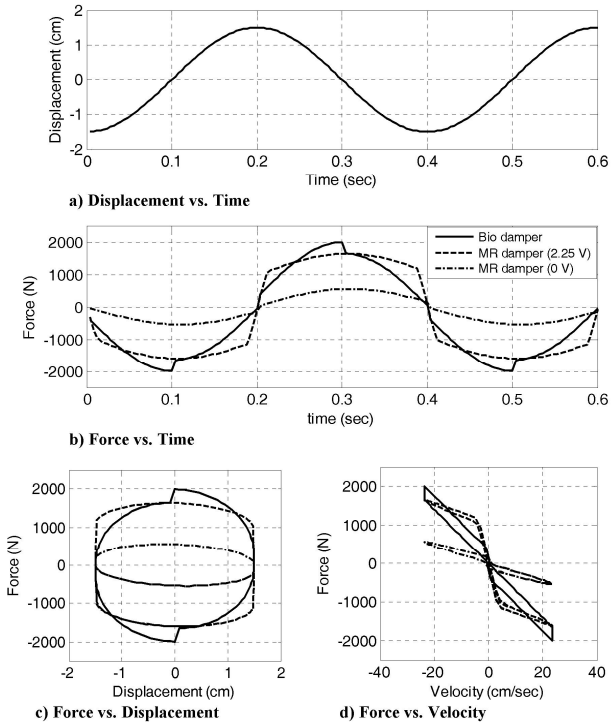

Figure 6 Simulation results of the bio-inspired passive actuator and MR damper for 2.5 Hz sinusoidal excitation with an amplitude of 1.5 cm.

The structural response of the example are compared to those using the semi-active MR damper (Dyke, Spencer Jr et al. 1996; Spencer Jr, Dyke et al. 1997) and both shown in Figure 8. The proposed bio-inspired passive actuator can achieve a similar level of performance in floor displacements and acceleration response as the semi-active MR damper.

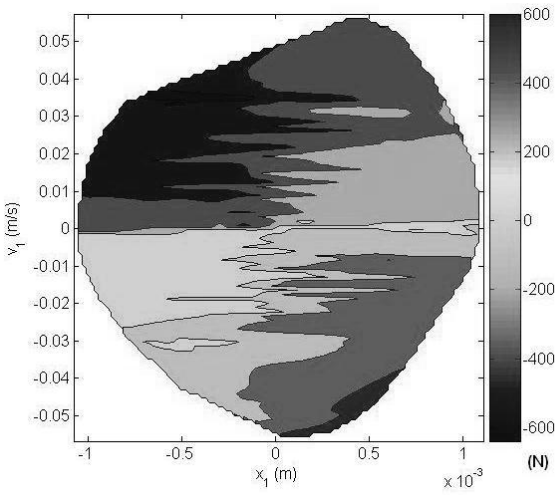

Figure 7 Force-Displacement-Velocity plots calculated on the model considered by Dyke et al. (1996) over the N-S acceleration components of the scaled 1940 El Centro Earthquake with bio-inspired passive actuator (C_0 = 70 N s/cm and f_{max} =350 N).

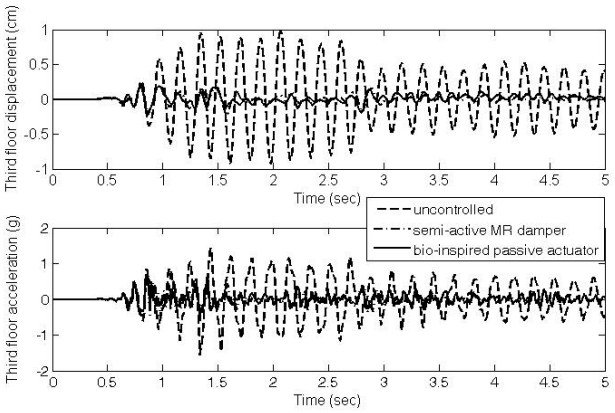

Figure 8 Uncontrolled structural responses as compared to these controlled by semi-active MR damper and bio-inspired passive actuator (C_0 = 70 N s/cm and f_{max} = 350 N), respectively, due to the N-S acceleration component of the scaled 1940 El Centro Earthquake.

In the illustrative example, it seems that bio-inspired passive actuator systems based on sacrificial bonds and hidden length coupled with dampers could yield results comparable in performance to the state-of-the-art semi-active actuators developed by widely referenced publications in the field (Dyke, Spencer Jr et al. 1996; Spencer Jr, Dyke et al. 1997; Scruggs and Iwan 2003).

To account for the model scale and to compare with the simulating results by Dyke et al. (1996), the considered earthquakes are time-scaled by a factor of 5 and used as the excitation to the structure model in the proposed simulation. The simulation results using the proposed methods, the previous bio-inspired actuators (Yang et al., 2010), and a simulation model of a conventional Magnetorheological

(MR) damper built by the authors that follows the computational model proposed by Spencer Jr et al. (1997), subjected to the three different earthquakes, are shown in the Tables 1-3. It is shown that the proposed methods may be adaptive to different earthquakes.

4.2 Experimental Validation

During this research, a specific three story model is built out of aluminum, as shown in Figure 9. The first three natural frequencies calculated from the finite element model are 2.15 Hz, 6.79 Hz, and 10.59 Hz, respectively. The experimentally measured frequencies are 2.00 Hz, 6.37 Hz, and 10.16 Hz, respectively.

Two types of passive actuators to be installed on the first floor of this model are designed, built, and tested using the N-S acceleration component of the 1940 El Centro Earthquake as the excitation. The first device is a simple friction block that slides on the platform of the present test model building (friction force = 0.2 N). The second one is a "negative spring" (spring constant = -4.3 N/cm) plus a damper (damping coefficient = 0.117 N s/cm) mounted on the test model building. The negative spring with damping prototype device uses a commercial airpot damper (the black cylinder) together with a novel element that uses three magnets. Two magnets on a linear slide are attracted to a stationary magnet that is held in the arched structure mounted on the base. Figure 10 shows a comparison between theoretically predictions and experimentally measurements using FDV plots for the two sets of prototype devices – friction damper and negative spring damper. The friction damper is employed here because it is a simple and common device. The negative spring damper has the desired property indicated in Figure 4, and the proposed bio-inspired passive actuator is inspired by this kind of damper. Furthermore, the structural response of third floor displacement corresponding to the comparison in Figure 10 is shown in Figure 11. The agreements in the two sets of the time-history displacement data for the first 10 seconds are convincing. Such comparison may indicate that reliable results can be obtained in the subsequent numerical

simulations and validations of the presently suggested concept of bio-inspired passive actuator.

5. CONCLUSIONS

Inspired and challenged by the simplicity and enormous capability of actuators present in bio-organisms, the authors have successfully built passive actuators which compare favorably with state-of-the-art semi-active actuators, and with potential in the direction of bio-inspired research in the future. This paper presents a fundamental method of designing and optimizing bio-inspired passive actuators for structural control. The Force-Displacement-Velocity plots based on LQR control and the statistic approach based on linear regression are adopted in this research.

Illustrative examples of two prototype passive dampers tested both theoretically and experimentally validate the development and also demonstrate the applications. The proposed bio-inspired actuators, although passive, are comparable in performance to the state-of-the-art semi-active actuators in numerical simulations. It is noted that once the peak ground acceleration is changed, the situation will likely change. The accuracy of the control parameters used in numerical simulations, such as damping coefficient, spring constant, and f_{max} are important in order to predict the structural response more realistically. Besides, due to the simplicity of the bio-inspired actuator, the control devices are easy to design, and there is no need of any active control strategy. Furthermore, the control device is independent of inadvertent condition such as power outage.

The illustrative examples of a three story building model under three different earthquakes are used in this research to demonstrate the effectiveness of the proposed methods. The proposed bio-inspired actuators, although

passive, are comparable in performance to the state-of-the-art semi-active actuators in numerical simulations. The proposed bio-inspired actuator is also shown to be more adaptive to different earthquakes. It is noted that once the peak ground acceleration is changed, i.e. under different earthquakes, the control performance will also change.

Abstract: Magneto-rheological (MR) dampers are a type of smart damper whose characteristics can be varied under dynamic loading by semi-active controllers. Currently, the application of MR dampers in seismic design is limited due to the non-existence of a performance-based design procedure. In this paper, a simplified design procedure (SDP) is presented for the performance-based design of structures with MR dampers. The SDP utilizes the characteristics of an equivalent linear structural system, where the loss factor and equivalent stiffness of the MR dampers are calculated from quasi-static MR damper models such as the simple frictional model or the Hershel-Bulkley visco-plastic model. The simple frictional MR damper model enables the required MR damper capacity to be approximated that has the structure satisfy performance objectives. Once the required MR damper capacity and properties are determined, the Hershel-Bulkley quasi-static MR damper model is used to more accurately predict the design demand for the structure and the design revised accordingly. The SDP is used to design a 3-story building, where steel moment resisting frames (MRFs) combined with the damped braced frames (DBFs) are selected as the lateral force resisting system for the building. The MRF is designed to satisfy the code strength requirement, and the story drift is controlled by the damped braced frames (DBFs) in which the MR dampers are installed. Statistical response of the nonlinear time history analysis of the structure using OpenSees and a suite of ground motions shows the performance objectives for the 3-story building are satisfied, demonstrating the robustness of the simplified design procedure for structures with MR dampers.

1. INTRODUCTION

It is well-known that supplemental damping devices increase the energy dissipation capacity of structures, reducing the seismic demand on the primary structure (Constantinou et al. 1998; Soong and Dargush 1997). A structural system with supplemental dampers is often represented by an equivalent linear system. Kwan and Billington (2003) derived optimal equations for the equivalent period and damping ratio of SDOF systems with various nonlinear hysteresis loops based on time history analysis and regression analysis. Symans and Constantinou (1998) studied the dynamic behavior of SDOF systems with linear or nonlinear viscous fluid dampers and derived an equation for the equivalent damping ratio of the nonlinear viscous fluid damper. Ramirez et al (2002) proposed a simplified method to estimate displacement, velocity and acceleration for yielding structures with linear or nonlinear viscous dampers. Lin and Chopra (2003) investigated the behavior of SDOF systems with a diagonal brace in series with a nonlinear viscous damper by transforming the system to an equivalent linear Kelvin model.

Fan (1998) investigated the behavior of non-ductile reinforced concrete frame buildings with viscoelastic dampers. He derived an equivalent elastic-viscous model based on the complex stiffness and energy dissipation of the viscoelastic system, and proposed a simplified design procedure for a structure with viscoelastic dampers. Lee et al. (2005 and 2009) applied this method to structures with elastomeric dampers and validated the simplified design procedure by comparing the design demand with the results from nonlinear time history analysis..

In this paper, a systematic procedure for the design of structures with MR dampers, referred to as the *Simplified Design Procedure* (SDP), is developed. The procedure is similar to that developed by Lee et al. (2005 and 2009), but with modifications to account for the characteristics of the MR dampers. A quasi-static MR damper model for determining the loss factor and the effective stiffness of an MR damper is introduced and incorporated into the procedure to calculate the design demand for the structure with MR dampers. The procedure is evaluated by comparing the predicted design demand to the seismic response determined from nonlinear time history analysis.

2. SIMPLIFIED DESIGN PROCEDURE (SDP)

In the SDP developed by Lee et al. (2005 and 2009), the supplemental damper properties are represented by β, which is the ratio of the damper stiffness per story in the

global direction to the lateral load resisting frame story stiffness, k_0, without dampers and braces of the structural system. The structural system with dampers is converted into a linear elastic system characterized by the initial stiffness of the structure, α (the ratio of brace stiffness per story in the global direction to the lateral load resisting frame story stiffness k_0), β, and η. α, β, and η may vary among the stories of the structure. By conducting an elastic-static analysis with the RSA method the design demand for the structure is determined.

Since the loss factor of an MR damper depends on the displacement of the structure, as can be shown below in Equation (8), the SDP for an elastomeric damper developed by Lee et al. (2005, 2009) needs to be modified for structures with MR dampers. The loss factor η is associated with the energy dissipation of the damper over a cycle. For the purpose of determining the energy dissipation over a cycle of displacement the properties of the MR damper are assumed to remain constant. The linearization and energy dissipation of an MR damper are discussed later.

Figure 1 summarizes the SDP for structures with MR dampers. In Step 1, the seismic performance objectives and associated design criteria are established for the design of the structure. In Step 2, the structure is designed without MR dampers in accordance with the design code selected in Step 1 to satisfy the strength requirement for the members in the structure. In Step 3, the MR dampers are incorporated into the design of the structure to satisfy the specified performance objectives. The design demand for the structure is estimated for a range of selected values for α, β, and a constant loss factor $\eta = 4/\pi$ using a *simplified analysis procedure*, discussed later. In the simplified analysis procedure the MR damper behavior is based on the simple frictional MR damper model (Chae 2010). The required MR damper sizes are then selected in Step 4 based on the smallest β value that meets the design criteria and performance objectives in Step 1. Since the simple frictional damper model does not account for the velocity dependent behavior of an MR damper, a more accurate determination of the design demand are determined in Step 5 using a more sophisticated MR damper model (i.e., Hershel-Bulkley model) in the simplified analysis procedure. The design is then revised with final member sizes and the MR damper sizes are selected (location, number, force capacity, etc.). If the performance objectives cannot be met in an economical manner, then the performance objectives and/or structural system design need to be revised as indicated in Figure 1.

3. EQUIVALENT LINEAR SYSTEM FOR AN MR DAMPER

The SDP requires that the structure with the nonlinear MR dampers be linearized. In order to linearize the system for estimating the response of structures with MR dampers, the Hershel-Bulkley quasi-static MR damper model is used. Figure 2 shows the force-velocity and force-displacement relationships for the model where the damper force f is given as

$$f = \text{sign}(\dot{u})\{f_0 + C|\dot{u}|^n\} \tag{1}$$

In Equation (1) u is the damper displacement relative to the initial position of the damper and $\dot{u}$ is the damper velocity. f_0 is the frictional force. C and n are the coefficients of the nonlinear dashpot. Suppose that the MR damper is subjected to a harmonic displacement motion

$$u(t) = u_0 \sin(\omega t) \tag{2}$$

where, u_0 is the amplitude of displacement and ω is the excitation frequency of the damper. The energy dissipated by the damper over one cycle of the harmonic motion is equal to

$$\begin{aligned} E_{MRD} &= \int_0^{\frac{2\pi}{\omega}} f(t)\dot{u}(t)dt \\ &= 4f_0u_0 + 2^{n+2}C\gamma(n)u_0^{1+n}\omega^n \end{aligned} \tag{3}$$

where

$$\gamma(n) = \frac{\Gamma^2\left(1+\frac{n}{2}\right)}{\Gamma(2+n)} \tag{4}$$

In Equation (4), $\Gamma()$ is the gamma function (Soong and Constantinou 1997). In general, diagonal bracing is installed in the building in series with the dampers. Therefore, the energy dissipation of an MR damper needs to be studied considering the stiffness of the diagonal bracing. Figure 3 shows an SDOF system with an MR damper and diagonal bracing. Under the harmonic motion $x = x_0 \sin(\omega t)$ the maximum damper displacement, u_{d0}, and velocity, $\dot{u}_{d0}$, of the MR damper occurs when the displacement x and velocity $\dot{x}$ are a maximum, respectively, where u_{d0} and $\dot{u}_{d0}$ can be calculated as (Chae 2011)

$$u_{d0} = x_0 - f_0/k_{br} \tag{5a}$$
$$\dot{u}_{d0} = \dot{x}_0 = x_0\omega \tag{5b}$$

In Equation (5) k_{br} is the stiffness of the diagonal bracing. Substitution of Equation (5a) into Equation (3) results in the expression for the energy dissipation of the MR damper for a SDOF system

$$E_{MRD} = 4f_0u_{d0} + 2^{n+2}C\gamma(n)u_{d0}^{n+1}\omega^n \tag{6}$$

The strain energy of the MR damper, E_S, is calculated from the equivalent stiffness of the damper and the maximum damper displacement:

$$E_S = \frac{1}{2}k_{eq}u_{d0}^2 \tag{7}$$

where k_{eq} is the equivalent stiffness of the MR damper, defined as $k_{eq} = f_0/u_{d0}$ and based on the secant stiffness from the force-displacement relationship of the Hershel-Bulkley model. The loss factor η of the MR damper by definition is

$$\eta = \frac{1}{2\pi}\frac{E_{MRD}}{E_S} = \frac{4\{f_0 + C\gamma(n)(2u_{d0}\omega)^n\}}{\pi k_{eq} u_{d0}} \quad (8)$$

4. SIMPLIFIED ANALYSIS PROCEDURE

The simplified analysis procedure provides an elastic-static method for calculation of the design demand of an MDOF system with MR dampers. The simplified analysis procedure utilizing the response spectrum analysis (RSA) method is summarized in Figures 4 and 5.

In the simplified analysis procedure, the maximum structural displacements are determined by the well-known equal displacement rule. In the equal displacement rule the maximum displacement of the nonlinear structure, whose lateral stiffness is based on its initial tangent stiffness, is assumed to be equal to that of a linear structure. The equal displacement rule is only applicable to structures that lie in the low-frequency and medium frequency spectral regions (Newmark and Hall 1973).

In order to obtain the equivalent period for an MDOF structure with MR dampers, the combined stiffness of the MR dampers and diagonal bracing needs to be added to the stiffness of the structure. Thus, the global effective stiffness of the MDOF system is given as

$$\mathbf{K_{eff}} = \mathbf{K_0} + \mathbf{K_{brsystem}} \quad (9)$$

where $\mathbf{K_0}$ is the stiffness of the structure without diagonal braces and MR dampers, and $\mathbf{K_{brsystem}}$ is the stiffness associated with the braces and MR dampers. The structure is assumed to have N DOF, thus the dimension of $\mathbf{K_{eff}}$ is $N \times N$. The combined stiffness $\mathrm{K}^i_{\mathrm{brsystem}}$ of the diagonal bracing and MR damper at the *i*-th MR damper location is

$$\mathrm{K}^i_{\mathrm{brsystem}} = \frac{k^i_{br} k^i_{eq}}{k^i_{br} + k^i_{eq}} \quad (10)$$

where k^i_{br} and k^i_{eq} are the horizontal stiffness of the diagonal bracing and the MR damper associated with the i^{th} MR damper, respectively. k^i_{eq} can be calculated utilizing the secant stiffness method as noted above. The individual combined stiffnesses based on Equation (10) are appropriately assembled to form $\mathbf{K_{brsystem}}$. The effective periods and mode shapes of the structure are then obtained by performing an eigenvalue analysis of the structure, considering the seismic mass of the structure.

The equivalent damping ratio ξ_{eq} of an MDOF system is determined using the lateral force energy method proposed by Sause et al. (1994), where

$$\xi_{eq} = \frac{1}{2}\frac{\sum_{i=1}^{L} \eta_i F^i_d u^i_d}{\mathbf{F}^{\mathrm{T}}\mathbf{x_0}} + \xi_{in} \quad (11)$$

In Equation (11) η_i and u^i_d are the loss factor and maximum damper displacement of the i^{th} MR damper, respectively, and L is the number of MR dampers. Since the damper displacement is unique for each MR damper, the loss factor of each MR damper, which is a function of damper displacement, is also unique for each damper. For each damper η_i is obtained from Equation (8). ξ_{in} in Equation (11) is the inherent damping ratio and $\mathbf{x_0}$ is the vector of the displacements of the structure that develop under the lateral force $\mathbf{F}$. The individual damper force F^i_d and the lateral force vector $\mathbf{F}$ are defined as

$$F^i_d = k^i_{eq} u^i_d, \ \mathbf{F} = \mathbf{K_{eff}}\mathbf{x_0} \quad (12)$$

In the simplified analysis procedure using the RSA, the relationships in Equation (12) are substituted into Equation (11), and the inherent damping ξ_{in} and $\mathbf{x_0}$ from each mode are considered, as indicated in Substep 3 in Figure 5.

5. PERFORMANCE-BASED DESIGN OF A 3-STORY BUILDING WITH MR DAMPERS

5.1 Prototype Building Structure

Based on the proposed SDP, a 3-story building with MR dampers is designed. The floor plan and elevation of the prototype structure is shown in Figures 6 and 7, respectively. It consists of a 3-story, 6-bay building and represents a typical office building located in Southern California. Lateral loads are resisted by a four perimeter moment resisting frames (MRFs) and four damped braced frames (DBFs) in the two orthogonal principle directions of the building's floor plan. MR dampers are installed in the DBFs to control the drift of the building, adding supplemental damping to the structure. The DBFs have continuous columns, with pin connections at the beam-to-column connections and at the ends of the diagonal bracing. A rigid diaphragm system is assumed to exist at each floor level and the roof of the building to transfer the floor inertia loads to the MRFs and DBFs. The building has a basement where a point of inflection is assigned at 1/3rd of the height of the column from the column base in the analysis model.

5.2 Performance Objectives

In this design, three different performance objectives for the building are considered:

1) Limit the story drift to 1.5% under the DBE ground motion;
2) Limit the story drift to 3.0% under the MCE ground motion;
3) Design strength of members in the DBF shall not be exceeded by the demand imposed by the DBE ground motion.

The MCE ground motion is represented by a response spectra that has a 2% probability of exceedance in 50 years, and the DBE ground motion is 2/3rd the intensity of the MCE ground motion. (FEMA 2000a). The performance objectives of 1.5% story drift satisfies the life safety performance level under the DBE and the 3% story drift satisfies the collapse prevention level under the MCE. The performance levels are defined in FEMA-356 (2000b). To minimize the damage and repair cost to the DBF structure,

the third performance objective is adopted to have the DBF structure remain elastic under the DBE.

5.3 Performance-Based Design

The prototype building structure is intended to provide the basis for an MRF and DBF with MR dampers which can be constructed in the laboratory for future tests. Due to laboratory constraints, the prototype building structure and resulting MRF and DBF were designed at 0.6-scale. The MRFs are designed to satisfy the strength requirement of the current building seismic code of ICC (2006); the member design criteria is based on the AISC steel design provisions (2005b). The design response spectrum is based on a site in Southern California where the spectral acceleration for the short period, S_S, and for a 1 second period, S_1, are equal to 1.5 and 0.6, respectively. The strength contribution from the DBFs and MR dampers is not considered when the MRFs are designed since, as noted above,+ the DBFs and MR dampers are intended only to control the story drift of the building system. More detailed information on the design of the MRFs and gravity frames can be found in Chae (2011).

Once the MRFs and gravity frames are designed for strength, the required capacity of the MR dampers to control the drift is determined. The DBF members are then designed by imposing the displacement and damper force demands on the DBF, which are obtained from the simplified analysis procedure and the required MR damper capacity. The maximum displacements and the maximum MR damper forces are assumed to occur concurrently in the SDP. The design of the 3-story building is revised until the performance objectives and strength requirements are satisfied.

Large-scale MR dampers were used for the study which can generate a 200kN damper force at a velocity of 0.1m/sec. (Chae et al. 2010). ,The parameters for the Hershel-Bulkley model associated with the large-scale MR damper are: $f_0 = 138.5$kN, $C = 161.8$kNsec/m, and $n = 0.46$.

The optimal damper location which satisfies the performance objectives is determined by using the simplified analysis procedure, resulting in one large-scale MR damper in the 2nd and 3rd stories, respectively, with $\alpha = 10$ and $\beta = 0.3$ (Chae 2011). Tables 1 and 2 summarize the member sizes for the MRFs, gravity frames, and DBFs. Table 3 summarizes the calculated design demand associated with maximum story drift and maximum damper forces. As can be observed, the design demand for the story drift under the DBE and MCE are less than 1.5% and 3.0%, respectively, in order to satisfy the performance objectives. Table 4 shows the DBE demand-to-capacity ratios for the DBF members. The demand-to-capacity ratio for each member is less than 1.0, which means the members are designed to remain elastic under the DBE. The design of the braces was controlled by stiffness, $\alpha = 10$, and not strength, hence, the demand-to-capacity ratios for the braces are small in Table 4.

6. ASSESSMENT OF SIMPLIFIED DESIGN PROCEDURE

The SDP is assessed by comparing the design demand from the SDP with results from a series of nonlinear time history analyses (NTHA) of the 3-story building using the nonlinear finite element program OpenSees (2009).

6.1 OpenSees Model

Symmetry in the floor plan and ground motions along only one principal axis of the building were considered in the analysis. Hence, only one-quarter of the building was modeled consisting of one MRF, one DBF, and the gravity frames that are within the tributary area of the MRF and DBF. The OpenSees model is shown in Figure 8. The beams and columns of the MRF structure are modeled with a nonlinear distributed plasticity force-based beam-column element with five fiber sections along the element length. The cross section of the element is discretized into 18 fibers, including 12 fibers for the web and 3 fibers each for the top and bottom flanges. Each fiber is modeled with a bilinear stress-strain relationship with a post-yielding stiffness that is 0.01 times the elastic stiffness. The beam-column joints in the MRF are modeled using a panel zone element, where shear and symmetric column bending deformations are considered (Seo et al. 2009). The doubler plates in the panel zones of the MRF are included in the model. The nonlinear force-based fiber element is also used to model the columns of the DBF. The beams and braces of the DBF are modeled using linear elastic truss elements. The gravity frames are idealized using the concept of a lean-on column, where an elastic beam-column element with geometric stiffness is used to model the lean-on column. The section properties of the lean-on column are obtained by taking the sum of the section properties of each gravity column within the tributary area (i.e., one quarter of the floor plan) of the MRF and the DBF. The MR dampers are modeled using the MNS MR damper model implemented into OpenSees by Chae et al. (2010). The MR damper is assumed to be located between the top of the brace and the adjacent beam-column joint, as shown in Figure 8. The results reported in this paper are for MR dampers that are passive controlled with a constant current input of 2.5A. Studies with the MR dampers in semi-active control mode are presented in Chae (2011).

The gravity loads from the tributary gravity frames are applied to the lean-on column to account for the P-Δ effect of the building. To model the effect of the rigid floor diaphragm the top node of the panel zone element in the MRF and the beam-column joint in the DBF are horizontally constrained to the node of the lean-on column at each floor level, while the vertical and rotational degrees of freedom of these nodes are unconstrained.

Rayleigh damping is used to model the inherent damping of the building with a 5% damping ratio for the 1st and 2nd modes.

6.2 Comparison of Response

An ensemble of 44 ground motions listed in FEMA P695 (ATC 2009) is scaled to the DBE and MCE levels using the procedure by Somerville et al. (1997) for the NTHA.

A summary of the median and standard deviation of maximum story drift and residual story drift from the NTHA is given in Table 5. Figures 9 and 10 compare the calculated design demand for drift from the SDP with the median values for maximum story drift from the NTHA under the DBE and MCE ground motions. The story drift design demand calculated by the SDP shows good agreement in Figure 9 with the median maximum story drifts from the NTHA. The calculated design demand for story drift from the SDP also shows good agreement with the median values from the NTHA under the MCE, see Figure 10. Figures 9 and 10 show that the median values of the maximum story drift from the NTHA satisfies the performance objectives of 1.5% and 3.0% under the DBE and MCE levels, respectively. The residual story drift of the building after the DBE has a maximum median value and standard deviation of 0.22% and 0.27%, respectively, which occurred in the 3rd story as summarized in Table 5. The residual drift is small.

Table 6 compares the design demand for maximum MR damper forces calculated by the SDP with the median maximum MR damper forces from the NTHA. The MR damper force design demands from the SDP are slightly smaller than the median NTHA results for the DBE. However, the differences between the SDP and the NTHA are only 3.9% and 3.3% for the MR dampers in the 2nd and 3rd stories, respectively. For the MCE, the differences between the median NTHA results and the SDP for the MR damper forces in the 2nd and 3rd stories are 1.6% and 0.5% respectively. The design demand calculated by the SDP shows reasonably good agreement with the median results from the NTHA for the maximum MR damper forces.

The linear elastic behavior of the DBF columns under the DBE is confirmed by checking the plastic rotation developed in the columns. Summarized in Table 7 are the median and standard deviation of the DBF maximum magnitude of column plastic rotation from the NTHA for the DBE ground motions. In the first story, some plastic rotation developed at the base of the column under the DBE. However, the median is zero and the standard deviation is 0.0005 radians for the maximum plastic rotation. The median and standard deviation of the maximum plastic rotation in the 2nd and 3rd stories columns are zero under the DBE ground motion, as given in Table 7, which indicates linear elastic behavior of the columns at these stories. The median of the residual plastic rotation at the base of the column is zero and the standard deviation for the residual plastic rotation is 0.0004 radians.

The building's response under the DBE and MCE determined by the NTHA appears to have met the performance objectives for the structure. Moreover, the performance under the DBE meets the immediate occupancy level (FEMA 2000b), where the maximum residual drift is practically equal to the allowable construction tolerance of 0.2% for steel structures (AISC 2005a), with minimal damage occurring in the building (the median of the maximum plastic rotations in the beams and columns of the MRF are 0.37% and 0.07% radians, respectively, with the MRF having the same residual drift statistics as the DBF due to the rigid diaphragm (Chae 2011)).

7. CONCLUSIONS

A simplified design procedure was developed to enable the performance-based design of structures with MR dampers. The design procedure utilizes a systematic approach to calculate the design demand of structures with MR dampers. The simplified analysis procedure enables the design demand to be determined without performing a nonlinear time history analysis by linearizing the structure and utilizing the response spectrum analysis method.

To linear the nonlinear MR dampers, the simplified analysis procedure is based on an equivalent linear MR damper model using the Hershel-Bulkley quasi-static MR damper model. The energy dissipated by the MR damper over one cycle of a harmonic motion is calculated and the equivalent stiffness determined based on the secant stiffness method from the damper force-displacement relationship. The loss factor of the MR damper is obtained from the energy dissipated by the damper and the strain energy calculated from the equivalent stiffness of the damper. Both the equivalent stiffness and loss factor of the MR damper are dependent on the maximum displacement of the damper. A 3-story building was designed using the SDP, where three performance objectives associated with two seismic hazard levels were selected. The SDP was assessed by comparing the design demand calculated by the SDP with the response determined from nonlinear time history analyses. The MNS MR damper model was implemented into the OpenSees computer program and statistics for the response to DBE and MCE ground motions were obtained from a series of nonlinear time history analyses using 44 different ground motions. The performance of the building from the nonlinear time history analysis indicated that building design satisfies the three performance objectives. The design demand associated with story drift and maximum MR damper forces from the SDP showed good agreement with the median values from the nonlinear time history analyses, confirming the robustness of the SDP.

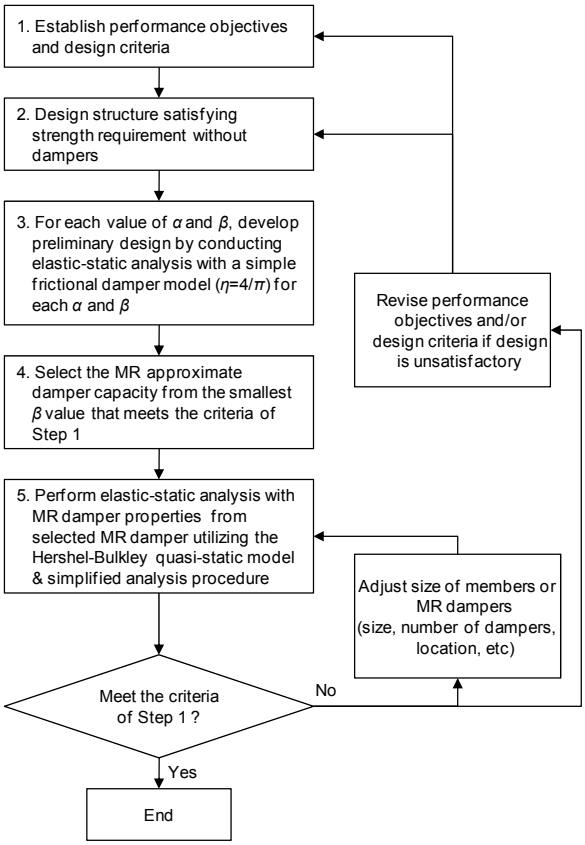

Figure 1 Generalized simplified design procedure (SDP) for structures with MR dampers

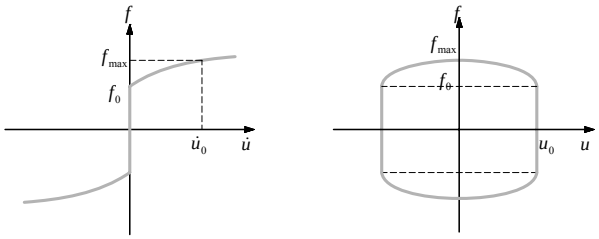

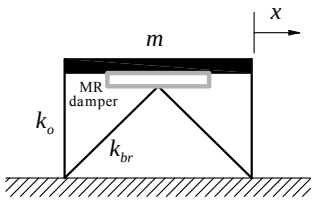

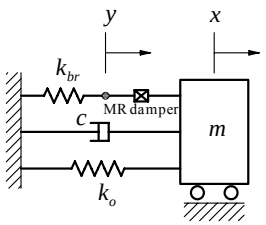

Figure 2 Hershel-Bulkley visco-plasticity MR damper model: (a) force-velocity relationship; (b) force-displacement relationship

(a)

(b)

Figure 3 SDOF system: (a) schematic of equivalent SDOF system with MR damper and brace; (b) mechanical model

Given:

- MR damper properties: $f_0^i,\ C_i,\ n_i$ (i: index for MR damper location)
- Structural properties: $\mathbf{M},\ \mathbf{K_0},\ k_{br}^i,\ \xi_{in}^j$ (inherent damping ratio of the j-th mode)

Step 1. Assume $\mathbf{x_0}$ and set $\omega_{eff}^1 = \omega_n^1$ (fundamental frequency of structure without MR dampers)

Step 2. Determine maximum damper displacements

$$u_{d0}^i = u_0^i - f_0^i/k_{br}^i$$

u_0^i: maximum deformation of damper and bracing of the i^{th} MR damper

Step 3. Calculate equivalent stiffness of each MR damper

$$k_{eq}^i = f_0^i/u_{d0}^i$$

Step 4. Determine $\mathrm{K}_{\mathrm{brsystem}}^i = \frac{k_{br}^i k_{eq}^i}{k_{br}^i + k_{eq}^i}$ for each MR damper and update $\mathbf{K_{eff}}$

Step 5. Update modal frequency ω_{eff}^j and modal vector $\boldsymbol{\phi}_j$ $(j = 1, \dots, N)$

ω_{eff}^j, $\boldsymbol{\phi}_j$ ← eig($\mathbf{K_{eff}}, \mathbf{M}$)

where $\mathbf{M}$ is the mass matrix of the structure

Step 6. Calculate loss factor of each MR damper

$$\eta_i = \frac{4\left\{f_0^i + C_i\gamma(n_i)\left(2u_{d0}^i\omega_{eff}^1\right)^{n_i}\right\}}{\pi k_{eq}^i u_{d0}^i}$$

where ω_{eff}^1 is the fundamental modal frequency

Step 7. Perform modal analysis described in Figure 5

Step 8. Apply the modal combination rule (e.g., SRSS or CQC) to get the final displacement $\mathbf{x_0}$ and velocity of each MR damper $\dot{u}_{d0}^i$

$\mathbf{x_0}$ = function of ($\mathbf{x_0^1}, \dots, \mathbf{x_0^N}$),

$\dot{u}_{d0}^i$ = function of ($\dot{u}_{d0}^{i1}, \dots, \dot{u}_{d0}^{iN}$)

Step 9. Repeat **Step 2** ~ **Step 8** until $\mathbf{x_0}$ convergence is achieved.

Step 10. Calculate maximum damper force for each MR damper

$$f_{max}^i = f_0 + C\left(\dot{u}_{d0}^i\right)^n$$

Figure 4 Simplified analysis procedure used to design MDOF structures with passive MR dampers utilizing response spectrum analysis (RSA) method

Step 7. For j=1 to N^{th} mode

Substep 1. Assume modal displacement vector $\mathbf{x_0^j}$

Substep 2. Determine maximum displacement for each damper u_{d0}^{ij}

$u_{d0}^{ij} = u_0^{ij} - f_0^i/k_{br}^i$

u_0^{ij}: maximum deformation of damper and bracing at the i^{th} MR damper in mode j

Substep 3. Calculate equivalent modal damping ratio

$$\xi_{eq}^j = \frac{1}{2}\frac{\sum_{i=1}^{L}\eta_i k_{eq}^i (u_{d0}^{ij})^2}{\mathbf{x_0^{jT}K_{eff}x_0^j}} + \xi_{in}^j$$

Substep 4. Find maximum modal displacement (y_0^j) from response spectrum

$y_0^j = S_d(T_{eff}^j, \xi_{eq}^j)$ where $T_{eff}^j = 2\pi/\omega_{eff}^j$

Substep 5. Update modal displacement vector $\mathbf{x_0^j}$

$\mathbf{x_0^j} = \Gamma_j \boldsymbol{\phi}_j y_0^j$

$\boldsymbol{\phi}_j$: mode vector; $\Gamma_j = \boldsymbol{\phi}_j^T\mathbf{M1}/\mathrm{M_j}$; $\mathbf{1}$: unit vector; $\mathrm{M_j}$: modal mass ($=\boldsymbol{\phi}_j^T\mathbf{M}\boldsymbol{\phi}_j$)

Substep 6. Repeat Substep 2 ~ 5 until convergence in $\mathbf{x}_0^j$ is achieved

Substep 7. Calculate maximum velocity $\dot{\mathrm{u}}_{\mathrm{d0}}^{\mathrm{ij}}$ for each MR damper, where for the i^{th} MR damper

$\dot{u}_{d0}^{ij} = u_0^{ij}\omega_{eff}^j$

SEISMIC INSTRUMENTATION OF BUILDINGS BY THE CALIFORNIA STRONG MOTION INSTRUMENTATION PROGRAM

Moh-jiann Huang and Anthony F. Shakal

California Geological Survey, Department of Conservation, Sacramento, California, U.S.A.
moh.huang@conservation.ca.gov, tony.shakal@conservation.ca.gov

Abstract: During the last 35 years the California Strong Motion Instrumentation Program (CSMIP) in the California Geological Survey has instrumented over 220 buildings, typically installing 12 to 32 sensors in each building. The primary objectives of the CSMIP building instrumentation are to obtain strong earthquake shaking data for improving seismic design codes and engineering design practices, and for post-earthquake evaluations of existing buildings. The instrumented buildings include steel, concrete, masonry and wood structures. Building heights range from one to 58 stories. Buildings with base isolators or other energy dissipation devices have also been instrumented.

CSMIP has obtained strong-motion earthquake records with building base motions larger than 0.1g from more than 80 instrumented buildings. Several of these buildings were damaged during earthquakes. These building records are available at the Center for Engineering Strong Motion Data (http://www.strongmotioncenter.org) for analyses of building response by researchers. Building records from new earthquakes are routinely processed and added to the Center. This paper presents several aspects of building instrumentation including strategies and criteria for the selection of buildings, development of sensor locations and instrumentation schemes, instrumentation installation and maintenance, data dissemination and utilization, and other factors considered by CSMIP in building instrumentation in California.

1. INTRODUCTION

The California Strong Motion Instrumentation Program (CSMIP) was established following the destructive 1971 San Fernando earthquake to increase data on strong earthquake shaking. The program installs and maintains strong-motion instruments in representative structures and geological environments throughout California. Strong-motion data recovered from the instruments are processed by CSMIP and made available to engineers and seismologists involved in designing for earthquake shaking and assessing seismic hazards. In addition, CSMIP funds data interpretation projects to facilitate utilization of strong-motion data in improving post-earthquake response and seismic design codes and practices.

Since the inception of the program over 1150 stations of various types have been instrumented, including 810 ground-response stations, 220 buildings, and 120 lifeline structures (bridges, dams and other structures). Locations of CSMIP stations are shown in Figure 1. Ground-response sites and structures are selected for instrumentation on the basis of recommendations of the Strong Motion Instrumentation Advisory Committee (SMIAC), an advisory committee that is part of the California Seismic Safety Commission. The Committee is made up of leading engineers and seismologists from universities, government, and private industry. The program funding is primarily provided through an assessment on construction costs for building permits issued by cities and counties in California (Shakal and Huang, 1989).

In 1989, the California Office of Statewide Health Planning and Development (OSHPD), which has responsibility for approving hospital design in California since the 1971 San Fernando earthquake, initiated a program providing funding for instrumentation of hospitals by CSMIP. In addition, base-isolated hospital buildings are required by OSHPD to be instrumented by the owner and maintained by CSMIP. The Instrumentation Committee of the Hospital Building Safety Board recommends the hospital buildings for instrumentation. A total of 48 hospital buildings have been instrumented and are now part of the CSMIP network.

Significant earthquakes, including the 1979 Imperial Valley, 1984 Morgan Hill, 1989 Loma Prieta, 1992 Landers, 1994 Northridge and 1999 Hector Mines earthquakes, have been recorded. Stations installed in the last few years include modern digital instruments and utilize a communication system that can transmit the recorded data to a central facility in Sacramento within a few minutes after the shaking occurs where the data are automatically processed (Shakal et al., 1995). The results are then disseminated rapidly to the users via the Internet at the Center for Engineering Strong Motion Data (Haddadi, et al., 2008).

CSMIP funds data interpretation projects to facilitate utilization of strong-motion data in improving

post-earthquake response, seismic design codes and practices. Twenty seminars have been held to disseminate research results to earthquake engineers and seismologists.

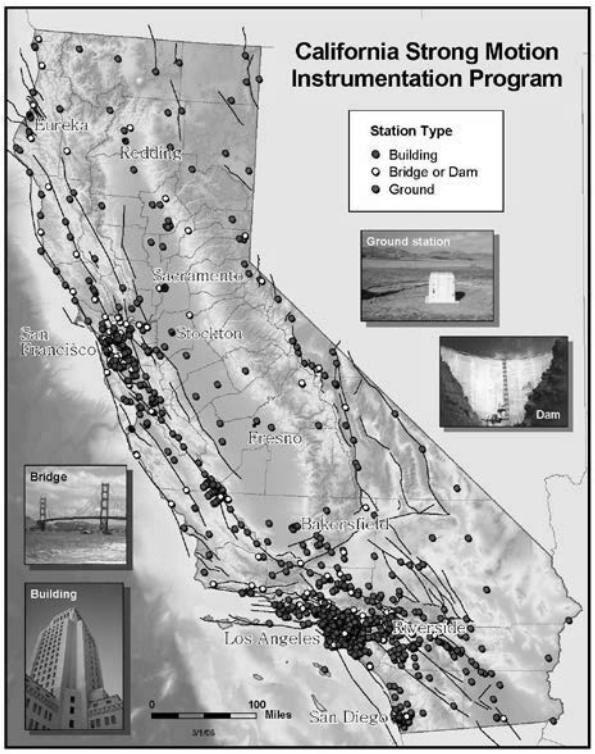

Figure 1. Locations of the California Strong Motion Instrumentation Program (CSMIP) stations in California.

2. CSMIP BUILDING INSTRUMENTATION

2.1 Building Selection Criteria

In 1985, the Buildings Subcommittee of the Strong Motion Instrumentation Advisory Committee (SMIAC) developed a long-term plan and established selection criteria for CSMIP building instrumentation (Shakal, et al., 2001). More than 200 buildings in California have been instrumented by CSMIP and these buildings have been selected for instrumentation based on these criteria. The primary goals of CSMIP building instrumentation are to obtain data to improve engineering design practices and to assess and mitigate the hazards posed by existing buildings. The ultimate goal is to save lives and property through the design of safer structures and the mitigation of seismic hazards posed by existing buildings. As shown in Figure 1, most of CSMIP-instrumented buildings are located in areas where significant ground shaking is likely to occur, one of the criteria for selection.

There are many thousands of buildings in California, and it is impossible to instrument all the buildings. In the building selection criteria, buildings in California were categorized into 30 representative groups by the construction materials (steel, concrete, masonry and wood) and the primary lateral force resisting systems (frames, shear walls and base isolation). These 30 groups are shown in Table 1. Each group is divided into several representative types according to distribution of the lateral force resisting elements and the vulnerability of each structural system. There are a total of 133 representative building types in the 30 groups. Representative buildings of all types are to be instrumented. It is planned that a total of 400 buildings will eventually be instrumented by CSMIP.

The long-term objective of CSMIP building instrumentation is to record significant structural response data in each of the representative building types. Strong-motion records from a specific building will be analyzed not only to learn about that specific building, but most importantly to study the behavior of the class of buildings of which the specific building has been selected as a typical member. It is expected that through study of the behavior of specific buildings of a class, representative lessons learned can be applied to all buildings of that class.

Table 1. Building Groups for CSMIP Instrumentation

Group No.	Building Type - Structural System [Height]	Total No. Needed	Instrumented as of Dec 2010
1	Unreinforced Masonry Bearing Wall [M]	6	0
2	Unreinforced Masonry Bearing Wall [L]	9	2
3	Unreinforced Masonry with Load Bearing Frame [M]	6	2
4	Unreinforced Masonry with Load Bearing Frame [L]	9	1
5	Unreinforced Masonry Bearing Wall [H]	6	0
6	Unreinforced Masonry with Load Bearing Frame [H]	6	2
7	Non-ductile Concrete Moment Frame [L]	9	1
8	Concrete Tilt-up [L]	12	7
9	Reinforced Masonry Wall w/o Moment Frame [M]	9	2
10	Concrete Shear Wall w/o Moment Frame [M]	12	6
11	Reinforced Masonry Shear Wall w/o Moment Frame[L]	15	8
12	Concrete Shear Wall w/o Moment Frame [L]	12	6
13	Non-ductile Concrete Moment Frame [M]	3	1
14	Concrete Shear Wall & Moment Frame [H]	24	8
15	Steel Braced Frame [M]	12	7
16	Precast Concrete (Not Tilt-up) [H]	6	3
17	Precast Concrete (Not Tilt-up) [M]	6	2
18	Concrete Shear Wall w/o Moment Frame [H]	3	1
19	Non-ductile Concrete Moment Frame [H]	3	2
20	Reinforced Masonry Shear Wall w/o Moment Frame[H]	6	3
21	Precast RC (Not Tilt-up) [L]	6	0
22	Braced Steel Frame [H]	21	11
23	RM Shear Wall & Moment Frame [H]	3	0
24	Ductile Concrete Moment Frame [H]	3	1
25	Moment Resisting Perimeter Steel Frame [H]	9	9
26	Wood Frame [L]	6	7
27	Base Isolated [L,M,H]	9	11
28	OSHPD Hospitals		48
29	Retrofitted		20
30	All Other Building Types	169	49
	Total:	400	220

[L] = Low Rise (1 to 3 stories); [M] = Medium Rise (4 to 7 stories); [H] = High Rise (8 or more stories)

2.2 Building Instrumentation Objectives

Instrumentation of a building involves the installation of small sensors (accelerometers in most cases), distributed throughout the structure, all connected to one or several central recorders, generally by low-voltage electrical cabling. Optimal locations for installing sensors in a building are developed by CSMIP engineering staff by studying lateral force resisting systems from the building design plans. Sensors are installed at key structural members so the important modes of vibration will be recorded and specific measurement objectives can be achieved. The sensor locations are reviewed by members of the SMIAC Buildings Subcommittee before the sensors are installed by CSMIP

technical staff. Procedures are implemented and followed to ensure the quality control in field installations of the instrumentation system in the building (Shakal and Petersen, 2001).

CSMIP instrumentation of buildings always includes installation of sensors at the base and the roof of the building. The instrumentation plan includes as many intermediate levels as appropriate for a particular building and a reference free-field site if possible. A typical instrumentation scheme is illustrated in Figure 2, and includes 10 to 30 sensors distributed on 3 or more levels of the building (Huang and Shakal, 2001 & 2002).

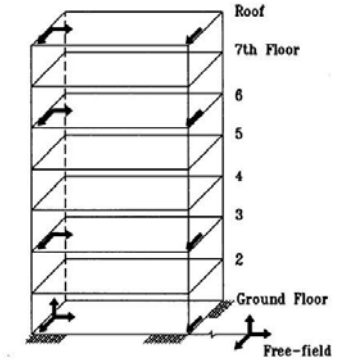

Figure 2. Sensor locations in a typical building instrumented by CSMIP.

The number of intermediate levels instrumented depends on the building height and configuration:

(a) For buildings up to three stories in height, each level is usually instrumented in order to calculate inter-story drift at each story from the records. An example, shown in Figure 3, is a 3-story steel building instrumented with 15 sensors in the building and 3 sensors at a reference free-field site in the parking lot.

(b) For mid-rise buildings, from four to seven stories, two intermediate levels are usually instrumented;

(c) For high-rise buildings, eight stories or more, at least two or three intermediate levels are instrumented, and additional instrument may be added at levels where there is a discontinuity in stiffness. An example of a 52-story building is shown in Figure 4.

As shown in Figure 2, torsional motion of the building base is measured and the instrumentation scheme provides information on soil-structure-interaction. However, a free-field station is not always possible in a metropolitan area where a lot of buildings surround the instrumented building. For concrete shear wall or steel braced frame buildings, vertical sensors can be added to measure rocking motion of the shear wall or braced frame. For a building with flexible diaphragms, such as tilt-up buildings, a sensor is added at the middle of a selected floor to measure diaphragm motion.

In general, the number of sensors installed in a building depends on the budget, instrumentation objectives and complexity of the structural system. Building instrumentation objectives generally include measurements of

(1) input ground motion,
(2) building base motion,
(3) lateral floor motion,
(4) torsional floor motion,
(5) floor or wall diaphragm motion,
(6) shear wall/braced frame rocking motion, and
(7) relative displacement/deformation of special structural members such as isolators, dampers or unbonded braces.

Other information such as building periods, damping ratios, base shears and inter-story drifts can generally be computed or derived from these measurements.

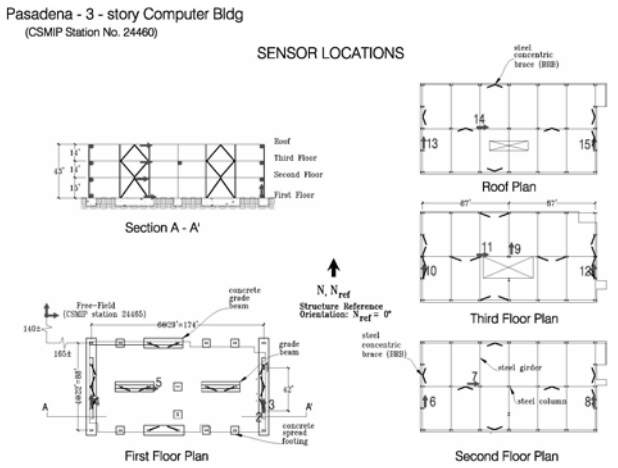

Figure 3. Locations of 15 sensors in a 3-story building in Pasadena and 3 sensors at a reference free-field site in the parking lot.

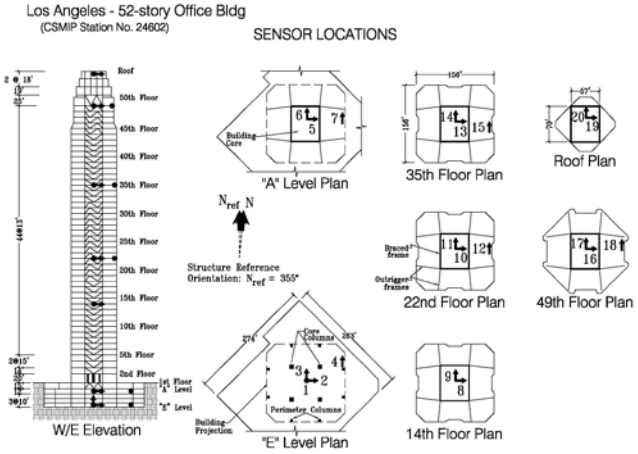

Figure 4. Locations of 20 sensors installed in a 52-story office building in downtown Los Angeles.

2.3 Building Record Processing

Strong motion records from a building include accelerations measured by individual accelerometers installed at various locations in the building. The data can be recorded by one or several recorders. The acceleration record from each sensor will have different amplitudes and frequencies. The record from each sensor may have a unique character or problem, and a different noise spectrum.

CSMIP routinely processes building records to compute velocities, displacements and response spectra by using the same procedure used for processing ground motion records (Shakal, et al., 2004). The records are processed uniformly for all channels despite the fact that each record has different a signal-to-noise ratio at long periods (Huang, 2004). If the record from a particular sensor has a unique problem, it is examined separately and a special procedure may be used to process the record.

CSMIP has processed building records using the following practices:

(1) Records from all the sensors in the building are processed with the same usable data bandwidth, i.e., same filter corners.

(2) The free-field record is processed using the same usable data bandwidth as the building records. The free-field data are distributed with the building data. However, it may be processed with a wider bandwidth for ground motion study purposes.

(3) The filter corners are chosen based on the horizontal sensor records rather than the vertical. Vertical records have a lower signal-to-noise ratio at long periods. Also, most CSMIP buildings have only one vertical sensor at the base of the building.

The fundamental period of a building depends on the lateral force resisting system and distribution of the resisting structural elements. It can be derived from previous earthquake records and ambient vibration data, or estimated from a rule-of-thumb formula, T=0.1N, where N is the number of stories. In general, a moment frame building would have a longer period, and a shear wall or braced-frame building would have a shorter period. In processing a building record, one has to avoid filtering out the motion of the building fundamental period. For example, the 52-story building in Los Angeles of Figure 4 has a fundamental period of about 6 seconds in each direction. The records from the 1994 Northridge earthquake, shown in Figure 5, were filtered at about 10 seconds. As shown in the acceleration response spectra in Figure 6, the fundamental mode was less prominent than the second and third modes in the building response to the Northridge earthquake.

The response of a building depends on the flexibility of the building, size of the earthquake, and the distance from the earthquake. For flexible building, the long-period filter corner has to be larger than the building fundamental period to avoid filtering out fundamental mode motions. On the other hand, it is better to filter out more long-period motions for stiff buildings, for record analysis purposes. If the building structural element had undergone permanent deformations during an earthquake, these permanent deformations cannot be obtained from acceleration records by the routine record processing using filters. At locations at which permanent displacements are expected to occur, such as base-isolators or buckling-restrained steel braces, relative displacement sensors can be installed, in addition to accelerometers, to provide direct measurement of the movement.

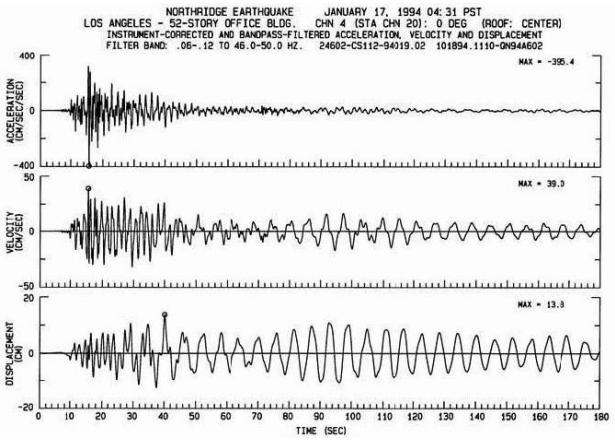

Figure 5. Acceleration, velocity and displacement records from sensor 20 on the roof of a 52-story building in Los Angeles during the 1994 Northridge earthquake.

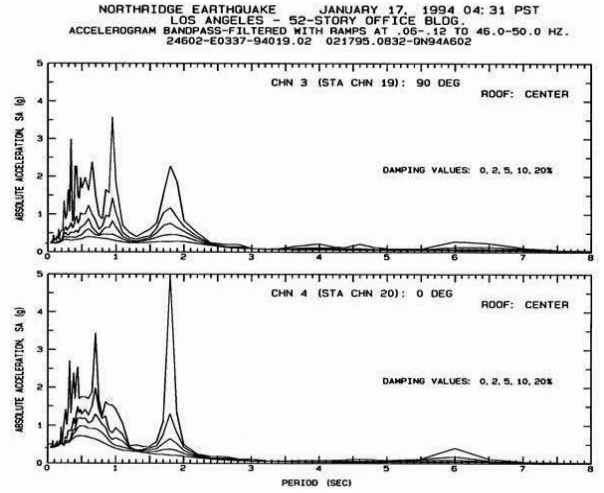

Figure 6. Response spectra of the roof records of a 52-story building in Los Angeles during the 1994 Northridge earthquake.

3. DATA DISSEMINATION VIA INTERNET

CSMIP has obtained strong-motion records with building base motions larger than 0.1g from more than 80 instrumented buildings. Several of these buildings were damaged during earthquakes (Huang, et al., 1996). These records are available at the Center for Engineering Strong Motion Data (CESMD) for analyses of building response by researchers. Figure 7 shows the home page of the CESMD (http://www.strongmotioncenter.org). The Center is a cooperative center established by the US Geological Survey (USGS) and the California Geological Survey (CGS) to integrate earthquake strong-motion data from the CGS California Strong Motion Instrumentation Program, the USGS National Strong Motion Project, and the Advanced National Seismic System (Haddadi, et al., 2008).

Buildings records from new earthquakes are routinely processed and the usable data bandwidth is always included in the text headers of the processed data. The processed data as well as raw data from new earthquakes are added to

the Center and available for earthquake engineering applications.

In addition to the strong-motion data, the Center also contains the metadata for the instrumented buildings. Users can find descriptions of the building structural system, design dates, and the sensor location diagram for a specific building, such as the 52-story building in Figure 8. At the Center, the users can also search for all the earthquakes which were recorded at a specific building, as shown in Figure 9. The records can be viewed and downloaded for analyses. The CESMD Center provides an interface with Google maps to show the building locations on street, terrain, or satellite maps. New features are periodically added to the CESMD Center to facilitate access by users to the data and information on buildings and earthquakes (Haddadi, et al., 2009).

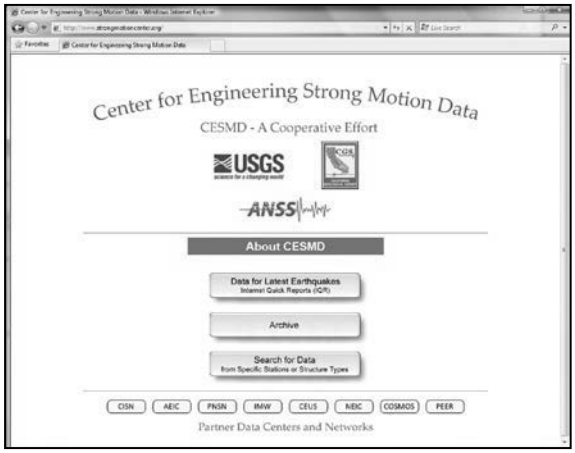

Figure 7. Home page of the Center of Engineering Strong Motion Data (http://www.strongmotioncenter.org).

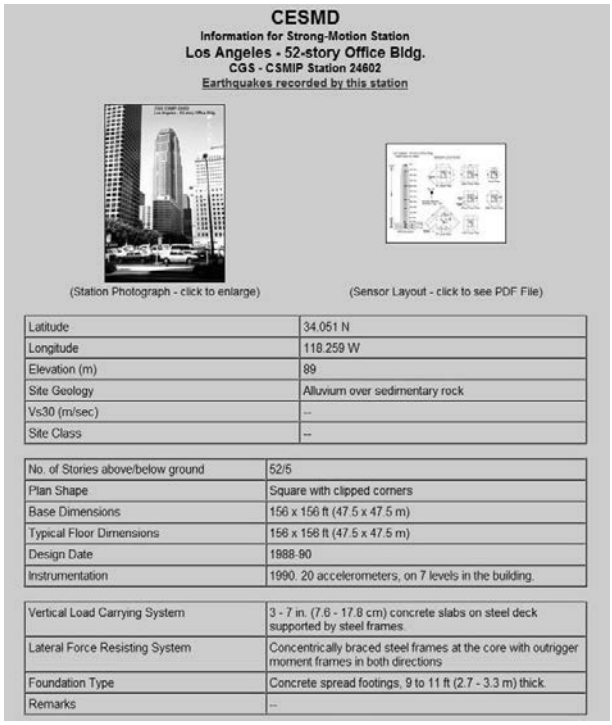

Figure 8. Description of the 52-story building and the sensor location diagram are available at CESMD.

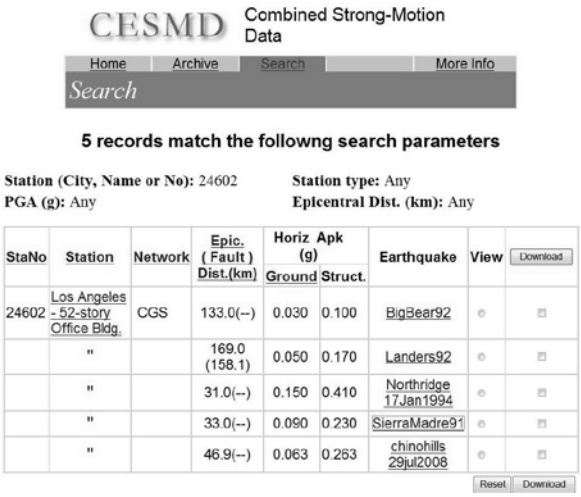

Figure 9. Result of search at CESMD for earthquakes that were recorded at the 52-story building.

4. ANALYSES OF BUILDING RECORDS

CSMIP established a Data Interpretation Project in 1989 to fund data interpretation projects for the analysis and utilization of strong-motion data. The primary objectives of the Data Interpretation Project are to further the understanding of strong ground shaking and the response of structures, and to increase the utilization of strong-motion data in improving post-earthquake response, seismic code provisions and design practices. Building records obtained during the 1989 Loma Prieta and the 1994 Northridge earthquakes have been the most significant data sets analyzed in the Project.

As part of the Data Interpretation Project, CSMIP holds annual seminars to transfer recent research findings on strong-motion data to practicing seismic design professionals, earth scientists and post-earthquake response personnel. The seminars include presentations by the investigators on the CSMIP-funded projects and invited speakers on topics related to strong-motion data. Twenty seminars have been held since 1989. The purpose of these seminars is to provide information that will be useful immediately in seismic design practice and post-earthquake response, and in the longer term, useful in the improvement of seismic design codes and practices. Proceedings and individual papers for each of the seminars are available at http://www.consrv.ca.gov/cgs/smip/pages/proceedings.aspx

Building records are traditionally analyzed to verify and improve analytical procedures for seismic response of a building, and to improve seismic design provisions in the building codes (e.g., Chopra, et al., 1998). Key response parameters are derived from the records and then compared with the results from a computer model based on the design plans. Frequently, a dynamic analysis using the recorded input motion is performed. The predicted response is compared with the recorded response to verify or improve the analysis procedure (e.g., Nagarajaiah, et al.; 1995, Naeim, et al., 1998 & 1999). Recently, the records have been utilized for post-earthquake damage assessment and safety

evaluation of buildings by rapid interpretation of the data (e.g., Rojahn, et al., 2003; Naeim, et al., 2005).

The dynamic characteristics of a building that can be obtained from strong-motion records include periods, damping, and participation factors of the first few modes. The mode shapes can also be estimated from the records if a sufficient number of floors are instrumented. The most important parameters that are related to the building performance during the earthquake are probably base shear force and inter-story drift, which can be derived directly or indirectly from the records (e.g., Jennings, 1997; Naeim, et al., 2005). The records can also be analyzed to study the nonlinear response of the building (e.g., Goel and Nishimoto, 2009), and the performance of non-structural components in the building.

In 2005, a CSMIP 3-D visualization software system was developed to visualize the response of instrumented buildings during earthquakes based on the recorded building response data (Naeim, et al., 2004). The system also allows users to analyze the building response data and learn about the performance of buildings during earthquakes. It has been a useful educational tool for understanding the seismic response of buildings.

5. CONCLUSIONS

The California Strong Motion Instrumentation Program (CSMIP) continues to instrument buildings to measure the ground motions and the building responses to these motions during earthquakes. The CSMIP building selection process and building instrumentation objectives and models continue to follow the long-term plan and criteria developed with the Strong Motion Instrumentation Advisory Committee. Strong-motion data recorded at these buildings have provided valuable information for understanding the seismic response of buildings and for improving seismic design and analysis procedures. In addition, the near-real-time recovery and processing of the recorded data is useful for post-earthquake evaluation of buildings. CSMIP continues to fund and facilitate efforts towards utilizing the near-real-time data for post-earthquake response and structural integrity assessments of buildings.

STRONG MOTION OBSERVATION FOR BUILDINGS BY BUILDING RESEARCH INSTITUTE

Toshihide Kashima[1] and Shin Koyama[2]

1) Senior Research Engineer, Building Research Institute, Japan
2) Chief Research Engineer, Building Research Institute, Japan
kashima@kenken.go.jp, skoyama@kenken.go.jp

Abstract: Strong motion observation in Japan has a history for more than 50 years. Building structures have been the main target of instrumentation at the dawn of the strong motion observation. Currently, many buildings are equipped with strong motion instruments by various bodies, such as national institutes, universities or private companies.
The Building Research Institute (BRI) of Japan is a national research institute specialising in the fields of architecture, building engineering and urban planning. BRI is operating the nationwide strong motion network as part of its research activities. The network has more than seventy strong motion stations located in major cities throughout Japan. The most important objective of strong motion observation is to contribute to an improvement in seismic safety of houses and buildings. The related researches are being conducted to elucidate dynamic properties and seismic performance of buildings, evaluate the effects of input seismic motions on buildings, and verify new earthquake-resistant technologies.
First this paper describes a state of the strong motion observation for buildings in Japan. Second, the outline of the BRI strong motion network and some outcomes are introduced.

1. INTRODUCTION

Strong motion observation in Japan has been started in 1950's under a cooperative project between universities and national institutions. Building Research Institute (BRI) is one of the members participating in the project from its launching. Expansion of the strong motion network and improvement of strong motion instruments have been continued for more than 50 years (Kashima 2010b).

With the 1995 Kobe Earthquake as a start, the strong motion network for monitoring earthquake ground motions has made great strides. Nearly 5,000 stations have been newly deployed all across Japan. The strong motion network for buildings is essential to preserve seismic safety of buildings; however, it has made very slow progress. BRI is making best efforts to accelerate the progress of the strong motion observation of building structures. The paper introduces the BRI strong motion network targeted at building structures and some of research activities using strong motion records of recent earthquakes.

2. STATE OF STRONG MOTION OBSERVATION FOR BUILDINGS IN JAPAN

In Japan, many bodies are conducting strong motion observation aimed at seismic response of buildings for their specific purposes. The chapter intends to take a general view of the situation of building instrumentation in Japan.

For instance, BRI is operating the nation-wide strong motion network of buildings as a part of research activities. The purpose of the observation is to contribute to the improvement in seismic safety of buildings as a national research institute. The chapter 3 described the BRI network in detail.

Urban Renaissance Agency (UR) is in charge of the urban development and the provision of residential and office buildings. UR has instrumented around 20 residential buildings to verify and preserve their seismic safety. Nippon Telegraph and Telephone Corporation (NTT) is the largest company providing communication service in Japan. NTT has a strong motion network with more than 50 stations. The target of instrumentation is office buildings of NTT and its group companies.

Many general contractors are maintaining their own strong motion networks. It is guessed that a large number of buildings and civil structures are instrumented. Generally, the observation is planned for development and investigation of new technology. The instrumented structures were constructed by them and owned by others. Therefore, it is difficult to bring the whole condition to light.

On the other hand, several universities are conducting strong motion monitoring in buildings for the purpose of research and education. The targets of instrumentation are usually their school buildings. Although the number of buildings is limited, creative plans specialised in research subjects can be found.

BRI investigated the actual conditions of the strong motion observation of buildings conducted by private bodies by means of questionnaires in 2003. Koyama et al. (2004) reported that 160 buildings were instrumented by 38 bodies in total. One fourth of the buildings were located in Tokyo, and a half of the buildings were equipped with base-isolation

devices or seismic control systems.

Okawa et al. (2003) reported the status of the strong motion recordings for buildings in Japan based on the literature survey by the study group of Tsukuba Building Research Institute Consortium. They surveyed technical papers of the AIJ annual meeting from 1990 to 2001 and summarised 128 cases. In addition, Kataoka et al. (2010) surveyed technical papers of the AIJ annual meeting from 2002 to 2008 and detected 119 instrumented buildings. They concluded that the total number of instrumented buildings would be estimated at approximately 300.

3. BRI STRONG MOTION NETWORK

3.1 Outline

To enhance the seismic safety of building structures, it is necessary to understand the characteristics of earthquake ground motions and the behaviours of buildings during an earthquake. BRI is performing strong motion observation to reveal the actual dynamic behaviours of buildings and is conducting research projects to clarify these motions.

BRI has installed strong motion instruments in major cities throughout Japan. Seventy-five observation stations are now in operation as shown in Fig. 1. One third of these stations are located in Tokyo and its outskirts. All of the stations are equipped with up-to-date digital instruments and most of them are connected to BRI via public telephone lines so that these instruments may be appropriately maintained and strong motion data may be collected immediately after an earthquake.

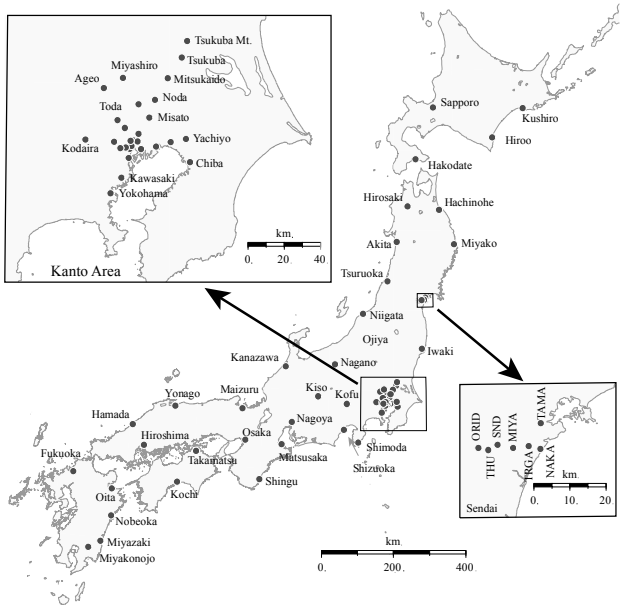

Figure 1 Locations of observation stations of BRI strong motion network

3.2 Installation Pattern

The stations of the BRI strong motion network can be classified according to installation patterns as shown in Fig. 2. Strong motion instruments are set up on the ground (and/or in the ground in some cases) at nine stations. A sensor is set up only on the first floor of a low-rise building at each of other eight stations. A quarter of the stations, therefore, are being operated for getting deep insight into characteristics of earthquake motions.

A half of the stations have two or more sensors placed on both the basement and top of their buildings. In some cases, additional sensors have been installed depending on building features. For example, sensors have been added at intermediate floors of high-rise buildings. In case of a base-isolated building, at least two sensors are necessary just above and below the floor on which base-isolation devices are installed. The dynamic soil-structure interaction is an important factor in estimating seismic responses of buildings; therefore, a sensor is preferably installed on the ground.

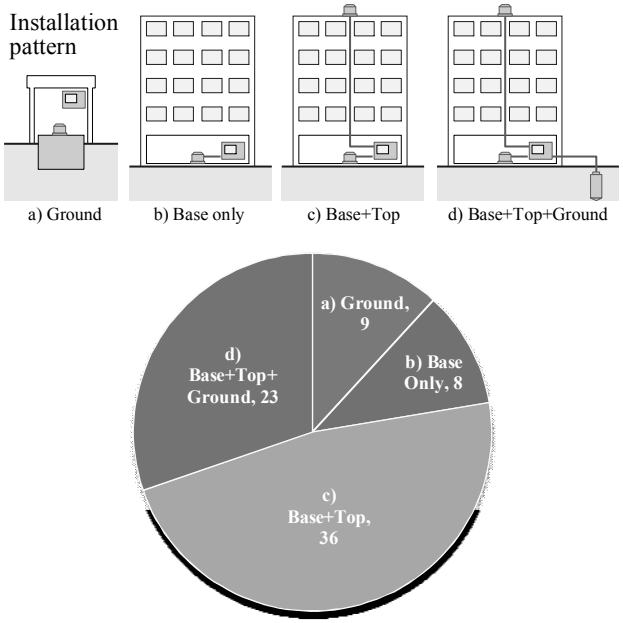

Figure 2 Classification of stations according to installation patterns

3.3 Building Types

Thus, 67 buildings are equipped with strong motion instruments. Most of the buildings are used as offices of the national or local governments. Figure 3 indicates the number of storeys and structural types of these buildings. Eighty percent of the buildings are of low- and middle-rise types which have ten or less storeys. There are five high-rise buildings with storeys more than 20, among which the highest one is a 37-storey residential building with the height of 119 meters. Low-rise buildings are usually built using reinforced concrete (RC) structures in Japan; therefore, a half of the buildings have the RC structure. The steel-framed reinforced concrete (SRC) structure is often used in middle-rise buildings with five or more storeys. Most of high-rise buildings are constructed using steel structures. There are seven steel high-rise buildings with 15 or more storeys in the BRI strong motion network.

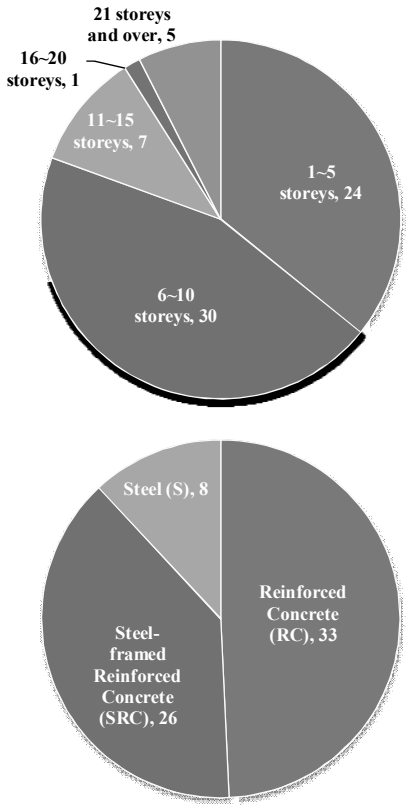

Figure 3 Classification of target buildings according to the number of storeys (upper) and structural type (lower)

4. RECENT TOPICS

4.1 Input Seismic Motions on Building

To evaluate the seismic safety of buildings, we need to understand the effects of input seismic motions on buildings correctly. Currently, we have about 5,000 strong motion stations on the ground throughout Japan. A huge number of ground motion records of every big earthquake have been accumulated. It is known, however, that the earthquake motions on the ground surface differ from the input seismic motions of buildings.

The mechanism of input seismic motions of buildings is extremely complicated, and no practical method for evaluating the input motions has been established. To address this problem, it is necessary to enhance simultaneous recording of strong motions both on the ground and of the buildings. The BRI strong motion network is tackling this problem proactively.

An example of observation results is introduced here. The annex building of the Hachinohe City Office is a ten-storey SRC building with the base isolation system. Hachinohe City, known as one of the most earthquake-prone areas, lies on the coast of the Pacific Ocean in the northernmost part of Honshu of Japan. Considering such a situation, BRI installed strong motion instrumentation in the annex building in 1999 (Kashima 2010a). The instrument has three sensors in the building and three sensors on/in the ground. One of the sensors is set up on the building basement (B1F) and other one is placed on the ground (GL) at a distance of about 50 meters from the building as shown in Fig. 4. The characteristics of input seismic motions of the building can be evaluated by comparing two strong motion records observed on both the ground and the building basement.

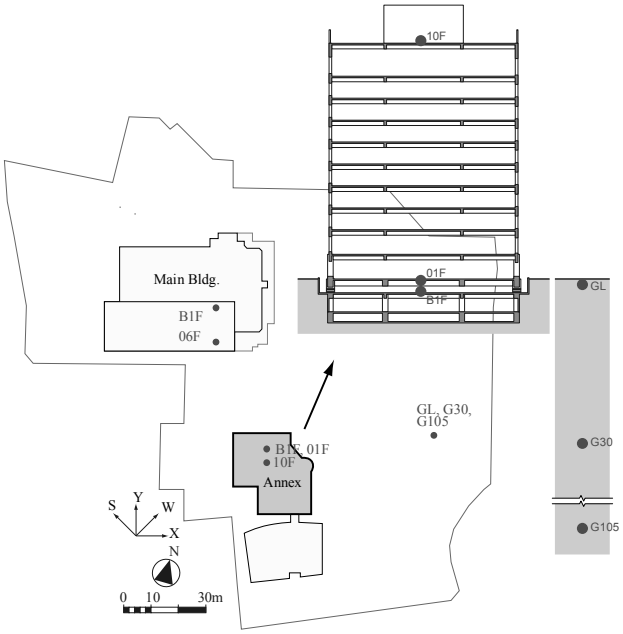

Figure 4 Sensor configuration at Hachinohe City Hall

Ninety-five strong motion records have been accumulated for the last ten years at this station. Figure 5 shows the correlations of peak accelerations between the ground (GL) and basement (B1F) levels. Red diamonds and blue squares correspond to X- and Y-directions, respectively (cf. Fig. 4). The peak acceleration on the basement is always smaller than that on the ground surface. The average of the ratio of the peak acceleration on the basement to that on the ground surface is less than 0.4.

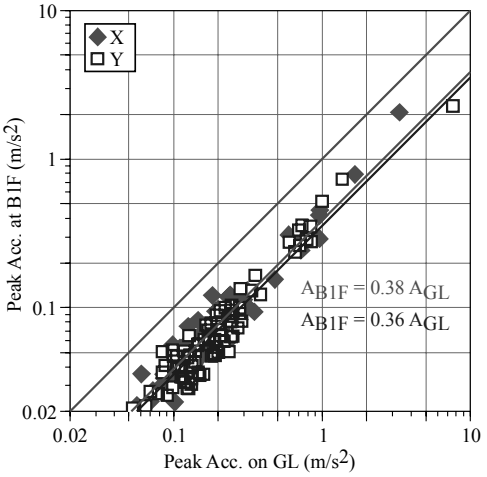

Figure 5 Correlations of peak accelerations and peak velocities between the ground and basement levels

As an example, the strong motion record of the Northern Coast of Iwate Prefecture Earthquake of 24 July,

2008, is shown in Fig. 6. The upper three waveforms and lower three waveforms show accelerations on the ground (GL) and on the basement (B1F), respectively. A difference in Y-direction acceleration is especially large, the peak acceleration on the basement attenuating down to 30 percent of that on the ground.

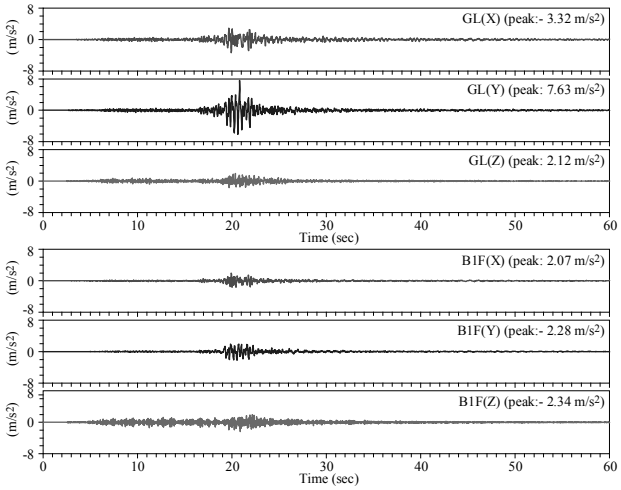

Figure 6 Acceleration records of the Northern Coast of Iwate Prefecture Earthquake of 24 July, 2008

The averaged Fourier spectrum ratios of the motions between the basement and ground levels (B1F/GL) for the 95 strong motion data are plotted in Fig. 7. Red and blue solid lines represent the average spectra in the X- and Y-directions, respectively. Dashed lines indicate positive-or-negative standard deviations. The Fourier spectra are smoothed using the Parzen window (Parzen, 1962) with a width of 0.1 Hz. The spectral ratios, which indicate about 1 in the low frequency of 1 Hz or less, drop significantly in the frequency range higher than 1.4 Hz. Consequently, it is suggested that the reduced acceleration on the building basement compared with that on the ground surface is caused by the loss of high frequency components of the earthquake motion.

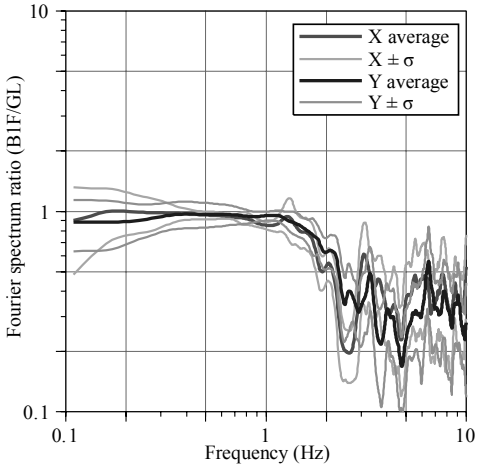

Figure 7 Fourier spectrum ratios between B1F and GL

4.2 Long-Period Earthquake Motions and Building Responses

In the urban areas in Japan, e.g. Tokyo, Osaka and Nagoya, the importance of the study on long-period earthquake motions has grown with an increase of high-rise buildings and base-isolated structures. This chapter discusses the characteristics of ground motions in Tokyo and seismic responses of a high-rise building using the strong motion data recorded in the BRI strong motion network.

The target building is a 37-storey apartment building made of reinforced concrete (RC) located in the waterfront of Tokyo. The instrumentation installed in this building has three sensors, each on the first, 18th and 37th floors.

Three major strong motion data recently recorded are taken up for discussion. Table 1 lists peak accelerations and peak velocities recorded on the first floor of the building with the earthquake parameters. The peak accelerations of EQ1 are lower than others, but the peak velocities are higher. The locations of the building and the epicentres are plotted in Fig. 8. The seismic waves of three earthquakes come from quite different directions.

Table 1 List of earthquakes and peak accelerations on the first floor

#	Date	h (km)	M_{JMA}	Δ (km)	Peak acc. (m/s^2)		
					N-S	E-W	U-D
EQ1	2007/07/16	17	6.8	235	0.050	0.058	0.025
EQ2	2008/05/08	51	7.0	175	0.123	0.095	0.051
EQ3	2009/08/11	23	6.5	153	0.141	0.132	0.046

h: focal depth, M_{JMA}: Magnitude by Japan Meteorological Agency (JMA), Δ: epicentral distance

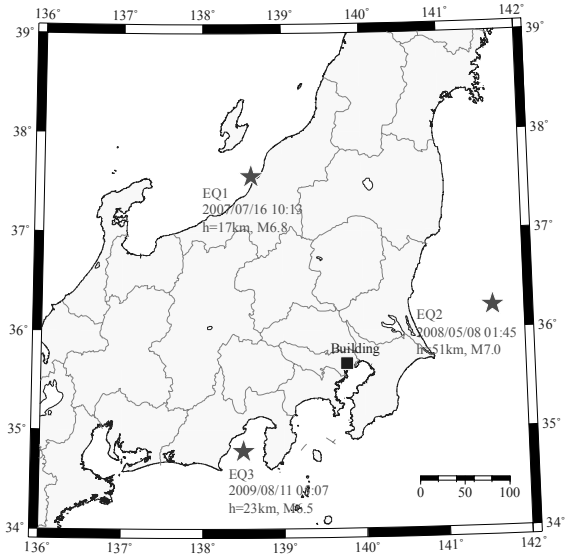

Figure 8 Locations of the instrumented building and the epicentres

Figure 9 shows acceleration waveforms of the strong motion data listed in Table 1. The upper, middle, and lower pairs of waveforms indicate accelerations in the North-South direction of EQ1, EQ2, and EQ3, respectively. The upper waveform of each pair is recorded on the 37th floor (37F) and the lower one is on the first floor (01F). Later phases of

long-period components can be clearly recognised on the waveform on the first floor of EQ1 recorded 60 seconds after the earthquake. In the cases of EQ1 and EQ2, the acceleration on the 37th floor is remarkably high and continues for long time of 4 minutes or more.

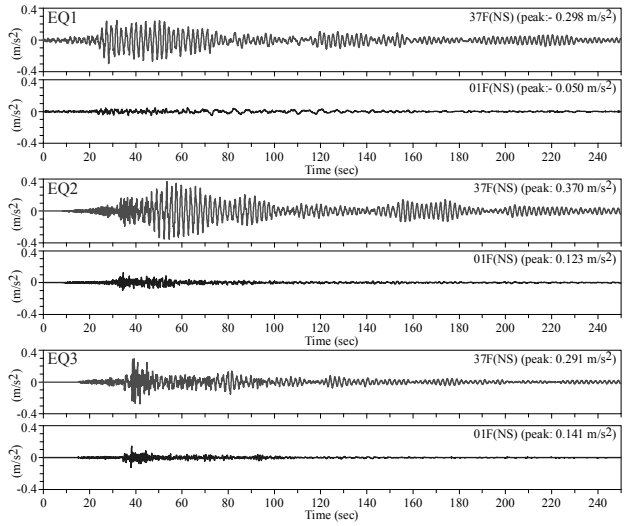

Figure 9 Acceleration records on the first and 37th floors in N-S direction

Pseudo velocity response spectra with the damping ratio of 5% of the acceleration records on the first floor are plotted in Fig. 10. The curve of the EQ1 response spectrum quite differs from others. The response spectrum has the highest peak at the period of around 7 seconds after the earthquake and attenuates gradually. The EQ3 response spectrum in the period longer than 2 seconds is extremely low in contrast to that of EQ1. The EQ2 response spectrum has high peaks in the period ranging from 2 to 3 seconds after the earthquake and attenuates to half or less in the period longer than 4 seconds.

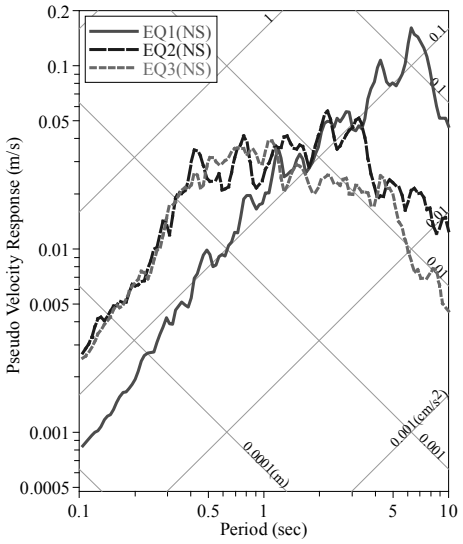

Figure 10 Pseudo velocity response spectra of N-S components of accelerations on the first floor

4.3 Strong Motion Database

BRI opened a website of the strong motion network at the address of http://smo.kenken.go.jp/ in 2009. The web site has a database which stores more than 5,000 strong motion data sets recorded on/in the ground or on the building basement levels. The search page of the website of the BRI strong motion network is shown in Fig. 11.

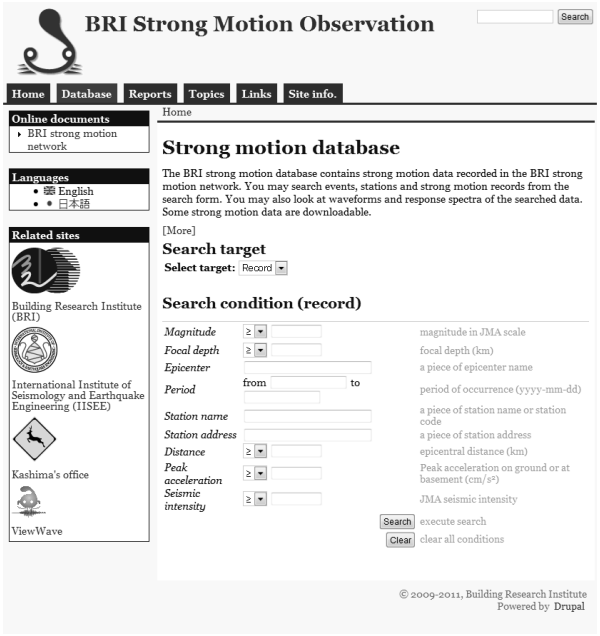

Figure 11 Search interface in the website of the BRI strong motion network (http://smo.kenken.go.jp/)

5. CONCLUSIONS

The paper summarised the current state of the strong motion observation for buildings in Japan. Approximately 300 buildings are instrumented by various institutions for various purposes.

The strong motion network operated by Building Research Institute (BRI) and some of the outcomes were also introduced. BRI is operating 76 strong motion stations aiming at capturing data on seismic responses of building structures. Importance of sensor installation both on the ground and in the building was suggested through the strong motion data analysis. This is essential for the estimation of motions input to buildings accurately. The characteristics of the earthquake motions in the Tokyo waterfront and seismic response of the high-rise building were also discussed. High-rise buildings may show strong and long responses even to moderate intensities of earthquake motions.

Acknowledgements:

The strong motion observation project of BRI is being executed with large cooperation of the owners and administrators of the target buildings. We express my gratitude to them for the assistance they gave.

Abstract: To better understand the seismic behavior of structures, the Central Weather Bureau in Taiwan initiated a strong-motion instrumentation program in 1993. Nowadays, 50 buildings and 17 bridges have been instrumented with accelerometers. The structural dynamic motions are continuously monitored and recorded when accelerations at certain accelerometers exceed a specific value. The 50 instrumented buildings are classified into low-rise (flat), mid-rise (ordinary), and high-rise (slender) buildings, and are located at soft, medium, and firm sites, respectively. The measured earthquake response records provide a great opportunity to make health monitoring and damage assessment of such buildings. In this paper, a story damage index was developed to evaluate the damage degree of a torsionally-coupled building based on its dominant modal frequencies and mode shapes. This index is expressed in an analytical formula and ranges from 0 (intact undamaged) to 1.0 (collapsed). It can be easily calculated once the modal parameters are obtained through system identification techniques from the acceleration measurements of an instrumented building. The damaged region in a specific floor can also be identified through tracking the change of floor eccentricity. This index was applied to the damage assessment of a four-story reinforced concrete building in Taitung, Taiwan, which experienced severe damage during the 2006 Taitung Beinan Earthquake (M=6.2). The results agree well with the visual inspection to show the applicability of the proposed damage assessment technique.

1. INTRODUCTION

Earthquake resistant design of buildings usually allows for a building to experience repairable damage during moderate and large earthquakes. It is important to acquire damage information of buildings to take appropriate actions after a strong earthquake event. Damaged buildings without immediate repair will probably encounter further damage and have the potential to collapse in the next extreme event. Therefore, the development of damage assessment techniques which can detect, locate, and quantify the damage of a structure, receives considerable attention and becomes a crucial topic in earthquake engineering research and practice. Damage assessment techniques are classified into global and local assessment techniques. The former is usually referred to as structural health monitoring (SHM), whereas the latter is called as non-destructive testing (NDT) which requires that the vicinity of the damage is known in advance. A well-established SHM system needs the installation of hardware incorporation with damage assessment algorithms. Nowadays, hardware technologies for SHM, such as sensors and data acquisition systems, are extensively developed, whereas a robust damage assessment technique remains unrecognized.

Damage assessment techniques based on vibration responses of structures are considered to be practical for SHM. This is due to the fact that damage in a structure will alter its dynamic characteristics, and then affect its vibration behavior (Elenas and Meskouris 2001, Park and Ang 1985). To employ these techniques, measurements of structural responses, such as acceleration and/or velocity are required. Then, damage-related features, calculated either from the measurements directly or on the basis of dynamic parameters extracted from the measurements, are obtained. With the pre-damaged and post-damaged features, damage information can be evaluated using developed algorithms. In the studies by Farrar et al. (2001) and by Yan et al. (2007), various vibration-based damage assessment techniques were summarized and reviewed.

Damage detection of a structure based on change of modal frequencies is intuitive because structural damage always leads to reduction of stiffness that is related to vibration frequency. Damage in different locations and components will cause different frequency changes in each vibration mode. Nevertheless, it remains difficult to determine the damage location just by observing the changes of modal frequencies. Among the modal parameters, mode shape is obviously the only location-related parameter. In previous studies, mode shape-based indices with simple expression, such as MAC (modal assurance criterion) (Allemang and Brown 1982), COMAC (coordinate modal assurance criterion) (Lieven and Ewins 1988), and modal

curvature index (Pandey et al. 1991, Farrar and Jauregui 1998), were applied to detect and locate structural damages. However, it was shown that these indices are insensitive to damages in some cases (Ndambi et al. 2002, Brasiliano et al. 2004). Considering both modal frequencies and mode shapes to detect the occurrence, degree, and location of a damage is a better way than relying on either one of them such as modal flexibility damage index (MFDI) (Pandey and Biswas 1994).The principle of this approach is based on flexibility matrices obtained from two sets of normalized modal parameters. Furthermore, some researchers developed more accurate damage indices but complicated expressions for various types of structures (Kim and Chun 2004, Kim et al. 2003, Di and Law 2007, Jiang and Mahadevan 2008, Gomes and Silva 2008). In recent, the authors (2007) developed a new story damage index (SDI) with analytical expression to accurately identify the damaged degree and location in elevation for buildings.

For the damage detection of a building, most of the previous researches regarded the building as a planar structure. However, it is generally recognized that the floor asymmetry resulting from the non-coincidence of its center of rigidity (C.R.) and center of mass (C.M.) always exists in a building. This results in the coupling of translational and torsional motions when the building is subjected to translational ground excitations. Relevant studies (Ueng et al. 2000, Lin et al. 2005a) reveal that this torsion-coupling (TC) effect will alter the dynamic characteristics as well as the vibration behavior of a building. To consider the TC effect, this study developed an innovative story damage index for TC buildings, called SDITC, based on the reduction of lateral story stiffness. A multi-story TC building model with two-way eccentricities is established for the derivation of SDITC which is expressed in terms of floor masses and only one modal frequency and mode shape. From the floor and excitation acceleration measurements, the dominant modal parameters of a TC building can be identified by employing the SRIM system identification technique (Juang 1997, Lin et al. 2005b, Lin et al. 2008) and then the change of floor eccentricity is used to detect the damaged region at each floor. To verify the applicability of SDITC, numerical analyses of a TC building model were performed using ETABS software with a series of damage scenarios. A planar building-based damage index (SDI) was also applied for comparison. It was proved that the SDITC can accurately identify the damaged degree and location in plan and in elevation of a building. The SDI will overestimate the damage degree. In this study, the SDI and SDITC were applied to evaluate two instrumented RC buildings in Taiwan which experienced moderate and severe damages during the 1999 Chi-Chi earthquake (M=7.3) and 2006 Taitung Beinan earthquake (M=6.2), respectively, based on their earthquake records before and after the damaged earthquake event. The agreement with the field visual inspection shows the accuracy and applicability of the proposed damage assessment technique.

2. PRATICAL CONSIDERATIONS OF MEASUREMENTS

In general, the soil surrounding the foundation of a building is not rigid resulting in complex 3-D soil-structure interaction (SSI) motions. The SSI effect affects building responses significantly and must be taken into account in the parametric identification of building systems. According to recent studies by the authors (Wu et al. 2001, Lin et al. 2008), the foundation of an irregular building-soil system behaves not only in lateral but also in torsional and rocking motions under translational seismic excitations, as shown in Figure 1. To catch these 3-D dynamic motions, measurements at free-field, base, ground floor, and the superstructure in horizontal and vertical directions are required to investigate the effects of SSI and embedment, and the vibration amplification of buildings. Because of limited number of sensors, it is not possible to measure all floor responses. Therefore, the measurements at intermediate floors with large change of story stiffness should be considered to evaluate the non-instrumented floor responses. The minimum number of sensors and their locations for different engineering purposes are illustrated in Table 1. In summary, at least total of 24 sensors are required for a general TC shear building as shown in Figure 2.

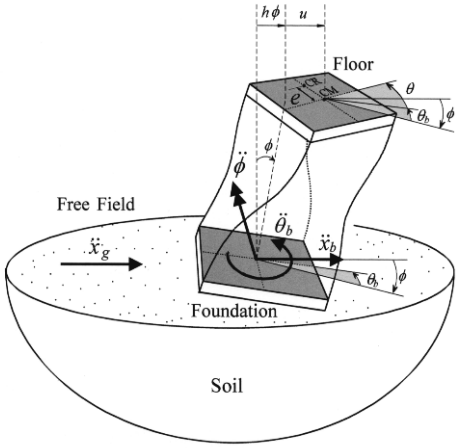

Figure 1. Irregular building-soil interaction system

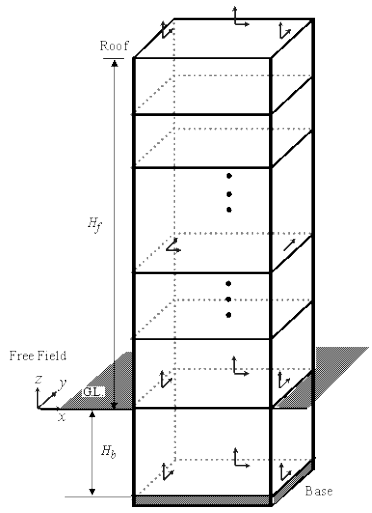
Table 1. Number of sensors and locations for different engineering purposes

Consideration	Sensor location	Number of sensor	Engineering purpose
Soil-structure interaction	Free-field	3	Building input motions (translation, torsion and rocking)
	Ground level	6	
Embedment	Ground level	6	Underground structures
	Base	6	
Floor amplification building rocking	Roof	6	Nonstructural components
	Intermediate floors	3	
Vibration mode shape	Intermediate floors with discontinuous stiffness or mass	3	Non-instrumented floor responses



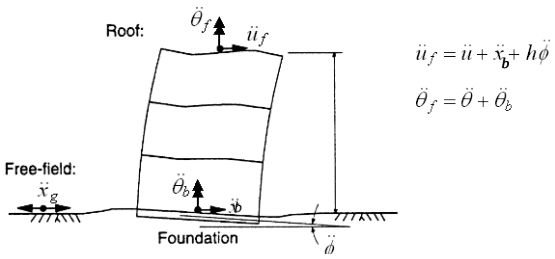


Figure 2. Sensor locations for practical considerations

For the identification of physical parameters (such as story stiffness) in the superstructure of an irregular building with consideration of SSI effect, the selected input motions should include horizontal, torsional as well as rocking motions of the foundation. Different input/output selections represent different structural systems as shown in Figure 3 (Stewart and Fenves 1998, Lin et al. 2008)

	Input	Output	System Model	ID Parameters
w/o SSI	$\ddot{x}_g$ (or $\ddot{x}_b$)	$\ddot{u}_f$, $\ddot{\theta}_f$	Fixed base	Structure
SSI	$\ddot{x}_g$	$\ddot{u}_f$, $\ddot{\theta}_f$	Flexible base	Soil + Structure
	$\ddot{x}_b$	$\ddot{u}_f$, $\ddot{\theta}_f$	Pseudo flexible-base (Stewart and Fenves 1998)	Pseudo Structure
	$\ddot{x}_b$, $\ddot{\phi}$, $\ddot{\theta}_b$	$\ddot{u}_f$, $\ddot{\theta}_f$	Fixed base (Lin et al. 2008)	Structure

Figure 3. Input/output selection in building identification

3. BUILDING INSTRUMENTATION IN TAIWAN

To better understand the seismic behavior of structures, the Taiwan Central Weather Bureau (CWB) initiated a strong-motion instrumentation program in 1993. Nowadays, 50 buildings and 17 bridges have been installed with accelerometers, as shown in Figure 4. The 50 instrumented buildings are classified into low-rise (flat), mid-rise (ordinary), and high-rise (slender) buildings, and are located at soft, medium, and firm sites, respectively. The variety of slenderness and site condition is useful for the study of both SSI and embedment effects and seismic response analysis of building systems.

For a typical building, about 30 sensors are distributed at the base, the ground floor, middle floors, and the roof. Most instrumented building systems are also equipped with a triaxial accelerometer in the free-field. The building motions are continuously monitored and the recording is triggered when accelerations of certain accelerometers exceed a specific value. All earthquake records are stored in an on-site computer and collected periodically to save at CWB. Since 2003, most measured stations have been updated with new data acquisition systems so that measurements can be on-line transmitted to CWB through ADSL (Asymmetric Digital Subscriber Line).

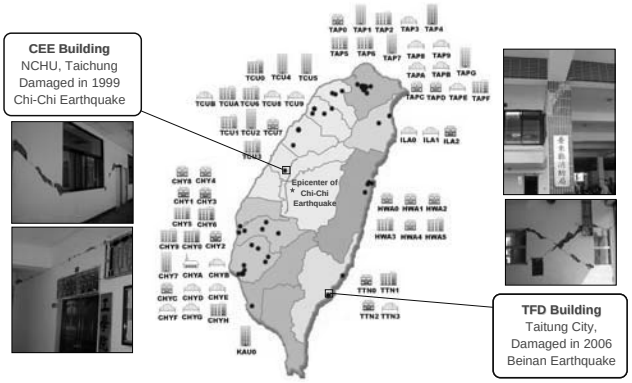

Figure 4 Map of instrumented buildings and bridges in Taiwan (http://www.cwb.gov.tw)

Among the 50 instrumented buildings, the Civil and Environmental Engineering (CEE) department building at National Chung Hsing University (NCHU) in central Taiwan experienced moderate damages during the 1999 Chi-Chi earthquake (M=7.3). Later on, the Taitung Fire Department (TFD) building was severely damaged by the 2006 Taitung Beinan earthquake (M=6.2). The measured earthquake records before and after the damaged earthquake event (such as aftershocks) are very useful for the health monitoring and damage assessment of such buildings.

4. STORY DAMAGE INDEX

4.1 Story Damage Index for TC Buildings

Define story damage of a building as the reduction ratio of lateral story stiffness after damage to that before damage. For an *N*-story TC building system, the damage index of the *l*th story in *x* direction, termed SDITC_{x_l}, can be expressed as

$$\mathrm{SDITC}_{x_l} = 1 - \frac{k^*_{x_l}}{k_{x_l}} = 1 - \frac{\omega^{*2}_j}{\omega^2_j} \frac{\sum_{i=l}^{N} \frac{m_i \phi^*_{x_i j}}{\Delta\phi^{CR*}_{x_l j}}}{\sum_{i=l}^{N} \frac{m_i \phi_{x_i j}}{\Delta\phi^{CR}_{x_l j}}} \qquad (1)$$

where k_{x_l} = story stiffness at the *l*th floor in *x* direction and m_l = the *l*th floor mass. The superscript asterisk (*) marks the

damage-state modal parameters. Superscript *CR* denotes the center of rigidity. ω_j represents the *j*th modal frequency while $\phi_{x_i j}$ represents the *j*th mode-shape values at the *i*th floor in *x* direction. *j* can be 1, 2, … or 3*N*, and

$$\Delta\phi_{x_l j}^{CR} = \begin{cases} \phi_{x_l j}^{CR} - \phi_{x_{l-1} j}^{CR} & \text{for } l = 2, 3, \ldots, N \\ \phi_{x_l j}^{CR} & \text{for } l = 1 \end{cases}$$

In the above equation,

$$\phi_{x_{l-1} j}^{CR} = \phi_{x_{l-1} j} - e_{y_{l-1,l}} \phi_{\theta_{l-1} j}, \quad \phi_{x_l j}^{CR} = \phi_{x_l j} - e_{y_{l,l}} \phi_{\theta_l j}$$

where $e_{x_{r,s}}$ (*r*, *s* =*l*-1, *l*, or *l*+1) represents the eccentricity of the center of rigidity (C.R.) from the center of mass (C.M.) of the *r*th floor due to the elements in *s*th story in *x* direction.

Similarly, damage index in *y* direction, SDITC_{y_l} can be obtained by replacing *x* by *y* in Equation (1). The value of SDITC, ranging from 0 (intact) to 1.0 (collapsed), provides a convenient index to indicate the location and degree of story damage.

As seen in Equation (1), the value of SDITC in both *x* and *y* directions can be easily obtained based on only the first dominant modal frequencies and mode shapes. This is highly beneficial in practice because the fundamental modal parameters can be identified accurately through system identification technique even with noise-contaminated measurements.

Moreover, the floor eccentricities can also be obtained based on the first three sets of modal frequencies and mode shapes and take the form as

$$\begin{Bmatrix} e_{x_{l,l}} \\ e_{x_{l-1,l}} \end{Bmatrix} = \frac{1}{(A_{x_{11}} A_{x_{22}} - A_{x_{21}} A_{x_{12}})} \begin{Bmatrix} A_{x_{22}} A_{x_{13}} - A_{x_{12}} A_{x_{23}} \\ -A_{x_{21}} A_{x_{13}} + A_{x_{11}} A_{x_{23}} \end{Bmatrix} \quad (2)$$

where

$$A_{x_{11}} = \phi_{\theta_l p_1} F_{y_l p_2} - \phi_{\theta_l p_2} F_{y_l p_1} \quad A_{x_{12}} = \phi_{\theta_{l-1} p_2} F_{y_l p_1} - \phi_{\theta_{l-1} p_1} F_{y_l p_2}$$

$$A_{x_{13}} = (\phi_{y_l p_2} - \phi_{y_{l-1} p_2}) F_{y_l p_1} - (\phi_{y_l p_1} - \phi_{y_{l-1} p_1}) F_{y_l p_2}$$

$$A_{x_{21}} = \phi_{\theta_l q_1} F_{y_l q_2} - \phi_{\theta_l q_2} F_{y_l q_1} \quad A_{x_{22}} = \phi_{\theta_{l-1} q_2} F_{y_l q_1} - \phi_{\theta_{l-1} q_1} F_{y_l q_2}$$

$$A_{x_{23}} = (\phi_{y_l q_2} - \phi_{y_{l-1} q_2}) F_{y_l q_1} - (\phi_{y_l q_1} - \phi_{y_{l-1} k_1}) F_{y_l q_2}$$

in which $\phi_{\theta_l j}$ and $\phi_{y_l j}$ denote the *j*th mode-shape values at θ and *y* directions in the *l*th floor, and

$$F_{y_l m} = \sum_{i=l}^{N} \omega_m^2 m_i \phi_{y_i m}, \quad F_{y_l n} = \sum_{i=l}^{N} \omega_n^2 m_i \phi_{x_i n} \quad (3)$$

In Equation (3), $m=p_1$ or p_2 and $n=q_1$ or q_2 which indicate specific structural modes. To make Equation (2) solvable, p_1 and p_2 have to be different, so are q_1 and q_2.

To interpret the story stiffness in Equation (1) from a physical point of view, one can imagine a building vibrating in *x* direction and in its *j*th mode. In this situation, the vibration frequency of the building is the *j*th modal frequency, ω_j, and mode shape value, $\phi_{x_l j}$ can be regarded as the displacement of the *l*th floor in *x* direction. Therefore, the *l*th floor acceleration in *x* direction equals to $\omega_j^2 \phi_{x_l j}$. Also, the inertial force of the *l*th floor in *x* direction is the mass multiplied by the acceleration, expressed as $m_l \omega_j^2 \phi_{x_l j}$. The resultant force (story shear force) applying to the *l*th story is the summation of the inertial forces above the story, $\sum_{i=l}^{N} m_i \omega_j^2 \phi_{x_i j}$. In addition, the lateral resisting force at the *l*th story is equal to the relative displacement at CRs of the *l*th and the (*l*-1)th floors, $\Delta\phi_{x_l j}^{CR}$, times the story stiffness k_x. Equating the resultant force and the resisting force, the formula of k_x is obtained and expressed as

$$k_{x_l} = \omega_j^2 \sum_{i=l}^{N} \frac{m_i \phi_{x_i j}}{\Delta\phi_{x_l j}^{CR}} \quad (4)$$

4.2 Story Damage Index for Planar Buildings

For a symmetric building, Wang et al. (2007) derived an approximate story damage index (ASDI) equation, which can be reduced from Equation (1) with same floor masses, to evaluate the damage degree of the *l*th story. The formula of ASDI takes the form as

$$\mathrm{ASDI}_l = 1 - \frac{\omega_j^{*2} \sum_{i=l}^{N} \frac{\phi_{ij}^*}{\Delta\phi_{lj}^*}}{\omega_j^2 \sum_{i=l}^{N} \frac{\phi_{ij}}{\Delta\phi_{lj}}} \quad (5)$$

This index has been proved superior to other indices (i.e. COMAC, MAC, and MFDI) for the damage assessment of a planar building (Wang et al, 2007). In this study, ASDI was also implemented to assess the damage of CEE and TFD buildings with neglect of TC effect. The results from ASDI overestimate the degree of story damage as compared with those of SDITC, as expected.

5. DAMAGE ASSESSMENT OF REAL BUILDINGS

5.1 CEE Building at NCHU

The Civil and Environmental Engineering Department building is located in the campus of National Chung Hsing University in central Taiwan. It is a seven-story reinforced concrete building with one-story basement, as shown in Figure 5. It is closely contacted with another three-story building at the right-hand side.

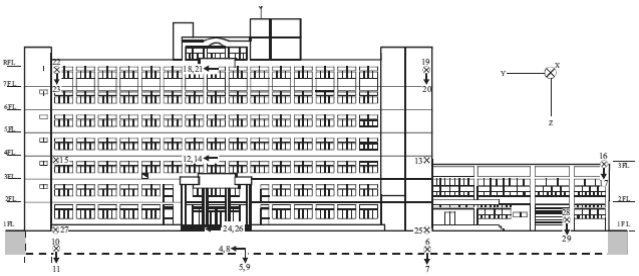

Figure 5. Elevation-view of CEE Building

A triaxial accelerograph is installed in the free-field near the CEE building and 26 unidirectional accelerometers are installed on the base, the ground floor (1FL), the fourth floor (4FL) and the roof. The location and measuring direction (indicated by arrows) of each accelerometer are shown in Figure 6. Building acceleration responses induced by the main shock and several aftershocks of the 1999 Chi-Chi earthquake were completely recorded. Cracks in the partition walls and at the junction of beams and walls of lower stories (1-4 FL) were visible after the main shock.

Table 2 presents the identified first modal parameters of the CEE building before and after the Ch-Chi earthquake using SRIM system identification technique. The values of ASDI in both horizontal directions were also calculated and shown in Table 2. It is seen that $(ASDI)_{EW} > (ASDI)_{NS}$ and $(ASDI)_{(1F-4F)} > (ASDI)_{(4F-RF)}$. Indicating that the damages at lower story and in EW direction are more serious than those at upper stories in NS direction. Moreover, the calculated ASDI values agree well with the results by visual inspection and by NDT.

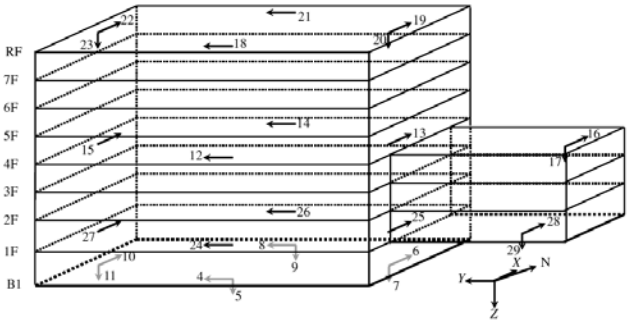

Figure 6. Sensor location and direction in the NCHU CEE building

Table 2. ASDI of CEE building under the 1999 Chi-Chi earthquake

Direction		X (NS)		Y (EW)	
Earthquake date		1999/7/7	1999/10/19	1999/7/7	1999/10/19
ω_1 or ω_1^* (Hz)		3.077	2.524	3.096	2.272
$1-\omega_1/\omega_1^*$		0.33		0.46	
ϕ_1 or ϕ_1^*	RF	1.000	1.000	1.000	1.000
	4F	0.460	0.506	0.459	0.486
ASDI	4F-RF	0.27		0.43	
	1F-4F	0.37		0.48	

5.2 TFD Building at Taitung

The Taitung Fire Department (TFD) building, located in Taitung City, was severely damaged by the 2006 Taitung Beinan earthquake. Acceleration measurements before, during, and after the earthquake were obtained and used for the verification of damage index SDITC.

The TFD building is a plan-irregular, four-story reinforced concrete building with one-story, half-excavated basement. The story height above the second floor is identical with 3.5 meters. However, the first story is 5 meter high with fewer walls than other stories to park fire fighting trucks and store essential equipments, as shown in Figure 7. Therefore, the outer and inner partition walls provide very large stiffness above the second floor resulting in soft first-story. Consequently, it is expected that the damage of this building will concentrate at the first story.

Figure 7. Photo of TFD Building

Twenty-two accelerometers were installed in the free field, ground level (GF), second floor (2F), and the roof (RF), respectively, as shown in Figure 8. The architectural drawings shown in Figure 9 indicate that the TFD building is irregular in plan which leads to translation-torsion coupling. Because each instrumented floor has four sensors, the translation along x and y directions and the torsion about the z- axis at center of mass of each floor can be calculated.

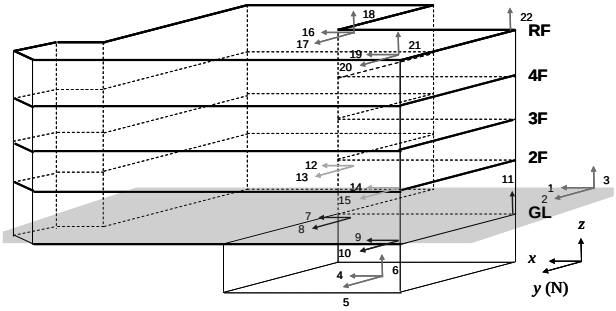

Figure 8. Sensor location and direction in the TFD building

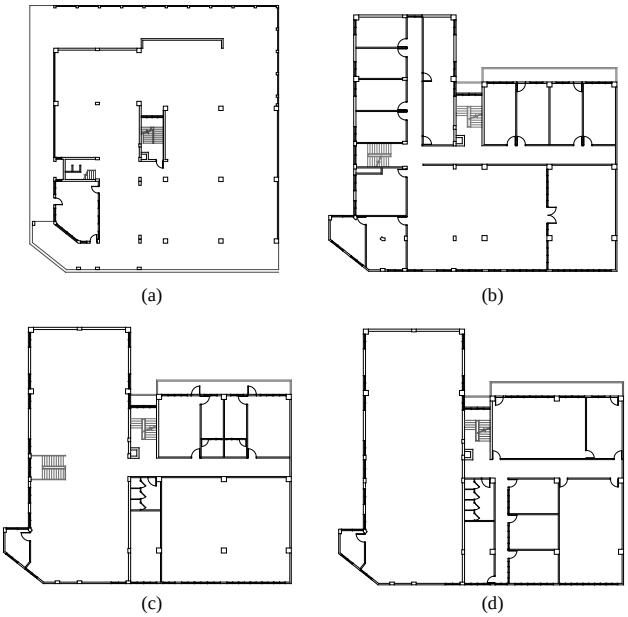

Figure 9. Plan view of TFD building: (a) GL; (b) 2F; (c) 3F; (d) 4F

During the 2006 Taitung Beinan earthquake, many columns and walls in the first story were severely damaged. It is seen from Figure 10 that most damages occurred at the north-side columns and east-side walls. For the damaged columns, moment failure near beam-column joint and shear failure due to short-column effect were observed. As to the walls, typical X-shape shear cracks happened. For the stories above second floor, no significant damage was found.

To evaluate the TFD building, the earthquake records of December 28, 2005, and aftershocks of the Taitung Beinan earthquake were used. Because this building has a soft bottom story, the SDITC was calculated only for the first story. Table 3 presents the identified first three modal parameters of the TFD building before and after the main earthquake event using SRIM system identification technique. The large reduction of fundamental modal frequencies (55% in the first mode and 42% in the second mode) reflects the occurrence of serious damage of the building. The changes of eccentricities (calculated by Equation (2)) in *x*- and *y*-directions and then the $SDITC_1$ are calculated and shown in Table 4. It is seen that the C.R. moved toward southwestern direction indicating that the damage is located at the northeastern region of the building. It agrees well with the results of visual inspections as shown in Figure 10. Moreover, the $(SDITC_1)_{EW}$ is larger than $(SDITC_1)_{NS}$, representing that the damage in EW direction is more severe than that in NS direction. The results can be reasonably expected because a wall contributes large lateral stiffness and more wall damages encountered along the EW-direction. For comparison, the $ASDI_1$ is also presented in Table 4. The results indicate that 81% of the EW-direction stiffness was reduced, which is overestimated due to large torsion coupling effect.

Table 3. Identified fundamental modal parameters of TFD building before and after the 2006 Taitung Benan earthquake

Earthquake Date		12/28/2005	4/1/2006
Peak Base Acceleration (gal)		x: 0.40 y: 0.53	x: 8.90 y: 12.7

Table 4. Damage indices of TFD building under the 2006 Taitung Beinan earthquake

Damage Index	EW-direction	NS-direction
Changes of Eccentricities	-369 cm	-433 cm
$SDITC_1$	0.66	0.49
$ASDI_1$	0.81	0.70

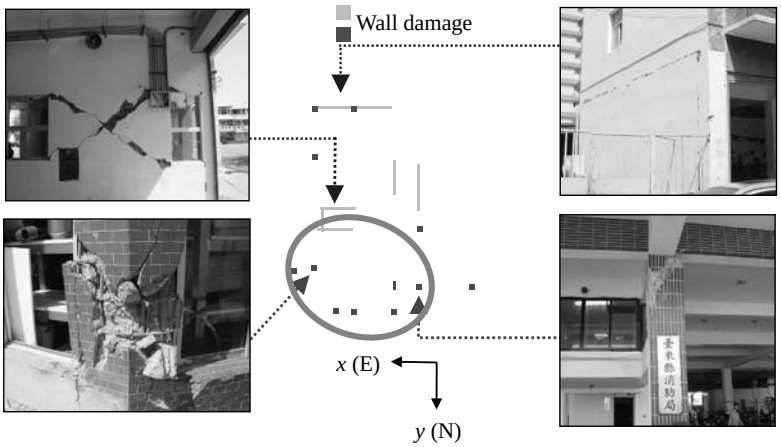

Figure 10. Wall and column failures in the first story of TFD building

6. CONCLUSIONS

Damage assessment of a building after a strong earthquake is very essential for post-earthquake recovery and has received great research interest from researchers and engineers in recent decade. This study applied a story damage index for TC buildings, named SDITC, expressed with closed form in terms of the first three modal frequencies and mode shapes of the building. For the damage assessment of the Taitung Fire Department building based on its real earthquake records, SDITC proves its accuracy and applicability to detect the damage degree and to identify the damage region in plan of a particular story. It is also shown that the assessed damage degrees in two directions agree with the visual inspection of the damaged buildings. Meanwhile, the damage degree indicated by SDITC is more reasonable than that by the planar damage index, ASDI.

OBSERVATION OF STRONG EARTHQUAKE MOTION AT PUBLIC WORKS BY NILIM

Shojiro Kataoka

Senior Researcher, National Institute for Land and Infrastructure Management, Japan
kataoka-s92rc@nilim.go.jp

Abstract: National Institute for Land and Infrastructure Management (NILIM) administers the observation of strong earthquake motion at public works throughout Japan. This paper describes current status of the observation at road and river facilities by NILIM and examples of utilization of observed records.

1. INTRODUCTION

The observation of strong earthquake motion at public works was initiated in 1957, when a SMAC-type strong motion accelerometer was installed at Sarutani Dam. Strong motion accelerograms recorded during the 1964 Niigata earthquake greatly contributed to study of damage caused by the earthquake, especially liquefaction of sandy soil, demonstrating necessity of the strong earthquake motion observation.

Therefore, a nationwide instrumentation plan of SMAC-type accelerometers was drawn up and has been steadily implemented by the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) and other organizations. National Institute for Land and Infrastructure Management (NILIM) has been in charge of collection, processing, and analysis of the strong motion records and conducts research on seismic design and earthquake disaster mitigation using the accumulated records.

Currently, NILIM administers two types of strong earthquake motion observation, in addition to supervising the MLIT Seismograph Network. Table 1 shows outlines and objectives of these strong motion observation systems. Locations of the observation stations at river and road facilities and those for dense instrument array observation are shown in Figure 1. Strong earthquake motion observations at national dams and ports are mainly conducted by dam work offices and Port and Airport Research Institute, respectively.

2. OBSERVATION AT RIVER FACILITIES

65 observation stations were installed at river facilities: 56 stations are at levees, 8 at weirs, and one at a sluice gate. A typical configuration of instruments at levee sites is shown in Figure 2. Accelerometers are located at the crown of the levee, on the ground surface nearby, and in the bedrock layer, while piezometers are set in the sandy soil layer.

Some stations have specific purposes such as observing influence of microtopography and examination of soil improvement. Figure 3 shows locations of accelerometers and piezometers at Nakashimo station, right-bank of Naruse River, Miyagi prefecture. The sensor arrays were installed at the berm, where liquefaction strength had been improved by the sand compaction pile (SCP) method, and near the crown, where no liquefaction remediation had been conducted.

Table 1 Outline of strong-motion observation administered by NILIM

Type of observation	Description of observation	Number of stations
Strong motion observation at public works	1) River facilities (levees, weirs, sluice gate) 2) Road facilities (bridges, embankments, slopes, retaining wall, common ducts) 3) Ground surface	123 stations (65 river facilities, 30 road facilities, 28 ground surface)
Dense instrument array observation of strong motion	Observation of amplification or attenuation characteristics caused by variations of local topography and geological conditions	92 stations in 9 areas
MLIT Seismograph Network	The stations are installed on ground surface with intervals of 20 to 40 km along rivers and national highways administered by MLIT. The observed data are sent to responsible sectors by telecommunication network for estimating seismic intensity distribution.	718 stations (http://www.nilim.go.jp/japanese/database/nwdb/index.htm)

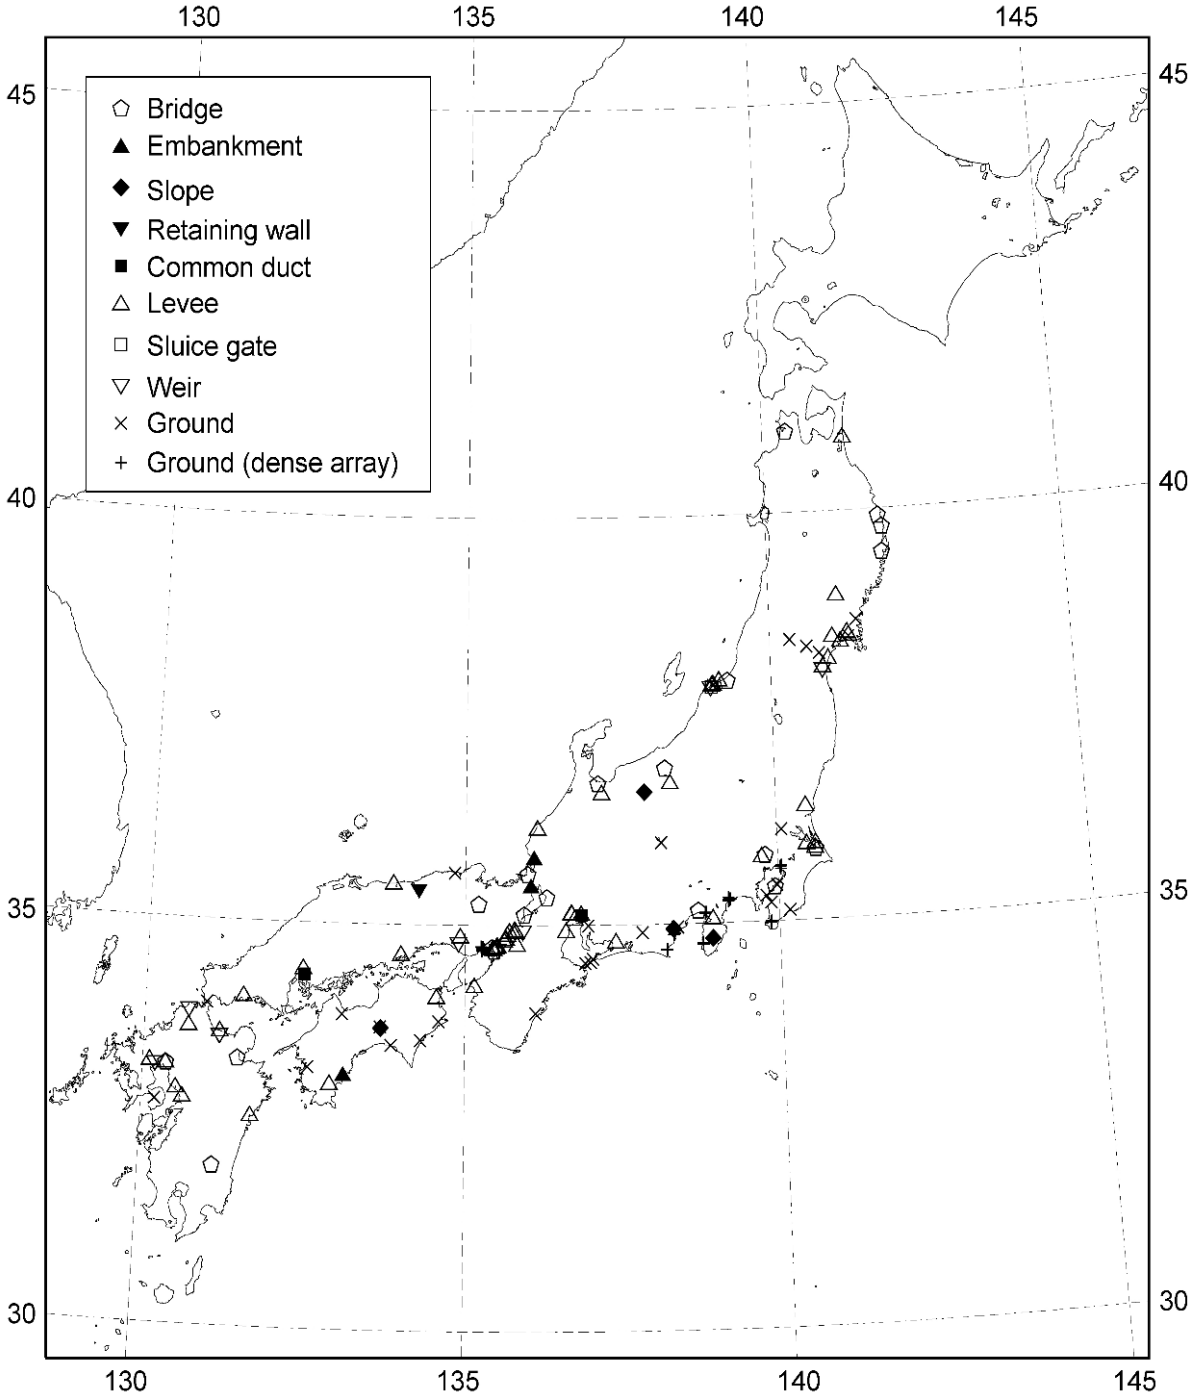

Figure 1 Strong motion observation stations at road and river facilities and those for dense instrument array observation.

Time history records of ground acceleration and pore water pressure were obtained at the station during northern Miyagi earthquakes on July 26, 2003. Figure 4 shows those recorded during the main shock (M6.4). Though the pore water pressure at 9m below the crown exceeded the maximum measurable value, 101.3[kPa]=1[atm], remarkable difference can be seen between the pore water pressure in the improved and non-improved soils. Liquefaction strengths of the improved and non-improved sandy soils were estimated using these observed records based on the accumulated damage analysis (Kataoka *et al.*, 2010). Cyclic triaxial strength ratios (R_L) of soils where the piezometers are located were estimated 0.34 and 0.40 for SCP-improved soil and 0.26 for non-improved soil.

These values are larger than R_L calculated from the equations in Specifications for highway bridges (Japan Road Association, 2002). Since the equations are used for liquefaction judgment in the seismic performance evaluation of river facilities (River Improvement and Management Division, 2007), this result can be used to reduce the cost for liquefaction remediation.

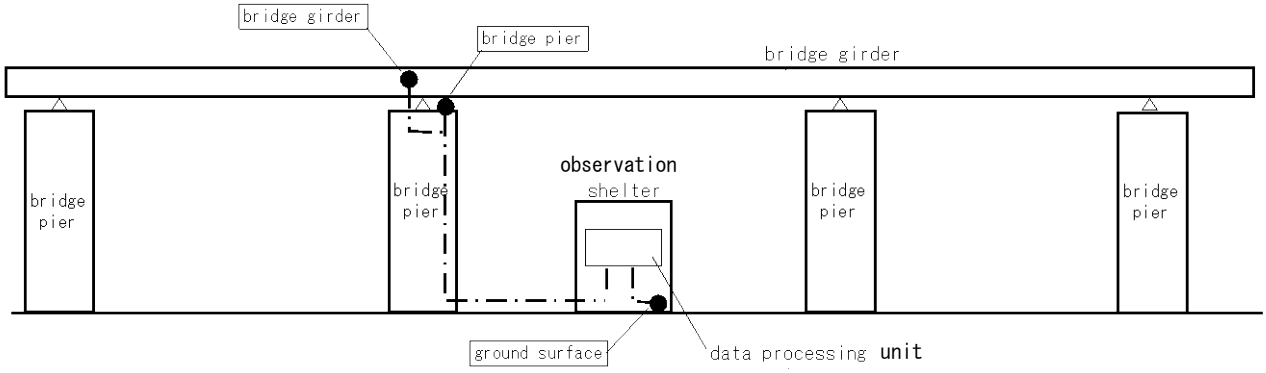

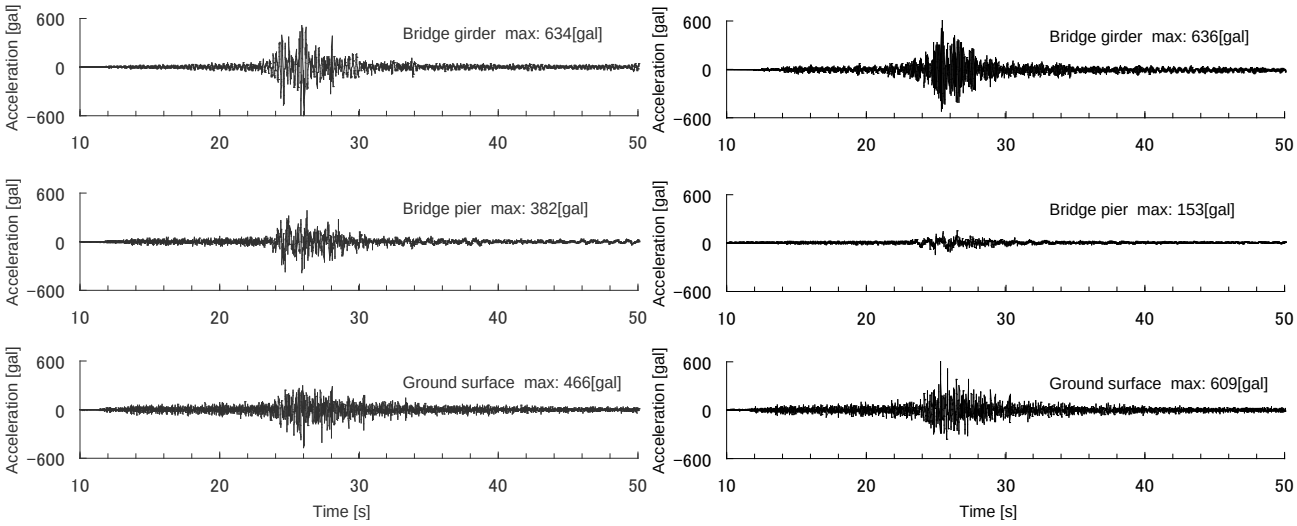

Figure 5 Typical configuration of instruments at a bridge site.

(a) Longitudinal direction (b) Transverse direction

Figure 6 Accelerograms recorded at Yamada viaduct during the northern Iwate coast earthquake (M6.8) on July 24, 2008.

3. OBSERVATION AT ROAD FACILITIES

30 observation stations were installed at road facilities: 20 stations are at bridges, 4 at slopes, 3 at embankments, 2 at common ducts, and one at a retaining wall. A typical configuration of instruments at bridge sites is shown in Figure 5. Accelerometers are located at the girder, pier, and on the ground surface nearby.

Figure 6 shows accelerograms recorded at Yamada viaduct during the northern Iwate coast earthquake (M6.8) on July 24, 2008. Horizontal force distribution structure was adopted for the viaduct, 470.7m long with two 4-span continuous steel box girders, using multi-layered rubber bearings. We conducted dynamic response analysis of the viaduct using the observed records and found the earthquake response of the viaduct cannot be reproduced well by a simple model (Matsuhashi *et al*., 2010). We have been investigating the reason that causes the difference between observed and analytical responses.

4. CONCLUDING REMARKS

NILIM has been intent on maintenance of the strong earthquake motion observation systems and utilizing the observed records for improving seismic design and earthquake disaster mitigation. We will be working on further development of the observation systems and improvement of the data utilization.

A NEW APPROACH FOR STRONG-MOTION OBSERVATION USING LOW-COST SENSORS IN COLLABORATION WITH NONPROFESSIONAL PARTNERS

Jun Tobita[1] and Nobuo Fukuwa[2]

1) Associate Professor, Graduate School of Environmental Studies, Nagoya University, Japan
2) Professor, Graduate School of Environmental Studies, Nagoya University, Japan
tobita@sharaku.nuac.nagoya-u.ac.jp, fukuwa@sharaku.nuac.nagoya-u.ac.jp

Abstract: A new strong-motion observation system, P-NET, is introduced and discussed for application of building response observation in collaboration with non-professional persons. The first aspect of the system is utilizing low cost seismometers including old and reused instruments of other observation systems such as seismic intensity networks for local governments. Daily maintenance, inspection and preservation of observed earthquake data are performed by non-professional users who are interested in earth and building science, aseismic building and disaster mitigation. To encourage such partners in continuous collaboration on earthquake observation, various vibration analysis and utility software, Web GIS contents and study programs are offered. The observation has already tested and performed in some high schools and houses by science teachers, engineers and university students. Observed data will be analyzed to show the effectiveness of the proposed system for long term observation in many buildings spread over a wide area. Furthermore the most important effect of the P-NET is that the partner will be interested in the field of earth science, earthquake engineering and disaster mitigation.

1. INTRODUCTION

An earthquake observation system that can be used to monitor various sites of ground and buildings over a wide area can contribute greatly to the disaster-mitigation measures for future earthquakes, and can be effective for the immediate reactions for an earthquake disaster.

There has been remarkable progress in Japan's strong-motion observation since the 1995 South Hyogo Prefecture Earthquake (NIED, 2004). Consequently, nationwide observation networks have been established by the central government and local authorities. Seismometers have been placed at a few thousand stations across the country by the Japan Meteorological Agency and local governments. The seismic intensity data provided by these stations are readily available for disaster response. An earthquake early-warning system based on real-time observation and data collection is also in use. However, seismic waveform records from these observation networks are not often collected, disseminated, and used. The Metropolitan Strong-Motion Observation Networks have been developed in 2000 for the major six urban areas in Japan and has created a database of waveform records such as the intensity networks measured by local governments (Tobita, *et al.*, 2001). However the networks have been continuously operated only in the districts of Tokai and Kanto until now.

NIED's K-NET and KIK-net uniformly cover all parts of the country, accumulate high-quality waveform data, and release them on the Internet. Then, these data are widely used for seismic engineering and disaster prevention (Okada, *et al*., 2004). However, the seismometers spaced within several tens of kilometers of each other in these networks do not provide sufficient data for the evaluation of strong motion with respect to the local ground conditions.

While a large number of observations have been carried out to analyze the earthquake response of the ground, there are very few observations of the earthquake response of buildings. Earthquake responses of buildings were observed at around 2000 sites in 1990 (NIED, 2004). However, only a few such records were released and used because many of the observed buildings are special ones such as high-rise buildings, base-isolated buildings and some large buildings for public use. The observed records are used only to confirm the basic response characteristics of the buildings because the good results are enough for engineers, and because the costs and labor required for long-term observation were relatively expensive. In addition, most of the buildings are private assets and thus the owners and users of the building are usually nervous to open the data to the public on the behavior of their buildings against earthquake. Such engineers' overconfidence in the existing technologies and the public's indifference to the observations are believed to contribute to the limited use of the observed data.

In light of the above, it is essential to ensure that there are as many observation targets and waveform observation records as possible and to establish a framework for the wide use of these records. We therefore propose a new strong-motion observation system, P-NET, which encourages collaboration with nonprofessional partners. P refers to the initials of People, Person, and Partner, etc. The two main objectives for the development of this system are as follows:

(1) To form a simplified observation system using low-cost and reused seismometers and to request local nonprofessional partners to maintain them and collect strong-motion records.

(2) To provide the partners software and web environments so that they understand the advantages of strong-motion observations, as well as educational programs related to the observations, in exchange for their contribution.

The system aims to reuse observation equipment and materials that have been discarded by local governments to provide stations at the lowest cost, and to increase the partners' awareness of and interest in strong-motion observations. This will lead to better seismic strengthening of buildings and improvement in the quality of education on earthquake disaster prevention. In this paper we summarize the development of equipment and materials, including recycled sensors and the Web GIS-based environment, as well as the installation of the seismometers and the observation results. We also describe the future development plans for this system in the later section.

2. BASIC SYSTEM FOR SEISMIC OBSERVATION

The basic system focuses on offline standalone observations on the assumption of the reuse of discarded seismometers and other low-cost sensors. Local partners are requested to collect observation records, transfer them to the servers, and maintain the equipment and materials. We provide a software package that can be individually used for strong-motion observations (Tobita, *et al*., 2009).

We tested the system in a school building; high-school science teachers were asked to help. The basic observation system is shown in Fig. 1. Sensors are individually placed on the first and top floors of the building. GPS-based time calibration and UPS-based power backup are performed to the extent possible. When an earthquake occurs, the school's PC and its special software are used to collect observation records. The records are attached to an email and sent to the University's server. The server creates a database for the records. The results are then made available on the Web GIS. The high-school staff can analyze the records collected offline and refer to area-wide observation records on the Web as well. The records can be used for education in science, social studies, disaster mitigation, and other subjects, in combination with other relevant information on the area. An example of such a learning tool is shown in Fig. 2. The left side of the figure shows the PC tool that is provided to users. This tool displays the maximum values, seismic intensities, waveforms, and response spectra calculated on the basis of the records collected from the sensors. It also displays one-degree-of-freedom response animations (Hirono, *et al*., 2008). The software is also effective for educational experiment using sensors. The right side of the figure shows an example where the Web GIS is used to display the status of strong-motion observation at the school and other sites in the area.

Because the responsibility of data observation and record collection should be entrusted to nonprofessional partners, we must set reasonable expectations for the precision, reliability, and immediacy of the records. This reduces the cost of the equipment and the installation and maintenance costs. It also reduces the effort involved, thereby enabling the development of the easy and rapid observation. Even if a large-scale disaster damages the network and electric power infrastructure, some data can be collected by this type of simple observation, and a database containing observation records for more buildings may be constructed than highly developed observation systems.

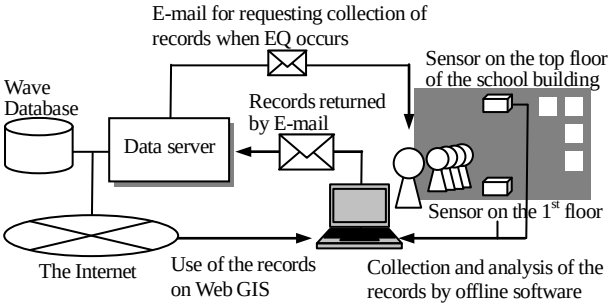

Figure 1 Strong-Motion Observation System

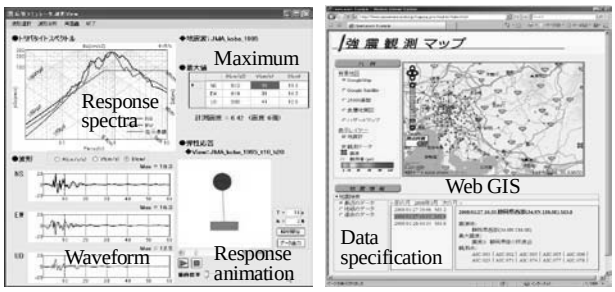

Figure 2 Example of Learning Tool

3. OBSERVATION EQUIPMENTS

The sensors used in this paper are mainly K-NET95 seismometers that were installed during 1995 and 1996, and removed for renewal during 2003 and 2004. An operational test on 133 sensors was conducted in Nagoya University in 2008. Out of the 133 sensors, 13 sensors could not be used for normal observations, while 11 others had some problems during use.

Before using the sensor, the battery box was removed and modified for direct connection to the AC power supply. When the battery is crucial to ensure uninterrupted power supply, a low-cost external UPS is connected to the seismometer to eliminate the need for inspection and

replacement of the built-in battery of conventional all-in-one type seismometers. Because its small capacity memory (8 MB) is not expandable, the seismometer requires frequent maintenance in the case of continuous noises and aftershocks. With GPS-based time calibration, the sensor can easily receive time data if an antenna is placed at the window with an unobstructed view of the sky. The seismometer has a serial interface that maintains the transfer rate at a value of up to 38,400 bps.

We performed a strong-motion observation test in the E-Defense using a conventional all-in-one type seismometer, the K-NET95 seismometer and a low-cost compact sensor (Tobita, *et al*., 2010). Outline of sensors and setup are shown in Fig. 3, and the specifications of the three sensors are given in Table 1. We compared the spectral characteristics of the sensors under white-noise excitation; see Fig. 4. The results revealed that the K-NET95 showed satisfactory performance for our applications. For reference, we used a low-cost compact semi-conductor type acceleration sensor that had problems in frequency content of upper/lower component and in its low resolutions but showed satisfactory characteristics in the horizontal components for amplitude level of large earthquake response.

We considered new approaches for the collection of the data recorded by the sensors, as the existing sensors have certain limitations. If the sensor is connected to a network such as ADSL or Cable TV, it can automatically transfer observation records to the server via email. Figures 5 and 6 show a network interface with a compact Linux Box and its application for observation. The interface gains access to the sensor on a regular basis, reads any new records, clears existing records when the available memory is low, and adjusts the time via NTP (Network Time Protocol). The interface automatically transmits collected records and its status via email. This significantly alleviates the memory restriction of the seismometer and the effect of GPS reception. Because of the non-direct external connection to the Internet, this method is suitable for ordinary households, where a global address cannot be used, and/or in cases where the rigid network security constraints were applied in the observation building, such as local governments' buildings.

Figure 5 Network Interface with Compact Linux Box

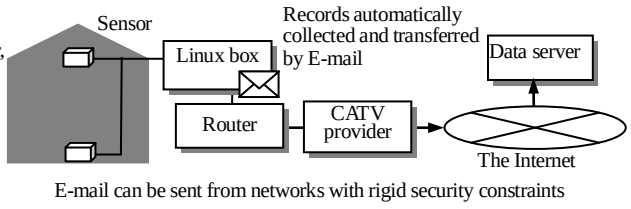

Figure 6 Observation System Using Linux Box

Thus, we can deal with constraints such as network connection, interface speed, time synchronization, and memory capacity and use any old or low-cost equipment. The seismometers installed by local governments have been upgraded nationwide since 2009. Our approach allows the reuse of large quantities of discarded equipment without any associated costs or labor.

4. EXAMPLE OF HIGH-SCHOOL OBSERVATION

We have used the introduced system to observe strong motions at high school buildings in Aichi Prefecture in cooperation with science teachers. Figure 7 shows the sensors placed on the first and fourth floors of a reinforced concrete four-story school building, and Fig. 8 shows an example of the observation records. In 2009, records for six earthquakes were obtained from this school in Okazaki City, Aichi Prefecture. The maximum seismic intensity (3 on the first floor) and response (approximately 50 cm/s^2 on the fourth floor of the building) were observed during the Suruga Bay Earthquake that occurred on August 11, 2009. A trigger interlock between the two sensors was not made, and it can also be seen that the GPS on the first floor did not receive data. However, the time could be adjusted with sufficient precision by using cross correlation of vertical components of observed data in the range of 0.5 to 3 Hz. Consequently, the transfer functions on the fourth/first floors were stably determined, as shown in Figs. 8(d) and 8(e). The

(Suruga Bay Earthquake on August 11, 2009)

natural frequencies identified for the different earthquakes are shown in Fig. 9. The structure is modeled as a linear, time-invariant system with classical normal modes. Two orthogonal horizontal acceleration records at the basement of the structure are used as system input to explain two-dimensional behavior of the structure (Tobita, 1996). Natural frequencies, damping ratios and participation vectors are estimated in the frequency domain. By using the system identification procedure, nonlinear inelastic behavior of the structure is evaluated by the equivalent linear system. Responses ranging from 4 to 50 cm/s^2 are recorded in the span and longitudinal directions, and the amplitude dependence of the natural frequencies can be clearly seen.

Figure 10 shows a comparison of the records from the K-NET station (AIC014) closest to the school building and on the first floor. Although the station and the building are separated by a distance of about 10 km, the characteristics of the long-period components in the displacement waveforms at the school are in good agreement with those at the station. From a performance test on a shaking table, it was confirmed that the displacements were stably determined by double integration of the acceleration by a low-cut filter of approximately 0.1 Hz. In the case of a large-amplitude response, the damage to the building can be assessed on the basis of story deformation (Tobita, *et al*., 2010).

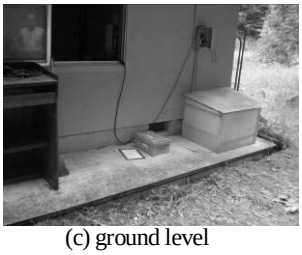
5. FUTURE DEVELOPMENT

Good and reliable observation data are collected by the sensors installed in the school buildings, as described in the previous section, but only keen science teachers and some particularly active students associate the observations with disaster mitigation education. Our next challenge is to make more high-school students as well as elementary-school and junior-high-school students aware of the school observations. High-school teachers often desire practical course materials for disaster prevention and physics (vibration) education as well as for geoscience (earthquake) and geography (society and disaster) classes, as these subjects might capture the attention of the students. Disaster-prevention education has been introduced in elementary-, junior-high-, and high-school curriculums. We believe that it is necessary to revitalize the education in existing subjects with strong focus on disaster mitigation.

Recent attempts to link observations and education include the earthquake observations at elementary schools in the Metropolitan area carried out by ERI, the University of Tokyo (Kasahara, *et al*., 2009), and educational application of observations with high-precision seismometer network "Manten project" by Prof. K. Yamori, DPRI, Kyoto University. In another project, many network-connected vibration observation instruments are provided to applicants and real-time motion information is released nationwide on a website ("Yure-project" by Weather News Inc., http://weathernews.jp/yure/, accessed on January 2nd, 2011). Recently, an attempt has been made with using high-performance smart phones, which have acceleration sensors and GPS-based location information. Observed vibration data is displayed on Web-GIS based map ("*i*Jishin" project with free software by Hakusan corporation, http://i-jishin.appspot.com/, and its introduction in English: http://www.hakusan.co.jp/LABO/i-jishin/iJishin_en.shtml, accessed on January 2nd, 2011). With this attempt, it has been possible to receive the attention of a large number of people.

However, our observation approach is clearly different from the above mentioned projects and attempts. The main purpose of our system is to observe wave data of earthquake response of as many buildings as possible. The observation partners will include high-school teachers, building engineers and researchers who are not specialized in strong-motion observation, engineers and researchers from other fields, administration and mass-media personnel, and interested individuals and building managers. Collaborations with these partners would enable various kinds of new functions by observation.

For example, seismic diagnosis of buildings could be performed not only based on the building information but also using observed building response. Damage prediction for coming large earthquake disaster could be performed clearly on the basis of the Web GIS-based ground conditions and predicted earthquake ground motions at the site of the building. Structural health monitoring and damage assessment of the building are also required by using the appropriate predictions and observations. Based on continuous observation, a building engineer can confirm whether a building under construction will show the desired performance or not and conduct long-term deterioration monitoring. The accumulation of small- and medium-level earthquake records clearly shows the actual response characteristics of the building and their changes, thereby enabling deterioration and damage assessments.



Another important aspect is that the observation is performed by the users and owners of the building, who are most influential with its safety. Figure 11 shows seismometers installed on wooden houses. Earthquake response data on their own house will lead their interest and positive preparedness on future earthquake disasters, e.g. seismic reinforcement of their houses.

6. CONCLUSION

Nonprofessional partner involvement in strong-motion observation through P-NET is expected to reduce operational loads and costs, promote data distribution, and broaden the base of strong-motion observation. In addition, a collaborative relationship with partners with various positions, interests, knowledge, and techniques could allow us to improve the use of strong-motion observation records for disaster prevention.

Acknowledgements:

High-school science teachers have contributed to our continuous observations; FALCON and HAKUSAN Corporation helped us in developing the software and other tools; and NIED permitted us to use the K-NET records. We are grateful for their cooperation. The part of this study was supported by Grant-in-Aid for Scientific Research (KAKENHI (B) No.20360250).

Abstract: As part of the project entitled "NEESR-GC: Simulation of the Seismic Performance of Nonstructural System," a series of system-level full-scale experiments of ceilings-piping-partition systems will be conducted at the University of Nevada, Reno NEES Site. This project is aimed at understanding the seismic response of these systems and their interaction with each other and the parent structure. A two-story, two-bay steel braced frame spanning across three biaxial shake tables was designed as a Test-Bed structure to simulate a variety of dynamic environments. After introducing the design considerations of the Test-Bed structure within this paper, the method proposed to develop the shake table drive motions is explained. To obtain the drive motion of the linear Test-Bed, a transfer function (TF) was formulated for a multi-support dynamic system under differential support excitation and combined with a TF previously developed for target floor acceleration of a generic structure. For the nonlinear Test-Bed structure, the drive motion was developed using the concept of drift TF. In the later case, the nonlinearities were accounted for in the formulations by using equivalent damping and effective frequency for the first mode.

1. INTRODUCTION

After an earthquake, the functionality of an essential facility, such as a hospital, relies heavily on the functionality of its nonstructural components, such as piping systems, fire suppression systems, elevators, and other equipment. In recent earthquakes, nonstructural components of hospitals and medical facilities have suffered severe damage, which consequently interrupted the functionality of these facilities (OSHPD, 2010). The 1971 San Fernando Earthquake caused excessive damage to many hospitals and medical facilities, which led to evacuation of four of the eleven damaged medical facilities in the area (Wasilweski, 1998). Due to this unacceptable performance, the State of California passed the Hospital Seismic Safety Act in 1973, requiring medical facilities to remain operational after earthquake events.

The repair and replacement costs of nonresidential buildings after the Northridge earthquake were $6.3 billion, with only $1.1 billion of the total in structural damage (Kircher, 2003). Immediately after this earthquake, 88% of the occupants of the hospital beds in the damaged area (13 hospitals) had to be evacuated as a result of nonstructural damage such as water damage, elevator failure, etc. (Ayres et al., 1998). Hospitals built in accordance with the 1973 Hospital Act, however, were successful in resisting structural damage. Nevertheless, nonstructural damage (plumbing, ceiling systems, etc.) in post 1973 construction was, and still is, extensive after strong seismic activities. This shows an urgent need to better understand the seismic behavior of nonstructural systems.

Extensive systematic experimental data is required as a supplement to previous experience to improve available nonstructural design provisions. Several studies have been conducted on the seismic response of nonstructural subassemblies and their components as early as 1980s on ceiling tiles and piping systems (ANCO, 1983; Hoehler et al., 2009; ATC, 2007); however, the understanding on the system-level response of these subassemblies is significantly limited necessitating the design of large-scale experiments on complete systems (Zaghi, 2010).

As a part of the NEESR Grand Challenge project "Simulation of the Seismic Performance of Nonstructural Systems," a large scale Test-Bed structure is constructed to conduct system-level experiments of full-scale, complex, nonstructural systems. The NEES earthquake simulator (three biaxial shake tables) at the Large Scale Structure Laboratory of University of Nevada, Reno will be used to subject the Test-Bed structure and nested nonstructural systems to desired levels of dynamic excitations.

Nonstructural components can be divided into two categories in terms of seismic performance: 1) acceleration sensitive elements such as ceiling and horizontal pipe runs;

and 2) drift sensitive components, including partition and riser pipes. The Test-Bed structure is designed in a way that it can subject the nested subassemblies to large accelerations as well as large inter-story drifts.

Before describing the methodology used for the development of the shake table input motion, a brief review of the NEESR Grand Challenge is presented, followed by the design philosophy and provisions of the proposed Test-Bed structure.

2. NEESR NONSTRUCTURAL GRAND CHALLENGE PROJECT

The Grand Challenge Project entitled "Simulation of the Seismic Performance of Nonstructural Systems" integrates multidisciplinary system-level studies that develop, for the first time, the simulation capabilities and implementation process for enhancing the seismic performance of ceiling-piping-partition (CPP) nonstructural systems. This project is led by the University of Nevada, Reno in collaboration with the Consortium of Universities for Research in Earthquake Engineering (CUREE), Cornell University, Georgia Institute of Technology, North Carolina Agricultural and Technical State University, North Carolina State University, Rutherford & Chekene, State University of New York at Buffalo, and University of California, San Diego. This paper reports on design considerations and characteristics of UNR Test-Bed structure.

3. TEST-BED STRUCTURE DESIGN PHLOSOPHY

To achieve the objectives of system-level experimental investigation, several key requirements were identified, particularly with respect to the design of the Test-Bed structure. During the experiments, it will be utmost importance to simulate experimentally and to capture the various types of interactions that will take place among the subassemblies and the parent Test-Bed structure. Moreover, the Test-Bed structure should allow investigators to study the effects of structural yielding on the response of the subassemblies. A discussion of the performance design concepts were utilized in the design of the Test-Bed structure with the provisions follows.

A two-story, two-bay (18.6 m-long, 3.66 m-wide, 7.57 m-high) Test-Bed structure was designed. The dimensions are typical of spans and story heights in multi-story buildings and allow for the installation of full height partition walls as well as large ceiling areas. The view of this structure is shown in Fig.1.

To study drift sensitive and acceleration sensitive nonstructural components, two designs were considered for the Test-Bed structure by implementing two sets of bracing systems. Elastic braces restrained against buckling (BRBs), used to achieve large floor accelerations, and buckling resistant braces, used to produce large inter-story drifts.

The test bed is designed for longitudinal excitation. Therefore, the transverse bracing system of the Test-Bed structure was significantly overdesigned to ensure that the longitudinal dynamic modes dominate vibration of the frame.

To understand the effects of the nonstructural subassemblies on the seismic response of structures (specifically stiffness, lateral strength, and added damping) structural dynamic characteristics of the Test-Bed structure should be well known, predictable, and controllable. The Test-Bed structure was designed with 'frictionless' tight-fit hinges in order to avoid any possible deviation of the physical responses from that of numerical models. The column-base and beam-column connections were pinned, minimizing the rotational fixity. The lateral stiffness and strength of the frame is provided by a set of eight brace members that are installed in a chevron configuration. This design methodology allows yielding to take place in predefined members (BRBs).

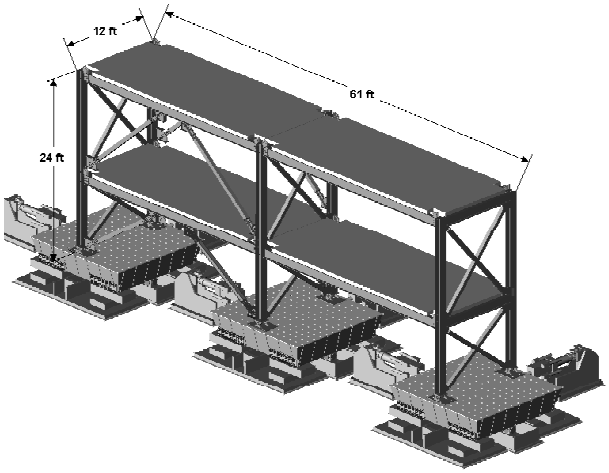

Figure 1 View of the Test-Bed Structure

The Test-Bed structure is planned to be used for multiple experiments, and therefore, should remain linear-elastic during the shake table testing. Utilization of the buckling restrained members as lateral resisting members enables the Test-Bed structure to be used a number of times after replacement of the yielded braces. Furthermore, to allow for a safe assembly and disassembly of the structure, each floor is divided into two prefabricated 5.5-in thick steel deck concrete composite slabs panels that were built off-site and will be shipped to the laboratory. These floor panels as well as other structural members can be stored in a small area before and after the test.

4. TARGET PERFORMANCE OF THE TEST-BED

Although the Test-Bed structure is a two-story frame, it may represent any two adjacent floors of a multi-story building (i.e., the j^{th} and $j+1^{th}$ floors.) Taking the limitations of the shake table into consideration, the Test-Bed was designed to reach a minimum for the inter-story drift and peak floor acceleration without exceeding the hydraulic

system restraints. The target performances of linear and nonlinear Test-Bed structures are separately discussed in this section.

4.1 Nonlinear Test-Bed Structure

This setup was designed to achieve large inter-story drifts similar to that of nonlinear frame structure. This setup was aimed at the evaluation of drift sensitive subassemblies such as in-plane partitions, pipe risers, and riser ducts. Design target of the nonlinear Test-Bed was to achieve an inter-story drift larger than 3% on both stories.

The nonlinear BRBs were designed for this setup and, on each floor, additional mass was provided using low profile lead baskets bolted to the floor to provide required inertial forces. The natural period of the structure was calculated as 0.43sec and the effective period of the structure at 3% drift was found to be 1.21sec.

4.2 Linear Test-Bed Structure

This setup was designed to investigate acceleration sensitive subassemblies including ceilings, sprinkler piping, and out-of-plane partitions. The linear Test-Bed was designed to simulate linear or stiff structures in which large floor acceleration is expected. The target peak floor acceleration (PFA) was larger than 2.0g on both floors.

Because conventional braces required a large cross-section area for local or global buckling requirements, buckling restrained elastic braces were used for the linear structure. This large area increases the elastic stiffness of the structure and as a consequence significantly reduces the effective periods. Although a high frequency Test-Bed experiences large floor accelerations, its period does not fall within the range of practical structures. To avoid yielding of the brace members in the linear structure, strength of the brace members was increased by using higher-grade steel for the brace cores to control the lateral stiffness. An additional mass was provided on the first floors to achieve the target period. The natural period of the structure was found to be 0.19sec.

It should be mentioned that the Test-Bed structure may be modified to achieve other performance limits in accordance with the purpose of the experiment.

5. DEVELOPMENT OF THE SHAKE TABLE INPUT MOTION

It is evident that if a ground acceleration is used as the shake table input motion, the Test-Bed structure will simulate the response of a two-story building supported on the ground. However, the Test-Bed structure is meant to simulate the floor response of any multistory building: a method was developed as part of this project to allow simulation of floor acceleration responses of multistory buildings by using the Test-Bed structure. The theory of a reduced-order earthquake demand assessment that is presented in detail by Taghavi and Miranda (2005) was adopted. The absolute acceleration transfer function (TF) was obtained by superposition of modal TFs. This TF was multiplied by the inverse of a TF for the Test-Bed structure that was formulated with the effect of multi-support excitation in mind. To satisfy the displacement and velocity limitations of the shake-tables, a high-pass filter was added to TF of the system. This method is described in detail in this section.

5.1 Description of Generic Buildings

The dynamic characteristics of multistory buildings are approximated (Taghavi and Miranda, 2005) by using an equivalent continuum model consisting of a flexural cantilever beam and a shear cantilever beam deforming in bending and shear, respectively (Fig. 2). These flexural and shear cantilever beams were assumed to undergo the same lateral deformation. Under a horizontal acceleration at the base, response of this continuum system can be expressed by the following partial differential equation (Taghavi and Miranda, 2005):

$$\rho(x)\frac{\partial^2 u(x,t)}{\partial t^2}+c(x)\frac{\partial u(x,t)}{\partial t^2}+\frac{1}{H^4}\frac{\partial^2}{\partial x^2}\left[EI(x)\frac{\partial^2 u(x,t)}{\partial x^2}\right] -\frac{1}{H^2}\frac{\partial}{\partial x}\left[GA(x)\frac{\partial u(x,t)}{\partial x}\right]=-\rho(x)\frac{\partial^2 u_g(t)}{\partial t^2} \quad (1)$$

where $\rho(x)$ is mass per unit height, $u(x,t)$ is the displacement at normalized height x at time t (x varies between zero, at the base of the building, and one, at the roof level), H is the total height of the building, $c(x)$ is damping coefficient per unit height, $EI(x)$ is flexural rigidity of the flexural beam along the height, $GA(x)$ is shear rigidity of the shear beam and $u_g(t)$is the ground displacement at time t.

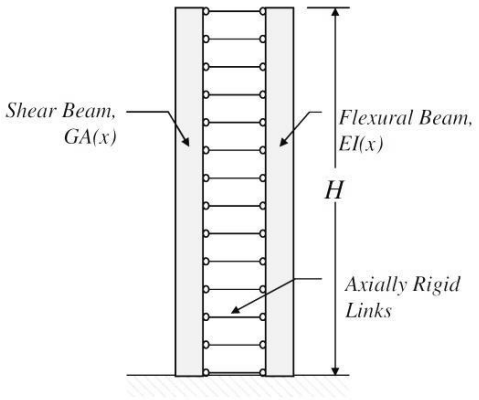

Figure 2 Generic Model to Estimate Dynamic Properties of Multi-Story Buildings (Taghavi and Miranda, 2005)

By solving Eq. (1), the shape of the mode of vibration corresponding to the i^{th} mode, normalized to unity at $x=1$ is found by:

$$\phi_i(x)=\frac{\begin{array}{l}\sin(\gamma_i x)-\gamma_i\left(\gamma_i^2+\alpha_o^2\right)^{-0.5}\sinh\left(x\sqrt{\gamma_i^2+\alpha_o^2}\right)\\+\eta_i\left[\cosh\left(x\sqrt{\gamma_i^2+\alpha_o^2}\right)-\cos(\gamma_i x)\right]\end{array}}{\begin{array}{l}\sin(\gamma_i)-\gamma_i\left(\gamma_i^2+\alpha_o^2\right)^{-0.5}\sinh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)\\+\eta_i\left[\cosh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)-\cos(\gamma_i)\right]\end{array}} \quad (2)$$

Where:

$$\eta_i=\frac{\gamma_i^2\sin(\gamma_i)+\gamma_i\sqrt{\gamma_i^2+\alpha_o^2}\sinh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)}{\gamma_i^2\cos(\gamma_i)+\left(\gamma_i^2+\alpha_o^2\right)\sinh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)} \quad (3)$$

In Eq. (2), γ_i is obtained from the solution of the characteristic equation shown as Eq. (4):

$$\begin{array}{l}2+\left[2+\dfrac{\alpha_o^4}{\gamma_i^2\left(\gamma_i^2+\alpha_o^2\right)}\right]\cos(\gamma_i)\cosh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)\\+\left[\dfrac{\alpha_o^2}{\gamma_i\left(\gamma_i^2+\alpha_o^2\right)}\right]\sin(\gamma_i)\sinh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)=0\end{array} \quad (4)$$

The dimensionless parameter α_o in Eq. (2) controls the degree of participation of overall flexural and overall shear deformations in the generic model of multistory buildings. A value of α_o equal to zero represents a pure flexural and a value larger than 30 corresponds to a shear dominated deformation for a building. In these equations *i* represent the mode number.

For a continuum model with uniformly distributed mass, the modal participation factor of the i^{th} mode of vibration is given by:

$$\Gamma_i=\frac{\int_0^1\phi_i(x)dx}{\int_0^1\phi_i^2(x)dx} \quad (5)$$

Eqs. (2) and (5) were implemented to generate the TF for the absolute acceleration of q^{th} floor of generic building. A method that is discussed in detail in Maddaloni et al. (2010) was utilized to obtain the TF shown in Eq. (6):

$$H_q(\omega)=\sum_{im=1}^{k}\frac{-\left(2i\omega\xi_{im}\omega_{im}+\omega_{im}^2\right)}{\omega_{im}^2-\omega^2+2i\omega\xi_{im}\omega_{im}}\phi_{im,q}\Gamma_{im} \quad (6)$$

Where ω_{im}^2 , Γ_{im} and ξ_{im} are the circular frequency, modal participation factor, and damping ratio of im^{th} mode of generic building, respectively. Only the first *k* significant modes were participated in this derivation. In this equation, $\phi_{im,q}$ corresponds to the value of the im^{th} mode in the q^{th} floor of the building.

5.2 Development Drive Motion of the Linear Test-Bed Structure for the Target Absolute Floor Acceleration

The Test-Bed structure is supported on three shake tables. Each shake table responds slightly different to the drive motion as can be explained by servo-valve control basics. The following formulation for a dynamic system with multiple support excitations was extended to include the support degrees of freedom (DOFs) in the system TF equations. The matrix form of the equation of motion for the Test-Bed Structure with two dynamic DOFs and three support DOFs can be written as (Chopra, 2001):

$$\begin{array}{l}\begin{bmatrix}{}_{2x2}M_{ss} & 0\\ 0 & {}_{3x3}M_{tt}\end{bmatrix}\begin{bmatrix}{}_{2x1}\ddot{u}_s^t\\ {}_{3x1}\ddot{u}_t\end{bmatrix}+\begin{bmatrix}{}_{2x2}C_{ss} & {}_{2x3}C_{st}\\ {}_{3x2}C_{ts} & {}_{3x3}C_{tt}\end{bmatrix}\begin{bmatrix}{}_{2x1}\dot{u}_s^t\\ {}_{3x1}\dot{u}_t\end{bmatrix}+\\ \begin{bmatrix}{}_{2x2}K_{ss} & {}_{2x3}K_{st}\\ {}_{3x2}K_{ts} & {}_{3x3}K_{tt}\end{bmatrix}\begin{bmatrix}{}_{2x1}u_s^t\\ {}_{1x3}u_t\end{bmatrix}=\begin{bmatrix}0\\ {}_{3x1}p_t(t)\end{bmatrix}\end{array} \quad (7)$$

The total displacements include contributions from dynamic and static displacements as:

$$\begin{bmatrix}{}_{2x1}u_s^t\\ {}_{3x1}u_t\end{bmatrix}=\begin{bmatrix}{}_{2x1}u_s^s\\ {}_{3x1}u_t\end{bmatrix}+\begin{bmatrix}{}_{2x1}u_s\\ 0\end{bmatrix} \quad (8)$$

Where [M], [C], [K] are the mass, stiffness, and viscous damping matrices, respectively. The vectors $[\ddot{u}]$, $[\dot{u}]$, $[u]$ are the acceleration, velocity, and displacement, respectively. The superscripts *t* and *s* stand for the total and static responses, accordingly. The subscripts *t* and *s* are related to the shake table's and the structure's responses, respectively. The $P_t(t)$ is the table force vector. Equation (7) can be reduced to Eq. (9) after satisfying static equilibrium.

$$\begin{array}{l}{}_{2x2}M_{ss}\,{}_{2x1}\ddot{u}_s(t)+{}_{2x2}C_{ss}\,{}_{2x1}\dot{u}_s(t)+{}_{2x2}K_{ss}\,{}_{2x1}u_s(t)=\\ -{}_{2x2}M_{ss}\,{}_{2x3}\iota\,{}_{3x1}\ddot{u}_t(t)\end{array} \quad (9)$$

Where ${}_{2x3}\iota=-{}_{2x2}K_{ss}^{-1}\,{}_{2x3}K_{st}$ describes the influence of support displacements (or accelerations) on structure displacement (or acceleration) at dynamic DOFs. Dynamic response of the structure may be decomposed in modal coordinates, $q_i(t)$, that $u(t)=\phi_i q_i(t)$ and ϕ_i is the i^{th} mass-normalized mode shape. Assuming that response is composed of harmonic functions, Eq. (9) can be transformed to Eq. (10) infrequency domain:

$$\begin{array}{l}-\omega^2 q_i(\omega)+2i\omega\xi_i\omega_i q_i(\omega)+\omega_i^2 q_i(\omega)=\\ -{}_{1x2}\Gamma_{i\,2x3}\iota\,{}_{3x1}\ddot{u}_t(\omega)\end{array} \quad (10)$$

Where $(\phi_i^T K_{ss}\phi_i)/M_{ss,i}^*=\omega_i^2$ is the circular frequency and $(C_{ss,i}^*/M_{ss,i}^*)/2\,\omega_i=\xi_i$ is the damping ratio of i^{th} mode of vibration. The absolute acceleration response vector, $\ddot{u}_s^t$, for the Test-Bed structure with two horizontal dynamic DOFs is the summation of the relative acceleration vector and the influence of table acceleration:

$${}_{2x1}\ddot{u}_s^t(\omega)=\sum_{i=1}^{2}-\omega^2\,{}_{2x1}\phi_i q(\omega)_i+{}_{2x3}\iota\,{}_{3x1}\ddot{u}_t(\omega) \quad (11)$$

Equation (11) was pre-multiplied by $({}_{1x2}\phi_i^T\,{}_{2x2}M_{ss})=-{}_{1x2}\Gamma_i$ and combined with Eq. (10) to obtain:

$$ {}_{1x2}\phi_i^T\ {}_{2x2}M_{ss}\ {}_{2x1}\ddot{u}_s^t(\omega) = \frac{-\left(2i\omega\xi_i\omega_i+\omega_i^2\right)}{\omega_i^2-\omega^2+2i\omega\xi_i\omega_i}\ {}_{1x2}\Gamma_{i\ 2x3}\iota_{3x1}\ddot{u}_t(\omega) \quad (12) $$

The mode shape is mass normalized, $\Phi^T M = \Phi^{-1}$, thus Eq. (12) can be manipulated to achieve the absolute acceleration of the j^{th} floor of the Test-Bed structure as:

$$ \ddot{u}_s^t(\omega)_j = \left[\sum_{i=1}^{2}\frac{-\left(2i\omega\xi_i\omega_i+\omega_i^2\right)}{\omega_i^2-\omega^2+2i\omega\xi_i\omega_i}\phi_{i,j\ 1x3}\kappa_i\right]_{3x1}\ddot{u}_t(\omega) \quad (13) $$

The term shown in the bracket is a TF that relates the accelerations of shake tables to the absolute floor acceleration of the Test-Bed. The TF that relates motion of the n^{th} shake table to the acceleration of the j^{th} floor is defined by Eq. (14).

$$ H_{sn,j}(\omega) = \frac{\ddot{u}_s^t(\omega)_j}{\ddot{u}_t(\omega)_n} = \sum_{i=1}^{2}\frac{-\left(2i\omega\xi_i\omega_i+\omega_i^2\right)}{\omega_i^2-\omega^2+2i\omega\xi_i\omega_i}\phi_{i,j}\kappa_{i,n} \quad (14) $$

In this equation, parameter $\kappa_{i,n} = ({}_{1x2}\Gamma_{i\ 2x3}\iota)_n$ is a measure of the participation of n^{th} table on the absolute acceleration of the j^{th} floor in i^{th} mode of vibration. As was mentioned earlier, the achieved table motions may be different from the drive motion (or target motion) due to several factors including the servo valve's dynamic response, the compressibility of the actuator fluid, oil leakage through the actuator seals, and the influence of the mass and stiffness of the test specimen (Maddaloni et al., 2010). The achieved and target shake table motions are assumed to be related through a transfer function H_{tn} for the n^{th} shake table. The TF that relates acceleration of the j^{th} floor to the drive motion can be obtained from the summation of the multiplication of structure TFs, as shown in Eq. (14), with H_{tn}. Figure 3 shows the structure-table dynamic system.

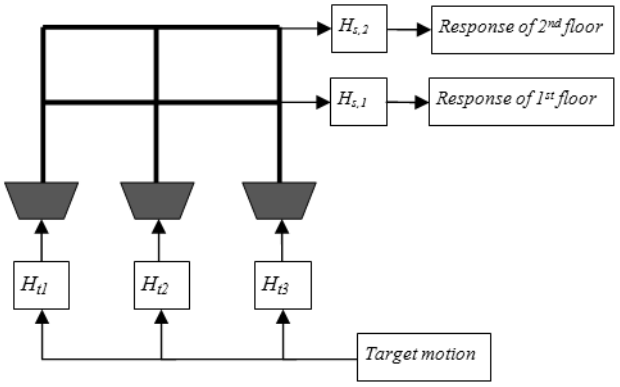

Figure 3 Structure-Table Dynamic System

$$ H_j(\omega) = \sum_{n=1}^{3} H_{tn}(\omega)\cdot H_{sn,j}(\omega) \quad (15) $$

The Test-Bed structure should simulate the specific floor responses of any target building. Floor response of a multistory building subjected to a ground motion, $\ddot{u}_g(\omega)$, can be obtained by using the TF presented as Eq.(6).

The drive motion of the shake tables to achieve the target floor motion can be generated by multiplication of the inverse of the TF of the Test-Bed shake table system shown in Fig. (3) and can express as:

$$ \ddot{u}_{Drive}(\omega) = H_q(\omega).H_j(\omega)^{-1}.\ddot{u}_g(\omega) \quad (16) $$

Expression of $\ddot{u}_{Drive}(\omega)$ in the time domain gives the time history of the drive motion of the shake tables. A suitable high-pass filter may be needed to insure that the demands on the shake tables are within acceptable limits to permit continued use. This method allows for the simulation of floor accelerations of any type of structural system subjected to any set of ground motions.

This work will be continued to develop a similar formulation that can be used for simulation of the inter-story drifts of the generic building. A simplified method will be used to account for the structural nonlinearities.

5.3 Development Drive Motion of the Nonlinear Test-Bed Structure for the Target Inter-Story Drift

Approximate solutions for nonlinear response of yielding structures have gained a wide interest as a simple analysis technique for seismic design procedures. One of the techniques used involves replacing the nonlinear structure with an equivalent linear structure whose maximum displacement response will be, approximately, equal to the original nonlinear structure response. Equivalent linear systems with equivalent damping and effective period were proposed to approximate the steady-state response of a damped nonlinear system after Jacobsen (1939). For a nonlinear system with a hysteretic response shown in Fig. 4, the equivalent hysteretic damping and frequency in a ductility of μ can be found as Eqs. (17) and (18), respectively.

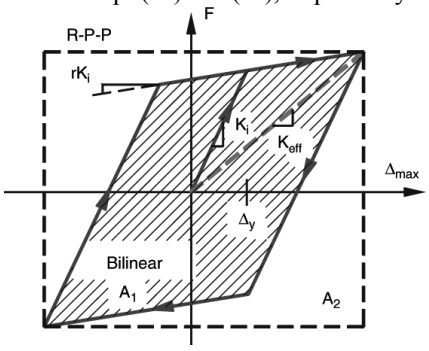

Figure 4 Equivalent Damping for Bilinear and R-P-P Hysteretic Models (Dwairi et. al, 2007).

$$ (\xi_{eq})_{Bilinear} = \xi_{viscus} + \frac{2(\mu-1)(1-r)}{\mu(1+r\mu-r)} \quad (17) $$

$$ \frac{\omega_{eff}}{\omega_i} = \sqrt{\frac{1+r\mu-r}{\mu}} \quad (18) $$

Extensive study was conducted by Dwairi et. al (2007) on four different hysteretic models, namely, (1) Ring-Spring, (2) Large Takeda, (3) Small Takeda, and (4) Elasto-Plastic. These models cover a wide range of structural systems including, concrete and steel frames. Four sets of formula for equivalent damping and effective stiffness have been developed for each hysteresis model.

To account for the nonlinearities of the generic structure, it was assumed that all the inelastic response happens in the first mode of vibrations which has the largest dynamic participation. This was accomplished by using equivalent and effective values for ξ_1 and ω_1, respectively in Eq. 6. For simplicity the shape of the first mode and modal participation factor were assumed to remain unchanged. For all the other dynamic modes, the same values of elastic system were used to develop the TF. In the same way, the damping and frequency of the first mode of vibration of the Test-Bed structure were incorporated in formulation of TF as shown in Eq. (14). Figure 5 shows how the yielding changes the shape of the TF of the test-bed structure. These curves were generated by subjecting the analytical model of the Test-Bed structural to increasing amplitudes of a white noise input motion.

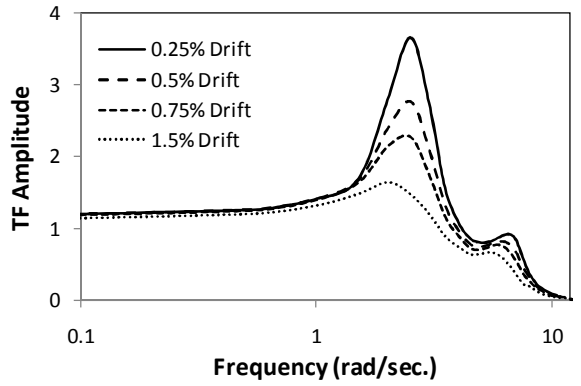

Figure 5 Change of the Shape of the Transfer Function of the Test-Bed Structure due to Yielding

This figure confirms that yielding introduces significant damping into the first mode of vibration. Slight change in value of the frequency of the first mode can also be detected.

The main goal for the nonlinear Test-Best structure is to achieve the drifts equivalent of the ones expected in the generic building with consideration of nonlinearities. Therefore, for the nonlinear Test-Bed, the transfer function for drifts was used, as oppose to the previously developed acceleration TF. This was done by finding the derivative of the TF functions of the displacement with respect to the height (i.e. the differential displacements of the floors divided by the height of the story.) Equation (19) shows how the Eq. (16) can be modified to develop the input motions to achieve any desired drift. This equation leads to a good estimate for the maximum drift response; however, it may not achieve the exact time history response of the drift.

$$\ddot{u}_{Drive}(\omega) = \frac{H_q(\omega) - H_{q-1}(\omega)}{h_q \sum_{im=1}^{k} \left(2i\omega\xi_{im}\omega_{im} + \omega_{im}^2\right)} \cdot \left[\frac{H_j(\omega) - H_{j-1}(\omega)}{h_j \sum_{i=1}^{2} \left(2i\omega\xi_i\omega_i + \omega_i^2\right)}\right]^{-1} \cdot \ddot{u}_g(\omega) \quad (19)$$

In this equation, h_q and h_j are the heights of the stories in the generic building and the Test-Bed Structure, respectively.

6. SUMMARY AND CONCLUSIONS

A reusable Test-Bed structure was developed for shake table investigations of nonstructural systems. The Test-Bed structure simulates two adjacent floors of a multistory building. This two-story, two-bay frame can accommodate full-scale subassemblies and subject them to large drifts and/or accelerations. The design of this frame allows for reusing the Test-Bed.

The drive motion of the shake tables was obtained in order to achieve a target floor motion for the linear Test-Bed and a target drift for nonlinear Test-Bed structure. This target floor motion, or drift, was obtained from analysis of a continuum dynamic system representing a generic multistory building, offering a notable versatility to simulate floor acceleration of any type of structure. Nonlinearities were included in this formulation making use of effective frequency and equivalent damping for the first mode of vibration.

Abstract: When the big damage does not occur for building structure by an earthquake, the damage occurs to the non-structural element, and there is the case that a building is not available for a long term. And when the disaster prevention facilities such as sprinklers are damaged, what cannot prevent a second fire after the earthquake not only the direct damages such as floods occur is the problem that is very important in disaster prevention.
In this study, we perform the vibration experiment of the ceiling where a sprinkler is installed in and aim at elucidating the mechanism of the damage of the sprinkler head at the time of the earthquake and the collision.

1. INTRODUCTION

Earthquakes not only damage the major structural parts of buildings, causing them to collapse, but they also cause serious damage to non-structural parts, such as ceilings, ducts and pipes. Severe loss may happen in buildings of which structures have no damage during an earthquake, for example, when collapsed or falling ceilings, furniture and facilities cause fatalities, or when buildings become non-functional and unusable because of damaged ducts and pipes. Even when building facilities can be restored in a short period of time, damaged pipes may lead to leaks and serious damage to the interiors of buildings, and expensive equipment and products.

There have been recent cases of damaged facilities or flooded rooms, such as in the damage caused by the Niigata Chuetsu-oki Earthquake on July 16, 2007, and the Iwate-Miyagi Nairiku Earthquake on June 14, 2008, and the Iwate Engan-hokubu Earthquake on July 24, 2008.

In some of these cases, damage to fire protection systems, such as broken sprinkler pipes and malfunctioning sprinkler heads, may cause leakage causing flooding, and prevent secondary fire occurring after an earthquake from being extinguished, which presents a very important issue in terms of fire protection.

Against this background, this study presents recent cases of damaged sprinkler systems. The study also aims to clarify the mechanisms behind sprinkler system damage and collision using vibration experiments with buildings and ceilings with sprinkler systems installed in them to understand the phenomenon of sprinkler heads and ceilings hitting each other during earthquakes. It is hoped this will provide useful data for earthquake-resistant measures for fire protection systems.

2. Examples of sprinklers damaged by earthquakes

Photos 1 to 3 show a sprinkler system and sprinkler heads damaged by the Iwate Engan-hokubu Earthquake on July 24, 2008. Photo 1 (sprinkler heads on the ceiling) and Photo 2 (the sprinkler system above the ceiling) show the resulting damage after sprinkler heads and ceiling tiles hit against each other in an amusement facility. Because sprinkler heads are made of precision components, the sprinkler heads malfunctioned and leaked when the sprinkler heads and the ceiling hit against each other. It is thought that the sprinkler heads and the ceiling hit against each other, because head fasteners were worn out, which changed the distance between the sprinkler heads and the ceiling

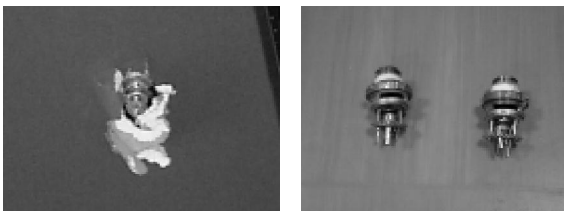

Photo 1 Damaged ceiling and sprinkler heads after hitting against each other

Photo 2 Damaged sprinkler pipes that had been fixed above the ceiling

openings.

Photo 3 shows ruptured sprinkler pipes in the Hachinohe City Auditorium. In this case, sprinkler heads did not hit against the ceiling openings, because the sprinkler pipes near the sprinkler heads were fixed firmly. However, because the sprinkler pipes swayed considerably, it is thought that great force was exerted on the bifurcation of adjoining vertical sprinkler pipes, and the sprinkler pipes ruptured at screwed sections.

These examples of damaged sprinkler systems indicate that a locational deviation between ceiling openings and sprinkler pipes affects sprinkler systems greatly at the time of an earthquake

3. Method of setting sprinklers

Figure 1 shows a typical method of setting sprinkler heads in the ceiling.

Water for sprinklers is drawn from water pipes to sprinkler heads via adjoining vertical sprinkler pipes. The sprinkler heads are fixed to metal carrying channels using main fasteners and auxiliary fasteners. With the ceiling and fasteners stabilized using this method, sprinkler heads are displaced simultaneously even when the ceiling surface is displaced by seismic activity. Therefore, this structure can prevent sprinkler heads and ceiling openings from hitting against each other.

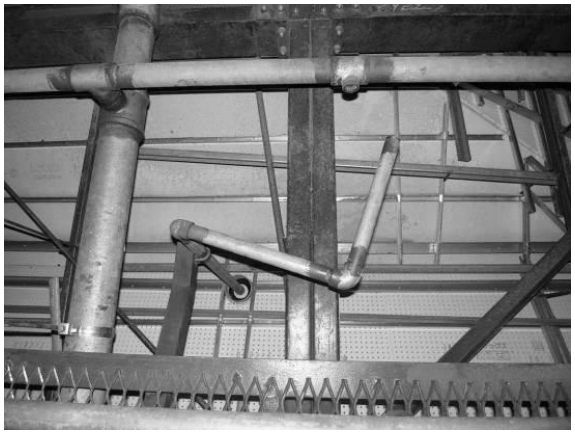
However, as shown in Photos 1 and 2, the ceiling and sprinkler heads actually hit against each other. This damaged the ceiling tiles and sprinkler heads, and impaired the function of water sprinkling. Several instances of ceiling tiles and sprinkler heads being damaged during an earthquake, as in this case, have been confirmed. It is thought that one of the reasons for the damage is the sprinkler heads are fixed with wire and thumbscrews of a simple structure, so the fastening devices for sprinkler heads slide or drop, and the sprinkler heads move differently from the ceiling during an earthquake disturbance.

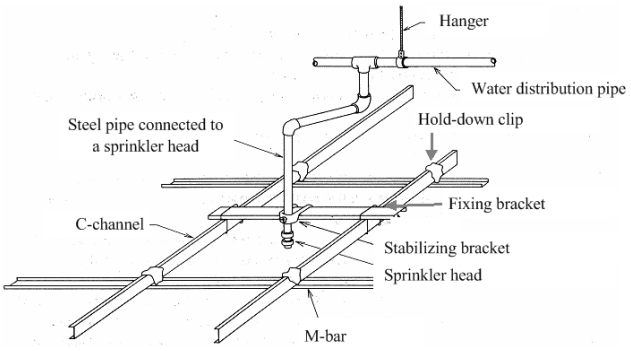
Because fastening devices for sprinkler heads are fastened to carrying channels, ceiling tile openings and sprinkler heads may jolt out of alignment and hit against each other when a hold-down clip between a main runner and a carrying channel slides, and even when fastening devices for sprinkler heads do not slide or drop.

The fact that hold-down clips between main runners and carrying channels slide during the occurrence of an earthquake has been confirmed by experiments conducted by Motoyui et al., and this causes the hold-down clips to fall and ceilings to collapse. Therefore, in order to prevent ceiling openings and sprinkler heads hitting against each other, attention must be paid to prevent the falling of hold-down clips.

Since vertical sprinkler pipes connected to sprinkler heads are particularly inflexible, stress generated in fastening devices for sprinkler heads becomes greater depending on the difference between the vibration properties of ceilings and water pipes. As a result, it is thought that fastening devices for sprinkler heads and hold-down clips start to slide easily. However, if fastening devices are reinforced to prevent them from sliding, all the stress generated due to the different motions of ceilings and water pipes will be placed on the vertical sprinkler pipes connected to sprinkler heads, and this may cause the pipes to rupture and lead to devastating flooding, as shown in Photo 3.

Because an emphasis has been put recently on the deformability of ceilings, flexible pipes are often used in place of vertical sprinkler pipes connected to sprinkler heads. Even in this case, the movement of hold-down clips between main runners and carrying channels cannot be controlled, so sprinkler heads and ceiling openings may hit against each other when the hold-down clips slide.





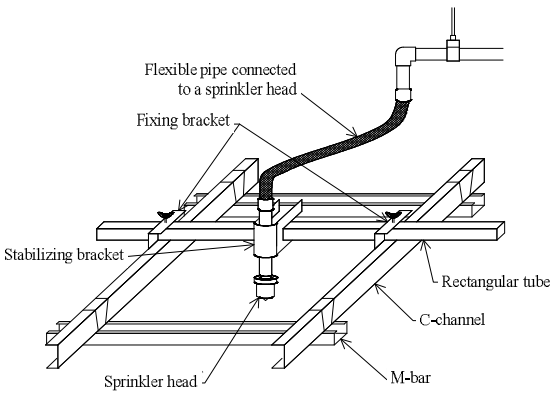


Photo 3 Ruptured sprinkler pipes in the Hachinohe City Auditorium

(2) Flexible pipe connection

Figure 1 Method of setting sprinklers

4. Preliminary dynamic experiment using an shaker

In order to recreate a situation in which a ceiling and sprinkler heads hit against each other, sprinklers were installed in a device with a ceiling shaker, as shown in Figure 2 and Photo 4, and a sweep vibration test was conducted with the frequency changed at a fixed rate. Photo 5 shows the damage caused after conducting the test. It was confirmed that the main fasteners that fixed the sprinkler heads slid considerably when vibration was added, and that the sprinkler heads hit against the ceiling tiles. It was also confirmed that when vibration was added with the main fasteners fixed firmly auxiliary fasteners sometimes dropped due to deformation of carrying channels, and the sprinkler heads hit against the ceiling tiles.

In addition, when vibration was added with the auxiliary fasteners fixed firmly, hold-down clips that connected the main runners and carrying channels slid and dropped, and this caused the collapse of the ceiling. It is thought that because the connection of the sprinkler heads was reinforced stress concentrated in the area near the fastening devices, and the hold-down clips started sliding quickly, leading to the collapse of the ceiling.

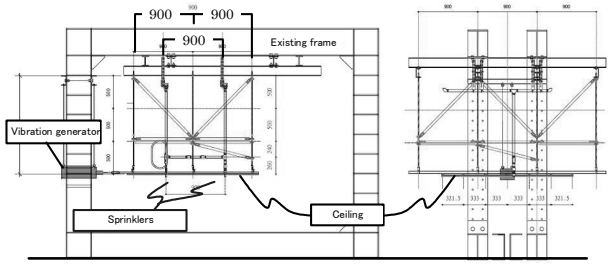

Figure 2 Apparatus of dynamic test with shaker

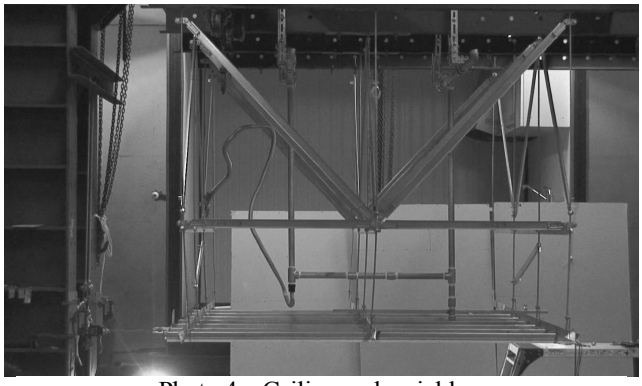

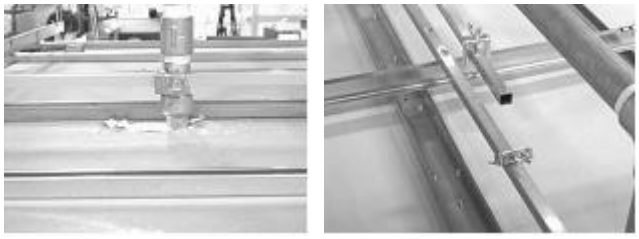

Photo 4 Ceiling and sprinklers

(a)Sprinkler head hitting the ceiling (b) Dropped auxiliary fastener

Photo 5 Damage simulated in the experiment with the use of an shaker

5. Shaking table test

When an earthquake actually occurs, the vibration of floor slabs prompts the vibration of sprinkler pipes and ceilings that are connected with the floor slabs. Therefore, a vibration test was conducted with the use of a shaking table as shown in Photo 6. Two types of pipes were used to connect with sprinkler heads: a conventional steel pipe and a flexible pipe.

Figure 3 shows the chronological change of the ceiling surface and sprinkler heads when 300% of El-Centro waves were added. The difference in displacement (relative displacement) between the ceiling and sprinkler heads was between 10 mm and minus 10 mm, and this indicates that the sprinkler heads repeatedly hit, touched or moved away from the ceiling openings. Photo 6 shows the final stage where 400% of El-Centro waves were added. The entire ceiling collapsed, though the ceiling without sprinkler heads did not collapse entirely. This indicates that increased rigidity and strength of sprinkler heads do not necessarily improve the earthquake-resistance of the ceiling, but they generate a concentration of stress and cause damage to the ceiling, like diagonal bracings. It was judged from the final stage that the fire-extinguishing function of the sprinklers was lost due to the collapse of the ceiling, even though the sprinkler system did not collapse.

(a)5.08 seconds after starting vibration (b)Flexible pipe after vibration

Photo 7 Damage made after 300% of El-Centro waves were added

6. Shaking table test with a full-scale five-story steel-frame building

In order to understand the behavior of a ceiling and a sprinkler system in a full-scale building at the time of an earthquake, we prepared a ceiling and sprinkler system on the fifth floor of a full-scale five-story steel-frame building for vibration testing (Photo 8) with the E-Defense table of the National Research Institute for Earth Science and Disaster Prevention, and conducted a vibration test using a JR Takatori wave in order to confirm the behavior of the ceiling and sprinkler system at the time of an earthquake.

As a result (Photo 9, Figure 4), we confirmed that, when the ceiling swayed significantly, vertical sprinkler pipes that were connected to sprinklers and steel pipes on the other end ruptured at points that were screwed. We also confirmed that, even when flexible pipes were used, sliding hold-down clips caused the ceiling and sprinkler heads to start hitting against each other, and that, after auxiliary fasteners came off, sprinkler heads moved and the sprinkler system was impaired.

7. Conclusion

We conducted various vibration tests for a sprinkler system installed above a conventional ceiling with steel framing, and confirmed the dynamic behaviors of the sprinkler system at the time of an earthquake. We will conduct a detailed study on the interaction of the ceiling and the sprinkler system in the future.

Abstract: The damage of non-structural components like a ceiling in earthquakes brings about the huge economical loss. There have been vague issues with regard to the reason of failure of ceiling while some significant properties have been found through our recent research. The structural characteristics of the ceiling are greatly influenced with metal joint parts used in the connection of steel furring. In this paper, we focus on the metal joint parts and show the mechanical characteristics via experimental results. Finally we suggest the numerical method for the system using metal joint parts.

1. INTRODUCTION

In the recent earthquakes, non-structural components like ceilings, walls and various equipments suffered several damage while structural frames in the buildings did not so. It is no doubt that such damage of non-structural components interrupts daily activity of people or discontinues running of its facility. Then it has been one of the most important issues to overcome immediately.

We have been already researched the characteristics of the Japanese style of ceiling and found out the reason why ceilings fell down during earthquakes. It is obvious that the detachment behavior of clips is the trigger of the falling of ceiling through the observation of the actual falling situation of ceilings after earthquakes. Photographs 1 show (a) the overview of damage situation after an earthquake and (b) gypsum boards fell down. In Photograph (a), it can be seen that a group of steel furring members called "channel" held the original position (height) though the most of gypsum boards fell down. Furthermore, in Photograph (b), another group of steel furring members called "M-bar" which was attached with screws to gypsum boards fell down with gypsum boards. The connection between M-bars and channels is jointed with unique metal parts called "clip". The detachment of clips causes the failure of the ceiling. Furthermore, according to our dynamic test of ceilings, the fatigue of metal joint parts between channels and M-bars is observed.

The main purpose in this paper is to clarify the mechanical characteristics of such metal joint parts and to establish the numerical method and model for accurately simulating the behavior of a ceiling during an earthquake including the strong nonlinear behavior of the connection by the metal joint parts.

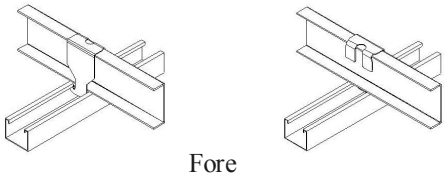

Figure 1 Setting pattern of Clips

2. EXPERIMENT FOR METAL JOINT PARTS

2.1 Clip

Clips are set in two ways. Each setting is called "Front setting" or "Back setting" shown in Figure 1. We have studied the mechanical characteristics of the fore setting type

but have not done ones of the back setting type. Then, we executed a test for the back setting type shown in Figure 2. The parameters are the length (L=250mm and 900mm) of a channel and the velocity (v=0.2cm/sec and 10cm/sec) of loading (see Figure 2).

Figures 4 show the experimental results. The influence of the loading velocity on the behavior of a clip is not considerable because the results in different velocity are the same load-displacement relationship macroscopically. At first, a clip slips with keeping the constant strength, of which value is less than 0.1kN. After unloading and reloading; point B, the clip resists to the horizontal load. At point C, the root of the clip buckles and the strength slightly decreases. The strength rapidly increases at Point D since another part of the clip root contacts with the M-bar. The strength of the connection reaches to the maximum value at Point E. After that, the contact point of the clip root slips and the strength sharply decreases. On the other hand, the influence of the length of a channel is much greater and the relationship between the load and displacement for L=900 is different from the above case; L=250. In particular, it is observed that the plateau and recovery of strength in the resistance phase for Point C and D in Figure 4(a) varnishes and the strength monotonically increases until reaching to the maximum strength.

It should be noted that the clip just slips without resisting to the horizontal load in both results. The behavior is quite different from one during the initial loading at the virgin condition. The reason is why the clip looses owing to the buckling of the clip root. Furthermore, in case of the Back setting, the detachment behavior cannot be observed at this test which extracts a joint part by a clip though such behavior occurred in case of the Fore setting.

2.2 Hanger

The mechanical characteristics of a hanger are examined with the simple test extracting only a hanger. Figure 5 show the apparatus of the test. The two loading patterns are considered. One is the cyclic loading and another is the cyclic in the uni-direction. Figure 6 is the load-displacement curve. The play in the connection is observed at the initial phase or neutral phase of the loading process. After some points on the hanger contact to the surface of the channel, the strength steadily increases. The maximum strength is determined with the yielding of the plate at the bottom of the hanger.

3. NUMERICAL METHOD FOR METAL JOINT PARTS

3.1 Outline of Numerical Method

The various resultant stresses generally act on the metal joint parts subject to the 3-dimensional forces and moments. The elastoplastic condition should be judged accurately to simulate the behavior of such members. The effect of shear stresses caused with shear forces and torsion is often

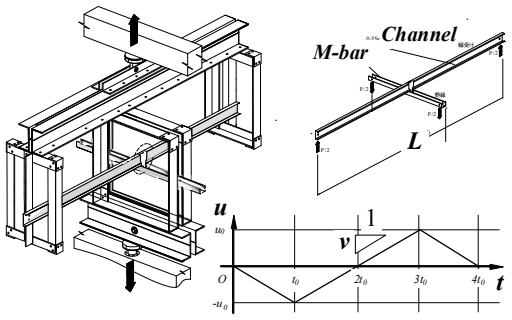

Figure 2 Test for Back setting type of connection with Clip

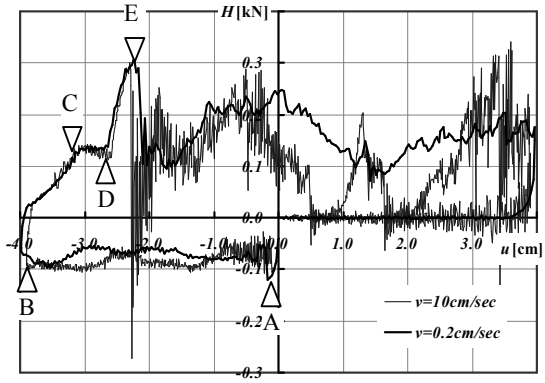

Figure 4(a) Experimental results for L=250

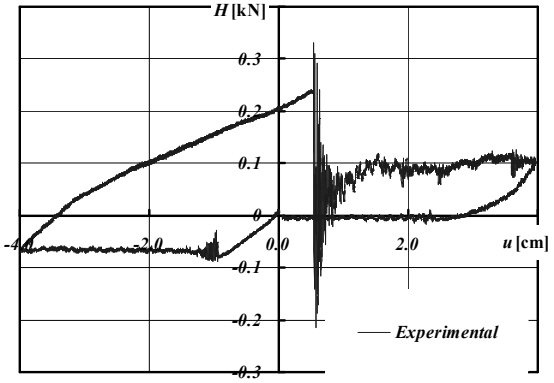

Figure 4(b) Experimental results for L=900

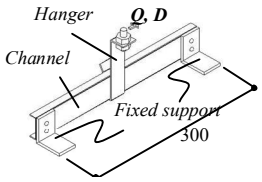

Figure 5 Test for Hanger

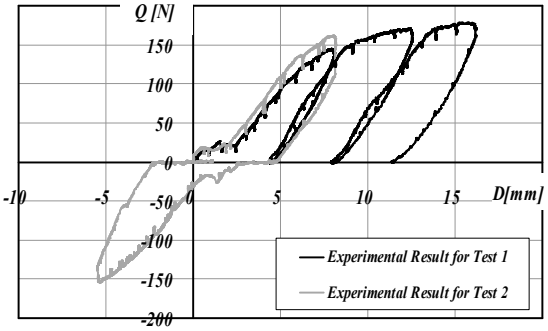

Figure 6 Experimental results for Hanger

neglected in using a co-rotational beam element. Particularly the influence of shear stresses in torsion should be considered when analyzing the 3-dimensional behavior of a hanger because the behavior of the hanger subjected to the lateral horizontal load is affected by the torsion of the bottom plate as mentioned in 2.2. On the other hand, when using the co-rotational beam element, the shear deformation including the pure torsion which is the so-called the Saint Venant's torsion, is generally assumed to keep the elastic condition while the yielding behavior is considered for the axial normal component of stress including the effect of the warping torsion which is the so-called the Wagner's torsion. In this paper, the yielding is considered for both types of torsion behavior. We explain the outline of the present method.

At first, we consider the relationship between the total strain and the displacement at both nodes. As the nodal displacement vector for calculating strains in the co-rotational formulation, one generally uses the vector $\tilde{\boldsymbol{u}}$ that is got with eliminating the effect of a rigid motion and rotation from the total displacement. Now $\boldsymbol{u}$ at an arbitrary point in the beam element is assumed to be expressed as

$$u(r,s,t)=u_0(r)-\gamma(r)s+\beta(r)t+\omega(s,t)\alpha'(r) \qquad (1.a)$$

$$v(r,s,t)=v_0(r)-\alpha(r)t\,,\quad w(r,s,t)=w_0(r)+\alpha(r)s \qquad (1.b,c)$$

where $(u_0,v_0,w_0),(\alpha,\beta,\gamma)$ are the displacement and rotations at the centroid axis of the element. ω,α' are a warping function and the rate of torsional rotation. (*r, s, t*) are co-rotational coordinate shown in Figure 7.Restricting to the thin plate, the strain components to be took account are only two components of ε_{rr}, ε_{rs}. Each component can be expressed by the nodal displacement vector through the definition of strain respectively and the usual finite element formulation.

$$\varepsilon=\boldsymbol{B}\tilde{\boldsymbol{u}}\,,\qquad \varepsilon^T=\langle\varepsilon_{rr}\quad\varepsilon_{rs}\rangle \qquad (2.a,b)$$

$$\tilde{\boldsymbol{u}}^T=\langle\tilde{u}\ \ \tilde{\alpha}_i\ \ \tilde{\beta}_i\ \ \tilde{\gamma}_i\ \ \alpha_i'\ \ \tilde{\alpha}_j\ \ \tilde{\beta}_j\ \ \tilde{\gamma}_j\ \ \alpha_j'\rangle \qquad (2.c)$$

where $\tilde{u},(\tilde{\alpha}_i,\tilde{\beta}_i,\tilde{\gamma}_i)$ are a stretch of beam, rotations around *r,s,t* axis at i-node, and α_i' are the rate of torsion at i-node.

Next, describe the treatment of the present elastoplastic problem. We apply the following yielding function to specify the allowable stress space.

$$f(\sigma,\lambda)=\sqrt{{\sigma_{rr}}^2+3{\sigma_{rs}}^2}-\sigma_y(\lambda) \qquad (3)$$

In this paper, the isotropic hardening is only considered. The associated flow rule for Eq.(3) is assumed to be satisfied and the plastic strain rate can be expressed as

$$d{\varepsilon^p}_{rr}=\frac{\partial f}{\partial\sigma_{rr}}d\lambda=\frac{\sigma_{rr}}{\sigma_y}d\lambda \qquad (4.a)$$

$$d{\varepsilon^p}_{rs}=\frac{\partial f}{\partial\sigma_{rs}}d\lambda=\frac{3\sigma_{rs}}{\sigma_y}d\lambda \qquad (4.b)$$

where $d\lambda\geq 0$ is the plastic consistent parameter. The return mapping algorithm is applied to the numerical

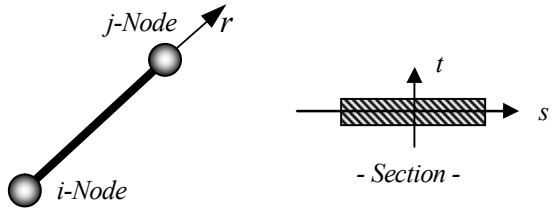

Figure 7 Co-rotational coordinate

calculation of actual stresses.

The tangent coefficient can be derived by using Eqs.(3) and (4) as following.

$$\begin{Bmatrix}d\sigma_{rr}\\ d\sigma_{rs}\end{Bmatrix}=\boldsymbol{D}^{ep}\begin{Bmatrix}d\varepsilon_{rr}\\ d\varepsilon_{rs}\end{Bmatrix},\quad \boldsymbol{D}^{ep}=\boldsymbol{E}-\frac{1}{\boldsymbol{g}\cdot\boldsymbol{E}\boldsymbol{g}}(\boldsymbol{E}\boldsymbol{g})\otimes(\boldsymbol{E}\boldsymbol{g})$$

$$\boldsymbol{E}=\begin{bmatrix}E & \cdot\\ \cdot & G\end{bmatrix},\quad \boldsymbol{g}^T=\begin{Bmatrix}\dfrac{\sigma_{rr}}{\sigma_y} & \dfrac{3\sigma_{rs}}{\sigma_y}\end{Bmatrix} \qquad (5)$$

The numerical method to simulate the slip or contact behavior is based on the 'master-slave model' which was suggested by Crisfield et.al.(2000). We have extended the master-slave model to the contact, slip and detachment problem. And the validation and efficiency of the extended method have already been shown by the authors (Motoyui 2009) through the application to the complicate nonlinear behavior of a Front setting type of a clip. In this paper, we extend it to more general problems like the slip behavior with Coulomb's friction condition.

$$\Phi^{\pm}=|T|+\mu N+c=0 \qquad \text{for } N<0 \qquad (6.a)$$

$$\Phi^{0}=T=0 \qquad \text{for } N\geqq 0 \qquad (6.b)$$

where *N,T* are forces normal or tangent to a slip surface, μ is a coefficient of friction and *c* is a coefficient of cohesion

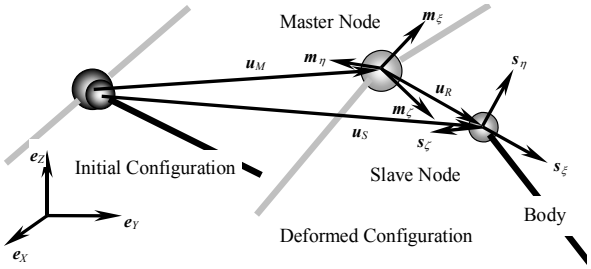

Figure 8 Master-slave model

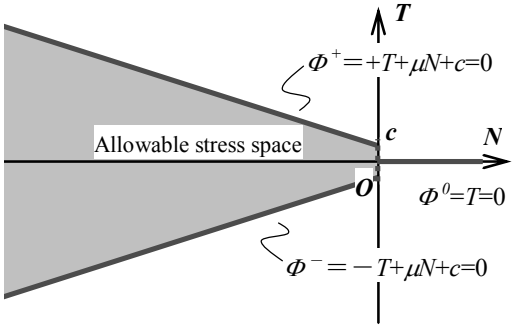

Figure 9 Coulomb's friction criteria

3.2 Validation of the present beam element

To examine the validation of our numerical method, we consider some simple numerical examples as shown in Figure 8. The first one is a thin plate subject to torsion. The second is a single of hanger with the clear boundary condition. In two cases, the width and thickness of plates are 24mm and 2mm. The material properties are also common: Young modulus; 206GPa, Poisson's ratio; 0.3, yield stress; 315MPa, Hardening coefficient; 0.0. The seven numerical integral points are arranged in the both direction of width and thickness.

Figure 9 shows the relationships between torque moment and torsional rotation for the thin plate in the Saint Venant's torsion and the Wagner's torsion. The warping of both ends can be freely developed in the Saint Venant's torsion model while it is constrained and a bi-moment is developed in the Wagner's torsion model. Solid lines are results by shell elements and symbols are ones by the present beam element. The results with the present beam elements both for the Saint Venant's torsion and the Wagner's torsion are close to ones with shell elements. Then, the present element can simulate the effect of the warping and the shear strain in torsion after yielding.

Figure 10 shows the load-displacement curve for the elastic or elastoplastic results of the hanger model with H=98mm. We calculate them using the present beam elements and shell elements. In the beam model, the effect of warping is considered. Each result with the present beam agrees with one with shell elements. These agreement means it is valid for the present beam element to be applied to the elastoplastic torsion problem. Furthermore, the full plastic strength is approximately equal to H times of the full plastic strength of the plate model. Through this equality, we should consider the effect of the warping when simulating the behavior of the hanger subject to the horizontal loading.

4. NUMERICAL ANALYSIS OF METAL JOINT PARTS

4.1 Modeling

For the connection with a clip, the numerical model as shown in Figures 11 and 12. The master nodes are arranged as shown in Figure 11. The master nodes in a channel, a M-bar and a clip are connected by some dummy elements. The dummy elements to represent contact and release, slipping and detaching are arranged and the total number of the dummy elements amounts to six. Show dummy element for contact between a channel and a M-bar as a example in Figure 12. The direction of contact or slipping is defined with the co-rotational unit basis ($\boldsymbol{e}_r$, $\boldsymbol{e}_s$, $\boldsymbol{e}_t$) . The unit basis initially is specified with both slave nodes of the dummy element. After deformation, they rotate with the rotation at the master nodes. Therefore, the slave nodes should be arranged correctly to simulate the contact or slipping behavior.

(a) L=250

(b) L=900

Figure 14 Interaction of tangential and normal force at slipping surface

4.2 Numerical results

Figures 13 show the load-displacement curves for the connection with clips. We dynamically analyze this problem since the vibration with high frequency occurs. The numerical results for both length of a channel are coincident to the experimental results in all the phase of initial slipping, resisting, second slipping after the maximum strength and slipping with loosening. Figures 14 show the interaction of tangential and normal forces at the slip surface between the clip and the M-bar. The plateau of strength after buckling of the root in the clip vanish in the load-displacement curve for L=900 as I mentioned above. The reason is that the slope of the channel delay the buckling of the root and the rate of the tangential and normal forces is different from one in the model of L=250.

Figure 15 shows the load-displacement curve for the connection with a hanger. The results for two types of loading agree with the experimental results respectively.

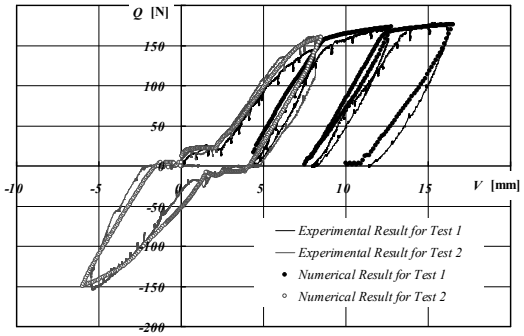

Figure 15 Load-displacement curve of Hanger

5. CONLUSION

In this paper, we examined and clarified the mechanical characteristics of the metal joint parts experimentally and numerically. And we suggested the numerical method and model for the connection by such parts and showed the validity of the present numerical method through some numerical examples and comparison with experimental results.

CEILING DAMAGE IN THE 2010 CANTERBURY EARTHQUAKE

Gregory MacRae[1], James Hair[2] and Rajesh P Dhakal[1]

1) Associate Professor, Dept. of Civil and Natural Resources Engineering, University of Canterbury, New Zealand
2) Structural Engineer, BECA Consultants, Christchurch, New Zealand

Abstract: The Canterbury (Darfield) earthquake of 4th September 2010 caused an intense shaking in New Zealand's second largest city, Christchurch. Fortunately there were no fatalities resulting from the earthquake. However, there was significant loss to structures on liquefiable soil, to URM structures, and due to non-structural damage in buildings subject to the strong shaking. Damage to ceilings contributed significantly to the non-structural damage which caused major business interruption. This paper describes the type of ceiling systems commonly used in NZ and the types of ceiling damage observed in the earthquake.

1. INTRODUCTION

The magnitude 7.1 Darfield (Canterbury) earthquake occurred at 4:35am on 4 September 2010 (NZST) on the previously unknown Greendale fault. The surface rupture was a right strike-slip extending about 30km. The maximum surface ground movement was approximately 4.6m and the rupture zone was 30 to 300 m. The focus was approximately 11km deep and was located about 8km southeast of Darfield and about 37km west of the centre of New Zealand's second largest city, Christchurch. This area is considered to be in a zone of moderate seismicity. In the weeks subsequent to the main shock a number of aftershocks, several with magnitudes greater than 5.0, rocked the Canterbury region and caused strong localized shaking leading to further damage and liquefaction. At the time of writing of this paper (almost 5 months after the earthquake), aftershocks are still very frequent; the most recent big one being the 5.1 magnitude aftershock on 20 January 2011.

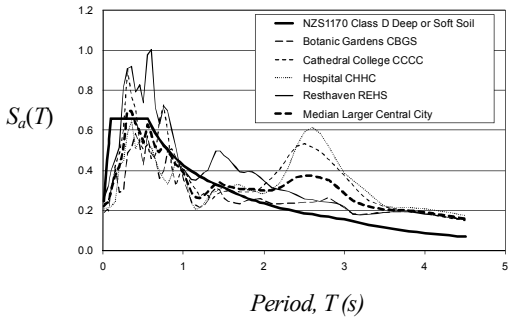

Figure 1. Recorded and NZS1170 Spectra (Cousins and McVerry, 2010)

The acceleration response spectra from the larger horizontal component for 4 sites within the Christchurch central business district (CBD) is compared with the NZS1170.5 elastic design spectra for deep soils, in Figure 1. It may be seen that both for structures with periods between 0.2s and 0.8s and greater than 2.2s that the elastic design level spectra is exceeded.

Possibly one of the most significant effects of the earthquake was the extensive damage to lifelines and residential houses resulting from liquefaction and lateral spreading. This occurred primarily in areas close to major streams, rivers and wetlands throughout Christchurch as well as Kaiapoi, approximately 19km north of Christchurch. Ejection of silt causing a blanket over 200mm thick occurred in many regions. Lateral spreading of up to 3m caused large cracks and damaged houses severely. Houses settled unevenly. Many kilometres of water pipe and wastewater pipe were damaged. Empty sumps floated and roads had up to 0.5m vertical offsets.

Older residential houses suffered collapse of brick chimneys, some of which fell through house roofs. Older houses often had vertical and horizontal cracks around the interior gypsum board. Many houses on good soil, especially those with lighter roofs built on a slab-on-grade foundation suffered no damage at all, but many lost brittle contents such as glasses and china.

A number of older unretrofitted unreinforced masonry (URM) structures in the CBD partially collapsed resulting in total demolition. Many unreinforced brick parapets collapsed onto the footpath below.

Newer multi-storey structures generally seemed to behave well, but information is still becoming available. One structure made from concrete indicated beam plastic hinge rotations with cracks in the hinge zone as big as 5mm. In another, damage was evident in gravity columns which had to follow through the displacements of the rest of the frame. In another, at the ends of simply supported precast beams, 45° cracking at the supports was evident. Most structures showed no distress, and the base-isolated hospital behaved well.

Whereas structural damage was mainly restricted to

old unretrofitted buildings, non-structural and contents damages were observed in all types of building (Dhakal 2010). The non-structural damages involved cracking in internal linings and contents falling to the ground, damage at separation joints and water damage from broken pipes which led to falling wall tiles. It occurred in both older and newer structures. Perhaps the damage which caused the most business interruption in non-URM structures on good soil conditions was that due to ceiling panels falling in many structures. This paper describes the damage to ceiling panels in the Canterbury (Darfield) earthquake. Many of these are taken from a ceiling damage reconnaissance report prepared after the earthquake (MacRae et al. 2010).

2. NZ CEILING SYSTEMS

New Zealand uses suspended ceilings; mainly manufactured and supplied by Rondo™, USG™ and Armstrong™. Many of these have used high mass to limit sound transmissibility. Even buildings constructed in the last 10 years have ceiling panels weighing 16kg/m^2 or more. More recently lighter panels with the same acoustic rating have been used. While concealed ceiling grids with screw fixed plasterboard sheets (such as are used in Japan) are available from companies such as USG, they are not popular. The most popular systems are two-way exposed ceiling grids with drop in panels sitting on the flanges of the inverted 'T' shaped members in the grid. One of these is shown in Figure 2. Here, the ceiling grid is suspended from the floor above using rods or wires. The panels fit loosely in the grid so that they can easily be popped up for access to services. The panels may be punctuated by HVAC or fire sprinkler services. Also, in some cases panels are removed and replaced by fluorescent lighting. Tile/panel tie downs are seldom used.

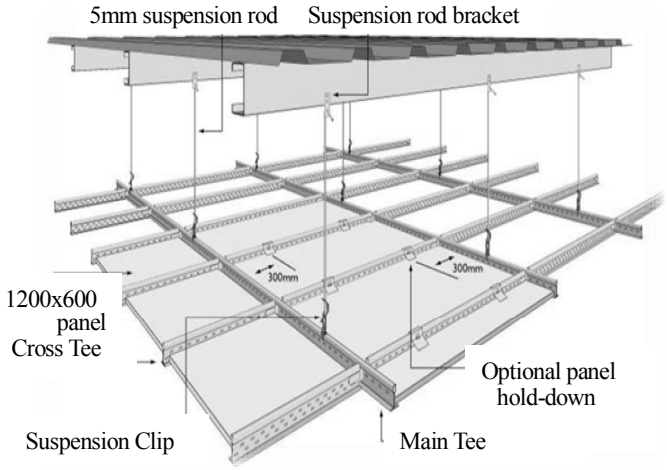

Figure 2: Typical Suspended Ceiling Installation (modified from Rondo DUO, 2008)

There are two common installation methods. *Floating ceilings* are braced to the floor above and a gap is left around the ceiling perimeter so that impact does not occur with the walls during the expected excitations. *Perimeter restrained* ceilings are restrained laterally by the walls around their perimeter. As the building moves laterally, the suspension clips and rods move on an angle to follow the deformations of the ceiling. Since the ceiling panels do not sit tightly in the grid, force is not directly transferred from one panel to another. Instead, forces from panel horizontal accelerations are transferred through the grid. In New Zealand, most of the ceilings are *perimeter restrained*.

Different framing systems have been developed by the major suppliers for use in zones of different seismicity. However, there are a number of issues which make the ceilings vulnerable. They are:

1. Seismic design methods for ceilings were first introduced in the 1970s so the many ceilings in existing structures are not designed for seismic loading.
2. Standards have been written for the design and installation of ceilings (e.g. AS/NZS 2785). The standards tend to be followed by the major installers but they are not enforced by national or local authorities and are not followed by all installers.
3. Ceiling seismic design tends to be inspired by seismic code provisions being used for other components which are designed to resist a level of seismic force less than that expected in a design level earthquake. While other elements of a building system may possess significant ductility, those in NZ ceilings generally do not.
4. Licensing of ceiling installers is not mandatory so it is possible for people without any training, or any appreciation of the important issues, to install ceilings. This may result in a significant range of construction quality.
5. The installation of the ceiling is usually performed by a subcontract to the main contractor. There is an incentive for the major contractor to obtain the cheapest possible ceiling installation in order to win the contract.
6. There are no enforced standardized protocols to ensure different services (e.g. HVAC, fire sprinkler systems, etc) work together to ensure that the final result is likely to meet specified minimum performance.
7. Anecdotal evidence indicates that both the cost and the quality of installation in Christchurch tends to be lower than that in other NZ centres.
8. There is evidence of some cases of very poor practice including such things as vertical partition walls having no out-of-plane resistance. This means that instead of them bracing the ceiling, they actually impart load to it during earthquake shaking.

3. DAMAGE SUSTAINED

The damage sustained by ceilings has been organised by damage type: grid damage; perimeter damage; interaction with services; one-way grid spreading; and combinations of these damage types. The photos given below are courtesy of Hush Interiors Ltd. unless otherwise stated.

Grid damage results from excessive force on the grid members or connections. This then results in buckling of the

grid members or failure of the connections. Figures 3-4 show grid damage sustained.

Perimeter damage results from the main tee or cross-tee losing seating on the perimeter angle around the ceiling. Loss of seating can result due to a lack of a rivet to connect the grid member to the angle or failure of the rivet itself. This results in the grid members and panels dropping from the ceiling. Edge perimeter hanging wires can prevent the member and panels from falling, however, this can result in the panel and members being forced back into the angle causing damage to the panels and members as shown in Figure 5.

Figure 3: Damage resulting from the disconnection of the cross-tee from the main beam resulting in localized grid collapse and panel loss

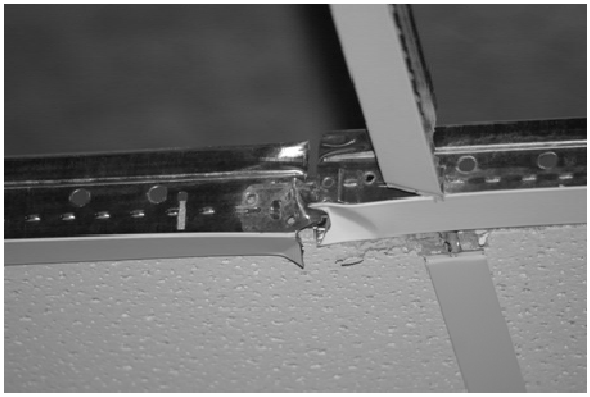

Figure 4: Damage resulting from main beam splice failure

Figure 5: Grid damage leading to panels being forced back into the wall angle causing damage

Damage to suspended ceilings resulted from force being transferred from services above the ceiling into the ceiling itself as shown in Figure 6. In a standard installation of a suspended ceiling the hanger wires are placed @ 1200c/c. However, the presence of services (e.g. HVAC and fire sprinklers) above the ceiling can mean this is not possible. As a result suspended ceiling are sometime partially hung from services within the ceiling (most commonly HVAC ducting and plant). As this plant is rarely secured properly when it moves it imparts force into the ceiling causing damage. Additionally, services above the ceiling moving during an earthquake can hit and impact the hanging wire of the suspended ceiling. Suspended ceilings are not designed to take these additional forces. Grills within the ceiling plane were often observed to have fallen from the ceiling and localized loss of panels often occurred around the location of these grills.

Figure 6: Damage caused by interaction with services above the ceiling

Older one-way grid systems were particularly susceptible to damage. An example is given in Figure 7. These grids consist of main beams hung from the structure above spanning one way. There are typically no transverse runners except where the ceiling may have been retrofitted with these. The drop-in panels limit the possibility of the grids spreading apart during an earthquake. However, if panels do drop out there are no members to stop the grids spreading apart. Further panels then fall from the ceiling. Also, as opposed to the two-way systems discussed above, the panels are not supported on all four edges by the grid system. The panels are instead interlocked, so when one panel falls it leaves the next panel susceptible to falling.

Damage to suspended ceilings can also result from elements connected to the ceiling that should actually be independent. Common examples of this are timber or steel framed bulkheads and partitions. Partitions in particular should not rely on lateral support during an earthquake from the suspended ceiling. This type of construction applies extra

force into the ceiling for which it is neither designed nor installed to carry; thereby causing damage during a seismic event.

Figure 7: Spreading and damage of Older One-Way Grids

Damage to residential ceiling also occurred during the earthquake. These types of ceilings are not suspended like the ceilings discussed above but are rather fixed directly to roof framing using glue and/or nails. Damage to these ceilings results from load being applied to the ceiling from the adjacent walls as the house undergoes lateral displacement. Some damage sustained to a residential structure is shown in Figure 8.

Figure8: Damage to residential ceilings
(courtesy Michael Newcombe)

The forms of damage described above can occur simultaneously during an earthquake causing widespread damage to a single ceiling system. Some examples of this are shown in Figures 9 and 10.

4. DISCUSSION

The widespread damage to ceilings from the earthquake resulted in business interruption as well as direct damage costs. For example, the University of Canterbury was closed for 2 weeks while fallen and not-fallen heavy ceiling panels were replaced with lighter panels in a better way over some lecture theatres.

While the Darfield Earthquake was similar in magnitude to the 2010 Mw 7.0 Haiti earthquake, there was no loss of life and only 2 injuries. One of the major reasons for this is the time of day the earthquake occurred. Nevertheless, it shows that a system of building construction controls, while never perfectly followed, can be very effective in limiting life and other losses.

Figure 9: Widespread Ceiling damage
(courtesy Univ. of Canterbury)

Figure 10: Further Widespread Ceiling Damage

In addition to the damage in the earthquake main shock, more ceiling panel and other damages occurred in the subsequent aftershocks.

In order to reduce damage to ceilings in the future the technical and political issues in the introduction need to be addressed for new ceilings and retrofit or replacement may be required for older ceilings. To have well behaving ceiling systems it is necessary to consider more than the ceiling itself. Appropriate consideration of all of the other design requirements for all elements interacting with the ceilings including services, walls etc. is necessary.

The aim of the NZ earthquake design of building structures criteria is to meet the “loss of life” limit state. While performance of modern buildings in recent earthquakes indicates that the seismically designed structural systems meet this criterion, the ongoing practice of designing and building non-structural components and

storing contents still pose a reasonable risk to life safety. For example; heavy ceiling panels falling from 7-8m high lecture theatres (as observed in the University of Canterbury) could have seriously injured a few students (with a fair probability of fatality) had the earthquake occurred during lecture hours. Similarly, masonry wall blocks and chimney blocks falling from a house (as observed in several buildings in Christchurch) and heavy/fragile contents falling from racks in supermarkets and industrial storages could easily have seriously injured a few people if the earthquake had struck in a normal business hour.

Whereas structural framing systems are designed for lower forces than the expected elastic response level due to their inelastic deformation capacity, such an approach is not appropriate for NZ ceilings. These are constructed of light-weight steel with connections which perform in a relatively brittle manner. Special consideration of this is required and they are likely to need to be designed for significantly higher accelerations than many other parts of the frame in order to protect life. Mandated regulations for the trades are required to ensure good and coordinated construction.

In early 2010, the University of Canterbury was awarded funding from the NZ Foundation for Research in Science and Technology (FRST) through the Natural Hazards Platform (NHP) in order to address the issues with non-structural elements including vertical elements (partitions and cladding) and horizontal elements (ceilings). The widespread damage to non-structural elements observed in this earthquake has emphasized the need of this research. Collaborations also exist between the Tokyo Institute of Technology (the Motoyui laboratory (e.g. Sato et al. 2011)) and the University of Canterbury. This allows not only the whole range of western ceiling systems to be evaluated (e.g. with the use of light weight panels), but also the Japanese approach to ceiling construction. This work, along with other efforts at the University of Canterbury, is aiming to produce cost-effective low damage seismically sustainable buildings. These are expected to have a lot less damage to the frame, slab, non-structural elements or contents during a major earthquake than that experienced in recent earthquakes.

5. CONCLUSIONS

The 2010 Darfield earthquake caused widespread structural and non-structural damage. Suspended ceilings and residential ceilings sustained damage of different forms, such as grid damage, perimeter damage, interaction with services, grid spreading damage. Major improvements in the ongoing practice of ceiling design and installation are required to achieve ceiling systems that do not incur significant damage in design level earthquakes as has been observed in this earthquake.

ROLE OF STANDARDS AND REGULATIONS FOR BUILDINGS

Jun Kanda

Professor, Graduate School of Frontier Sciences, University of Tokyo, Japan
kandaj@k.u-tokyo.ac.jp

Abstract: In Japan, building regulations are provided by Ministry in terms of laws and enforcement orders. The standard should provide a basic framework for engineers to follow. When Building Standard Law was first established in 1950, the structural requirements in the regulation were simple. Only simple rules for the design load and allowable stresses for structural materials were specified. After several occasions of revision, now enforcement orders are extensive and complex. Then some discussions for a new Building Basic Law are introduced. A scheme for conference by stakeholders in order to make decisions for appropriate safety for the society can be proposed. New role of standards and regulations are discussed for sustainable society.

1. INTRODUCTION

Building regulations are provided by the government in terms of laws and enforcement orders. In Japan, the fundamental law for buildings is called Building Standard Law which clearly states that the minimum requirements of performances including the safety are specified. Nevertheless most people understand that if buildings are designed to be consistent to the regulations, they are sufficiently safe.

When Building Standard Law was first established in 1950, the structural requirements were simple. Only simple specifications for the load and allowable stresses for structural materials were described. Now enforcement orders are extensive and complex, after revisions for taking engineering advances into account. Calculation procedures are also specified.

The building approval system in Japan is called as a conformity system and building officials are believed to have no choice for their own decision but only to check if building documents are consistent to the regulations. This is one of reasons to introduce conformity check offices of private sector in 1999.

However in reality it is not possible to write every condition and situation in regulations. Then the structural design becomes restricted and only possible when evaluation procedures are specified in the regulations. The uniform specifications for minimum requirements do not mean the uniform degree for the safety for different locations or different types of structures.

Regulations with detailed uniform specifications may be convenient for efficient designs and constructions in an economically growing society, but when the quality of buildings is preferred for a longer life and safer and sustainable society, building approval system should be based on the consensus of stakeholders in the society. Then the role of regulations has to be also reconsidered.

2. CURRENT REGULATIONS IN JAPAN

The Building Standard Law of Japan was enacted in 1950 together with the architectural engineer law at the same time. The structural requirements are specified in enforcement orders which mostly followed the structural rules specified in the Law of Buildings in Urban Area established at the time of the Kanto earthquake (1923). The seismic safety checking is quite simple as the allowable stress design procedure is only one available structural calculation procedure and the allowable stresses of structural materials are given together with the base shear coefficient of 0.2 for the seismic safety. Qualified architectural engineers can make structural calculations by hands before the introduction of capacity design for the seismic safety in 1981.

For the improvement of seismic safety a new structural performance parameter called Ds factor was introduced to take the deformation capability into account. The corresponding base shear coefficient is 1.0 which is 5 times of the allowable stress design criteria. The Ds factor varies from 0.25 to 0.6 according to the deformation capability after the elastic limit of strength and is multiplied to the base shear coefficient as a reduction factor. This reduction is rather conservative in comparison with a similar factor in other countries such as U.S. and New Zealand.

Many computer programs have been developed not only for the structural analysis but also for the design of sections of components. Since the local authority cannot have sufficient engineering staff for checking the conformity as the regulation becomes rather complicated. Some of computer programs for structural calculations are approved

by the Ministry for the purpose of reduction of checking time by the authority.

After the Hyogoken Nambu Earthquake in 1995, the performance-based design was discussed to be implemented in the regulations, as discussed in California after Northridge earthquake in 1994. Then in 1998 another revision was made for the Building Standard Law by the Ministry of Construction (Now it is reformed as Ministry of Land, Infrastructure, Transport and Tourism (MLIT)). In the approval system, private organizations were newly introduced for conformity checking of applied design documents including structural calculations. Another great change of the law for the structural design is that the structural calculations are specified in the enforcement order. In other words, the only calculation procedures specified by MLIT are accepted for building conformity applications.

A rather serious offence in building approval system occurred. It was reported that Mr. Aneha (formerly qualified architectural engineer) intentionally falsified structural calculation documents by reducing the input seismic load into a half of required value or in a similar order in order to reduce the structural cost. Local authorities as well as private organizations could not find the inconsistency during their checking procedures. Number of buildings with insufficient strengths was reported as 60 to 80 for 8 years. The MLIT took this incident seriously and proposed a revision of the Law in order to make the conformity checking process very strict by introducing new organizations for structural calculation conformity checking at the same time additional structural requirements were also introduced for calculation procedures.

Engineers are forced to produce much thicker calculation documents than before and only officially approved calculation procedures are accepted. When this restricted system was first introduced, the new approval system was very inefficient and building construction market was seriously influenced. The reduction of GDP in 2006 due to this revision was reported to be 0.8%. The efficiency of conformity checking system can be improved once people are accustomed to the system, but the influence of restricted regulations on the structural design or the quality of structure is more serious as the creative efforts by engineers are discouraged and people tend to concern about only the conformity to the regulation but do not consider the quality of real safety. Although the Building Standard Law clearly states that the minimum requirements are specified, MLIT claimed that strict rules of regulations are necessary to keep the consistency of the safety. Then people tend to consider that the buildings are safe once the conformity checking was made.

3. PROPOSAL OF BUILDING BASIC LAW

A movement for the building basic law was formed in August 2003 by a group of building professionals including the author. The purpose of the movement is to reform whole social system for buildings in Japan. The main idea for the new system is to establish basic understandings for good quality buildings. As in most countries the regulation specifies the minimum requirements. But the minimum safety is not sufficient or even appropriate. It worked well when we needed to build houses efficiently but now we have more houses than the necessary demand in Japan. The average lifetime of houses in Japan is about only 30 years which is very short in comparison with European or American statistics. We need to design a good quality houses for a longer life.

The constitutional reasoning for the current building standard law is to assure the private property right for land. It may apply to an isolated private house in a wide land, but now houses in a city have some interactions with neighboring houses. Some condominiums are sometimes huge residential complexes. Some tall office buildings have spaces for more than 10,000 people. In these cases the building owner should obtain sufficient consent from neighbors. Buildings in general are regarded as social properties and performances and qualities of buildings should be approved by the local community. Only the fulfillments of specifications of minimum requirements may not be sufficient.

Engineering developments are so rapid and the social acceptance criteria differ based on the cultural and historical background. Therefore the law should only provides basic rules and local communities should prepare specific rules if necessary. The quality and performance of building has to be good enough and the owner is responsible for them. The safety, health and environment are basic demands for buildings and professionals have to provide sufficient information regarding design performances to the client, users and even to the neighbors. The accountability and the transparency are commonly essentially required.

When detailed specifications are provided by regulations, the consistency to the regulation tends to mean the quality of building is approved by the society. However since the regulation does not necessarily provide appropriate qualities in various aspects for the society, such appropriateness can only be achieved by the decision of building owners consulted by architects and engineers.

One of important purposes of Building Basic Law is to make responsibilities of stakeholders clear, in particular the building owner must make appropriate decisions on the quality of building for the society. We should recognize that the appropriateness of structural safety is not the same for different stakeholders. Therefore the social consensus is important

It is expected that proper considerations for the quality of buildings are made when deregulations are introduced. Regulations should be simplified to be understood by every stakeholder, but the accountability has to be recognized in a more transparent manner and the local society should be able to observe the safety quality of buildings.

MLIT in Japan was rather reluctant to discuss the Building Basic Law, as the Building Standard Law is a basic law for many related legislations. And the power of controlling the safety requirements based on the Building Standard Law is centralized in MLIT. However, since laws

for scenery of buildings were established in 2004, more discussions in local community have been encouraged, and decisions for the approval are made by local governments.

In September 2008, MLIT organized a committee for governmental actions for buildings with a higher quality including discussions of Building Basic Law. Although MLIT did not consider the whole reformation of legislation system for buildings then, a new government formed in September 2009 has been keen to establish the Building Basic Law in order to reform the current legislation system as well as the qualification system.

Discussions on the new building legislation system among professionals and industries are now quite frequent. They may influence the political direction of building regulations. We should make efforts to establish a new system which maximizes the potentials of architects and engineers for a sustainable society.

4. SOCIAL CONSENSUS SYTEM

Since buildings occupy the space of land for a long period of time, the owner is responsible for the consequences due to the existence of building. If a natural or man-made disaster occurs, the society will be affected by its consequences. Therefore buildings are sufficiently safe against such expected events.

However future natural or man-made hazard is not easily expected and the failure probability of a building is controlled based on the safety performance of structure. Engineers should provide sufficient information on the safety with possible consequences to the client and the final decision should be made by the consensus in the society.

In the past, the safety requirements were believed to be determined by experts based on scientific findings. Then people can simply follow the decision by experts. But the safety quality is quantitative as expressed in terms of probability and cost dependent. Then demands for the safety can be different among different stakeholders. Investors may require less safety than the neighbors to the building.

As discussed in Risk and Culture by Douglas and Wildavsky(1982), hierarchists and individualists both have disadvantages for risk managements of environments in particular when large uncertainties exist. Sectarians instead have better opportunities for good risk managements. Transparent discussions among stakeholders will provide consensus base decision making for the society. Local community should participate for decision making for the safety of their public facilities, including power plants, schools, city halls and even condominiums.

Failure of structures by an earthquake influences the activity of local community seriously. The consequences of failure may be different from buildings to buildings. Then the local community has rather a power to contProl the safety rather than the central government. Optimal safety of structure has been discussed since 1970's and more individual decisions should be made for an individual building. A basic equation for the optimal safety can be written as minimizing the total expected costs as,

$$C_T = C_I + C_M + \sum \Delta P_{Fi} C_{Fi} \qquad (1)$$

where C_T is the total cost, C_I is the initial construction cost, C_M is the maintenance cost, ΔP_{Fi} is the increment of probability of failure for the i-th damage, C_{Fi} is the failure cost for the i-th damage.

It is the time to use the cost-benefit discussions more seriously for the decision making by individuals. (Kanda, 2009) The cost in ordinary terms in equation (1) is the initial cost and the benefit is the reduction of failure probability or the expected failure cost.

Then engineers are expected to provide more information contributing to the target structural safety. Among many factors for considering the target safety, consequences of failure are important factors formulated in cost-benefit consideration. Engineers should pay sufficient attentions to possible consequences. (Kanda and Shah, 1997) It may be difficult for ordinary people to understand the meaning of probability especially when it is very small, but it may be rather imaginable for anybody to make a scenario for failure consequences with cost estimations. The optimal safety obtained as minimization of equation (1) can transfer the discussion of safety degree or probability of failure to that of failure cost.

As an example of the conference for consensus of the structural safety by stakeholders, the target seismic safety of a school gymnasium may be discussed as one of familiar examples for social decision making in a local community. Should parents provide a safer building for young children? When the school gymnasium is to be used a shelter for refugee at the occasion of earthquake disaster, it must be significantly safer. If the school gymnasium collapsed or even severely damaged after the earthquake, the failure cost is much greater than its construction cost. The quantitative decision may not be easily achieved as the minimization of equation (1) may not be fully understood by ordinary people. Nevertheless discussions with many materials related to the seismic safety of building, such as the soil condition, the seismic hazard including active fault information, current safety degree of buildings with statistical information of past earthquake disaster such as the Hyogoken-Nambu earthquake and the estimated cost due to failure are extremely helpful for making their own community protective to the natural disaster.

Catastrophic risk exists in the modern society with buildings of huge scale and sophisticated technologies. One way control by regulations and conformity checking cannot optimize the minimization of failure consequences. Since the local community has direct consequences from failures, it should have the role to make decision and controlling power in constructions. Contributions from citizens with fully support of professional experts are essential for such decision making procedures.

5. INTERNATIONAL STANSARDS

Many International standards are published in structural engineering area as documents of ISO. International standards for construction materials are beneficial for fair trades, but international standards for structural safety have been also developed for fair engineering services of overseas activities.

ISO 2394: General Principles on Reliability of Structures is the basic documents for the structural engineering. In many countries the structural engineering practices have shifted from the allowable stress design to the limit state design which is developed based on the reliability theory. Therefore if principles provided in ISO 2394 are adopted for the developments of national codes, the structural safety concept can be commonly understood or harmonized in different countries.

ISO documents are also published for actions and loads for the structural design. The uncertainties in actions on structures are significant and common probabilistic models are described according to ISO 2394. When transparency and accountability are essential to achieve the appropriate degree of safety for structures as discussed above, ISO documents have an important role to provide rational procedures for determining the design loads for structures.

In general ISO documents for basis of structural design are developed for code writers. Therefore it is expected for national standard bodies or governments to make their standards and regulations consistent to ISO. But the incentive is not generally so strong in comparison with industries' attitudes to adopt ISO for their products. However the common understanding of structural design against natural hazard among professionals representing their national bodies can be expected in Working Groups for drafting documents. Discussions in technical committees and sub-committees under TC also contribute to the international harmonization of codes.

Unfortunately Japanese structural regulations provided in enforcement orders of the Building Standard Law are not consistent to ISO 2394. The wind load and the snow load is given in terms of the return period such as 50 years for the damage limit and 500 years for the safety limit, but the earthquake loads are considerably inconsistent to the hazard map as the same regional factor from 0.8 to 1.0 has been still used since 1981.

6. ATTITUDE AGAINST CATASTROPHES

Buildings are vulnerable against extreme actions such as terrorist attacks, typhoons and earthquakes. Although regulations require the safety performance of buildings, the minimum requirements cannot cover these rare events except for very important structures such as nuclear power plants or major hospitals.

As discussed in previous chapters, technologies are available to avoid the catastrophic losses by proper design with a higher target safety when the economy allows. And many experiences have been studies for the nature of environmental extremes and extraordinary consequences of disasters in densely populated area.

We have to consider rational attitude against global catastrophes. (Smil, 2008) In general we cannot be free from global catastrophes, then our actions should be minimizing risks. And such decisions should only be possible by decisions of society. According to Smil,

We can do much to be better prepared for a number of anticipated catastrophes, and we can take many steps to moderate negative impacts of some of the most worrisome trends. The precautionary principle should be involved precisely when facing those high risks whose understanding is characterized by uncertainty or outright ignorance. Preventive, preparatory, or mitigating actions are called for in order to avoid extreme consequences of unmanaged outcomes, whether a viral pandemic, global warning, or the use of weapons of mass destruction by terrorists. In such situations imperfect scientific understanding or substantial uncertainties regarding the most likely mode and intensity of the next catastrophic event should not be used as an excuse for inaction or for postponing known effective measures.
(Smil, 2008, p.238)

Regulations cannot deal with such catastrophe preventions. Local communities with a help from the central government by providing sufficient information and supported by professional experts have to make decisions of safety of environments including buildings and houses. Communications between professionals and citizens are essential tools for the decision makings of society.

7. ROLE OF REGULATIONS AND ROLE OF ENGINEERS

The role of national government and that of local government should be identified. The major role of government is to help the local government by providing technical information for building approval system. The local government should have a leading role for regional planning of cities and towns. More active contributions from structural engineers to mitigate natural disaster by considering the hazard potential are expected for regional planning.

Professionals should contribute more to the society in a wide aspect. A new system for the approval of buildings is expected for a sustainable society. Professionals can lead a consensus based discussions for the appropriate safety of a building in their local communities.

The current Building Standard Law only deals each building in a site and a group of buildings in an area is not an object of the law. When scenery of a group of buildings is discussed or when the seismic robustness of a city is considered, the local culture and life style are important factors as well as natural conditions such as soil conditions or climates. Then the collaboration between the local government and architects and engineers becomes extremely

important for sustainable development of the area.

Academic associations of professional are also expected to play an important role by publishing good technical standards and codes for engineering practices. It is common to make excuse that the association does not take responsibility for the results caused by the standards and codes. The engineer should take his/her responsible decision on the application of standards in practices.

When regulations do not cover detailed rules for the structural evaluation, engineers have to choose and use a most appropriate technical code which they can understand well and rely on. This situation is much better than the current system of detailed regulations under Building Standard Law for the safety quality of buildings.

8. CONCLUSIONS

Current Japanese building system under the Building Standard Law is critically reviewed as it is rather old-fashion. Role of standard and regulations in the sustainable society is discussed. Performance-based design is almost global standard as clearly described by ISO documents. In order to mitigate disasters the local community should take actions with supports by professional engineers. The social consensus of local community is a key issue for the structural safety. The regulations should be minimized for encouraging such actions. Engineers should fully utilize available standards to provide sufficient information to the society.

Abstract: This paper presents an overview of a recently released document *Guidelines for Performance-Based Seismic Design of Tall buildings*. The Guidelines were developed as part of a larger program, the Tall Buildings Initiative (TBI). The TBI was coordinated by the Pacific Earthquake Engineering Research Center (PEER), with close collaboration with practicing structural and geotechnical engineers in the tall building design community. The Guidelines represent the latest practical implementation of performance-based seismic design (PBD), and improve upon the PBD procedures developed during the past 10 years. A brief review of the evolution of the PBD in the United States is presented in this paper, followed by an overview of the TBI and development of the Guidelines. Few specific critical items proposed in the Guidelines are also elaborated in this paper.

1. INTRODUCTION

Performance-based seismic design methods in the United States originated as a practical and effective means to mitigate the seismic risks posed by existing buildings and were later extended to permit development of new buildings capable of superior seismic performance. These methods were quickly adapted to justify design of new buildings that do not conform to building code requirements, and which are intended only to provide equivalent performance to buildings conforming to code criteria. This practice has become particularly prevalent in the design of very tall buildings in the Western United States.

Initial development of performance-based seismic design procedures in the United States occurred in response to societal reactions to the nearly annual occurrence of damaging earthquakes in the Western United States during the period 1979-1994. These earthquakes provided many illustrations of both the strengths and weaknesses of seismic provisions in U.S. building codes and spurred substantial evolution and improvement of these provisions. Most buildings designed to the code provisions achieved the life-safety intent of the building code, but several experienced extensive damage resulting in large economic loss. These earthquakes also provided frequent reminders that the inventory of existing buildings included many older structures that were susceptible to life-threatening damage and which posed unacceptable seismic risks.

Some corporations and institutions became interested in voluntary seismic upgrades. Engineers working on their behalf quickly found that decision-makers in these organizations wanted to know how their buildings would perform, in terms meaningful to them, before they would commit to retrofit. Often these decision-makers wanted to tailor retrofit programs to optimize their costs and benefits. These same decision-makers quickly became interested in seismic performance issues in the design of new buildings as well, to assure that their important facilities would adequately protect their business and operational needs and that they did not encumber unacceptable future economic losses.

Many owners of hazardous buildings were not interested in seismic upgrades, prompting governments to adopt mandatory upgrade programs. To justify adopting such programs, it was necessary to contrast the likely performance of hazardous buildings and the consequences if no action were taken. Performance-based seismic engineering was developed to enable engineers to respond to the need to reliably assess the probable performance of new and existing buildings under a variety of design scenarios

The Federal Emergency Management Agency (FEMA) provided the primary financial support for development of performance-based seismic engineering procedures. FEMA funded the Applied Technology Council's (ATC) development of a series of performance-based engineering criteria and guidelines including FEMA-273/274(ATC, 1997a, b) that form the basis for present generation performance-based seismic engineering practice. The American Society of Civil Engineers subsequently converted these documents into the ASCE-31(ASCE, 2002) and ASCE-41(ASCE, 2006) standards that could be adopted by building codes.

These first-generation procedures experienced widespread acceptance and application, both in their intended use, evaluation and upgrade of existing buildings; and also for application to the new building design.

However, for new building design, the primary application of these procedures is to demonstrate that nonconforming designs have equivalent performance capability as that intended by the building code, allowing development of buildings at lower cost or with other attributes attractive to developers. This practice became particularly popular in design of very tall buildings, contributing to the development of many of these structures in the period 2003-2008 in Los Angeles, Seattle, San Francisco and other western cities with significant seismic hazards.

Many of these structures are tall residential buildings, having post-tensioned concrete flat slabs supported by a ring of perimeter reinforced concrete columns and tubular bearing walls surrounding the central core. Prescriptive U.S. code provisions prohibit such construction in excess of 50 meters tall, without provision of a dual special moment-resisting frame capable of resisting at least 25% of specified seismic design forces. By using performance-based procedures, engineers were able to eliminate the moment-resisting frame, saving cost, and more importantly permitting exterior designs that accommodated floor to ceiling windows and reduced story heights in buildings extending to 200 meters tall.

2. BUILDING CODE COMPLIANCE

In 2003, Western U.S. cities generally adopt and rigorously enforce building regulations based on the *International Building Code* (ICC, 2006). These codes adopt prescriptive seismic design provisions through reference to the *ASCE 7*(ASCE, 2005) standard, which is based on the *NEHRP Recommended Provisions for Buildings and Other Structures* [BSSC, 2003]. The *International Building Code* also includes permissive language that enables the use of alternative procedures demonstrated to provide performance equivalent to the prescriptive requirements. The design professional must demonstrate equivalence to the satisfaction of the building official. Many, but not all building officials have proven amenable to the use of these procedures.

The code does not limit the procedures that can be used to demonstrate equivalence, nor does the code state, in other than generic and qualitative terms, what performance is acceptable. Most engineers and building officials adopt target performance based on the commentary to the *NEHRP Recommended Provisions*. This commentary states that for ordinary structures the objective is to provide a low conditional probability of collapse, given the occurrence of Maximum Considered Earthquake shaking, and to preclude, to the extent practicable, economic losses associated with more frequent and moderate events. The recently published *FEMA P695* [ATC, 2009a] and *FEMA P750* [BSSC, 2009] reports clarify that the acceptable conditional collapse probability is 10% and specify rigorous analytical and statistical methods for collapse probability quantification. However, these methods are complex and have not yet been adopted into general practice. Instead, engineers have adapted procedures based on ASCE-41.

Engineers have typically performed preliminary design in general conformance with the prescriptive code requirements, but taking a limited number of well-defined exceptions. The resulting near conformance to the code requirements provides both building officials and engineers a foundation level of comfort with the designs. Nonlinear response history analysis is used to demonstrate adequate collapse resistance. Performance is evaluated on an element by element basis using acceptance criteria contained in the ASCE-41 standard, sometimes supplemented with project-specific criteria derived from available laboratory testing to demonstrate acceptable behavior. Since analysis tools used in most design offices are incapable of reliably predicting response of structures nearing collapse, acceptance criteria are often conservatively selected to assure response within the range of analysis reliability.

Many building officials lack the technical expertise to review complex analyses or interpret laboratory test reports and have required independent third party review as a condition of acceptance of performance-based designs. Though procedures vary, third party reviews are typically performed by teams including a practicing engineer with expertise in tall building design and seismic technology, a researcher with particular knowledge of the types of structural systems to be employed (e.g., reinforced concrete walls, steel frames, etc.) and a geotechnical engineer. Reviews can be rigorous and include consideration of the design criteria, ground motion selection and scaling, analytical modeling and results, and structural detailing. The review process can be lengthy and can have significant effect on the design.

3. FIRST-GENERATION PERFORMANCE-BASED PROCEDURES

Initially engineers adopted ad hoc procedures for performance-based design of tall buildings. Later, documents produced by engineers in Northern California (SEAOC, 2007) and Southern California (LATBC, 2006) formalized these procedures. Generally, designs conform to the prescriptive code provisions with limited exceptions. These exceptions may include exceedance of code-specified height limits, violation of code requirements with regard to redundancy, and occasional use of materials, e.g., high strength steel and detailing procedures not specifically recognized by the code. Given the general similarity of these buildings to code-prescriptive designs, the procedures that developed typically included: development and approval of a formal criteria document, preliminary design, code-level analysis; and verification of adequacy for Maximum Considered Earthquake shaking.

Design criteria development and approval is an important first step. The formal criteria document includes a description of the overall structure and its intended load-resisting mechanisms; identification of any exceptions to the building code requirements and the justification for these exceptions; and identification of analytical procedures, load combinations, design ground motions, material properties, and detailing. The intent is to identify all substantive issues before the designer has expended large

effort in actually performing the design. In theory, if all procedures and assumptions are agreed to at project inception, approval of the finished design should be straightforward and attainable without controversy. In practice, however, it is rarely possible to foresee all issues that will arise during the design development, and many substantive criteria issues are resolved through cooperative efforts of the designers and reviewers throughout the project.

The preliminary design provides the basis for succeeding steps. Capacity-based design procedures, wherein a preferred yield mechanism is identified and other elements of the structure are proportioned to remain elastic, or essentially so, are typically used. Initial sizing of elements is often controlled by considerations of dead, live, and wind loads. In many structures, lateral design for wind forces controls even the final sizing of many elements.

The-code level design is used to confirm the adequacy of preliminary sizing and also to provide building officials with confidence, at a primary level, that the structure is comparable to one designed to conform to the code in all respects. In this step, the engineer typically performs the code-prescribed analyses, and evaluates all relevant code-prescribed strength, deformation, and detailing requirements, except those which were specifically exempted in the formal design criteria. Since the building systems used in these structures are not strictly code-compliant, *R*-coefficients and other factors required in the code procedures are typically selected jointly by the designers and reviewers based on judgment.

Verification of behavior in MCE-level shaking is performed using three-dimensional nonlinear response history analyses. Typically, suites of seven horizontal ground motion pairs are used. Ductile behaviors including wall, slab, and beam flexure are evaluated using the mean of the maxima for relevant demand parameters (flexural strain, plastic rotation, etc.). Brittle behaviors, and those with a potential to result in catastrophic failure, including wall shear, column axial force, slab punching shear, etc. are typically evaluated using either maximum demands obtained from the suites of analyses or mean demands that have been amplified by an estimated value of the standard deviation with the intent to provide a low probability of failure. Following procedures contained in *ASCE-41,* models and acceptance criteria for ductile behaviors are typically constructed using expected (mean) values of material properties, considering potential variability and strain hardening effects. Acceptance criteria for brittle and catastrophic behaviors are typically developed using lower bound material properties and sometimes using resistance factors to account for potential dimensional variability and construction quality issues.

4. THE TALL BUILDINGS INITIATIVE

The PEER Tall Buildings Initiative is a cooperative program of research and development undertaken by researchers at the Pacific Earthquake Engineering Research Center (PEER) and practicing structural and geotechnical engineers experienced in tall building design. Spurred by the rapid growth in the use of performance-based seismic design methodologies for the design of tall buildings, the goal of this initiative is to provide a sound and reliable basis for these procedures and to help assure appropriate seismic performance of the resulting new generation of tall buildings.

The program, initiated in 2006, encompasses a range of tasks intended to investigate: the dynamic characteristics of tall buildings; the performance capability of buildings designed using alternative procedures; societal preferences for tall building performance; alternative means of developing ground motions for design; soil-foundation-structure interaction effects, modeling, and analysis procedures; and development of design guidelines. An important companion report on modeling, analysis, and acceptance criteria for tall buildings [ATC, 2009b] is available from the Applied Technology Council. Reports on other task activities can be obtained at http://peer.berkeley.edu/tbi/index.html.

5. SEISMIC DESIGN GUIDELINES

The TBI Guidelines for Performance-Based Seismic Design of Tall Buildings (TBI Guidelines] represents an evolutionary step in the practice of performance-based seismic design of tall buildings. The guidelines embrace the same analytical technologies adopted by engineers following the San Francisco AB-083 and Los Angeles Tall Buildings Council criteria but provide more guidance on structural modeling, acceptance criteria, and ground motion selection and scaling. There are two important departures from prior practice. First, the guidelines do not require a code-level analysis in that it is anticipated that the procedures may be applied to structural systems for which the code response modification coefficients will not be defined, leaving the code analysis with questionable value. Second, the guidelines use more advanced procedures for evaluating structural performance, anticipating the availability of software that can reliably assess the response of structures in a near-collapse state.

The guidelines focus evaluation procedures on verification that the design performance objectives can be achieved, rather than verification that the building mostly complies with prescriptive criteria. The design performance objectives are those most commonly adopted by leading earthquake professionals today as the intent of the building code, that is, serviceability with minimal repair for frequent earthquake shaking levels and safety for rare earthquake shaking levels. With the exception of exterior cladding systems, the failure of which could cause numerous casualties in a crowded city, the guidelines address structural performance only. The procedures presume that nonstructural components and systems will be designed to conform to the prescriptive code criteria, but do caution that if a building's response characteristics are substantially different from that of typical code-conforming buildings, additional precautions may be required. The guidelines are written in a "recommendation" and commentary format. Recommendations are written in mandatory language, while commentary explains the basis for the recommendations

and warns of significant design issues that may not be adequately covered by the recommendations.

As with the AB-083 and Los Angeles Tall Buildings Council criteria, designers must prepare a formal, project-specific design criteria document. The guidelines recommend independent third party review of the criteria, the analyses, and the design. The guidelines employ two levels of analysis: a Service level and a Maximum Considered level.

5.1 Service-Level Evaluation

The purpose of the Service-level check is to assure that the buildings will not experience significant damage from frequent earthquakes. Much controversy surrounded the selection of a Service-level shaking intensity. The 2008 edition of the Los Angeles Tall Buildings Council guidelines[LATBC, 2008] specified service-level shaking with a 50% exceedance probability in 30 years (43-year mean recurrence interval), but permitted Service-level analyses to use 5% viscous damping. Studies conducted by the Applied Technology Council as part of the TBI effort, and summarized in the ATC-72 (ATC, 2009b) report, suggest that 5% viscous damping is excessive for tall buildings. Instead, 2.5% equivalent viscous damping is more justifiable and, in keeping with this, some participants argued for use of a Service-level event with a 25-year mean recurrence, arguing that the response spectrum for such an event, when used with 2.5% damping, would be comparable to the 5%-damped 50%-30 year spectrum. Other participants believed that a 25-year recurrence for onset of damage to these buildings was not an appropriate design objective. Eventually consensus support was achieved for the use of a 2.5% damped, 50%-30 year spectrum as the Service-level loading.

The stated performance goal for the Service-level loading is to avoid onset of damage that would reduce the building's ability to withstand Maximum Considered-level shaking or which would require repair that would necessitate removing the building from service. It is expected that some repair of structural elements may be necessary to restore cosmetic appearance, and fire and weather resistance. Nonstructural damage is anticipated to be minor, but is not specifically evaluated.

The guidelines recommend an elastic, three-dimensional response spectrum analysis for the Service-level because the desired behavior is intended to be essentially elastic and also because it is desired to assure that an elastic analysis is available to benchmark and evaluate nonlinear models used in the Maximum Considered-level evaluation. Carrying out a nonlinear response history analysis, to distribute the loads on very limited number of overstressed elements, is optional. Analytical models must extend to the structure's true base, which for most tall buildings is located several levels below grade. Soil-foundation-structure interaction effects need not be explicitly modeled, though it is permitted to do so. Based on analytical studies of typical buildings conducted under the Tall Buildings Initiative, when soil-foundation-structure interaction effects are not modeled explicitly, mass of subgrade levels is permitted to be neglected.

Acceptance criteria include both strength and deformation. Strength is evaluated by comparing computed strength demands against design strength. Design strength is computed using the strength formula contained in the design specifications referenced by the building code using specified material properties multiplied by strength reduction factors. Recognizing that expected strength will exceed this design strength by a considerable margin, and that some overload is acceptable in a ductile structure, computed demand to capacity ratios may be as large as 1.5. Story drift at any level is not permitted to exceed 0.5% of the story height.

If some computed demand to capacity ratios exceed a value of 1.5, designers are permitted to use three-dimensional nonlinear response history analysis to demonstrate acceptable Service-level performance. When such analyses are performed, a suite of not less than three horizontal ground motion pairs must be selected and modified to be compatible with the Service-level spectrum previously discussed. Either amplitude scaling or spectral matching may be used to achieve spectrum compatibility following procedures presented in the guidelines. Acceptance criteria must be developed based on suitable laboratory test data. Mean values of response parameters obtained from the suite of analyses cannot exceed demand levels at which the test data suggest the onset of strength degradation or damage, the appearance or repair of which would result in occupancy loss.

The Service-level event in effect serves to define the minimum required base shear strength of the building. In some highly active seismic regions such as Los Angeles and San Francisco the 2.5% damped 50%-30 year spectrum will result in strength demand comparable to that obtained following the prescriptive code criteria. In regions of lower seismicity such as Portland, Oregon, and Salt Lake City, Utah, the Service-level spectrum will result in substantially less strength than would be required for a code-conforming building. Commentary warns designers in these regions that additional strength may be required to provide adequate margin against collapse at the Maximum Considered level.

5.2 Maximum Considered-Level Evaluation

MCE-level evaluations are performed for the same level of shaking specified by the building code for this hazard level. The intent of the MCE evaluation is to demonstrate that the structure is capable of surviving this level of shaking with low probability of collapse. However, since the procedure does not include either explicit collapse or statistical analyses as does the *FEMA P-695* procedure, building adequacy is implied through limiting nonlinear response to levels at which significant margin would seem to remain. MCE evaluations are performed using nonlinear response history analysis and at least seven pairs of motions that are modified, either amplitude scaled or spectrally matched, to be compatible with the MCE spectrum.

The guidelines provide extensive discussion of structural modeling techniques and assumptions. The subject

of strength degradation, in particular, receives extensive discussion. Where strength degradation is explicitly modeled in a manner that reasonably predicts the hysteretic behavior obtained from testing using varied loading protocols, permissible levels of nonlinear response are relaxed relative to analyses conducted with models that have less explicit incorporation of cyclic strength degradation. Specifically, there are no limitations on the acceptability of nonlinear deformation demand for ductile elements, so long as element response remains within levels at which the hysteretic models employed are valid and loss of gravity load carrying capacity does not occur. The guidelines suggest limitations on deformation demand when analytical models are used that do not properly account for element strength and stiffness degradation effects.

As with Service-level evaluations, models must extend to the structure's true base level. Modeling of soil-foundation-structure interaction is not required but can be performed. Models are based on mean material properties. Acceptance criteria include both strength and deformation considerations.

Actions that are not ductile are evaluated using demand obtained from the equation:

$$Q = D + L_{\text{exp}} + F_E \tag{3}$$

where D is the dead load and L_{exp} is the expected live load, taken as 25% of the code-specified load. The earthquake effect, F_E is taken either as 150% of the mean earthquake demand $\overline{E}$ computed for the suite of analyses or, for actions with strength demand limited by yielding of other elements, FE may be taken as $\overline{E} + 1.3\sigma \geq 1.2\overline{E}$, where σ is the standard deviation of the response parameter as obtained from the suite of analyses. It is widely recognized that the true dispersion of responses cannot be adequately gauged using only seven earthquake ground motion pairs. The factor 1.5 applied to the mean response is intended to produce a low probability (around 10%) of exceeding the reliable strength in any one earthquake ground motion at the MCE level. It would be applicable, for example, to wall shear strength. The alternative equation is applicable, for example, to shear in an outrigger beam designed by capacity design methods to be limited by flexural strength. Strength capacities are computed using expected material properties and a resistance factor. The resistance factor may be taken as unity where failure of the element would not result in catastrophic failure and must be taken in accordance with the building code otherwise.

The mean story drift from the suite of response history analyses in any story is not permitted to exceed 3% and the story drift for any single analysis run is not permitted to exceed 4.5%. These limits were selected somewhat arbitrarily based on the guideline writers' comfort with the ability of present analytical methods to predict response at very large deformation. In addition to limits on maximum transient story drift, the guidelines also limit maximum residual (permanent) drift. The mean value of residual drift from the suite of analyses cannot exceed 1% of story height in any story and the maximum residual drift in any story from any analysis cannot exceed 1.5% of story height.

6. CONCLUSIONS

The PEER Tall Buildings Initiative has been a successful collaboration of earthquake engineering researchers, practicing structural and geotechnical engineers, and building code officials to address the need for appropriate consensus criteria for performance-based design of tall buildings in the Western U.S. Though evolutionary rather than revolutionary in nature, the PEER Tall Building Design Guidelines introduce significant improvements to practice in the design of these buildings. Of particular note is the provision of modeling guidelines that more realistically account for the nonlinear behavior of buildings than approaches previously used by the profession, together with incorporation of more rational acceptance criteria. The authors believe that the new guidelines will permit the development of tall buildings that are more likely to meet the intended performance objectives embedded in the building code, either than buildings designed to the prescriptive code provisions, or buildings that have been recently designed using performance-based approaches. Future development in this area should include further guidance on selection and scaling of ground motions, direct consideration of nonstructural behaviors, and incorporation of explicit collapse margin investigations.

Abstract: In this paper the moderate earthquake event of 1999, which affected the large urban area of Athens, is presented as a case study for the evaluation of the effects of strong directivity in the near field region for small to moderate events. Ground motion records at a distance from the causative fault are analyzed in order to estimate crucial characteristics associated with the event, as possible directivity pulses and their predominant period. Ground motions recorded at rock sites are scaled up to new generation attenuation models of characteristic spectra, accounting for either mean, near field, acceleration amplification or possible directivity related velocity pulses. These ground motions are used as input at the bedrock of typical soil deposits in order to obtain surface ground motions accounting for different soil profiles at various distances from the causative fault in the near field region. Inelastic spectra are generated and the difference between mean and strong, directivity affected, ground motion is established. For ground motions affected by forward directivity it is concluded that even for medium events seismic coefficients, provided by aseismic codes are inadequate for safe structural design. Seismic zonation coefficients must be re-examined and most likely upgraded in order to account for near field directivity, even in the case of moderate earthquake events.

1. INTRODUCTION

During the last decade a serious effort has been made in order to estimate the expected ground motion and spectral values in the near field region. New generation attenuation relationships have been developed in order to account for different parameters affecting the response of ground motion. Such parameters are associated with characteristics as moment magnitude, distance from the fault, type of fault, soil conditions, etc. These new generation attenuation relationships estimate ground motion values associated with a geometric mean of the horizontal spectral demand, lower than the maximum demand in the near field region affected by forward directivity. As a result, further investigation has been conducted in order to associate the predicted spectral values with this maximum spectral demand (Huang et al, 2008). Up to now this investigation has been undertaken for events with moment magnitude greater than 6.5. In the present paper such an investigation is conducted for events with a moment magnitude in the range of 6.0 presenting a larger frequency of occurrence and consequently more probable events at the vicinity of great urban centers.

As a case study, the Athens earthquake of 1999 is presented and an effort is made to develop the elastic and inelastic spectra associated with such an event of M_w = 5.9, for different soil conditions, at a distance of 2 and 5 kilometers from the causative fault. Two cases of spectral values are considered, associated, on the one hand with new generation relationships, predicting mean values at the near field zone, and, on the other, with the maximum spectral demand in the region, associated with directivity effects. In the case of the Athens earthquake the existing data for the earthquake ground motion are records taken at a distance from the most affected region. These records are at soft rock sites mostly, next to subway stations, near the center of the metropolitan area of Athens.

The analysis of these records presents a pulse with a period of around 1.5 to 2.0 seconds on the time history of ground velocity, which appears to be associated with the directivity pulses expected for events of such magnitude, according to existing relationships. Pulses of that period affect the frequency content lower than 1 Hz, an observation conforming with the prediction of Somerville (1998), separating the frequency content in a region higher than 1 Hz that remains unaffected from directivity amplification, and a region lower than 1 Hz, affected by the directivity phenomenon and presenting amplification dependent on the azimuth of the recording site. This directivity amplification is expected to strongly influence the ratio between the maximum spectral demand and the geometric mean spectral values at the near field region.

Up to now, comparison between the maximum and the

mean spectral values has been conducted for earthquakes larger than 6.5 and distances from the fault plane less than 15 kilometers. The ratios between maximum and mean spectral demands have been evaluated for different period ranges. According to Huang et al (2008), for most periods the strike normal component of the forward directivity records can be considered to represent the maximum spectral demand. Furthermore, for strong forward directivity and for periods 1.0 and 3.0 seconds, spectral ratios of 1.5 to 2.0 have been estimated.

These results present average values for magnitudes larger than 6.5 and do not account for the effect of magnitude variation on the estimated ratios. As well known from many studies (Alavi and Krawinkler (2000), Rodriguez-Marek (2000), Somerville (2003)), the predominant period of the directivity pulses depends on the moment magnitude of the event and varies exponentially with magnitude. Consequently, the spectral amplification associated with these pulses is magnitude and period dependent. In order to estimate appropriate ratios between maximum and mean spectral demands for moderate events, the case of the Athens earthquake is presented in this study.

2. THE ATHENS 1999 EARTHQUAKE

On September 7 1999, an earthquake event with moment magnitude 5.9 rocked the city of Athens (Psycharis et al, 1999). The strongly affected area was within a radius of 12 km from the epicenter. A number of modern buildings collapsed causing the death of 140 persons. About a hundred thousand people became homeless.

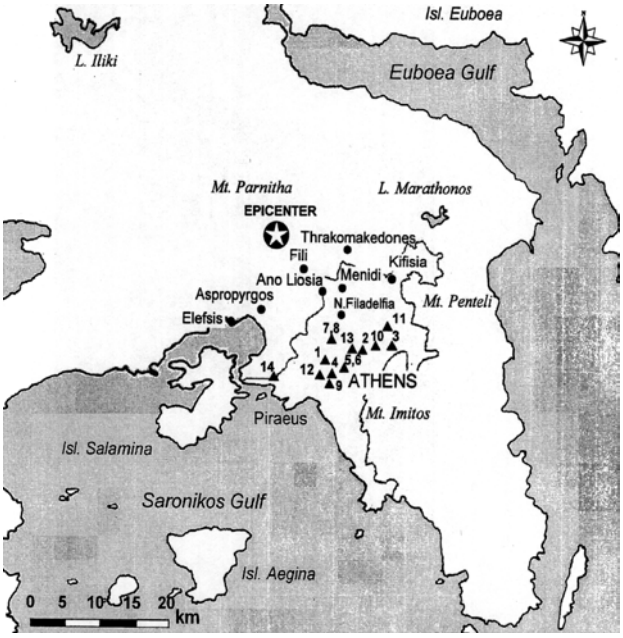

Fig.1. The urban area of Athens affected by the 1999 earthquake. Circles show the mostly affected sites and triangles the sites of recording stations (Psycharis et al, 1999) (see Table 1).

A number of strong ground motion time histories were recorded on soft rock sites at distances of 15 to 20 km from the epicenter (see Fig.1 and Table 1).

3. PRESENTATION OF THE ANALYSIS PROCEDURE

The existing records have been used in order to determine the referred ratios between maximum and mean spectral demands according to the following procedure:

- The original accelerograms FIX1 and DFN1 are filtered in order to obtain two frequency components, a component of high frequency, i.e., higher than 1 Hz, and a component with frequencies lower than 1 Hz.
- The two components are scaled in order to represent mean near field ground motion at rock sites, at a distance of 2 and 5 kilometers from the fault plane. Consequently, the high and low frequency components are scaled up to the values given by a representative attenuation relationship for the near field ground motion acceleration spectra, given by Ambraseys and Douglas (2003). The target spectral values are related to the 50% and 84% probability of non-exceedence and the frequency components are combined after scaling. The resulting time histories are considered to represent the mean near field records at rock sites at the referred distances from the fault and probabilities.
- The two components of the original accelerograms are scaled in order to represent maximum near field records, affected by forward directivity, at rock sites located at distances of 2 and 5 kilometers from the fault plane. The high frequency component is scaled, as before, up to the values given by Ambraseys and Douglas (2003). This scaling conforms to the observation presented by Somerville (1998) that the high frequency component of the ground motion remains unaffected from near field directivity. The low frequency component is scaled in order to attain a

maximum velocity, comparable to that predicted by the attenuation relationship proposed by Rodriguez-Marek (2000), for near field ground motions affected by forward directivity. The scaling is performed for 5.9 moment magnitude, rock sites at 2 and 5 km distance from the fault and 50% as well as 84% probabilities of non-exceedance.

- The artificial accelerograms generated by this procedure are used as rock outcrop ground motions in order to estimate the response and the subsequent ground motions at the top of soil deposits corresponding to A, B and C categories of the EC8 regulations. As a result of this procedure, a large sample of artificial time histories, approximating cases of near field ground motions, were generated. These time histories represent ground motion either affected or not by forward directivity, for a moment magnitude 5.9, distance from the fault plane of 2 and 5 kilometers, three different soil conditions and two levels of non-exceedance probability.
- The spectra of these artificial ground motions are used in order to determine the ratios between maximum and mean near field spectral demands.
- The artificial ground motions are used in order to estimate inelastic spectra and especially the design spectral acceleration values in order to attain a ductility level of 2 for representative SDOF systems.
- Finally, the obtained elastic and inelastic spectra are compared with spectra obtained during the San Salvador 1986 earthquake, an event considered to represent the case of near field directivity effects for small to moderate earthquakes (Bommer et al, 2001).

4. SPECTRAL ACCELERATIONS GIVEN BY AMBRASEYS AND DOUGLAS

Ambraseys and Douglas (2003) have studied the horizontal and vertical ground motions for near field and developed attenuation relationships for spectral accelerations. These relationships depend on the surface-wave magnitude, the distance from the horizontal projection of the fault plane and the soil conditions. Forward directivity is not taken into account. Consequently, the corresponding spectra are associated with the mean near field ground motions. The general form of the relationship given by Ambraseys and Douglas is:

$$logy = b_1 + b_2 M_s + b_3 d + b_4 S_A + b_s S_S \qquad (1)$$

with M_S denoting the surface wave magnitude, d is the distance from the horizontal projection of the fault plane, S_A and S_S take the value of 1 for stiff and for soft soil respectively. For rock S_A and S_S are zero. The relationships have been developed with the aid of a worldwide set of 186 strong ground motion records recorded within 15 kilometers from the surface projection of the fault rupture and for event surface magnitudes of 5.8 up to 7.8. Figures 2 and 3 present the target near field spectral accelerations, used for scaling the original records.

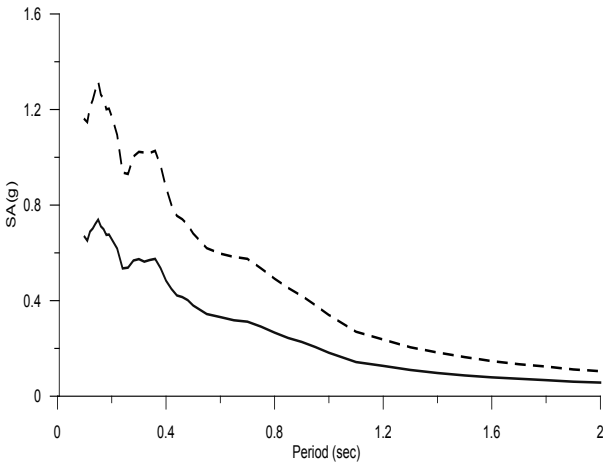

Fig.2 Target acceleration spectra as developed by Ambraseys and Douglas (2003) for surface magnitude 5.9, rock sites at 2 km from the fault and 50%, 84% probabilities in non exceedance.

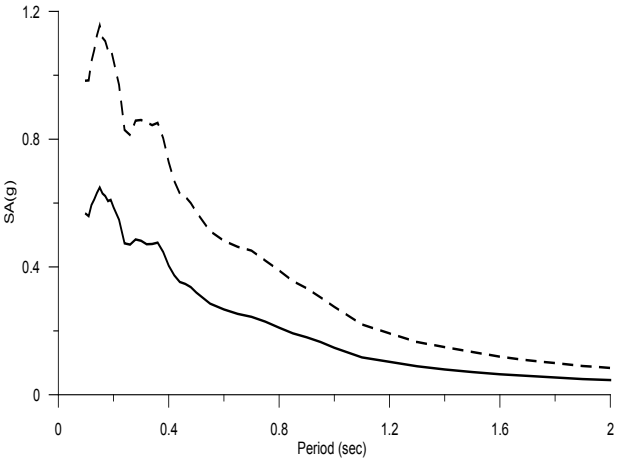

Fig.3 Target acceleration spectra as developed by Ambraseys and Douglas (2003) for surface magnitude 5.9, rock sites at 5 km from the fault and 50%, 84% probabilities in non exceedance.

5. RELATIONSHIPS PROPOSED BY RODRIGUEZ-MAREK TO ESTIMATE DIRECTIVITY PULSE PERIOD AND MAXIMUM GROUND VELOCITY

Rodriguez-Marek in his dissertation (2000) presented relationships to estimate the pulse periods associated with forward directivity, as well as attenuation relationships for the maximum ground velocity associated with directivity velocity pulses. The former relationship is presented in Fig. 4 in order to demonstrate that the pulse period estimated for the Athens records is close to those estimated for 5.9 moment magnitude. The velocity attenuation relationship presented in Fig. 5 was used to scale the low frequency component of the original records in order to simulate near field time histories affected by near field forward directivity.

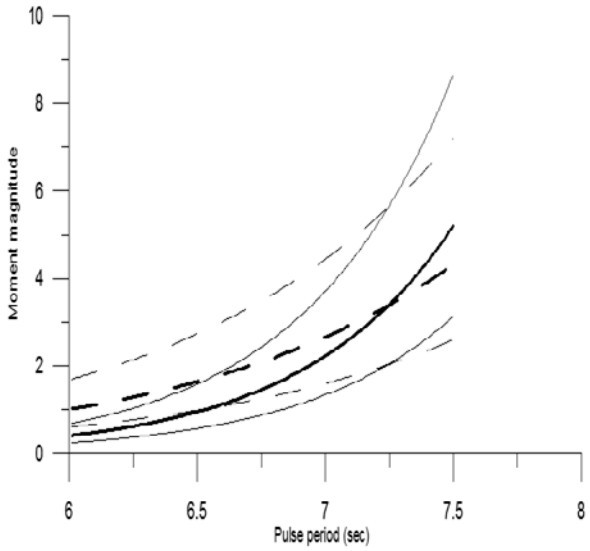

Fig 4. Relationships estimating directivity pulse period for rock sites (continuous line, mean-σ,mean,mean+σ) and soil sites (dashed, mean-σ,mean,mean+σ) (Rodriguez-Marek 2000)

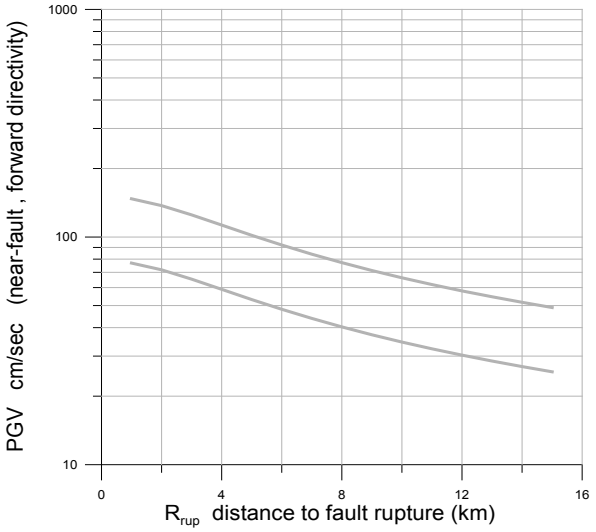

Fig 5. Relationships estimating max ground velocity for 6.1 and 7.4 moment magnitude. (Rodriguez-Marek 2000)

6. ANALYSIS RESULTS

In fig.6 spectra produced from the scaling of the original FIX1 accelerogram are presented. The maximum ground accelerations range from 0.30g for mean near field ground motion and B soil category at a distance of 5 km from the fault plane for a 50% percentile of non exceedance to 0.70g for strong forward directivity and B soil category at a distance of 2 km from the fault plane for a 84% percentile of non exceedance. At the 1 sec period the estimated spectral values are the following, for B soil category:

- At a distance of 5 km from the fault plane, for mean near field ground motion and a 50% probability of non exceedance 0.35g.
- At a distance of 5 km from the fault plane, for mean near field ground motion and a 84% probability of non exceedance 0.6g.
- At a distance of 2 km from the fault plane, for mean near field ground motion and a 50% probability of non exceedance 0.4g.
- At a distance of 2 km from the fault plane, for mean near field ground motion and a 84% probability of non exceedance 0.7g.
- At a distance of 5 km from the fault plane, for near field strong forward directivity and a 50% probability of non exceedance 0.7g.
- At a distance of 5 km from the fault plane, for near field strong forward directivity and a 84% probability of non exceedance 1.2g.
- At a distance of 2 km from the fault plane, for near field strong forward directivity and a 50% probability of non exceedance 0.9g.
- At a distance of 2 km from the fault plane, for near field strong forward directivity and a 84% probability of non exceedance 1.4g.

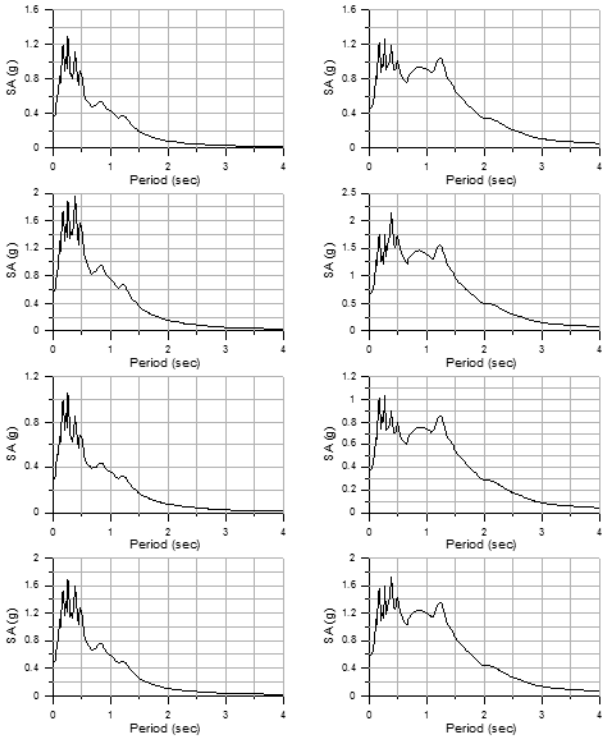

Fig.6 Spectra of artificial accelerograms produced from the FIX1 record. First column presents scaling to the Ambraseys-Douglas spectral values a) mean at 2 km b) mean+σ at 2 km c) mean at 5 km d) mean+σ at 5 km and the second column the same cases but with the low frequency range scaled up to the appropriate max ground velocity as given by Rodriguez-Marek.

In Fig.7 spectra produced from the scaling of the original DFN1 accelerogram are presented. The maximum ground accelerations range from 0.35g for mean near field ground motion and B soil category, at a distance of 5 km

from the fault plane for a 50% percentile of non exceedance to 0.60g for strong forward directivity and B soil category at a distance of 2 km from the fault plane for a 50% percentile of non exceedance. At the 1 sec period the estimated spectral values are the following, for B soil category:

- At a distance of 5 km from the fault plane, for mean near field ground motion and a 50% probability of non exceedance 0.25g.
- At a distance of 2 km from the fault plane, for mean near field ground motion and a 50% probability of non exceedance 0.30g.
- At a distance of 5 km from the fault plane, for near field strong forward directivity and a 50% probability of non exceedance 0.6g.
- At a distance of 2 km from the fault plane, for near field strong forward directivity and a 50% probability of non exceedance 0.8g.

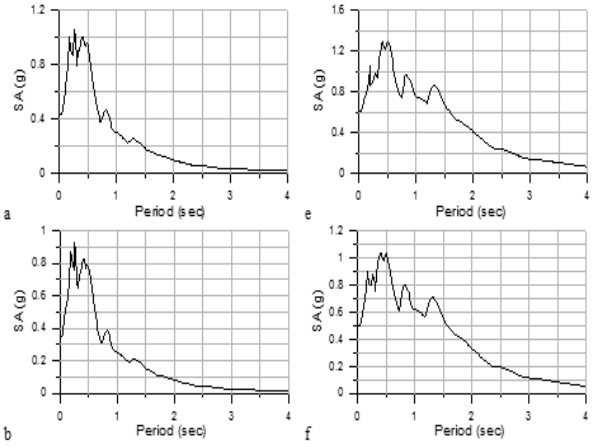

Fig.7 Spectra of artificial accelerograms produced from the DFN1 record. First column presents a) scaling to the Ambraseys-Douglas spectral values mean at 2 km b) at 5km.The second column presents the same with the low frequency range scaled up to the appropriate max ground velocity as given by Rodriguez-Marek.

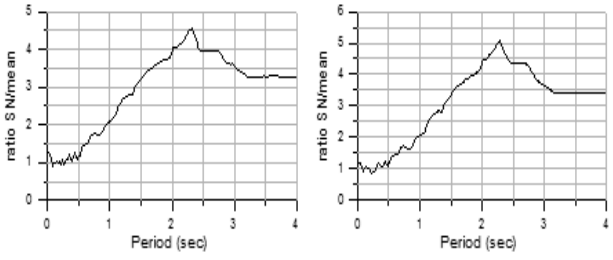

Fig. 8 Ratios between strike-normal (maximum) and mean spectral demand for different artificial accelerograms produced from the FIX1 record.

The values for the latter cases are slightly lower than those for the FIX1 record. For both records, as shown in Figs 6 and 7, a strong amplification in the range of 1 to 2 seconds characterizes the forward directivity records. This amplification is associated with the velocity pulse presenting a period around 1.5 sec.

In what regards the amplification factors between the mean near field and the maximum forward directivity spectra for the artificial accelerograms, these, for all cases, fluctuate between the values of 2 and 4 with a mean value about 3. These amplification values refer to the period range between 1 and 2 sec, where quite a lot of existing structures have their larger natural period. The amplification values given by Huang et al (2008) to estimate forward directivity spectra through new generation attenuation relationships range from 1.5 to 2. This discrepancy could be attributed to the fact that amplification factors for those studies are computed from earthquakes with moment magnitudes larger than 6.5. For such earthquakes the pulse period is expected to be larger than 2 seconds. Consequently, the amplification in the range from 1 to 2 seconds is not associated with the velocity pulses of the directivity effects. In the case presented in our study, earthquake events with magnitude around 6.0 present, as already seen, periods in the referred range of 1 to 2 seconds.

In order to assess the obtained results, a real record obtained at San Salvador in 1986 for a 5.6 earthquake, near the fault plane, at an epicentral distance of 4 km, is compared with the spectra obtained through the presented procedure from the Athens strong motion records. Bommer et al (2001) presented such records as a justification of the assumption that there exist forward directivity effects even for small to moderate earthquake events. Figure 9 shows the acceleration response spectrum of the San Salvador record and the spectrum corresponding to the artifical FIX1 record for a B soil deposit at a distance of 5 klm from the fault plane. The artificial record spectral values correlate very well to those of the real record for the forward directivity effects, which permits the assumption that the Rodriguez-Marek relationships are a good estimator for the maximum ground velocity caused by directivity effects.

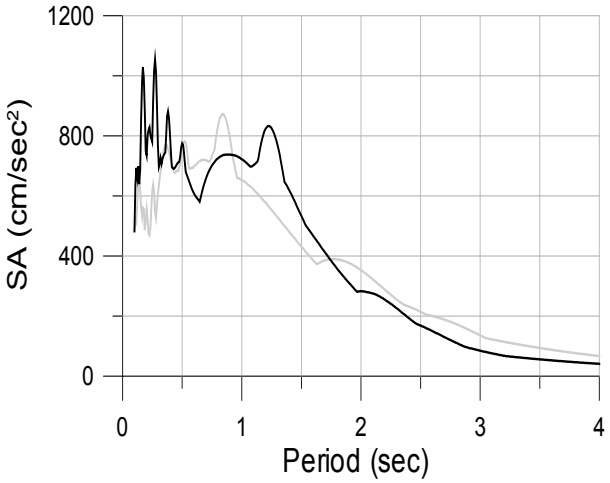

Fig.9 Comparison of spectral acceleration for the artificial ground motion (strong forward directivity, B soil category, at 5 km distance from fault plane, with 50% probability of non-exceedance),(black line), produced from the FIX1 record, with the CIG (San Salvador, 1986),(gray line) record.

Accordingly, these relationships appear to be an appropriate tool to scale accelerograms in the low frequency range, in order to simulate ground motions affected by forward directivity.

Further evaluation of the effects of strong forward directivity on structures with natural periods in the range of 1 to 2 seconds is presented by a series of inelastic spectra, for the artificial FIX1 record, as well as, for the CIG San Salvador record. From the inelastic analyses of SDOF systems the design spectral acceleration for a ductility 2 has been determined.

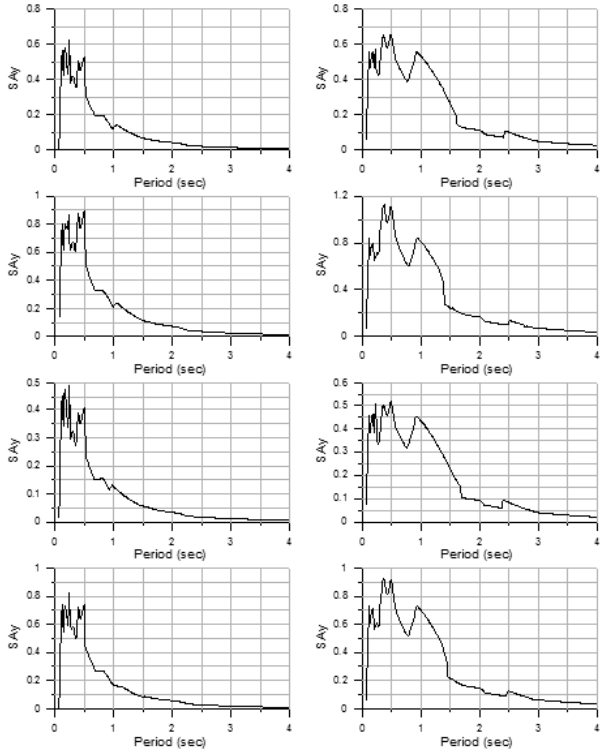

Fig.10 Design spectral acceleration for μ=2 for artificial ground motions produced from the FIX1 record, (first column) scaled to Ambraseys-Douglas for mean and mean+σ at 2 and 5 km and (second column) low frequencies scaled to max ground velocity given by Rodriquez-Marek for the same cases.

As can be seen from Fig.10, at the 1 sec period the estimated design spectral values, for a ductility of 2 and soil category B, are the following:

- At a distance of 5 km from the fault plane, for near field strong forward directivity and a 50% probability of non exceedance, 0.45g.
- At a distance of 5 km from the fault plane, for near field strong forward directivity and a 84% probability of non exceedance, 0.7g.
- At a distance of 2 km from the fault plane, for near field strong forward directivity and a 50% probability of non exceedance, 0.55g.
- At a distance of 2 km from the fault plane, for near field strong forward directivity and a 84% probability of non exceedance, 0.8g.

In Fig. 11 a comparison is made with the design spectral values for ductility 2 for the CIG record. The values are close to those of the FIX1 artificial record at a distance of 5 km from the fault plane, for near field strong forward directivity and a 50% probability of non exceedance.

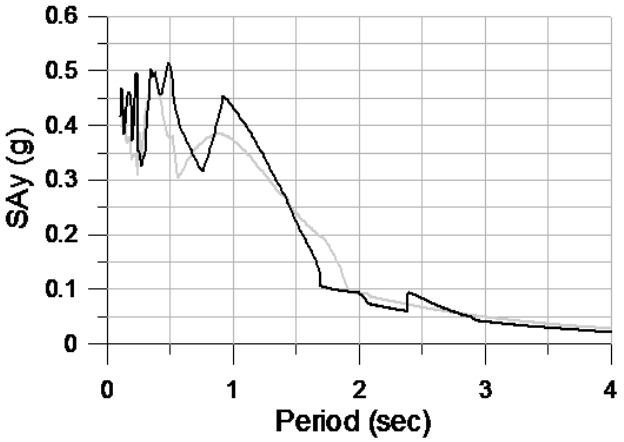

Fig.11 Comparison of design spectral values (μ=2) for the artificial ground motion (strong forward directivity, B soil category, at 5 km distance from fault plane, with 50% probability of non-exceedance),(black line), produced from the FIX1 record, with the CIG (San Salvador, 1986),(gray line) record.

7. CONCLUSIONS

This paper presents a procedure to determine spectral acceleration accounting for strong forward directivity effects of moderate earthquakes, in the period range of 1 to 2 sec. Ground motions recorded at rock sites during the Athens 1999 earthquake are scaled up using new generation attenuation models of characteristic spectra, that account for either mean, near field, acceleration amplification or possible directivity related velocity pulses. Consequently, the ground motions are used as input at the bedrock of typical soil deposits. Surface ground motions, accounting for different soil profiles at various distances from the causative fault, are produced. Elastic and inelastic spectra have been generated and the difference between mean and strong forward directivity ground motion is established. Recent studies estimate the ratio between maximum and mean near field spectral values at about 1.5 to 2. This study, taking explicitly into account the amplification attributed to directivity velocity pulses for moderate events, demonstrates that the ratios may present values of 2 to 4, almost doubling the expected effects. As a result, the spectral values at a period of 1 sec, caused by this strong amplification, may range from 0.7 to 1.4g, according to the distance from the fault plane and the estimated probability of non exceedance. The produced spectral values are compared with those of a characteristic near field record for moderate events. The real spectrum appears to correlate very well to the spectral values of artificial ground motion at a similar distance from the causal fault. Consequently, even for moderate events in the

period range of 1 to 2 sec, a larger amplification of spectral values, even for moderate events, in the period range of 1 to 2 sec, appears to be induced by near field directivity effects.

Abstract: Structural damages induced during the Wenchuan Earthquake have revealed the inadequacy of the previous version China Code for Seismic Design of Building Structures in many aspects and the room for potential improvement. Recently a new round of code revision has been completed. In this paper, the major revision, supplement and refinement made to the previous version code is introduced in terms of seismic fortification intensity, performance-based design method, structural analysis requirement, selection of structural system, failure pattern control and miscellaneous structural seismic measures. The impact and change on future seismic design due to the code revision is briefly discussed. In addition, the difference between the seismic design methods of China and Japan is compared and analyzed.

1. INTRODUCTION

Building structures and engineering facilities were destroyed in large numbers during the Wenchuan Earthquake of May 12, 2008. Ever since then progress has been made in terms of the understanding on failure mechanisms of structures, owing to the in-depth investigation work on the observed structural damages caused by the Wenchuan earthquake and the study on the collected information. In order to comply with the national laws and regulations regarding the earthquake hazard prevention policies and to fulfill the needs for the reconstruction of Wenchuan, the Ministry of Housing and Urban-rural Development of China set up boards and committees consisting of experts in related fields shortly after the earthquake to revise the standard code for seismic design of buildings based on the lessons learnt from the Wenchuan earthquake. As a result, the partial revisions of the Standard for Classification of Seismic Protection of Building Constructions (GB50223-2008) and the Code for Seismic Design of Buildings (2008 version of GB50011-2001, or the 2001 code later on) were completed very soon. The Code for Seismic Design of Buildings (GB50011-2010, or the 2010 code later on) was then issued on May 31, 2010, considering the economic conditions and the characteristics of engineering practice in China and adopting the most recent research results in earthquake engineering. In this paper, the major revisions that were incorporated into the new version Code for Seismic Design of Buildings are introduced. The codes for seismic design of buildings used in China and Japan are also compared so as to identify their common points as well as their differences, which will be of great significance for the reconstruction after the Wencuan earthquake and the improvement of the seismic performance of newly built structures.

2. OVERVIEW OF REVISIONS IN CODE 2010

Compared with the Code 2001, the following revisions were incorporated into the Code 2010:

In terms of the seismic parameters of ground motion, the seismic fortification intensities of seismic regions were partially adjusted, i.e. provisions were added regarding the seismic fortification measures in seismic regions with 0.15g and 0.30g PGA. The classification of design earthquakes was adjusted according to the Seismic Ground Motion Parameter Zonation Map of China. In terms of the site soil liquefaction, the liquefaction discrimination equation was improved; in terms of the calculation of design earthquake action, the damping adjusting coefficient of the design response spectrum, damping ratio and seismic adjusting factor for bearing capacity of members of steel structures, the horizontal seismic-reduced factor for seismic-isolated structures were adjusted and the calculation method for the horizontal and vertical earthquake actions of long-span roof

structures was added; for reinforced concrete structures, the seismic fortification criteria for frame buildings and masonry buildings with bottom-frame; for masonry structures, seismic fortification measures for multi-story masonry buildings, concrete seismic-wall structures and reinforced masonry structures were improved; for steel structures, anti-seismic grade of steel buildings was introduced and the design requirements for seismic fortification measures were adjusted accordingly; for seismic-isolated and seismic-energy-dissipating buildings, the range of their applicability was expanded. In addition, the following contents were adjusted: the performance-based design method was added; seismic design provisions for large-span roof structures, underground structures, portal frame factory structures, reinforced concrete frames with steel brace and the steel frame-reinforced concrete core structures were added; the contents regarding the brick buildings with inner-frame were deleted.

3. MAIN REVISED CONTENTS OF CODE 2010

3.1 Seismic Fortification and Basic Principle of Design

The main revised contents include:

(1) Adjustment of parameters of design earthquake

According to the distribution characteristics of earthquake hazard in Wenchuan Earthquake, 2008, the parameters of design earthquake (fortification intensity or design earthquake groups) in some influenced-places are adjusted. It is shown in Table 1.

Table 1 Adjustment on Fortification Intensity and PGA of Some Places

Location	Code 2001	Code 2010
Wenchuan	7(0.10g)	8(0.20g)
Beichuan*	7(0.10g)	8(0.20g)
Qingchuan	7(0.10g)	7(0.15g)
Pingwu	7(0.15g)	8(0.20g)
Dujiangyan	7(0.10g)	8(0.20g)
Pengzhou	7(0.10g)	7(0.15g)
Shifang	7(0.10g)	7(0.15g)
Mianzhu*	7(0.10g)	7(0.15g)
Anxian*	7(0.10g)	7(0.15g)
Jiangyou	7(0.10g)	7(0.15g)
Chengdu*	7(0.10g)	7(0.10g)
Deyang*	6	7(0.10g)
Mianyang	6	7(0.10g)

Notes: *The design characteristic period, T_g, of response spectra are increased by 0.05 second than Code 2001.

(2) Adjustment on classification of seismic fortification

According to the Standard for classification of seismic protection of building constructions (GBJ50223-2008), the classification of seismic fortification of some important buildings such as hospital buildings and school buildings is changed from "standard fortification" to "important fortification". That means the seismic measurement of theses buildings should be taken according to higher intensity than the fortification intensity.

(3) Adjustment on internal forces of irregular structure

According to the damage phenomenon of irregular structure under earthquake and design experience, the Code 2010 provides the ways to adjust the internal forces based on the different irregularities respectively. For plan irregular and vertical regular structure, the limit value of rotation displacement ratio is loosened in Code 2010. For plan regular and vertical irregular structure, the adjustment focuses on the cases of vertical lateral-force-resisting member with discontinuity. In theses cases, the adjustment factors of seismic internal force for the horizontal transmission members were changed from 1.25~1.5 to 1.25~2.0, which shall be determined by fortification intensity, types of horizontal transmission members, stress type and dimension of cross-section of the members.

(4) Performance based design method

In Code 2010, the newly involved performance based design method provides four performance levels, as shown in Table 2. For the seismic design method of structure members, the demonstration on referenced index of load capacity, story drift, etc. is shown in Table 3, Table 4 and Table 5 respectively.

Table 2 Expected Four Performance Levels Specified in Code 2010

Standard of Earthquake Influence	Level 1	Level 2	Level 3	Level 4
Frequent earthquake	No damage	No damage	No damage	No damage
Fortification earthquake	No damage, can be used without repair	Basically inact, can be continuously used after checking	Slightly damage, can be use after simple repair	Slightly to moderate damage, displacement<3[⊿ue]
Rare earthquake	Basically inact, can be continuously used after checking	Slightly to moderate damage, can be continuously used after repair	Can be used after reinforcing the damage place	Near to serious damage, Can be used after thorough repair

Table 3 Demonstration on Referenced Index of Load Capacity for Structural Members

Requirement of performance	Frequent earthquake	Fortification earthquake	Rare earthquake
Level 1	No damage, can be designed as usual	No damage, load capacity should be checked while design value is employed	Seldom damage, load capacity should be checked while design value is employed and

		and the seismic effects shall be adjusted considering earthquake measure grade	the seismic effects shall not be adjusted considering earthquake measure grade
Level 2	No damage, can be designed as usual	Basically inact, load capacity should be checked while design value is employed and the seismic effects shall not be adjusted considering earthquake measure grade	Slightly to moderate damage, load capacity should be checked while ultimate value is employed
Level 3	No damage, can be designed as usual	Slightly damage, load capacity should be checked while standard value is employed	moderate damage, load capacity shall be maintained in a steady status as the ultimate value is achieved, even has some decrease, the decrease ratio is lower than 5%
Level 4	No damage, can be designed as usual	Slightly to moderate damage, load capacity should be checked while ultimate value is employed	Unserious damage, load capacity shall be maintained in a almost steady status as the ultimate value is achieved, even has some decrease, the decrease ratio is lower than 10%

Table 4 Demonstration on Referenced Index of Story Drift for Structural Members

Requirement of performance	Frequent earthquake	Fortification earthquake	Rare earthquake
Level 1	No damage, drift is far less than the limit value of elastic story drift	No damage, drift is less than the limit value of elastic story drift	Basically inact, drift is slightly great than the limit value of elastic story drift
Level 2	No damage, drift is far less than the limit value of elastic story drift	Basically inact, drift is slightly great than the limit value of elastic story drift	Slightly plastic drift occurred, drift is less than the 2 times limit value of elastic story drift
Level 3	No damage, drift is obviously less than the limit value of elastic story drift	Slightly damage, drift is less than the 2 times limit value of elastic story drift	Obvious plastic drift occurred, drift is about to the 4 times limit value of elastic story drift
Level 4	No damage, drift is less than the limit value of elastic story drift	Slightly to moderate damage, load capacity should be checked while ultimate value is employed	Unserious damage, drift is less than the 0.9 times limit value of plastic story drift

Table 5 Demonstration on Grade for Seismic Details for Structural Members

Requirement of performance	Earthquake measure grade of seismic details
Level 1	Basic seismic details
Level 2	Low-ductility requirement seismic details
Level 3	Moderate-ductility requirement seismic details
Level 4	High-ductility requirement seismic details

3.2 Site, Soil and Foundation

(1) Adjustment on plat category

Based on the three categories of site, favorable plat, unfavorable plat and hazard plat specified in Code 2001, a new plat category, general plat, is assigned to describe the common plat between the favorable plat and the unfavorable plat.

Considering the phenomenon of historical earthquake hazard, the minimum distance of avoidance for seismogenic fault is decreased, as shown in Table 6.

Table 6 Adjustment on the Minimum Distance of Avoidance for Seismogenic Fault(uints:m)

Fortification intensity	Fortification category of buildings	
	Important Fortification	Standard Fortification
8	200(300)	100(200)
9	400(500)	200(300)

Note: The values in brackets are given by Code 2001

(2) Adjustment on the criterion of site category

The construction sites can be classified as four categories depending on the equivalent shear-wave velocity and the overlay depth of soil profile. Category I is divided into two sub-categories, Category I_0 and Category I_1, as shown in Table 7.

Table 7 Two Sub-categories of Site Category I

Code 2010		Code 2001
I_0	I_1	I
V_s>800, D_o=0		V_s>500, D_o=0
	800>V_s>500, D_o=0	

Note: Vs is the equivalent shear-wave velocity, D_o is the overlay depth of soil profile.

(3) Adjustment on the criteria for liquefaction discrimination

The adjustments on the criteria for liquefaction discrimination include two aspects. First, the required depth of soil on liquefaction discrimination is enlarged from 15m (Code 2001) to 20m (Code 2010). Second, the calculate equation of critical value of standard penetration resistance for liquefaction discrimination is changed as a logarithm one, which is deduced based on method of probability theory.

3.3 Seismic Action and Seismic Checking for Structures

(1) Adjustment on the characteristic parameters of standard design response spectrum

There was a mistake that the response spectra would cross each other when the period is larger than 5.0sec in Code 2001. The characteristic parameters of standard design response spectra have been changed to correct the mistake. Figure 1 shows an example of the revised response spectra.

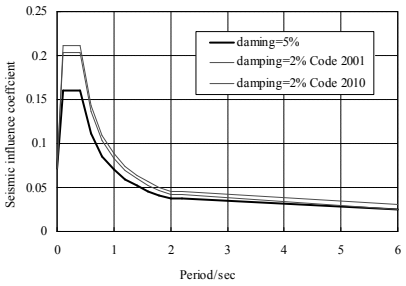

Figure 1 An Example of Design Spectra

(2) Adjustment on the minimum value of story seismic shear force

The minimum values of factor for story seismic shear force are revised. For Intensity 6, it may be 0.006 or 0.008; for long period structures in Intensity 9, it is increased from 0.040 to 0.048.

3.4 RC Buildings

(1) Applicable maximum height for RC buildings

The applicable maximum height for RC buildings in intensity 8 (0.30g) is added in Code 2010. And the one for Slab-Column-Wall structure is also increase from 40m, 35m and 30m to 80m, 70m and 40m respectively corresponding to Intensity 6, 7 and 8. The aspect ratio of the diaphragm between two adjacent seismic walls of slab-column-wall structure is also required in Code 2010.

(2) Grade of RC structures

For RC Frame-seismic Wall structure and Seismic-wall structure, different measure grade shall be adopted according to the intensity, the buildings height and Fortification Category. In Code 2010, the height boundary of 24m is used to classify the structural grade more accurately. And the frame with only one bay is not permitted for the building whose Fortification Category is A, B or its height is over 24m.

(3) The minimum clear width of the isolated joint

In Code 2010, the minimum clear width of the isolated joint has been increased. Taken a frame in intensity 7 as an example, the minimum clear width of the isolated joint would be increased from 110mm to 140mm when the lower building height is 23m.

(4) Requirement for stairs

Because much severe damage had been happened for RC stairs, the effect of component of stairs should be considered in structural analysis.

(5) Factors of the combinatory force design value

Because failure mechanism of strong column-weak beam was rarely developed during Wenchuan earthquake occurred in China on May 12th 2008, the factors of the combinatory force design value have been adjusted in Code 2010 as Table 8.

Table 8 Amplifying Factors of Combined Force Design Values

Grade of RC structures	Amplifying factors			
	Moment of columns	Moment of columns' foot	Shear of columns	Shear of joints
Grade 1	1.7(1.4)	1.7(1.5)	1.5(1.4)	1.50(1.35)
Grade 2	1.5(1.2)	1.5(1.2)	1.3(1.2)	1.35(1.20)
Grade 3	1.3(1.1)	1.3(1.1)	1.2(1.1)	1.20(1.00)
Grade 4	1.2(1.0)	1.1(1.0)	1.1(1.0)	1.0

Note: The factors in brackets are given by Code 2001.

(6) The compression ratio of columns

The compression ratio of columns for frame, frame-seismic-wall, slab-column-wall, frame-core-tube and tube-in- tube structures is strictly limited in Code 2010 shown in Table 9.

Table 9 Comparison of Compression Ratio of Columns

Type of structures	Grade of RC structures			
	Grade 1	Grade 2	Grade 3	Grade 4
Frame	0.65 (0.70)	0.75 (0.80)	0.85 (0.90)	0.90 (-)
Frame-Seismic-Wall Slab-Column-Wall Frame-Core-Tube Tube-In- Tube	0.75 (0.75)	0.85 (0.85)	0.90 (0.95)	0.95 (-)

(7) Requirement of longitudinal bars

The requirement of longitudinal bars for columns, seismic walls and ordinary boundary elements of seismic walls are increased in Code 2010.

(8) Seismic checking for joints

Seismic check for joints in frame of Grade 3 and Slab-Column-Wall has been required in Code 2010 but not in Code 2001.

(9) The minimum seismic shear forces for Frame-Core-Tube structures

For Frame-Core-Tube structures, the seismic story shear force distributed to columns of frame is supplemented in Code 2010, i.e. the seismic story shear force of column shall be not less than 10% of total base shear force of structures.

3.5 Masonry Buildings and Brick Buildings with Bottom-Frame

(1) Limit values of total height and number of stories

The limit values of total height and number of stories are supplemented for structures in intensity 7 (0.15g) and intensity 8 (0.30g) in Code 2010 and the one for other structures is adjusted. The maximum spacing of adjacent transverse seismic-walls is also adjusted in Code 2010 shown in Table 10.

Table 10 Maximum Spacing of Adjacent Transverse Seismic-walls (units: m)

Type of buildings	Type of floor or roof	Intensity			
		6	7	8	9
Multi-Story Masonry	Cast-in-place RC	15 (18)	15 (18)	11 (15)	7 (11)
	Assembled RC	11 (15)	11 (15)	9 (11)	4 (7)
	Timber	9 (11)	9 (11)	4 (7)	- (4)
Multi-Story Masonry with Bottom-Frame	Frame stories	18 (21)	15 (18)	11 (15)	-

(2) Requirement for Multi-Story Masonry with Bottom-Frame

The effect of tie-columns shall be considered to

calculate the stiffness of upper masonry wall. The details for the transition story between the Bottom-Frame and upper masonry wall are required in Code 2010. And seismic shear bearing capacity for Multi-Story Masonry with Bottom-Frame structures with small concrete blocks in intensity 6 should be checked. The details for stairs are required more strictly and use of fabricated stairs is limited.

3.6 Steel Buildings

(1) Applicable maximum height for RC buildings

The applicable maximum height for steel buildings in intensity 7 (0.15g) and intensity 8 (0.30g) is added in Code 2010. And the former frame-braced structure was divided into two types, frame-central braced and frame- eccentric braced structure. Their applicable maximum heights are also established. Meanwhile, the single-bay frame is banned if its fortification category is A or B.

(2) The amplifying factors of design moment force for columns

The measures are given to classify the Grade of steel structures and the amplifying factors of design moment force for columns are adjusted according to their Grade shown in Table 11.

Table 11 Amplifying Factors of Design Moment Force for Columns

Grade of steel structures			
Grade 1	Grade 2	Grade 3	Grade 4
1.15(1.15)	1.10(1.05)	1.05(1.00)	-(-)

3) The damping ratio of the steel structure

The damping ratio of the steel structure is adjusted as Table 12.

Table 12 Damping Ratio of Steel Structures

Earthquake level	Code 2001	Code 2010
Frequently Earthquake	0.035, <=12 stories 0.020, >12 stories	0.04, H<50m 0.03, H=50~120m 0.02, H>120m
Rarely Earthquake	0.05	

Note: H is total height of the structure.

3.7 Single-story Factory Buildings

(1) Single-story factory buildings with reinforced concrete columns

The construction requirement of the dense stirrup region for the lateral restraint bent column which the shear-span ratio is less than 2 is added. The section and reinforcement requirements of column for large-span factory are also added.

(2) Single-story steel factory buildings

Supplementary provisions are proposed as follows. The column braces should be used for factory in intensity 8 or 9 zone and the slenderness ratio limit values of frame columns are determined by different axial-force-ratio. The damping ratios of single-story steel factory buildings could be selected as 0.045~0.05 according to the type of the roof and the enclosure wall. The width thickness ratios of the plates are determined according to whether the contribution of the seismic load is dominated. The stiffness value chosen methods for different type of enclosure wall are also added for the calculation of earthquake action.

(3) Single-story factory buildings with brick columns

The provisions, single-story factory buildings with brick columns used in intensity 9, are deleted.

3.8 Single-story Spacious Buildings and Structures with Large-span Roof

The single-story spacious buildings are consisted of different types of structures，including spacious single-story hall and multilayer annex buildings. In the new code，the structural styles and details of seismic design of the single-story spacious buildings are revised，mainly includes：

(1)The single-story space building with brick column is only applicable to low intensity zone, the span of the brick column and the height of the column are proposed a stricter request than the 2001 Code.

(2)The seismic grade of reinforced column and cross wall of the single-story hall is upgraded. It is cleared that the brick wall on the girder in front of the stage should be light partition wall in intensity 9 zone.

In recent years, the large-span roof buildings are widely used. The content of seismic design of the large-span roof buildings is added in this revision, mainly includes：

(1)The types of the steel roof are classified to the following 7 basic types and their combination，including：arch, plane truss, space truss, grids, network shell，beam string structure and suspending system.

(2)The calculation method of the earthquake reaction，seismic analysis model, combination method of the earthquake reaction and the adjustment method of designed internal forces value of earthquake combination are proposed.

(3)The damping ratio of the steel roof and the concrete supporting structure is different，The damping ratio of the entire structure is ruled in the new Code.

(4)The slenderness ratio of the steel member of the roof is proposed, the details of seismic design of the joint and the support are specified.

3.9 Seismic-isolation and Seismic Energy-dissipating Design

Seismic-isolation and seismic energy-dissipating are effective technology for mitigation of earthquake hazards of the building structure. The new code modifies the design range of the seismic-isolation and seismic energy-dissipating.

New location for the isolation story is added. The isolation story can not only be installed on the base of the structure but also can be installed on the top of the column in ground floor or the chassis of multi-tower-building.

The limitation applied seismic-isolation technology only for multi-story masonry and reinforced concrete frame building is deleted.

Seismic-isolation technology is more appropriate for low-rise and multi-storey buildings. But the correlated studies both at home and abroad show that the technology is still effective for the structure which the fundamental period is more than 1.0s when it non-isolated. So the limitation

applied seismic-isolation technology only for the structure which the fundamental period is less than 1.0s is canceled.

Since the rubber isolation units have low tensile resistance, the horizontal load of non-earthquake action should be limited. So the limitation of height-width ratio of the buildings, which general should be less than 4, is added in the new code.

The concept of horizontal seismic-reduced factor is adjusted. It defined as the ratio of maximal horizontal shear force between the seismic-isolation structures and non-seismic-isolation structures.

The provisions for the total thickness, ultimate displacement and limited velocity of the viscoelastic material are added.

Energy-dissipation device and joint unit for main structure should work in the elastic range.

When the seismic influence coefficient of energy dissipation designed structure is less than 50% of that the non-energy dissipation designed structure, the seismic details requirements of the main structure could be taken as that for intensity of one grade lowers than local fortification intensity.

3.10 Nonstructural Components

During the Wenchuan earthquake, nonstructural components were severely damaged. As a consequence, the new code enhanced the design requirements and seismic measures for the nonstructural components. The major revisions included:

(1) Masonry parapet

Different anchorage methods at different locations of a parapet and the limiting parapet heights corresponding to different seismic fortification intensity were specified. The clear width of the isolation joints should be sufficient, and the free ends of the parapet at the two sides of the joints should be intensified.

(2) Infill wall

Strength indices for different unit types for masonry infill walls in RC structures were introduced. The development lengths for the splice bars between infill walls and columns were increased. Intensifying measures for stairwells and flow channels were added.

In terms of the envelop structures and partition walls of single story RC factory buildings, layout requirements for the perimeter beams of the masonry envelop walls were increased

3.11 Underground Structures

Seismic design for underground structures has attracted more and more attention. This round of code revision introduced the seismic design method for single building type underground structures such as underground parking structures.

(1)Seismic fortification objectives and general requirements

Seismic fortification criteria for underground structures are basically the same as or even higher than those for superstructures. Due to the uniqueness of the underground structures, the structural system should be as simple, uniform and regular as possible to ensure the seismic performance. The anti-seismic grade of RC underground structures is higher than that of basement of high rise buildings,

(2) Computing model and method for seismic design of underground structures

The computing model of underground structures should be able to simulate the influence of surrounding soils. Generally it is preferred to use spatial structural model for the analysis.

Simplified methods such as response displacement method, equivalent horizontal earthquake acceleration method and equivalent lateral force method are only applicable to seismic response analysis of plane strain problems. In most cases the time history method should be used for calculation.

(3) Main design parameters of seismic calculation for underground structures

In terms of the earthquake actions on underground structures, the design fundamental earthquake acceleration can be reduced according to the location. Rock foundation can be taken as one half of the ground surface and others can be reduced in proportion.

Characteristic values of gravity loads should account for water and soil pressure.

(4) Seismic design of underground structures

In general the load carrying capacity and deformation under frequent earthquakes should be checked. Considering the difficulty in repairing, elasto-plastic interstory drift angle of RC underground structures under rare earthquakes should be limited by1/250.

(5) seismic details for underground structures

Construction method of components, connections between components, minimum dimensions, steel ratio and the anti-liquefaction measures for top slab, bottom slab and floor slab are introduced.

4. COMPARISON OF SEISMIC FORTIFICATION OBJECTIVES AND DESIGN METHOD FOR RC BUILDINGS IN CHINA AND JAPAN

In recent years, the comparative studies on seismic fortification objectives and design methods among codes of different countries have attracted attention. Table 13 and Table 14 demonstrate the differences in the seismic fortification objectives and design methods for RC buildings in China and Japan.

Table13 Comparison of the First Stage Design

	China Code	Japan Code
Earthquake level	exceeding probability of 63.2% in 50 years; 50 years of return period	exceeding probability of 50% in 50 years; 43 years of return period
Performance level	The buildings will no damage or slightly damage with continue serviceable without repair subjected to frequently earthquake.	Main structural components remain elastic and no significant damage to nonstructural components
Analysis method	Linear elastic method (without reduction in stiffness)	Linear elastic analysis(with reduction in stiffness）
Member design	Limit state design	Allowable stress design
Deformation control	Inter-story drift angle less than: 1/550 for frame structure; 1/1000 for shear wall structures; 1/800 for frame-shear wall structures	1/200

Note: design at stage one in China code includes the performance level of reparable under moderate earthquake by conceptual design and seismic measures corresponding to the earthquake level with 10% of exceeding probability in 50 years.

Table14 Comparison of the Second Stage Design

	China code	Japan code
Earthquake level	exceeding probability of 2%-3% in 50 years; 2000 years of return period	exceeding probability of 10% in 50 years; 475 years of return period 5
Performance level	The buildings will no damage or slightly damage with continue serviceable without repair subjected to rarely earthquake.	Design limit state(reparable limit state）：sufficient load carrying capacity sustained at deformation corresponding to limit state(ensured by expected load carrying capacity of plastic hinge) and reusable by simple retrofit after earthquake； Safety limit state: ensured by the load carrying capacity of non plastic hinge regions and the ultimate deformation capacity of system
Analysis method	simplified method, static elasto-plastic analysis or dynamic elasto-plastic analysis	Yield mechanism design: Mechanism analysis method, pushover analysis method or linear elastic method (stiffness reduction and internal forces redistribution) to ensure the yield mechanism Mechanism analysis method or pushover analysis method(reliable material strength)
Deformation control	Inter-story drift angle less than: 1/50 for frame structure; 1/1000 for shear wall structures; 1/100 for frame-shear wall structures	Design limit state: 1/100 Safety limit state: 1/67

It can be seen that codes of China and Japan are different in earthquake action calculation, internal force calculation, control of structural performance level, etc. Both countries can learn from each other by conducting comparative studies in terms of specific topics.

5. SUMMARY

This paper summarizes the major revisions that were incorporated into the recently issued new version of China Code for Seismic Design of Buildings (GB50011-2010). The main differences between the old and new versions of code are briefly introduced. The seismic fortification criteria and design method of RC structures specified in the Chinese and Japanese codes are compared and studied, aiming to provide reference for better understanding the new code.

HISTORICAL REVIEW OF THE ITALIAN SEISMIC CODE FROM THE PERSPECTIVE OF THE 2009 L'AQUILA EARTHQUAKE

Giuseppe Oliveto[1] and Luis D Decanini[2]

1) Professor, Structural Division, Department of Civil and Environmental Engineering, University of Catania, Italy
2) Professor, Department of Structural and Geotechnical Engineering, University of Rome "La Sapienza", Italy
goliveto@dica.unict.it, luis.decanini@uniroma1.it

Abstract: The evolution of the Italian seismic code is traced for about a century, starting from the document issued after the 1908 Messina and Reggio Calabria earthquake and ending with the current NTC-08 code. The aspects that have been mainly investigated are the provisions for seismic inputs and for ductility requirements. The NTC-08 design spectrum parameters for the L'Aquila area are compared to measured ground motion characteristics showing that the earthquake had spectral peculiarities not covered by the present code. Finally the behavior of reinforced concrete buildings is considered with the goal of identifying the sources of vulnerability which determined catastrophic collapses and loss of human lives.

1. INTRODUCTION

The 6.3 Mw earthquake that struck L'Aquila on April 6th 2009 was ranked 14th in a list of the most severe historical Italian earthquakes which include, among others, the 1693 Sicily (M=7.5), the 1908 Messina and Reggio Calabria (M=7.2), the 1703 L'Aquila (M=6.9) and the 1915 Avezzano (or Marsica) (M=6.8) earthquakes.

The latter two are of some relevance because the first one, locally known as *the great earthquake*, occurred in the same area as the 2009 one, while the *Marsica* event invested a neighboring area, south west of L'Aquila. Most relevant is the fact that, following the 1915 Avezzano (Marsica) earthquake, a new law was passed which classified L'Aquila and several municipalities in its proximity as seismic zones.

The 2009 earthquake has several characteristics which make it quite unique and worth studying. The city of L'Aquila is in a near fault, hanging wall position about 6 km northeast of the epicenter. With the hypocenter of the main shock located by INGV at a depth of 8.8 km, the earthquake is a shallow one.

These aspects were reflected in the characteristics of the ground motion which determined the collapse of a number of buildings causing 305 casualties, thousands of injuries, tenths of thousands of homeless, and significant damage to a vast majority of masonry historical buildings, to a number of essential and modern facilities, to several commercial and industrial buildings, to transportation facilities, electrical substations, lifelines and utilities.

The second author has had a role as a forensic engineer, advising the local court of justice on the collapse of a number of reinforced concrete buildings, 11 of which caused casualties. Seismic codes in Italy have evolved continuously, with more or less significant improvements after every moderate or catastrophic earthquake. Reinforced concrete buildings have been constructed starting from the early thirties and have evolved according to technological enhancements and, to some extent, according to the technical regulations that have interpreted such changes and absorbed the improvements in the state of the art of structural and earthquake engineering.

The purpose of the present work is twofold; on one side the characteristics of the recorded ground motion, which are typical of near fault conditions, shall be examined and on the other the collapse of some reinforced concrete buildings shall be analyzed in the light of the statutory seismic regulations at the time of construction. Some conclusions shall be drawn on the causes of the collapses and whether these could have been avoided if all the pro-tempore statutory recommendations for anti-seismic design and construction had been applied.

Since the scope of the present work is limited, the reader interested in the general aspects of the 2009 L'Aquila earthquake is referred to several reports published by private and public institutions such as Global Risk - Miyamoto (2009), EERI (2009), INGV (2009), AON Benfield UCL HRC (2010), Mori (2010), Celebi (2010), Decanini et al. (2009, 2010a, 2010b, 2011).

2. SEISMOLOGICAL ASPECTS

The earthquake occurred in a region characterized by a normal faulting system striking at 147 and dipping at 43 degrees approximately. Interestingly the striking angle is approximately coincident with the NW-SE orientation of the Italian peninsula. Interferometric Synthetic Aperture Radar

(InSAR), body wave seismology and GPS data identified with the Paganica fault the causative normal fault dipping 50° SW and estimated the maximum slip at 0.6-0.9 m. For more details and specific references AON Benfield UCL HRC (2010) may be consulted. Evidence of the surface traces of this fault rupture is provided by the INGV (2010) EMERGEO Working Group. The InSAR analysis allowed for the identification of the overall surface area where permanent vertical displacements were measurable distinguishing between the uplifted part NE of the fault line and the subsided one to the SW, with the separation line clearly identifying the trace of the rupture plane on the ground surface. The fringe lines that identify the subsided area are ellipsoids with the main axis oriented from NW to SE.

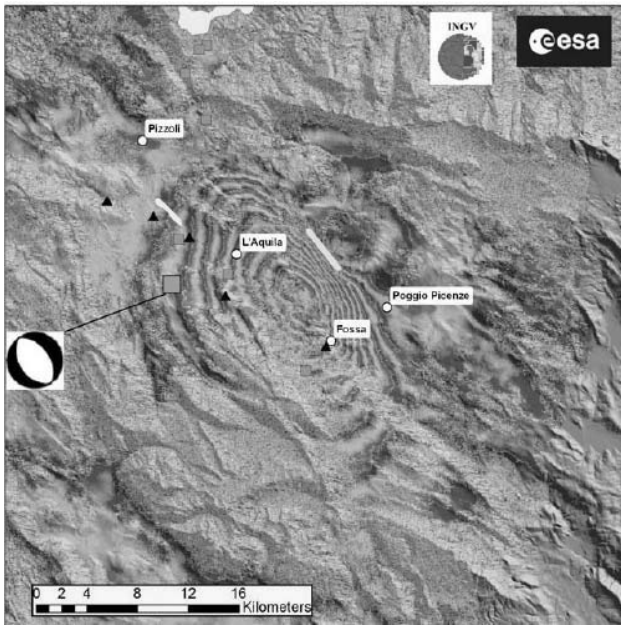

Figure 1 ENVISAT interferogram, focal mechanism and fault line (yellow).

As it may be seen from Fig. 1, the city of L'Aquila lies in the middle of the subsided area, midway between the fault line and the epicenter of the main shock, somewhat along the main axis of the ellipsoid towards NW. Two aftershocks of magnitude larger than 5 followed the main shock. The first one of magnitude M_w=5.6 occurred on April 7th , 40 hours after the main shock, along the principal axis of the fringes of the top event, towards SE. The second aftershock of magnitude M_w=5.4 occurred on April 9th near Campotosto, about 16 km north of L'Aquila. This shows that the rupture process initially progressed towards SE and later migrated to the north and NW. As it may be seen from Fig.1 of INGV EMERGEO Working Group (2009), the city of L'Aquila is roughly located at the centroid of a triangle with vertices at the epicenters of the three main shocks of the seismic sequence of April 2009. Finally it is worth noticing that the subsided area identified by the InSAR fringes lies on the hanging wall of the normal fault, while the uplifted area belongs to its foot wall.

3. GROUND MOTION CHARACTERISTICS

A study of the ground motion characteristics of the earthquake considered has been presented by Akinci et al. (2010). The main conclusions of this study are the presence of long pulses in the near fault records, the presence of some local amplification effects, the dependence of those effects on the magnitude of the shock, with smaller amplifications for larger magnitudes indicating nonlinear material behavior, elastic spectral responses much larger than present code requirements in the short period range.

The ground motion has been recorded by 58 stations of the Italian Strong Ground Motion Network (RAN) managed by the Italian Department of Civil Defense. These concur with the findings of the present study in the assessment of the relative severity of the earthquake and of its short effective duration 3-10 s.

In the present study only the near fault records shall be considered, that is those collected at stations within 6 km from the epicenter.

Figure 2 Strong ground motion recording stations in and around the city of L'Aquila

The recording stations considered are all located within the great metropolitan area of L'Aquila, Fig. 2. Two of the stations are situated downtown with AQU near the castle and AQK near the main bus station; three are located in the Aterno river valley with AQG on the southern bank, AQA and AQV on the northern bank, and finally AQF and AQP are somewhat NE of the latter three. However, stations AQF and AQP did not record due to failure of power supply, while station AQM was found faulty due to maintenance problems; therefore only the records from the remaining five stations are considered. The typical ground motion parameters PGA, PGV and PGD are shown in Tab.1 together with the Effective Peak Acceleration (EPA), evaluated in the 01-05 s period range, and the maximum spectral displacement $S_{D,max}$.

New Technical Rules for Constructions in the Italian Republic were enforced by Inter-Ministry Decree on January 14th 2008 (NTC-08).

Table 1 Ground motion parameters; recorded PGA and calculated PGV, PGD, EPA, $S_{D,max}$

Considered Record	PGA (g)	PGV (cm/s)	PGD (cm)	EPA (g)	$S_{D,max}$ (cm)
AQV-EW	0.626	36.7	8.4	0.471	12.2
AQV-NS	0.598	40.5	4.2	0.502	8.0
AQG-EW	0.416	33.6	8.0	0.316	13.1
AQG-NS	0.434	35.9	3.9	0.309	12.0
AQA-EW	0.394	30.5	6.4	0.254	10.1
AQA-NS	0.451	24.5	4.0	0.384	7.2
AQK-EW	0.342	30.3	8.0	0.220	24.2
AQK-NS	0.340	38.6	11.0	0.245	22.6
AQU-EW	0.263	20.6	3.6	0.209	9.5
AQU-NS	0.316	30.7	5.8	0.157	12.4
Mean	0.418	32.2	6.3	0.307	13.1

These rules superseded previous ones and in fact replaced the four seismic zones in which the Italian territory was divided by a continuous medium where spectral parameters are provided on the basis of the site coordinates in terms of latitude and longitude. For instance the recording stations quoted above are identified by the coordinates shown in Tab.2.

Table 2 Geographical coordinates of recording stations

Station	Latitude	Longitude	Soil Class
AQA	42.375530	13.339298	B
AQG	42.373474	13.337026	B
AQK	42.344967	13.400949	B
AQU	42.353880	13.401930	B
AQV	42.377222	13.343888	B

The soil class profile according to the Eurocode 8 is also provided for the station site because the spectral parameters are affected by the soil properties.

Table 3 Life safety design spectrum parameters

Station	a_g (g)	F_0	T_C^* (s)
AQA	0.260	2.360	0.347
AQG	0.260	2.360	0.347
AQK	0.261	2.360	0.349
AQU	0.261	2.360	0.350
AQV	0.261	2.360	0.350

According to NTC-08 two performance classes are considered; the life safety limit state and the collapse prevention one. For each limit state the code provides a set of parameters for the definition of the elastic design spectrum of the site. The parameters associated with the life safety limit state are given in Tab. 3 for each of the recording stations identified in Tab. 2.

These parameters are almost identical because the stations are not too far apart and the soil class is the same for all of them. Of the four parameters shown in Tab. 4, a_g (g) is the anchorage acceleration of the spectrum to be compared with either the PGA or with EPA, v_g is the peak ground velocity and derives from the spectrum formulation, d_g is the peak ground displacement associated to the given design spectrum, and d_{max} is the maximum predicted displacement.

Table 4 Life safety design ground motion parameters and maximum spectral displacement

Station	a_g (g)	v_g (cm/s)	d_g (cm)	d_{max} (cm)
AQA	0.260	27.4	12.6	21.6
AQG	0.260	27.4	12.6	21.6
AQK	0.261	27.5	12.6	21.8
AQU	0.261	27.5	12.6	21.9
AQV	0.261	27.5	12.6	21.9

Comparison between the first column of Tab. 1 and the first column of Tab. 4 shows that the recorded PGA is generally much larger than the anchorage acceleration for the spectrum, nearly 2.4 times larger for AQV-EW and on average 1.6 times larger. On the other hand, if EPA is considered, which is the average spectral acceleration in the period range 0.1-0.5 s divided by 2.5, the average ratio is about 1.18. In fact the code PGA cannot be compared to the instrumental PGA; the significant comparison is between code PGA and EPA. The most reliable seismic codes in the world make reference to EPA, not to instrumental PGA.

When the PGV is considered, the largest measurement of 40.5 cm/s is provided by AQV-NS; this exceeds the corresponding spectrum value by 1.47 while on average the ratio is about 1.17. It is evident that the code Design Spectrum underestimates both the acceleration and velocity ground motion parameters of the earthquake considered by about 20 % on average. This poses doubts on the reliability of the present specification of the Life Safety Design Spectrum for the area considered, especially when it is realized that the 2009 earthquake has a shorter return period (325 years) than the Life Safety Design event (475 years), Decanini (2010).

However it should be recognized that the two stations closer to the damaged buildings were AQU and AQK. The pseudo-acceleration spectra of these stations are large for periods shorter than 0.5s, but for longer periods their decay is rather steep, Fig. 3. Therefore, the demands for reinforced concrete buildings, especially the inelastic ones, have not been extraordinarily large. This points to intrinsic vulnerability of the affected buildings rather than to exceptional demands.

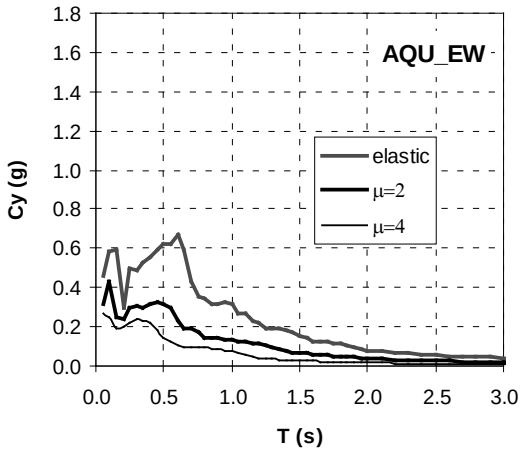

Figure 3 Inelastic acceleration spectra for ductility ratios $\mu=1$, $\mu=2$ and $\mu=4$.

Contrary to acceleration and velocity, the code specification largely overestimates the peak displacements, both for the ground motion and for the structure, as can be seen by comparison between the PGD column of Tab. 1 and the d_g column of Tab. 4, for ground displacements, and between the $S_{D,max}$ column of Tab. 1 and the d_{max} column of Tab. 4 for structural displacements. Only with reference to station AQK the peak structural displacement predicted by the code (21.8 cm) slightly underestimates the corresponding one from the ground motion record (24.2 cm).

A word of caution should be spent with regard to the records of station AQK where the peak ground displacement and the peak structural deformation appear to be much larger than in any other station. This might be due to the positioning of the recording station on a secondary structure, and therefore the recorded motion may not refer to the ground but to the supporting structure.

In concluding this section it appears that the present code specification underestimates by a considerable margin the seismic demands in the acceleration and velocity sensitive parts of the spectrum while it overestimates them in the displacement sensitive portion. On one hand, this may be due to the particular characteristics of the present earthquake, that is near fault and hanging wall position for L'Aquila city. On the other hand, the fact that the earthquake considered appears to be more frequent than the one considered by the code, see previous observation on return period, seems to suggest that stronger events can be expected. Overall it appears that it would be advisable to include the L'Aquila area within the 1st category seismic zones.

4. SEISMIC CODE EVOLUTION FOR L'AQUILA

In what follows a synthesis of the evolution of the Italian seismic code is presented with specific reference to its application to the Abruzzo region of which L'Aquila is the capital city. The topic is covered from the aspect of specification of the ground motion and from the perspective of applying the seismic action to a structural model.

4.1 Specification of the Ground Motion

A synthetic history of the evolution of the seismic code with reference to the L'Aquila area under the aspect considered is provided by Meletti and Stucchi (2009). A brief summary is provided herein in order to clarify some concepts introduced in the previous section and for setting the stage for the following analyses.

The municipality of L'Aquila was classified as seismic after the Avezzano earthquake of 1915, RDL 29 April 1915, No 573. In 1927 seismic classes (later called seismic zones) were introduced and L'Aquila was assigned to class 2, RDL 13 March 1927, No 431. Following the 1980 Campania and Basilicata earthquake, all the Italian territory was reclassified according to homogenous criteria and for the L'Aquila area the earlier classification was maintained, DM 13 September 1982. The municipalities struck by the 1915 (Marsica) and 1933 (Maiella) earthquakes were assigned to class 1 (zone 1 with the highest level of seismic shaking) while L'Aquila city and the remaining areas were assigned to class 2 (zone 2 with medium level of ground shaking).

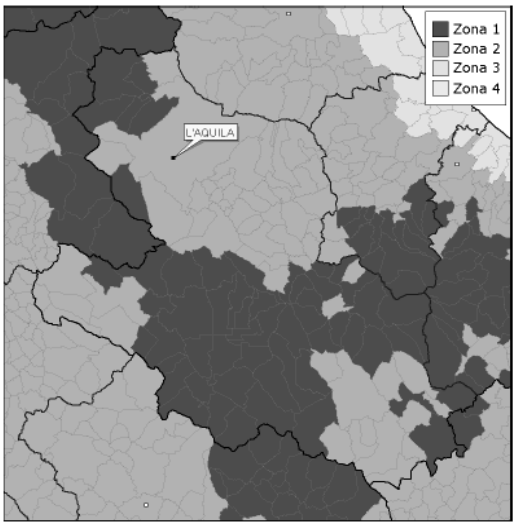

Figure 3 Seismic zones of the Abruzzo region according to OPCM 3274/2003

After the 2002 San Giuliano di Puglia earthquake, with the so called OPCM 3274/2003, the classification of the Italian territory in seismic zones was updated with the introduction of zone 4 in addition to the previously existing zones 1, 2 and 3. At this stage the situation for the Abruzzo region appeared as shown by the map of Fig. 3. Each zone was characterized by a zero period spectral acceleration respectively equal to 0.35g, 0.25g, 0.15g and 0.05g with a probability of being exceeded of 10% in 50 years.

However, with the publication and enforcement of the "Norme tecniche per le costruzioni" (Technical rules for constructions), D.M. 14 January 2008, the seismic zones no longer exist because the whole Italian territory is one large seismic zone with shaking intensity varying smoothly from point to point defined in terms of geographical coordinates.

4.2 Structural Aspects

After the 1908 Messina and Reggio Calabria earthquake, Compulsory Building Rules were issued by the Italian government for the municipalities struck by that earthquake and by previous ones, Committee Report (1909) and Oliveto (2004). The report clearly specified the actions to be considered in the resistance and stability calculations as follows at article 24:

1) static actions representing self weight, dead and live loads increased by a percentage to represent the effects of up and down vibratory motion;
2) Dynamic actions due to lateral ground motion, represented as accelerations applied to the masses of the building in the two directions (longitudinal and transverse) and acting in both senses for each direction.

At the time buildings had mostly two storeys and the horizontal forces were specified as 1/12 of the story weight at the first story and 1/8 of the story weight on the second story. It is apparent that the Committee was aware of the increase of the seismic acceleration along the height of the building and that all the three components of the ground motion needed to be considered. Most important were the examples of calculations that were provided as Annexes to the rules.

The first complete evolution of this set of rules appeared with the RDL 13 March 1927 No 431. The territories struck by earthquakes are divided into two categories according to the severity of the expected shaking and to the local geology, article 2 of the law. The rules for the stability and resistance calculations of buildings with frame structure are provided separately for each seismic zone by article 28 of the law. Notably, the three components of the ground motion are accounted for by three sets of forces. To account for the vertical component of the ground motion, the dead weight of each construction part and the corresponding maximum live load are increased by 50%. Horizontal forces are applied to the various masses of the building according to the experienced horizontal acceleration. Such forces should be applied in both senses in the longitudinal direction of the building as well as in the transverse one. In 1st category zones such forces shall be equal to 1/8 of the weight of the corresponding masses on the ground storey and to 1/6 of the weight of the higher storeys for buildings of height less than 12m (two or three story buildings). For all other buildings such ratio shall be 1/6 at all storeys. In 2nd category zones the effect of the vertical ground motion shall be accounted for by increasing the weight of each structural mass and the corresponding maximum live load by one third. For buildings of height less than 15 m the ratio of the horizontal force to the storey weight shall be 1/10 while for buildings of height equal or greater than 15 m such ratio shall be 1/8. At this point it is apparent that buildings designed and constructed in the following years were calculated as if they were subjected to a constant (spatially independent) acceleration. Also, the horizontal forces were increased considerably with respect to the 1909 regulations.

Ten years later a further evolution occurs with the RDL 22 November 1937, No 2105. Again the forces are specified separately for each category or seismic zone. For the first category the vertical component of the ground motion is accounted for by considering the dead weight and one third of the maximum live load increased by 40%, provided that the resulting load is not smaller than the sum of the dead and the live load. This can be expressed mathematically by the following inequality:

$$\left(D+\frac{L}{3}\right)\left(1+\frac{4}{10}\right)\geq D+L \qquad (1)$$

where D is the dead load and L is the live and/or accidental load. Horizontal forces to account for the horizontal components of the ground motion are taken equal to 1/10 of the weight of the masses on which they are acting, independently of the number of storeys of the building considered. As a contribution to the mass of the building the live load should be accounted only for one third of its maximum value. For the second category zones the forces considered above change as follows. The forces to be considered to account for the vertical component of the ground motion are given by the following expression:

$$\left(D+\frac{L}{3}\right)\left(1+\frac{1}{4}\right)\geq D+L \qquad (2)$$

Horizontal forces are evaluated as before and taken equal to 5% of the weight of the masses producing them.

This new version of the code presents significant changes, as compared to the previous one which represented the completion of the process started after the 1908 earthquake. Probabilistic concepts appear in the evaluation of the masses to be considered for establishing the vertical and the horizontal seismic forces. The seismic acceleration, albeit considered again spatially constant, is considerably abated. From g/6 is reduced to g/10 for 1st category seismic zones and from g/8 is reduced to g/20 for 2nd category zones. This amounts to a substantial reduction, especially for 2nd category zones. The reduction is even more significant when considered in the light of the reduced amount of live load in the evaluation of the seismic weights.

The next significant overhaul of the seismic code occurs in 1962 with Law 25 November 1962, No 1684. The specific reference to the effects of the vertical ground motion is lost in this version of the code, apart from the general prescription that the accidental and/or live load should be applied in such a way as to produce in each structural element the most unfavorable loading condition, prescription already existing in the previous code. The horizontal seismic acceleration is confirmed to be g/10 for 1st category seismic zones and increased to 0.07g, which is slightly larger than

g/15, for 2nd category seismic zones.

The Law 2 February 1974 represents a milestone in the historic development of the Italian seismic code, although it becomes fully operational only with the approval of DM 24 January 1986 dictating " Technical Rules for Anti-Seismic Constructions ". Terms like *"Fundamental Period"* of a structure, *"Response Coefficient"* (alias *Response Spectrum*), *"Dynamic Analysis"* become parts of the knowledge patrimony of the Italian community of practicing Structural Engineers. Also three levels of seismic protection are introduced through the *Importance Coefficient I* which is given the values 1, 1.2 and 1.4. Static Analysis is permitted for buildings with fundamental period less than 1.4 s but dynamic analysis is compulsory for structures with longer periods. Most relevant is also the introduction of the spatial distribution of the seismic forces according to the first mode of vibration when the static analysis is used, albeit through a linear mode shape for buildings with framed structure. Three levels of seismic acceleration are assigned to each of the three seismic zones that are established in the Italian territory. In the zones of *high seismicity*, corresponding to the previous 1st category, the value g/10 is maintained. The previous 2nd category zones are now labeled as zones of *medium seismicity* and the 0.07g seismic acceleration is also preserved. To the newly introduced third category, including *low seismicity* zones, a seismic acceleration level of g/25 is assigned. Little attention is paid to the vertical component of the ground motion for ordinary buildings, while for long span structures or for important structures a theoretical or experimental dynamic analysis is required. For the evaluation of the seismic weight, the contribution of the live or accidental load is evaluated on a statistical base. For residential and commercial buildings 1/3 of the maximum value is considered, for public buildings such as shops, restaurants, coffee houses, schools, military barracks, hospitals etc. 1/2 of the maximum is considered, while the maximum value is considered for theatres, churches, libraries, archives etc. Perhaps it may be useful to observe that these changes in the seismic code matured after the Campania and Basilicata (Southern Italy) earthquake of November 23 1980, M_w=6.5.

Some further evolution in the code occurred a decade later with the DM 16 January 1996. The epochal change was in the safety checks that for the first time were allowed in terms of stress resultants with reference to specified ultimate resistance limit states, instead of the method of allowable stresses that had been used ever before. Notable is also the specific reference to structural regularity with static analysis allowed only for regular structures. Finally the attention returned to the vertical component of the ground motion with the specification of vertical seismic forces proportional to the existing masses evaluated through a constant seismic acceleration. However, when buildings with framed skeleton are addressed, it is suggested that vertical action not be considered with the exception of large spans or overhanging elements.

The next steps of the code evolution have occurred in the third millennium with the issue of OPCM No 3274 on 20 March 2002 and of OPCM No 3431 on 3 May 2005. These led to the introduction of 4 seismic zones as described in section 4.1 Although the two documents were short lived, they are important because they set the ground for the present code NTC-2008 (D.M. 14 January 2008). This is a performance based code that aims at controlling damage from earthquakes occurring at the construction site during the life of the structure. Two service and two ultimate limit states are considered. The service limit states are the Operational Limit State (OLS) and the Damage Limit State (DLS) while the ultimate limit states are the Life Safety Limit State (LSLS) and Collapse Prevention Limit State (CPLS). A reference time span V_R is defined as a function of the nominal life of the construction V_N and of its utilization class C_U with $V_R = C_U \times V_N$. To each considered Limit State corresponds a given probability that the corresponding seismic action is exceeded in the V_R time span. These probabilities are assigned as follows OLS (0.81), DLS (0.63), LSLS (0.10), CPLS (0.05). The return period of the earthquake is calculated through the formula:

$$T_R = -\frac{V_R}{\ln(1-P_{V_R})} \tag{3}$$

A database is provided for the ground motion spectral parameters corresponding to return periods of 30, 50, 72, 101, 140, 201, 475, 975, 2475 years. When the calculated return period does not correspond to any of the above ones, an interpolation formula is provided as a function of the two adjacent return periods. Elastic response spectra are provided for both vertical and horizontal components of the ground motion. For the service limit states the design spectrum shall be the elastic spectrum associated to the probability of being exceeded evaluated as previously outlined. Ultimate limit states should be checked through step by step non linear dynamic analyses using three components of ground motion which can derive from recorded ground motions, artificial and/or simulated ground motions. The ground motions used, whether natural, artificial or simulated should be consistent with the specified elastic design spectrum. Response spectrum analysis and design is also allowed through a reduction of the elastic forces which accounts, in a simplified way, for the inelastic dissipation capacity of the structure, its over-strength and the lengthening of its period of vibration following plastic deformation as described above.

5. EVOLUTION OF DESIGN PGA

At this point it may be interesting to compare the seismic accelerations used by the Italian codes of various epochs. This comparison will be made exclusively for 1st and 2nd category seismic zones, the first being important for obvious reasons and the second referring specifically to the L'Aquila territory. From the previous analysis it may be gathered that from 1909 until 1996 the method of allowable stresses has been used for safety checks. This method is

characterized by an implicit safety factor s_A which is the product of the load safety factor s_L and of the material safety factor s_M. Therefore the elastic spectral acceleration S_E which may be attributed to the old codes can be expressed by the following equality:

$$S_E = s_A \cdot q \cdot S_A = s_L \cdot s_M \cdot q \cdot S_A \qquad (4)$$

where q is a factor accounting for the plastic dissipation capacity of the structure and S_A is the spectral acceleration used to evaluate the seismic loads when using the allowable stress method. It is obvious that any comparison depends on reliable values for s_L, s_M and q. While the values for s_L and s_M can be reasonably set to 1.5, the energy dissipation capacity factor q is affected by many variables and may be different from case to case. For this reason three different values of q will be used here, namely 1, 2 and 4. The actual value will in fact remain unknown, but the behavior of buildings during earthquakes occurred in various epochs could give a fair idea of the most appropriate value of q for each epoch. By assuming a dynamic amplification factor F_0=2.5, the results can be compared directly in terms of effective peak ground acceleration. For each of the time periods between significant code changes, the results obtained are shown in Tab. 5. The analysis of the results provides an interesting perspective in the EPA used for about a century of Italian seismic history in the design of buildings and other structures. After the 1908 Messina and Reggio Calabria earthquake the EPA or design PGA could vary from a minimum of *0.09g*, for buildings without any energy dissipation capacity, to *0.36g* for buildings with a dissipation capacity corresponding to *q=4*. It is unlikely that a dissipation capacity factor q=4 could be provided at the time; a factor *q=2* would seem more appropriate, leading to an *EPA=0.18g*. This however appears too small for a first category zone. This may be the reason why, with the 1927 code, seismic acceleration was increased by *2/3* leading to EPA values in the range 0.*15g* to *0.60g* with a *0.30g* value corresponding to *q=2* .

Table 5 Historic Effective Peak Ground Acceleration (g)

Time Period	First Category			Second Category		
	q=1	q=2	q=4	q=1	q=2	q=4
1909-1927	0.09	0.18	0.36			
1928-1937	0.15	0.30	0.60	0.11	0.23	0.45
1938-1962	0.09	0.18	0.36	0.045	0.09	0.18
1963-1986	0.09	0.18	0.36	0.06	0.12	0.255
1987-2002	0.09	0.18	0.36	0.06	0.12	0.255
2003-2008	0.35			0.25		

That same code introduced second category zones and attributed to them an EPA equal to ¾ of that assigned to the first category zones, that is in the range 0.11-0.45g. By 1937 it must have been realized that the applied seismic forces were too large and therefore they were taken back to the initial value of 0.09-0.36g for 1st category zones, while the corresponding value for 2nd category zone was set to ½ of the value for 1st category, that is 0.045-0.18g. Apparently the EPA value for the 2nd category zones appeared to be too low and so it was increased to 70% of the value for the 1st category zones in 1962.

It may be interesting to notice that, with the exception of the decade 1928-1937, the results shown in Tab. 5 seem to suggest that the Italian code has always assumed an EPA of about 0.35-0.36g for first category zones and of 0.25g for second category zones with an implied seismic dissipation capacity factor *q=4*. With an insider's view it can be said that the situation improved considerably starting from the mid eighties because in the seventies the Italian universities started to offer courses on Structural Dynamics to Civil Engineering students. The 1986 changes in the code were made possible because of the newly acquired background by the structural engineering community. The changes that occurred in the early years of the last decade led to the inclusion of Performance Based Earthquake Engineering concepts and methods.

As a general comment on the seismic regulations of the XX century in Italy, the design effective peak ground acceleration (EPA) has always had the present values if not larger ones for an implied energy dissipation factor *q=4*. When this capacity was not assured by adequate structural detailing, the result was an extremely unsatisfactory behaviour during actual earthquakes, as the three most severe events of the past 50 years have clearly shown.

6. REINFORCED CONCRETE BUILDINGS

According to the Italian Institute of Statistics (ISTAT) the building stock in the L'Aquila region is composed by 24% of reinforced concrete buildings, by 68% of unreinforced masonry buildings and the remaining 8% is qualified as others. Furthermore about 55% of all buildings was erected after 1945. Concerning the height it is found that 20% of the stock has just one storey, 53% has two storeys, 23% has three storeys and only 5% has more than three storeys.

Reinforced concrete buildings were mostly built after the second world war and are mostly low rise (2-4 storeys) and mid rise (5-8 storeys) residential buildings. The most recent ones sometimes present commercial activities on the ground floor. The structural framework is predominantly composed of plane frames along only one direction with slabs of the mixed reinforced concrete - hollow brick system. Shear walls are rare and only present at times as staircase and lift elements.

Out of 4113 reinforced concrete buildings, according to the 2001 census, about 20 overall collapses were reported and about 130 buildings suffered serious damage. Therefore the buildings collapsed were in number slightly less than five in a thousand and the seriously damaged ones only little more than three in a hundred. The unfortunate circumstance that 134 lives were lost in a dozen of collapsed reinforced concrete buildings attracted a lot of attention from the media.

6.1 Age of Collapsed Reinforced Concrete Buildings

Out of the 12 reinforced concrete buildings where loss of life occurred, 9 were built between 1961 and 1965, 2 were built between 1950 and 1955 and another between 1959 and 1960. Also a hospital building complex, built between 1972 and 1992, experienced overall collapses in some of its units. No information is currently available to the authors about the age of the remaining collapsed buildings. Most of the collapsed buildings for which the epoch of construction is known were built in the postwar period of economic expansion when the 1937 code was still statutory and quality control was probably lax. It may be easily observed, Tab.5, that in that construction period the seismic action for 2nd category zones, where the L'Aquila area belonged, was assigned the lowest value ever.

6.2 Probable Causes of Collapse

One of the causes that may have contributed to the collapse of the buildings considered is the pro tempore design seismic action which in some cases may have been insufficient for the event considered. Comparison between data in Tab.1 and Tab.5, with reference to the time of construction, seems to suggest this as a possibility at least. However, this cause has been compounded with several other sources of vulnerability present in the collapsed buildings and discovered by inspection and study of available documents after the event. The design and construction deficiencies that led to structural vulnerability are listed as follows.

a) Resisting frameworks present only along one direction in the horizontal plane, but lacking in the perpendicular direction or in any other direction.
b) Soft storey configurations.
c) Inadequate detailing to assure implied ductility.
d) Poor concrete quality.
e) Strong beam – weak column frameworks.
f) Presence of short columns.
g) Structural irregularity.

Some comments will be provided below for each of the causes of collapse.

Figure 4 Unidirectional resistant system

6.3 Unidirectional Structural Skeleton

With reference to the cause considered at point a), this is the standard arrangement used in Italy for structures designed to resist vertical loads only, Fig. 4. The resistance in the direction perpendicular to the main frames is assured by the frame action provided by the mixed slabs composed of parallel thin concrete beams and hollow bricks. Sometimes slab–thick concrete beams are present along the columns alignments. In both cases the provided resistance is considerably smaller than the one in the perpendicular direction and of the required one. This structural arrangement determines a weaker direction for the building structures along which the collapse can develop.

6.4 Soft Storey

Soft storey configurations may derive from several factors among which the most important can be the need to provide large open spaces for commercial uses, often on the first storey, special architectural space distributions, and finally the search for an overall architectural form totally disjointed from the requirements of structural soundness and efficiency. These situations may have been favored at a time when seismic resistance was still little understood, mainly due to the insufficient background of the field structural engineers and architects.

6.5 Ductility Provisions

For a long time Italian seismic and structural codes have paid little attention to member and joint detailing as essential to ensure an adequate ductility level to structural members and to the overall structure. Until 1939 the only prescription about reinforcement concerned only the longitudinal one; it was only with RDL 25 March 1939, No 640, that transverse reinforcement was explicitly mentioned by requiring stirrups at a distance not larger than half the minimum size of the cross-section nor than ten times the diameter of the longitudinal reinforcement. Again in the seventies a specification required longitudinal reinforcement of diameter not smaller than 12mm and stirrups at a distance not larger than 15 times the minimum diameter of the longitudinal reinforcement with a maximum of 25cm. The diameter of the stirrups could not be smaller than 6mm. All these requirements appear insufficient to ensure a ductile seismic behavior. Finally in 1997 some instructions issued by the Ministry of Public Works with CMLLPP 10 April 1997, No 65, provided considerable improvement towards the objective of achieving a design that ensured ductile seismic behavior. Minimum and maximum bounds (1% and 4%) are provided for the longitudinal reinforcement while the transverse reinforcement must satisfy strict requirements. The distance shall be shorter at the two ends (never larger than 15cm) for a length not shorter than 45cm, and can be longer in the central part but not longer than 25cm. Of course most times the limits turn out to be more strict than the bounds provided here only to convey the idea. At any rate the transverse reinforcement must pass the check for shear resistance. For the first time in an Italian technical regulation, provisions are given for providing confining

transverse reinforcement to columns within the body of beam-column joints. It is prescribed that this reinforcement should not be less than the maximum between that provided at the column end below the joint and that provided at the end above the joint. Because this provision came so late it is not surprising that most of the Italian reinforced concrete buildings built in the XX century present brittle joints and most of the collapses are initiated by joint failure, Fig.5.

Figure 5 Joint failures showing careless detailing

6.6 Structural Irregularities

Several types of irregularities in the collapsed buildings have already been described at previous points. Other irregularities such as the presence of short columns and/or strong beam-weak column frame design have long been recognized as sources of seismic vulnerability. However, weird cases of spatial irregularities have been discovered

Figure 6 Irregular building before earthquake

among the collapsed buildings. In a single case plan irregularities, height irregularities, soft-weak storey conditions and more can be discovered. As mentioned at section 6.3, a cause of seismic vulnerability is the existence of plane frameworks in one direction, but not in the perpendicular one, providing some seismic resistance along one direction but a much smaller one along the orthogonal one. Due to the continuously varying direction of the seismic motion, this results in an extremely vulnerable construction even if it had sufficient resistance in the direction of the plane frames.

But in some cases reality can exceed even imagination in conceiving special types of irregularities. In one of the collapsed buildings the first four storeys showed the main beams aligned along one direction and the next three exhibited main beams aligned along the perpendicular direction. Given sufficient resistance and ductility to structural members and joints and provided that the seismic input can be described with sufficient accuracy such situations should not result in structural vulnerability. However, considered that structural detailing ensures little or no ductility, that structural models are even today inadequate to describe such situations, that the seismic input prescribed by the pro-tempore regulations was largely under-estimated, the result could be nothing else but catastrophic collapse.

Figure 7 Irregular building after earthquake; collapsed left wing

Torsion effects derive also from structural irregularities, Fig 6 and Fig.7. Such effects must have been present in most of the occurred collapses. However, the technical regulations of the time never considered explicitly torsion effects. It was only with the Law 25 November 1962, No 1684 that these effects were fully recognized in the form of mass, stiffness and accidental eccentricities.

6.7 Steel and Concrete Quality

Smooth steel bars were used as reinforcement according to the standards at the time of construction. The mechanical properties of the steel used were in agreement with the statutory code requirements. Concrete strength was generally below the pro tempore code requirements and sometimes below by a large amount. Moreover concrete strength showed a great spatial variability within the same building, perhaps due to the fact that the material was manually mixed at the construction site. Local defects like aggregate segregation and cold joints were also observed.

7. CONCLUSIONS

The earthquake that struck the city of L'Aquila on April 6 2009 had several aspects that made it interesting for their implications in the enhancement of Earthquake Engineering. The earthquake was caused by a normal fault mechanism with the metropolitan area of L'Aquila on the hanging wall. The fault line and fault rupture surface were identified with great accuracy by a combination of scientific means.

Several strong motion recording stations were within the near fault area and five produced useful records. Some ground motion parameters were compared indirectly with the spectral parameters provided for the area by NTC-08, showing disagreement in the short, medium and long period range, underestimating the response in the short-medium range and overestimating it in the long period one.

Since the earthquake was less severe in terms of magnitude and seismic intensity than the design one, it should be considered whether the assumed design spectral parameters are appropriate for the description of a similar event of the expected magnitude.

The historical analysis of the Italian seismic code has shown that until the turn of the century the provisions were somewhat defective in terms of specification of the intensity of the ground motion and of the provision of ductility, especially in view of the synergy played by strength and energy dissipation capacity in earthquake resistant design .

After the 1908 Messina and Reggio Calabria earthquake perhaps Italy had the most advanced seismic code in the world. This code was subject to a continuous improvement until the 1927 version. A relatively large design spectral acceleration was considered, probably to account for the limited ductility that the building technology of the time was able to provide.

Ominously, in the code version of 1937, the spectral acceleration was nearly halved for first category zones and more than halved for second category ones. The spectral acceleration for second category zones was a little increased with the code issue of 1962, but just enough to put the requirements on the same basis as for first category zones.

However, as it is always the case in those circumstances, the new code was not used for the buildings that had already been designed and were being built at the time. Thus it can be established with reasonable accuracy that most of the collapsed buildings were designed according to the 1937 code. This, together with the other sources of vulnerability considered, can explain the catastrophic collapses of reinforced concrete buildings during the 2009 L'Aquila earthquake.

The near fault on hanging wall position of the city of L'Aquila, the intense damage produced by the 6 April 2009 earthquake, the recognition that a stronger earthquake can be expected in the area with a 10% probability of being exceeded in 50 years, as specified by the current code for the Life Safety Limit State, appear to justify a proposal for the inclusion of the area among the 1st category seismic zones.

Abstract: The 2010 Haiti Earthquake resulted in 300,000 deaths, 1.3 million homeless people, and 200,000 damaged or collapsed structures. An unprecedented earthquake damage assessment and reconstruction program under the authorization of the Haitian Public Works with United Nations Office of Project Services and Pan American Development Foundation was developed and implemented. A massive damage assessment program was undertaken with three strategic goals: (1) rapid damage and safety assessment; (2) reconstruction database development; and (3) development of technical capabilities of Haitian engineers. A modified ATC-20 technical platform, accounting for Haitian construction, was developed. As part of this program, personal digital assistant–based data collection techniques and quality assurance programs were implemented. 600 Haitian engineers were trained and 400,000 buildings have been assessed. This database was used to develop; 1) repair construction strategic plan of damaged structures, and 2) demolition and debris plan of collapsed structures. Based on this database and plans, construction management platform was developed and repair of 100,000 damaged structures are underway. This ambitious program combines rapid damage assessment, reconstruction strategic plan development, and construction management platform development. It is considered state of the art practice. This methodology can be implemented as a platform for damage evaluation and reconstruction in other parts of the world including developed countries.

1. INTRODUCTION

The 2010 Haiti Earthquake affected on the lives of more than 3 million people. This paper describes the work performed by The Haitian Ministry of Public Works, Transport, and Communications (MTPTC) to assess rapidly the safety and reparability of much of the affected building inventory in Port-au-Prince and other affected communities..

In light of the enormity of the damage caused by the earthquake, the MTPTC created the Bureau d'Évaluation Technique des Bâtiments (BETB), charged with the task of assessing damage to all buildings in earthquake-affected areas, developing criteria for repair and reconstruction, and providing QC reconstruction. With funding provided by the World Bank (WB), and U.S. Agency for International Development (USAID), field logistics provided by United Nations Office of Project Services (UNOPS), and Pan American Development Foundation (PADF), and technical expertise provided by the authors, BETB embarked on an ambitious program to organize and train a cadre of approximately 250 Haitian national engineers to perform rapid evaluation of all affected buildings using the internationally accepted ATC-20 (ATC 2005) and FEMA 310 (FEMA 1998) methodology

The authors led a four-day intensive classroom session on the fundamentals of earthquake engineering and assessment for more than 600 applicants. Course work was followed by a written examination, from which approximately 250 candidates were selected as evaluators. Among these, 10 of the most qualified were selected as division leaders. Each division consisted of a division leader, four team leaders, and eight to ten evaluators, all taken from the ranks of the 250 trainees.

2. 2010 HAITI EARTHQUAKE

2.1 Overview

The magnitude 7.0 Haiti Earthquake occurred at 1653 local time on Tuesday, 12 January 2010, with an epicenter approximately 25 km west-southwest of the densely populated capital city of Port-au-Prince. This event caused shaking of Modified Mercalli Intensity (MMI) X in the city; see Figure 1 (USGS 2010). In the two weeks following the main event, at least 52 aftershocks in the magnitude range of 4.2 to 5.9 were recorded.

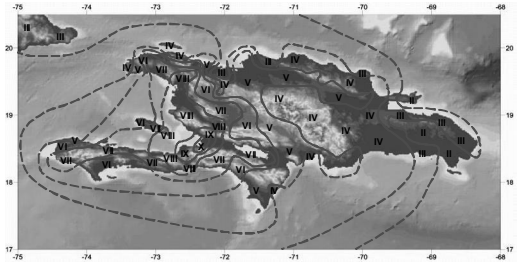

Figure 1. MMI shaking in Haiti (USGS 2010)

The earthquake caused major damage to Port-au-Prince

and other cities in the region. More than 200,000 structures were damaged or collapsed, including many essential buildings, such as the Presidential Palace National Assembly building, Port-au-Prince Cathedral, and main jail. The headquarters of the United Nations Stabilization Mission in Haiti (MINUSTAH) also collapsed, killing many, including the mission's chief.

The Haitian government reported that more than 230,000 people died, 300,000 were injured, and 1.3 million were made homeless. Six months after the earthquake, more than 1.3 million people still lived in temporary camps many of which may offer only minimal services and protection from natural hazards such as hurricanes, floods, and landslides (see Figure 2).

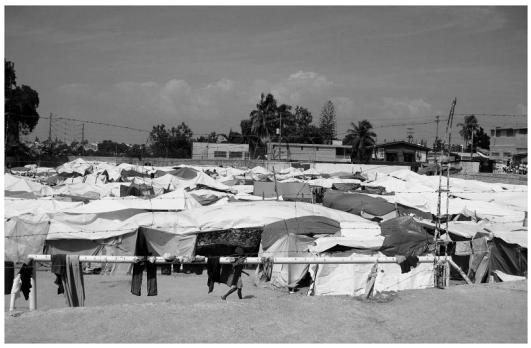

Figure 2. Temporary camps

2.2 Main causes of observed damage

This earthquake caused devastation disproportional to its magnitude. If the international standards of seismic design and construction had been used in Haiti, much of the life and economic loss could have been avoided. The main contributing factors exacerbating this tragedy were the following:

a. In Haiti, design and construction practices had not considered earthquake forces. In addition, many engineers and contractors had neither education nor experience in earthquake-resistant design methodology.
b. Haiti lacked an seismic code.
c. The past decade has seen rapid growth of low-income neighborhoods because of migration into the city from outlying areas. In these neighborhoods, unsafe housing had been built using substandard construction materials and practices.

Many of the structures in Haiti are of a building type that is vulnerable to seismic damage. These buildings use a variation of confined masonry construction comprising weak hollow concrete blocks (HCBs) with lightly reinforced and nonductile beams and columns.

3. DAMAGE ASSESSMENT

3.1 Methodology

The evaluation method chosen for this program was the ATC-20 (ATC 2005) Rapid Assessment, with modifications to adapt to Haitian conditions and to provide more useful information to the MTPTC. This methodology, which was first developed in California in the 1980s, has been used successfully for evaluation after many major earthquakes in the United States. The Rapid Assessment Form allows evaluators to characterize buildings in one of three ways: "Inspected" (also known as "green-tagged"), meaning that the building is structurally undamaged and may be occupied full-time; "Restricted Entry" (or "yellow-tagged"), meaning that the building should not be occupied for extended periods and that parts of the building might be considered off-limits; or "Unsafe" (or "red-tagged"), meaning that the building cannot be safely inhabited. The form was modified to provide evaluators with a checklist of Earthquake Vulnerability Factors per FEMA 310 (FEMA 1998), which has allowed evaluators to list the features of each structure that would make it more prone to earthquake damage.

One important consideration that was stressed to the evaluators is that while the three-color evaluation system provides an understanding of the hazard associated with a building at the time of the evaluation, it does not state whether a building must be demolished. Some buildings given "Unsafe" ratings are considered repairable, but the nature of the damage has rendered them hazardous to occupy until repairs can be completed. In the same way, the "Inspected" rating does not guarantee that a building will not be seriously damaged in the event of future earthquakes. If another major event of equal or greater magnitude were to take place along a section of the fault closer to the city, damage would in all likelihood be much more widespread. In general, the nature of local design and construction in Haiti is such that nearly all buildings can be considered seismically hazardous.

One feature of the process has been the use of Personal digital assistant (PDA)s with Global Positioning System (GPS) capability to assist in performing the evaluations. The PDAs are preloaded with the modified ATC-20 Damage Assessment Form, and evaluators would fill out the forms electronically during the course of each assessment. At the end of the day, all information from the more than 150 PDAs is uploaded to a main server. Because some of the street layout of Port-au-Prince is unmapped and many residences have no addresses, the GPS coordinates of each structure have been used as the primary means of identification. The use of GPS has also proved to be an invaluable tool in developing overall damage maps and a reconstruction strategic plan.

Evaluations have been performed systematically, with each division given the responsibility to evaluate all the structures in a given zone each day. Zones are determined by MTPTC using aerial maps, which are updated daily to show the status (green, yellow, red) of each evaluated structure. As each zone is completed, new ones are assigned.

As the program evolved, and as additional funding became available through USAID and PADF, the 10 teams were expanded to 17. With all 17 teams working at capacity, it was possible to assess more than 3,000 structures daily. The initial target of 100,000 structures evaluated was met on

31 May 2010, and by 15 June 2010, 132,662 buildings had been assessed. By the end of August 2010, more than 250,000 structures had been evaluated. Over 400,000 structures in the earthquake-affected area were assessed by December 2010.

3.2 Typical building properties

Although the buildings observed have displayed a wide variety of sizes and architectural styles, virtually all were constructed using a similar structural system: a cast-in-place concrete gravity frame with unreinforced HCB infill panels acting as incidental infill shear walls.

In such structures, the concrete floor and roof slabs are supported by lightly reinforced concrete columns, sometimes as small as 150 mm on side. Floor and roof framing consists in some cases of a grid of concrete joists framing between the beams; voids between the joists are formed using HCBs as stay-in-place forms. Exterior wall cladding and interior partition walls universally consist of HCBs joined with cement mortar. These infill wall panels effectively serve as the seismic-force-resisting system; however, there has typically been no evidence of any system intentionally designed for that purpose. Buildings typically have lacked a seismic load path; in other words, they do not appear to have a system by which inertial forces generated in one portion of the structure could be transferred to other parts of the structure and then to the ground. In seismic zones, this load path commonly comprises diaphragms, collector elements such as chord and drag reinforcing, special vertical reinforcing at shear wall corners, and doweling between the walls and surrounding elements. None of these have been present in the vast majority of buildings observed.

Concrete gravity frames have displayed numerous design and construction practices that would be considered defective by international standards, particularly in seismic zones. Figure 3 through Figure 5 show some of the common seismic deficiencies.

Figure 3. Beam with exposed reinforcement

Figure 4. Poor concrete consolidation in column

Figure 5. Overhanging upper floor

The design defects include the following:

a. Use of smooth reinforcing bars,
b. Lack of column confinement reinforcing,
c. Inadequate lap splices and rebar development length

The construction defects consist of the following:

a. Segregation, voids, and rock pockets evident in finished concrete, particularly in columns and at construction joints
b. Exposed rebar, poor aggregate shape and grading
c. Poorly located construction joints, and paper and other debris left in joints; formwork embedded in finished concrete
d. Out-of-plumb columns.

Typical masonry construction also has numerous defects, including irregular coursing, missing or inadequate vertical mortar joints, inadequate horizontal joints, poor material quality, and extensive use of broken block. These conditions have been commonly found in nearly all buildings, regardless of age, size, or number of stories. These design and construction practices led to a combination of heavy buildings with little lateral strength and essentially no post-yielding capacity, and were key factors in the vast majority of failures observed.

4. BUILDING DAMAGE SUMMARY

4.1 Overview

By 15 June 2010, 130,000 buildings have been assessed. The damage from this population sample is presented in this paper. Data from the complete population sample of 410,000-surveyed building is currently being analyzed and the results will be presented at a later date.

4.2 Summary data

Table 1summarizes the number and the median (50th percentile) damage estimate for the population sample. As indicated in the table, the median damage estimate for buildings in all assessment categories was in the 1% to 10% damage range. Forty-eight percent is building stock that is undamaged and safe to use. Twenty-eight percent has moderate damage and most likely can be repaired. These numbers are significant, because they indicate that 76% of buildings affected by the earthquake can be immediately occupied or repaired with relative ease.

Table 1. Summary data for damage assessment

Category	Green-tagged	Yellow-tagged	Red-tagged
Number of structures	62,000	36,000	32,000
Percentage	48%	28%	24%
Median damage estimate	0–1%	1–30%	60–100%

The majority of damaged and collapsed buildings are located in the low-lying districts west of the airport, which includes downtown Port-au-Prince, Nazon, Turgeau, Canape Vert, Carrefour, and the lower portion of Delmas. By contrast, more southerly and easterly regions, in particular Juvenat and Pétionville, suffered much lighter damage. The difference in damage levels is mainly a result of soft-soil amplification. Softer soil is found in many of the highly-damage areas.

4.3 Damage classification

By far, the most common damage found among the buildings evaluated has been cracking or collapse of the HCB walls, which is a natural consequence of both the lack of reinforcing and the poor material quality, (see Table 2).. Among the buildings evaluated, moderate or serious wall cracking was cited in nearly 56,000 cases. Wall collapse was noted in slightly more than 40,000 cases. Cracking was observed to be most widespread in the lower levels of multistory buildings, where shear forces were highest. The next most common damage mode was either cracking or crushing failure of concrete columns in about 31,000 cases which was typically a result of flexural forces. Soft-story conditions were observed to be a major contributor to column bending and shear failures.

Table 2. Damage types found in greater Port-au-Prince area

Damage classification	Moderate	Serious
Column cracking or spalling	15,468	15,762
Slab, beam, joist cracking or spalling	12,360	11,715
Ground movement or cracking	12,124	6,204
Exterior, interior wall collapse	20,952	19,536
Exterior, interior wall cracking	30,207	25,711
Parapet, canopy, deck, stair damage	10,479	10,281

4.4 Damage by building occupancy

Overall damage has not varied significantly between building occupancies, but some trends can be seen from the data. The vast majority of buildings evaluated, nearly 95%, were residential structures. These structures varied widely in quality of construction, and ranged from large, engineered mansions to improvised shacks. Table 3 presents the distribution of damage for various building occupancies. Examination of data in this table shows the following:

a. Commercial/industrial, healthcare, and civic buildings, which are often larger engineered structures, had better performance overall, with 52% to 57% of these building types being green-tagged, as opposed to 48% for single-family housing.
b. The performance of essential facilities such as hospitals and public-safety facilities is not adequate. In healthcare, for example, the damage rate corresponds to a loss of healthcare capacity of approximately 44% immediately after the earthquake, a time when this capacity is needed most.
c. The best overall performance (as measured by the largest percentage of green-tagged buildings) was experienced not by essential facilities (such as hospitals and police and fire stations), but by commercial/industrial facilities.
d. One alarming finding was that one of the worst performance among occupancy types was experienced by schools with only 44% of the structures being green tagged.

Table 3. Damage classification for various occupancy types

Building occupancy	Green-tagged	Yellow-tagged	Red-tagged
Single-family residential buildings	48%	27%	25%
Multifamily residential buildings	45%	32%	23%
Schools	44%	34%	22%
Healthcare buildings	56%	25%	19%
Civic/public-safety facilities	52%	30%	18%
Commercial/industrial facilities	57%	24%	19%
Other	51%	32%	17%

4.5 Damage by number of stories

In general, among the structures evaluated, building

performance (as measured by the percentage of red-tagged structures in each group) was progressively worse as building height increased, and tall buildings were much more prone to severe damage. Of the buildings that were four stories or more in height, 44% were red-tagged; versus 24% for one-story buildings (see Table 4). In other words, the potential for catastrophic failure or collapse is almost twice as high for four-story or taller buildings than for one-story buildings.

Table 4. Damage classification for various number of stories

No. of stories	Green-tagged	Yellow-tagged	Red-tagged
One	49%	27%	24%
Two	46%	29%	25%
Three	36%	29%	35%
Four and more	30%	26%	44%

5. REPAIR AND RECONSTRUCTION

5.1 Yellow-tagged buildings

A large number of buildings with HCB and masonry construction have experienced HCB cracking damage. Given the need to use of readily available local material, considering the capabilities of Haiti's masons, and accounting for the economics involved in the repair of such a large number of structures, many of these options are not feasible for the current program in Haiti. For the vast majority of Haitian structures, therefore, the preferred method is placing of horizontal and vertical reinforcement in the HCB walls, and using superior concrete mortar mix and masonry blocks. This is one of the procedures discussed in ASTM (1993). This method was selected as the primary approach for the repairing of failed HCB due to good earthquake performance, economic benefits, and the presence of locally available labor and material for implementation. To demonstrate its efficacy, a sample zone has been selected and is undergoing reconstruction before the effort is extended to wider areas of the country.

The assessment of data shows that approximately 27% are classified as yellow-tagged. These structures must be repaired expediently using safe earthquake engineering techniques to help reduce the number of people living in temporary camps.

Unfortunately, there is ample evidence of reconstruction and repair of these collapsed or damaged structures using pre-earthquake, unsafe methods. Such an approach would place the lives of the citizens of Haiti at risk again in the event of another large earthquake. Therefore, it is imperative to use an improved and safe repair and reconstruction plan that focuses on techniques, quality-control quality assurance (QC-QA), and an approval mechanism to reduce the future life-safety risk. The proposed plan comprises the following components:

a. Develop cost-effective and simple repair methodologies for typical residential buildings. The platform uses the existing research undertaken at leading technical research institutes that focus on these and similar types of construction as described previously.
b. Develop guidelines and programs to communicate and train contractors and communities to repair and reconstruct residential structures. A simple illustrated guideline and training program was developed based on the information listed above. This guideline and training program has been developed for community implementation.
c. Develop a repair assessment method and construction inspection plan. PDA-based repair assessment and QA was developed.
d. Develop community-based reconstruction strategic plans based on the damage assessment database. The damage assessment database and the field knowledge developed during the assessment will be used to create a reconstruction strategic plan for each community. This plan will include possible total reconstruction areas, utilities requirements, and the cost of reconstruction and repair.
e. Develop and implement a project communications program for the repair guidelines. A mass media, strategic public communications campaign will be initiated using the available modes of communication (including radio and community meetings) to inform the public about the reconstruction plan and promote the use of improved repair and reconstruction methods.

5.2 Red-tagged buildings

The non-collapsed structures will be assessed in detail to confirm their red-tagged status and reparability. If the red-tagged structures are evaluated as feasible for repair, the repair assessment program will be conducted on the structure. If the red-tagged status and condition as infeasible for repair are confirmed, then the following data is recorded:

a. Classification of demolition. The demolition will be classified into one of the four groups listed in the following section and information will be recorded to document the reasoning behind the qualification.
b. Means and method of demolition. Given the classification of the demolition, on-site recommendations will be recorded on the means of demolition and the type of equipment and personnel that would be required for a removal.
c. Quality of site access. The quality of access to the site will be determined; for example, what type of construction and demolition equipment can be brought to the site, if any, and whether the site allows for debris-hauling equipment. In addition, it will be determined whether the site would allow access for implementing the demolition requirements listed in the next section.
d. Estimation of debris volume. An estimate of the volume of debris that would be generated after the demotion is completed will be identified.

e. Means and methods of debris removal. Given the volume and type of debris, on-site recommendations will be recorded on the type of debris removal and equipment needed to achieve such a task.
f. Identification of T shelter requirements. Given the size of the site and the number of tenants that the building had, an estimate will be made of the size and number of temporary shelters and housing that would be required until a new replacement structure had been erected.
g. Identification of natural- and geohazard conditions. An estimate of flood hazards and geohazards at the site will also be made. This estimate involves documenting any unusual site conditions, including flooding potential; noting any peculiarities about the site that had amplified the response; and noting other hazards such as slope stability and proximity to faulting. This data will then help engineers in the next phase of the reconstruction effort

5.3 Classification of the demolition

During the detailed red-tagged structure evaluation, the engineers will also assess and document the means by which the building could be demolished. Four categories will be used:

a. None or Minor. These buildings collapsed completely, essentially turning into rubble. No or only minor demolition or structural removal is required. The only task remaining is the debris removal and cleaning of the site.
b. Simple. These buildings are typically one story tall. They still have some small parts standing. However, the remaining portions can be dismantled and removed by hand crews using simple hand tools. No engineering technical support is needed because the remaining structure does not present a life-safety hazard to the crew removing it.
c. Medium. These structures are two to three stories tall and experienced partial collapse at some floors. They require engineering expertise to safely remove the remaining portions of the units.
d. Complex. These groups of buildings are typically tall and experienced collapse of floors at intermediate levels. The buildings are still standing. The removal of these buildings should be undertaken by construction and demolition specialists who have the experience, technical support, and heavy equipment required to remove the buildings safely and incrementally.

5.4 Quality management

Ten engineering divisions (150 national engineers) should be deployed as part of the repair assessment program and another 10 engineering divisions should be deployed for a red-tagged structure assessment program to conduct detailed engineering assessment of 200,000 damaged structures for reconstruction within a reasonable time frame. The repair assessment program was initiated in Delmas 32 in August 2010.

The QC program should support yellow- and red-tagged structure assessment and reconstruction programs. The QC-QA program includes:

a. QC of yellow- and red-tagged structure assessment programs. A construction-quality monitoring platform has been developed and a PDA-based monitoring tool is being implemented for yellow-tagged structure repair and reconstruction. This tool should also be used to provide a construction QA process. A similar tool will be developed for new construction.

These programs are critical activities for reconstruction. The authors have found that many Haitian engineers are more than capable of being trained in and implementing these yellow- and red-tagged structure programs with a proper QA program. This QC-QA program is also an integral part of the capacity development program in Haiti. Trained and experienced engineers from damage assessment, yellow-tagged structure assessment, and red-tagged structure assessment programs should be brought over to the QC-QA programs

6. CONCLUSIONS

The 2010 Haiti Earthquake once again revealed the vulnerability of unreinforced masonry and nonductile concrete construction to earthquake damage. The problem was more severe in Haiti because the country was unprepared for a major earthquake. To address the special circumstances and damage assessment in Haiti, an international and national partnership was formed, and it focused on inspection and reconstruction. This effort showed that:

a. An innovative assessment approach that relies on the expertise of international engineers to train national engineers in using state-of-the-art technology—such as ATC-20 and FEMA 310 protocols, PDAs, and GPS—is effective for rapid assessment and data collection.
b. Such an event provides a unique opportunity to collect field data and to develop fragility functions for various building types, occupancies, and construction.
c. Using a rapid assessment program as a database for reconstruction is an effective methodology. The methodology developed in Haiti can be implemented in other parts of the world as an effective damage assessment and reconstruction method.

Acknowledgements:

The The authors express gratitude to the management of MTPTC, including: Mr Jacques Gabriel (The Minister), Mrs. Viviane St Dic (Chief of Staff), Mr Evelt Eveillard (General Director), Mr Alfred Piard, (Director of Public Work) and, Mr Raymond Hygin (Assistant Director of Public Work). The work

described in this paper would not have been possible without the tireless efforts of the 250 Haitian engineers that participated in this unprecedented task. Similarly, the efforts of the many engineers from the US offices of the Miyamoto International who have spent many months in Haiti participating in this program are recognized. The financial and technical contributions of UNOPS, PADF, and WB OFDA/USAID are acknowledged. Their leadership and understanding of Haiti has been fundamental to the success of this project.

Most important of all, the authors wish to thank and acknowledge the citizens of Haiti. Their resiliency, hospitality, and courage are remarkable. They never quit hoping and smiling in the face of the most severe disaster any human has ever had to endure. They are an incredible people..

Abstract: During the San Fernando earthquake (1971) two of the three triaxial recording instruments placed in an 16 story steel building in Los Angeles recorded the impact with an adjacent reinforced concrete parking structure. This provided an excellent opportunity to evaluate the modeling of such an event using current computer programs (time step, structure damping, impact damping and use of a gapped element), to evaluate the effect of the impact on the strength demands and to evaluate the design implications (necessary separation). Although only the base recorder functioned during the Northridge earthquake, it was possible to evaluate the computer modeling using the San Fernando data and then use the model to evaluate the building behavior under the stronger Northridge earthquake (1994). Results indicate that the extensive cracking indicated in the two transverse frames of the steel building show general agreement with the results of a damage investigation following the Northridge earthquake. Much of this damage in the lower ten floors of the transverse frames was probably due to the impact with the adjacent parking structure at the fifth floor level. Damage in the upper portions is thought to be due to the increased response in the higher modes of vibration caused by the impact and by the horizontal setback at the fifth level.

1. INTRODUCTION

For more than 40 years, the collisions (pounding) of buildings during earthquakes has been of concern to structural engineers. The pounding between buildings during the Tokatioki Earthquake (1968) in Japan has been discussed by Shimazu (T. Shimazu, 2007). During the San Fernando Earthquake (1971) pounding occurred between a 16 story building and an adjacent parking structure (Gates, 1973). At the same time, pounding between the stair towers and the main building of the Olive View Hospital had a significant effect on the damage experienced (Bertero and Collins, 1973). Following. the Mexico City Earthquake (1985), pounding was identified as present in over 40% of the 330 buildings that collapsed (Rosenblueth and Meli, 1986). Bertero (1986), has also documented much of the structural pounding that occurred during this earthquake. During the Northridge earthquake (1994), the 16 story building mentioned above suffered much more severe pounding between the building and an adjacent parking structure. The steel building required substantial repair as did the reinforced concrete parking structure. The behavior of this building during these two earthquakes will be the main topic of this paper.

While data-mining the records obtained during the San Fernando Earthquake for another study, the authors noted that instruments located at the mid-height and roof levels of the 16 story building had recorded the impacts with the five story adjacent structure. This provides an excellent opportunity to evaluate the analytical modeling of this type of event using current, commercial computer programs and to evaluate the effect of these impacts on the overall performance of the building during the San Fernando earthquake.

Unfortunately, the instrumentation at the mid-height and roof did not function properly during the much stronger Northridge earthquake and important records at these locations are not available. However, the base motions were recorded. Therefore, a computer model has been developed and correlated with the recorded San Fernando data. It was then used to predict the response due to the much stronger Northridge earthquake and the effects of multiple impacts on the structure. Calculated response from the computer model is compared with the damage reported by investigators following the two earthquakes.

2. CASE STUDY BUILDING

2.1 Description of Building

The building considered in this study is a 16 story, structural steel office tower, shown in Figure 1. It was designed in 1969 under the building code requirements of the City of Los Angeles. The typical floor plan, shown in Figure 2, is rectangular with three bays in the transverse (N-S) direction and six bays in the longitudinal (E-W) direction. A typical bay width is 8.4 m. The tower rises out of a four story base structure and has a horizontal offset on three sides. On the fourth (longitudinal) side it abuts an adjacent four story parking structure that has a seismic

separation of two inches. Seismic resistance is provided by rigid moment frames on the perimeter of the tower. Due to the location of the building relative to both the San Fernando and Northridge earthquakes, the transverse moment frames experienced the strongest motion. In the case of the Northridge earthquake these frames also experienced the most damage, which required extensive repair. Therefore this study will be focused one of these two identical frames.

A typical elevation of a transverse frame is shown in Figure 3, which is taken from an earlier study following the San Fernando earthquake (Gates, 1973). The beams of the frames consist of 107 cm deep welded plate girders and standard W14, wide flange columns. According to the reference, the deep girders were used to stiffen the frame, thereby reducing the lateral story drift under lateral loading. However, this results in a strong girder/weak column design that will force the higher stresses and possible plastic hinging into the more vulnerable columns rather than the girders. Also shown in Fig. 3 are the locations of the three recording instruments (SMA-1's); one at the base, one on the ninth floor and one on the roof. All three are located near to the center of the floor plan.

Figure 1: 16 Story Building

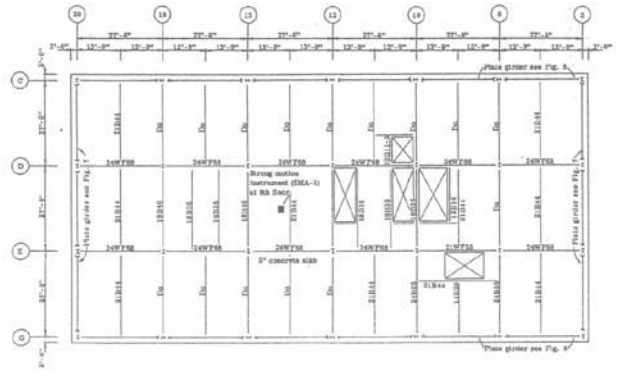

Figure 2: Typical Floor Plan (Gates, 1973)

The adjacent parking structure is constructed with pre-stressed concrete girders resting on column haunches with shear walls providing the lateral resistance. This structure has five levels of parking and is similar to several others that were built in Los Angeles during this time period. An instrumented parking structure of this type is located on the USC campus so that the dynamic properties are well known. There is a two inch seismic separation between the two structures.

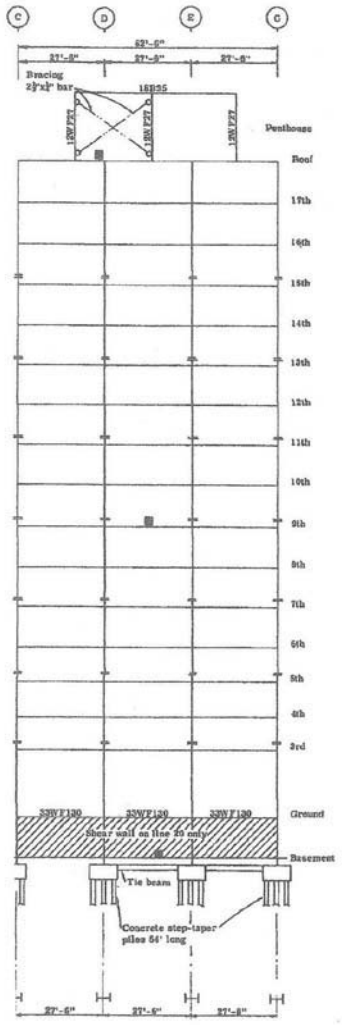

Figure 3: Elevation and Instrument Locations (Gates, 1973)

The computer model of the transverse frame developed for SAP2000 vs.14 (CSI, 2009) is shown in Figure 4. The main tower is modeled using standard beam and column elements with rigid connections. The story weight (mass) is equally divided between the two frames and lumped at the nodal points. The dynamic response of the parking structure is simulated using a lumped mass, chain model having the dynamic properties that approximate those of the actual structure Based on the results reported by Gates (1971) and on the results of preliminary studies by the authors, it was concluded that the response of the structural members to this earthquake was only weakly nonlinear.

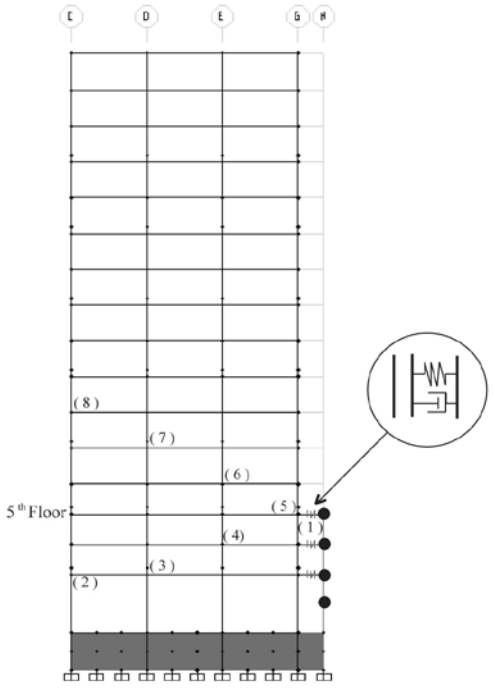

Figure 4: 2D Sap2000 Model

The maximum demand/capacity ratio (DCR) occurred in an interior column of the 15th floor and had a value of 1.6. Therefore it was decided to use the SAP model with linear elastic material properties and with nonlinear geometric properties for the gap elements. The adjacent parking structure is connected to the main building using the gap element available in the SAP program. This element uses a linear spring of stiffness k and a linear dashpot. The stiffness was determined from a three-dimensional analysis of a similar structure on the USC campus. The damping constant c, which is related to the coefficient of restitution, was determined as suggested by Anagnostopoulos (2004). Although the recorded data was digitized with a time step of 0.02 seconds, a time step of 0.005 seconds was used for the analysis in order to more accurately capture the action in the gap. An initial Fourier analysis of the recorded data indicated a damping of 5% of critical in the first mode with lower damping in the next three modes. However, later analysis of the building response indicated that a higher damping was needed to obtain a better agreement with the recorded response. Therefore, the damping in the first mode was increased to 8% and the modified damping function is shown in Figure 5.

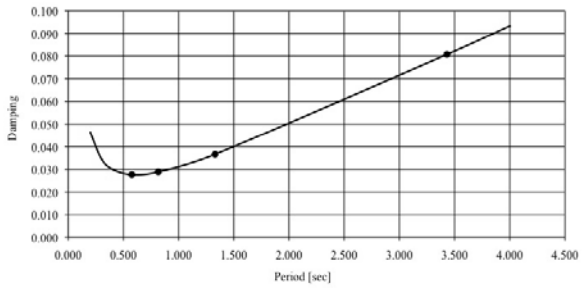

Figure 5: Percent Critical Damping

2.2 San Fernando Earthquake (1971)

Nine excellent records of seismic response were obtained from the three instruments during the San Fernando earthquake, approximately 28.2 Km from the building site. The recorded response in the transverse direction at the roof level is compared with the calculated response in Figure 6. The acceleration responses are compared in Figure 6a. It can be seen that the maximum recorded acceleration is 0.22g, whereas, the maximum calculated acceleration is an acceleration spike that reaches 0.43g at 20.2 seconds. It will be shown that this acceleration spike is due to contact with the parking structure. The maximum displacement, shown in Figure 6b, occurs at the same time and is recorded as 14.5 inches compared with the calculated 48.3 cm. The recorded acceleration response at the ninth level is compared with the calculated response in Fig. 6c. The comparison is quite good with the exception of the two acceleration spikes that occur 12.6 seconds and 19.4 seconds which are due to contact with the parking structure. The displacements, shown in Figure 6d, are in good agreement.

The forces in the link elements which represent impacts with the garage are shown in Figure 6e. Relatively strong impacts can be seen to occur at 12.6 seconds and 19.5 seconds. Recall that these impacts are occurring at the fifth floor level, which is 51 m below the roof. Measuring the time lag in the acceleration spike between the hit at the fifth level and the roof (20.1s – 19.4s) and dividing this into the distance to the roof gives an estimate of the shear wave velocity in the building, which is 72.85 m/sec. An analytical calculation suggested by Tedesco et.al., 1999, expresses the shear wave velocity for a shear building having uniform properties as: $c = 4L/T_n(2n-1)$, where L is the height and T_n is the period of the nth mode. Using L=64 m and T_n = 3.43 seconds this results in a shear wave velocity of 74.83 m/sec.

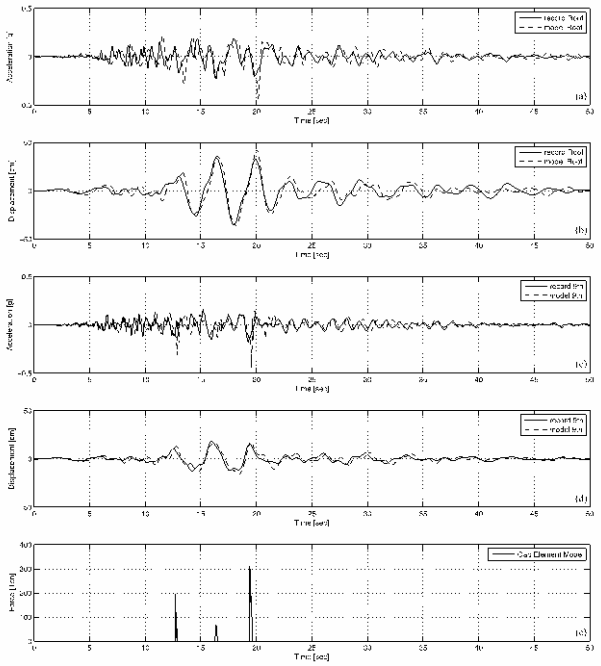

Figure 6: Response Comparisons between Recorded vs Calculated, San Fernando 1971

Demand Capacity Ratios (DCR's) are shown in Figure 7 for the beams and columns of the transverse frames. Two conditions are considered: one with the parking structure in place (P) and the other without the parking structure (N). It can be seen that for the beams, shown in Fig. 7a, the behavior has remained elastic with the exception of the exterior beam at the sixteenth level and the interior beam at the 15th level where the inclusion of the parking structure has increased the DCR's to 1.1 and 1.06 respectively. It can also be seen that in general, the effect of the impact at the fifth level is to increase the DCR's relative to the case where the parking structure is removed as shown by the broken lines. Considering the columns, shown in Fig. 7b, substantial inelastic behavior is indicated in the upper half of the building by several of the DCR 's exceeding unity. A maximum value of 1.5 occurs at the sixteenth floor level, representing a 25% increase due to the impact.. This may indicate the effect of an amplified second mode response due to the impact. In the mid-height region, the opposite is true and the DCR's without the impact are greater than those with the impact and in the lower third of the tower the the DCR's without the parking structure are larger than those with parking although both are less than unity. This may be representative of the restraining effect or the of the adjacent structure. Note that below the 10th floor level, the DCR's are all less than unity indicating elastic behavior.

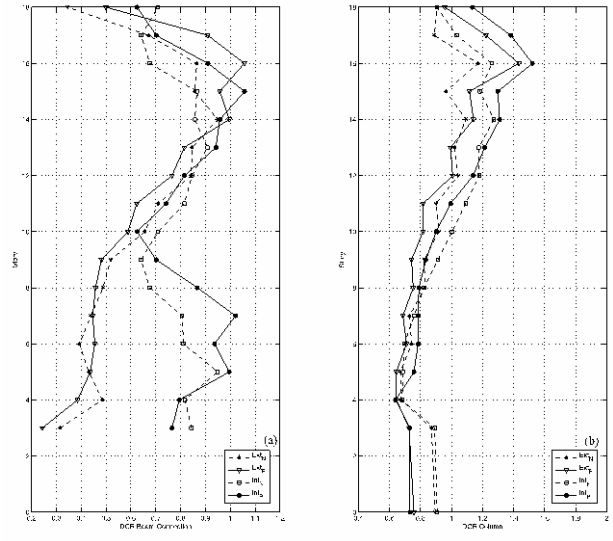

Figure 7: Demand Capacity Ratios, San Fernando 1971

The strong motion portion of the column shear response is shown in Figure 8 for the four locations across the transverse frame shown in Figure 4. The initial impact with the parking structure occurs at 12.6 seconds into the record as shown in Fig. 8 at position 5 which represents the top of the parking structure. This initiates a shear wave that propagates up and down across the structure. The time history of the shear at the first exterior column is shown in Fig. 8(5). Here, the impact effect appears as a short duration blip on the shear response curve of the building without the impact, shown by the dashed line.

The path of the impact wave moving up the structure is tracked across the structure in Figures 8(5), 8(6), 8(7) and 8(8). The second major impact occurs at 19.3 seconds into the record as shown in Fig. 8. Note that the pulse reaches location 8, three stories and three bays from the impact point, at 19.43 seconds into the record for a travel time of 0.13 seconds. As might be expected, the largest effect of the impact on the shear force occurs at position 6 which is the column next to the impact point and results in an increase of 33% over the condition without impact. By the time the pulse reaches position 8, the maximum shear with the impact is just equal to that without impact. The path of the impact wave moving down the structure is tracked across the structure in Figures 8(5), 8(4), 8(3) and 8(2). At these locations, the effect of the impact produces a shear that is either equal to or less than that of the unrestrained structure. However, this was a rather mild impact that did not cause any known damage to either building but left marks indicating that it had occurred. Repair costs were reported to be very minimal.

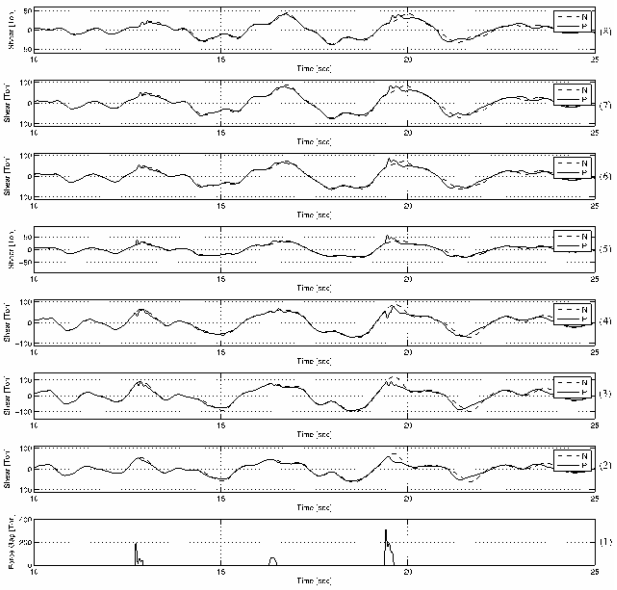

Figure 8: Column Shear Time History, San Fernando 1971

2.2 Northridge Earthquake (1994)

As mentioned previously, at the time of the Northridge earthquake, only the recording instrument at the base of the building was operational. Therefore, comparisons cannot be made with the calculated and recorded response data for this earthquake. The recorded acceleration at the base for the San Fernando earthquake is shown in Figure 9a along with the calculated displacement in Figure 9b. The calculated hits against the parking structure are shown in Figure 9c. Similar data for the Northridge earthquake are presented in Figures 9d, 9e and 9f respectively.

It can be seen immediately that the motion at this site due to the Northridge earthquake was considerably stronger than that due to the San Fernando earthquake. Note that the peak acceleration for San Fernando is approximately 0.12g whereas that for Northridge is almost 0.3g. The increase in displacement is not as large with San Fernando having a

peak displacement of 8.9 cm and Northridge reaching 10.7 cm. This increased response for Northridge has increased both the number and intensity of hits against the adjacent structure. As can be seen in Figure 9f, there are six hits for Northridge versus only three for San Fernando, Figure 9c. These figures also indicate that the intensity of the impact for Northridge is approximately three times that due to the San Fernando ground motion.

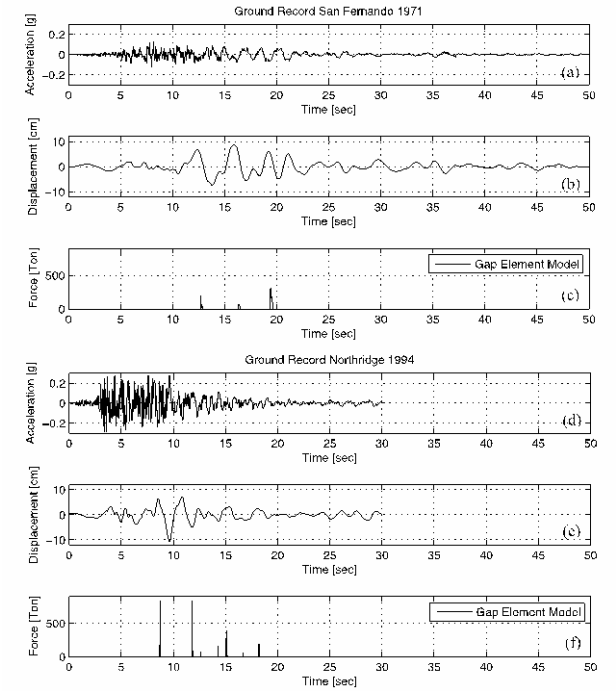

Figure 9: Ground Motion Comparisons

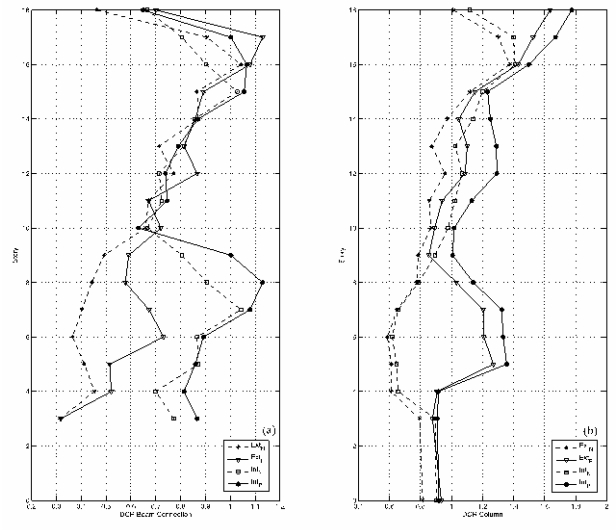

Figure 10: Demand Capacity Ratios, Northridge 1994

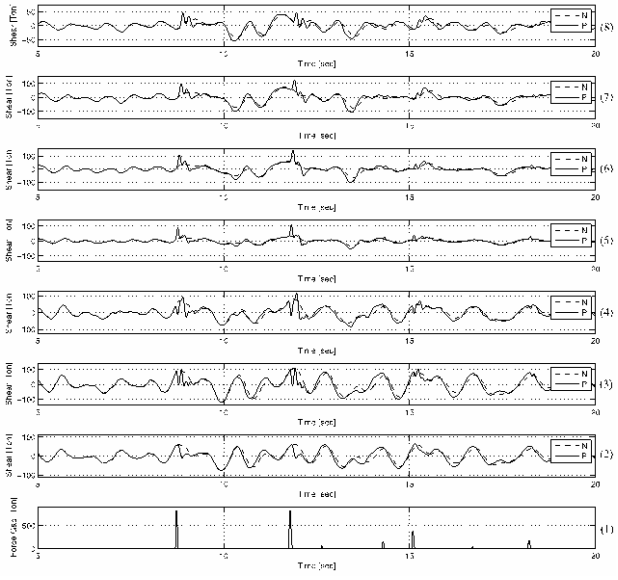
The Demand Capacity ratios for the beams and columns of the transverse frames considering both with and without the parking structure are shown in Figure 10. Considering the beams, shown in Figure 10a, there is no significant change in the DCR's over the height of the structure. Most of the increases are in the elastic range and all values are less than 1.2. However, at all beam locations over the height, the impact with the parking structure increases the DCR's. The column DCR's are shown in Figure 10b. Here there is a significant change beginning at the 5th floor level and extending to the 8th floor level. Recall that this is the region shown in Figure 8 that was affected by the impact pulse. The columns in this region have had the DCR's increase from a maximum of just under 0.6 to as much as 1.3, indicating an increase of more than 100% and the initiation of inelastic behavior in levels 5 to 8. The columns in the upper three floors are also increased from values of 1.1 to values of 1.7. This indicates that the amount of inelastic behavior has increased significantly and particularly in the more vulnerable columns.

The strong motion portion of the column shear response is shown in Figure 11 for the four locations across the transverse frame shown in Figure 4. The initial impact with the parking structure occurs at 8.7 seconds into the record as shown in Fig. 11(1). As for the San Fernando record, this initiates a shear wave that propagates up and across the structure. The time history of the shear at the first exterior column is shown in Fig. 11(5). Here, the impact effect appears as a short duration blip on the shear response curve of the building without the impact, shown by the dashed line. The path of the impact wave is tracked across the structure in Figures 11(5), 11(6), 11(7) and 11(8). A second major impact occurs at 11.7 seconds into the record as shown in Fig. 11(1) and this impact results in the largest shear increase of 50% at position 6 shown in Figure 11(6). Note that the pulse reaches location 8, three stories and three bays from the impact point, at 8.82 seconds into the record for a travel time of 0.12 seconds. For this earthquake record, the largest effect of the impact on the shear force occurs at position 6, which is the interior column. By the time the pulse reaches position 8, the effect of the impact on the maximum shear is beginning to decrease and by the time it reaches the other side of the structure at position 4 it is no longer affecting the maximum (design) value.



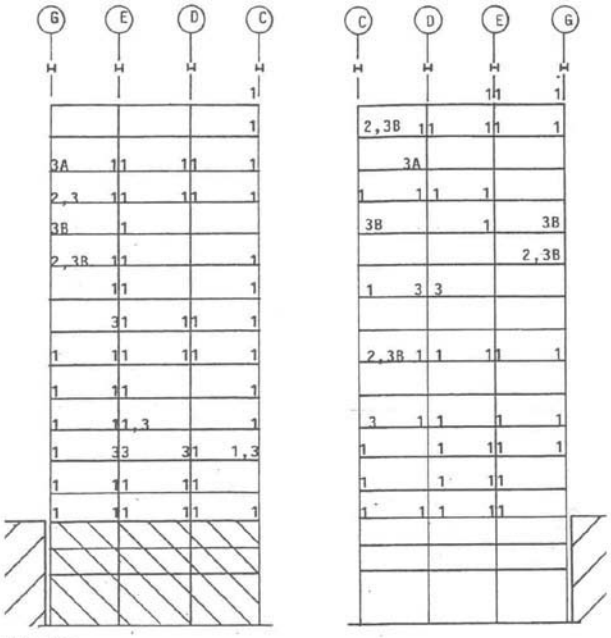


Figure 11: Column Shear Time History, Northridge 1994

Considering the case of no impact (Fig. 10), it can be

seen that below the impact point, the behavior is almost completely elastic with only the columns at the base having DCR's that are just at unity. There are no DCR's greater than unity until reaching the ninth floor level. In the case of the actual building, Fig 10, the impact causes DCR's in all but the far side exterior columns to be in the inelastic range for four story levels, one below the impact level and three above.

Following the Northridge earthquake a comprehensive evaluation and repair program was conducted. The determined damage has been reported (Kariotis, et.al., 1995) as part of the "SAC Program on Steel Moment Frame Structures." This data indicated that the distribution of earthquake damage was primarily confined to the transverse frames. The summary of the damage in the transverse (N-S) frames is reproduced from this reference in Figure 11.This data indicates that there is significant weld cracking at the floor level of the impact (5^{th}) and for two or three levels above the impact level. Data below the impact point were not included in the reference report although the results of this study indicate an increase in the DCR's in the first story below the impact point. In the west elevation there is also cracking in the column flanges two floor levels above the impact point. Increases in the DCR's in the upper half of the structure due to the impact are thought to be a result of the increased response in the second and possibly third mode of vibration.

3. CONCLUSIONS

The application of an impact load to a steel frame results in a short duration impact load that appears as a blip on the displacement response curve of the frame without the impact. Close to the point of impact, this will cause a significant increase in the calculated DCR. Due to the short duration of the load, it would not appear that there is enough time for a plastic hinge to form. However, the short duration impact may cause cracking in the weld material of welded moment frames. This is particularly true of frames that were constructed prior to 1994 using a weld material with a low fracture-toughness. Since welded plate girders were used for the beams, this may have made the building more susceptible to cracking due to impact load.

The results of this study also illustrate the need for building separation in seismic regions. At the impact point (5^{th} floor level) the displacement due to the San Fernando earthquake was 1.07 cm for the parking structure and 6.81 cm for the main building. For the Northridge earthquake the displacement of the parking structure was calculated to be 2.39 cm and 8.36 cm for the main building. Both of these ground motions required more separation of the buildings than the 5 cm provided in order to prevent pounding. Although there was no apparent danger to life safety, there was undoubtedly a high repair cost for the numerous weld cracks. There was also a substantial repair cost for the concrete parking structure, which came out second best in its encounter with the steel frame and was severely damaged.

It is quite possible that some of these cracks in the steel frame may have been initiated during the San Fernando earthquake. Due to cover by the fire proofing and nonstructural wall boards they remained undetected until the stronger Northridge earthquake required removal of some of this covering material. Hence, the cracking could have been cumulative, particularly in the more critical locations. It is not clear why the post-earthquake investigations did not consider the floors below the impact point.

The results of this study indicate that the effect of the impact on the story shear tends to diminish with distance and after approximately four story levels has no direct effect on the maximum displacement.

A significant increase occurred in the response of the second and possibly the third modes of vibration. Gates (1973) also noted this effect in his earlier study. This may be due to the combination of the horizontal offset at the fifth level and the impact with the parking structure at the fifth level.

The increase in the DCR's above the impact floor level was also noted in an earlier study by Maison and Kasai (1992). This led them to conclude that ignoring these effects may lead to an unconservative evaluation or design.

Many of the results of this study would not have been possible with only a single instrument on the roof. The single instrument most likely would have been to far from the point of impact to even record the resulting change of the acceleration and displacement. Once again the importance of having at least three instruments in tall buildings has been reconfirmed.

EVALUATION OF THE POLICIES FOR SEISMIC RETROFIT OF BUILDINGS

Shoichi Ando

Director of International Institute of Seismology and Earthquake Engineering (IISEE),
The Building Research Institute (BRI), Tsukuba, and Professor of The University of Tokyo,
Department of Urban Engineering, Graduate School of Engineering (Machizukuri-Daigakuin)
ando@kenken.go.jp (IISEE/BRI, Japan), ando@mps.t.u-tokyo.ac.jp (The University of Tokyo)

Abstract: The Japanese government has established a law to promote seismic retrofitting of buildings immediately after the Great Hanshin-Awaji Earthquake in 1995. This paper evaluates the effectiveness, efficiency, administrative feasibility and technological incentives of the policies related to the law. The data shows that the policy target of seismic safety of buildings will be achieved in 2018 if the current trends of improvement will be continued. In the field of school buildings, national government supports the school retrofit works that are carried out by the local governments, using the guideline for school retrofit. However, there are still significant issues to make all houses safe. One of the key challenges is how to persuade the elderly who would not invest their money to improve their old houses. Another challenge is to make housewives understand the importance and have priority in improving the seismic safety of houses. Currently many efforts are taken by the local governments, such as holding seminars for local communities, preparing financial support schemes, providing consultancy for seismic assessment and making earthquake hazard maps. This paper also provides comments on the improvement of the current policies for promoting seismic retrofit based on some international experiences of house and building retrofit.

1. INTRODUCTION

After the Great Hanshin-Awaji Earthquake in 1995, the Japanese government has established around 20 legal systems including the "Act for Promotion of the Earthquake Proof Retrofit of Buildings" (Retrofit Promotion Act) that has been established in 1995 as one of new legal systems. Moreover, many Japanese local governments become to provide various support systems in order to promote seismic retrofit conducted by owners and the private sector. The national government also provides new subsidy systems such as the regional housing grants and the community renovation grants based on the Retrofit Promotion Act. Furthermore a tax reduction system of loans for seismic retrofitting has started from the fiscal year 2006.

Why so many public assistance systems for housing seismic retrofitting exist, though houses are private assets? Originally, this argument arose immediately after the Great Hanshin-Awaji Earthquake. Has the government decided not to appropriate tax revenue (public assistance) for the reconstruction of individual houses, then?

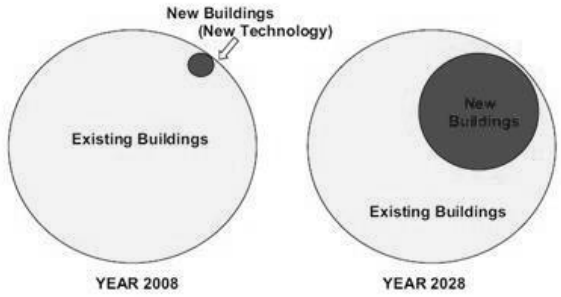
One of the reasons why such a policy change has made, may result from the establishment of the "Act concerning Support for Reconstructing Livelihoods of Disaster Victims" in 1998 and its revision in 2004. This Act is legislation at the instance of house members on the basis of several disasters after the Great Hanshin-Awaji Earthquake. According to this Act, in case of completely or partially destroyed houses, a certain amount of public assistance can be provided to owners of such private assets. For instance, the owner of a completely destroyed house can allow one million yen for purchasing household effects and two million yen for reconstruction of the house, i.e. in total three million yen will be granted.

In addition, collapse of houses often causes streets blockade and this may bring about crucial obstacles to escape, fire fighting and/or relief activities, when an urban fire occurs as the experience at the Great Kanto Earthquake in 1923 and in Nagata ward of Kobe city at the Great Hanshin-Awaji Earthquake. Namely, seismic retrofitting of buildings including house, is indispensable in order to secure entire urban safety. Therefore, public assistance can be provided, even though houses are private assets.

Taking a view of the estimated tolls by the Tokai Earthquake published by the Cabinet Secretary in 2005 as a reference, the maximum number of death toll will reach to approximately 9,200 persons by the assumed ocean-type Tokai Earthquake. And around 85 % of death toll, i.e. approximately 7,900 dead persons will be due to the collapse of buildings and the like. At the same time, the Cabinet Secretary announced a target to reduce those tolls by half in the "Earthquake Disaster Mitigation Strategy" for Tokai Earthquake. For that purpose, a detailed target to improve housing seismic retrofitting ratio was set up from current 75 % to 90 % within 10 years (till 2015). The "Earthquake Disaster Mitigation Strategy" was also created for coming Tohnankai and Nankai (South-east Ocean and South Ocean) Earthquake in 2005 and the main targets consist of housing seismic retrofit and tsunami disaster prevention measures.

These are the backgrounds of movement that many actors established new supporting measures for housing seismic retrofit in all parts of Japan from the establishment of the Strategy in 2005 till now.

2. RETROFIT SYSTEMS IN JAPAN



2.1 Technical Background

"The 1995 Great Hanshin-Awaji Earthquake disaster revealed the weakness of reinforced concrete (RC) structures that were designed in accordance with the pre-1981 design code. Failure of RC columns was primarily in the lack of lateral reinforcement. Larger deformation capacity may be attained by enhancing the capacity by (a) jacketing RC columns with steel plates and (b) wrapping RC columns with fiber reinforced plastics (FRP). The use of FRP sheets has merit of easy construction work and of light material weight. Placement of bracing structures (structural walls or steel braces) is effective limiting the response deformation of the structure, thus avoiding the failure of brittle members.

The occupancy of a building during the retrofit work should be considered in selecting retrofit works. For example, the strengthening work of RC columns normally requires the removal of mortar and other finishing materials (tiles) from the concrete surface. The noise, vibration and dust during the retrofit work will not allow occupants to stay in the building.

If advanced technology is affordable, especially in hospitals for post-earthquake medical treatment of the injured, the earthquake induced forces may be reduced by placing isolation devices at the base. The response of a structure may be reduced by installing dampers or energy dissipating devices are available. The failure of foundation piles was reported after the 1995 Kobe earthquake disaster. In some structures, the failure of pile foundation is said to reduce the earthquake ground motion input to the structure and limit the damage in the super-structure. However, the cost of damage investigation of foundation as well as the repair work of damaged foundation is expensive. It is normally desired to provide the foundation structure with higher resistance". (Prof. Shunsuke Otani, 2008)[i]

Fig. 1: Relation of Design Code for New Construction (by Prof. Shunsuke Otani)

2.2 Retrofit Promotion Act and its support systems

The Retrofit Promotion Act was enforced in 1995 immediately after the Great Hanshin-Awaji Earthquake in January 1995, since the lessons learnt from the devastated disaster urged quick response of the government and policy makers to secure the safety of urban built-environment that are mainly consisted of houses and buildings. Key components of the new Act are;

- Obligation of owners to make best efforts to assess and retrofit the buildings that are utilized many people,
- Exemption of retroactive application of building code except for seismic related code to approved retrofit works,
- Guidance, advices and instructions from the responsible governmental agency.

With regard to new obligation for the owners of building that is utilized by many people, such building is defined as, more than 3 stories and more than 1,000 m2 of floor area and its use is in line with designated one such as school, hospital, department store, office, shop, hotel, care facility for the elderly and so on.

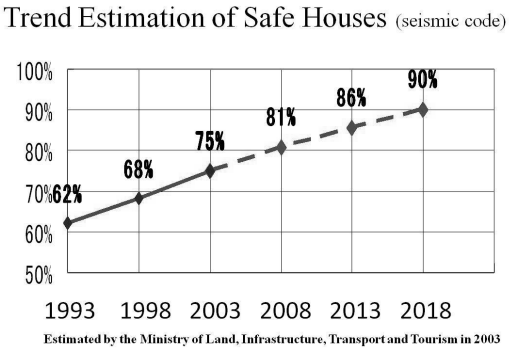
When the Retrofit Promotion Act was established, the Japanese Ministry of Land, Infrastructure, Transport and Tourism (MLIT) surveyed the conditions of houses and buildings in terms of applicability to seismic code (in 1981, the current level of seismic safety). The updated result of the survey was indicated in the Table 1. The target of applicable level of seismic code is also shown in the Figure 2.

Table 1:

Number of buildings under (1981) seismic code level

Houses

	Total houses in Japan
Total number of houses	47 million units
Under seismic code level	11.5 million units
(percentage of under level)	around 25 %



Estimated based on the data in 2003

Non-residential Building

Total number	3.4 million buildings
Under seismic code level	1.2 million buildings
(percentage of under level)	around 35 %

Estimated by the Ministry of Land, Infrastructure, Transport and Tourism in 2002

Figure 2:

The Act was established to introduce retrofit of houses and buildings. Therefore, in addition to regulatory measures some economic measures have been prepared at the same time by the national government. Those economic measures are available only in the local government that established "Plan for Retrofit Promotion". Table 2 shows the number

and ratio of the local governments that have established the Plan for Retrofit Promotion. Table 3 shows the number and percentage of the municipalities that have prepared the subsidy systems for seismic assessment and retrofitting.

Table 2:

Number of Local Governments that have Retrofit Promotion Plans (as of 1 April 2009)

		Have plans	-2009.9	-2010.3	2010.4-
Prefecture		47			
	Total	47			
	(%)	100.0%			
Municipality		1,193	50	185	70
	Total	1,193	1,243	1,428	1,428
	(%)	66.3%	69.1%	79.3%	83.2%

Table 3:

Subsidy System for Seismic Assessment and Retrofit

as of 1 April 2009 (Japan)

Building type	Project type	Applicable Local Govt. for Retrofit subsidy	
		Number of local Govt.	Ratio: Applicable Govt.
Detached house	Assessment	1,227	68.2% (62.7%)
	Retrofitting	857	47.6% (37.2%)
Condominium	Assessment	450	25.0% (19.0%)
	Retrofitting	321	17.8% (12.1%)
Non-residential	Assessment	310	17.2% (13.2%)
	Retrofitting	154	8.6% (5.9%)

Those tables show the fact that even in 2009, one quarter (25%) of municipalities have prepared the subsidy system for condominium to assess/evaluate the vulnerability to earthquake. In case of detached houses, almost 2/3 of municipalities have established subsidy system by 2009 for assessment and almost half of them have prepared financial support for retrofitting of houses. Figures of the Table 4 in the entre- parenthesis indicate the number of percentage of the April 2008. Within only one year, the percentage has been significantly improved because of the following policy measures, while a limit of financial support to the retrofit can be observed especially in the field of condominium and non-residential buildings.

The following policies are described as the MLIT has reported as below;

(1) Formulation of municipal Retrofit Promotion Plans
(2) Establishment of prefectural/municipal subsidy system
(3) Promotion of retrofitting of public buildings
(4) Securing engineers who manage assessment/retrofit
(5) Utilization of tax incentives for business use buildings
(6) Preparation of seismic hazard mapping
(7) Best practices for seismic assessment/retrofit
(8) Model projects on seismic safety houses and buildings

Those measures are comprehensive and are including 1) socio-economic measures, 2) information measures, 3) technical measures, and 4) institutional measures, to promote the policy for seismic assessment and retrofit of buildings.[ii]

2.3 Retrofit of Schools in Japan[iii]

"Because of the Great Hanshin-Awaji Earthquake in 1995, school buildings were also severely damaged by the shake. According to a report provided by the Ministry of Education, Culture, Sports, Science & Technology (MEXT), approximately 4,500 educational facilities were structurally or non- structurally damaged, though there were fortunately no death tolls resulted from damaged schools since the Great Hanshin- Awaji Earthquake occurred in early morning at 5:46 a.m.. After the strike of the Earthquake, 390 schools took the role for evacuation shelter and these schools accommodated approximately 180,000 evacuated people.

Furthermore, at the time of recent major earthquakes such as Niigata-Chuetsu Earthquake in October 2004 and Iwate-Miyagi Nairiku Earthquake in June 2008, while many school buildings were damaged, non-damaged schools accommodated many evacuated people. On the basis of these experiences, it is critical to ensure that school students are safe and school facilities are fit to serve as evacuation shelters for local populations. MEXT's policies on structural and nonstructural retrofitting of school buildings are introduced. Since school buildings have the following crucial roles, it is indispensable to assure the safety of school buildings against earthquakes.

1) Place for educating children: school buildings are the place where many children study and live most part of their days. It is, therefore, vital to keep school buildings in safer and healthier environment.

2) Place for cultural and sporting activities: school is a well-known building to the people who live near the school. School buildings are, therefore, often utilized for the cultural and sporting events for the local population.

3) Place for evacuation: school often becomes an evacuation shelter when a major natural disaster occurs. To this end, it is important that school buildings accommodate necessary functions for evacuation shelter.

The Building Standard Law of Japan was revised in 1981 and new seismic resistant design methods were adopted. According to the revised law, the buildings constructed based on the new design would have no damage in the case of middle class earthquakes (about JMA 5 upper scale). Moreover, there would be no casualties in these buildings and no severe collapse of these buildings even in the case of major earthquakes (about JMA 6 upper).

Table 4:

Difference between New and Old Seismic Resistant Design

Type of Earthquake (JMA Scale)	Medium Scale Earthquake (about 5 Upper)	Larger Scale Earthquake (over 6 Upper)
Old Seismic Resistant Design (until 1981)	No major damage	Not verified
New Seismic Resistant Design (since 1981)	No major damage	Will not collapse

JMA Scale: Scale indicating the strength of seismic motion, which was formed by JMA (Japan Meteorology Agency)

5 Upper: Many people are considerably frightened and find it difficult to move

6 Upper: Impossible to keep standing and to move without crawling

In order to evaluate the seismic capacity of an existing school building, the seismic capacity index of structure (Is) is used in Japan based on the regulation of the Retrofit Promotion Act. The law regulates that a building has low risk of collapsing if the "Is" of the building is more than 0.6. However, in consideration of the importance of school building, MEXT recommends that the "Is" of school building should surpass 0.7 after retrofitting.

Is (Seismic Capacity Index of Structure):
An index to define the seismic capacity of an existing reinforced concrete building

Is = Eo×S×T

Eo : A basic structural seismic capacity index calculated by the elements of Strength index (C), Ductility index (F) and Story Index (St)

Eo= C×F×St

S: A reduction factor to modify Eo index, which is based on the structural balance in both plan and elevation

T: A reduction factor to modify Eo index, which is graded by time-dependent deterioration

Table 5:
Evaluation of Seismic Capacity Index of Structure (Is)

Is < 0.3	There is high risk of collapsing
0.3 < Is <0.6	There is risk of collapsing
0.6 < Is	There is low risk of collapsing

A survey carried out by MEXT in April 2002 showed that public school buildings had not been satisfactorily retrofitted. It emerged from the 2002 survey that seismic assessment/ diagnosis was carried out on only 30% of buildings built based on the pre-1981 Old Seismic Resistant Design, and only about 45% of public primary and junior high school buildings had been retrofitted.

In this connection, a council called "Co-operators' Meeting for the Survey and Study of the Promotion of Earthquake-Resistant School Buildings" was established by MEXT in October 2002. The outcomes of the council's discussions were submitted to MEXT in April 2003 in a report entitled the "Promotion of Earthquake-Resistant School Buildings". Based on this report, the "Guidelines for the Promotion of Earthquake-Resistant School Buildings" was stipulated by MEXT in July 2003.

Chapter 1 of this guideline describes the basic concept of the "earthquake-resistant school building;" and Chapter 2 outlines the methods for devising earthquake-resistant promotion plans, the points to bear in mind, and the suggested methods for determining the urgency of earthquake resistance projects.

The basic principles pointed out in this guideline are:
(1) to prioritize earthquake resistant measures for school buildings at high risk of collapse or severe damage; (2) to implement seismic resistant capacity evaluation promptly; (3) to develop a plan for promoting earthquake resistance promptly; (4) to disclose the results of the seismic resistant capacity evaluation and the plans for promoting earthquake resistance; and (5) to check and take measures for the earthquake resistance of non-structural elements.
(http://www.nier.go.jp/shisetsu/pdf/e-taishinsuishin.pdf)

MEXT has been urging municipal governments, which are responsible for school buildings, to promote school building's retrofitting based on the above-mentioned guideline. In addition, as the following figure shows, MEXT has a subsidy system regarding public school buildings. In line with the Sichuan Earthquake in China in May 2008, MEXT has raised the subsidy rate for vulnerable school buildings (Is<0.3) from a half to two thirds in June 2008.

Table 6: Subsidy Rate for Public School Building

Type of Construction	Subsidy Rate from MEXT
New construction	1/2
Reconstruction	1/3, 1/2 (Is<0.3)
Renovation	1/3
Seismic Rehabilitation	1/3, 1/2 (Is<0.3)

Budget of fiscal 2008: 229 billion JPY

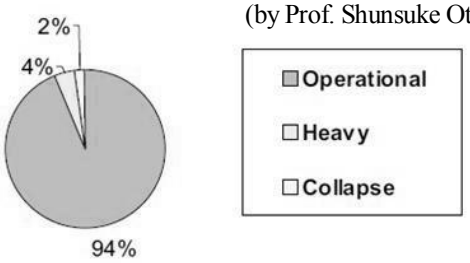
By utilizing the above-mentioned subsidy system, the retrofitting of school buildings has been implemented in Japan. The data shows the status of earthquake resistance on elementary and lower secondary public schools in Japan as of April 1 2008. Approximately 48,000 of school buildings, or 38% of school buildings were found lacking needed earthquake resistance or needed further assessment. Above all, 10,000 of these buildings were estimated to be at high risk of collapse in expected large scale earthquakes. A commitment was made to reinforce all of these buildings at high risk within 5 years. In addition, as mentioned, the subsidy rate for vulnerable school buildings has been raised in June 2008. Moreover, in order to accelerate the 5 years retrofitting program into 4 years, MEXT has added an additional national fund (114 billion JPY) to the regular budget of fiscal 2008 (115 billion JPY, total 229 billion JPY) in the supplementary budget of fiscal 2008 of Japanese government in October 2008.

Even though structural parts of school buildings such as columns, beams and walls are enough retrofitted, if non-structural members such as ceiling materials, various fixtures and furniture are not sufficiently retrofitted, these non-structural members may fall or topple when a major earthquake occurs. Children and evacuated local people can be killed or injured by these vulnerable non-structural members. Therefore, the retrofitting of non-structural members of school building is extremely important.

In order to urge municipalities to implement non-structural seismic retrofitting of school buildings, the National Institute for Educational Policy Research of Japan (NIER) published a reference book on non-structural seismic retrofitting of school building in December 2005.
The following case is an example in this reference book.
(Web: http://www.nier.go.jp/shisetsu/pdf/e-jirei.pdf)"

3. ISSUES OF RETROFIT WORKS

3.1 Technical Issues[iv]



It should be noted that these countermeasures may not be the same from a country to another because the expected performance (minimum required strength and acceptable damage) of buildings varies from a country to another. Each country has different levels of (a) seismic risk, (b) hazard tolerance, (c) economic background, and (d) technical development (construction practices and materials).

Most building codes in the world explicitly or implicitly accept structural damage to occur in a building during strong earthquakes as long as the hazard to life is prevented. Indeed, many earthquakes caused such damage in the past. Then, what percentage of buildings suffered heavy damage in major earthquakes. The Architectural Institute of Japan (AIJ) collected damage statistics in Mexico City and Lazaro Cardenas after the 1985 Mexico Earthquake, Baguio after the 1990 Luzon, Philippines Earthquake, Erzincan after the 1992 Turkey Earthquake, and Kobe after the Hyogo-ken Nambu 1995 (Great Hanshi-Awaji) Earthquake. A heavily damaged area was first identified in each city, and the damage level of all buildings in the identified area was assessed by structural engineers and researchers.

Table 7: Damage Statistics from Major Earthquakes
(by Prof. Shunsuke Otani)

City, year of earthquake	Operational damage	Heavy damage	Collapse	Total
Mexico City, 1985	4,251(93.8%)	194(4.3%)	87(1.9%)	4,532
Lazaro Cardenas, Mexico, 1985	137(83.5%)	25(15.2%)	2(1.2%)	164
Baguio City, Philippines, 1990	138(76.2%)	34(18.8%)	9(5.0%)	181
Erzincan City, Turkey, 1992	328(77.4%)	68(16.8%)	28(6.6%)	424
Kobe (pre-1981 construction), 1995	1,186(79.4%)	149(10.0%)	158(10.6%)	1,493
Kobe (post-1982 construction), 1995	1,733(94.0%)	73(4.0%)	38(2.1%)	1,844

Figure 3: Damage Distribution of Mexico City
(by Prof. Shunsuke Otani)

From damage statistics, the importance of identifying the small percentage of those buildings possibly vulnerable in future earthquakes can be easily realized. Therefore a simple procedure is desirable to examine the vulnerability of all existing buildings in a region, spending a few hours at most for a building, and "screen out" the majority of safe buildings. A more detailed and sophisticated procedure, spending a few weeks, may be utilized to those buildings identified as vulnerable by the simple procedure.

In a screening procedure, for example, dimensions of columns and structural walls per floor areas may be used to roughly estimate lateral load resistance. The lateral load strength is not a single index to represent the safety of a building, but gives some idea if the structure has a sufficient capacity to resist earthquake motions by strength. Those buildings, identified as questionable by the simple procedure, must be analyzed by more sophisticated procedure

The following development and application of technology are needed to mitigate earthquake disaster from construction point of view: i.e.,

(a) Effective earthquake resistant building codes for new construction,
(b) Earthquake vulnerability assessment methods for existing buildings,
(c) Seismic strengthening technology for vulnerable buildings,
(d) Seismic damage evaluation methods for damaged buildings after an earthquake,
(e) Technology to repair damage for immediate occupancy, and
(f) Technology to rehabilitate damaged buildings for permanent use.

3.2 Socio-economic Issues

An examination of allocation of government resources, in terms of financial and human, for pre-disaster and post-disaster disaster programs reveals that more resources are devoted recovery than to disaster prevention. They commit a large amount of financial and human support after a disaster. This is particularly true for the international community. Disaster prevention programs attract little attention. However, because emergency operations take place after a disaster when many lives have already been lost, only few lives can be saved. In contrast, the implementation of disaster preventative measures can potentially save many more lives.

Hence, we must shift our done on seismic resistance and isolation technologies of high rise buildings, but little research is done on conventional houses. But over 80 % of total stock in the world is non-engineered. Because these unsafe buildings are occupied by humans, we cannot reduce disaster losses unless we improve the safety of non-engineered buildings (in case of Japan, wooden houses). However, they attract little attention and research funds. Similarly, when spending habits for new and existing houses are compared, people tend to spend generously for new houses but not as much for the maintenance. However, many more lives can be saved by improving the safety of existing houses.

Another essential aspect is cost reduction. There are several ways to achieve this, for instance, technological development and government subsidies. It is also necessary to train masons and carpenters on available techniques.

The political commitment is also crucial. The reason is that many individual house owners would pay to reinforce their houses if they understand the need; but not all house owners would. Everybody dies eventually. Considering this, the probability of death from an earthquake, which chance of occurrence is 40 percent in every 30 years, might seem negligible. Just like the fact that many smokers wouldn't stop smoking even if they are told to do so, not all individual house owners would

reinforce their houses.[v]

One of the key challenges is how to persuade the elderly who would not invest their money to improve their old houses. Another challenge is to make the housewives understand the importance and have priority in improving the seismic safety of houses.

4. RETROFIT EXAMPLES IN THE WORLD

This section shows four retrofitting examples in the world.

4.1 Example 1 (Houses in Nepal)

Nepal faces a variety of disaster risks owning both to its natural characteristics and human induced factors. Nepal has experienced several major earthquakes: The Bihar Earthquake in 1934 which measured 8.3 on the Richter scale killed 4,300 people, and destroyed 20% of all structures (Earthquake and Megacities Initiatives, 2005). Three earthquakes of similar size occurred in Kathmandu Valley in the 19th century: in 1810, 1833, and 1866. In 1988, there was another earthquake, which caused to loss of 709 lives (The National Society for Earthquake Technology NSET- Nepal).

United Nations Centre for Regional Development (UNCRD) has carried out a training project in Nepal in 2007. The training was organized with technical support from NSET to train practical measures that can be applied at the house level. 20 female members from target communities participated in the training. In the workshop, they learnt the basic science of earthquakes, importance of disaster risk reduction, and how to apply non-structural risk mitigation measures in their homes. For example, they visited several houses to learn practical ways of securing refrigerators and shelves by using brackets and props.

After the initial training, follow-up evaluation meetings were held with the participants. 19 participants reported that they have applied non-structural measurements in their homes within one or two weeks after the training by themselves (13 people) and/or with male members in the family (16 people), while there was one person who hired a handyman. 17 participants reported having talked about the training with relatives and/or friends, and 15 participants had showed their relatives and/or friends what they had done in their homes to secure their furniture.

Furthermore, 14 participants answered that they know relatives/friends who have implemented such non-structural risk reduction measures in their homes after observing their examples. The result showed that there was a strong potential for using women's network and communication to disseminate disaster risk reduction strategy. [vi]

Though the project has not aimed at retrofitting itself, fixture of nonstructural part of a house is recognized as the first step to raise awareness of community people, especially for housewives who must play an important role as decision makers for house maintenance. And this case study shows the communication network among housewives effectively works to disseminate the seismic measures for houses like fixture of furniture.

Fig 4. Household assessment of non-structural part (NSET)

Fig 5. A trainer of NSET secures furniture using anchors in a community participant's home in Kathmandu. (by UNCRD)

4.2 Example 2 (Schools of Indonesia)

Earthquakes in the past have exposed that vulnerability of school buildings is disproportionately high compared to the other infrastructures. For instance, in the 1999 Chi-Chi Earthquake, Taiwan 43 schools in Nantou and Taichung area were completely destroyed and a total of 700 schools nationwide were damaged to different extent. The 2001 Gujarat Earthquake in India caused damages to over 11,600 schools. The 2005 Kashmir earthquake resulted in collapse of 6,700 schools in North-West Frontier Province and 1,300 in Pakistan-administered Kashmir.[vii] Recently in May 2008, Wenchuan Earthquake in China killed about 7,000 students trapped in damaged school buildings. When an earthquake hit Spitak area of Northern Armenia during school hours in 1988, many children lost their lives due to collapse of school buildings. For example, 285 children out of 302 in total died at one school. This resulted in almost 2/3 of total deaths of 25,000 were children and adolescents.

UNCRD and the Center for Disaster Mitigation (CDM) of the Institute of Technology Bandung (ITB) conducted a collaborative project to reduce the vulnerability of existing school buildings in the corridor of the School Earthquake Safety Initiative (SESI) project. Two school buildings, SD Cirateun Kulon II and SD Padasuka II both in

Bandung County, were selected for this project due to the dire needs of improvement and severe deficiencies of earthquake resistant systems. The project included retrofitting and strengthening of school buildings, and other activities to improve school community preparedness regarding earthquake.

Fig 6. Retrofit work of School Building I (ITB)

Prior to conducting any physical work to the structure, the locations and building layouts were checked to ensure that the buildings could be retrofitted. The existing structures were investigated to determine the type and quality of materials used, as well as the existing lateral resisting system. Then, the retrofitting was designed based on the structural deficiencies/weak parts and their accessibilities, weighing in retrofit factors on buildings' life time, earthquake resistance capacity, their function, and appropriate retrofit strategy/ techniques. The design of retrofit strategy also considered factors of continuation of normal function, availability of materials and skilled construction workers, needs of upgrades for non structural components, and total costs.

The retrofitting project was first conducted at the school SD Cirateun Kulon II. The school buildings consisted of two buildings made of RC frames and masonry walls. Each building has four rooms. Based on results from survey and tests, structural analyses were performed on the existing structures using the actual material and structural components. Earthquake risks were introduced to the buildings by applying loads based on potential seismic risks and local soil conditions. The analysis showed that both buildings were considered likely to behave poorly under seismic loadings, thus required retrofitting. The physical works were then conducted to improve the structural quality and reduce the earthquake vulnerability.

Building I which was considered to have lower quality was retrofitted by adding adequate RC frames with mat footings. Anchorage was provided to connect walls with columns and beams. Building II which was in better condition was retrofitted using wire mesh for strengthening wall elements. Double tie beams were added adjacent to the existing one for better foundation system. For both structures, proper detailing was applied to roof truss systems, and repair was carried out for nonstructural elements such as doors/windows and ceilings. Finishing/cosmetic repair and improvement of sanitary facilities were also conducted for both structures.

4.3 Example 3 (Schools of Uzbekistan)

In Tashkent city, there are more than 360 schools. Nearly 20 % of school buildings have had deficiencies of different level at present. Preliminary analysis of seismic risk for Tashkent city showed that more than 25% of school buildings may be completely destroyed and 30% may be heavily damaged in case of design earthquake.

The buildings of schools in Tashkent are represented mainly by two construction systems: bricks and RC frame-panel consisting major portion of school building stock and a few buildings made up of from adobe bricks. Nearly 35 % of school buildings were constructed before Tashkent earthquake of 1966 for design intensity 7 by MSK scale. Since 1966, half of school buildings were constructed using assembled RC frames of IIS-04, which are inherently weak in seismic resistance. The weakness of this construction type was revealed Spitak (1988), Kairakkum earthquakes (1985) and also confirmed by through the engineering analysis of earthquake consequences.

Many school buildings in Tashkent are located in the zone with slumping soils, and as a result many buildings, both brick walled and frame panel type are likely to be damaged. The survey showed that typical structures used for school building in Tashkent basically consist of brick works up to 4 stories in old construction, and reinforced concrete frame-panel for the more recent buildings. Recurrent structure typologies for school buildings are categorized in the following three groups:

1. Mixed type of brickwork and reinforced concrete or wood reinforcing frame - year of construction '40s;
2. Brickwork structures, frequent typology used until '60s;
3. Frame-panel, widely used in the modern construction.

In order to establish an effective and recognizable linkage to the local professional practice in the Central Asian region, and to follow the standard analysis procedure, it is ensured that the characterization is in compliance with the previous study on the Risk Assessment of Tashkent city in the framework of IDNDR RADIUS project in 1990's.[viii]

Fig 7. Retrofit of RC panel school in Tashkent (UNCRD)

4.4 Example 4 (Buildings of China)

Ministry of Housing and Urban-Rural Development of People's Republic of China (MOHURD) has held several investigations on the disaster after the Wenchuan Earthquake. Upon the analysis and research, MOHURD has constituted "Technical Guide for Appraiser and Strengthening of Earthquake Affected Buildings" on July 23rd, 2008, and promptly issued "Seismic Technical Specification for Building Construction in Town and Village" on June 13th, 2008, and implemented on October 1st, 2008.

The Chinese "Standard for Classification of Seismic Protection of Building Constructions" GB50223 -2008 has been enacted on July 30th, 2008. It has been partially amended on the original "Standard for Classification of Seismic Protection of Building Constructions" GB50223 -2004. In addition, "Code for Seismic Design of Buildings" GB50011 -2008 (enacted on July 30th, 2008) has been amended on the original "Code for Seismic Design of Buildings" GB50011 -2001.

Wenchuan earthquake provided abundant experiences for seismic project constructions. In order to improve the capability of disaster area's reconstruction and Chinese project construction disaster-prevention, MOHURD and experts from relevant departments have researched and analyzed earthquake experiences, and have summed up the seismic engineering research results.

On the above amendments, MOHURD has adjusted some seismic standard, especially enhancing the public building seismic standard on secondary & primary schools and hospitals, extending the seismic prevention scope of public seismic buildings including retrofitting works. Besides, MOHURD has also amended the design code and criteria from the aspects of specific technologies.

To learn from Japan's accumulated seismic building technology and further promote the application of seismic technology, to improve the capability of earthquake and hazardous prevention, and to increase the technical level in China, Financing & Foreign Affairs Dept. of MOHURD and Japan International Cooperation Agency (JICA) has reached an agreement on the "China-Japan Seismic Training Program" on May 12th, 2009. This program will last 3 years and be fully supported by Ministry of Land, Infrastructure, Transport and Tourism (MLIT) of Japan.

The International Institute of Seismology and Earthquake Engineering (IISEE) of the Building Research Institute (BRI), Tsukuba, Japan is the implementing agency of the training on assessment, retrofit and design for seismic building since 2009.

5. CONCLUSIONS

The Japanese government has established a law to promote seismic retrofitting of buildings immediately after the Great Hanshin-Awaji Earthquake in 1995. This paper evaluates the policies related to the Retrofit Promotion Act. The data shows that the policy target of seismic safety of buildings (90% of buildings follow the 1981 seismic code) will be achieved in 2015-2018 if the current trends of improvement will be continued. In the field of school buildings, national government supports the school retrofit works that are carried out by the local governments, using the guideline for school retrofit.

However, there are still significant issues to make all houses safe. One of the key challenges is how to persuade the elderly who would not invest their money to improve their old houses. Another challenge is to make the housewives understand the importance and have priority in improving the seismic safety of houses.

Currently many efforts are taken by the Japanese local governments, such as holding seminars for communities, preparing financial support schemes, providing consultancy for seismic assessment and making earthquake hazard maps. This paper also provides comments on the improvement of the current policies for promoting seismic retrofit based on some international experiences of house and building retrofit. Some international cases will help to develop an effective Japanese policy for promoting retrofit, such as the case of Nepal shows the role of females to disseminate the seismic safety of non-structural part of houses.

The Japanese experiences on seismic retrofit will be able to contribute to the disaster risk reduction in the other seismic-prone countries in the world. The lessons from Kobe and lessons from all over the world should be disseminated to find solutions towards challenges to promote policies and actions of seismic assessment and retrofitting.

Abstract: The North of Algeria is an area prone to seismicity. Buildings located in this area, are either made of masonry, reinforced concrete, steel or combined (masonry and steel). The seismic feedback experience showed a great disparity in the behaviour of such structures as a regard to seismic action. Within this paper, an assessment of these structures, using the "Vulnerability Index" method is presented. This method was developed in order to be used by engineers and to allow a good classification and description of the "Seismic Quality" of such structures, by considering numbers of structural and non structural parameters. A technical data sheet and an associated developed calculating computer program named Vulnerability Index Program (VIP) using "Delphi" have been used and validated to get the structural and non structural parameters as well as the vulnerability index to establish their classification. The results show that the established classification confirmed what has been observed in situ.

1. INTRODUCTION

Buildings made from masonry, reinforced concrete and from masonry and steel combined together are the most significant structures found in the Algerian cities, located along the North band, an area prone to seismicity.

Such structures have known consequent damages as a result of the latest earthquakes that stroke many north regions of Algeria such as the 1999 earthquake which hit the city of Ain-Temouchent and 2003 which hit the city of Boumerdes. Thus it is important to quantify the seismic vulnerability of these constructions in order to prevent heavy damages.

There are several tools to estimate the seismic vulnerability functions, it depends mainly of the constituent material of the structure, the purpose of their uses and the typology. To provide these functions several methods do exist.

The two main methods considering vulnerability functions are the global approach method named HAZUS, RISK-UE (2003) or RADIUS (Oyo 1999), and the more specific one named Push-over and Time History Analysis, requesting skilled persons.

However an intermediate method named "Vulnerability Index Method" can be considered to be used by engineers to give a realistic estimation of the seismic quality of structures. This method has been considered in this present work.

One of the first studies carried out on vulnerability index was initiated by the GNDT (Group of National Defense against earthquake) (Corsanego and Petrini 1994), named as the methodology of level II. This method is based upon observations and given data relative to the constructions. The structural and non structural parameters playing a significant role in the seismic response of the structure should belong to one of the four vulnerability classes (A, B, C or D) described by (Benedetti and Petrini 1984) and (Benedetti et al. 1988). This method was used in a study undertaken in the south of Italy. It has allowed a classification of constructions in vulnerability classes with a development of a reinforcement methodology for these constructions (Parisi and Chesi 2006). This method was modified in order to be applied to confined masonry buildings in southern Europe (Franch et al. 2008). Based on the same principles, the group of "vulnerability of existing buildings" of the AFPS (Jacquet and Souloumiac, 1999) has written a guide giving the evaluation of the seismic

vulnerability of buildings. A study on vulnerability of existing buildings was done by Lang (2002) and Yépez et al. (1996). The vulnerability of the city of Catania was investigated by Lagomarsino (Lagomarsino and Giovinazzi 2006).

In Algeria, work relating to the estimate of the constructions vulnerability using vulnerability index was undertaken using the Algerian seismic code (CGS 2003). These studies allowed the classification of buildings in vulnerability class translating its seismic quality (Bensaibi et al. 2003), (Boukri and Bensaibi 2006), (Belheouane 2006), (Boukri and Bensaibi 2007), (Amellal 2008), (Boukri and Bensaibi 2008) (Djaalali and Bensaibi 2009) and (Yousfi 2010).

2. PARAMETERS OF THE DEVELOPED VULNERABILITY INDEX METHOD

This approach considers numbers of structural and non structural parameters. These parameters have an influence on the seismic vulnerability of the structures. These parameters are determined by post-seismic observations and seismic experience feedbacks. The parameters taken into account are chosen for each kind of structure.

2.1 Parameters for Masonry Structure

The considered parameters are as follow:

1) Total shear resistance of walls, 2) Plan regularity, 3) Elevation regularity , 4) Walls connection, 5) Walls type, 6) Floor, 7) Roof, 8) Soil conditions, 9) Pounding effect, 10) Modifications, 11) Details, 12) Maintenance conditions

2.2 Parameters for Reinforced Concrete Structure

For reinforced concrete (RC) structure, the considered parameters are as follow:

1) Frame system, 2) Quality of the Frame system, 3) Seismic capacity, 4) Type of soil, 5) Roof , 6) Plan Regularity, 7) Elevation Regularity, 8) Quality of the nodes, 9) Short column, 10) Details, 11) Maintenance conditions, 12) Modifications, 13) Pounding effect, 14) Ground conditions.

2.3 Parameters for Steel Structure

For steel structure, the considered parameters are set as follow:

1) Ductility, 2) Bearing capacity, 3) Assemblage, 4) Maintenance conditions, 5) Type of soils, 6) Floor, 7) Buckling, 8) Plan regularity, 9) Modifications, 10) Elevation regularity, 11) Pounding effect, 12) Ground conditions, 13) Roof, 14. Details.

2.4 Parameters for Combined Masonry and Steel Structure

For this kind of structure, the considered parameters are:

1) Walls connection, 2) Seismic capacity, 3) Type of soils, 4) Ductility, 5) Assemblage, 6) Floor, 7) Modifications, 8) Plan regularity, 9) Elevation regularity, 10) Maintenance conditions, 11) Ground conditions, 12) Pounding effect , 13) Roof, 14) Details.

3. QUANTIFICATION OF EACH PARAMETER

Weighting factors for each parameter are proposed on table 1, 2, 3 and 4. These factors are determined on a basis of a statistical data containing constructions damaged by different earthquakes (Ain Temouchent (1999) and Boumerdes (2003)). The considered parameter can take only one factor.

For masonry construction, each parameter considered can belong to one of the four defined categories C1, C2, C3 and C4. These categories are declined as follows:

C1 expresses a parameter inducing a good behaviour of the structure during an earthquake,

C4, expresses a parameter inducing a bad behaviour of the structure during an earthquake,

C2 and C3 expresses an intermediate behaviour of the structure during an earthquake.

For the other kind of structure the intermediate behaviour is represented by only one category i.e. (C2).

For each parameter and each category considered, a coefficient (k) is identified expressing its seismic quality.

The “Details” parameter was specified as follows: studwork, dividing walls, balconies, railing, cornices, chimneys, ventilation space, electrical network, gas network, water network and sewage network.

Table 1 Weighting Factors of Vulnerability Index Evaluation for Masonry Structure

N°	Parameter	Categories/k			
		C1	C2	C3	C4
1	Total shear resistance of walls	0	0.05	0.12	0.21

13	Roof	0.50	0.75	1.00
14	Details	0.50	0.75	1.00

Table 4 Weighting Factors of Vulnerability Index Evaluation for Combined Masonry and Steel Structure

N°	Parameter	Categories/k		
		C1	C2	C3
1	Walls connection	0.00	0.12	0.20
2	Seismic capacity	0.00	0.09	0.12
3	Type of soils	0.01	0.08	0.09
4	Ductility	0.01	0.07	0.08
5	Assemblage	0.01	0.04	0.06
6	Floor	0.01	0.04	0.05
7	Modifications	0.01	0.04	0.05
8	Plan regularity	0.01	0.04	0.05
9	Elevation regularity	0.01	0.04	0.05
10	Maintenance conditions	0.01	0.04	0.05
11	Ground conditions	0.01	0.04	0.05
12	Pounding effect	0.01	0.04	0.05
13	Roof	0.01	0.04	0.05
14	Details	0.01	0.04	0.05

Some parameters need calculation and some others are related to the in situ observation.

4. VULNERABILITY INDEX AND CLASSIFICATION

The vulnerability index, VI, of a construction is expressed according to the formula (1):

$$VI = \sum_{i=1}^{n} k_i \qquad (1)$$

According to the value obtained for the vulnerability index, three vulnerability classes Green, Orange and Red are proposed for each category of construction (table 5, 6, 7 and 8).

Table 5 Vulnerability Index Classes for Masonry Structure

Class	Green	Orange	Red
VI	0 - 0.20	0.20 - 0.60	0.60 - 1

Table 6 Vulnerability Index Classes for RC Structure

Class	Green	Orange	Red
VI	3.25 - 6.25	6.25 - 10.25	10.25 - 13.25

Table 7 Vulnerability Index Classes for Steel Structure

Class	Green	Orange	Red
VI	5.75 - 9.5	9.5 - 19	16 - 19

Table 8 Vulnerability Index Classes for Combined Masonry and Steel Structure

Class	Green	Orange	Red
VI	0.12 - 0.44	0.44 - 0.88	0.88 - 1

The first class associated to the green color classifies the construction as resistant with no requirement to any repairs.

The second class associated to the orange color classifies the construction as moderately resistant requiring reinforcement.

The third class associated to the red color classifies the construction to be a construction with low resistance requiring demolition or significant strengthening.

5. ELABORATED CHART

In situ observations on structures are important information required to assess the vulnerability of structures. An investigation chart for a survey was elaborated. The chart contains:

a) General data , b) Geometric characteristics, c) Information on the structural system, d) Information on the ground, e) Details on the non structural elements, f) General maintenance conditions.

6. DEVELOPED PROGRAM

A program called Vulnerability Index Program "VIP" using Delphi was elaborated providing the vulnerability index values for structures. It uses the elaborated chart in order to estimate the coefficient of the different parameters and classify the structures. The front page of the program is given on figure 1.

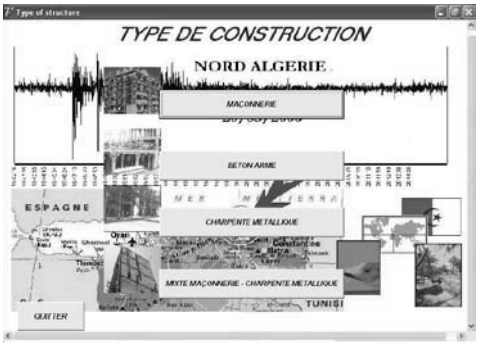

Figure 1 Front Page of the VIP

On the figure 2, a displaying window for masonry structure is shown as a sample.

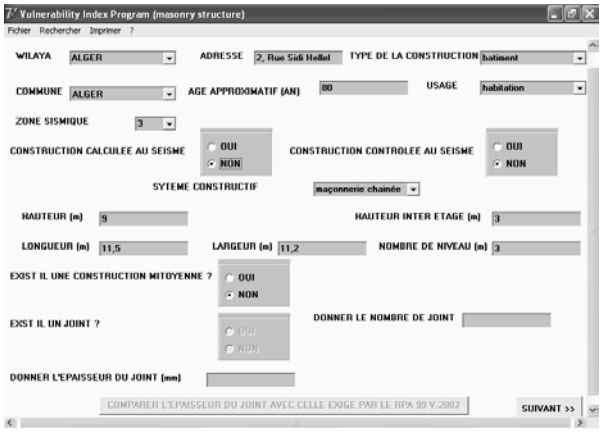

Figure 2 VIP Page for Masonry Structure

7. APPLICATION

Several examples have been treated by the developed program. Here in, are three case studies presented as an example.

7.1 First Case Study

It is a Zinc production manufacture in steel material, built in 1949 and located in the West part of Algeria. The following figures (3, 4 and 5) show the damage undergone by this structure.

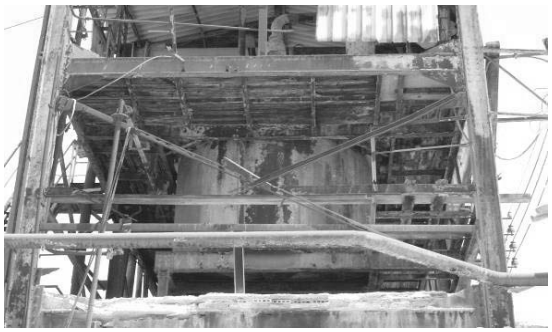

Figure 3 Damage in the Bracing System

Figure 4 Corrosion of Columns

Figure 5 Damage in Beams and Floors

The results given by the program are as follow (table 9):

Table 9 Manufacture Parameters Vulnerability

N°	Parameters	Category	k
1	Ductility	C2	1.5
2	Bearing capacity	C3	2.00
3	Assemblage	C3	2.5
4	Maintenance conditions	C3	1.5
5	Type of soil	C2	0.75
6	Floor	C3	1
7	Buckling	C3	1.5
8	Plan regularity	C3	1
9	Modifications	C1	0.5
10	Elevation regularity	C3	1
11	Pounding effect	C2	0.75
12	Ground conditions	C1	0.5
13	Roof	C2	0.75
14	Details	C3	1

A vulnerability index of 16.25 was found, this indicates that the structure belong to the Red class.

The conclusions provided by the Structural Engineering Control (CTC: official organization in charge of control in Algeria) suggest demolition and the reconstruction according the latest standards.

So, the two conclusions are in adequacy.

7.2 Second Case Study

It is a building in RC located in the city of Blida (a town near Algiers). It has four floors, each one with two dwellings.

An in situ expertise and a data process gave the results presented in table 10.

Table 10 Building in RC Parameters Vulnerability

N°	Parameters	Category	k
1	Walls connection	C1	0.00
2	Seismic capacity	C1	0.00
3	Type of soils	C1	0.01
4	Ductility	C1	0.01
5	Assemblage	C2	0.04
6	Floor	C1	0.01
7	Modifications	C1	0.01
8	Plan regularity	C2	0.04
9	Elevation regularity	C2	0.04
10	Maintenance conditions	C1	0.01
11	Ground conditions	C3	0.05
12	Pounding effect	C1	0.01
13	Roof	C1	0.01
14	Details	C1	0.01

This gives a vulnerability index of 6.50, it means this construction is classified Orange.

Figure 6 Damage in a Node and Short Columns

This result is in adequacy with what have been observed on site (transformation of the balconies into rooms and presence of short columns and node degradation, see figure 6).

7.3 Third Case Study

It is a pavilion in combined materials (masonry and steel) located in Algiers, with a ground floor and two levels. The construction is built on an inclined ground (see figure 7).

Figure 7 Front View of the Pavilion

The VIP gives the following results (table 11):

Table 11 Pavilion Parameters Vulnerability

N°	Parameters	Category	k
1	Frame system	C1	0.25
2	Quality of the Frame system	C1	0.25
3	Seismic capacity	C3	0.50
4	Type of soil	C3	0.75
5	Horizontal diaphragm	C1	0.25
6	Plan Regularity	C1	0.25
7	Elevation Regularity	C1	0.25
8	Quality of the nodes	C2	0.50
9	Short column	C3	0.75
10	Details	C1	0.25
11	Maintenance condition	C2	0.75
12	Modifications	C3	0.75
13	Pounding effect	C3	0.75
14	Soil conditions	C1	0.25

The program gives VI = 0.25, so the structure is classified Green.

This result is in adequacy with the conclusion of an official organism in Algeria witch classify this construction as Green level 1 i.e. a construction with very good resistance.

8. CONCLUSIONS

A vulnerability index method for different type of structures has been developed and presented in this study. Even though the method is an intermediate one, it gives reasonable results regarding the influence of the different parameters on the seismic behaviour of the structure.

A classification has been established according to the damage undergone by the structures. The results from this classification are in accordance with the one done in situ. As a result, this classification can be used by engineers to reduce seismic risk and casualties in case of an earthquake.

REVITALIZATION OF CIRCULAR CONCRETE COLUMNS BY HIGH PERFORMANCE FERROCEMENT

Ivy F.Y. Ho[1] and Eddie S.S. Lam[2]

1) PhD student, Dept. of Civil & Structural Engineering, The Hong Kong Polytechnic University, Hong Kong
2) Associate Professor, Dept. of Civil & Structural Engineering, The Hong Kong Polytechnic University, Hong Kong
ivy.ho@polyu.edu.hk, cesslam@inet.polyu.edu.hk

Abstract: Hong Kong is within the Eurasian Plate with moderate seismic risk. According to the Chinese seismic design code (GB 50011-2001), Hong Kong is an area with seismic intensity 7.5. However, reinforced concrete buildings in Hong Kong are traditionally designed without seismic provision and detailed with low volumetric ratio of transverse reinforcement. These columns fall short of providing sufficient seismic resistance. It is the aim of this study to investigate the use of high performance ferrocement ("HPF") to strengthen reinforced concrete columns detailed with large spacing of transverse reinforcement. Totally 19 full-scale circular reinforced concrete columns were prepared and tested to failure under axial compression. 8 of them were casted in Oct 2009 and tested between Dec 2009 and Jan 2010. The results were reported in the preceding conference of CUEE (Ho and Lam 2010). 11 of them were subsequently casted in July 2010 and tested in Aug 2010 or Jan 2011. In the present study, HPF is applied circumferentially on 8 reinforced concrete columns and 4 plain concrete columns to study the confinement action provided by HPF comprises different mesh density and different rendering materials. It is observed that specimens detailed with volumetric ratios of transverse reinforcement (ρ_s) of 0.230% and strengthened by HPF can achieve a load carrying capacity at 23.3% higher than specimen detailed with ρ_s of 0.918%. In addition, significant increase in peak strength from 29.8-58.7% is observed in plain concrete specimens confined with HPF. These show that HPF is effective to upgrade existing column detailed with low volumetric ratio of transverse reinforcement. Test results also show that compressive strength of confined concrete increases with tensile strength of HPF and better confinement can be provided by HPF using epoxy based rendering material instead of polymer modified cementitious based rendering material or cement-sand screeding. Further study is necessary to fully understand the correlation between overall confinement action provided by HPF and confined compressive strength of concrete in the presence of transverse reinforcement.

1. INTRODUCTION

Although there is no known active fault within the territories of Hong Kong and the risk to have a major tremor is low, Hong Kong is a region with moderate seismic risk with seismic intensity 7.5 ("GB 50011-2001"). Structural condition of our buildings becomes a popular local issue after the collapse of a 55-year-old five storey building and a recently occurred earthquake which can be felt locally with epicenter located in Deep Bay in Shenzhen.

Most buildings in Hong Kong were designed without seismic consideration (Lam et al. 2002) since it is not required by the design code currently in force (i.e. Code of Practice for Structural Use of Concrete 2004 ("CoP2004")). When comparing CoP2004 with its predecessor Code of Practice for Structural Use of Concrete 1987 ("CoP1987"), a few concepts on seismic design have been implemented into CoP2004. For instance, in the provisions on detailing of columns in critical region, CoP2004 takes into account the axial load factor to reduce the maximum allowable spacing of transverse reinforcement. As it is common to find columns with low depth-to-height ratio (i.e. short columns), spacing of transverse reinforcement at critical region is usually applied to the whole column for ease of construction. Thus, columns designed to CoP2004 are usually detailed with high volumetric ratio of transverse reinforcement when compared with those designed to CoP1987. In fact, CoP2004 has reduced the allowable maximum spacing of transverse reinforcement to 1/4 of the preceding requirement specified in CoP1987.

Columns with low volumetric ratio of transverse reinforcement are less sustainable in resisting seismic motion as evidenced for instance in Kobe earthquake 1995, Chi-Chi earthquake in 1999 and Wenchuan earthquake in 2008. Besides, it is well accepted that compressive strength of concrete can be significantly enhanced by proper confinement (Richart et al. 1928, Balmer 1949, Popovics 1973, Sheikh and Uzumeri 1980, Ahmad and Shah 1982, Mander 1983, Mander et al. 1988 and Li 1994). Columns designed to CoP2004 have higher load carrying capacity than columns designed to CoP1987. To strengthen existing columns to meet the current standard, it is necessary to provide additional confinement to existing columns in order to enhance their load carrying capacity. It is the objective of this study to use high performance ferrocement ("HPF") for providing additional confinement to existing columns

detailed to CoP1987.

2. STRENGTHENING USING FERROCEMENT

Many different materials for strengthening of columns were proposed and studied by researchers including, *inter alia*, Ersoy et al. (1993) on the application of steel and concrete jacketing, Wu et al. (2006) on the use of steel/FRP jacketing, and Harries et al (2006) on the use of CFRP jacketing. Study carried out by Han et al. (2006) reveals that it is necessary to provide additional fire protection to steel/FRP jackets in order to avoid rapid reduction in strength at elevated temperature. Similar conclusion is drawn by Tadeu and Branco (2000) on the bonding material used in externally bonded steel plate. In Hong Kong, materials for building works are subjected to stringent requirement on fire rating. Considering the need for strengthening materials to have promising fire resistance, ferrocement and HPF are chosen in this study. HPF has compatible fire resistance as concrete (Williamson and Fisher 1983) and can provide external protection to concrete columns under fire (Kaushik et al. 1996).

Ferrocement can be regarded as a kind of thin reinforced concrete structure. It was extensively used in manufacturing fishing boats in the last century (Abercrombie 1978). Traditionally, it comprises of cementitious based rendering material embedded with multiple layers of closely spaced small-diameter wire mesh. It is recommended to use rendering material with small particle size since large particle may not be able to pass though the closely spaced wire mesh and thus adversely affect the structural integrity and density of ferrocement (ACI 549.1R-93 and Naaman 2000). Besides, workability of rendering material should also be taken into account when designed to be used vertically. Detailed description of ferrocement is referred to publications of Shah et al. (1986), ACI 549.1R-93, Naaman (2000) and CECS 242:2008 (a technical specification in China).

On the subject of strengthening reinforced concrete columns, ferrocement has been used to enhance both ductility and load carrying capacity of columns (卜良桃 2007, Kondraivendhan and Pradhan 2009, Jiang et al. 2009, Kim and Choi 2010). Lim et al. (2000) studied the structural improvement of T-beams strengthened by ferrocement. Cao et al. (2007) studied the use of HPF comprises of high strength steel wire mesh and polymer based rendering material for strengthening beam-column joints. In another paper presented in this conference titled "Reinforced concrete beam-column joint strengthened by HPF jacket with diagonal reinforcements", beam-column joints are strengthened by ferrocement jacket with diagonal reinforcements. All the above have shown that HPF is an effective material for revitalization of existing buildings.

The significant of this study is to quantify the confinement action provided by HPF with two different densities of wire mesh and different rendering materials.

3. THE SPECIMENS

Totally 19 specimens were prepared using Grade C30/20 ready mixed concrete. 8 of them were casted in 2009 ("Group 1") and 11 of them were casted in 2010 ("Group 2"). Group 1 consists of specimens TPC1, TA300C-1, TB75C-1, TB300C, TA300CS3, TA300SD1-1, TA300SD3-1 and TA300ST3-1. They were tested to failure under axial compression in Dec 2009 and Jan 2010. The test results were reported in the preceding conference of CUEE (Ho and Lam 2010). Group 2 consists of specimens TPC2, TA300C-2, TB75C-2, T0SD1, T0SD3, T0ST1, T0ST3, TA300SD1-2, TA300SD3-2, TA300ST1 and TA300ST3-2. They were tested in Aug 2010 or Jan 2011.

5 combinations of HPF consisting of 2 types of mesh density and 3 types of rendering materials are considered. 4 parameters are studied includes (i) angle of hooks, (ii) spacing of transverse reinforcement, (iii) tensile strength of rendering materials and (iv) mesh densities. Rendering materials include cement-sand screeding, polymer modified cementitious based repair mortar and epoxy based repair mortar (denoted as "CS", "PMC" and "EM" respectively in the tables).

All specimens are in full-scale of 350mm diameter and 980mm height with concrete cover of 25mm. Material properties of the specimens are summarized in Table 1. 28-day strength and young modulus of concrete are obtained by carrying out compression test on three 100mm cubes and three 100mm x 150mm cylinders respectively. Material properties of reinforcement are obtained by coupon test on a pair of steel bars.

Table 1 Material properties

Materials	Properties	Group 1	Group 2
Concrete	Density (kg/m^3)	2315	2395
	28-day strength (MPa)	41.7	57.1
	Young modulus (GPa)	25.8	23.1
Main reinforcement	Yield Strength (MPa)	522.9	617.5
	Young modulus (GPa)	218.2	218.6
Transverse reinforcement	Yield Strength (MPa)	523.0	452.2
	Young modulus (GPa)	217.7	213.5

Detailed information of the specimens is listed in Tables 2A and 2B. Specimen TPC1 and TPC2 are control specimens made of plain concrete. Specimens TA300C-1 and TA300C-2 are detailed in accordance with CoP 1987 whereas specimens TB75C-1 and TB75C-2 are detailed to CoP 2004. Specimens strengthened with HPF are designed in the absence of seismic provisions and provided with 8T25 (or 4% main reinforcement ratio) as the main reinforcement. Two volumetric ratios of transverse reinforcement (ρ_s) at 0.230% and 0.918% are considered in accordance with the design provisions of CoP1987 and CoP2004 respectively.

Specimens TA300CS3, TA300SD1-1, TA300SD3-1, TA300ST3-1, TA300ST1, TA300ST3-2, TA300SD1-2 and TA300SD3-2 are detailed to CoP1987 and strengthened with

different types of HPF as per Tables 2A and 2B. Specimen TA300CS3 is detailed to CoP1987, strengthened with traditional ferrocement and served as a control specimen to compare with the result of those strengthened with HPF. These 9 specimens were used to study the confinement action induced by transverse reinforcement together with ferrocement or HPF.

Specimens TA0ST1, TA0ST3, TA0SD1 and TA0SD3 are plain concrete specimens strengthened with different types of HPF as detailed in Table 2. These 4 specimens are used to study the confinement action induced by HPF.

Table 2A Basic properties of specimens – Group 1

Table 4 Properties of rendering materials (MPa)

Material	Tensile splitting strength
CS (10-day)	2.70
PMC (30-day)	2.71
EM (30-day)	10.35

Square welded mesh is used as reinforcement in HPF. Measured material properties are listed in Table 3. Table 4 summarizes material properties of rendering materials. Mix proportion of the cement-sand mortar is characterized by water-cement ratio at 0.55 and sand-cement ratio at 3.00. Properties of cement-sand mortar are obtained by carrying out compression tests and tensile splitting tests on a pair of 150mm cubes and 150mm x 300mm cylinders respectively. Properties of the other two types of rendering materials are obtained by carrying out compression tests and tensile splitting tests on three 100mm cubes and three 100mm x 200mm cylinders respectively.

A method statement has been prepared to systematically outline the procedure of strengthening existing reinforced concrete columns using HPF. The method statement is referred to Ho and Lam (2010). Strengthening of all specimens strictly follows the method statement.

Figure 1 shows typical elevations and sections of specimens detailed to CoP1987 and CoP2004. Observed zones of the specimens are at the middle portion and spacing of transverse reinforcement is reduced by half at both ends to prevent failure at the ends due to stress concentration. Strain gauges with 5mm gauge length are installed on all main reinforcement in specimens in Group 1 and on alternative main reinforcement in specimens in Group 2. 5 strain gauges are installed on the transverse reinforcement at mid height of specimens. 2 strain gauges are located next to the hooks and 3 of them are at 90^0 apart. Detailed location and identification of strain gauges installed on the transverse reinforcement are referred to Figure 1. Figure 2 shows the arrangement of LVDTs at 90^0 apart with gauge length of 400mm in the observed zones.

Figure 3 shows the test setup. All specimens were tested by a Computer-Electro-Hydraulic Servo Controlled Multi-Purpose Testing System. The testing system is displacement control with a maximum loading capacity of 10,000kN.

Strain rate varies in different stages and is illustrated in Figure 4. The specimens are subjected to progressive increase in end shortening as follows:-

- At the linear elastic portion of the load-displacement curve, strain rate is applied at 0.5mm/min.
- At the non-linear pre-peak portion, strain rate is reduced to 0.2mm/min.
- When approaching the maximum load, strain rate is further reduced to 0.1mm/min.
- At the post-peak region, the strain rate is 0.05mm/min.

The loading test is terminated when the axial load carrying capacity of a specimen is reduced by more than 15% from the maximum.

4. TEST RESULTS

Figures 5(a) and 5(b) show typical modes of failure of specimens provided with 300mm and 75mm spacing of transverse reinforcement and without any HPF confinement.

Figures 5(c) and 5(d) show typical modes of failure of plain concrete specimens strengthened with HPF. Vertical cracks develop on the external HPF layer and steel wires of the wire mesh fractured in transverse direction at peak strength. Core concrete of the specimens fails in a cone shape with fully developed diagonal cracks at approximately 45^0 similar to the modes of failure of plain concrete specimen TPC2.

Figures 5(e) and 5(f) show typical modes of failure of reinforced concrete specimens strengthened with HPF. Crack patterns and condition of steel wires are similar to that observed from the above-mentioned specimens. However, integrity of core concrete is reserved by the HPF without significant damage. Hooks of the transverse reinforcement remain intact throughout the tests. Sign of arching effect can also be observed in the specimens.

In all the tests, concrete covers of non-strengthened specimens spalled off before reaching the peak strength.

Typical load-strain plots of main reinforcement and transverse reinforcement are shown in Figure 6. Strains are

recorded by strain gauges installed on the reinforcement as described in Section 3.

Figure 7 shows the load-strain plots of specimens without strengthening. Strains are based on the overall vertical displacement of the specimens measured by the LVDTs. Figures 8 and 9 show the load-strain plots of the specimens in Group 1 and Group 2 respectively with the strain based on the overall vertical displacement of the specimens obtained from LVDTs.

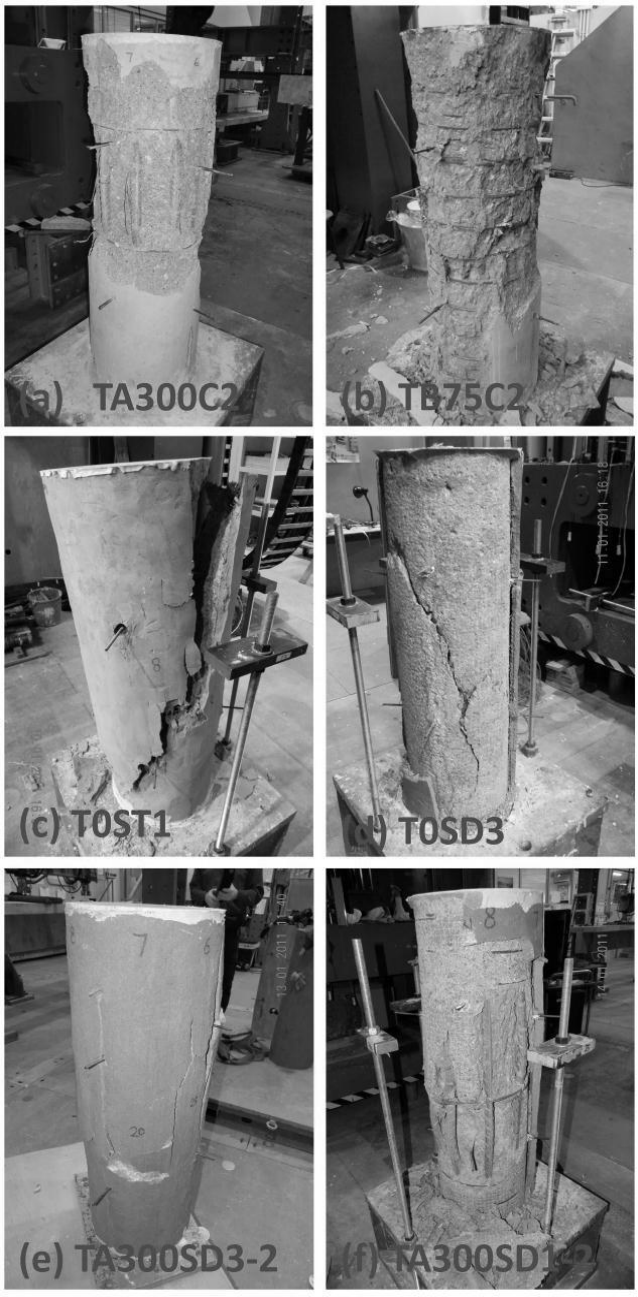

Figure 5 Typical failure modes of specimens.

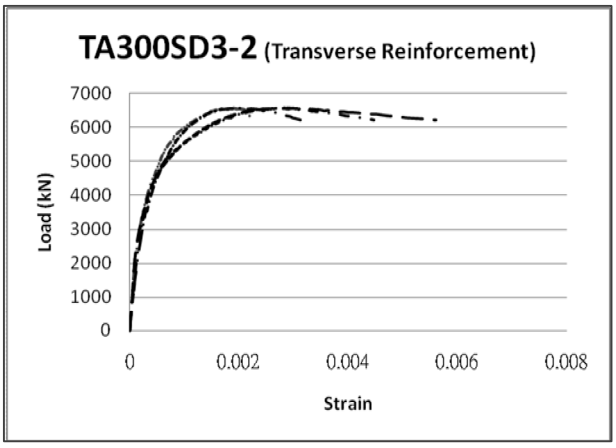

Figure 6(a) Load-strain plots of main reinforcement.

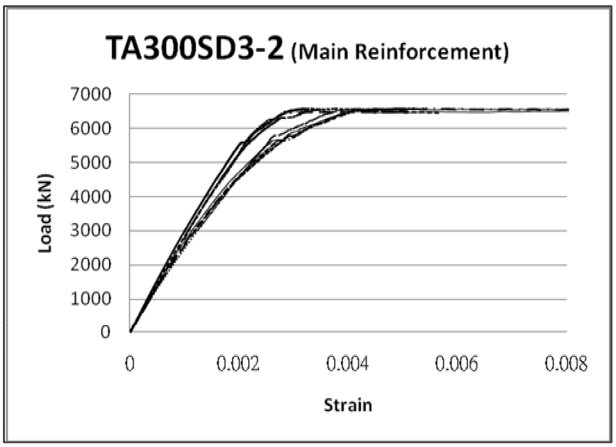

Figure 6(b) Load-strain plots of transverse reinforcement.

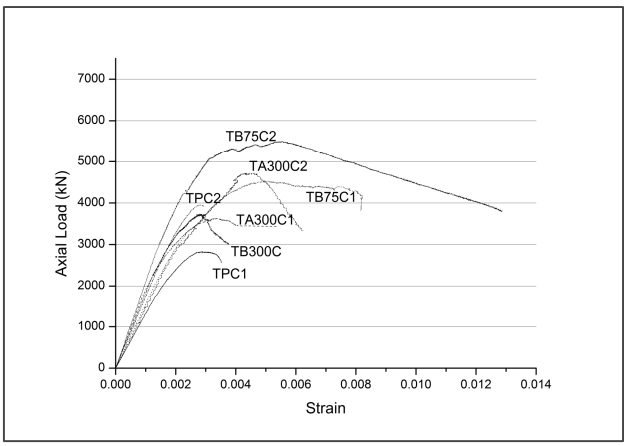

Figure 7 Load-strain plot of non-strengthened specimens.

A non-HPF strengthened reinforced concrete specimen will expand laterally on progressive increase in axial compression. When the lateral expanding stress exceeds the tensile strength of concrete, concrete cover will spall off. As a result, compressive strength of core concrete will increase to compensate for the loss in the load carrying capacity due to reduction on cross sectional area. Compressive force will gradually transfer to and resist by the main reinforcement

and core concrete. When lateral strain of concrete attains a critical level, there will be interaction between core concrete and transverse reinforcement. The transverse reinforcement will provide a confining pressure to confine the core concrete by restraining lateral expansion of concrete. The interaction works in a mechanism similar to the triaxial action of soil and the compressive strength of concrete is enhanced by this interaction (Richart et al. 1928, Balmer 1949, Popovics 1973, Sheikh and Uzumeri 1980, Ahmad and Shah 1982, Mander 1983, Mander et al. 1988 and Li 1994).

Table 5C Peak strength of plain concrete specimens confined with HPF– Group 2

Specimen	P_{peak} (kN)	$P_{peak}/P_{peak(TPC2)}$
TPC2	2907.7[2]	1.000
T0ST1	4003.4	1.377
T0ST3	3774.8	1.298
T0SD1	4615.8	1.587
T0SD3	4378.1	1.506

Similar interaction between HPF and concrete can be assumed when a HPF strengthened specimen is subjected to uniaxial compression. Increase in peak strength due to confinement action provided by HPF is observed from the test results. However, it is unclear as to the contribution of individual component in situation where confinement action is provided by both transverse reinforcement and HPF. The resulting confinement action may be equal to or less than the sum of the confinement action provided by individual component. Further analysis on the test results is needed.

Tables 5A, 5B and 5C list the peak strengths (P_{peak}) obtained by all 19 specimens. The test results are separated into two groups, namely Group 1 and Group 2, due to different compressive strength of concrete being used in these two groups. In Table 5C, equivalent peak value of specimen TPC2 is estimated based on a diameter of 300 mm instead of 350 mm. For ease of comparison, P_{peak} of specimens in Group 1 are divided by $P_{peak(TB75C-1)}$ (Peak strength of specimen TB75C-1) whereas P_{peak} of specimens in Group 2 are divided by $P_{peak(TB75C-2)}$ (Peak strength of specimen TB75C-2). If the ratio obtained is larger than 1, it means that this particular specimen has a load carrying capacity comparable to column designed to CoP2004. Besides, P_{peak} of plain concrete specimens in Group 2 are divided by $P_{peak(TPC2)}$ (Peak strength of specimen TPC2) to study the improvement in peak strength provided by HPF to plain concrete.

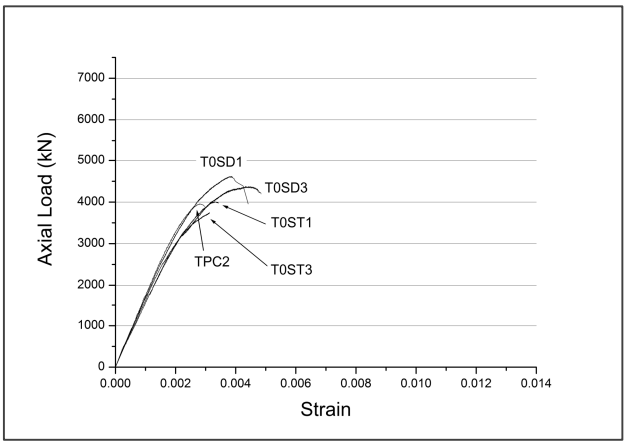

Figure 9(a) Load-strain plots of plain concrete specimens in Group 2.

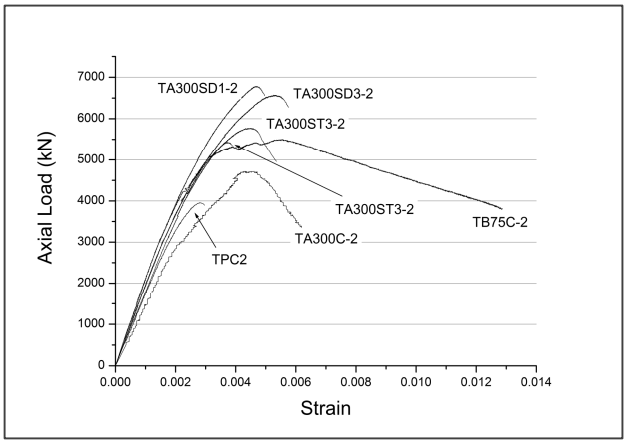

Figure 9(b) Load-strain plots of reinforced concrete specimens in Group 2.

By comparing the peak strengths of specimens TA300C-1 and TB300C, difference in angle of hooks (i.e. 90^0 hooks in specimen TA300C-1 and 135^0 hooks in specimen TB300C) does not have significant influence to load carrying capacity of specimens. This seems to suggest that as far as axial load is considered, the use of 90^0 hooks in lieu of 135^0 hooks causes minor effect to the confinement action.

From Table 5B, it is observed that reinforced concrete specimens (like specimen TA300SD1-2) detailed to CoP1987 and strengthened with HPF can achieved peak strength up to 23.3% higher than reinforced concrete specimens detailed to CoP2004.

Table 5C lists the measured peak strength of plain concrete specimens confined with HPF. Significant increase in peak strength is observed. The improvement in peak strength of specimens T0ST1 and T0ST3 is 29.8-37.7% and of specimens T0SD1 and T0SD3 is 50.6-58.7%. It shows that epoxy based rendering material can provide better confinement to enhance the compressive strength of concrete when compared with polymer modified cementitious based rendering material. HPF strengthening is an effective way to improve the load carrying capacity of columns.

Tables 6A and 6B list the confined compressive strength of concrete ($f_{cc(Meas)}$) estimated based on the following equation

$$f_{cc(Meas)} = (P_{Peak} - A_{st}f_y)/A'_{cc} \quad (1)$$

Where A_{st}, f_y and A'_{cc} are the respective area of main reinforcement, yield strength of main reinforcement and area of confined concrete.

From Table 6A, it is observed that specimens TA300SD1-1, TA300SD3-1 and TA300ST3-1 show substantial increase in confined compressive strength of concrete as compared with specimen TB75C-1. For the other specimens TA300C1, TB300C1 and TA300CS3, core concrete is not effectively confined due to low volumetric ratio of transverse reinforcement. This results in greater reduction of cross sectional area of core concrete. In addition, the result of specimen TA300CS-3 demonstrates that traditional ferrocement may not be able to provide sufficient confinement to core concrete when compared with HPF.

Test results also show that HPF confinement using epoxy based rendering material has better confining capability than using cement-sand screeding or polymer modified cementitious based rendering material. The main difference is that epoxy based rendering material has a tensile strength of 3-4 times higher than polymer modified cementitious based rendering material. It shows that large increase in confined compressive strength of concrete can be achieved by adopting HPF with higher tensile strength.

Similar phenomenon is observed in specimens in Group 2. From Table 6B, it is observed that all specimens except specimens TA300C-2 and TA300ST1 have confined compressive strength of concrete greater than that achieved by specimen TB75C-2. Although specimen TA300ST1 is confined with HPF using polymer modified cementitious based rendering material, confining strength provided by the HPF layer is still insufficient.

Table 6A Confined compressive strength of specimens – Group 1

Specimen	A'_{cc} (mm^2)	$f'_{cc(Meas)}$ (MPa)
TPC1	96211.3	--
TA300C-1	63039.2	25.06
TB75C-1	63039.2	39.28
TB300C	63039.2	26.70
TA300CS3	66540.7	29.81
TA300SD1-1	66540.7	40.75
TA300SD3-1	66540.7	43.06
TA300ST3-1	66540.7	34.79

Table 6B Confined compressive strength of specimens – Group 2

Specimen	A'_{cc} (mm^2)	$f'_{cc(Meas)}$(MPa)
TPC2	96211.3	--
TA300C-2	63039.2	36.36
TB75C-2	63039.2	48.82
TA300SD1-	66540.7	65.48
TA300SD3-	66540.7	62.36
TA300ST1	66540.7	45.22
TA300ST3-2	66540.7	50.33
T0ST1	70685.8	65.30
T0ST3	70685.8	61.94
T0SD1	70685.8	56.64
T0SD3	70685.8	53.40

Tables 7A and 7B list out the predicted compressive strength of confined concrete ($f_{cc(Predicted)}$) of each specimen based on the correlation proposed by Mander et al. (1988), Eq. 2 as follows,

$$f_{cc(Predicted)} = f'_{co}(-1.254 + 2.254\sqrt{1 + \frac{7.94f'_l}{f'_{co}}} - 2\frac{f'_l}{f'_{co}}) \quad (2)$$

Where, f'_{co} is unconfined compressive strength of concrete, and f'_l is overall lateral confining stress on the concrete.

When applying Eq. 2 to the present case, it is assumed

that the overall lateral confining stress (f'_l) induced is the sum of the effective lateral confining stress provided by HPF and transverse reinforcement in the form of,

$$f'_l = f'_{l(Trans)} + f'_{l(HPF)} \quad (3)$$

$f'_{l(Trans)}$ is the effective lateral confining stress on the concrete provided by transverse reinforcement in the form of,

$$f'_{l(Trans)} = 0.5 k_e \rho_s f_{(Trans)} \quad (4a)$$

$$k_e = (1 - 0.5 s'/d_s)^2 / 1 - \rho_{cc} \quad (4b)$$

Where s' is clear distance between consecutive transverse reinforcement, d_s is diameter of core section enclosed by the center lines of the transverse reinforcement, ρ_{cc} is ratio of area of main reinforcement to area of core section, ρ_s is volumetric ratio of transverse reinforcement and $f_{(Trans)}$ is yield strength of transverse reinforcement.

$f'_{l(HPF)}$ is the effective lateral confining stress on the concrete provided by HPF in the form of,

$$f'_{l(HPF)} = 0.5 \rho_{HPF} f_{(HPF)} \quad (4c)$$

$$\rho_{HPF} = 4 t_{HPF} / d_{s(HPF)} \quad (4d)$$

t_{HPF} is the thickness of HPF layer, $d_{s(HPF)}$ is the diameter of core section enclosed by HPF and $f_{(HPF)}$ is the tensile strength of HPF.

Unconfined compressive strength of concrete (f'_{co}) is estimated based on the compressive strength of plain concrete specimens. Considering specimen TCP2 was tested in Aug 2010, the unconfined compressive strength of concrete (f'_{co}) for specimens tested in Jan 2011 is adjusted by correlating the cube strengths measured in Aug 2010 and Jan 2011. The correlation is based on three 100mm cubes tested in Aug 2010 and five 100mm cubes tested in Jan 2011. In general, Eq. 2 provides accurate prediction on the confined compressive strength of concrete for specimens with high volumetric ratio of transverse reinforcement.

In Table 7, percentage different between $f_{cc(Predicted)}$ and $f_{cc(Meas)}$ is denoted by the abbreviation "Diff". "Diff" is defined as $(1- f_{cc(Predicted)}/f_{cc(Meas)})$x100. A positive value means an overestimation of f_{cc} by Eq. 2-4 and a negative value means an underestimation of f_{cc} by Eq. 2-4.

From Table 7B, it is observed that difference between $f_{cc(Predicted)}$ and $f_{cc(Meas)}$ of specimens T0ST1, T0ST3, T0SD1 and T0SD3 is below 10%. The difference between $f_{cc(Predicted)}$ and $f_{cc(Meas)}$ of specimens TA300SD1-1, TA300SD3-1, TA300SD1-2 and TA300SD3-2 are -5.71 to +3.10%. However, the errors of specimens TA300CS3, TA300ST3-1, TA300ST1 and TA300ST3-2 are -28.76 to -10.33%. It shows that Eq. 2 may not be directly applied (i.e. using Eq. 3) to predict the confined compressive strength of concrete in reinforced concrete specimens confined with HPF of low tensile strength.

Further study in this area is necessary to fully understand the correlation between confinement action provided by HPF and confined compressive strength of concrete in the presence of transverse reinforcement.

5. CONCLUSIONS

In this study, 19 full-scale specimens with detailing in accordance with CoP1987 or CoP2004 are subjected to unaxial compression. 12 of the specimens detailed in accordance with CoP1987 are strengthened with different types of HPF. From the results of the compression tests, preliminary conclusions are drawn as follow:-

(i) Variation of angle of hooks does not have significant influence on the load carrying capacity.
(ii) Load carrying capacity increase with volumetric ratio of transverse reinforcement.
(iii) Peak strength of plain concrete specimen can significantly be improved by 29.8-58.7% by HPF strengthening.
(iv) Reinforced concrete specimens detailed to CoP1987 and strengthened with HPF can achieve peak strength up to 23.3% higher than reinforced concrete specimens detailed to CoP2004.
(v) Load carrying capacity of specimens can be enhanced by HPF strengthening.
(vi) Compressive strength of confined concrete increases with tensile strength of HPF.

(vii) Tensile strength of HPF is found to be a crucial factor in providing sufficient confinement.

(viii) Better confinement can be provided by HPF using epoxy based rendering material instead of polymer modified cementitious based rendering material or cement-sand screeding.

All in all, test results have shown that specimens detailed to CoP1987 and strengthened with HPF can achieve axial load carrying capacity comparable to specimens detailed in accordance with CoP2004. The enhancement in axial load carrying capacity is greatly dominated by the tensile strength of HPF.

Further study in this area is necessary to fully understand the correlation between confinement action provided by HPF and confined compressive strength of concrete in the presence of transverse reinforcement.

Abstract: This paper presents recent improvements of parallel computing performance of Integrated Earthquake Simulation (IES); parallel computing is applied for IES to carry out seismic structure response of all buildings located in a large urban area. In previous studies, IES has been enhanced with standard parallel computing techniques, but there are bottlenecks which limit the number of buildings analyzed to several tens of thousands with hours of run time. Parallel computing performance is significantly improved by eradicating the bottlenecks; the modules for I/O are replaced with better ones and the link to seismic structure analysis programs is strengthened. In addition, a new program that uses a fiber model is plugged into IES, so that seismic response analysis is applied to mid/high-rise buildings. As test cases, seismic response analysis of all the buildings in a part of central Tokyo has been conducted.

1. INTRODUCTION

Quantitative prediction of infrastructural damages is necessary in preparation for earthquake disasters and both immediate and long term recovery process after a major earthquake. The conventional predictions based on past events would fail to provide a correct picture of damages since drastic changes in the built environment have taken place compared to the time of those past events. Therefore, a numerical tool capable of simulating the existing built environment considering the current conditions of structures, code of practice used for the structure designs, construction materials used, etc. would be indispensable. With the aim of filling the vacancy of such a numerical tool, a system called Integrated Earthquake Simulation (IES) is being developed (Ichimura et al. 2004, Hori et al. 2008). Its long term objective is to simulate earthquakes from source to their aftermaths; namely, strong ground motion from source to site, damages to structures, emergency evacuation and long and short term social and economic recovery. Evidently, most of the IES objectives require seismic response analysis and damage assessment of large number of structures in the target simulation domain within a reasonably short time. Some potential applications of IES are 1) as an aid for accelerating decision making in evacuation, rescue and relief supply right after an earthquake, 2) quantitative estimation of damages due to anticipating large earthquakes with Monte-Carlo simulations, etc... In this paper, we report the strengthening of parallel computation extension of the SRA module making it possible to reach these targets.

The parallel computation extension for the SRA module, developed prior to this work, has several performance bottlenecks. Some of those bottlenecks are due to the use for temporary files to exchange data between IES and independent SRA executable, unbalanced work load assigned to CPUs, large number of unnecessary inter-processor communications and use of large number of temporary files to reorganize the output data. As it will be shown in the next section, these bottlenecks seriously limit the number of building to several tens of thousands and extend the compute time to several hours.

In implementing countermeasures for bottlenecks, priority is given to elimination of temporary files, since extensive use of temporary files in parallel environment can harm computer systems. In this work, the use of temporary files is totally eliminated either with library or system-V shared memory segment and semaphore IPC mechanisms. All-worker model with several orders of magnitude less number of message passing is implemented instead of master-slave model in the current version. We implemented static load balancing based on the previously recorded run time information. Only static load balancing is implemented since changes to the core of IES is required for implementing dynamic load balancing .Since the SRA run time may not differ more than 5%, with different input seismic waves, static load balancing would be a reasonable solution. However, if considerable load imbalance occurs with different input strong ground motion data, a hybrid of static and dynamic load balancing should be added.

The rest of the paper is organized as follows. Section two presents more details of the bottlenecks, countermeasures and details of the implemented countermeasures. The section three presents simulation of

14000 buildings in central Tokyo as a demonstration of IES and discusses scalability of the modified IES. Some concluding remarks are given in the section four. In this paper, the term current IES refers to that with performance bottlenecks and the outcome of this work is referred as the modified IES.

2. PERFORMANCE BOTTLENECKS AND REMEDIES

As mentioned in the previous section, current IES is equipped with standard parallel computing techniques. However, the numbers of structures are limited to several tens of thousands with hours of computing time due to bottlenecks. Figure 1 shows its scalability when simulating 10,000 buildings with a nonlinear Discrete Element Method (DEM) code. Speedup, defined as the ratio of run time with single CPU and many CPUs, is a standard index to measure the scalability of a parallel program. As is seen in Figure 1, it rapidly deviates and from the ideal curve and tends to saturate somewhere around 128 CPUs. Currently, IES uses simplified SRA methods like nonlinear DEM, nonlinear one component model (OCM), etc... Parallel computation is not required to conduct SRA of one building since the run time of these simplified SRA methods is short. It is for simulating a large number of buildings in a reasonably short time, IES needs parallel computation enhancements. In this sense, IES is an embarrassingly parallel program. Obviously, the parallel performance shown in Figure 1 is unacceptably low for an embarrassingly parallel problem and there should be enough room to improve. In this section, details of the parallel performance bottlenecks in current IES and remedies are discussed.

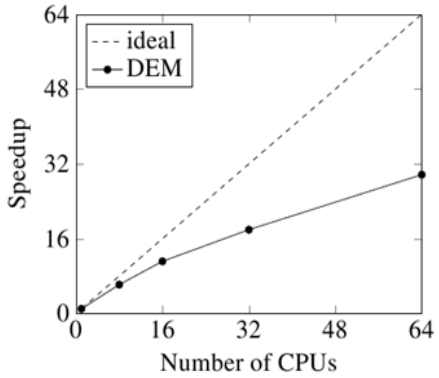

Figure 1 Speedup of the current IES parallel extension.

2.1 Inter-process communication with temporary files

The current IES does not have inbuilt SRA programs. It generates input data for different types of SRA methods and call third party SRA executable with *system*( ) command, using temporary files to exchange data between the two programs. Though this is a common inter process communication (IPC) method in serial computing, it becomes a serious bottleneck in parallel computation. In the current implementation, OCM model requires 10 file I/O operations totaling around 20 million file I/O operations for a city like Tokyo. Further, the file system may stresses heavily when all the CPUs start to simulate two or three storied residential buildings. These small buildings are the most common in any city and the simplified SRA models in IES can simulate these in a very short time.

The standard technique to eliminate the use of temporary files for IPC is calling the external program as a static or dynamic library. We converted some of the SRA programs, with permissions to modify, to libraries. However, converting some of the codes is difficult due to the non-standard compiler options used by their developers. Under such situations, we adopted shared memory and semaphore mechanisms provided by SystemV IPC (commonly abbreviated SysV IPC) (Daniel et al. 2000, Stevens 1999) for inter-process communication and called the SRA programs as independent executable with *system*() command. As the name implies, shared memory mechanism allow multiple processes to share a common segment of memory to exchange a large volume of data. Semaphores can be used to prevent multiple processes simultaneously accessing a shared memory segment. In addition to attaching as libraries, the major SRA programs are attached to IES using these IPC mechanisms. In the future, a propitiatory software code for estimating the life time of damaged concrete structures is to be attached with these two IPC mechanisms.

One disadvantage of using shared memory segments and semaphores is that those persist even after termination of the processes accessing it, unless explicitly cleaned. Under normal operations, IPC classes in IES take care of the cleaning. However, if the main program dies prematurely, allocated IPC resources should be cleaned with the command *ipcrm* <*-s/-m*> <*shmid/semid*>, on each computing node. *shmid* and *semid* of allocated resources can be found with *ipcs* <-s/-m> commands. Otherwise, it become a system wide memory leak and persists until the whole system or all the used nodes are rebooted.

2.2 Large number of file I/O operations in output data handling

When used to simulate a large urban area, IES produces a large volume of output data. The demonstration simulation given in the next section produced 12GB of binary data when seismic responses of 14,000 buildings are saved for 2,400 time steps. Such amount of data may not be needed for some applications. However, the current target is to provide the almost all the available data so that IES can deal with any end user requests. When saving the output data, extremely large amount of file I/O operations are done by the current IES SRA module; two files per time step of each structure are written by all the CPUs using POSIX file I/O functions. Later the master CPUs reads all those back, reorganize, group the buildings in thousands and write to disk formatted for the visualization software. In total, it involves 9.6 million I/O operations per 1000 buildings.

One of the best solutions for this serious file I/O bottleneck is to reorganize data into ready to visualize format (i.e. visualization software can directly read with little or no

preprocessing) and write output into small number of files, large in sizes. However, with POSIX type I/O it's difficult to save data in ready to visualize format. To explain why, it needs to explain how the data is distributed over the CPUs. As will be explained in the section 2.3, buildings from one GIS tile are distributed over many CPUs to attain good load balancing. With POSIX IO, saving data of one GIS tile, scattered over many CPUs, to a single file can be done only with sequential file access; either sending all the data to master CPU to re-organize and save or each CPU opens and saves data to one file sequentially. Utilizing parallel I/O operations, one can attain better performance than either of these options.

We utilized the MPI-IO functionalities comes with the MPI-2 standard to write the SRA output in ready to visualize format, thereby achieving higher parallel performance and reducing the visualization time. Compared to POSIX IO, MPI-IO can deliver much higher IO performance in parallel environment, provided a supporting parallel files system is available. MPI-IO provides four levels of file access; independent or collective access of contiguous or noncontiguous data. We utilized the level 3 access function *MPI_File_write_all*( ) which allow non-contiguous collective access to a file, to write SRA output data to a ready to visualize format.

2.3 Unbalanced work load assigned to CPUs

Though the SRA module of IES is embarrassingly parallel, proper load balancing is important to achieve a good scalability. Current IES SRA module does not assign equal amount of work to each CPU leading to large run time difference among CPUs. The exact run time for each structure cannot be predicted since it depends on location and magnitude of an earthquake, etc... Therefore, some form of dynamic load balancing is necessary to attain a perfect load balance. Possibly, hybrid solution like static load balancing for the first 95% and switching to dynamic load balancing for the remaining would be the best since this involves less number of message passing.

Though hybrid of static and dynamic load balancing is a good choice for this problem, only static load balancing is implemented since dynamic load balancing requires changes to the core of IES. In the simple static load balancer, first all the building shape and previous run time data are shared among all the CPUs by either broadcasting or pipe-lining. The shared shape data contain a group of building shapes from one or more GIS tile and each data set is compressed to reduce to size of the message. CPUs pick a subset of data so that each has equal amount of run time based on the previous run time data. The examples given in the next section provide parallel performance of this static load balancer. The use of static load balancer is an acceptable solution since the run time difference of a given building due different input SGM data would not be greater than 5%.

2.4 More on load balancing

Achieving a perfect load balancing with static or static-cum-dynamic load balancing may not necessarily reduce the total run time. To achieve the best load balance in the modified IES, a building is considered as the smallest computation unit or the grain size in partitioning the computational load. As a result buildings from one GIS tile are scattered over almost all the CPUs. This leads to longer time for collective IO operations since the number of participating CPUs is large and each CPU contribute relatively small amount of data. One potential solution is to form several CPU sub groups and make only the masters of those subgroups to perform the collective IO. However, this method does not perform well when the data size from each CPU is greater than 100kB (Latham et al. 2004), which is the case with IES data.

Another option is to group the buildings from a GIS tile to several sets with approximately equal total run time and use these sets as the smallest computational grain size. When this larger grain sizes have large total run time, buildings from one GIS tile is scattered over less number of CPUs effectively reducing collective IO time. However, larger grain size increases the load imbalance. Therefore, an intermediate grain size should be chosen to get the optimal behavior. The major advantage of this method is possibility to further reduce file saving time with concurrent collective IO of several CPU subgroups. Since buildings are scattered over smaller number of CPUs, it could be possible to finds disjoint sets of CPUs which has data from different GIS tiles. These CPU sub groups can concurrently save corresponding data with collective IO on subgroup communicators. When using over 200 CPUs, this may reduce the total run time.

Though, choosing a moderate computation grain size can reduce the total run time, it may not be the best solution for real-time applications. Having a moderate computation grain size would be good for intended Monte-Carlo simulations or other non-real-time applications. However, what real-time applications needs is not the smaller total run time, but the faster production of outputs even partially. As an example, it would be more useful for relief supply agencies to have results of high priority areas quicker rather than having results of millions of structures at once after longer wait. These high priority areas could be those predicted to suffer severe damage, where most people are depending the time of the earthquake, etc... One method for such early production of results is modifying the core of IES to flush all the data after completing the simulation of one data set and accept new sets of buildings from a different GIS tile. Another method is to implement dynamic processor management of MPI-2 to spawn small groups of CPUs for each GIS tile. Once a spawned processor group dies completing the assigned work, the master CPU spawn new group with those CPUs and assigns the next GIS tile in a queue. The former, modifying core of IES, is preferred to the latter since still processor spawning is complex and not much supported with commodity clusters.

3. ILLUSTRATIVE EXAMPLE WITH FIBER ELEMENT MODEL

The modified parallel extension of IES SRA module involves message passing only at the very beginning and the

very end of a simulation; at the beginning to share some configuration files and building shapes and run time data of each GIS tile and at the end for reorganizing output data and saving with collective IO. The modified parallel module should scale well with the number of CPUs as long as there are large numbers of buildings and SRA data is saved as large group of buildings. To test the scalability of the modified parallel extension, we simulated all the buildings the GIS tile 09ld171 in which 14,000 buildings are located. The objective of this simulation is to demonstrate IES SRA module, check the scalability against number of CPUs, find out the remaining bottlenecks and roughly estimate the necessary computational resources for a given number of buildings, etc...

3.1 Details of the computation model and the computer environment

The most sophisticated SRA method attached to current IES is OCM which is only applicable to low-rise buildings. A modern city is full of medium-rise and high-rise buildings and these tall buildings host most of the economically and administratively important entities. In order to conduct SRA of these important structures, a third party code of fiber element model is attached as a library to IES. Fiber element model is a simple and computationally light, but still allows significant insight to the seismic response of both the structural members and the entire structure. It is said to have the best compromise between the simplicity and the accuracy in non-linear seismic response studies of concrete buildings (Spacone et al. part I- II, 1996). The third party fiber element method code attached to IES uses the modified Kent-Park to model non-linear concrete member response.

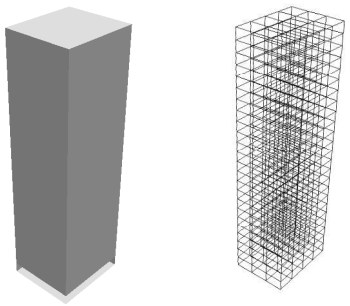

Figure 2 A shape of a building and automatically generated beam column skeleton.

The input beam column structural skeletons for the fiber element model (or other SRA models) are automatically generated from the GIS data since the actual structural details are not available to the authors. Dimensions and the spacing of the beams and columns are decided based on the Japanese code of practice for building design. Figure 2 shows an example of building shape generated from GIS data and its beam column skeleton. IES can simulate different buildings with different SRA program like Fiber, OCM, DEM, MDOF, etc. in a single simulation. However, for this demonstration simulation, all the buildings are simulated with the fiber element model. In addition, all the structures are excited by a strong ground motion data observed during the 1995 Kobe earthquake. Therefore, the current simulation does not reflect the naturally observed complex behavior due to the effects of complicated underground soil and rock structures. IES would be able to capture these complex behaviors either using observed SGM data at the neighborhood of each building or with synthetically generated high resolution SGM data with the multi-scale SGM simulation module of IES, which takes the details of the underground structures in to account.

All the simulations are conducted in a commodity Linux cluster made of connecting 8 workstation nodes with a Gigabit switching hub. Each workstation has a 32GB DDR2 600MHz memory and two Quad-Core AMD Opteron 2379 HE processors. Output data is saved to a raid array, NFS mounted on each node. It is well known that MPI-IO has poor performance on NFS mounted file systems (Latham et al. 2004). Therefore, the current simulation does not reflect the performance advantage of utilizing MPI-IO collective operations.

3.2 Scalability w.r.t the number of CPUs

As shown in Figure 3, the modified parallel module has almost the ideal scalability with respect to the number of CPUs. This is a significant improvement compared to the performance curve shown in Figure 1. When the fiber element model is called as an independent executable with SysV IPC resources for inter-process communication, it only took additional 30 seconds with 64 CPUs. This indicates that there is no serious penalty of calling a third party executable with SysV IPC resources in parallel environment. According to Table 1 the run time for 14,000 structures is around two hours with 64 CPUs. The graphs in Figure 3 and the Table 1 provide run time including and excluding the time for data reorganizing and saving at the last step. According to Table 1, it takes around 200 seconds to cast displacement data from beam-column skeleton actual building shape, reorganize and save 12GB displacement data with MPI collective file operations. As it was mentioned, the cluster used for the simulation had a NFS which is known to have poor support for parallel IO operations. The current file saving time could be reduced by 75% when a file system

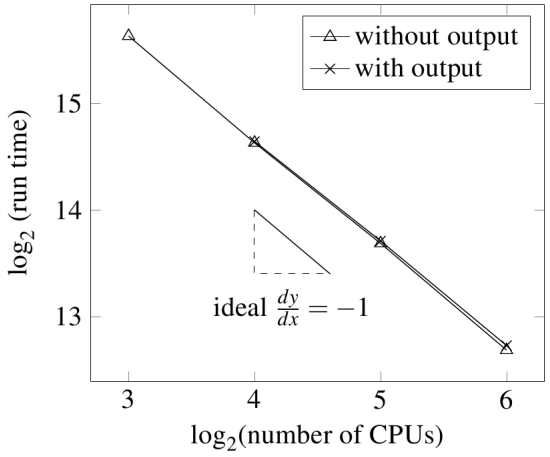

Figure 3 A shape of a building and automatically generated beam column skeleton.

Table 1 Runtimes of 14,000 structures in GIS tile 09ld171

No. of CPUs	Run time /(s)		Time for mapping data to shape and collective file IO
	without output	with output	
8	50631	--	--
16	25606	25820	214
32	13536	13754	218
64	6819	7008	189

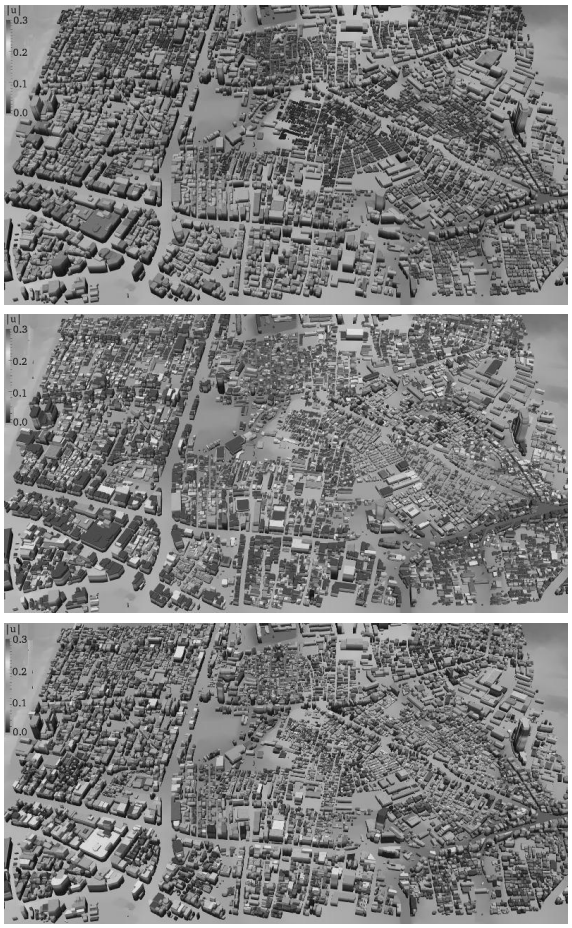

Figure 4 Snapshots of displacement time history of buildings in GIS tile 09ld171, simulated with fiber element model.

with a parallel IO support is used. Figure 4 shows some snapshot of displacement of buildings.

According to the results of this simulation, the shortest run time for an urban area with mid/high rise buildings are to be decided by the time for the fiber model to simulate the most complex mid/high rise building in the selected domain. In the case of this example, the run time for one of the tall building was around 6400 seconds. Therefore, the shortest run time for this GIS tile is around 6600 seconds irrespective of the number of CPUs. In order to further reduce run time, the seismic response programs have to be parallelized either with OpenMP or MPI.

4. CONCLDING REMARKS

We improved the parallel performance of seismic response analysis module of IES by eradicating all the bottlenecks in the former model. The extensive use of temporary files, unreasonably large number of message passing, unbalanced work assignment and poorly designed output data saving are the identified performance bottlenecks. With a relatively small simulation of 14,000 structures, it was demonstrated that the modified parallel module has almost the linear scalability with respect to the number of CPUs. Almost the same linear scalability curve is observed even when saving of a large volume of output data is included. It was observed that using SysV IPC resources for data exchanging between independent executable does not degrade the parallel performance. With SysV IPC, the run time is extended by a relatively small amount compared to the use of libraries. The shortest run time, when simulating a large urban area, could be decided by the runtime for the largest structure in the domain. According to the demonstration problem presented here, 10,000 15,000 CPUs may be needed to simulate whole Tokyo area. In future, increasing the computation grain size used for load balancing and concurrent data saving by multiple groups of CPUs are to be implemented to further improve the parallel performance when using large number of CPUs.

Abstract: This article presents an extension of the consecutive modal pushover (CMP) procedure for estimating the seismic demands of one-way unsymmetric-plan tall buildings. The procedure employs the multi-stage and classical single-stage pushover analyses and benefits from the elastic modal properties of structure. The seismic demands are obtained by enveloping the peak inelastic responses resulting from the multi-stage and single-stage pushover analyses. To verify and validate the procedure, it is applied to the 10, and 15-storey one-way unsymmetric-plan buildings including torsionally-stiff (TS), torsionally-similarly-stiff (TSS) and torsionally-flexible (TF) systems. The modal pushover analysis (MPA) procedure is implemented for the purpose of comparison as well. The results from the extended pushover procedure and MPA are compared with those obtained by the nonlinear response history analysis (NL-RHA). It is demonstrated that the extended CMP procedure can predict to a reasonable accuracy the peak inelastic responses, such as displacements and storey drifts. The CMP procedure represents an important improvement in estimating the plastic rotations of hinges at the flexible and stiff sides of unsymmetric-plan tall buildings in comparison with the MPA procedure.

1. INTRODUCTION

Several research efforts have been made to extend and apply the pushover analysis to unsymmetric-plan buildings whose inelastic seismic responses are intricate. Kilar and Fajfar [1997; 2001], De Stefano and Rutenberg [1998], Faella and Kilar [1998], Moghadam and Tso [1998; 2000], Ayala et al. [2002], Fujii et al. [2004], Barros and Almeida [2005] investigated on the application of pushover analysis to unsymmetric buildings. Recently, modal pushover analysis (MPA) [Chopra and Goel 2004], the N2 method [Fajfar et al. 2005 and 2008] and a simplified seismic analysis [Lin and Tsai 2007] were extended to the unsymmetric-plan buildings. In the MPA procedure, torsional moments were applied in addition to lateral forces at each floor level. The seismic demands were separately calculated for each of the modal pushover analyses and combined by using CQC modal combination scheme. The MPA procedure is unable to accurately compute the plastic rotation of hinges. In the extended N2 method, the results produced by pushover analysis (based on the N2 method) were combined with the results from elastic spectral analysis by using a correction factor. The correction factor was defined as the ratio between the normalized roof displacements derived from elastic spectral analysis and those resulting from pushover analysis. De-amplification of displacements due to torsion was not taken into consideration. This method is limited to low-rise buildings where higher mode effects are not significant.

The main objective of this paper is to extend the consecutive modal pushover (CMP) procedure to the one-way unsymmetric-plan tall buildings in which torsional and higher mode effects play an important role in estimating the seismic responses.

2. EXTENSION OF THE CONSECUTIVE MODAL PUSHOVER (CMP) PROCEDURE

The consecutive modal pushover (CMP) procedure was proposed to estimate the seismic demands of symmetric tall buildings [Poursha et al. 2009]. Herein, this procedure is extended to the one-way unsymmetric-plan tall buildings. Multi-stage and single-stage pushover

analyses are used in the procedure. In the multi-stage pushover analysis, modal pushover analyses are carried out continuously, so that when one stage (one modal pushover analysis) has been completely performed, the subsequent stage (subsequent modal pushover analysis) starts with an initial structural state (stress and deformation) which is the same as the condition at the end of the previous stage. The lateral forces are incrementally applied in the multi-stage pushover analysis. The number of stages in the multi-stage pushover analysis depends on the period (height) of the structure and type of unsymmetric-plan system. Linearly-elastic modal properties are used to implement the multi-stage pushover analysis. The displacement increment at the roof, in each stage of multi-stage pushover analysis, is determined as the product of a factor, β_i, and the total target displacement, δ_t, at the roof. The factor, β_i, is calculated from the initial modal properties of the structure. Displacement increment, u_{ri}, at the center of mass (CM) at the roof in the *i*th stage of multi-stage pushover analysis, is determined as

$$u_{ri} = \beta_i \delta_t \quad (1)$$

in which

$$\beta_i = \alpha_i \quad \text{for the stages before the last stage} \quad (2)$$

and

$$\beta_i = 1 - \sum_{j=1}^{N_s - 1} \alpha_j \quad \text{for the last stage} \quad (3)$$

where N_s is the number of stages in the multi-stage pushover analysis and α_i is the effective modal mass ratio for the *i*th mode. It is noted that it can be shown that the sum of the effective modal participating mass ratios over all modes is equal to unity [Chopra 2007] .

The two, and three-stage pushover analyses are used for the multi-stage pushover analysis in the torsionally-stiff and torsionally-flexible systems. In the case of torsionally-similarly-stiff systems, a four-stage pushover analysis is utilized in addition to the two, and three-stage pushover analyses. A classical single-stage pushover analysis is separately performed for all of the unsymmetric-plan systems. At the end, the seismic responses are obtained by enveloping the peak responses derived from the multi-stage and single-stage pushover analyses since it is possible to use different pushover analyses and to envelope the results [Fajfar 2000].

Accordingly, the CMP procedure can be expressed as a sequence of following steps:

1. Calculate the natural frequencies, ω_n, and the mode-shapes, Φ_n. The mode-shapes are normalized so that the lateral component of Φ_n, at the roof, equals unity ($\phi_{ryn} = 1$).
2. Compute the incremental lateral forces, $\mathbf{s}_n^* = \mathbf{M}\Phi_n$, over the height of the structure for different stages of multi-stage pushover analysis.
3. Compute the total target displacement, δ_t, at the roof. The target displacement increment for each stage of the multi-stage pushover analysis is obtained by Eqs. (1) to (3).
4. Apply the gravity loads and then perform the single-stage and multi-stage pushover analyses according to the following sub-steps until the control node (CM) at the roof sways to the predetermined total target displacement, δ_t.

    4.1. Perform a single-stage pushover analysis by using an inverted triangular load pattern for medium-rise unsymmetric-plan buildings and a uniform force distribution for high-rise ones until the total target displacement, δ_t, at the roof is reached. For torsionally-flexible buildings, this analysis is carried out by using the force distribution derived from the modal properties of the fundamental effective mode.

    4.2. Perform a two-stage pushover analysis. In the first stage, implement pushover analysis, using the force distribution $\mathbf{s}_1^* = \mathbf{M}\Phi_1$, until the displacement increment at the roof reaches $u_{r1} = \beta_1 \delta_t$ (Eq. (1); $i = 1$) in which $\beta_1 = \alpha_1$ (Eq. (2); $i = 1$). Subsequently, in the second stage, continue the analysis with the incremental lateral forces $\mathbf{s}_2^* = \mathbf{M}\Phi_2$ until the displacement increment at the roof equals $u_{r2} = \beta_2 \delta_t$ (Eq. (1); $i = 2$) where $\beta_2 = 1 - \alpha_1$ (Eq. (3); $i = 2$).

    4.3. The third analysis is a three-stage pushover analysis which can be done in a similar process as defined for the two-stage pushover analysis.

    4.4. Similarly to the previous multi-stage pushover analyses described above, perform a four-stage pushover analysis. This analysis is performed only for torsionally-similarly-stiff systems.
5. Calculate the peak values of the seismic responses for the single- and multi-stage pushover analyses. The peak values for these analyses are denoted by r_i. Index *i* denotes the number of stage(s).
6. Calculate the envelope, r, of the peak responses as follows:

$$r = Max\{r_1, r_2\} \quad \text{for the TS and TF unsymmetric-plan systems with } T < 2.2 \text{ seconds} \quad (4)$$

$$r = Max\{r_1, r_2, r_3\} \quad \text{for the TS and TF unsymmetric-plan systems with } T \geq 2.2 \text{ seconds} \quad (5)$$

$$r = Max\{r_1, r_2, r_3 \; r_4\} \quad \text{for the TSS unsymmetric-plan systems} \quad (6)$$

where *T* is the period of the mode which has the largest effective modal mass ratio for the unsymmetric-plan building in the direction under consideration.

3. DEFENITION OF STRUCTURAL MODELS

Unsymmetric-plan models were created from symmetric-plan model. First, symmetric-plan building and relevant assumptions are described. The original symmetric-plan building considered in this investigation was 10-storey building. The building was 15 m by 15 m in plan and comprised three bays in each direction. All bays were 5 m. The storey heights were equal to 3.2 m.

The lateral load-resisting system of the building was a special steel moment-resisting frame (SMRF) in both directions. P-Δ (second order) effects due to gravity loads were included. The dead and live loads were equal to 650 and 200 kg/m^2 on the floor area. Seismic effects were determined according to the requirements of Iranian code of practice for the seismic resistant design of buildings [Standard No. 2800-05, 2005]. The seismic masses at all floor levels were assumed to be equal and to consist of the dead load plus 20% of the live load. The building was designed according to the allowable stress design method [AISC-ASD 1989]. The structure satisfied the detail requirements of the Iranian seismic code including the deformation limitation and strong column-weak beam criterion.

Unsymmetric-plan buildings were considered as variations of the symmetric-plan building. They were assumed to be mass-eccentric and one-way unsymmetric, i.e. symmetric about x-axis but unsymmetric about y-axis. In order to create the mass-eccentric systems, symmetric-plan building was modified. For this purpose, the stiffness properties of the symmetric-plan building were maintained and the centre of mass (CM) was specified eccentric relative to the centre of stiffness (CS) only along the x-axis [see figure. 1]. The eccentricity between the CM and CS was assumed to be 15% of the plan dimension. Three types of unsymmetric-plan buildings were created corresponding to the symmetric-plan building by modifying the ratio of the floor moment of inertia (I_{oj}) to the floor mass (m_j) [Chopra and Goel 2004]. The created systems, which have different degrees of coupling between the translational and torsional motions, involve torsionally-stiff (TS), torsionally-similarly-stiff (TSS) and torsionally-flexible (TF) systems. The ratios of the floor moment of inertia to the floor mass between the unsymmetric-plan buildings and the symmetric-plan building, the first four periods of linearly-elastic structures, as well as the heights of all buildings are listed in Table 1.

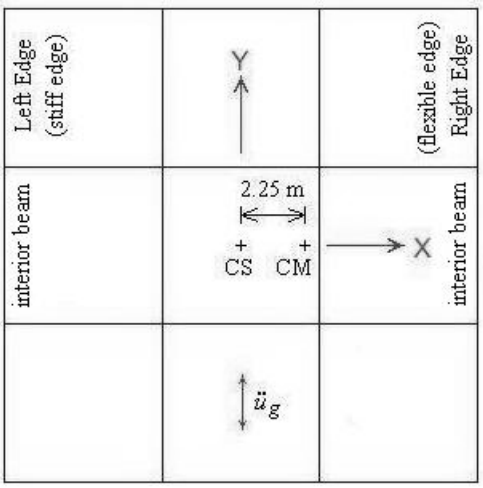

Figure. 1. Plan of the analyzed one-way unsymmetric-plan tall building

Table 1. Details of the analyzed 10-storey building structures

Type of buildings	$\frac{(I_{oj}/m_j)_{unsymmetric}}{(I_{oj}/m_j)_{symmetric}}$	Periods (seconds)			
		T_1	T_2	T_3	T_4
symmetric	-	1.52	0.51	0.29	0.19
TS	.28	1.63h	0.69	0.55	0.31
TSS	1.36	1.84	1.33	0.62	0.45
TF	5.67	3.33	1.50	1.14	0.63

4. DESCREPTION OF ANALYSES

The CMP procedure was performed together with the NL-RHA to investigate the accuracy of the CMP procedure. The MPA procedure was also carried out for the purpose of comparison. The NL-RHA was conducted by using the numerical implicit $Wilson-\theta$ time integration method. Seven ground motion records including the Imperial valley(1979), Victoria(1980), Morgan hill(1984), Hollister(1986), Landers(1992), Northridge(1994) and Duzce(1999) were used in NL-RHA. These selected ground motions were far-field records, and corresponded to locations which were at least 12 km from a rupturing fault. More details of the ground motion records are available in Reference [Poursha et al. 2009]. The records were scaled up to 1g to produce nonlinear responses. The second order ($P-\Delta$) effects were included within all the nonlinear static and dynamic analyses. $P-\Delta$ effects were also taken into consideration for all modes in the MPA and CMP procedures. The responses estimated by the aforementioned approximate pushover procedures were compared with the mean values of maximum seismic responses obtained from seven nonlinear response history analyses (NL-RHAs). In this research, the target displacement at the roof for the CMP procedure was determined as the mean value of the maximum top floor displacements (at the CM in the y-direction) resulting from NL-RHAs. The nonlinear version of computer program SAP2000 was used to perform the nonlinear analyses [Computers and Structures 2004]. It should be noted that point rigid-plastic hinges were used to represent the nonlinear behavior in the static and dynamic analyses. Hinges were defined at the ends of the frame members. The hinge properties and relative modeling parameters were specified according to the FEMA-273 [BSSC 1997]. The hysteretic behavior of the hinges is bilinear with 3% post-yield stiffness. Stiffness degradation was ignored for the NL-RHA.

5. RESULTS AND DISCUSSIONS

Seismic responses including the floor displacements, storey drift ratios and hinge plastic rotations are presented and discussed. The mean value of the maximum responses from NL-RHAs and the mean value plus standard deviation (σ) have been shown. Figure 2 displays displacements for different systems of the 10-storey building at the right (flexible) and left (stiff) edges. The figure demonstrates that the MPA and CMP procedures can estimate the displacements with acceptable accuracy at the flexible and stiff edges of the torsionally-stiff and torsionally-flexible systems. It's of interest to note that the displacements obtained by the MPA and CMP procedures at the flexible edge are more agreeable with the results produced by NL-RHA than those at the stiff edge. At the stiff side of the torsionally-stiff building, the CMP procedure provides relatively better predictions of displacements than the MPA procedure. As seen from figure 2, displacements estimated by the MPA at the flexible edge and by the CMP at the stiff edge may occasionally deteriorate (be underestimated) for the torsionally-similarly-stiff building. Deterioration of the predictions can be due to strong coupling between lateral and rotational motions in each mode of vibration [Chopra and Goel 2004].

A comparison of storey drifts predicted by the CMP and MPA procedures with those obtained by NL-RHA indicates that estimates obtained by these approximate procedures are accurate enough for the torsionally-stiff and torsionally-flexible buildings (see figure 3). The figure illustrates that the estimates of storey drift ratios derived from the CMP procedure are more accurate (sometimes relatively more conservative) than those resulting from the MPA procedure in some cases, especially at the mid and upper storeys. In some other cases, the MPA gives better estimates than the CMP. There is an improvement in estimating the storey drifts through the CMP at the flexible edge of the torsionally-similarly-stiff building (see figure 3(b)), but the predictions from the CMP procedure may occasionally deteriorate at the stiff edge of this building in comparison with the MPA. For example, the storey drift ratios are underestimated by up to 32% by the CMP and overestimated by up to 31% by the MPA at the stiff side of the 10-storey torsionally-similarly-stiff building. Figure 4 shows the height-wise variation of hinge plastic rotations at the interior beam of the frames at the right and left sides of the unsymmetric-plan buildings. The figure obviously demonstrates that the predictions obtained by the CMP procedure are mostly in excellent agreement with results produced by NL-RHA at the flexible and stiff sides of the unsymmetric-plan buildings. The MPA procedure fails to estimate the plastic rotations with acceptable accuracy for all the unsymmetric-plan buildings and it considerably underestimates the plastic rotations. The CMP procedure represents a significant improvement in predicting plastic rotations at the flexible and stiff sides in comparison with the MPA procedure. The improvement is achieved by incrementally applying the lateral forces during the stages in the multi-stage pushover analysis which controls the results at the mid and upper storeys of the unsymmetric-plan tall buildings. By incrementally applying the lateral forces, rotations of the plastic hinges are consecutively accumulated. Then, the plastic hinges, in the CMP procedure, deform into the inelastic range at the mid and upper storeys, whereas in the MPA procedure they remain elastic or deform slightly into the inelastic range at these storeys because the modal pushover analyses are performed independently. It is important to note that cumulative rotations of the plastic hinges due to cyclic hysteretic behavior are not taken

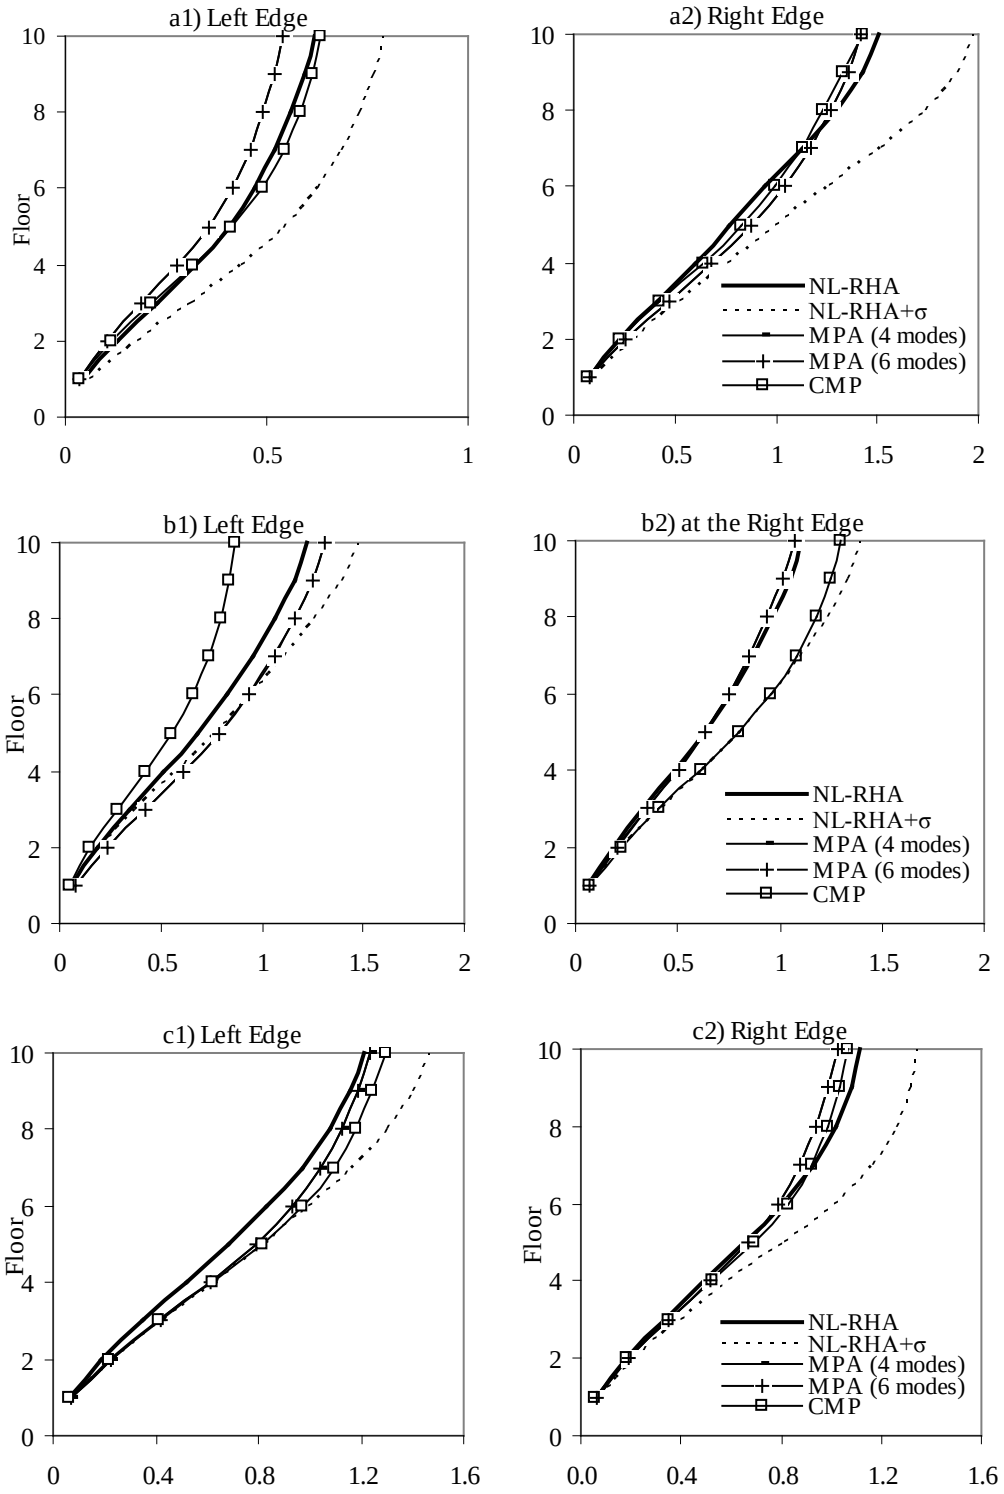

Figure 2. Height-wise variation of the displacements at the left and right edges: a) torsionally-stiff system b) torsionally-similarly-stiff system c) torsionally-flexible system

into consideration in an approximate pushover analysis such as the CMP procedure. As seen from figure 4(c), the improvement through the CMP procedure is also noticeable at the stiff side of torsionally-flexible systems where the prediction on this side was found to be so difficult in the previous investigations [Fajfar et al. 2008].

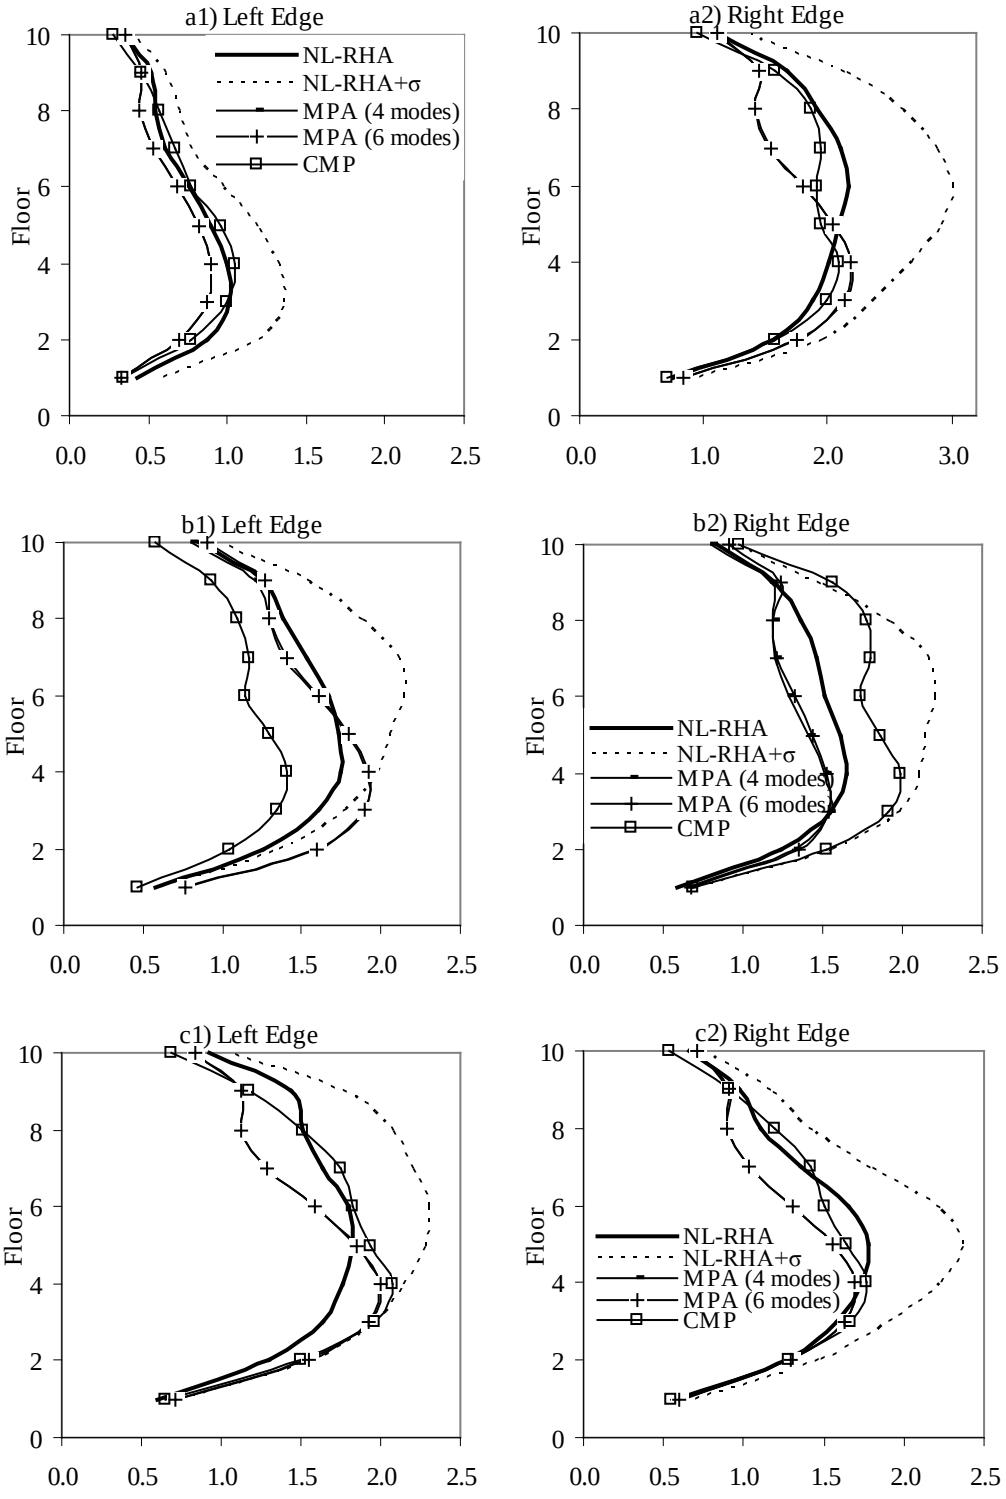

Figure 3. Height-wise variation of the storey drifts at the left and right edges: a) torsionally-stiff system; b) torsionally-similarly-stiff system; c) torsionally-flexible system

6. CONCLUSIONS

This article extends the consecutive modal pushover (CMP) procedure for unsymmetric-plan tall buildings to take torsional and higher mode effects into consideration. By conducting a large amount of analyses for the three types of unsymmetric-plan systems with different heights covering a wide range of periods, several

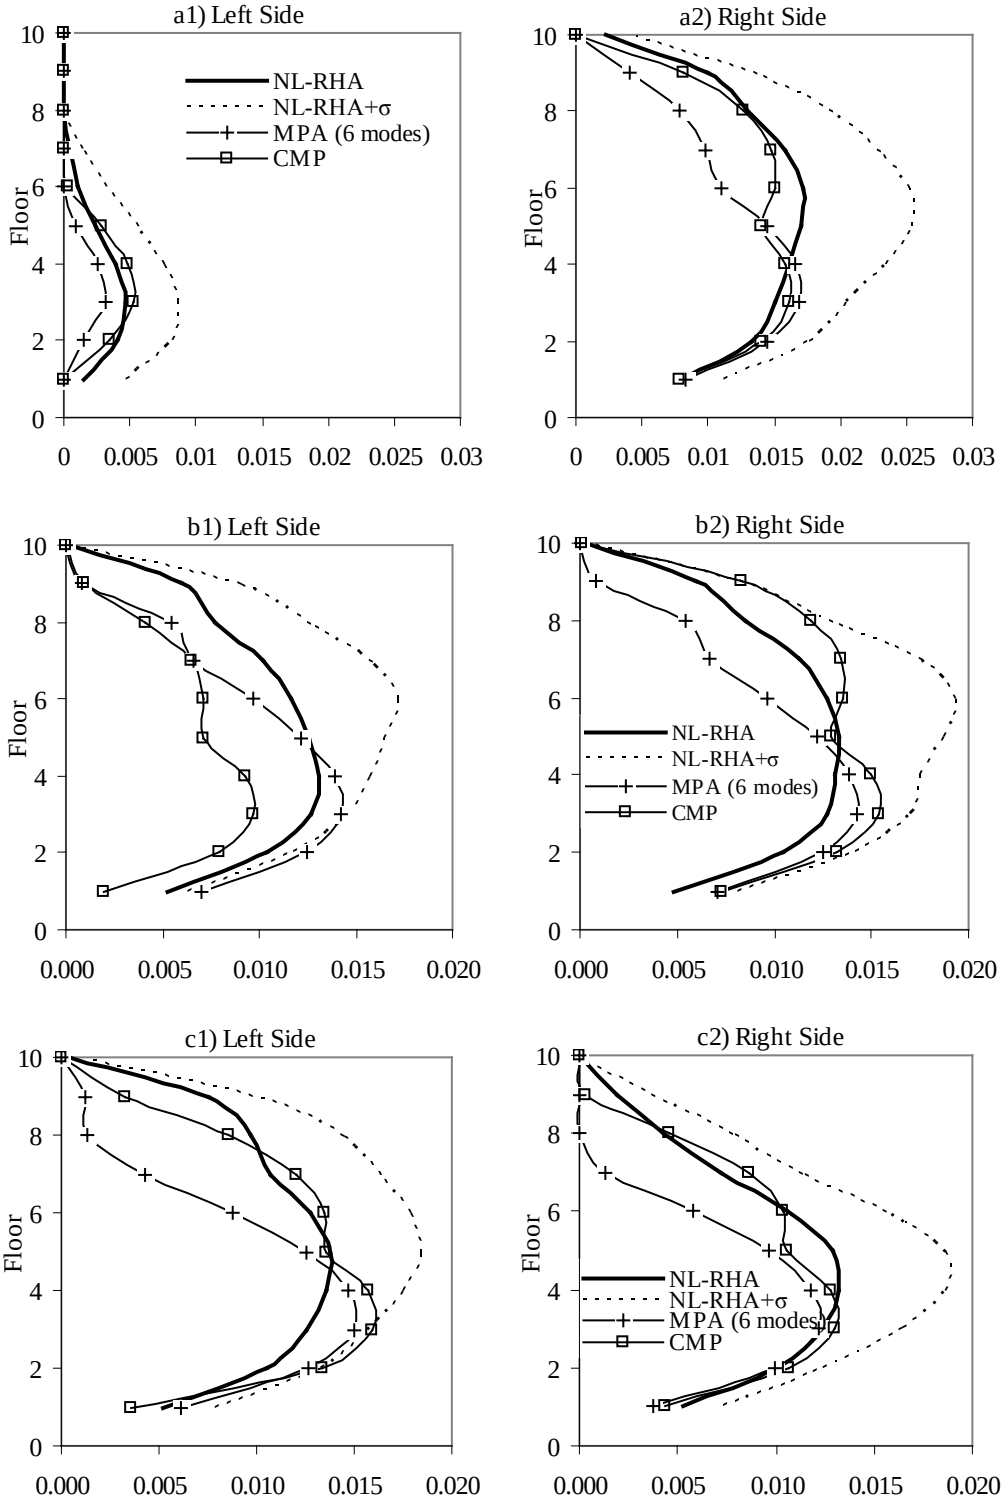

Figure 4. Height-wise variation of the hinge plastic rotations at the left and right edges: a) torsionally-stiff system; b) torsionally-similarly-stiff system; c) torsionally-flexible system

important conclusions are derived. The CMP procedure in general, provides accurate estimates of displacements and storey drifts at both flexible and stiff edges of torsionally-stiff, torsionally-similarly-stiff and torsionally-flexible systems, except at the stiff edge of torsionally-similarly-stiff systems, for which the predictions may occasionally deteriorate to some extent due to strong coupling of the lateral and torsional motions.

- There is, in general, not a large difference between displacements and storey drifts derived from the CMP and MPA procedures. Estimates of the storey drifts from the CMP procedure may be relatively better (sometimes more conservative) than those from the MPA procedure in several cases, especially at the mid and upper storeys. In other cases, the MPA gives better estimates of storey drifts than the CMP. Displacements and storey drifts derived from the CMP are better than those derived from the MPA at the flexible edge of torsionally-similarly-stiff systems, but the MPA procedure gives better estimates than the CMP procedure at the stiff edge of these systems.
- An excellent improvement has been, in general, achieved through the CMP procedure in predicting plastic rotations of the hinges at both flexible and stiff sides of unsymmetric-plan tall buildings in comparison with the MPA procedure. The improvement is achieved by incrementally applying the lateral forces during the stages of the multi-stage pushover analysis. This results in continuous accumulation of the plastic hinge rotations at the mid and upper storeys of unsymmetric-plan tall buildings.

Abstract: We developed an IT triage system for collecting disaster medical information in real time. FeliCa cards and card readers are used to obtain the number and condition of patients. The system is composed of two elements. First, the number of patients for each triage level and the accepted number of patients in each diagnosis and treatment department are obtained in real time, including response for changing triage level. Second, this information is shared in real time among hospitals, the administration, and residents who are searching for their family. A disaster drill utilizing this system was held at the University of Yamanashi Hospital with 450 participants.

1. INTRODUCTION

Disaster medical care during accidents and disasters both large and small is carried out with less medical resources in normal situations.

Disaster medical care consists of triage, transport and treatment. In the case of a disaster or accident, it is necessary to exert maximum effect with limited medical resources, but to accomplish these hospitals need to estimate the expected number and condition of patients. The advancement of triage, including understanding and ensuring the capacity of beds, tracking the status of patients' visits and transport to other hospitals, managing the assignment of the appropriate medical staff and the distribution of medical materials is necessary. On the other hand, information sharing is important effective acceptance and transportation. These actions are required across the entire region outside the hospital for setting up the disaster headquarters, coordinating all tasks with the government and other hospitals, and supporting the patients' family and media.

To advance the triage, it is necessary to obtain patient information, such as the victim's status and number staying at hospital, discharging from hospital, and being transported to other hospital, in digital form and in real time.

Research using a digital pen with triage results can digitize patient information (Ashida et al. 2008). However, it is difficult to manage patient status when triage level is changed and to understand the number of patient in different triage levels. In addition, the usage of RFID tags and mobile RFID network equipment collection system can collect the patient information using mobile devices in real time (Sonoda et al. 2007, Kusuda et al. 2009), but it is necessary to overwrite data when the triage level is changed so the management is complicated. Furthermore, the flow line of patients cannot be confirmed when patients are moved between departments.

For information sharing across an entire region, an information sharing system has been built to consolidate all kinds of information related to disaster conditions (The Ministry of Health and Welfare Health Policy Bureau 1996). With this system, staffs are necessary for entering the data in this system, but it is difficult to assign staff under the limited conditions during a disaster.

The purpose of this study is to develop a triage system which can collect and share the disaster medical information in real-time among hospitals including emergency medical institution both inside and outside the disaster area, with residents and with the government. In order to examine the feasibility and effectiveness of this system, it was applied to a large-scale disaster drill with 450 participants at the Yamanashi University Hospital.

Using this system, it is possible to estimate the number of patients in different triage levels in real time, to identify the number of patients visiting each department, to manage the triage level changes in real time and to share this information with related institutions across an entire region including

people looking for their family in hospitals.

2. PROBLEM SETTING

Traditional triage problems are summarized from the result of the triage drill held at Yamanashi University Hospital.

2.1 Summary of triage

A triage team normally consists of the triage officer, nurse and support staff. The team conducts the triage in front of the hospital building. Patients taken to the triage are transferred to the treatment zones: the mild zone (green), the moderate zone (yellow), the severe zone (red) and death zone (black), depending on the level of injury. If the hospital cannot treat the patient with heavy injuries or due to lack of resources, the patient is transferred to another other hospital.

2.2 Triage problem

The following problems with the current triage method were obtained from the result of the triage drill at Yamanashi University Hospital.

1. *Real-time information*: It takes a certain amount of time for the disaster headquarters to know the latest patient information such as the number of accepted patients and the number of patients in the different triage levels because the copy of the current triage tag containing patient information such as name, age, etc. and triage level is carried by volunteer staff to the headquarters after a certain amount of information is collected in each zone. Furthermore, it takes time to copy the information to the patient's list handwriting one by one. In addition, patient information is written on a white board in front of the hospital near the triage zone to for people looking for their family in hospitals.

Therefore, it is difficult to grasp the number of patients in real time and assign the proper medical staff to the each zone in this triage method. When there is a change of triage level, the management of its change is very difficult to update in real time. Also, some staff needs to work only for the management of patient's list. It can be wasted work under the limited resources of medical staff in the disaster.

2. *Information sharing with other medical institutions*: It is necessary to determine that; the patient needs to be transferred to other hospitals by such as the doctor helicopter, because of the heavy status of patient or the luck of hospital's resources. However, hospitals which need to transfer the patient cannot make a plan of transference of patient. Because hospitals don't know which other hospitals can accept the patient. On the other hand, the accepting hospital management also doesn't understand the status of coming patients.

The information sharing among related medical institutions is necessary for the effective transport in the entire region.

3. *Information sharing with the family and government*: The people look for the location of hospital in which their family is accepted due to the injury in the disaster. The hospital and the government asked by the people need to answer the location of hospital and the status of the family.

However, immediate response is difficult for the hospital in a situation of a huge number of patients. Because they cannot search the patient whom the family looking for in the paper-based patient's information and it takes a certain time to obtain the latest information.

In the point of the local government, even if the government needs to find the family where they are, the local government has to ask the possible hospitals one by one.
This situation is inefficient for all the relations, the family, the hospital and the government.

3. IT TRIAGE SYSTEM (TRACY)

TRACY has been developed as the triage system to solve the traditional problems observed in the result of triage drill and the things discuss as mentioned above. The structure and framework of this present system has been set after several interview and meetings with doctors and nurses in emergency department. This section describes the overview of this system.

3.1 System framework

We discussed the obtaining patient's information in real time and the sharing it in the whole area as main features. The obtained patient's information including the location, triage level and status of patient need to be updated in real time. It is effective and efficient to share the information for the patient transference to the other hospital. On the other hand, there are some advantages in traditional triage tag. When we need to know the patient's information such as name, age and triage level, the current triage tag can show those by seeing it without special operation. Therefore, both present system and current paper based triage tag are used.

3.2 Management of triage level changing

We discussed when the triage level change the information about triage level also should be changed without special operation of the system in real time. If there is a change of triage level of the patient such as patient moves to the new triage zone. When the patient arrive the entrance of the new zone, we proposed that the change can be recorded by the usual pass-processing used in present system. This method can update the triage level automatically without special and/or additional work. This method also can confirm the movement of the patient correctly.

3.3 Patient's family

To respond quickly to the people who are searching for their family member in the hospital, the staff can search the patient by using the search function of present system in the patient list. In addition, if the list can share in the whole area, it is beneficial for the government and the family living far from disaster area.

3.4 Sharing of patient information for transportation

We discussed that it is important to conduct the effective transporting in the entire region. This could be done

by understanding the condition of accepting patients in other hospital and then to decide whether the transporting is available. Therefore, the present system is required to show the condition of all related hospitals to decide the available transportation in the entire region.

3.5 Discussion of equipment

The following three points in selecting the equipment for this system were considered. 1) Using the equipment on a daily basis, because other than daily-life equipment does not work in a disaster. 2) Using low-cost equipment in order to spread to the lot of hospitals under the current economic condition for sharing information in entire area. 3) Using simple-operating equipment that is not required the special training for operation only for the disaster.

First, we discussed a handheld wireless UHF IC tag reader/writer that can write the patient information to the tag. But when the medical staff try to know the patient's information in the IC tag, the special operation is required. In addition to that, for the sharing information of patient in the entire area, same equipment is necessary to install in all related hospitals. In the consideration of cost, the writing function of the patient information to IC tags/cards is not the low-cost option.

Therefore, the concept of this system is to manage the patient's information in the server side. Then, the three method, IC tag, bar codes and FeliCa, were discussed how to recognize the patient ID. The IC tag is expensive, even for the models without the function of a tag writer. For bar codes, we have to consider the accuracy of reading the bar code, the preparation of bar codes in advance and the problem of cost. As the result of these factors, the bar code is actually difficult to apply to the management of patient for triage. For FeliCa, USB-friendly FeliCa reader can be purchased at lower prices. It is available to use the PC, which is used on the daily treatment in hospitals, for connecting it. In addition, FeliCa cards are used by a lot of people for the train pass, student ID, and electronic money on a daily basis. Recently, there is also mobile phone with a FeliCa function. Therefore, FeliCa can be applied on a daily basis to conduct the triage in the disaster. The operation is simple "waving the card to the reader" and there is potential to be expanded further spread.

From the above discussions, FeliCa is used as the configuration of the equipment in this system.

3.6 Constitution of "TRACY"

Table 1 shows the configuration of the equipment for this system by using FeliCa. There are advantages by applying FeliCa on the daily basis to the triage. For example, the database of the personal information such as name, date of birth and address for the daily service can be applied for the triage to recognize the each patient in the disaster by using FeliCa ID. In this case, the hospital is not required to ask the patient for the personal information and can be understand the patient personal data who cannot speak due to heavy injury. As there are many people who have the FeliCa for daily service, therefore hospitals are not necessary to ready the FeliCa card in advance for all unpredictable large number of patients.

The unique serial number of FeliCa can be considered as the patient ID. Therefore the hospitals and other related institution can easily share and manage the patient transfer by using FeliCa ID for the entire region.

Figure 1 shows an overview of this system. FeliCa reader and PC for pass processing are set at triage zone and each zone such as Black (deceased), Red (immediate), Yellow (delayed) and Green (minor), and the department of medicine and radiation. PC and FeliCa reader at the each point for pass processing can record the patient's zone pass time and location in the database server (Figure 2).

In the case for example, that the symptoms of patient is changed to the worse, the latest triage level can automatically be update in database server without special work or operation by conducting the usual pass processing in this system. This is same case, even if the symptoms improve.

Table 1 Constitution of "TRACY"

Equipment	Content	Setting location
FeliCa card	Managing the FeliCa ID as the patient's ID	Triage tag (bounded at back of triage tag)
FeliCa reader	Connecting to the PC for pass processing to read the FeliCa card	Doorway at each zone
PC for pass-processing	Pass-processing window	
PC for server	Consolidate information	Outside of damaged area

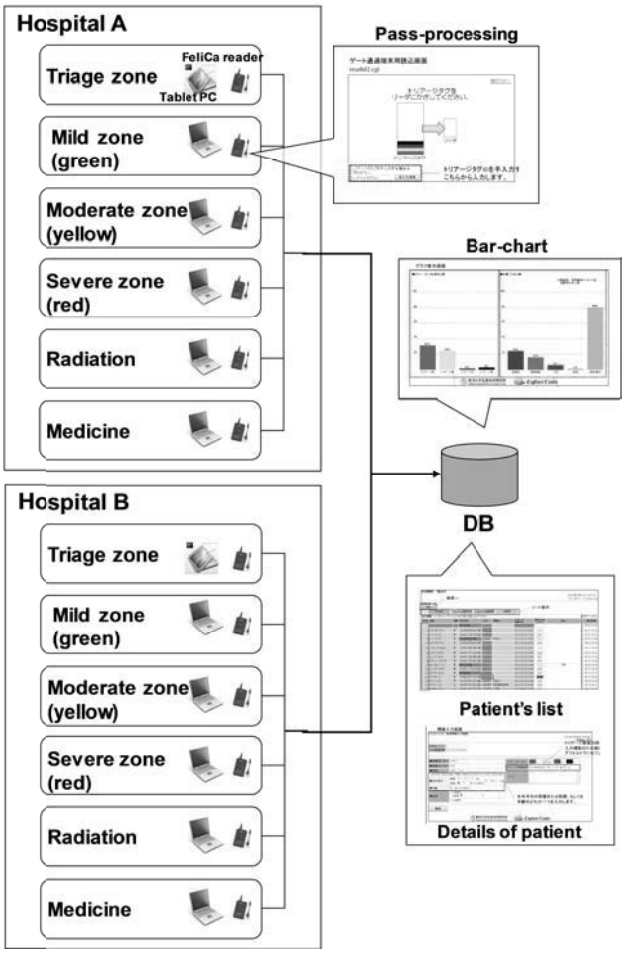

Figure 1 Overview of triage system "TRACY"

3.7 Content of input item

We consider following kinds of information are necessary for triage in TRACY.

From the hospital point of view, patient personal information and medical information are taken in to account as patient detail. But this triage system only covers the personal information (name, gender, date of date, etc.) but not medical information. Because misunderstood medical information may lead to medical errors and troubles.

As the result, input items of personal information such as name, date of birth, age, address, and free entry for the remarks are read with the triage tag. One example of using remarks is to write the patient exterior features such as the color of shirts, jacket, glass etc. to identify an individual who cannot speak due to heavy injured. Figure 3 shows the list of patients.

There is high possibility to stay or transfer to other hospitals for the patient with the level of Red (immediate) and Yellow (delayed). In case of those, the room or building of staying and the hospital name of transferring can be entered in this system.

The interface of the personal information window was made considering easy to be used by hospital staffs (Figure 4).

3.8 Visualization of patient data at the headquarters

It is important for the forward-command-headquarters directing the assignment of medical staff and the emergency-response-headquarters to take a proper action to manage the triage work based on understanding the situation such as the number of current accepted patients in the hospital, the number in the different triage level for each treatment zone in real time.

We discuss how to show those data in present system. As the result, the bar-chart showing the patient number in different triage level and the all patient list are necessary to analyze the condition of hospital for the triage officer at the both headquarters. The chart and the list can be updated automatically every 5 seconds. (Figure 5). When the patient's information is needed to edit, the details window of patient is available from the list of patient.

3.9 Preparation System

When a disaster occurs, the system must quickly starts with a minimum preparation of work as much as possible.

The present system is developed on the CGI (Common Gateway Interface). This system can work by the PC which can use WEB browser, is independent of PC type, and doesn't need any additional installation. The CGI program that runs on the WWW-server is independent of PC type/ OS and it can be work by the access form the browser of PC for pass-processing at the each zone. The result of the working of CGI returns to the browser of each PC at the zone.

As mentioned above, the digitize the patient information by FeliCa in real time can achieve not only the advancement of triage such as tracing of the patient treatment but also the sharing patient's information such as the transfer to the other hospitals, quick response to the person who asking of his/her family's location and coordination with the administration for the entire region.

4. VERIFICATION OF TRACY BY DEPARTMENT OF YAMANASHI UNIVERSITY HOSPITAL

The Yamanashi University Hospital in Yamanashi prefecture has experienced the triage drill since 2001. This triage drill becomes 10 times in total. The purpose of this drill is that the hospital staff makes accurate safety, accept the patient, implement triage and handle the treatment when the big earthquake occurs in Yamanashi prefecture.

The present triage system, TRACY, was examined its availability and practicality in the real disaster by applying the triage drill on this hospital with enough experience.

4.1 Triage drill of Yamanashi university hospital

In this triage drill, 48 doctors, 21 medical engineers, 48 nurses, 47 office staffs, 145 patients and support staff, totally approximately 450 people were attended. Participants were not only from this hospital, but also from the other hospital, the fire station, the government of Yamanashi Prefecture, the government of Kofu City, the government of Central City and residents.

The drill assumes the disaster level that, there is damage in the hospital building, but the lifeline and other medical equipment work normally. Therefore the triage and treatment are available even for a large number of visiting patients.

At 9:00 am a big earthquake with the epicenter of the west and southern area in Yamanashi prefecture caused a damage of houses, a fire and a traffic accident around the hospital. Then the staff in the hospital checks the status of the building damage and secures the safety of responsible department based on the disaster manuals and according to the instruction of the leaders of each department. All staff prepares to accept the number of patients as soon as possible. The team of triage set the necessary materials in the front of hospital building and to decide the triage level of each patient on the symptoms. After triage, the patient moves to the triage zone or is transferred to other hospital depending on the triage level.

4.2 Outline of installation of system

Table 2 shows the list of equipment of present system used in this triage drill. The PC set at Triage area in the front of hospital building, each triage zone, each treatment department and headquarters. Figure 6 shows the PC and FeliCa reader set at Department of Radiology. FeliCa cards is adhered to the back of triage tag, and managed to integrate triage tag and FeliCa cards together. As the reader of FeliCa card, the FeliCa port/ pasori (RC-S320) which is compatible with USB was used.

In this triage drill, FeliCa card has not been entered personal information such as name and date of birth, and assuming a situation in which these information was enter at the hospital. As for the timing and the person who enter the personal information, the patient information is input at the upstream process of triage to answer the person who asking from patient family as soon as possible. The special person who only input the patient data are assigned beside the doctors, nurses, clerks separately. By this way it can solve the

problem that the patient cannot move during the entering their triage result or personal information in present system. In the case of a large number of patients compared with the number of staff for data input, even if all the data entering is not completed, the personal data can be registered on a temporary basis, and then all staff can modify or update the content of the personal data at the each triage zone or headquarter.

All four triage teams consisted of triage officer (doctor), nurse and support staff (clerk) at the triage area.

The triage officer and nurse carry out usual triage work same as traditional triage way. On the other hand, the clerk read the FeliCa card to recognize its ID by Felica reader connected to the mobile PC by USB. Then clerks give the triage tag to triage officer, when just before triage officer

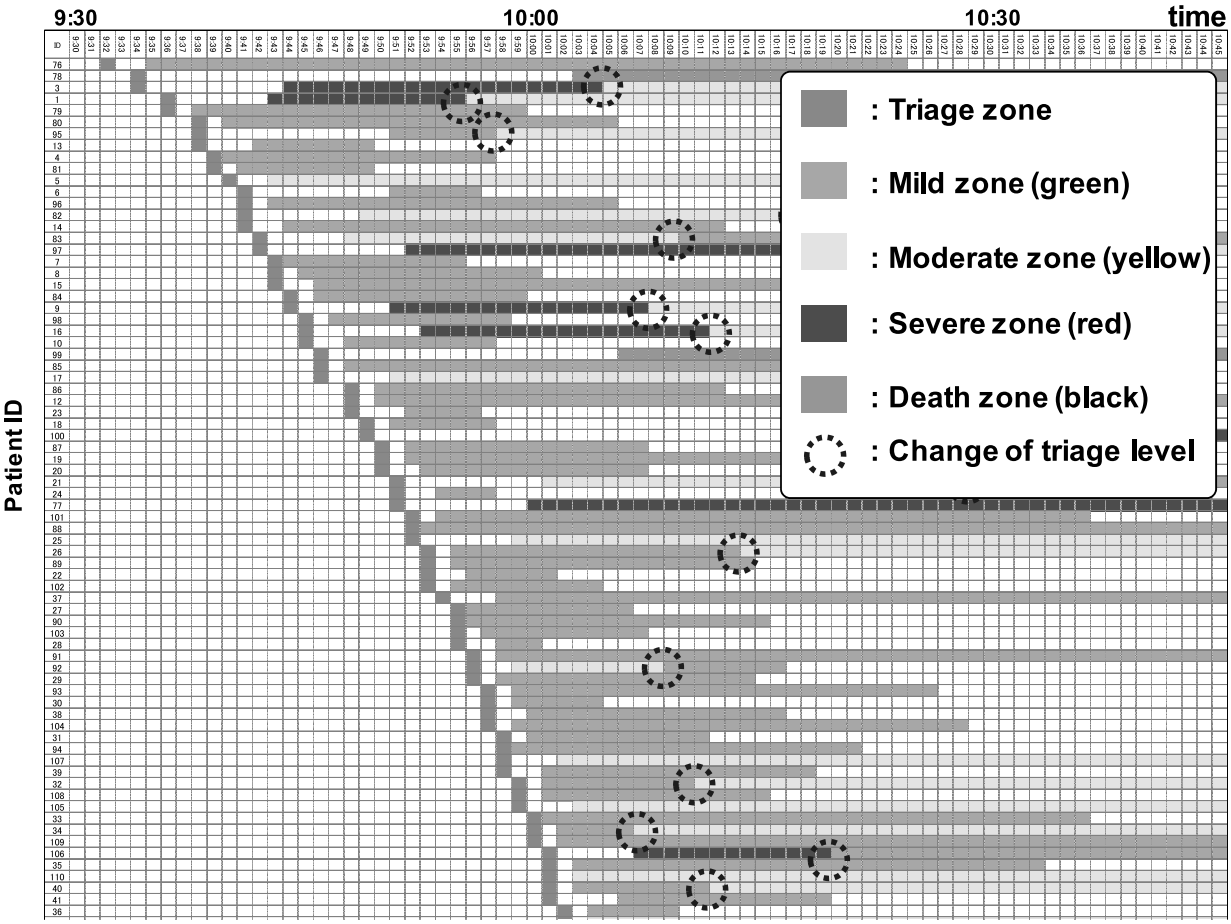

Figure 7 Time history of patient triage level

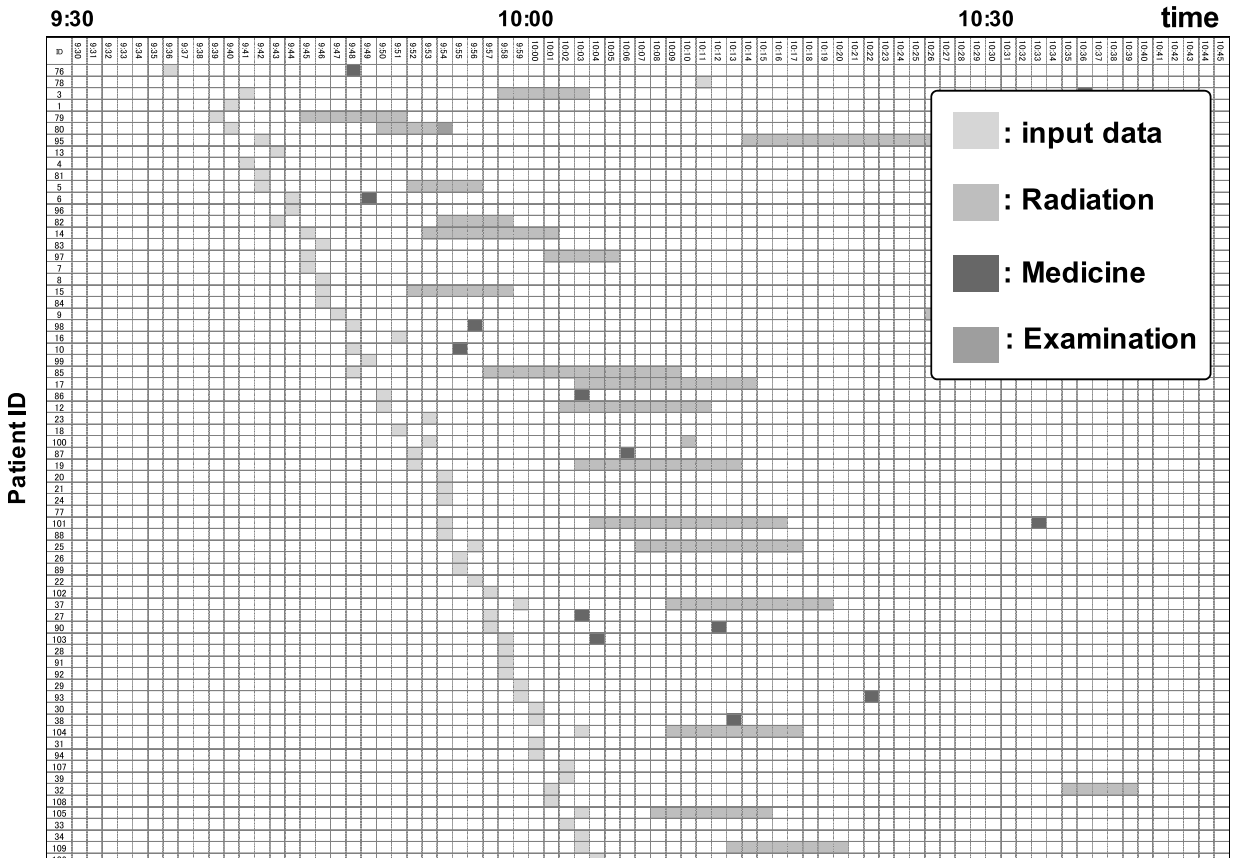

Figure 8 Time history of treatment department

begin to conduct triage. In this time, the only patient ID is input in the database.

After finishing triage, the clerk brings the first piece of triage tag (copy the paper written patient's information by triage officer) to the data-input-desk. Then the staff at the data-input-desk enters the patient's information such as the name, date of birth, age, address, remarks by reading the copy paper in the present system.

On the other hand, the patient who finished the triage moves to the each treatment zone. When the patient arrives at the zone entrance, the FeliCa card is read by the FeliCa reader to record the location and the time automatically as the pass-processing. This is same way for the other zone or department where the PC for the present system is set.

Thus, even if there is a change of triage level, it is possible to conduct the same pass-processing at the new place. The new triage level can be updated in the present system automatically in this way.

4.3 Result

1. *Time history of the patient changes*: Figure 7 shows the time history of each patient's triage level, taking the patient in the vertical axis and time in the horizontal axis. The staff in medical institute and the government can understand the triage level of all patients from the time when the patients are received in hospital to discharge from the hospital by following time history. The change of triage level also can be understood in this figure.

Figure 8 shows the time history of when each patient are taken the treatment in neuroradiology department, pharmaceutical department and inspection department. In the case of neuroradiology department, the time when the patient stay there is shown and maximum time of stay was 14 minutes for this drill.

Figure 9 shows the time history of the number of patients in each triage level. The number of patient in the Green zone has increased just after the triage drill starts, 50 patients stay there at 10:12, then, showing the tendency to decrease until 10:17. After that, the number of patients in green zone reached the maximum at 10:24. The first patient in red zone was accepted at 9:43, 5 patients were received treatment at 9:53. The first patient in black zone was accepted at 10:03, 3 patients were received at 10:21.

Similarly, Figure 10 shows the time history of the number of patients in each treatment zone. Neuroradiology department received the 9 patients at 10:09. Pharmaceutical department received 2 patients at 10:03, and not seeing the any remarkable concentration. Inspection department also did not show the remarkable concentration of patients, receiving 1 patient at 9:54.

2. *Response to the Changes of triage level*: Totally, there is the change of triage level for 20 patients (Figure 11). The change from the green to yellow was 8 patients, 1 patient from green to red, 5 patients from red to yellow, 5 patients from yellow to green, 1 patient from red to green. In this drill, because of over-triage was conscious, the change of triage level was affected by the over-triage.

b) Bar-chart seen at the forward headquarter

Figure 16 The forward headquarter

3. *Transport after triage*: It is possible to start treatment early, if we can reduce the lead-time from the triage zone in the front of hospital building to the each treatment. In particular, it is necessary to transport as soon as possible for the patients to be mild who is the majority to the all patients and not to make dwell time at triage zone in front of hospital building.

Figure 12 shows the lead-time from triage zone to the green zone for the 112 patients who were judged to be mild. 19 patients arrived at the green zone by taking 1 minute after triage, in the same way, 66 patients by 2 minutes, 17 patients by 3 minutes, and the average leading-time was 2 minutes and 18 seconds. This data can be understood that the support member respond quickly to transfer the patients.

Figure 13 shows the average travel time from triage zone to each treatment zone. The green zone shows the shortest time, 2 minutes and 18 seconds as described above. And also, the travel time from triage zone to yellow zone shows the average of 6 minutes and 18 seconds (20 patients), to red zone shows the average 12 minutes and 13 seconds (9 patients) and to the black zone shows the average 19 minutes 20 seconds (3 patients) respectively. The yellow and red zone shows the longer moving time. This is because that these zones locate far from triage zone compared to the green and black zone, and there are many patients transferred by using a stretcher or wheelchair due to the heavily injured.

4. *Input of personal information*: The time take from the triage to the complete of the personal data input such as name, day of birth etc. was average 3 minutes, minimum 1 minute and maximum 37 minutes (Figure 14).

The patient with the longest time of 37 minutes was deceased (black zone), it takes time to identify the individual. There is record that shows the personal features like "blonde hair, blue shirt, confirm of the dead at 9:34" in remarks. And also, from the time history, triage at 9:34, the dead is confirmed 9 minutes after that, transferred to the black zone, and then the personal data is entered.

As for the accuracy of the input item, there are 5 patients is with no input of name, 2 patients with no input of gender, 6 patients without date of birth data, 65 patients without address.(Figure 15). The 3 patients out of 5 patients without input of name are recorded showing with their feature like wearing black clothes as for personally identifiable information in the remarks.

5. *Assignment of medical staff*: The forward-command-headquarters directing the assignment of medical staff could take a proper action to manage the triage work based on understanding the situation such as the number of current accepted patients in the hospital, the number in the different triage level at each treatment zone in real time provided by the present system (Figure 16).

6. *Family support*: The family of patient visits to the hospital, which can be considered as that the family stays to look for patient status and location. However, immediate response is difficult for the hospital in a situation of a huge number of patients. Because they cannot search the patient, for whom the family is looking for in the paper-based patient's information. By using the key-word search function in the

present system in this drill, the all staff in hospital can search immediately the patient they are looking for.

5. CONCLUSION

This research developed an IT triage system for collecting disaster medical information in real time and sharing it among related institution in entire area. Felicia card and card-reader are used to constitute of this system to obtain the number and condition of patients etc. in real time.

A disaster drill was held at the Yamanashi University Hospital with 450 participants. TRACY was examined its availability and practicability by using in this drill. From the result of that, the present system can obtain the number of patients for each triage level and the accepted number of patients in each diagnosis and treatment department in real time, including response for changing triage level and the people looking for their family in hospital. In the point of the information sharing in the entire area, the patient's information can be shared among hospitals, the administration, and residents in real time.

The feedback and opinions were widely obtained from the entire evaluation meeting and the meeting with the mainly triage officer held after the triage drill.

From the results, the present system can solve the traditional problem such as the hospital cannot make a plan to receive the patients, the hospital cannot immediately answer the location and triage level of the patient to their families who are looking for details and it is impossible to take a proper action to manage the staff assignment for the forward-command-headquarters.

In addition, information on the degree of concentration of patients at each hospital can be shared between medical agencies and the governments in real time through the database. Therefore the patient transportation can be conducted by avoiding to the hospital which is busy or over capacity, and effective transportation is able to be achieved in the entire region. Although the patient concentration information is required high real-time data-collection, this system can work even if a large number of patients in the case of large-scale disaster.

Therefore, this system has the availability and practicability to the triage in the disaster.

On the other hand, we also discuss the issues and needs in the future.

(1) How we can consider the patients without reading the FeliCa card in the confusion/busy of hospital and the patient whose arm cannot move due to injury. We discuss the mobile type FeliCa reader is available to those patients.

(2) It is better to show the bar-chart and patient list at each zone or department to understand/share the latest status of entire hospital.

(3) The pass-processing can be additional work for the patients and staff. However, as this system can provide the status of hospital and share the data in entire region, the related people can take a better action.

(4) How we can set up the system as soon as possible after the disaster occurs. The present system can install to the PC which are used in the daily hospital working. This system is developed as the Web application, the client PC is not required installation in advance, and also, the present system can be used in a PC machine-independent. Therefore, the system can work by connecting only FeliCa reader to its PC.

These discussions are implementing to increase more practical level in the next drill. We will expand and examine TRACY according to the result obtained this triage drill.

Acknowledgements:

The authors acknowledge complete cooperation from the Department of Medicine at Yamanashi University hospital. This cooperation makes possible to develop and examine the present system. Especially, the authors got the valuable advice about system function and structures from Professor Kenichi Matsuda and Dr. Shoji Suzuki as a specialist of the emergency medicine. The authors also acknowledge support from the Japan Ministry of Education, Culture, Sport, Science, and Technology (MEXT) for development of present system.

Abstract: In recent years, performance-based engineering (PBE) has emerged as a viable alternative to prescriptive code-based procedures for design and analysis of individual buildings. However, growing interest in the prediction of community performance necessitates an updated and expanded design and evaluation framework for communities. This paper explores the many issues that arise when the PBE methodology is extended from individual buildings to entire communities. A conceptual framework for the performance-based design and evaluation of communities is presented and discussed. The proposed framework comprises two main parts: the first part outlines a procedure for establishing a graded set of performance objective for a community; the second part outlines a procedure-neutral methodology for evaluating whether specified performance objectives have been satisfied. An implementation strategy for the proposed framework is also discussed. While the proposed framework is currently in early stages of research and development, it lays foundations for a more consistent and transparent approach to predicting community performance.

1. INTRODUCTION

Currently, the design and evaluation process for individual buildings centers on satisfying various requirements specified in building codes. In the United States, most jurisdictions have adopted the *International Building Code*. These code-based procedures, which are deterministic and prescriptive in nature, provide the minimum criteria considered prudent for the protection of life safety (BSSC 2004, 2009). Structures that satisfy these requirements implicitly achieve certain levels of performance. However, an assessment of actual performance is not required. As a result, a building may perform better or worse than the level implicitly assumed by the building code (ATC 2006).

In recent years, performance-based engineering (PBE) has emerged as a viable alternative to traditional code-based procedures, offering several important improvements to the current design and evaluation process. First, PBE requires establishment of explicit performance objectives for a building. A performance objective typically comprises a reliability target, performance level, and hazard scenario; for example, a 90% probability of being operational immediately following the maximum considered earthquake. And second, PBE requires an evaluation of actual building performance, incorporating uncertainty in both demand and capacity. As a result, PBE provides a more accurate and reliable estimate of the expected performance of individual buildings in different hazard scenarios. Furthermore, building performance can be quantified in terms of repair costs, casualties, and downtime, metrics that are more meaningful to building owners and decision makers than estimates of forces and displacements.

Currently, the PBE methodology addresses the design and evaluation of individual buildings. In general, performance objectives established for individual buildings are not linked to broader performance targets for a community, which can frustrate efforts to reliably predict the performance of communities in different hazard scenarios. This growing interest in community performance necessitates an updated and expanded design and evaluation framework for individual buildings, as well as other important community components (including lifelines and organizations).

This paper explores issues relating to extending the PBE methodology from individual buildings to entire communities. Specifically, a performance-based framework for design and evaluation of communities is proposed and discussed. This conceptual framework enables a more complete understanding of community performance to be obtained.

2. EXTENSION OF PBE METHODOLOGY TO COMMUNITIES

2.1 Definition of Community

A community comprises three primary systems (adapted from Mileti 1999): the natural environment, social infrastructure, and physical infrastructure (see Figure 1). The

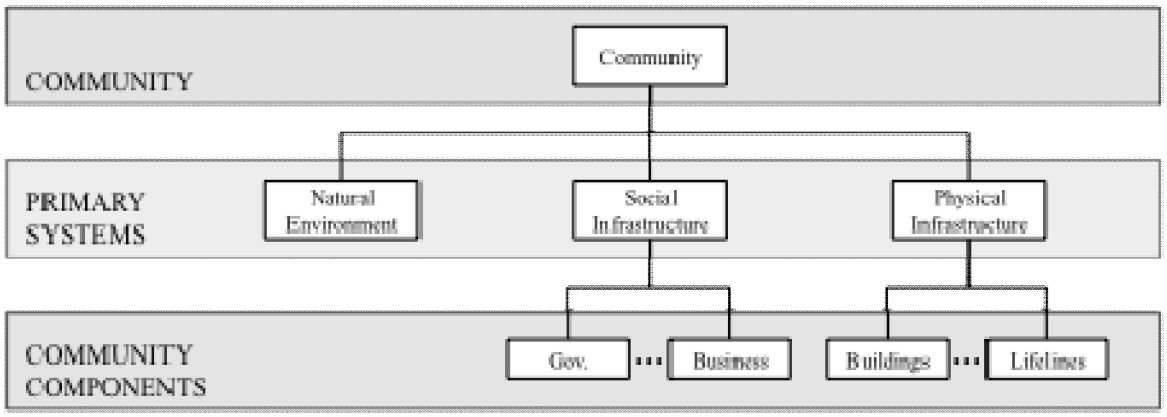

Figure 1 Hierarchal organization of a typical community

natural environment includes the land, water, and air surrounding a community, which give rise to natural hazards (earthquakes, hurricanes, floods, etc.). Social infrastructure refers to the public and private organizations and institutions that provide goods and services to a community. The physical infrastructure includes the human-made structures and systems that support the necessary functions of a community. These three systems are highly interdependent and interrelated. For example, many organizations within the social infrastructure rely on various components within the physical infrastructure to produce and deliver goods and services. These same organizations, however, may also have direct control over how the physical infrastructure is developed and maintained. Therefore, to obtain a more complete understanding of community performance, each system must be adequately addressed.

Each primary system comprises individual community components (see Figure 1). A community component is an element, network, or organization that performs a specific function in a community. Within the social infrastructure are government agencies (police and fire departments, etc.), businesses (banks, grocery stores, etc.), and other organizations. Within the physical infrastructure are buildings and lifelines. Lifelines include communication, electric power, liquid fuel, transportation, water, and waste disposal systems. Again, if a more complete understanding of community performance is to be obtained, all relevant community components need to be addressed in the design and evaluation process.

2.2 Proposed Framework

The proposed framework extends the PBE methodology from individual buildings to entire communities. It comprises two main parts. The first part of the framework (Figure 2) outlines a procedure for establishing performance objectives, first for the community in general and then for specific community components (buildings, lifelines, organizations, etc.). This graded approach ensures that performance objectives for individual community components are consistent with broader objectives established for the community, a step missing from current procedures. It also ensures that performance objectives are specified for all those components necessary to satisfying community-level objectives, including components in the physical and social infrastructure. A clear, well-graded set of performance objectives is crucial to improving the transparency and consistency of the design and evaluation process.

The second part of the framework (Figure 3) describes a methodology for evaluating whether specified performance objectives have been satisfied. The methodology attempts to be procedure-neutral: any analysis procedure can be used to evaluate performance as long as it produces an estimate of component reliability, where reliability is defined as the probability that specified performance levels are satisfied. This neutrality gives the

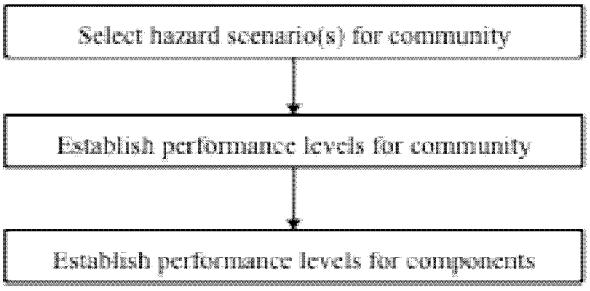

Figure 2 Procedure for establishing a graded set of performance objectives for a community

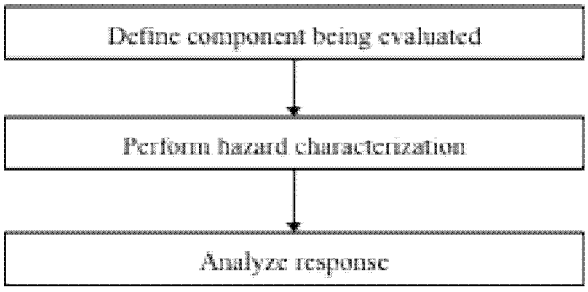

Figure 3 Procedure for evaluating the performance of a specific community component

designer or analyst flexibility in choosing the most appropriate or efficient method for evaluating performance. However, it should be noted that probabilistic procedures that address uncertainty in a consistent and transparent manner are preferable to deterministic ones.

3. DISCUSSION

In extending the PBE methodology from individual buildings to entire communities, many important issues arise. The following subsections discuss several of these issues.

3.1 Functional Correlation

Interaction between community components can significantly affect performance. Therefore, for a complete understanding of community performance to be obtained, these sources of interaction need to be identified and addressed. One source of interaction stems from functional correlation. Functional correlation arises when the functionality of one component depends on the functionality of other components.

To illustrate this concept, consider a hypothetical hospital with the following performance objective: 90% probability of remaining operational immediately after the maximum considered earthquake (MCE). In order to remain operational, the hospital building must suffer only minor structural and nonstructural damage. Furthermore, the hospital must also have uninterrupted access to important utilities (telecommunications, electricity, etc.). Both of these events must occur for the hospital to remain operational. The reliability, P_S, of the hospital can be computed using Eq. (1):

$$P_S = P(E_1 \cup E_2) = P(E_1 | E_2)\, P(E_2) \quad (1)$$

Where: E_1 and E_2 are the events defined in Table 1; the symbol $\cup$ denotes the intersection of two events (both events occur); $P(E_1 \cup E_2)$ is the probability that both E_1 and E_2 occur; $P(E_1 | E_2)$ is the probability that E_1 occurs given that E_2 has occurred; and $P(E_2)$ is the probability that E_2 occurs. So to calculate P_S, both $P(E_1 | E_2)$ and $P(E_2)$ need to be determined. $P(E_2)$ can be calculated directly through an analysis of the lifelines and/or emergency backup equipment that supply required utilities to the hospital. Computation of $P(E_1 | E_2)$ is less straightforward; however, Eq. (2) can be used to establish a lower bound on $P(E_1 | E_2)$:

$$P(E_1 | E_2) \geq P(E_1) \quad (2)$$

Table 1 Description of events that must occur for a hospital to remain operational

Event	Description
E_1	Hospital building suffers only minor structural and nonstructural damage
E_2	Hospital has uninterrupted access to important utilities

Eq. (2) results from the fact that E_1 and E_2 are positively related: if E_2 occurs (the hospital has access to required utilities), then E_1 is more likely to occur (the hospital suffers only minor structural and nonstructural damage). $P(E_1)$ can be calculated directly through an analysis of the hospital building. Using Eq. (2), a lower bound can be established for P_S:

$$P_S \geq P(E_1)\, P(E_2) \quad (3)$$

To make this example more concrete, consider that separate analyses have revealed $P(E_1) = 0.90$ and $P(E_2) = 0.90$. Using Eq. (3), $P_S \geq 0.90^2 = 0.81$. In other words, a lower bound estimate of the reliability of the hospital is 81%. Recall that the specified reliability target is 90%. Therefore, the hospital will likely fail to satisfy its specified performance objective.

This example highlights the significant impact of functional correlation. Under the current design and analysis process, a performance evaluation of the hospital would consider only the response of the building. In this scenario, the reliability of the hospital becomes:

$$P'_S = P(E_1) \quad (4)$$

Using the same quantities as before, $P'_S = P(E_1) = 0.90$. Therefore, the hospital appears to satisfy its specified performance objective. However, due to functional correlation, the actual reliability of the hospital will likely be less than 90% (and probably closer to 81%).

Because of its potentially significant impact on component reliability, functional correlation needs to be included in all applicable performance evaluations.

3.2 Human and Organizational Factors

In expanding the focus of the design and evaluation process to entire communities, the role of the social infrastructure must now be considered explicitly. Performance objectives should be established for important organizations and institutions within a community. The performance of these organizations and institutions should then be evaluated to determine whether specified objectives have been satisfied. These performance evaluations can be quite complex, as the following example illustrates.

Consider a hypothetical fire department with the following performance objective: 90% probability that all fires are suppressed within 24 hours of the MCE. To evaluate whether the department satisfies this objective, it is beneficial to translate it into more traditional engineering parameters of capacity and demand: 90% probability that the capacity of the fire department exceeds the demand induced within 24 hours of the MCE. Both capacity and demand depend on the performance of various components within the physical infrastructure. Capacity depends on the condition of water, electric, transportation, and communication lifelines, while demand depends on the number of damaged buildings and ruptured gas mains throughout the community. Furthermore, the capacity of the

fire department also depends on various human and organizational factors, including (but not limited to) the management structure of the department and the level of training and experience of personnel.

Because of their potentially significant impact on reliability, human and organizational factors need to be included in all applicable performance evaluations.

3.3 Community Boundaries

Unlike buildings, which have well-defined physical boundaries, communities are nebulous, complicated systems of components and interactions. As a result, it may be difficult to establish appropriate boundaries for a community. Geographical boundaries alone may be insufficient. Certain lifelines can span and/or service multiple cities, and may fall under the jurisdiction of various public or private agencies. As a result, individual cities may have varying levels of control over the lifelines within their geographical boundaries.

Furthermore, actions taken (or not taken) by one community may impact adjacent ones. For example, in an effort to improve resilience, a city might require local businesses to retrofit their buildings to decrease downtime and interruption following an earthquake. However, if these businesses rely on goods and services provided by businesses outside the jurisdiction of the city, the retrofit program may not be effective unless nearby cities do the same (because they will likely experience similar earthquake effects).

4. IMPLEMENTATION

The conceptual framework proposed in this paper is currently in early stages of research and development. As a result, many issues identified in the previous section require additional investigation. Despite this, it is beneficial to consider how the proposed framework might eventually be implemented in practice. The following subsections discuss several pertinent issues.

4.1 Community Code

To ensure uniform levels of performance from community to community, a national community code should be developed. This document would serve a similar role for communities as building codes do for buildings. It would specify a graded set of minimum performance objectives for a community. To ensure both consistency and feasibility, this set of minimum performance objectives should be established by a diverse group of community stakeholders, including engineers, government officials, city planners, economists, politicians, residents, and building owners. Minimum performance objectives should be established for all important community components, including buildings, lifelines, and various organizations.

Unlike current building codes, the proposed community code would not contain specific procedures for analysis of individual components. Instead, it would specify confidence factors associated with the use of different types of procedures. For example, more realistic, probabilistic analysis procedures, like those outlined in ATC (2009), would be assigned higher confidence factors than simple, deterministic ones, like those contained in current building codes (ICC 2006). This would allow the designer or analyst flexibility in choosing the most appropriate or efficient method for evaluating performance, while at the same time promoting use of more realistic analysis procedures.

4.2 Rating System

Because a large number of existing buildings, lifelines, and organizations would likely fail to satisfy the minimum performance objectives contained in the community code, a rating system should be developed. This rating system would expand the set of possible outcomes of a performance evaluation; instead of either satisfying or failing to satisfy its performance objective, a component would be given a rating based on its computed reliability.

For example, consider the hypothetical hospital analyzed in the previous section. The performance objective for the hospital specified a 90% probability of remaining operational immediately after the MCE. A performance evaluation revealed the actual reliability to be greater than 81% but less than 90%. Therefore, the hospital fails to satisfy its specified performance objective. However, if the rating system described in Table 2 were employed, the hospital would receive a rating of three stars.

A simple, clearly defined rating system would facilitate communication with the public regarding the expected performance of different components within a community, and may even incentivize retrofits or other performance upgrades.

4.3 Compatibility with Existing Procedures

One important feature of the proposed framework is that it is procedure-neutral: any analysis procedure can be used as long as it produces an estimate of reliability, P_S. As a result, current code-based procedures can be made compatible with the new framework. At the moment, however, these procedures do not require an estimate of P_S to be computed. To address this deficiency, standard values of P_S could be developed for various prototypical buildings with different occupancy categories and lateral force resisting systems. These standard values, which would represent conservative estimates of actual reliability, would automatically be achieved if the requirements of the building code are satisfied. This backwards compatibility is essential if the proposed framework is to be implemented successfully,

Table 2 Description of a simple rating system for community components

Rating	Reliability
Four stars	$P_S \geq 0.90$
Three stars	$0.80 \leq P_S < 0.90$
Two stars	$0.70 \leq P_S < 0.80$
One star	$P_S < 0.70$

as it eases the transition from current code-based procedures to more realistic, probabilistic ones.

5. CONCLUSIONS

The extension of the PBE methodology from individual buildings to entire communities requires consideration of many important issues overlooked by the current design and evaluation process, including functional correlation and human and organizational factors. If an improved understanding of community performance is to be obtained, these issues need to be addressed.

This paper has presented a conceptual framework for the performance-based design and evaluation of communities subject to hazards. The proposed framework comprises two main parts: the first part outlines a procedure for establishing a graded set of performance objective for a community; the second part outlines a procedure-neutral methodology for evaluating whether specified performance objectives have been satisfied. This paper has also discussed a possible implementation strategy for the proposed framework, including development of a community code, rating system, and standard P_S values for current code-based procedures.

While the proposed framework is currently in early stages of research and development, it lays foundations for a more consistent and transparent approach to predicting community performance.

Abstract: In Japan, the performance of modern seismically designed building structures has been good. However, non-structural damage is still significant and several people were injured by the collapse of ceiling boards in a 2005 earthquake. Ceiling failure can cause significant downtime and economic loss in addition to life safety risk. Previous studies have shown that ceiling collapse generally occurs at the connections behavior. Connection can be simulated by using a detailed numerical model. The ceiling system describes the likelihood of ceiling damage resulting from the connection damage. This paper describes the development of fragility curves for typical Japanese ceilings. Strength of the connection is obtained from previous experimental testing, and the connection shear force demand is calculated by using the elastic and inelastic 2D finite element analysis. The fragility of a typical Japanese ceiling system is then obtained by comparing the member/connection forces obtained from these analyses with the corresponding strengths generated randomly through Monte-Carlo analysis. Thus developed fragility is validated against the response of ceiling system in the shaking table test. The fragility curves can be used to probabilistically interpret ceiling performance as well as to estimate ceiling contribution to the overall building loss in earthquakes.

1. INTRODUCTION

Earthquakes are of concern because they can produce losses. The loss inducing process is simply described in Figure 1. Faulting occurs beneath the ground (1). This results in waves being distributed within the rock and soil which travel to the base of different structures (2). The shaking at the base of the structure, measured by an *Intensity Measure (IM)* such as peak ground acceleration or spectral acceleration, causes the structure to respond. *Engineering Demand Parameters (EDPs)* such as displacements and drifts tend to affect the structural elements and also partitions and cladding elements which are in contact with the different floors. On the other hand, *EDPs* in the form of accelerations at different levels can affect contents and other elements. If the *EDPs* are sufficiently large they can produce different types of damage, quantified by *a Damage Measure (DM)*. This damage results in loss, which can be measured in terms of the 3 D's – damage, death (injuries and life loss) and downtime (or business interruption). All of these can be expressed in terms of dollars, at least by the insurance industry. The probabilistic relationships between the different parameters should consider aleatory and epistemic uncertainty, before being combined through total probability theorem, to enable the uncertainty in the likely loss to be rationally evaluated.

Ceilings are the subject of investigation of this paper.

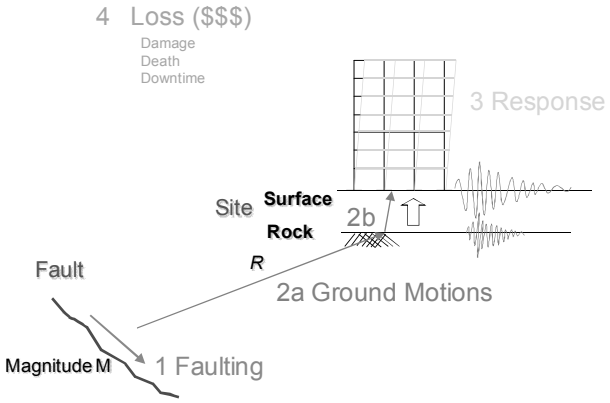

Figure 1. The effects of Earthquake Faulting on a Building

Figure 2. 2005 Miyagi prefecture earthquake damages

These may be attached in different ways to the floor above. Traditionally ceilings have not been designed by structural engineers, but have been considered to be architectural elements. However, as a result of ceiling damage and collapse, which has resulted in injuries and significant loss due to business interruption, it has been realized that a proper ceiling design is necessary.

Significant ceiling damage has been observed in the 2003 Tokachi oki earthquake, the 2005 Miyagi-ken oki earthquake (as shown for a swimming pool in Figure 2), the 2010 Chile earthquake, and the 2010 Canterbury Earthquake (Dhakal.R.P (2010)). In many of these cases the downtime had significant economic consequences. For example, the University of Canterbury was closed for 2 weeks because of heavy tile damage and ceiling collapse in several of the lecture theatres and libraries as a result of the Canterbury earthquake (Dhakal.R.P (2010)).

The aim of this paper is to describe and illustrate a method to answer the following questions:

1. How is a typical Japanese ceiling system constructed?
2. Which component is the most critical and hence important for *a Damage Measure (DM)* of a typical Japanese ceiling system?
3. What models are there to compute the demand force of the clips and the ceiling?
4. What methods are there to determine the capacity of the ceiling? And then, what is the capacity of a specific ceiling configuration, considering the statistical variation in element capacity, for a specified level of shaking?

2. TYPICAL JAPANESE CEILING SYSTEM

The typical Japanese ceiling system considered herein is composed of steel members and plaster board as shown in Figure 3. The M-bar, which is attached directly to the plaster board is connected to the channel with a clip. The clip is a unique metal part. It can be connected either in the front, or back, type of configuration as shown in Figure 4. This system is easily constructed and is widely used in Japan.

3. CEILING SYSTEM BEHAVIOR

The past earthquake damages and the previous studies (Motoyui et al. (2009)) have shown that the clip is the critical element that can cause the ceiling to fail and collapse. For horizontal loading along the axis of the channel, the channel can slide through the clip in both directions. There is no maximum displacement capacity in this direction. The failures that have been observed are due to horizontal loading of the ceiling perpendicular to the direction of the channel in Figure 4. To evaluate this behavior, experiments were performed with the setup shown in Figure 5 (Motoyui et al. (2009)). Here the ceiling is tested vertically, rather than horizontally, for simplicity in the direction perpendicular to the channel.

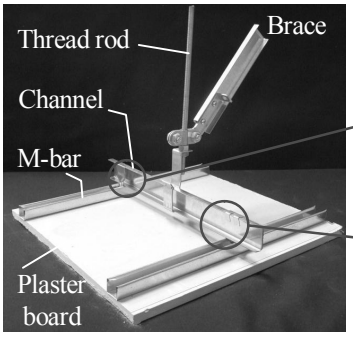

Figure 3. The typical Japanese ceiling

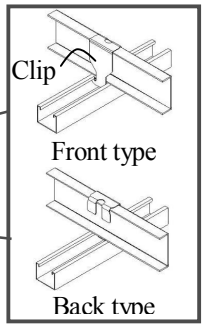

Figure 4. Clip type

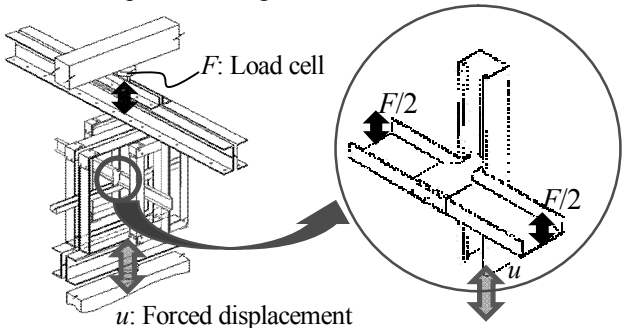

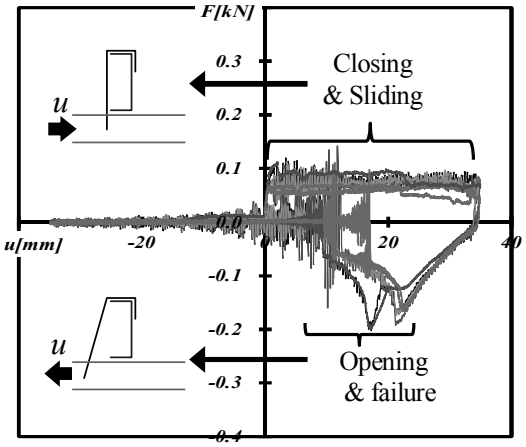

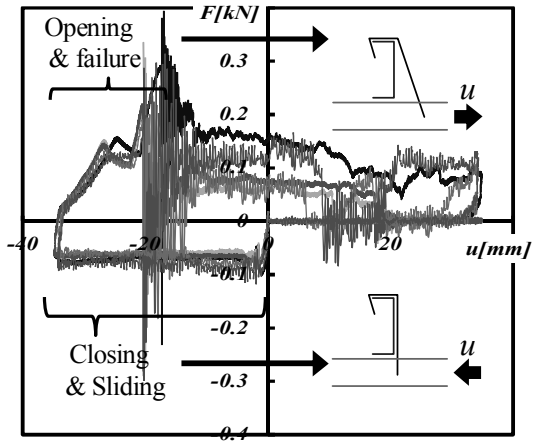

Figure 5. Experiment for Clip connection

a) The front type of clip

b) The back type of clip

Figure 6. The behavior of the clip connection

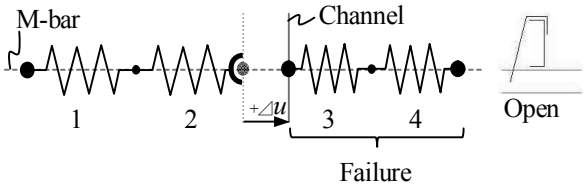
Figure 6 shows the cyclic push-pull behavior of the clip connection. It may be seen that the connection has two maximum strengths. When the clip moves away from the channel, it opens. As it opens, it undergoes plastic deformation and eventually separates from the channel allowing collapse. When the clip moves toward the channel, it slides on the m-bar when it reaches the sliding strength.

Table 1 describes the maximum strength in each test. The means and the standard deviation are obtained from these strengths. The information is used to create the connection strength in Monte Carlo method. Note that the sliding and failure strengths are different for opening and closing loading. This is because in one case the clip is on the back of the channel, and in the other case it is on the front.

4. THE ANALYSIS MODEL OF CEILING

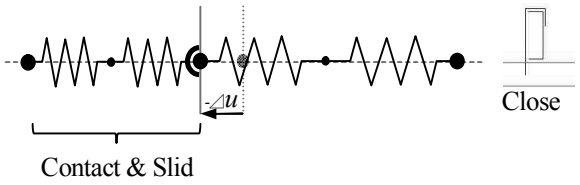
4.1 THE CONNECTION MODEL

The clip that first reaches its "failure" force, then governs the capacity of the system and determines the horizontal force resisted by the ceiling. The force in each clip can be computed with a structure analysis. The previous studies have developed numerical models to simulate the behavior of clip connections using sophisticated FE models (Motoyui et al. (2010)). This model is complicated and a long time is needed to perform the analysis. A simpler model described in Figure 7 is used in this paper. The model is composed of several beam elements. Element (1) has the sliding behavior by elastoplastic type restoring characteristic. The yield strength is equivalent to the sliding strength. Element (2) releases from or contacts with the channel. The gap between the m-bar and the channel occurs when the clip is opening. The compressive force in this element does not occur until the gap reaches zero. Element (3) has the opening behavior and failure strength, and resists only compressive force. Element (4) is the elastic element for supplying the stiffness when the clip is opening. The node between element (1) and element (2) (and between element (3) and element (4)), is independent of the m-bar element.



It may be seen in Figure 8 that the numerical model simulate the clip behavior well until the peak opening strength is reached. After this peak, the clip loses the performance of connection in the experiment. A more complex model is required to simulate the performance loss of connection. However, the model shown in Figure 7 can be reasonable to investigate the limit state of the ceiling system which changes from linear to nonlinear.

4.2 THE CEILING MODEL



The ceiling configuration selected for this study is one which was set on the roof slab in the 5 story full-scale building test on E-defense in 2009 (Motoyui et al. (2009)). The ceiling has the area of 4.5m x 6.5m and the mass of 585kg. The m-bars are placed 0.303 meters apart. The ground motions used were scaled versions (5%, 20%, 30%, 40%) of the records from the JR Takatori station captured during the

Figure 8. Comparison analysis and experiment

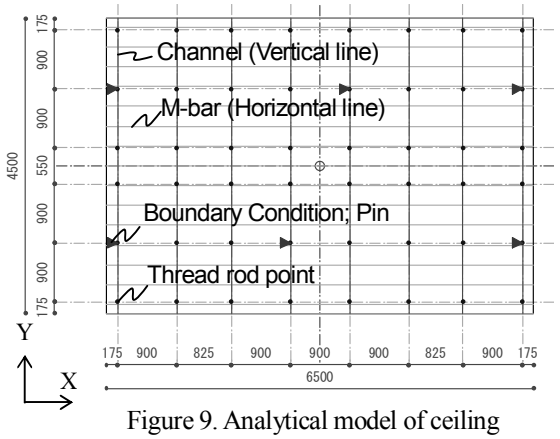

Figure 9. Analytical model of ceiling

M6.9 Kobe earthquake in Japan on 17th January, 1995.

The analysis model for investigating the capacity of the ceiling is described in Figure 9. This model has pin as the boundary condition at the points on Channels which have a brace. The direction of loading is parallel to the mbar, because the clips can be damaged significantly in this way of loading. Several models can be made by considering different combinations of the two types of clip.

Figure 10 shows the experimental measured response acceleration records of the ceiling when the ground motion was scaled to 5% and 20%. The result for the 5% records is scaled up 4 times in Figure 10. When the ground motion level was 20% in the E-defense test, it was observed in Figure 10 that the restoring force characteristic of the ceiling specimen became nonlinear. As a result of this the ceiling was damaged. When the ceiling behavior became nonlinear, the response acceleration of the ceiling was about 0.4g.

5. THE CAPACITY OF CEILING

The performance of a ceiling can be obtained directly from a suite of floor acceleration records. However, this is too complex for most designers. Also, it would be difficult to know if an error had been made in the analysis. For this reason two different methods are described below.

5.1 ELASTIC ANALYSIS

Computation of either the sliding or failure limit state acceleration is easily conducted using the following process.

For sliding and failure, the likely strengths of each connection, F_c, can be generated by the statistical Monte Carlo analysis. An analysis is carried out to determine the demand in each clip, F_d. The analysis model of a ceiling is composed of elastic beam elements and an arbitrary horizontal force, F_H, is applied to the ceiling model. The demand-to-capacity ratio for all clips, R (i.e. $R = F_d/F_c$), is determined for the limit state considered. The clip with the highest ratio is critical. The ceiling horizontal force for the limit state can therefore be computed by scaling the applied horizontal force by R, (i.e. $F_H/R = F_H'$). The acceleration corresponding to this limit state is $F_H'/m = A_{elastic}$. This calculation is then repeated many times with different values of capacity randomly generated from the capacity probability distribution obtained from MC analysis. The resulting accelerations therefore form a distribution which can be described by a cumulative density function or fragility curve.

The ceiling fragility curve from this process is shown in Figure 11. The ceiling can slide with the ceiling acceleration, about 0.2g and occurs of about 0.4g. For a given failure probability, the ceiling acceleration required to cause failure is about twice of that required for sliding. The ceiling fragility is close to the response acceleration of the ceiling obtained from the shaking table test; i.e. about 0.4g. This indicates that this simple approach of generating ceiling fragility curve is reasonably reliable.

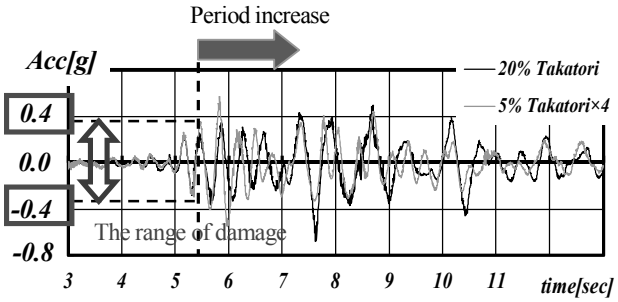

Figure 10. The response acceleration of ceiling

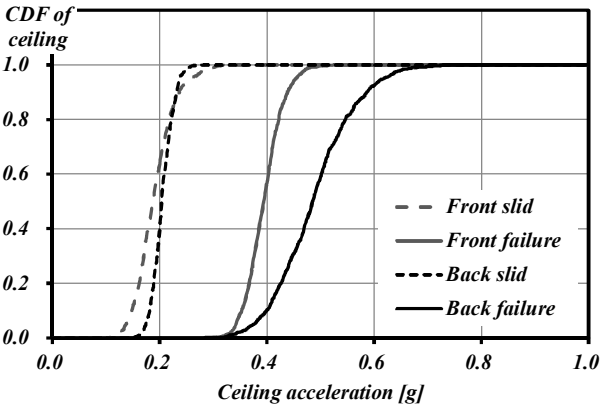

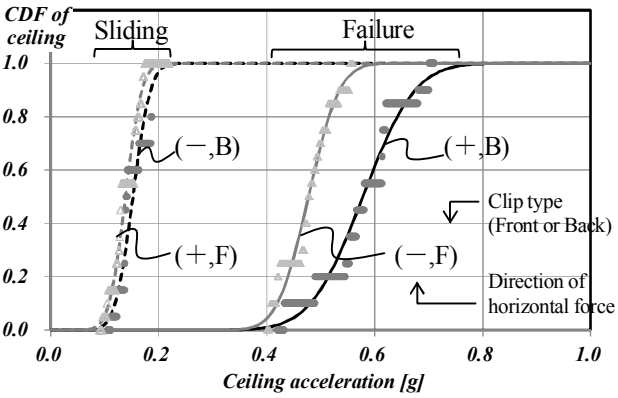

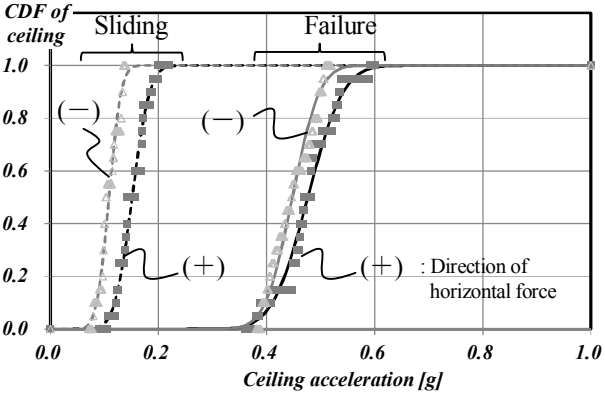

Figure 11. Ceiling fragility by elastic

a) All of clips are either front or back type

b) Front and back type alternately

Figure 12. Ceiling fragility by pushover analysis

5.2 PUSHOVER ANALYSIS

In the pushover method, strengths are generated for all clips based on Monte Carlo approach. A nonlinear static analysis is then conducted on the ceiling. Analysis stops when the force (or displacement) corresponding to the critical limit state is reached. Because of non-linearly, a new analysis must be conducted each time. This analysis is repeated with different sets of randomly generated clip strengths until a distribution of failure force is obtained. The failure force then needs to be converted into a failure acceleration. This may be done in several ways. In this study, the following method was used for simplicity. A conservative estimate of the acceleration may be simply determined as the forces divided by the mass, F_{max}/m.

In this study, three models were made; the first two had either front or back type at all clips while the thirds had both types alternately. The ceiling fragility curves from this method are shown in Figures 12. The connection can slide at a ceiling acceleration of, about 0.15g, and fail at about 0.5g. It is seen in Figure 12(a) that the capacity of ceiling depends on the direction of horizontal force when all clips are either front or back type. This is because the clips engage the sliding or failure strength according to the direction of loading. However, it is seen in Figure 12(b) that the effect of loading direction can be modified if two types of clip are arranged alternately in the ceiling. The ceiling fragility obtained from this approach is also close to the response acceleration of the ceiling measured in the shaking table test.

6. CONCLUSIONS

This paper describes methods of assessing the level of safety of a typical Japanese ceiling system. It was shown that:

1) The typical Japanese ceiling considered herein is composed of steel members and plaster board. The steel members are made of thin plate and have unique shapes. The clips, which connect the m-bar with the channels, can be connected either in the front or back type
2) The damage of clip can cause the ceiling to fail and collapse. The failures are due to horizontal loading of the ceiling perpendicular to the direction of the channel. The clip has two different values of maximum strengths in two directions of loading which correspond to the sliding and failure strength.
3) The behavior of clip can be simulated by using a simple model consisting of an elastoplastic beam element and contact beam element.
4) The capacity of ceiling was computed with 2 different methods which include a 2D static analysis and a statistical Monte Carlo analysis. These methods have different levels of conservatism and accuracy. The ceiling fragility curves by both methods were close to the response acceleration of ceiling when the ceiling was tested on a shaking table. This result describes that these methods to generate ceiling fragility curves are valid.

RESIDUAL HORIZONTAL DISPLACEMENT OF WATER PARTICLES IN THE VICINITY OF TSUNAMI SOURCE

Mikhail A. Nosov

Professor, Faculty of Physics, M.V. Lomonosov Moscow State University, Russia
nosov@phys.msu.ru

Abstract: Along with the tsunami waves, co-seismic bottom deformations result in formation of residual hydrodynamic fields in the ocean such as horizontal displacements of water particles and geostrophic vortex. This study is aimed at developing a method of calculation of the residual hydrodynamic fields. Initially, the problem is considered in the case of ocean of constant depth and cylindrically symmetric analytical solution of the problem is obtained. It is shown that under typical conditions the residual horizontal displacements of water particles can exceed tens or even hundreds of meters. At the same time, velocity and free surface disturbance in the geostrophic vortex exhibits negligibly small values. Considering the assumption of zero disturbance of free surface in the geostrophic vortex a practical method of calculation of the residual horizontal displacements of water particles is suggested. The method takes into account sphericity of the Earth, real bathymetry and co-seismic bottom deformation in a tsunami source. Finally, the method is applied for the estimation of the residual horizontal displacements of water particles in the vicinity of the 2003 Tokachi-oki tsunami source. Perspectives of usage of the static hydrodynamic fields for the sake of tsunami warning are discussed.

1. INTRODUCTION

Strong bottom earthquakes are the most widespread cause of origin of tsunami waves (Historical Tsunami Database for the World Ocean, http://tsun.sscc.ru/nh/tsunami.php). The most effective mechanism of tsunami generation is associated with the so called co-seismic (residual, permanent, static) deformation of ocean bottom resulted from earthquake (e.g. Dotsenko and Soloviev 1995, Levin and Nosov 2008, Nosov and Kolesov 2010). The permanent deformation implies that during the generation process of a tsunami a huge volume of water (up to tens of cubic kilometers) is been displaced from its equilibrium position (Grilli et al. 2007, Nosov and Kolesov 2009, Bolshakova and Nosov 2011). The spreading of this huge volume of water in the vicinity of tsunami source has certainly to result in a horizontal displacement of water particles from their initial positions. At the same time, due to the Earth rotation, a geostrophic vortex should arise in the vicinity of tsunami source (e.g. Dotsenko 1999). In what follows, we shall call the horizontal displacements of water particles and the geostrophic vortex the "residual hydrodynamic fields".

The main purpose of this study is to develop a practical method of calculation of the residual hydrodynamic fields and to reveal which of them could be detectable in reality, e.g. by means of GPS buoys (drifters). In fact, along with DART and JAMSTEC deep-water tsunami measurements (Hirata et al 2002, Meinig et al 2005), the residual hydrodynamic fields represent an additional set of parameters which may be useful in tsunami warning system.

Note that the idea of using of GPS buoys for tsunami detection had been already discussed in some papers (Kato et al. 2000, Falck et al. 2010, Nagai 2010). However, authors of these publications suggested detecting tsunamis by means of measurement of vertical displacement of a GPS buoy while a tsunami is passing. In the long oceanic waves (including tsunamis) the horizontal displacements of water particles turn out to be many times larger as compared with the vertical ones and, in particular, with the displacements of ocean surface. So, as for tsunami detection in the open ocean with use of GPS buoys, measurements of the horizontal displacements are surely more promising.

In this study, first, we suggest a method of calculation of the residual fields. Second, we consider a simplified case of constant ocean depth and analytically derive some general assessments for the horizontal displacements of water particles and for the velocity in geostrophic vortex. Third, we develop practical method of calculation of the horizontal displacements taking into account sphericity of the Earth, real bathymetry and bottom deformation. Finally, we apply the developed method to the 2003 Tokachi-oki tsunami source and discuss perspectives of usage of the residual hydrodynamic field in tsunami warning system.

2. MATHEMATICAL MODEL

2.1 Basic Equations and Assumptions

Consider a layer, infinite in the horizontal directions, of an ideal incompressible homogeneous liquid of variable

depth H in the field of gravity on a rotating Earth. We restrict ourselves to the linear long-wave theory which represents traditional approximation in tsunami simulation technique. Initially we assume the domain under consideration to be small enough to neglect the sphericity of the Earth. So, the set of shallow water equations can be written in the Cartesian reference frame ($0x$-axis is directed eastward, $0y$-axis - northward)

$$\frac{\partial \xi}{\partial t} - \frac{\partial \eta}{\partial t} + \frac{\partial M}{\partial x} + \frac{\partial N}{\partial y} = 0, \quad (1)$$

$$\frac{\partial M}{\partial t} = -gH\frac{\partial \xi}{\partial x} + fN, \quad (2)$$

$$\frac{\partial N}{\partial t} = -gH\frac{\partial \xi}{\partial y} - fM, \quad (3)$$

where ξ is the free-surface displacement from the equilibrium position, $M = UH$, $N = VH$ are components of the total water flux along the $0x$ and $0y$ axes, respectively, U and V are the respective flow velocity components, η is vertical bottom deformation, g is the acceleration of gravity, $f = 2\omega \sin\varphi$ is the Coriolis parameter, ω is the angular velocity of the Earth's rotation, φ is the latitude.

The liquid is at rest until the time moment $t = 0$, i.e. $M = N = \xi = \eta = 0$. The dynamic bottom deformation occurs in accordance with an arbitrary law, $\eta(x,y,t)$. The motion will take place during a time interval τ, upon which the ocean bottom stops. Such a process results in a residual deformation of bottom, $\eta(x,y,\tau)$. Bottom motions give rise to disturbances of water layer including tsunami waves and residual hydrodynamic fields: potential and rotational.

According to Helmholtz's theorem, a vector field can be resolved into the sum of an irrotational (curl-free) vector field and a solenoidal (divergence-free) vector field. Let us express the 2D vector field of water flux (M,N) via the potential φ and the stream function ψ

$$M = \frac{\partial \varphi}{\partial x} + \frac{\partial \psi}{\partial y}, \quad (4)$$

$$N = \frac{\partial \varphi}{\partial y} - \frac{\partial \psi}{\partial x}. \quad (5)$$

Substituting expressions (4) and (5) in the continuity equation (1) we readily eliminate the stream function ψ and arrive at the following equation:

$$\Delta\varphi = \frac{\partial \eta}{\partial t} - \frac{\partial \xi}{\partial t}. \quad (6)$$

Integrating equation (6) with respect to time from 0 to T, we reduce the evolutionary problem to static problem

$$\Delta\Phi = \eta_T - \xi_T, \quad (7)$$

$$\Phi \equiv \int_0^T \varphi \, dt, \quad (8)$$

where T is the time moment upon which tsunami waves leave the area under consideration, $\eta_T \equiv \eta(x,y,T) = \eta(x,y,\tau)$ is the residual deformation of bottom, ξ_T is the residual free surface disturbance associated with geostrophic vortex in tsunami source. In formula (7) we introduce, instead of the velocity potential, a new quantity Φ which can be interpreted as the displacement potential. Potential residual field, i.e. residual displacements of water particles in the horizontal direction, can be expressed via Φ in the following way:

$$X_T = \frac{1}{H}\frac{\partial \Phi}{\partial x}, \quad (9)$$

$$Y_T = \frac{1}{H}\frac{\partial \Phi}{\partial y}. \quad (10)$$

In case of arbitrary bottom topography, determining of the vortex residual field involves certain difficulties. The point is that a static vortex current should be adapted to the bottom topography so that the current is directed along isobath (e.g. Zyryanov 2006). Considering the case of constant depth, one easily avoids the problem of adaptation. So, in the next section, we process further evaluations of the equation (2) and (3) under the following condition: $H = const$.

2.2 Constant Depth Case: Analytical Solution

In what follows, along with the assumption of constant ocean depth, for simplicity, let us also consider the Coriolis parameter to be constant. Note that this assumption is quite reasonable if the domain under consideration is small enough. Taking the x-component partial derivative of (3) and subtracting from it the y-component partial derivative of (2) we eliminate the quantity ξ. Introducing potential and stream function in accordance with formulae (4) and (5), we ultimately obtain

$$\frac{\partial}{\partial t}\Delta\psi = f\Delta\varphi. \quad (11)$$

Integrating equation (11) with respect to time from 0 to T, we arrive at the following formula:

$$\Delta\psi_T = f\Delta\Phi, \quad (12)$$

where ψ_T is the stream function at the time moment T. Velocity components in the residual geostrophic vortex can be expressed via the stream function in the following way:

$$U_T = \frac{1}{H}\frac{\partial \psi_T}{\partial y}, \quad (13)$$

$$V_T = -\frac{1}{H}\frac{\partial \psi_T}{\partial x}. \quad (14)$$

From the time moment $t = T$, all the motions of water exist in the form of a static geostrophic vortex. Setting in equations (2) and (3) $\partial/\partial t = 0$ and taking the x-component partial derivative of (2) and the y-component partial derivative of (3), we summarize the equations. Finally, expressing components of vortex flux via the stream

function, we arrive at the following equation:

$$\Delta\xi_T + \frac{f}{gH}\Delta\psi_T = 0. \qquad (15)$$

Equations (7), (12) and (15) represent a closed system of equations (unknown functions: ξ_T, ψ_T, and Φ) which allows determining all the residual hydrodynamic fields in the vicinity of tsunami source from the known static bottom deformation, η_T.

From equations (7), (12) and (15) one can easily derive the following equation for the static disturbance of water surface, ξ_T:

$$\Delta\xi_T + \frac{f^2}{gH}(\eta_T - \xi_T) = 0. \qquad (16)$$

Note that the equation (16) can be solved separately. This is the first step in solving the whole problem (7), (12) and (15). Knowing the function ξ_T, one can make the next steps, i.e. solve equations (7) and (12).

In practice, ξ_T turns out often to be negligible as compared with η_T. In order to prove it, let us introduce the horizontal scale L which can be interpreted as horizontal extension of tsunami source. Equation (16) gives us ground to link amplitudes of ξ_T and η_T by the following approximate formula:

$$|\xi_T| \sim \frac{\alpha}{1-\alpha}|\eta_T|, \qquad (17)$$

$$\alpha = \frac{f^2 L^2}{gH}.$$

Under typical conditions ($f \sim 10^{-4} s^{-1}$, $H \sim 10^3 m$, $L \sim 10^5 m$, $g \sim 10\, m \cdot s^{-2}$: $\alpha \sim 0.01$) the free surface disturbance in geostrophic vortex turns out to be much smaller than bottom deformations, $|\xi_T| << |\eta_T|$. This makes it possible to essentially simplify equation (7) at the expense of neglecting the unknown term, ξ_T. So, equation (7) is reduced to the following one:

$$\Delta\Phi = \eta_T. \qquad (18)$$

Poisson's equations (18) can be readily solved. At the same time, with account of equation (18), formula (12) reduces to the following form:

$$\Delta\psi_T = f\,\eta_T. \qquad (19)$$

Ultimately, with use of Poisson's equations (18) and (19) the residual hydrodynamic fields can be estimated from known static deformation of bottom, η_T.

Let us next consider the case of cylindrical symmetry. We shall further restrict ourselves to dealing with the residual bottom deformations specified by formula

$$\eta_T(r) = \eta_0[1 - \theta(r - R)], \qquad (20)$$

where θ is the Heaviside step function, R is the radius of tsunami source, η_0 is the amplitude of vertical bottom deformation.

In the cylindrical coordinates, equations (18) and (19) take the following forms:

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\Phi}{\partial r}\right) = \eta_T(r), \qquad (21)$$

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\psi_T}{\partial r}\right) = f\,\eta_T(r). \qquad (22)$$

Analytical solutions of (21) and (22) allow determining residual displacements of water particles in horizontal direction (along radius)

$$D_T(r) = \frac{1}{rH}\int_0^r \hat{r}\,\eta_T(\hat{r})\,d\hat{r} \qquad (23)$$

and vortex velocity (normal to radius)

$$V_T(r) = -\frac{f}{rH}\int_0^r \hat{r}\,\eta_T(\hat{r})\,d\hat{r}. \qquad (24)$$

The sign in formula (24) means that in the Northern hemisphere bottom uplift ($\eta_T > 0$) result in formation of geostrophic vortex rotating in the negative direction, i.e. clockwise.

Substituting formula (20) in the solutions (23) and (24), one can derive the following simple formulae for the horizontal displacement, D_T and the vortex velocity, V_T:

$$D_T(r) = \frac{\eta_0 R}{2H}\begin{cases} r/R, r \le R \\ R/r, r > R \end{cases}, \qquad (25)$$

$$V_T(r) = -\frac{\eta_0 R f}{2H}\begin{cases} r/R, r \le R \\ R/r, r > R \end{cases}. \qquad (26)$$

Functions (25) and (26) have local maxima at the boundary of the tsunami source, i.e. at $r = R$. Under typical conditions ($\eta_0 = 1\,m$, $R \sim 10^5 m$, $H \sim 10^3 m$, $f \sim 10^{-4} s^{-1}$), the horizontal displacement and the vortex velocity reach the value of $D_{max} = 50\,m$ and $V_{max} = 5 \cdot 10^{-3}\, m \cdot s^{-1}$. In accordance with formula (17), free surface disturbance in geostrophic vortex can be estimated as $|\xi_T| \sim 0.01|\eta_T| = 0.01m$. So, the horizontal displacement is large enough to be detected in-situ whereas the vortex velocity and free surface disturbance in geostrophic vortex are negligible and hardly detectable on practice. However, the maximal values can be significantly increased in the case of large amplitude of bottom deformation and shallow water. For example, taking the following set of parameters: $\eta_0 = 5\,m$, $R \sim 10^5 m$, $H \sim 250\,m$, $f \sim 10^{-4} s^{-1}$, one readily obtains $D_{max} = 1000\,m$ and $V_{max} = 0.1 m \cdot s^{-1}$. Note that in this case, in accordance with formula (17), free surface disturbance in geostrophic vortex still remains much smaller as compared with bottom deformation, $|\xi_T| \sim 0.04|\eta_T| = 0.2\,m$.

2.3 Arbitrary Bathymetry Case: Numerical Solution

The most important outcome of the analytical part of this study is that the residual horizontal displacements of water particles due to co-seismic bottom deformation can

reach tens or even hundreds of meters. Such values can be easily registered in-situ, e.g. by means of GPS drifters. At the same time, velocity in geostrophic vortex due to co-seismic bottom deformation is very slow, i.e. the vortex can not disturb the field of residual horizontal displacements much. Moreover, as it has been shown in previous section, $|\xi_T| << |\eta_T|$. This relation gives us ground to assume the function $\xi_T = 0$ in equation (7).

In this section we suggest a practical method of calculation of the residual horizontal displacements of water particles for real tsunami source and real bathymetry. Here we cancel the restriction of smallness of the domain under consideration. Taking into account the sphericity of the Earth we write the equation of continuity in spherical coordinates

$$\frac{\partial \xi}{\partial t} - \frac{\partial \eta}{\partial t} + \frac{1}{\rho \cos(Lat)} \frac{\partial M}{\partial Lon} + \frac{1}{\rho \cos(Lat)} \frac{\partial (\cos(Lat) N)}{\partial Lat} = 0, \quad (27)$$

where Lon is the longitude, Lat is the latitude, $\rho = 6371\,km$ is the mean radius of the Earth, $M = HV_{Lon}$, $N = HV_{Lat}$ are the water flux components along the parallel (west–east) and along the meridian (north–south), respectively.

In the same way as it has been done in section 2.1, introducing potential φ and stream function ψ in (27) and integrating the equation with respect to time from 0 to T, we arrive at the following expression:

$$\frac{1}{\rho^2 \cos^2(Lat)} \frac{\partial^2 \Phi}{\partial Lon^2} + \frac{1}{\rho^2 \cos(Lat)} \frac{\partial}{\partial Lat} \left(\cos(Lat) \frac{\partial \Phi}{\partial Lat} \right) = \eta_T . \quad (28)$$

While deriving equation (28), we assume $\xi_T = 0$.

Components of the residual displacements of water particles along the parallel, D_{Lon}, and along the meridian, D_{Lat}, are expressed via the potential as follows:

$$D_{Lon} = \frac{1}{H \rho \cos(Lat)} \frac{\partial \Phi}{\partial Lon}, \quad (29)$$

$$D_{Lat} = \frac{1}{H \rho} \frac{\partial \Phi}{\partial Lat}. \quad (30)$$

At the coastline the residual displacements of water particles normal to the coastline vanishes. So, at the coastline one have to require the equality to zero of the derivative normal to the coastline of the potential, Φ:

$$\frac{\partial \Phi}{\partial \vec{n}} = 0. \quad (31)$$

Simple free pass boundary condition is specified on the ocean-crossing outer borders of the computational domain

$$Lon = Lon_{min}, Lon_{max} : \frac{\partial^2 \Phi}{\partial Lon^2} = 0, \quad (32)$$

$$Lat = Lat_{min}, Lat_{max} : \frac{\partial^2 \Phi}{\partial Lat^2} = 0. \quad (33)$$

The conditions (32) and (33) imply that the residual displacements at boundary and at the closest internal points are equal.

Poisson's equation (28), supplemented with the boundary conditions (31) – (33) was solved numerically on a rectangular net with use of implicit finite differences method.

3. RESULTS AND DISCUSSION

In this section, taking the 2003 Tokachi-oki earthquake as an example, we shall describe how the method developed above can be applied in practice. The 2003 Tokachi-oki earthquake of JMA magnitude (MJ) 8.0 occurred off the south-eastern coast of Tokachi district at 04:50:06 JST on September 26, 2003. This earthquake turned out to be the strongest seismic event of the year. In spite of its strength, the 2003 Tokachi-oki earthquake generated rather moderate tsunami with a wave height up to 4.3 m (Ohmachi and Inoue 2010).

The computational domain extends from 139.6^oE to 149.2^oE in longitude and from 39^oN to 45.7^oN in latitude. Bathymetric data extracted from the 1-minute digital atlas GEBCO (General Bathymetric Chart of the Oceans) were employed to build the computational grid. In calculations the following values of space increments were used: $\Delta Lon = \Delta Lat = 1'$. For specification of the boundary condition (31) the isobath of $H = -1\,m$ was chosen.

The residual bottom deformation was calculated by group of Prof. Ohmachi on the base of the fault model proposed by Koketsu et al. (2004). We adopted this data to the computational grid with use of triangulation with linear interpolation gridding method.

Input data, such as the bathymetry and the residual bottom deformation in the 2003 Tokachi-oki tsunami source, and results of numerical computations, i.e. residual horizontal displacements of water particles, are presented in Figure 1. The isobaths are drawn with an interval of 1 km. The residual bottom deformation is shown by white isolines: solid lines stand for uplift, dashed lines – for subsidence. The maximum values of uplift and subsidence reach of 1.4 m and 0.4 m, respectively. Black arrows denote residual horizontal displacements of water particles in terms of "total fluxes", i.e. the length of each vector is proportional to the value of displacement multiplied by ocean depth. Areas within which the amplitude of the residual horizontal displacements exceeds 3 m are shown by different colors in accordance with the color scale depicted in the left bottom corner.

As it is seen from Figure 1, there exist rather wide areas within which the amplitude of the residual horizontal displacements of water particles exceeds 10 meters. In some cases the amplitude reaches tens or even hundreds of meters.

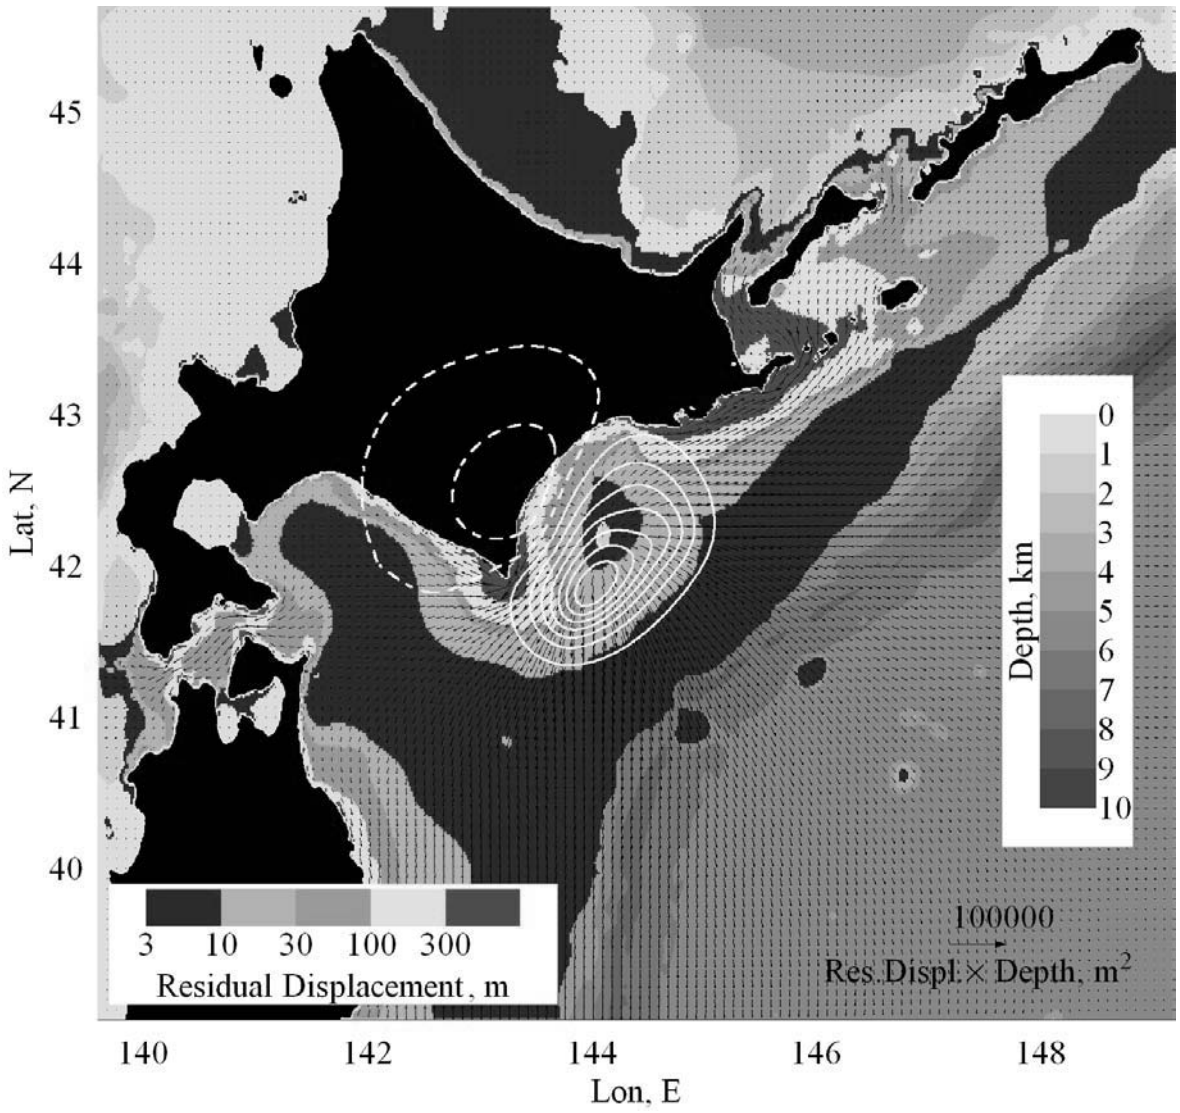

Figure 1 Computational domain. The residual bottom deformation is shown by white isolines: solid lines stand for uplift (up to 1.4 m), dashed lines – for subsidence (up to 0.4 m). Black arrows denote residual horizontal displacements of water particles in terms of "total fluxes", i.e. the length of each vector is proportional to the value of displacement multiplied by ocean depth. Areas within which amplitude of horizontal displacements exceeds 3 m are shown by different colors in accordance with the color scale depicted in the left bottom corner

Amplitude and direction of the residual horizontal displacements is a complex function of residual bottom deformation and bathymetry. Far from shore, direction of displacement of water particles is mostly defined by distribution of bottom deformation in tsunami source. In the vicinity of shoreline, vectors tend to be directed parallel to the shore. The most significant displacements are observed in the vicinity of Cape Erimo and near east coast of Hokkaido (Kushiro – Nemuro – Rausuin).

Among all other factors, amplitude of displacement of water particles strongly depends on water depth. Large displacements are mostly associated with shallow water areas. The amplitude of the residual horizontal displacements of water particles versus ocean depth for all the points in the computational domain is shown in Figure 2. From the figure one can quickly assess that the amplitude of horizontal displacement of 100 m can be achieved only in case of ocean depth $H < 300\ m$, whereas the amplitude of 1000 m – in case of $H < 50\ m$. So, it makes sense to detect the horizontal displacements of water particles in-situ in a shallow water (shelf) area where the amplitude is expected to be large enough. Displacements of large amplitude can be easily detectable by means of GPS drifters. The other option here involves processing of sequential satellite imagery with use of the maximum cross correlation technique (e.g. Crocker et al. 2007).

Vertical profile of horizontal velocity measured by means of bottom ADCP also can be used to derive residual horizontal displacements in-situ. Note that horizontal currents associated with long waves (tsunamis and tides) virtually do not depend on the vertical coordinate. Taking advantage of this feature one can easily select tsunami signal on the background of other currents. As for the tides, these currents can be precalculated. For the sake of tsunami

forecast ADSPs should be deployed at shelf depths of 100 m or so. In deep water areas, due to relatively small velocities, measurements of much higher accuracy are required. Anyway, just after the 2003 Tokachi-oki earthquake, at the depth 2540 m (Cable-end station, electro-magnetic current meter) a bottom velocity disturbance of a few centimeters per second in amplitude was registered (Mikada et al. 2006). Cable-end station is also equipped by ADSP. Unfortunately, because of too long sampling interval (30 min), tsunami signal was not registered by means of ADSP.

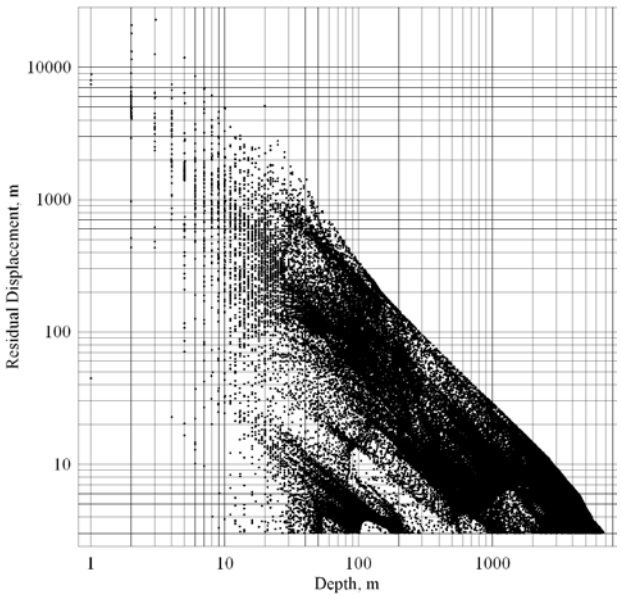

Figure 2 Residual horizontal displacements of water particles versus ocean depth

Inside of the tsunami source a "dead area" exists (approx. $144^o E, 42.2^o N$). Within this area the amplitude of horizontal displacement of water particles nearly vanishes. In case of a single measurement within such dead area a tsunami may be underestimated or even missed. This is why for the sake of tsunami warning, not a single GPS buoy or bottom ADSP but a number of devices should be used. Estimation of minimal number of devices necessary to provide reliable forecast of tsunami as well as the influence of existing oceanic currents on the detection of residual displacements lie beyond of the present study.

Obviously, we do not intend to make a tsunami warning system fully rely on the method of residual hydrodynamic fields. Seismic data and deep water bottom pressure measurements had already proved their efficiency in tsunami warning. However, residual hydrodynamic fields can serve as an alternate set of data to confirm the fact of tsunami generation and estimate its strength.

Abstract: We conducted the field survey of the tsunami generated by the M8.8 great earthquake in Chile triggered on 27 February 2010 (UTC). The survey focused on the measurements of tsunami inundation/run-up height, flow depth, extent of inundation zone, structural damage inspection, and collecting eyewitness accounts. In total, tsunami heights and flow depths at approximately 155 points were measured along the coast of Biobio region, Chile, to understand the tsunami features during this event.

1. INTRODUCTION

On 27 February 2010, a megathrust earthquake of M8.8 (Figure.1) generated a destructive tsunami. It struck not only Chilean coast but propagated all the way to Japan. After the event occurred, the post-tsunami survey team was assembled, funded by JST, to survey the area of severely affected by the tsunami. The main purpose of the survey was to examine the damage, measure the tsunami run-up and inundation height, flow depth and extent of inundation, and interview the eyewitnesses of the tsunami. A joint survey team was consisted of the members from SATREPS and the researchers from Central Research Institute of Electric Power Industry (5 researchers from Japan and two researchers from Peru).

The following report aims to describe the findings and knowledge from the survey.

2. POST TSUNAMI FIELD SURVEY

2.1 Logistics

Because the tsunami hit quite long extent of Chilean coast, the survey area needed to be prioritized. We decided to deploy the most severely affected area in Biobio region. The survey team was deployed along the central coast of Chile from 18 to 25 April 2010. Figure.2 shows the route of the survey team. Setting the base lodging in Concepcion, we started the survey on 18 April from Talcahuano to visit eight coastal communities using a car.

2.2 Methods

Conventionally, the post-tsunami survey measures tsunami inundation and run-up height, flow depth, and extent of inundation zone. The inundation height is measured as the height of watermarks on structures or debris on trees above sea level (after tide correction), and the run-up height as the altitude of the inland limit of tsunami penetration. Flow depth is the thickness of tsunami inundation flow measured as the height of the watermark from the local ground level. Measurements were conducted using the laser range finder (Laser Technology Inc.) with survey rods and digital cameras with GPS and compass. During the survey, we inter-viewed witnesses to collect the information of tsunami features (time of the tsunami arrival, polarity of the first wave, timing of maximum wave). In total, we obtained 155 points along the coast as the measurement of tsunami inundation and run-up heights, and flow depths. Figures. 3 and 4 show the longshore distribution of the measured tsunami heights and depths. We made the tide correction for all the data by using tide table at Talcahuano.

Along with the field measurements, we used high-resolution optical satellite images to inspect the impact of tsunami disaster. Table 1 is the list of high-resolution satellite images used in the inspection of tsunami-affected area.

3. RESULTS

3.1 Talcahuano

Talcahuano is the port city in Biobio Region, which contains the naval base, and has approximately 250,000 inhabitants as a population (2002 census). According to the tide gauge record (NOAA, 2010), the first wave of tsunami reached Talcahuano at 3:30 (Local time) with receded wave. After the arrival of first wave, the tide gauge at Talcahuano did not successfully record the tsunami and stopped transmitting data. CATOE (Centro de Alertamiento Temprano y Oficina de Emergencia) reported that the tsunami attacked the coast at least four times with its period of 45 to 60 minutes, and the fourth wave was the largest.
Figure. 5 represents the result of tsunami inundation height measurement in Talcahuano. The tsunami penetrated approximately 300 m inland in the port-town area and more than 1 km in the southern coastal marsh. Tsunami inundation reached to 6-8 m in port-town area and 10 m in the coastal marsh. This figure also shows the comparison of pre and post event satellite images in Talcahuano port (Figures. 5(b), (c)). Significant amount of containers and fishing boats were left as tsunami debris, which caused long duration of failure of port and harbor facilities. While the tsunami left considerable damage to the town of Talcahuano (eastern bottom of the bay), no damage was found in the western port area (San Vicente). The measured tsunami run-up height in San Vicente was 3.4 m (Figure. 5(a)).

According to the interview with eyewitness, the tsunami slightly overtopped the dock of the harbor but did not inundate out of the port. Possible causes of this discrepancy may be local effect of tsunami source mechanisms and the condition of harbor oscillation related to the size and shape of the bay.

In the town of Talcahuano, the tsunami penetrated with up to 2-3 m of flow depth (Figure. 6). After inspect-ing the structural damage in the town, some washed-away structures were found, but it was limited within the port facilities (north-west) and industrial area (south-west). Most of the structural damage in the town was likely to be caused by ground shaking, but minor damage, e.g. bending shutters of commercial buildings and broken windows.

3.2 Inspection of satellite images

Inspecting pre and post event satellite images and ground photos helps to understand multi aspects of tsuna-mi disaster. Figure. 7 is the comparison of pre and post event satellite images in Talcahuano. We acquired the pre-tsunami image from GoogleEarth (QuickBird image taken on 13 April, 2009), and used WorldView-2 pan-sharpened composite image as post-tsunami image. From post-tsunami image and field survey, we found the tumbled ship at the west of waterway in Tulcahuano bay that has been stably stood in the bay (even though it was not in use). In the coastal marsh, considerable changes of shoreline and tsunami debris are seen in the satellite images, and it was found from the ground photos (Figure. 8) that the coastal sand were eroded by inland penetration of tsunami.

3.3 Detection of salt-water penetration

Since salt-water penetration causes death of vegetation, sometimes it is used as a clear indicator of tsunami inundation. Using a specific feature of vegetation, i.e. strong absorption of visible red-band and strong reflection of nir-band, NDVI is defined by Equation (1) using the reflectance of near infrared and visible red bands.

$$NDVI=(\text{Near infrared} - \text{Red})/(\text{Near infrared} + \text{Red}) \quad (1)$$

Here, we focused on the eastern bank of the canal in Talcahuano. Figure. 9 indicates the area of investigation and illustrates the result of detecting tsunami penetration by the analysis of WorldView-2 pan-sharpened multi-spectral image and the multi spectral camera (Tetracam ADC3). As shown in the ground photos (Figures. 9 A and B), considerable inundation was found on the western bank of the canal while the eyewitness testified that the tsunami slightly overtopped the eastern bank (no inundation in houses). Using the multi spectral camera that takes visible red, green and near infrared bands, we first calculated NDVI at the top of the bank where the tsunami did not overtop (Figure. 9B). As a result, we found that NDVI of the dead vegetation be-comes less than 0.3. Using the threshold value determined by the spectral camera, we discuss the salt-water penetration on the eastern bank of the canal. Figure. 9 (c) shows the distribution of NDVI calculated from the post-tsunami WorldView-2 image (pan-sharpened). NDVI indicates lower value on the western bank (inundated) while relatively higher value on eastern bank (not inundated), and these features are quite consistent with the ground photos A and B.

3.4 Tumbes, Puerto Ingles and Llico

Tumbes locates and Puerto Ingles are the coastal communities, which were isolated by the limited road access. Figure.10 represents the overview of tsunami height measurements. Tsunami attacked these communities with up to 11 m height and caused significant damage. Along the coast from Tumbes to Puerto Ingles, the tsunami was particularly devastating to demolish the houses of isolated villages (Figure.11). Some survivors mentioned that the first wave was withdrawal and the 2nd wave was the largest. Having the experience and lessons from the 1960 Chilean tsunami, most of the village people evacuated to the hill immediately after the ground shaking. They mentioned that the tsunami in 1960 was witnessed only as receded sea and did not cause inundation.

3.5 Dichato

Dichato is a coastal village of approximately 3,000 inhabitants (Census 2002), which belongs to the municipality of Tome, located 37 km north of the city of Concepcion. Having a beautiful sandy beach, Dichato was very popular in summer for water sports and recreation. Attacked by the tsunami, Dichato became one of the most

devastated towns. According to Dichato-Tome Emergency office, 405 families living in camps, and 1223 families were affected on their properties. Figure. 14 represents the measured tsunami run-up height and flow depths. The tsunami penetrated approximately 800 m inland to 10 m altitude. Figures. 15 and 16 illustrates the devastating damage in Dichato. In this area, most of the houses were washed away and the tsunami left considerable amount of debris. According to the eyewitness who watched the tsunami from 8-story building, the first wave of tsunami hit at 5:00 (AM) after most of the people evacuated. In addition, he said that the tsunami attack was at least 3 times and the 3rd wave was the largest. The other eyewitness said that the tsunami did not come first from the sea, but from the backside with not so much power (first wave).

Number of fatality and missing reported is 66 and the surviving resident believe that most of the victims are not from Dichato but tourists or different regions, also heart attack elders or drunken people. This is mainly because the residents of Dichato knew about the possible tsunami after the earthquake and had evacuation drills.

4. SUMMARY

In summary, the results of our survey provide a dataset of tsunami run-up and inundation heights, flow depths and extent of inundation at approximately 150 points. The survey extent was from Dichato to Llico, the areas mostly devastated by the tsunami.

The tsunami inundation heights and flow depths were well recorded and will be used as a constraint in developing tsunami source model to comprehend the features of tsunami propagation and coastal inundation. Also, we collected the eyewitness accounts to describe the picture of tsunami attack. Most of the eyewitnesses said that the largest tsunami did not occur in the first wave.

Throughout the trip, we found that many of survivors knew the past event 1960 and evacuated immediately after the ground shaking. Again we found that education and passing the lessons from the past event is highly valued to mitigate the tsunami fatalities.

3) Nagoya University

Abstract: At 3:34 in February 27, 2010, an earthquake of Mw = 8.8 occurred offshore of central Chile and a tsunami attacked the Chilean coasts. This is a report of a survey conducted by a Japanese team from April 23 to 30. Major results of the survey are as follows: 1) Huge tsunami inundation heights were measured in the surveys: very high at Robinson Crusoe Island (6-16 m), very high at Dichato and Talcahuano (6-9 m), and moderate at Valdivia (1-2 m). 2) Although the tsunami was huge, the casualties were less than 500, relatively small compared with previous tsunami disasters since many people evacuated after the earthquake. 3) Similar devastating damages to those in previous tsunami disasters were found in the surveys. Talcahuano port was damaged significantly. Nearly 700 containers were washed away causing secondary damages by their drifting.

1. INTRODUCTION

A joint survey team from Japan conducted a disaster survey of the Chilean coasts after the 2010 Chilean Earthquake and Tsunami from April 23 to 30. The team consisted of nine members from the Port and Airport Research Institute, Coastal Development Institute of Technology, and Nagoya University. This is a brief report of the survey.

Chile (Republic of Chile) is located in the southern hemisphere, on the opposite side of the earth from Japan. It covers a narrow (less than 200 km) but very long (more than 4000 km) territory in the South American continent. The territory is twice that of Japan and the population is 16 million, with 6 million people living in Santiago, the capital city. Santiago is located at 33 degrees latitude, the same as that of Fukuoka City, Japan, in the northern hemisphere. The central district of Chile including Santiago has a Mediterranean climate with a dry summer (December to Feb.) and a rainy winter (June to August).

Chile faces a subduction zone of the Peru-Chile Trench between the Nazca Plate and the South American Plate and has many earthquakes and tsunamis. It has suffered from 71 large earthquakes (M 7.0 and larger) during the last 200 years. Among them, 13 earthquakes caused casualties of more than 50. Large earthquakes with tsunamis occurred in 1835, 1928 and 1939 near Concepcion. The huge 1835 earthquake and tsunami disaster in the area is described in the book on the Beagle's circumnavigation of the globe written by Charles Darwin(1839).

In 1960, a huge earthquake with a magnitude of 9.5, the largest in the 20th century, occurred near Valdivia The tsunami induced by the earthquake impacted not only the Chilean coasts but also all coasts of the Pacific Ocean. Devastating disasters in Japan and the United States led to international cooperation to establish an early warning system for distant tsunamis.

2. CHILEAN EARTHQUAKE and TSUNAMI

At 3:34 in February 27, 2010 (15:34 Japan standard time), an earthquake of Mw = 8.8 occurred offshore of central Chile. The epicenter was 335 km southwest of Santiago, and 105 km northeast of Concepcion at a depth of 30 km. The shaking along the coasts of central Chile was very strong and buildings and roads were damaged in these areas. The weather was fine and it was relatively light due to the full moon.

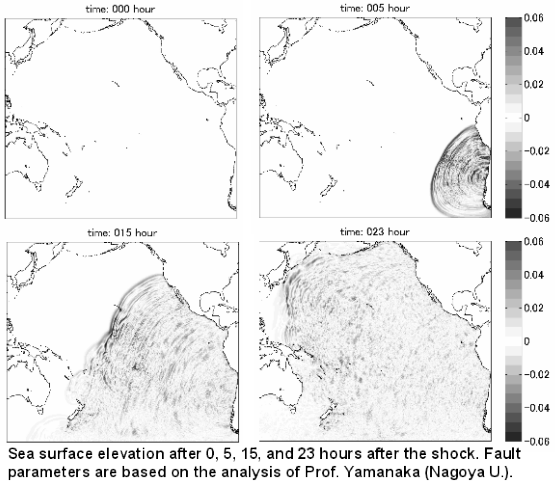

Figure 1 Calculated tsunami propagation

Immediately after the earthquake at 3:46 a tsunami warning was issued from PTWC (Pacific Tsunami Warning Center) to Chile and Peru. The tide in the coasts at that time was ebb tide (about 50 cm below the mean water level) at 4 o'clock and the high tide (about 50 cm above the mean water level) was to be at 10 o'clock. At 4:00 (16:00 Japan standard time), JMA (Japan Meteorological Agency) issued the first information on the distant tsunami. Figure 1 shows the results of the numerical simulation of tsunami propagation in the Pacific Ocean. The tsunami traveled more than 17,000 km within a day and hit the Japanese coast. Casualties in Chile due to the disaster were more than 500 and most of them were presumably due to the tsunami.

3. SURVEY METHOD

3.1 Preparation of Survey

After the earthquake, many disaster surveys were conducted by the Chilean government and local organizations in addition to international survey teams. The Asian Pacific Center for Coastal Disaster Research (APAC-CDR) of the Port and Airport Research Institute started to gather information on the earthquake and tsunami with the cooperation of the Japanese Ministry of the Land Infrastructure, Transport and Tourism. The Japan Society of Civil Engineers with the cooperation of Architectural Institute of Japan, the Japan Association for Earthquake Engineering and the Japanese Geotechnical Society decided to conduct a disaster survey in Chile from the end of March(Kawashima and Imamura, 2010). Two members from APAC-CDR, namely Drs. Sugano and Arikawa, could join the survey team with recommendations from Professors Kitagawa of Keio University, Midorikawa of Tokyo Institute of Technology, Kawashima of Tokyo Institute of Technology, and Imamura of Tohoku University. The joint survey team was organized to conduct more detailed surveys in the port and coast areas to extend the field survey results. The survey team had much help and advice including from Professor Emeritus K. Horikawa(1961) of the University Tokyo who had visited Chile just after the 1960 Chilean Earthquake and Tsunami.

Many organizations in Japan responded to the emergency of the distant tsunami after the JMA early warning. Many people were evacuated from the coasts, and in some areas, inundation occurred. APAC-CDR of PARI together with the Ministry of Land, Infrastructure, Transport and Tourism gathered information on the distant tsunami and conducted field surveys of the tsunami damage in Japan from March 4 to 6. For example, a tsunami height of more than 2 m was measured by the tsunami survey of APAC-CDR and the Tohoku Regional Bureau of the Ministry.

3.2 Objective and Itinerary of Survey

The joint survey for the disaster in ports and coasts in Chile was conducted from April 22 to May 2. The survey had two objectives. The first one was to reveal the nature of the disaster in coastal areas due to the Earthquake and Tsunami. Future tsunami disasters can be predicted more precisely using knowledge accumulated of actual disasters. The second objective was to enhance the cooperative relationship between Chile and Japan for disaster mitigation measures.

The survey was conducted by two groups. The disaster outline survey was conducted to reveal the overall view of the disaster in central Chile from Valparaiso to Valdivia including Robinson Crusoe Island. The Concepcion survey investigated the details of the disaster near Talcahuano Port including Concepcion Bay and San Vicente Bay. Figure 2 shows the map in central Chile, where Concepcion is located 340 km south of Santiago, Valdivia is 750 km south of Santiago and Robinson Crusoe Island is 670 km West of Valparaiso. The itinerary of the survey was as follows:

April 23: Visits to Chile office of Japan International Cooperation Agency (JICA), Japanese Embassy at Santiago, and Chilean Ministry of Public Works

April 24-28 Concepcion survey (Dichato, Tome, Penco, Talcahuano and Huachipato Steel Company) and Disaster outline survey (Robinson Crusoe Island, Valdivia areas)

April 28 pm Workshop at Concepcion University

April 29 Discussion at Valparaiso University

April 30 JICA and Japanese Embassy

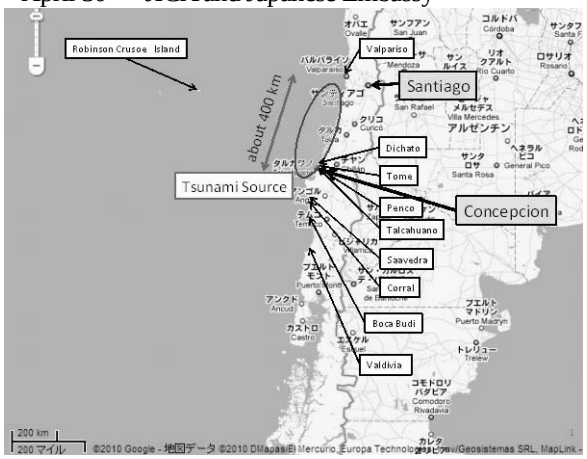

Figure 2 Map of Central Chile

The surveys were conducted with the kind cooperation of the Japanese Embassy and JICA Chile Office and the JICA Global Environment Department in Tokyo and the Japanese Ministry of Land, Infrastructure, Transport and Tourism. The survey at each location was conducted with the cooperation of many people from the Chilean Government, private companies, and universities. This enabled intensive investigation although the time was very limited.

4. DAMAGE IN EACH CITY

4.1 Talcahuano

Concepcion is a city in Province of Concepcion of

Region of Bio Bio and the second largest city in Chile. The city had moved from the Penco area to the present location due to the tsunami disaster in 1751. Talcahuano is a port city near Concepcion with a population of 250 thousand. Figure 3 shows the map near Talcahuano including Concepcion Bay and San Vicente Bay. Talcahuano Port is located in Concepcion bay with a large Navy base which could not be entered this time. Tome and Penco are located on the east coast of Concepcion Bay while Huachipato Steel Company is located in San Vicente Bay. Dichato is a little to the north of Concepcion Bay.

Photo 1 shows the south district of Talcahuano Port after the tsunami attack. The 680 containers stored in a wharf in the south district had all drifted shoreward from the wharf due to the first tsunami attack and 30% of the containers were moved into sea by the receding tsunami. Some of the containers collided with houses causing secondary damage. Many ships were moved onto the land or sank into the sea as can be seen in Photo 2. Drifting of containers and ships can be a major cause of disasters in coastal cities. This needs to be investigated further with numerical simulation of the drifting of containers and the collision mechanism of the containers.

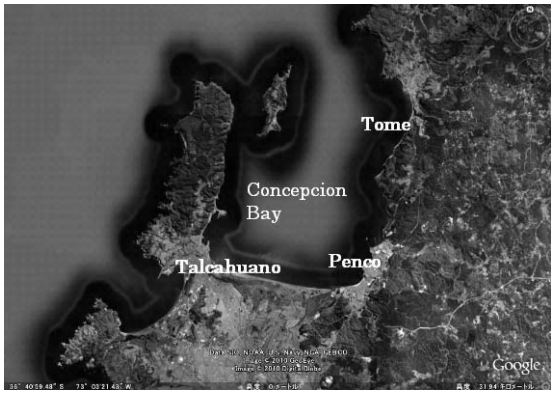

Figure 3 Concepcion Bay (from Google Earth)

Photo 1 Scattered containers at Talcahuano Port (Copyright: The International Federation of Red Cross and Red Crescent Societies (IFRC))

Photo 2 Damaged ships at Talcahuano Port (on April 27, 2010)

Huachipato steel mill is located along the coast of San Vicente Bay. The tsunami did not run up to the industrial zone which is located more than 5 m above sea level. The tsunami in the bay was relatively small compared with that in Concepcion Bay. However, although the tsunami damage was small, the damage due to shaking was significant and the recovery was only partial even after 2 months from the earthquake. The damage due to shaking will be explained later in this paper.

The recovery of the port seems to be slow. Recovery of the port and adjacent industrial areas is vital for the recovery of the economy of the city.

4.2 Dichato

Dichato village is a part of Tome City and is located in Coliumo Bay (above Concepcion Bay). The village has a long sandy beach and is a resort village with a population of more than 3000. There is a river in the middle of the village which flows into the bay through the beach. The area near the river is relatively low.

The tsunami arrived at the beach from the baymouth with a height of 8 to 9 m. The first wave arrived 40 to 50 minutes after the earthquake which could be seen from the highlands. The largest one was the fourth wave at around 7:30. Photo 3 shows the tsunami flowing into the village. The tsunami impacted the low-lying areas near the river in the town. Since the inundation depth was more than 4 m, all the houses were washed away. In the relatively high areas set apart from the river, the damage was limited as the inundation depth was less than 1 m.

There were 18 casualties, which was relatively small considering the tsunami height. Since the village was attacked by the 1960 tsunami, many people remembered the disaster and escaped to the highland areas nearby. Many tourists were in the village since the day was the Saturday at the end of the vacation season. Some of them did not know the danger of the tsunami and did not escape. Many of them did not know where the evacuation places were, and there was much confusion including the traffic jams in the town

with people using cars to escape. Drifting cars were seen with people inside. Unfortunately, the tsunami alert was canceled too quickly and some people returned to their houses and were involved in the tsunami attack.

Photo 3 Tsunami intrusion into Dichato

4.3 Penco

As mentioned above, Penco was the old Concepcion. It is located on the east coast of Concepcion Bay. The city has suffered from many tsunami disasters. It has a long sandy beach and is protected by a relatively high bank behind the beach used for a railway.

The first wave did not exceed the railway bank but the wave at around 7:30 exceeded the bank and inundated the town. Figure 4 shows the inundation depth measured along a road perpendicular to the bank. The ground level is lower than the bank and the overtopping water became a strong current penetrating 300 m into the town although the height of the overtopping water above the bank was less than 1 m. The overtopping water destroyed the front line of the houses and carried cars and boats through the road.

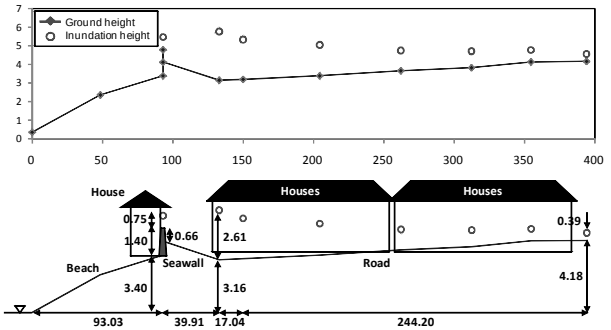

Figure 4 Ground height and inundation height at Penco

4.4 Robinson Crusoe Island

Robinson Crusoe Island (Juan Fernandez Island) is the largest island of the Juan Fernández archipelago, more than 600 km west of Valparaiso. It is a volcanic island surrounded by steep cliffs and inhabitable areas are very limited. Six hundred people live in the village of San Juan Bautista in Cumberland Bay, which faces the mainland where the earthquake was generated.

Three major tsunami waves are said to have attacked the bay. The first and the second were not very large and the inundation was limited to near the shore. The third wave at 4:20 was a huge one of more than 15 m. The arrival times of the first and second waves were 10 to 20 minutes before the third wave.

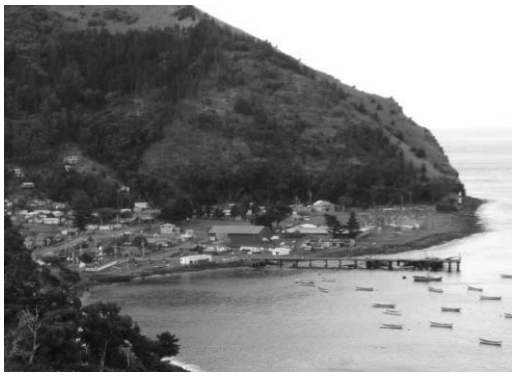

Photo-4 Before and After the tsunami at Robinson Crusoe Island (from Professor Patricio Winckler Grez of U.Valparaiso)

Photo-5 Beach at Robinson Crusoe Island (from Dr. Hector Saldias Rodreguez)

The maximum measured inundation depth was 7.6 m and the maximum tsunami height was 16.4 m. Clearly, a tsunami of more than 15 m attacked the village. Photo 4

compares the village before and after the attacks. The ground up to 200 m from the sea in the village is relatively low with a mild slope and then the slope becomes very steep. The low area near the sea was totally demolished by the tsunami especially since most of the houses were made of wood. A great amount of debris can be seen in Photo 5.

5. SUMMARY OF EARTHQUAKE DAMAGE

5.1 Shaking

The earthquake occurred in the subduction zone between the Nazca and South American Plates. The moment magnitude Mw was 8.8 according to the report of USGS (US Geological Survey). The general characteristics of the shaking on Chilean Coasts is a short predominant period of less than 0.5 s according to many observations but a long duration time of more than 60 s. This is the reason for the non-devastating damage to buildings and infrastructures although the magnitude was large.

5.2 Damage to Port Facilities

Failures of gravity and pile type quay walls at land reclamation sites were seen in the ports. Photo 6 shows the damage to a gravity type quay wall in Talcahuano Port where the retaining wall moved about 50 cm shoreward and the apron behind the wall settled down about 1 m. The through-wash effect of backfill sand can be seen due to tsunami and tidal changes. A seawall of the block masonry type was not damaged as seen in Photo 7. The gravity type (sheet pile type) quay walls were considered to have been destroyed due to deterioration since the shaking was considered to be not very large and liquefaction did not occur due to the relatively large diameter of the reclaimed sand. Similar damage can be seen in Photo 8 at Talcahuano Port.

Photo 9 shows a large piled jetty which was damaged slightly due to residual movement of the ground as in Photo 10 and shear damage to the pile heads as in Photo 11 which were under repair. The wheels of the ship unloaders on the pier had moved due to shaking as can be seen from Photo 12. It should be noted that the anchor of the unloader penetrated the plate of the superstructure, which was not seen even in Kobe port after the Hanshin-Awaji Great Earthquake although the unloaders had derailed significantly. This difference seems to be due to the difference in the superstructures of a piled pier and a concrete caisson pier. A seismically isolated structure should be introduced for unloaders to prevent derailing. It should be noted that the tsunami was low here and did not cause visible damage.

Since the propagation speed of the shaking was large (3000-6000 m/s) and the facilities were first attacked by shaking and then by tsunami waves, it is necessary to investigate the combined effects to the coastal facilities. One of the objectives of the survey was to reveal the combined effects to the coastal structures. Through the survey, we could not find any obvious case of the combined effects. Further investigation is needed using physical and numerical experiments.

5.3 Privatization of Port Facilities and Seismic Design

In Chile, from the beginning of 1980, many public services were privatized, such as electric power supply, telecommunication, banking, and steel, airline and shipping industries. Services such as expressways, airports and seaports are also being operated as concessions. Ports are operated by private companies of European capital. Although public funds are limited for the development of ports, the modernization of port operations using IT is being encouraged by privatization. The privatization is the so-called concession method where private companies invest in the construction of port facilities and operate the port for a certain period of time. Port operation should naturally maximize the benefit. However, it is very important to prepare for disasters, which is usually forgotten. Business continuity planning is essential for long-term port operation.

The survey revealed the absence of public design standards for port facilities in Chile, with the facilities being constructed based on consideration of the concession companies. If these companies or the design consulting companies have no experience in dealing with earthquakes they often do not possess the know-how to deal properly with the effects of earthquakes and tsunamis.

Photo 10 Deformation of crane rails on the jetty

Photo 11 Damage to the pile head of the jetty (ϕ 900 mm)

Photo 12 Anchor of unloader penetrating the jetty superstructure

5.4 Recovery Process and Ports

Ports can be used as a base for recovery from disaster to enhance the recovery since sea routes can substitute for transportation using roads and railways and emergency supplies can be stored in ports. In Japan, the government has a recovery plan utilizing ports as recovery bases. In Chile, ports are not expected to function as recovery bases and thus were not used in this manner. Cooperation of ports and local government is needed to expedite recovery from disaster.

6. SUMMARY OF TSUNAMI DAMAGE

6.1 Measured Water Marks

Figure 5 shows the measured water marks during the survey including detailed data around Talcahuano. The symbol (+) indicates the run-up height which is significantly affected by the topography while the symbol (●) indicates the inundation height without the effect of topography. It was confirmed that the inundation height was very large, 6 to 10 m near the hypocentral region as expected from the large magnitude of the earthquake. The inundation height decreased according to the distance from the hypocentral region, but was still high at Corral near Valdivia. On Robinson Crusoe Island, the inundation height was significantly high at 6 to 15 m.

The inundation height was confirmed to change significantly due to the topography as suggested from previous disasters. For example, the tsunami height at Talcahuano port was large compared with those at Tome and Penco even in the same Concepcion Bay. The tsunami height at Conception Bay was much larger than that at San Vicente Bay although they are located very close to each other. The reasons should be investigated through numerical simulations.

6.2 Evacuation and Casualties

Most people in the coastal areas felt the strong shaking and escaped. In some areas, like in Talcahuano, the evacuation was hampered due to damage by the strong shaking including cracks in the roads. Some people in areas where the shaking was not very strong, like Corral and

Saavedra, did not escape and even visited the coasts to see the tsunami. On Robinson Crusoe Island, most of the people were asleep and did not notice the shaking. Some people felt the shaking and/or saw the first and second tsunami waves and then evacuated together with their neighbors. The warning came to the island just before the tsunami attack and did not function sufficiently.

Unfortunately, the tsunami warning was cancelled after the first tsunami wave. However, most of the people believed that a tsunami comes in three waves and remained away for hours. Some people including children returned home but encountered the following tsunami in Talcahuano and more than 10 people died after returning home in Dichato. In Dichato, 7000 people were there at night and 50 people died or went missing. The rate was less than 1%.

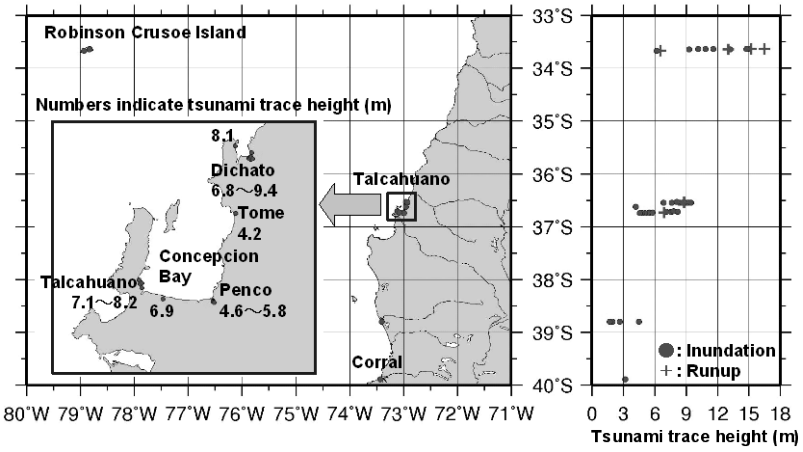

Figure 5 Measured tsunami water marks

Figure 6 shows the houses of the victims on Robinson Crusoe Island. It should be noted that many people lived near the edge of the inundation areas. The inundation boundary was actually a cliff or steep slope and they could not climb up the cliff but escaped using the roads indicated by yellow lines in the figure. During the evacuation, some were caught by the tsunami. Many of them were carried into sea by the tsunami and some were saved by boats. About 600 people lived in the village and 160 in the inundation areas. Sixteen people were killed, and the rate of 10% is relatively high, confirming the importance of proper early warning.

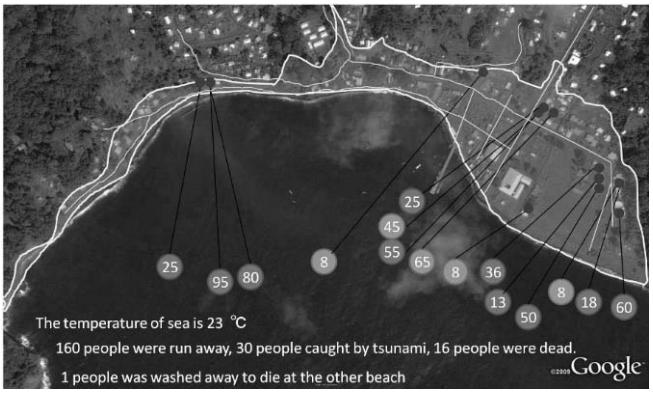

Figure 6 Places where victims were found at Robinson Crusoe Island (the number indicates the age, red color indicates female and blue, male)

6.3 Drifting Objects

Drifting of ships and containers is an important issue in a tsunami disaster. For example, in the Indian Ocean Tsunami, many ships drifted onto land. In the Chile tsunami, the drifting of a mass of containers occurred for the first time, involving 680 containers. Many ships also drifted and cars were found in the sea in Talcahuano and in other towns. Secondary damages including the collision of containers occurred in many places. Sunken objects hindered the navigation of ships and delayed the recovery of port activities. Numerical simulation of the drifting of a container is being investigated and will be checked with the field data obtained for this tsunami disaster.

7. CONCLUSIONS

Major results of the survey are as follows:

1) The earthquake occurred in the subduction zone between the Nazca and South American Plates with Mw =8.8 . The general characteristics of the shaking on Chilean Coasts is a short predominant period of less than 0.5 s according to many observations but a long duration time of more than 60 s. This is the reason for the non-devastating damage to buildings and infrastructures in the ports although the magnitude was large. One of the objectives of the survey was to reveal the combined effects of shaking and tsunami to the coastal structures. Through the survey, we could not find any obvious case of the combined effects. Further investigation is needed using physical and numerical experiments.
2) Huge tsunami inundation heights were measured in the surveys: very high at Robinson Crusoe Island (6-16 m), very high at Dichato and Talcahuano (6-9 m), and moderate at Valdivia (1-2 m). The maximum height occurred not with the first wave but the 3-5th waves. The tsunami inundation height changes significantly depending on the topography (for example, the south beach of Talcahuano (San Vicente Bay) is very low compared with that on the north side of Talcahuano (Concepcion Bay.) It should be noted that these are not unusual features of tsunamis. Obvious combined damage effect due to shaking and tsunami was not observed in the survey.
3) Although the tsunami was huge, the casualties were relatively small compared with previous tsunami disasters since many people evacuated after the earthquake. Sixteen

people were killed on Robinson Crusoe Island; it was difficult to transmit the warning as the earthquake occurred during the night.

4) Similar devastating damages to those in previous tsunami disasters were found in the surveys. For example, almost all the houses were washed away where the tsunami height exceeded 8 m and about 50% of the houses were damaged by a tsunami of 4 m. Wooden houses were very weak and reinforced concrete buildings were relatively strong.
5) Talcahuano port was damaged significantly. Nearly 700 containers were washed away causing secondary damages by their drifting. Many ships were also damaged. The quay walls were severely damaged by earthquake shaking. Early recovery of the port and industry areas near the port is vital for the economic recovery of the areas around Concepcion.

In addition to the field survey, the survey team discussed technical cooperation with various organizations in Chile, including Concepcion University, Valparaiso University and Catolica University, in addition to the Japanese Embassy, the JICA office in Santiago and the Chilean Ministry of Public Works. Knowledge on tsunami has accumulated in Japan due to repeated tsunami disasters(CDIT, 2010; Murata et.al., 2010; PIANC WG53, 2010). Knowledge on disaster mitigation developed further after the Kobe Earthquake disaster. Japanese experiences with disasters should contribute to disaster mitigation in Chile.

Acknowledgements:

Field survey is only possible with help of many people. All the members of the survey team would like to express their sincere appreciation to the people in Chile and Japan for their kind help and cooperation.

Abstract: On 23 June 2001, at 15:33 local time, the Camaná city and all the peruvian southern region were hit by a strong earthquake of magnitude 8.4 Mw and maximal intensity VIII in Mercalli scale, the epicenter was located on the sea in the forefront of Ocoña (Arequipa). 15 minutes later a localized tsunami was generated, which destroyed the seaside town of Camana and caused the death of 24 people and 62 missing people. With the help of numerical modeling TIME and the use of computers, it is possible to make the numerical simulation of tsunami and to obtain parameters such as arrival times, run up (maximal height of flooding), synthetic tidal gage recordings and flooding maps, which will be useful for disaster mitigation for the corresponding authorities.

1. INTRODUCTION

A tsunami is a series of water waves of great length (with periods ranging from 5 to 60 minutes, or higher), generated by mechanisms such as volcanic explosions on islands, underwater landslides, falling rocks or bays ocean and tectonic movements associated with earthquakes. An earthquake tsunami generator is usually associated with subduction zones. Since many of these areas are along the Pacific Rim, the vast majority of tsunamis occur in the Pacific Ocean.

Tsunamis are classified in the place of arrival to the coast, according to the distance (or travel time) from their place of origin, in:

a) Local Tsunami, if the place of arrival on the coast is very near or within the area of generation (defined by the area of seafloor displacement) of the tsunami, or less than one hour travel time from the beginning.

b) Distant Tsunamis, if the place of arrival is more than 1000 km away from the zone of generation or end-opposite shores across the Pacific Ocean and about half a day or more of the tsunami travel time from that area (Jimenez, 2008).

According to the testimonies of survivors, shortly before the earthquake a refolding of the sea in some places and then the earthquake on 15 minutes started the tsunami destroyed the resort of Camaná. This was a small local tsunami that affected only Camaná coastal resorts. The height of the waves reached up to 7 m in some places, with a run-up to 7 m and a maximum flooding distance of 1350 m. There were 24 dead and 2 missing and large losses. This tunamigenic earthquake is the strongest since 1868 in the southern region of Peru. The period of recurrence of this type of event for the region of Peru and northern Chile is of 100 years (Kulikov et al., 2005).

The parameters obtained by the Geophysical Institute of Peru (IGP) were:

Local Time = 15h 33m 23 June 2001
Latitude = -16.20 º
Longitude = -73.75 º
Depth = 29 km
Magnitude Mw = 8.4
Intensity = VIII Ocoña, Camana
Location: 82 miles north west of Ocoña (Arequipa)

1.1 Area of study

Camana province is located in the Midwestern part of the Arequipa region to 172 km from the capital of the Department of Arequipa, and has about 56 thousand inhabitants. This is the first city that sent the conqueror Francisco Pizarro founded. Predominant economic activity is agriculture. Bounded on the north by the province Condesuyos, province of Castilla, Arequipa province (San Juan de Siguas) for the north-west province Caravelí and Penthouse, on the south by the Pacific Ocean on the east by the province of Islay. In 2001 a strong earthquake rocked the region and a tsunami devastated the coastal resorts of the city of Camana.

2. FOCAL PARAMETERS CALCULATION

From the empirical relationship of Papazachos 2004, between the seismic moment magnitude Mw and the focal parameters: length L (km), width W (km), and displacement

U (cm) of the failure to subduction zones :

$$\log(L) = 0.55M - 2.19$$
$$\log(W) = 0.31M - 0.63 \qquad (1)$$
$$\log(U) = 0.64M - 2.78$$

The following results were obtained for Mw = 8.4:

Rupture length	L = 269 km
Rupture width	W = 94 km
Fault displacement:	U = 3.9 m

The seismic moment Mo is defined as: Mo = μLWU = $4.9*10^{21}$ Nm, where μ = 4.5*1010 N/m2 is the modulus of the medium. Talandier 1993, provides a relationship between seismic moment Mo and the destructive potential of a tsunami. The value of Mo indicates that the Camana earthquake generated a small tsunami (Talandier, 1993). However, it was destructive in the area of the coastal resorts due to the vulnerability of buildings.

Table 1. Classification of tsunamis according Talandier.

Value range	Tsunami type
Mo < 10^{21} N.m	No tsunami was generated
10^{21} < Mo < $5*10^{21}$ N.m	Small tsunami
$5*10^{21}$ < Mo < $2*10^{22}$ N.m	Potencially destructive
Mo > $2*10^{22}$ N.m	Great and destructive

3. DATA AND SELECTION OF THE DOMAIN OF INTEGRATION

To model the tsunami flood zones need the following information:

a) Global bathymetry grid.- To simulate the largest where the tsunami spread. The data are taken Etopo2 model with a resolution of 3.6 km (Smith, 2006).

b) Local bathymetry.- These fine details are obtained from drilling conducted in the area.

c) Local topography.- To model the flooding caused by the tsunami. Data are taken on-site survey and satellite survey data SRTM 90 (Jarvis et al., 2006).

With all these data we obtain a digital elevation model and proceeds to draw 4 nested grids: A, B, C and D (see Figure 1). Where grid A is the largest and contains the area of rupture. The grid D is the smallest, but the data are finest and contains the region where we want to evaluate the flood. The boundaries of the grid are:

```
region_a = [-20    -13      282.0     290.0 ];
region_b = [-17    -15.8    285.5     287.5 ];
region_c = [-17    -16.2    286.5     287.5];
region_d = [-16.85 -16.59 287.258    287.373];
```

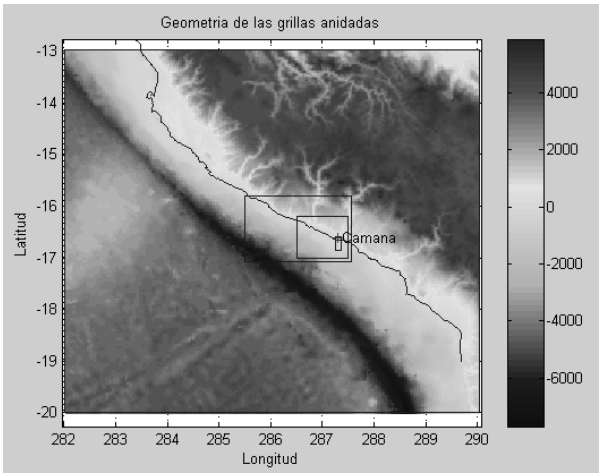

Fig. 1 Nested grids for the present model

4. TSUNAMI GENERATION PHASE

For an earthquake generates a tsunami is necessary to meet the following requirements:

a) The epicenter of the earthquake, or a majority of its rupture area, is under the seabed at a depth less than 60 km (shallow earthquake).

b) Occurring in a sink edge of tectonic plates in the sea, ie the failure to have vertical movement and is not just lateral strike slip motion.

c) The earthquake releases enough energy in a certain period of time and this is efficiently transmitted. In general, magnitude Mw > 7.0.

The initial condition of tsunami (strain field due to displacement or fault line) is determined using the model of Mansinha and Smylie (1971) assuming an instantaneous deformation of the ocean's surface equal to the vertical component of the strain field of the bed ocean. This is a model of fracture and requires knowledge of the earthquake focal mechanism (Okal, 2002). It has been considered the following values:

Strike angle = 301º
Dip angle = 20º
Slip angle = 90º

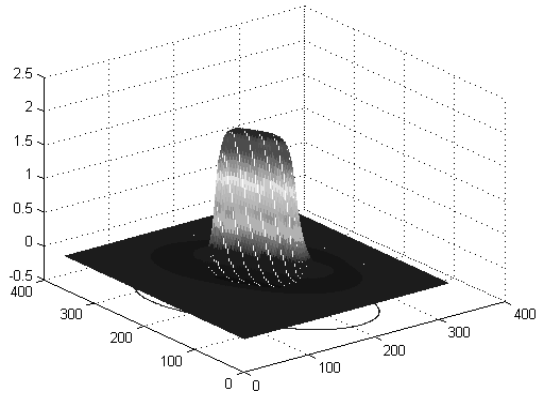

Fig. 2 Model of initial co-seismic deformation.

For this model the maximum height of the deformation is of 2.04 m. This creates the "piston effect" that destabilizes the water column causing tsunami waves.

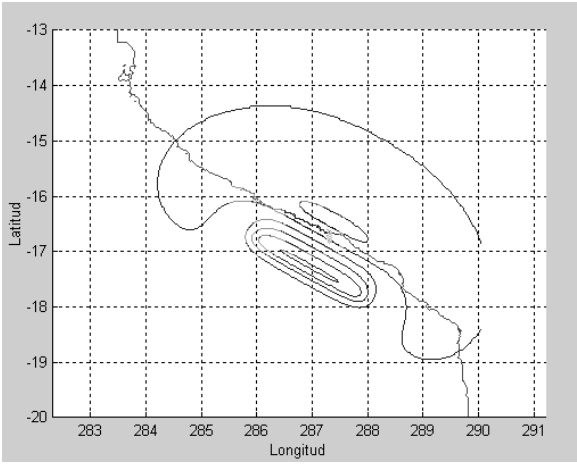

Fig. 3 Contours of initial co-seismic deformation.

Using the inversion of the tsunami waveforms from tidal gauge stations is possible to get the source parameters for a heterogeneous slip model as shown in Figure 4 (Adriano, 2010).

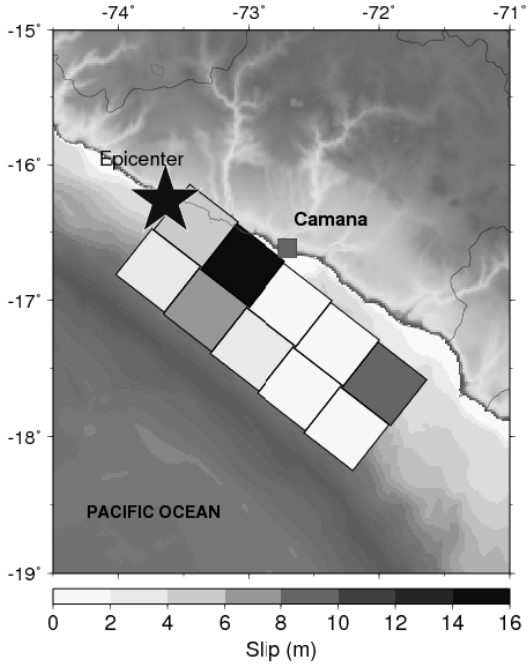

Fig. 4 Heterogeneous slip model from inversion of tsunami waveform data (Adriano, 2010).

5. PROPAGATION PHASE OF TSUNAMI

The propagation of the tsunami is simulated with the model of Goto and Ogawa (1982) that integrates the shallow water equations by the numerical method of finite differences. The TIME model (and other models) uses the linear equations for the propagation of the tsunami through the ocean floor in shallow water:

$$\frac{\partial \eta}{\partial t} + \nabla . \vec{U} = 0 \qquad (2)$$

$$\frac{\partial \vec{U}}{\partial t} + gh\nabla \eta = 0 \qquad (3)$$

where η is the disturbance of sea level, U represents the velocity field, g is the acceleration of gravity, h is the depth and t is time. In Figure 5 shows the initial stage of propagation of tsunami waves for the homogeneous slip model.

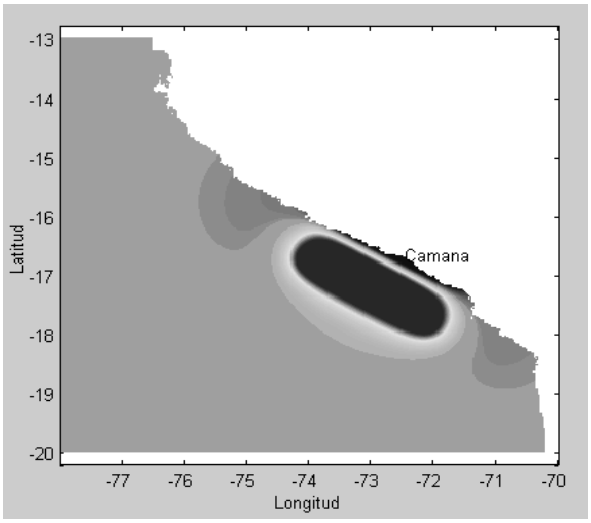

Fig. 5 Start time of Tsunami Propagation

6. INUNDATION PHASE OF TSUNAMI

The height reached by a tsunami, upon reaching the coast is due to the interaction of various physical and morphological factors such as characteristics of waves at sea, bathymetry, seabed slope, configuration of the sea boundary, diffraction, refraction, reflection, dispersion of the normal modes of resonance of the coastal formations and the formation of bores on beaches, estuaries and coastal lagoons. These factors determine that the arrival of the tsunami on the coastline is a complex process, which generates significant differences in height of the tsunami even over short distances along the coast.

In Figure 6 shows that the maximum wave height (according to model) to the shoreline was 9 m at the position corresponding to -72.75 degrees longitude (outside the area of interest: grid D). The maximum wave height is 7 m.

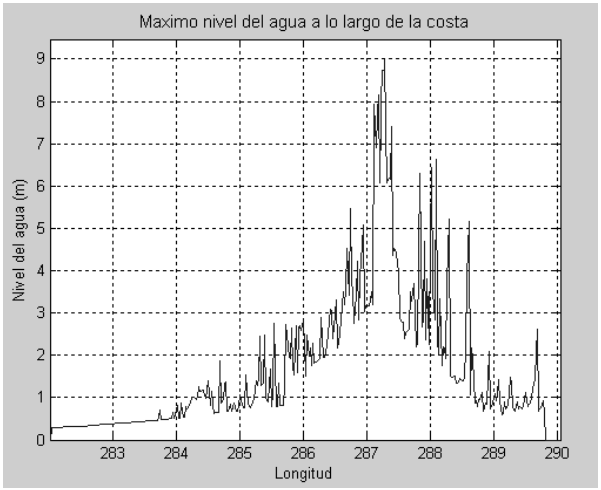

Fig. 6 Maximum wave height along the coast.

In Figure 7, we can see a tsunami inundation map according to the homogeneous slip model for Camana area. The narrow strip for the seaside resort (right side) is completely flooded, with the South Panamerican highway and the adjacent hills as boundary. The maximum horizontal inundation distance is about 1350 m, according to this model.

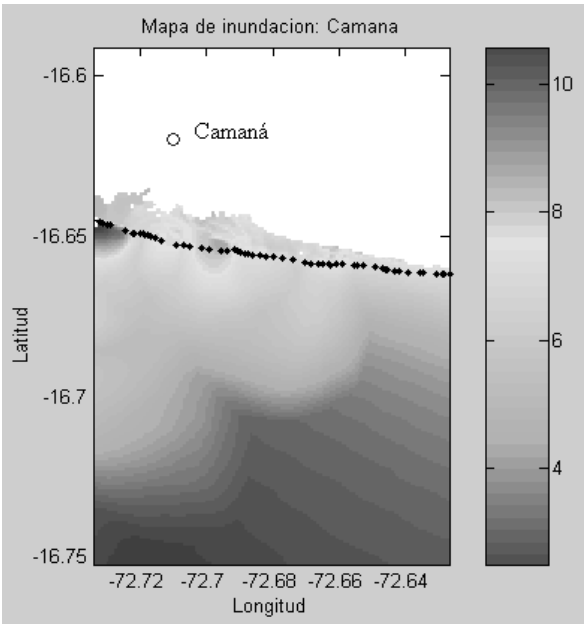

Fig. 7 Flooding map from the homogeneous slip model (scale in meter).

In Figure 8, we can see the inundation map for the heterogeneous slip model. This means that the tsunami would reach to Camana city, that did not happen, and this is because the values obtained for the slip amount on the northern part of the fault in the Tsunami waveform inversion model (for to get the heterogeneous slip model) are overestimated (Adriano, 2010).

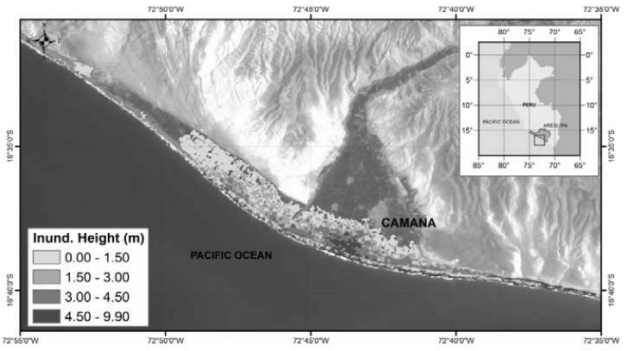

Fig. 8 Flooding map from the heterogeneous slip model (Adriano, 2010).

Figure 9 shows an aerial photograph in which is traced the flooding observed, it appears that the homogeneous slip model agrees quite closely with the observation in situ, thus validating this modeling tsunami inundation.

Fig. 9 Flooding map as in-situ (Source: DHN)

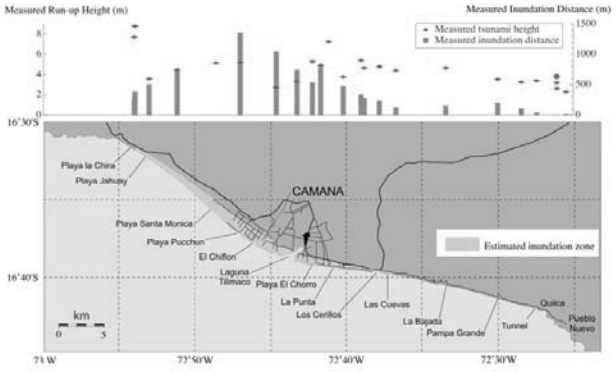

Fig. 10 Measured inundation distances (ITST)

In Figure 11 shows a synthetic waveform (tidal meter) located in the region of the grid D. The peak of the first wave arrives about 12 minutes and the next largest wave arrives at 28 min. The maximum wave height is about 7 m (which is consistent with the observation in situ). After 3

hours the wave amplitude has been reduced to little more than 1 m.

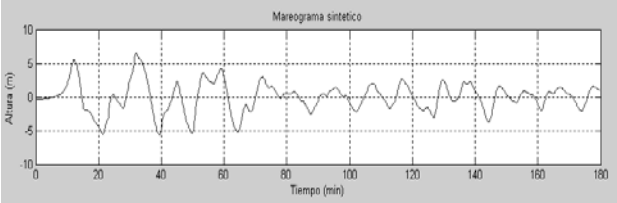

Fig.11 Synthetic waveform tsunami from a virtual tidal station located in the coastline of the flood region.

7. CONCLUSIONS

Camana City is well located, but not the coastal resort in an area that is highly vulnerable to the occurrence of a tsunami, which means that in future similar event may occur as in 2001.

The value of seismic moment Mo = $4.9*10^{21}$ Nm calculated in this work indicates that the earthquake of Camana 2001 generated small but destructive tsunami.

For a local tsunami, the arrival time of the first wave will be about 12 minutes, which provides little time for evacuation. However, not always the first wave is the largest.

The run-up (maximum flood height) reached a height of 7 m on average, implying that some places like the resort, would be potential flood spots.

The results in this paper are a mathematical physical model to some extent validated by field data and evidence.

The relevant authorities should develop plans for disaster mitigation in the event of an earthquake and tsunami. The coastal population must learn to be forewarned before the occurrence of these events.

Abstract: On 11 August, 2009, at 05:07 JST, a moderate-to-large earthquake took place in the Suruga Bay of central Japan. It struck two deep ocean water pipes in the near source area, of which the temperature and the turbidity of deep ocean water respectively became higher and larger than usual right after the earthquake, inferring that some damages have happened on the water pipes due to the earthquake. In the meantime, we carried out two in-situ surveys in order to reveal damages of the water pipes and its cause. The first survey was done by using ROV "Hyper-Dolphin", which contained the visual surveys. As a result, we have discovered one water pipe at least 2 kilometers downstream from the original position. The second survey by R/V "Natsushima" was done in order to reproduce the bathymetry map in the source area. Comparing with the topography obtained before the earthquake, we can recognize an erosion pattern near the water pipe, whereas a sediment pattern has been found in the downstream, suggesting possibly a submarine landslide trace caused by the earthquake. This submarine landslide might contribute to the tsunami excitation, which still cannot be interpreted by the seismic faulting alone.

1. INTRODUCTION

On 11 August, 2009 at 05:07 JST, a moderate-to-large earthquake took place, of which the magnitude was 6.5 and the hypocenter depth was 23 km in the Suruga Bay, central Japan. According to the preliminary report of Japan Metrological Agency (JMA, 2009), maximum seismic intensity was recorded to be 6 in the near source area, e.g., Izu, Yaizu, Makinohara, and Omaezaki cities. This earthquake is referred as the Suruga Bay earthquake here after. JMA issued the information for Tokai earthquake for the first time immediately after the Suruga Bay earthquake. The mechanism of the Suruga Bay earthquake was the thrust fault type with NNE-SSW lateral component (Fig. 1). The hypocenter is located in the subducting Philippine Sea plate and this was the typical intra plate earthquake. After shocks' distribution implies that the fault plate extended 20 km x 20 km.

The human and material disasters have been occurred at Shizuoka, Kanagawa, Tokyo and Nagano prefectures during the Suruga Bay earthquake. Among them, a land slide was occurred at the bank edge of the Tomei high way in Makinohara city. Fisheries, port and harbor structures were also damaged. Liquefaction was occurred at the Yaizu port. And a water pipe facility operated by Shizuoka prefecture exists in the source area of the Suruga Bay earthquake. Both the temperature and the turbidity sudden changes were observed after the Suruga Bay earthquake. We postulated that something has happened to the water pipe.

In the meantime, Japan Agency for Marine-Earth Science and Technology carried out in-situ two surveys; the first survey was to observe the water pipe, the second survey was to obtain bathymetry after the earthquake and the last survey is to do high resolution bathymetric mapping within a half year after the Suruga Bay earthquake. This paper describes the report of two surveys performed in the near source area of the Suruga Bay earthquake.

2. SURUGA BAY DEEP-SEA WATER PIPE AND ITS DAMAGE

Shizuoka prefecture has been operating two deep-sea water pipes off Yaizu city since 2001 and getting two different layered deep-sea waters. The shallower water pipe reaches 397 meters deep and the other deeper one reaches 687 meters deep. Deep-sea water is used for not only scientific and technological researches but also resources of original foods, which contributes to the local industrial development. Two water pipes have been deployed from Yaizu port parallel to eastward offshore. Length of two water pipes are 3.3 kilometers and 7.3 kilometers for 397 m and 687 m water pipes as shown Fig. 1. Water pipe is made by seamless high density polyethylene (HDPE) armored by steel. Though diameters are slightly different between 397 m and 687 m water pipes, proof load is about 2 kN. Sluice gates attached with 7.5 meters high truss scaffold are deployed at the end of the both water pipes.

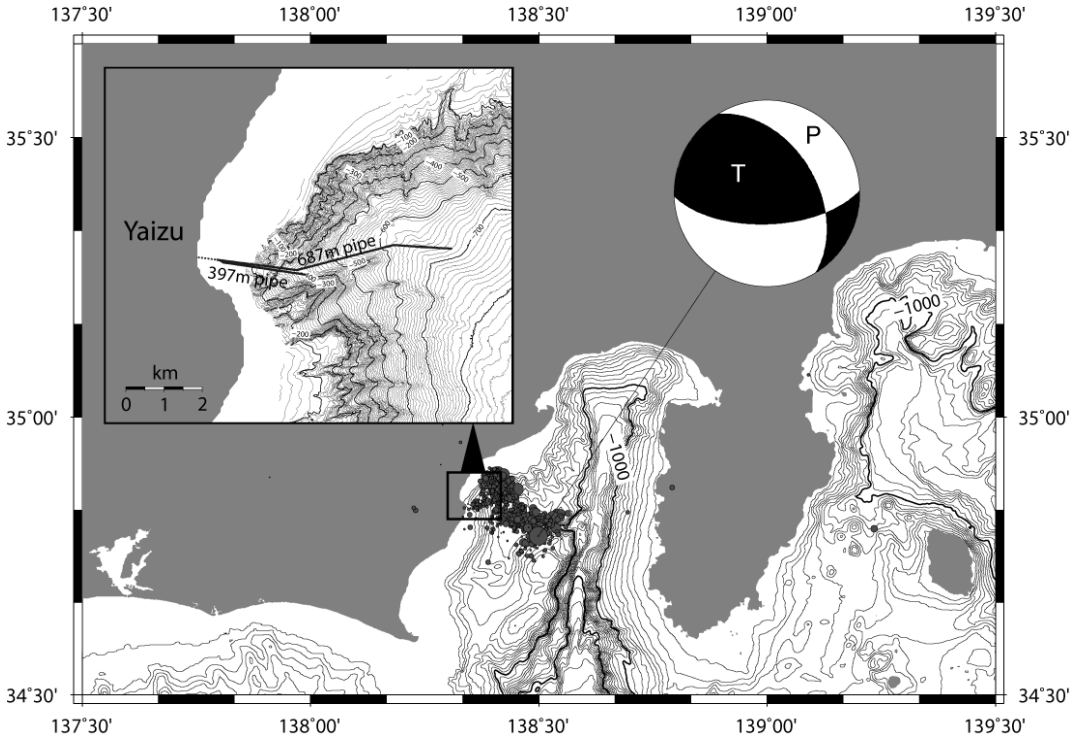

Figure 1 Map showing the epicenter of the earthquake taken place on 11 August, 2009 and the water pipes deployed in the Suruga Bay

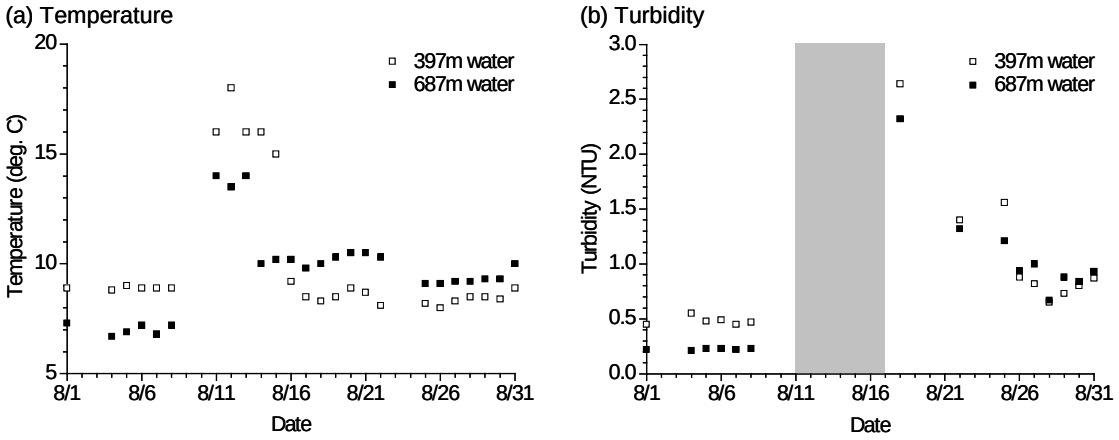

Figure 2 Time histories of deep-sea water on August, 2009 regarding (a) temperature and (b) turbidity. Note that data was saturated during the shaded period.

Basically, temperature and turbidity of deep-sea water are instrumentally measured once a day at the water pipe landing station. Figure 2 shows the time histories of deep-sea waters' temperature and turbidity on August 2009. Figure 2 (a) represents the temperature, in which it usually remained 9 degree C and 7 degree C for 397 m and 687 m waters, respectively. After the Suruga Bay earthquake, however, they changed 15 to 18 degree C and 13 to 14 degree C once, and high temperature continued for four days. On 16 August, the temperature of 397 m water was recovered, but that of 687 m water was still kept 9 degree C. Although the deeper 687 m water must be lower than the shallower 397 m water, thermal inversion occurred after the earthquake.

On the other hand, according to the turbidity data observed by 2100P produced by HACH Company in Fig. 2 (b), it remained 0.2 NTU and 0.5 NTU for 397 m water and 687 m water, respectively. But, they were saturated the dynamic range during a week after the earthquake, and it was impossible to measure the data. And about 0.5 NTU higher turbidity than the usual continued even after it became possible to do it again.

Continuous abnormal temperature increase and high turbidity from the 687 m water pipe implied that something happened to the 687 m water pipe.

Figure 3 Research Vessel "Natsushima"

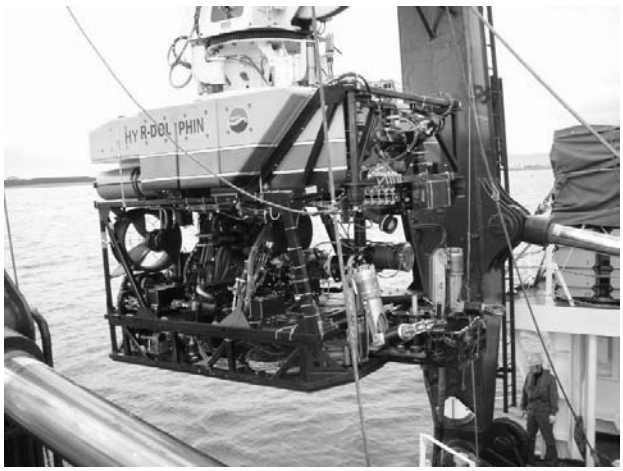

Figure 4 Remotely Operated Vehicle "Hyper-Dolphin"

3. IN-SITU SURVEY OF THE EARTHQUAKE SOURCE AREA

3.1. Overview

JAMSTEC planned to conduct two surveys in order to understand what happened in the near source area during the Suruga Bay earthquake both by using Research Vessel "Natsushima" (Fig. 3). The first survey was to carry out visual survey of the water pipes by Remotely Operated Vehicle "Hyper-Dolphin" (Fig. 4), and the second survey was to obtain bathymetry data by multi-narrow beam echo sounder equipped by "Natsushima".

3.2. "Hyper-Dolphin" survey

Because any damages have been considered to be taken place on the 687 m water pipe as mentioned previous section, two ROV's dives were carried out in order to know where to be damaged and the actual condition of the water pipe on 13 and 14 December 2009. ROV "Hyper-Dolphin" is carried by R/V "Natsushima", which can move flexibly under the water equipped with plural cameras to do visual survey. Figure 5 shows the "Hyper Dolphin" dive tracks after reaching the seabed measured by super short base line (SSBL) positioning system by "Natsushima".

The first dive, i.e., 1066 dive on 13 December was carried out at the water depth 200 to 300 meters. This is because the temperature from the 687 m water pipe is higher than that from 397 m water pipe after the earthquake. Damage has been take place at the shallower location than 397 m. "Hyper-Dolphin" dived across two water pipes, but it could cross the 397 m water pipe only. At last we could not find the 687 m water pipe during this dive, suggesting the 687 m water pipe has been moved away. Figure 6 shows the 397 m water pipe found by "Hyper-Dolphin". Half of 240 mm diameters pipe has been buried under the seabed. Moreover, we found 397 m water pipe has been suspended like a bridge at the submarine canyon.

The second dive, i.e., 1067 dive, on 14 December was carried out in order to find the sluice gate at the end of the 687 m water pipe. Figure 5 shows the dive track in which "Hyper-Dolphin" started to dive 200 m south from the pipe end. However, the sonar did detect nothing at the point of the 687 m water pipe end, and nothing could be found. Another survey line was made parallel to the first track to cross the 687 m water pipe again, but we could not find the 687 m water pipe. Then "Hyper -Dolphin" turned to westward and came across the 687 m water pipe denoted by A in Fig. 5. This is 500 meters away from the original water pipe laid position. After finding the 687 m water pipe, "Hyper-Dolphin" move to SE i.e., downstream along the water pipe. Debris has been deposited relatively on the SW side against the water pipe where "Hyper-Dolphin" came across the 687 m water pipe. We also found the wreck of submerged ship on the way as shown in Fig. 7. The further offshore "Hyper-Dolphin" proceeded, the more frequent the 687 m water pipe was lost and up cropping. At last we lost the 687 m water pipe at water depth of 782 meters denoted by B in Fig. 5. Section between A and B is the current 687 m water pipe location, but it is still unknown how the NW end of the 687 m water pipe is laid. After the visual survey by "Hyper-Dolphin", we have realized that the 687 m water pipe at least 2 km has been washed away toward the offshore from the original position.

3.2. "Natsushima" survey

It has become clear that the 687 m water pipe has been washed away offshore after the "Hyper-Dolphin" dives. Bathymetry survey by multi-narrow beam echo sounder equipped by "Natsushima" was carried out from 26 through 31 December 2009 in order to reveal the cause of 687 m water pipe washed away. Multi-narrow beam echo sounder used in the present survey is SeaBat 8160, Reson inc. Principal of multi-narrow beam echo sounder is simply described as follows. An acoustic beam is periodically transmitted to the seabed from the bottom of the ship. Hydrophone array receives the acoustic beams reflected from the seabed in order to determine the distance between the ship and the seabed. The bathymetry map is

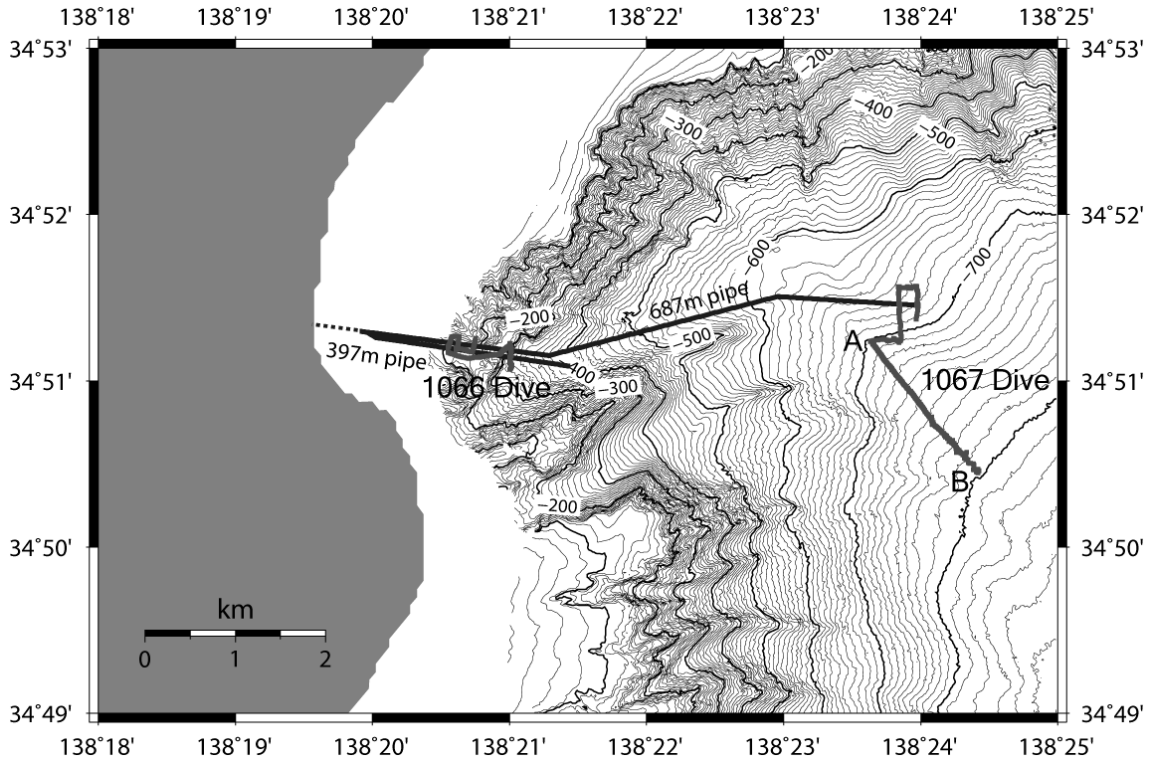

Figure 5 Dive tracks of ROV "Hyper-Dolphin" and the location of the water pipes

Figure 6 397 m water pipe observed by ROV "Hyper-Dolphin" during the 1066 dive

Figure 7 687 m water pipe and submerged ship found during the 1067 dive

made based on this procedure. In 2004, "Natsushima" also carried out bathymetry survey by using the same equipment, and it makes us possible to compare the bathymetry obtained before and after the earthquake. But it is noted that the resolution of bathymetry obtained before the earthquake is not good enough, because ship speed "Nastsushima" was relatively high. Moreover, area obtained the bathymetry is not completely coincident each other.

Ship track of "Natsushima", i.e., survey line by multi-narrow beam echo sounder in addition to the obtained bathymetry after the earthquake are superposed in Fig. 8. A lot of submarine canyons at the edge of the spur shaped by fan exist on the continental slope in the Suruga Bay (Otsuka, 1982). And the deep-sea water pipes are laid along one submarine canyon.

Difference between bathymetry dataset obtained before and after the Suruga Bay earthquake has been reproduced and its enlarged view in near the 687 m water pipe is shown in Fig. 9. Original laid position of the 687 m water pipe and the current water pipe location by "Hyper-Dolphin" are also drawn in Fig. 9.

Since contour lines are very close near submarine canyons and the resolution is not so good before the earthquake, it is difficult to evaluate the deformation due to the earthquake. Ignoring such topographies, difference is significantly large at the terrace around the depth of 600

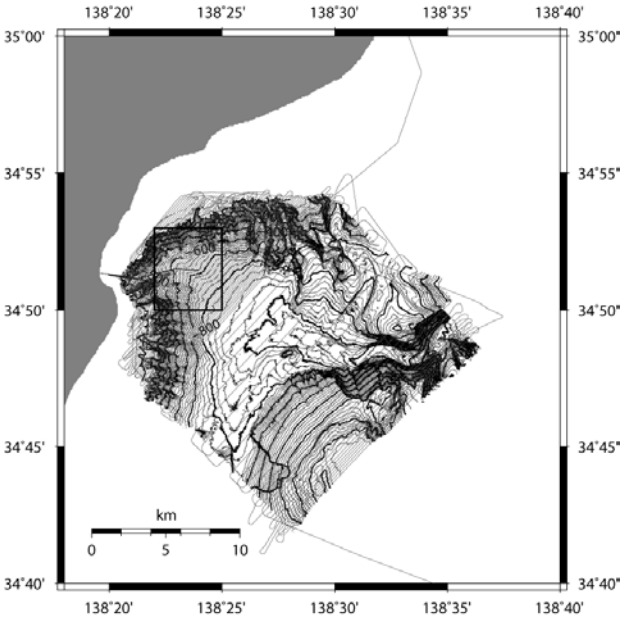

Figure 8 Bathymetry survey result by multi-narrow beam echo sounder of R/V "Natsushima"

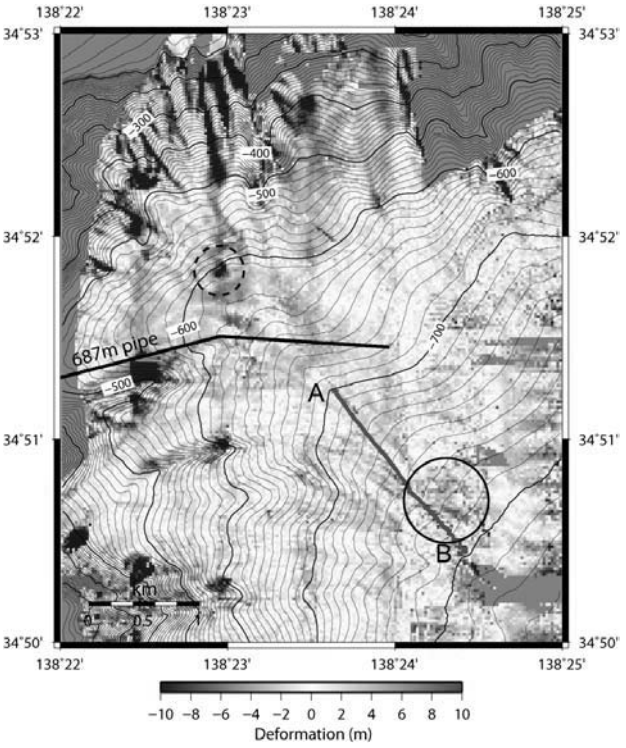

Figure 9 Difference between bathymetries obtained before/after the earthquake

meters near the 687 m water pipe denoted by dashed circle in Fig. 9. About 10 meter subsidence is appeared there and 3 to 5 meters subsidences aside. Contour lines are retrieved suggesting erosion pattern were taken place. This means that the submarine landslide has been taken place at this location. Turbidity current due to the submarine landslide flew SE along the submarine canyon, and washed away the 687 m water pipe laid at 900 m downstream. Location where "Hyper-Dolphin" lost the 687 m water pipe became uplift pattern denoted by solid circle in Fig. 9. This suggests that the turbidity originated by the submarine landslide has been deposited there.

4. CONCLUSING REMARKS

Deep-sea water pipes deployed in the near source area of the Suruga Bay earthquake occurred on 11 August 2009 have been damaged. For deepen understanding how the accidents have been happened and its cause, two surveys were carried out in December 2009. Two survey results are conclusively summarized as follows,

(1) Among two deep-sea water pipes, 687 m water pipe at least 2 kilometers has been washed away from the original position by visual survey by ROV "Hyper-Dolphin" during the 2009 Suruga Bay earthquake. Broken point separated from originals is still unknown.

(2) Bathymetry mapping by R/V "Natsushima" has revealed that the submarine landslide origin is possibly located at the northward upstream of the 687 m water pipe, where an erosion pattern is obviously visible. The current 687 m water pipe is covered with debris including that from the submerged ship.

It is worthwhile noted that the submarine cable located in the Suruga trough, about 100 km south from the earthquake source has been also damaged after 15 hours and 52 min after the Suruga Bay earthquake. Turbidity current due to the submarine landslide might reach there.

Entire damages of the deep-sea water pipes due to the submarine landslide earthquake have not been revealed in the preset surveys. Further survey and qualitative studies are necessary in the near source area, which may contribute to other similar submarine life lines such as submarine cable etc and mitigate their damages.

NUMERICAL MODEL OF DYNAMICS OF COMPRESSIBLE OCEAN IN TSUNAMI SOURCE: SENSITIVITY TO INPUT PARAMETERS

Sergey V. Kolesov

Research junior, Physics Faculty, M.V.Lomonosov Moscow State University, Russia
kolesov@ocean.phys.msu.ru

Abstract: In this study 3D numerical model of compressible ocean behavior in a tsunami source is considered. The model is based on the linear potential theory of ideal homogeneous compressible fluid in the field of gravity. The water layer is bounded with free surface above and with absolutely rigid moving bottom below. Dynamic bottom displacement is specified as vector velocity field. The explicit finite-difference scheme on a rectangular grid is used to solve the problem. Testing of numerical model with use of exact analytical solution of the problem in the case of horizontal flat bottom is described. Taking the 2003 Tokachi-Oki tsunamigenic earthquake as an example the role of horizontal components of dynamic bottom deformation is examined.

1. INTRODUCTION

The issue of accounting for the compressibility of water in the problem of tsunami generation has been raised repeatedly in the literature (e.g. Miyoshi 1954, Sells 1965, Kajiura 1970, Nosov 2000, Ohmachi et al. 2001, Nosov et al. 2007, Gisler 2008, Ohmachi and Inoue 2010). In case of a horizontal absolutely rigid bottom a compressible ocean behaves as an waveguide which is characterized by a discrete set of normal frequencies

$$\nu_n = c(1+2n)/4H, \qquad (1)$$

where $n = 0,1,2,3...$, H is the ocean depth and c is the sound speed in water.

When JAMSTEC (Japan Agency for Marine-Earth Science and Technology) deployed a real-time observatory at the continental slope close to the islands of Japan (Hirata et al. 2002), it became possible to investigate a tsunami formation, including hydroacoustic phenomena, just at its source. 3D numerical model taking into account dynamic bottom deformations and water compressibility was created with the intent to reproduce in-situ measured bottom pressure variations during 2003 Tokachi-Oki earthquake (Kolesov et al. 2010). During simulation it becomes clear, that calculation results are rather sensitive to input parameters. The goal of present study is to test the model on the exact analytical solution and investigate the role of horizontal components of bottom deformation.

2. 3D NUMERICAL MODEL

Let us consider a layer of an ideal incompressible homogeneous liquid of variable depth $H(x,y)$ in the field of gravity. We assume the calculation domain to be small enough to neglect the sphericity of the Earth. The origin of the Cartesian reference frame $0xyz$ is on the unperturbed free surface, the $0z$ axis is directed vertically upward. To describe elastic oscillations of water column we shall resolve the problem with respect to the velocity potential $F(x,y,z,t)$ (Landau, Lifshitz, 1987):

$$\frac{\partial^2 F}{\partial t^2} - c^2 \Delta F = 0, \qquad (2)$$

$$\frac{\partial^2 F}{\partial t^2} = -g\frac{\partial F}{\partial z}, \quad z = 0, \qquad (3)$$

$$\frac{\partial F}{\partial \vec{\mathbf{n}}} = (\vec{u}, \vec{\mathbf{n}}), \quad z = -H(x,y), \qquad (4)$$

where $\vec{\mathbf{n}}$ is the unit vector normal to the bottom surface, $\vec{u} \equiv (u_x, u_y, u_z)$ is the velocity vector of bottom deformation. We assume the deformation of the basin bottom takes place during a time interval τ, upon which the basin bottom stops. Bottom deformations are assumed small, thus depth H and vector normal $\vec{\mathbf{n}}$ do not depend on time. Free surface displacement and dynamic pressure can be easily obtained using the following formulae:

$$\xi = -\frac{1}{g}\frac{\partial F}{\partial t}\Big|_{z=0}, \qquad (5)$$

$$p(x,y,z,t) = -\rho\frac{\partial F}{\partial t}, \qquad (6)$$

where ρ is the density of liquid. After the time moment $t = \tau$, i.e. when the bottom deformation stops, we can try to describe a gradual damping of hydroacoustic waves due to their absorption in the bottom. This can be archived by changing boundary condition (4) from “fully reflective” to the semi-transparent one:

$$\frac{\partial F}{\partial \vec{n}} = \frac{\partial F}{\partial t}\frac{1}{c}\frac{R_A - 1}{R_A + 1}, \qquad (7)$$

where R_A is amplitude reflection coefficient at the "water-bottom" boundary for a normally incident hydroacoustic wave. Generally, amplitude reflection coefficient R_A depends on parameters of the ground in particular site. In this study the value of $R_A = 0.89$ was taken.

The equations (2)-(7) are solved numerically with use of traditional explicit Finite Difference scheme (z-leveled model, rectangular grid). As a condition for stability of the scheme a well-known CFL criterion is used.

More comprehensive model description and numerical scheme implementation peculiarities can be found in following papers (Nosov and Kolesov 2007, Kolesov et al. 2010).

3. RESULTS AND DISCUSSION

Let us consider the case of a flat horizontal bottom. Due to simple shape of basin, boundary condition (4) could be rewritten in following form:

$$\frac{\partial F}{\partial z} = \frac{\partial \eta}{\partial t}, \quad z = -H, \qquad (8)$$

where η is bottom deformation. As a source of the waves, let us choose a cylindrically symmetric deformation of the bottom with duration τ:

$$\eta(r,t) = \sin\frac{\pi t}{\tau} e^{-\frac{r^2}{R^2}} \left(\Theta(t) - \Theta(t-\tau)\right), \qquad (9)$$

where R is the radius of the source, Θ is the Heaviside step function. Analytic solution of a cylindrically symmetric problem (2), (3), (8) obtained in Nosov (2000), allows us to calculate the free surface displacement as follows:

$$\xi(r,t) = -g^{-1}\int_0^\infty dk \int_{s-i\infty}^{s+i\infty} dp\, p \exp(pt)\, J_0(kr)\, A(p,k), \qquad (10)$$

$$A(p,k) = -\frac{p\, k\, \Psi(p,k)}{\alpha\left[\mathrm{sh}(\alpha h) + p^2 g^{-1}\alpha^{-1}\mathrm{ch}(\alpha h)\right]},$$

$$\Psi(p,k) = \frac{1}{2\pi\pi}\int_0^\infty dr \int_0^\infty dt\, \eta(r,t)\, r\, J_0(kr) \exp(-pt), \qquad (11)$$

$$\alpha^2 = k^2 + p^2 c^{-2}.$$

Integrals in (11) for a bottom deformation (9) can be easily calculated analytically. Integrals in (10) are calculated numerically.

For the numerical simulation a calculation domain with size of 220x220 km and depth 5.6 km was chosen. Number of grid nodes was varied within the following bounds: horizontal — from 200 to 800, vertical — from 20 to 80. Duration of the bottom deformation was τ=3.7 and 37 s. For the chosen depth source with short duration effectively excite only acoustic waves, source with long duration — only gravitational waves. Horizontal size of bottom deformation R was chosen to be equal the water layer depth H. Generally, the size of tsunami source area is much bigger than the depth of the ocean. Such a small source is chosen to demonstrate the model efficiency on horizontal discontinuities of small scale.

At the first stage, the influence of the grid horizontal spacing in the accuracy of the numerical solution was studied. The results are shown in Fig. 1. It's easy to see that the numerical model reproduces the amplitude of both acoustic (short-period) and gravitational waves. Over time, the accumulation of the phase difference between the analytical and numerical solutions becomes visible. The smallest phase difference corresponds to the most detailed resolution the grid, principally vertical resolution.

Simulation with a fixed number of nodes in the horizontal and variable in the vertical direction is shown on the Fig. 2. As in the previous case, the choice of spatial grid step does not significantly affects on the amplitude of oscillations. It is notable, that a phase difference tends to grow with reducing of the vertical resolution of the grid. Test calculations showed that for a correct reproduction of the amplitude characteristics it is sufficient 20 grid nodes vertically. Of course, vertical spatial step must satisfy following relation: $\Delta z < cT_{min}$, where T_{min} is the minimum period of acoustic waves generated by the source. To minimize the phase difference we should maximize vertical resolution of the grid. The choice of horizontal grid spacing is determined by the scale of the horizontal discontinuities of the source. In the simulation shown in Fig. 1, the horizontal steps $\Delta x = \Delta y \approx 1$km ($N_x = N_y = 200$) is sufficient to adequately reproduce the waves generated by a source with radius $R = H = 5.6$km.

From figures 1 and 2 one can conclude that the phase difference is accumulated over time for both acoustic and gravitational waves. However, accumulation for acoustic waves goes faster. Velocity of gravitational waves as well as the period of the acoustic waves depends on the depth of the water layer. The peculiarity of the finite difference method is that the approximation of boundary conditions utilizes 2-3 vertical nodes and, thus, reduces the true depth. A simple estimation shows that the error in determining the depth in sole node over time T will lead to the phase difference for the acoustic waves:

$$\Delta\Phi_a = \left(\frac{c}{4(H+\Delta z)} - \frac{c}{4H}\right) 2\pi T \qquad (12)$$

and for gravitational waves:

$$\Delta\Phi_g = \left(\frac{\sqrt{gH}}{L} - \frac{\sqrt{g(H+\Delta z)}}{L}\right) 2\pi T \qquad (13)$$

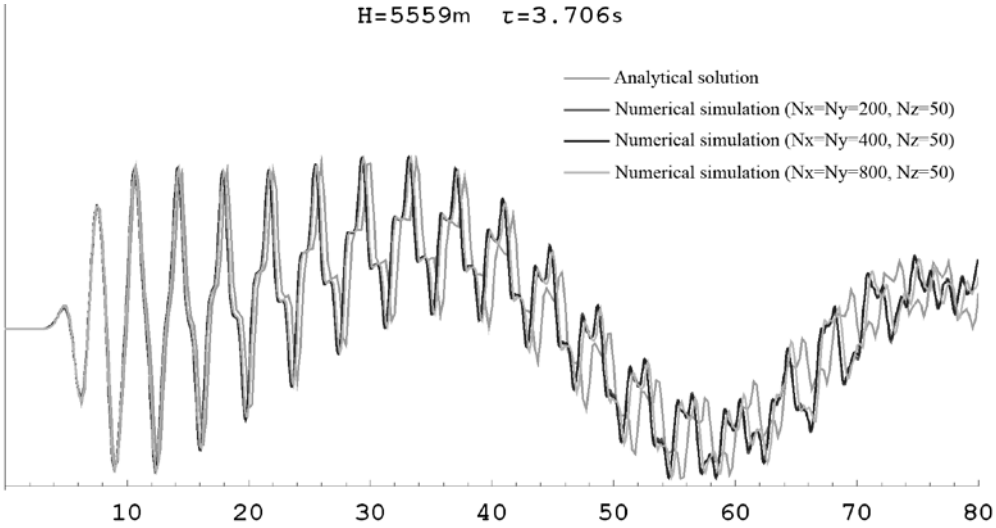

Figure 1. Free surface displacement in the center of calculation domain: influence of horizontal grid resolution.

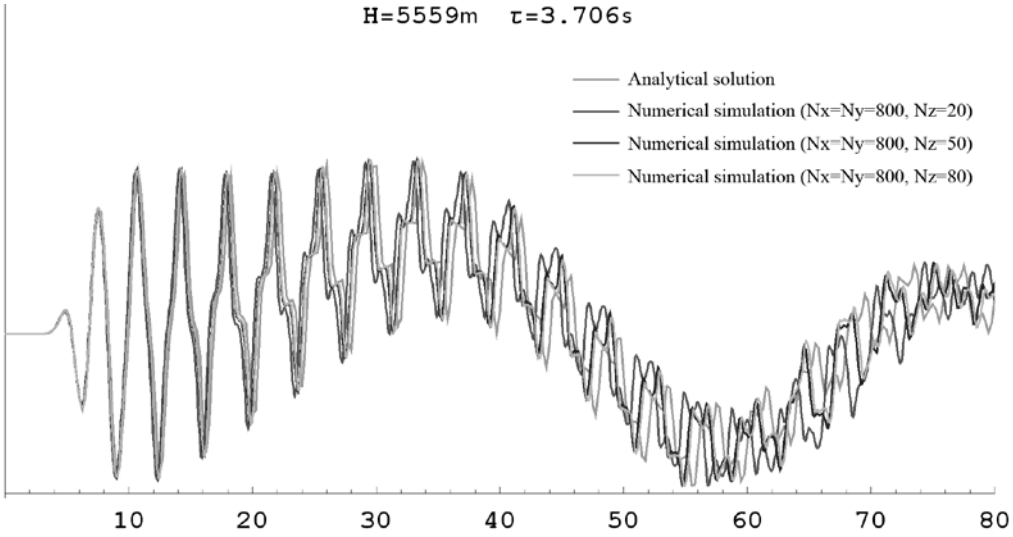

Figure 2. Free surface displacement in the center of calculation domain: influence of vertical grid resolution.

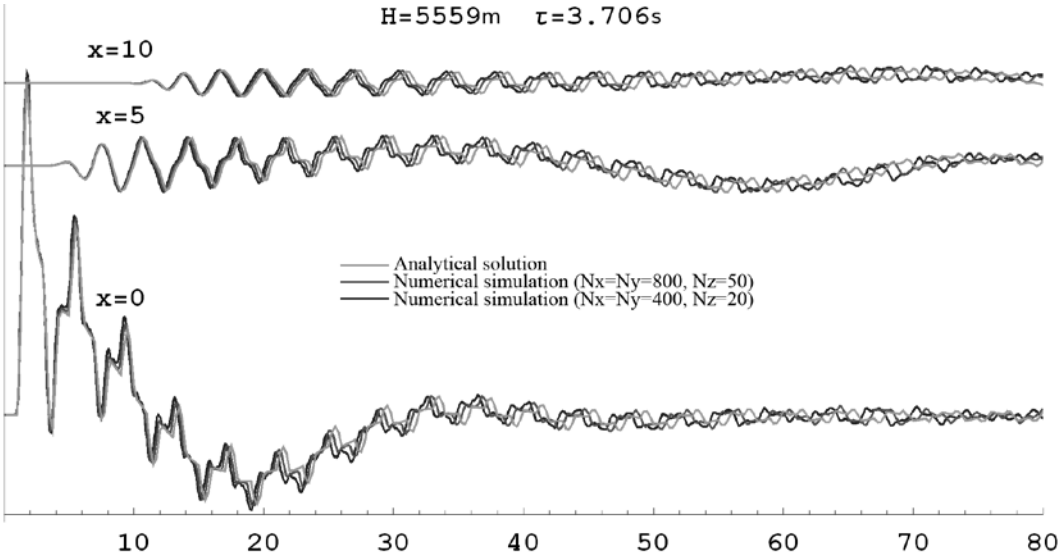

Figure 3. Free surface displacement at different distance from the center: fast bottom motion.

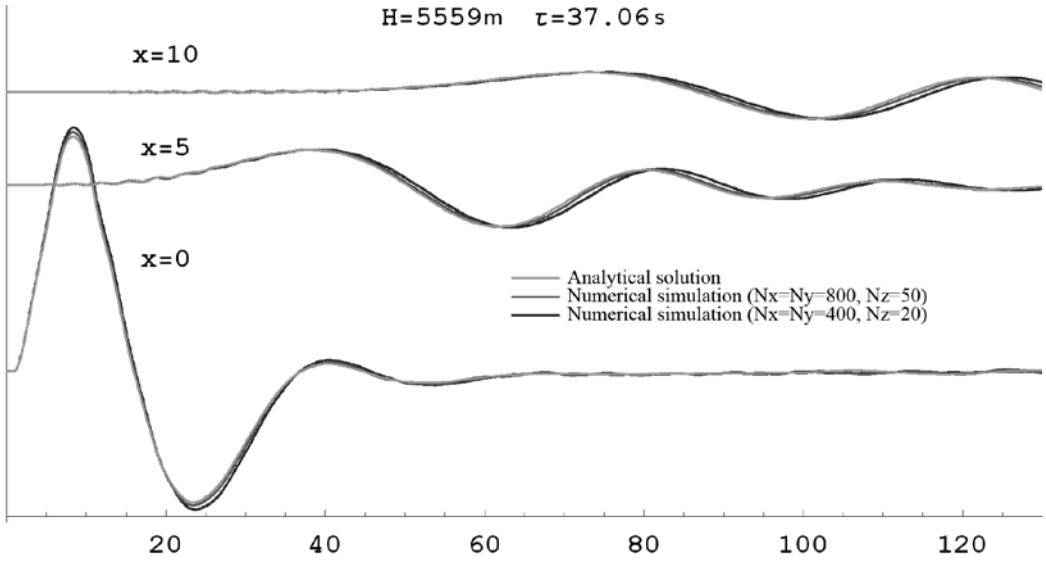

Figure 4. Free surface displacement at different distance from the center: slow bottom motion.

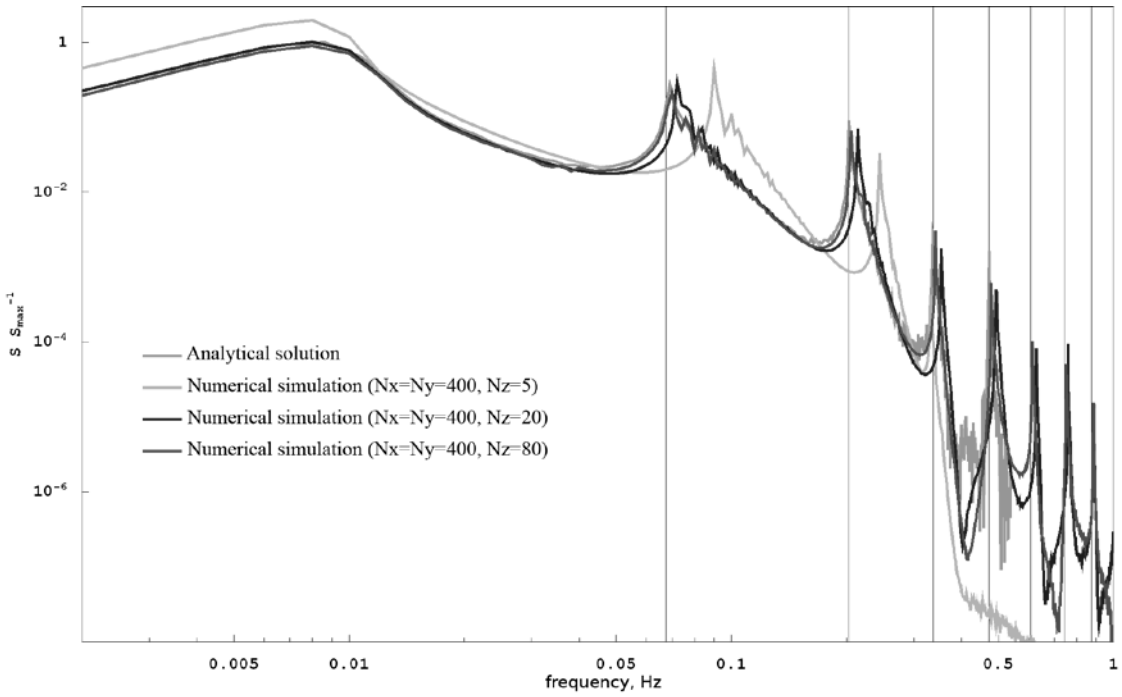

Figure 5. Normalized frequency spectra of free surface displacement in the center of calculation domain. Time series were calculated numerically and analytically at .bottom displacement duration of 3.7s. Vertical grid lines stand for the position of the normal frequencies of water layer.

In this particular case, if the computational domain has vertical resolution of 20 and 19 nodes, the phase difference between the first mode of elastic oscillations at 2π will be achieved at the 20th period. Same phase difference of gravitational waves will be achieved at the 39th period. It worth to note that the period of the gravitational waves is usually much longer than the period elastic oscillations of the water layer, it is obvious that the significant phase difference of acoustic waves will occur much earlier.

Fig. 3 presents a comparison of analytical and numerical solutions at three points away from the center at $0,\ 5H$ and $10H$. Calculations performed using the numerical model presented for large and small number of nodes in the computational grid. The numerical model shows good coincidence with the exact analytical solution, especially with greater number of grid nodes. A similar calculation but with longer duration of bottom deformation is shown in Fig. 4. In this case, we have a prevailing component of the gravitational wave motion. As one can see under these conditions the numerical model gives a nearly perfect coincide with the analytical solution.

Comparison of normalized energy spectra of the numerical and analytical solution is presented on Fig. 5. Normalization was carried out at maximum level, corresponding to the analytical solution. Vertical grid lines stand for the normal frequencies of water layer. It is seen that the numerical model precisely describes the frequency characteristics of the system. Accuracy of calculation increases with better vertical resolution of the grid. Cut-off of the spectrum of the analytical solution and the spectrum of numerical simulation with the least number of grid nodes could be explained by a low sampling rate of the data.

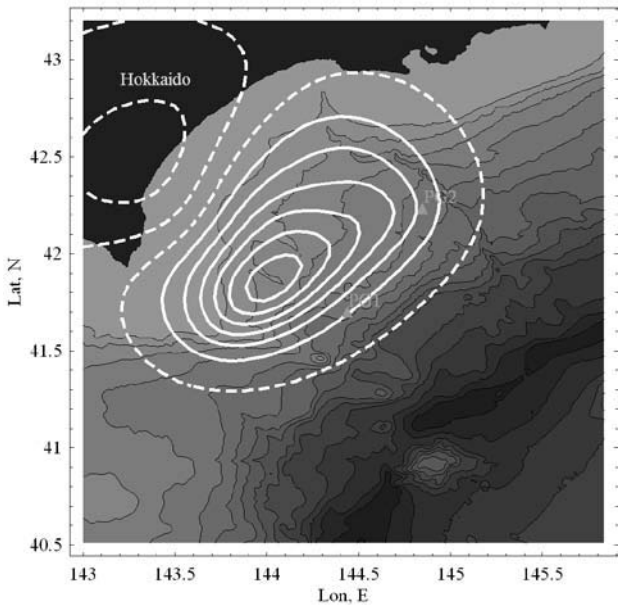

Figure 6. Computational domain. Vertical coseismic bottom deformation is shown by solid (uplift) and dashed (subsidence).

To examine the role of horizontal components of dynamic bottom deformation the simulation of the 2003 Tokachi-Oki tsunamigenic earthquake was performed. Fig. 6 depicts a computational domain with bathymetry, residual bottom deformation and points of virtual bottom pressure sensors. Computational area dimension was approximately 220x320 km (301x301 nodes); the number of vertical nodes was 15 with the spatial step 535 m. The dynamic bottom deformation was computed using fault model proposed in Koketsu et al. (2004). The calculation technique and parameters of the fault and ground are described in papers (Ohmachi et al. 2001, Kolesov et al. 2010). The duration of bottom motion was 128 seconds. Despite the fact that PG1 and PG2 points correspond to bottom cable stations deployed by JAMSTEC, in this study these points are chosen just for example. The ability of the numerical model to reproduce the in situ measured signal was discussed in Kolesov et al. (2010).

Two series of calculation was performed. First one using three-component dynamic bottom deformation ($\vec{u} \equiv (u_x, u_y, u_z)$), second one using only vertical velocity component ($\vec{u} \equiv (0, 0, u_z)$). Time-history of bottom pressure variations was recorded for both points PG1 and PG2. In Fig. 7 elastic oscillations generated by three-component source are plotted with red, blue curve stands for difference between synthetic signals, generated by both sources, in other words this is contribution of horizontal components of bottom deformation into resulting signal. It's clearly evident that mentioned contribution is almost negligible.

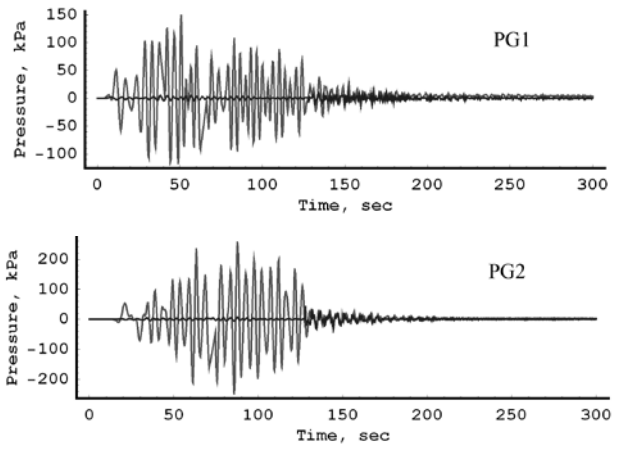

Figure 7. Bottom pressure variations in points PG1 and PG2. Acoustic waves from three-component source are shown with red, contribution of horizontal components are shown with blue.

4. CONCLUSIONS

3D numerical model was tested with use of exact analytical solution of the problem in the case of horizontal flat bottom. Good coincidence between analytical and numerical simulations was found. Numerical model

reproduces both amplitude and frequency characteristics of the system. Vertical grid resolution seems to be the most important parameter affecting the accuracy of calculations. The contribution of horizontal components of dynamic bottom deformation into hydroacoustic effects in tsunami source turned out to be small.

Abstract: The validation of the tsunami inundation modeling for the June 23, 2001 Peru earthquake is carried out by using three different tsunami source models. The source parameters for this event have been estimated from seismological analysis. We use the Global Centroid Moment Tensor solution to estimate the first model. The second model was taken from the result of another seismic analysis, which determined the slip distribution of 40 subfault by using teleseismic broadband P-waves. The third model, called Tsunami Waveform Inversion Model, it is constructed in this study by using tsunami waveforms that were recorded at eleven tide gauge stations around the source region. In this model we determined the slip distribution in detail of 10 subfault segments. The numerical simulation of tsunami inundation is carried out. The inundation results from the three models are validated through comparison in terms of the run-up height and inundation distance with the field survey data measured around Camana city. The tsunami inundation modeling results in terms of the run-up height shows that the third model is more appropriate approximation compared to the field survey data, and in terms of the inundation distance the first model is more appropriate approximation.

1. INTRODUCTION

Due to the location in a highly seismic area, Peru has experienced some of the largest tsunamis that have occurred in the world. For example, the tsunami that occurred on June 23, 2001 in the southern part of Peru was generated by the earthquake of Mw 8.4.

The purpose of this study is to validate the tsunami inundation modelling of the June 23, 2001 Peru earthquake, in order to use it as model to create future tsunami hazard maps for the hazard assessment along the coastal area of Peru. In this study three different tsunami source models are simulated by tsunami inundation modeling and the results are validated through a comparison with field survey data in terms of the run-up height and inundation distance recorded along the coastal area of Camana city.

2. DATA AND METHOD

2.1 Bathymetry and Topography Data

In order to perform tsunami numerical modeling the computational area is divided into four domains to construct the nested grid system. The bathymetry data for the first to the third domains are interpolated from the General Bathymetry Chart of the Ocean (GEBCO) 30 arc-seconds grid data and for the fourth domain the bathymetry is generated from the nautical chart of Directorate of Hydrography and Navigation (DHN), Navy of Peru. The topography data for the first and second domains are interpolated from GEBCO, and for the third domain it is taken from the Shuttle Radar Topography Mission (SRTM) 3arc-second resolution data and for the fourth domain it was taken from the Thermal Emission and Reflection Radiometer (ASTER) 1 arc-second resolution data. Table 1 shows the boundary and resolution for each domain.

Table 1 Boundary, resolution and data source for each computational domain

Domain	Longitude		Latitude		Resolution
	Min.	Max.	Min.	Max.	arc-second
1	-78.00°	-70.00°	-19.00°	-11.00°	27
2	-74.00°	-72.00°	-18.00°	-16.00°	9
3	-73.15°	-72.40°	-17.00°	-16.25°	3
4	-72.92°	-72.58°	-16.75°	-16.50°	1

2.2 Tide Gauge Data

The June 23, 2001 Peru tsunami was recorded in several tide gauges around the world. In this study the tide gauge data are taken from the National Oceanic and Atmospheric Administration (NOAA)/Pacific Marine Environmental Laboratory (PMEL), Center for Tsunami

Research and are provided by the National Oceanic Services (NOS)/NOAA, Field Operation Division, Pacific Regional Office.

Among all tide gauge stations data, only eleven tide gauges are used as input data which has 1 minute data sampling, three tide gauge stations located in Peru and the rest of them located in Chile. In order to obtain the tsunami signal from each tide gauge data, firstly the initial time of the earthquake must be subtracted (T0 = 06/23 20:33:14 UTC, according to USGS). After that the astronomical signal must be estimated by fitting a polynomial regression model using the entire data. Then it can be removed from the original data. Finally these observed tsunami signals are compared with the synthetic tsunami signal obtained in the tsunami simulations.

2.3 Field Survey Data

The International Tsunami Survey Team (ITST) conducted a field survey along the area affected by the tsunami with the main purpose to examine the tsunami damage, to measure the tsunami run-up height and the extent of inundation and also to interview the eyewitnesses of the event. The measured tsunami run-up height, and inundation distance around Camana city done by the ITST (2001abc) are used in this study to validate the tsunami inundation model.

2.4 Tsunami Simulation

The numerical simulation is conducted by using TUNAMI-N2 (Tohoku University's Numerical Analysis Model for Investigation of Near-filed tsunami No.2) code based on shallow water theory and Cartesian coordinate system (Imamura, 1995), which was developed by Disaster Control Research Center (DCRC), Tohoku University, Japan. The computation time for the tsunami propagation is 3.5 hour. In order to satisfy the stability condition, the time step is 0.2 s. The tsunami inundation is calculated on the fourth domain using 1 arc-second of bathymetry and topography grid data (Table 2), and in this domain there are 1200 x 900 grid points along the longitude and latitude directions, respectively, for which the total computation time is 3.5 hours. The value of the Manning's roughness coefficient is assumed to be equal to 0.025 (Koshimura et al, 2009).

3. RESULTS AND DISCUSSION

3.1 Tsunami Source Models

The source parameters of the 2001 Peru earthquake have been estimated from two different seismological analyses, the Global Centroid Moment Tensor (GCMT) and Kikuchi and Yamanaka (2001). The results of these studies are used for two different models of Uniform Slip Model (USM) and Heterogeneous Slip Model (HSM). Another model called Tsunami Waveform Inversion Model (TWIM), estimated from tsunami waveform in this study is also used.

The USM is a single fault based on the GCMT solution which proposed some parameters of the seismic source (magnitude, strike, slip angle, centroid latitude and centroid longitude). By using the magnitude, it is possible to estimate the slip, length and width of the fault (Papazachos et al, 2004). Table 2 shows the magnitude and the source parameters for this simple model.

Table 2 Magnitude and source parameters for the Uniform Slip Model.

Magnitude (Mw)	Strike	Dip	Slip angle	Length (km)	Width (km)	Slip (m)	Top depth (km)
8.4	310°	18°	63°	270	95	4	29.6

The source parameters for the HSM are taken from the seismic inversion results by Kikuchi and Yamanaka (2001). They analyzed teleseismic broadband P waves retrieved from 24 seismic stations to determine the general source parameters. They determined the slip distribution in detail of 40 subfault segments in the rupture area of 150 km by 240 km (Figure 1). Each subfault segment has an area of 30 km x 30 km.

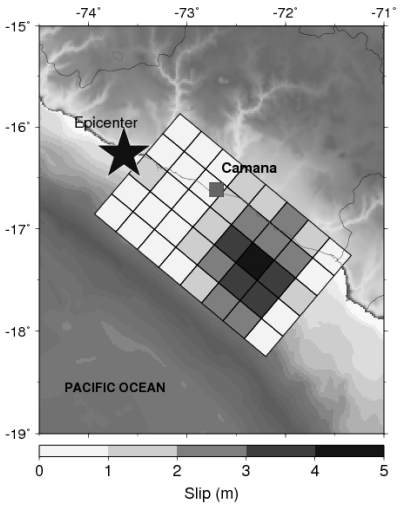

Figure 1 Slip distribution obtained by Kikuchi and Yamanaka (2001)

The source parameters for the TWIM are estimated by the inversion of the tsunami waveforms from tide gauge data (Satake, 1987). The computation area extends from 70°W to 85°W and 5°S to 35°S using GEBCO 30 arc-seconds bathymetry grid data, and consequently, there are 1800 x 3600 grid points along the longitude and latitude direction, respectively. The computation time for the tsunami numerical propagation is 4 hours. The time step is 2.0 s to satisfy the stability condition. The initial seafloor deformation for each subfault is calculated based on Okada (1985) and Tanioka and Satake (1996).

Figure 2 shows the spatial slip distribution obtained by the tsunami waveform inversion which is divided into ten subfault segments. The subfault size is 50 km x 50 km. The rupture area is 250 km by 100 km. Because of the spatial distribution of the stations around the fault area, the accuracy of the result in the southern part is better comparing to the

northern part. Therefore, this result is used to compute the initial seafloor deformation for the tsunami inundation model on Camana city that is located in the central part of the fault area. Table 3 shows the fault parameters obtained from the tsunami waveform inversion model.

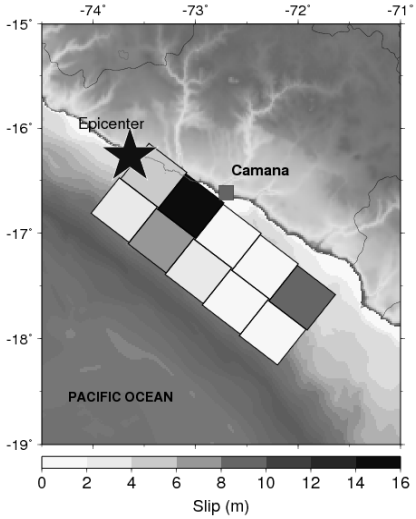

Figure 2 Results obtained from the tsunami waveform inversion

Table 3 Subfault parameters obtained from the tsunami waveform inversion

No.	Strike	Dip	Slip angle	Length (km)	Width (km)	Slip (m)	Error (m) +/-	Top depth (km)
1	308°	18°	63°	50	50	1.15	0.91	14.15
2	308°	18°	63°	50	50	0.35	0.43	14.15
3	308°	18°	63°	50	50	2.84	1.78	14.15
4	308°	18°	63°	50	50	7.78	4.79	14.15
5	308°	18°	63°	50	50	3.8	1.83	14.15
6	308°	18°	63°	50	50	8.38	4.18	29.6
7	308°	18°	63°	50	50	0.36	0.22	29.6
8	308°	18°	63°	50	50	0.68	2.01	29.6
9	308°	18°	63°	50	50	14.18	6.56	29.6
10	308°	18°	63°	50	50	5.92	2.89	29.6

3.2 Seafloor Deformation due to the Source Models

The initial seafloor deformation for each model was calculated by using the Okada (1985) formula (Figure 3). The spatial distribution of the uplift part is located offshore, while the subsidence part is extended towards the land area for all models.

Figure 4 shows the cross section of deformation height between 74.75°W and 71°W along the 17°S for each model. It shows that the uplift of the TWIM is higher than the USM and HSM, which is approximately two times compared with the uplift of the USM, and this is because the values obtained for the slip amount on the northern part of the fault in the TWIM are overestimated. The values of the subsidence from TWIM and UHM are approximately similar at about 0.5 m.

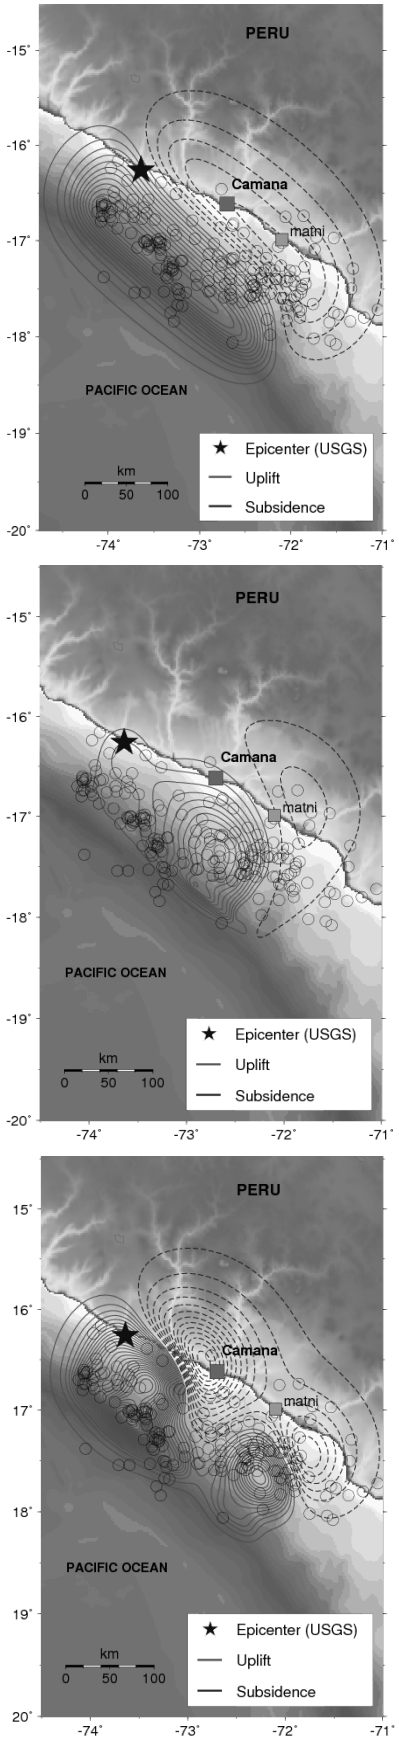

Figure 3 Seafloor deformation for each model top: USM, center: HSM and bottom: TWIM. Contour lines are drawn in every 0.1 m for uplift and subsidence part

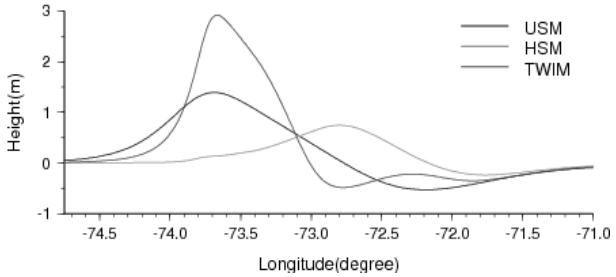

Figure 4 Cross section of seafloor deformation height for each model

3.3 Run-up Height and Inundation Distance

The calculated inundation results from each model are validated through a comparison with field survey data from ITST (2001abc) in terms of the run-up height and inundation distance. According to the ITST (2001abc), approximately 15 points were obtained for tsunami run-up height and inundation distance from the field survey.

The comparison between the computed and observed tsunami run-up height is shown in Figure 5. In general the computed tsunami run-up height along the coastline of Camana city from each model is underestimated compared to the measured run-up height. This might indicate the limitation of the tsunami inundation model using the shallow water approximation, and the possibility that the field data represents the extreme feature of tsunami run-up height, or lack of bathymetry and topography features in the model (Koshimura et al, 2009). However, the computed tsunami run-up height from the TWIM shows a better approximation on the southern part of Camana city from 72.61°W to 72.76°W.

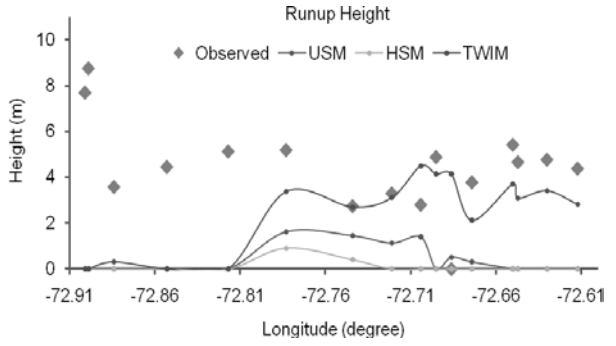

Figure 5 Comparison between the observed tsunami run-up height (gray diamond) and the computed tsunami run-up height from each model (line in blue: USM, line in green: HSM and line in red: TWIM)

The comparison between the computed and observed inundation distance is shown in Figure 6. It shows that the result from the HSM is underestimated on the entire area around Camana city. Figure 6, also shows that the result from the TWIM is overestimated predominantly on the south from 72.61°W to 72.81°W. However, the result from the USM fitted better, this is predominantly shown on the southern part of coastline of Camana city from 72.61°W to 72.81°W. This also might indicate the possibility that the field survey data represents the extreme feature of the tsunami inundation distance in the northern part of Camana city (from 72.81°W to 72.91°W).

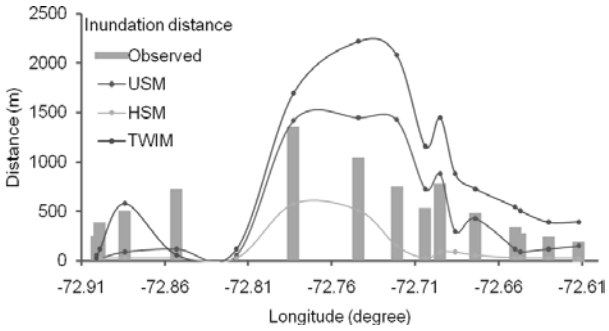

Figure 6 Comparison between observed tsunami inundation distance (gray bar) and computed tsunami inundation distance, from each model (line in blue: USM, line in green: HSM and line in red: TWIM)

I order to investigate the reason of underestimation of run-up height and inundation distance, we compare the real topography image and the topography data used in this study. The cross section shown in Figure 7 covers from 16.54°S, 72.91°W to 16.53°S, 72.90°W on the northern part of Camana city and shows a hill that is approximately 10 m height which does not exist in the real topography. This represents an incompatibility between the real topography and topography data used in this study, indicating that calculated tsunami waves less than 6 m at the coast line cannot pass through the hill.

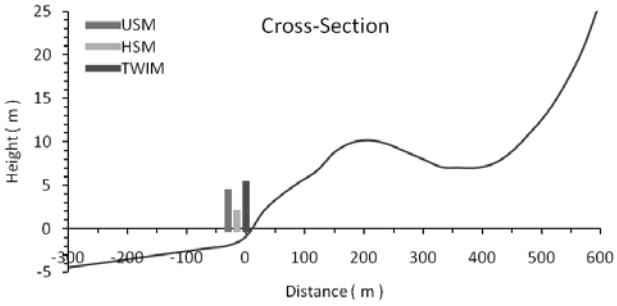

Figure 7 Cross section of topography and bathymetry data on the northern part of Camana city. Blue, green and red bars show calculated tsunami height al coast from USM, HSM and TWIM, respectively

3. CONCLUSIONS

The tsunami numerical modeling is performed using three different models for the June 23, 2001 Peru earthquake, based on the shallow water approximation and by using four computational domains that are connected with nested grid system. The results of tsunami inundation modeling in terms of the run-up height around Camana city shows that the third model from the Tsunami Waveform Inversion Model is more appropriate approximation compared to the field survey. In terms of the inundation distance the first model of

the Uniform slip model is more appropriate approximation. Considering the accuracy of the bathymetry and topography data, the third model can be used as tsunami source of June 23, Peru earthquake. However, we may need to improve the tsunami source inversion results. And also, topography and bathymetry data should be investigate and be improved.

Abstract: Tsunami vulnerability assessment along the coast of Peru was carried out based on the modeling of the 2001 Camana tsunami. We first conducted field survey of the 2001 Canama tsunami to measure tsunami flow depth and topography of the Camana coast. Based on the field observation, we found that 1 - 3 m of tsunami flow depth inundated the Camana coast and caused significant damage on houses. We then modeled the 2001 Camana tsunami using nonlinear shallow-water theory to examine the validation of a tsunami modeling. As a result, our numerical model is consistent with measured data. Developing the tsunami hazard scenarios, we examined potential tsunami hazard in Peruvian coast using the probability of potential tsunami exposure. Consequently, we found that Lima and Callao face a high risk of major tsunami disaster.

1. INTRODUCTION

Peruvian coast is one of the most important seismologic regions in the world. In the Peru-Chile border region, the largest earthquakes with moment magnitude close to 9.0 occurred in 1604, 1868 and 1877. In recent years, large earthquakes with moment magnitude more than 8.0 occurred in 2001 and 2007. These earthquakes have accompanied large tsunamis which were responsible for extensive property and human damage in Peruvian coast. To develop the effective countermeasure against the tsunamis, the area prone to be tsunami damage should be determined considering tsunami hazards, population and frequency of earthquakes. The purpose of this study is to provide vulnerability assessment to possible tsunami damage for the coastal area of Peru.

According to Koshimura et al.,(2009), tsunami hydrodynamic feature such as tsunami height is greatly related to damage ratio of human or buildings. Therefore, the accurate estimation of tsunami hazards is much required to conduct tsunami vulnerability assessment. We thus estimate tsunami hazards using numerical simulation to determine the detail of tsunami hydraulic feature. We first conduct the modeling of 2001 Camana tsunami to validate the numerical model. We then conduct vulnerability assessment developing tsunami hazard scenarios using population data, the fragility function of human damage and the computed tsunami hazards.

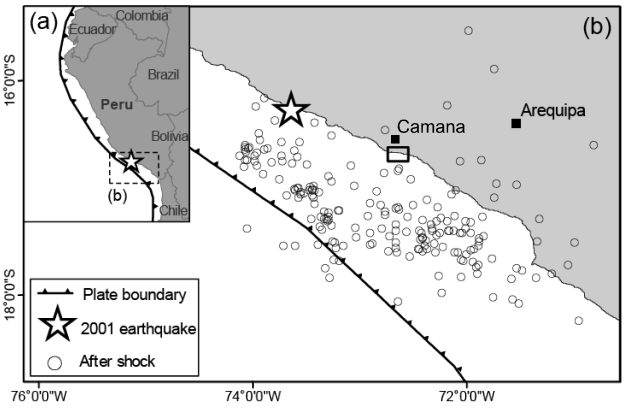

Figure 1 Map of southern coast of Peru showing the epicenter and after shocks of 2001 earthquake. The survey area is shown in the solid line.

2. FIELD SURVEY OF 2001 CAMANA TSUNAMI

2.1 Study area

On June 2001, a major earthquake of moment magnitude 8.4 generated a destructive tsunami that hit the southern coast of Peru (Fig. 1). The tsunami killed at least 25 people with additional 62 missing in the Camana area (Jaffe et al., 2003). Tsunami runup height around Camana area were estimated to have been approximately 3 - 8 m and the tsunami inundation distance extended more than 1 km inland

from coast (Okal et al., 2002). Nine years after the tsunami damage, some destroyed houses have been left derelict in the coast of Camana city, which was once the developed beach resort area. To find the evidence of 2001 tsunami, we conducted field investigation at the coast of Camana city.

2.2 Results of field survey

Although 9 years have passed since the tsunami impact, water marks of the tsunami have been remained on walls of some damaged houses. Figure 2 shows the tsunami flow depth inferred from the water marks on damaged houses and witness of the tsunami. The tsunami flow depth is the measuring water depth above the ground. These results show that 1.6 – 3.1 m tsunami inundated the beach resort area. The residential area on flat land stretches approximately 0.3－1.0 km inland so that the tsunami could have easily inundated the overall flat area and caused significant damage to houses (Fig. 2). We also found the trace of damage on the foundation of the house caused by tsunami wave erosion, which is mostly the same as it was when the tsunami attacked (Fig. 3). From field observation 9 years after the tsunami damage in Camana, we found valid data to estimate the tsunami flow.

3. NUMERICAL MODELING OF 2001 CAMANA TSUNAMI

3.1 Fault parameter

The 2001 earthquake ruptured a portion of the plate boundary between the Pacific and Nazca Plates. According to Harvard CMT catalog, the magnitude of 2001 earthquake is estimated to be *Mw*8.4 ($M_0 = 4.67 \times 10^{21} N/m$). To determine the fault length and width, we applied the empirical relationships between moment magnitude *Mw*, fault length *L* and width *W* obtained by Papazachos et al (2004) as equation (1) and (2).

$$Log(L) = 0.5Mw - 2.19 \quad (1)$$
$$Log(W) = 0.31Mw - 0.63 \quad (2)$$

Using the fault area *A* (=*L*×*W*) and scalar moment M_0, the fault displacement *D* is determined by equation (3).

$$M_0 = \mu DA \quad (3)$$

where μ is the rigidity. Table 1 shows the determined fault parameters for 2001 earthquake. We applied the fault depth, angle of strike, dip and slip acquired by Harvard University. For the initial conditions of the tsunami modeling, we estimated the vertical seismic deformation of the land and sea bottom using the theory of Manshinha and Smylie (1971). We assumed instantaneous displacement of the sea surface identical to the vertical seafloor displacement.

3.2 Modeling of tsunami propagation and inundation

To validate a tsunami modeling, we performed numerical simulation of the 2001 Camana tsunami. Tsunami propagation in coastal areas was simulated based on the nonlinear shallow-water theory, which includes the bottom friction in the form of Manning's formula. For tsunami modeling, we made 1350 m grid digital bathymetry/topography data, interpolated from the data provided by the General Bathymetry Chart of the Oceans (GEBCO) Digital Atlas. In addition to GEBCO, we compiled local bathymetric/topography data of southern Peru provided by Directorate of Hydrography and Navigation (DHN), Shuttle Radar Topography Mission (SRTM) data and our measured data to construct merged bathymetry/topography data. The grid size varies from 1350 m to 50 m, constructing a nested grid system.

We compared measured tsunami runup heights with computed values. The local tsunami runup height is the result of measuring the water marks above the astronomical tide level when the tsunami arrived. According to Okal et al. (2002) and this study, totally 25 points of local tsunami

Table 1 Fault parameters for the 2001 Camana tsunami

Mw	Origin of the fault (°)		Length	Width	Dislocation	Dip	Slip	Strike	Depth
	Latitude	Longitude	(km)	(km)	(m)	(°)	(°)	(°)	(km)
8.4	-18.40	-72.30	260	95	4.1	18	63	310	29.6

runup height and inundation flow depth were obtained in the study area. The inundation flow depth (above ground level) is changed to the tsunami runup height using the compiled topography data acquired by this study. The validation of the model is performed by K and κ proposed by Aida (1978) as equations (4), (5) and (6).

$$\log K = \frac{1}{n}\sum_{i=1}^{n} \log K_i \tag{4}$$

$$\log \kappa = \sqrt{\frac{1}{n}\sum_{i=1}^{n} (\log K_i)^2 - (\log K)^2} \tag{5}$$

$$K_i = R_i / H_i \tag{6}$$

where R_i and H_i are the measured and modeled values of tsunami runup height at point *i*. JSCE (2002) empirically provides the guideline for a tsunami numerical modeling suggesting that $0.95 < K < 1.05$ and $\kappa < 1.45$ as the threshold of valid tsunami source to develop the tsunami hazard assessment.

3.3 Numerical results of 2001 Camana tsunami

To validate our numerical results, we compared measured tsunami runup heights with maximum tsunami runup heights computed from our model. Figure 4 shows the special distribution of the computed maximum tsunami runup height. The tsunami run up averagely 5 meters along the coast of Camana. Figure 5 shows the comparison between measured and computed tsunami runup height. The numerical results were approximately consistent with the measured data, excluding the higher values resulting from water splashing. Our model is sufficiently satisfied with the value of JSCE (2002) (K=0.98, κ=1.34). This finding confirms that our numerical model can be used with confidence to develop the tsunami hazard scenarios.

4. VULNERABILITY ASSESSMENT IN PERUVIAN COAST

4.1 Development of tsunami hazard scenario

During the past 430 years, the 11 largest earthquakes (from *Mw* 8.0 to 8.8) with accompanying large tsunamis have occurred along the plate boundary between the Pacific and Nazca Plates near the Peruvian coast (e.g., Dorbath et al., 1990; Kulikov et al., 2005). To estimate tsunami hazards, we assumed 53 earthquake scenarios with *Mw*8.0, 8.2, 8.4, 8.6, 8.8 along the plate boundary (Fig. 6). Based on the modeling of 2001 tsunami, the fault length, width and displacement of each moment magnitude were determined by equations (1), (2) and (3). The remaining parameters were determined using example of 2001 earthquake (table 2). Tsunami propagation was simulated based on the nonlinear shallow-water theory using spherical coordinate system, which includes the bottom friction in the form of Manning's formula. Here, we used 0.5 sec grid digital bathymetry/topography data provided by GEBCO.

To estimate potential human damage, we used the

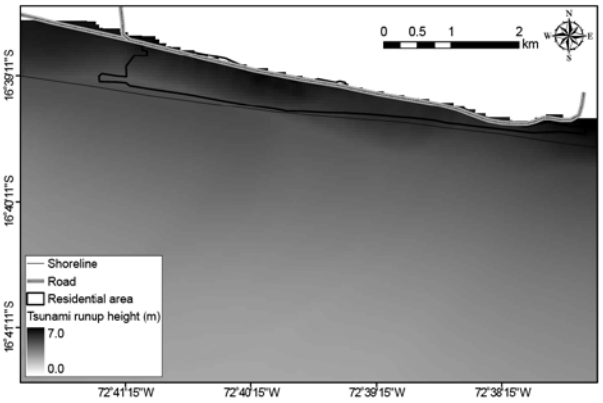

Figure 5 Comparison between measured tsunami runup height and computed maximum tsunami heights. The black outline square presents the higher value resulting from water splashing (Okal et al., 2002)

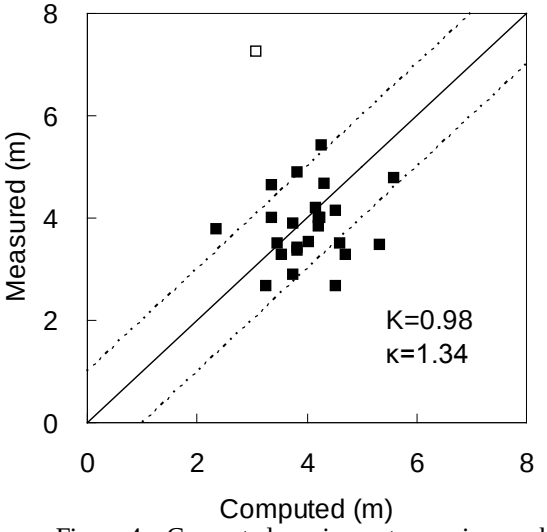

Figure 4 Computed maximum tsunami runup height

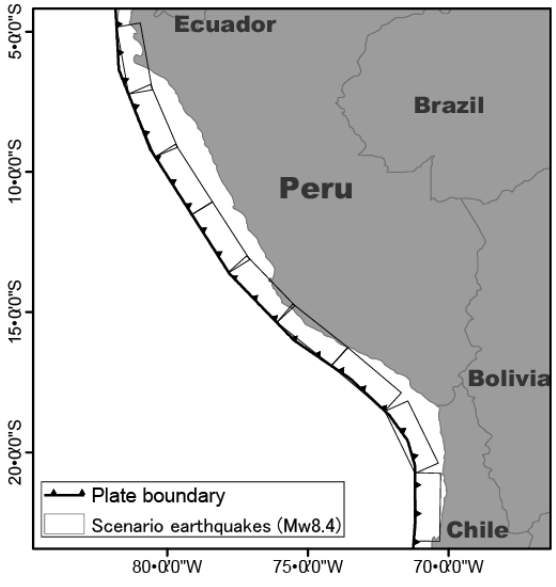

Figure 6 Scenario earthquakes for tsunami vulnerability assessment in the case of *Mw*8.4

following fragility function, which is the relationship between the computed maximum tsunami runup height η and the ratio of human damage $\alpha(\eta)$, which was acquired by the analysis of damage of the 2004 Indian Ocean tsunami (Koshimura et al, 2009).

$$\alpha(\eta) = \Phi\left[(\eta - \mu)/\sigma\right] \qquad (7)$$

where Φ is the cumulative density function of a standard normal distribution, μ and σ are the mean and standard deviation of η ($\mu = 5.37$, $\sigma = 0.72$). Using the Geographic Information System (GIS), we estimated the Potential Tsunami Exposure (*PTE*) multiplying the human damage ratio $\alpha(\eta)$ by global grid population data at shoreline (Ork Ridge National Laboratory, 2006). We further estimate the *t* year probability of exceedance using Poisson process as equation (8),

$$P\left[PTE \geq a; t\right] = 1 - \exp(-\lambda t) \qquad (8)$$

where $P\left[PTE \geq a; t\right]$ is the probability that *PTE* will exceed *a* value at least once in the 50-year, and λ is annual frequency of occurrence. We simply estimated λ by the following equation,

$$\lambda = \sum_{m=1}^{n} \frac{N\left[PTE \geq a\right]}{N_m} \times \frac{1}{n} \times \frac{1}{T} \qquad (9)$$

where $N\left[PTE \geq a\right]$ is the number of scenarios in each magnitude that *PTE* exceeds *a* value, N_m is the number of scenarios in each magnitude, *n* is the number of magnitude (=5) and *T* is the average return period. Here, we assumed that the frequency of occurrence of earthquakes in each magnitude is constant because Peruvian coast is lacking in certain data of the largest earthquakes.

4.2 Results and Discussion

Figure 7 shows the 50 year probability of exceedance when *PTE* will exceed 100 people. This result indicated that the coast of Lima and Callao face a high risk of major tsunami disaster (P > 10%). These results provide basic information for the tsunami disaster prevention planning. However, this study is preliminary assessment to detect area prone to be tsunami damage. Thus, additional studies are required to conduct a detailed assessment of the possible tsunami damage in the highest tsunami-risk areas.

Abstract: Today, the structural safety of buildings has been improved with a resulting improvement in quake resistance. There are, however, many mid-to-high-rise buildings, not only in big cities like Tokyo, Osaka or Nagoya, and it is necessary to think about measures to keep fixtures and furniture inside from moving or tipping during a long-period ground motion as the higher floors of these buildings are expected to generate the floor response during an earthquake. This study attempted to re-create the impact of evacuation obstacles such as scattered goods and blackout on people's evacuation behavior in a building at the time of an earthquake. The authors conducted experimental study on walking speed in the presence of obstacle and blackout on a walkway assuming evacuation in high rise buildings.

1. INTRODUCTION

Modern high-rise buildings, which have been increasing rapidly, are securely constructed regarding both quake and fire resistance. However, secondary elements such as ceilings and partitions may be damaged together with interior and/or articles inside the rooms, although the main structural elements are not damaged at all due to a moderate earthquake. Moreover, fire protection systems such as sprinklers are particularly vulnerable to strong earthquake motion. Nevertheless, there are a very few reports of the impact of obstacles and blackout on the evacuation road, while many studies on evacuation behavior during the fire in a high-rise building have been done so far. Human behavior and walking speed caused by scattered obstacles and blackout require more investigation for the case of evacuation during the fire or other possible emergency after an earthquake. The authors, therefore, conducted real scale experiments to observed and measure the impact of scattered goods and blackout on the walkway using the simulated corridors assuming evacuation after an earthquake in a high rise building.

2. SCATTERED GOODS EXPERIMENTS

2.1 Assumption of the Experiments

The walking experiment, as shown in Figure 1 was conducted based on several conditions. Table 1 shows the scattering density of goods from nothing 0% up to 90% in

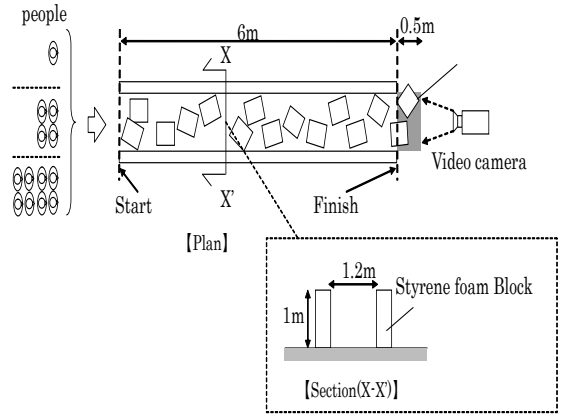

Figure 1 Appearance of Conditions in the Experiments

coverage for each case. The Number of participants was 48 and all of them were young students consisting of 30 male students and 18 female students. They participated each case in a random manner. They instructed to walk the lane like the evacuation drill “not rash” but “promptly evacuate” in each case including free walking.

Table 1 Conditions of Cases in the Experiments

Case No.	Scattering Density of Goods on a Walkway	Number of Persons who walk together
1	A(30%)	1
2	B(60%)	1
3	C(90%)	1
4	D(60%+ broken acrylic boards)	1
5	B (60%)	4
6	C (90%)	4
7	B (60%)	8
8	C (90%)	8

2.2 Results on “speed”

Figure 2 indicates the results of the experiments for a single walking in each condition of scattered density, in which the average walking speed and its band within±1σ(standard deviation) are shown. As the scattered density increases, the walking speed decreases substantially. It is worth noting that the walking speed goes drastically down by 57% to compare with the case of no obstacles in the case of scattering density of only 30%. And, the walking speeds in the cases of larger density of scattered goods does not drop so much from the level in the case A (30%) to the largest case C (90%).

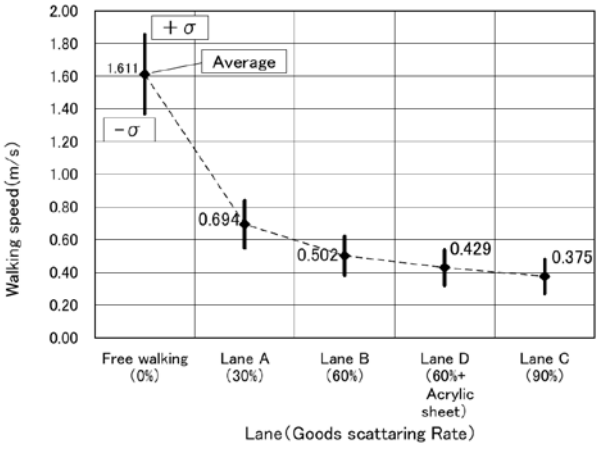

Figure 2 Average Waling Speed in Different Density of Scattered Goods

Figure 3 Free waling along 20m lane

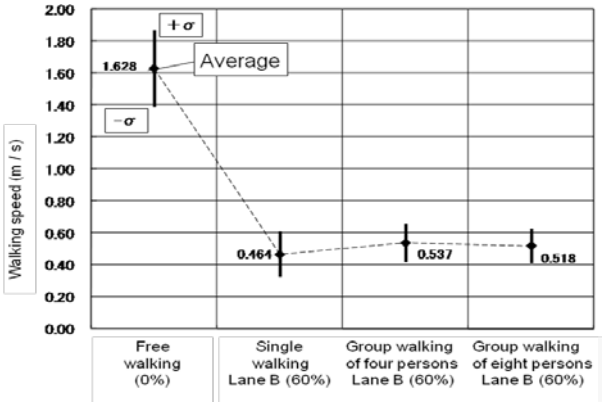

Figure 5 Average Waling Speed in condition of single walking and group walking of four and eight

The Figure 5 indicates the results of the experiments in condition of single walking and group walking of four and eight for Lane B of 60% scattered density, in which the average walking speed and its band within±1σ(standard deviation) are shown.

Figure 6 Group walking of four persons

Figure 7 Group walking of eight persons

2.3 Results on “Questionnaire”

We questioned the participants in the experiments. In this questionnaire, we asked chiefly the following personal attributes and feelings.

・Age, Sex, Height, Clothes, Height of heel, Custom of

Sports

・Difficult to Walk
・Feeling about Obstacles
・Fear in the Walking

If they were difficult to walk, they answered “5”(most difficult). In Figure 8, this ratio is shown by dark-red color. And if they were easy to walk, they answered “1”(most easy), this ratio is shown by light-blue color.

Figure 9 show what they felt most nuisance. Acrylic boards is most nuisance, big obstacles (cardboard box) follow and small obstacles (plastic bottle) have a small influence on walking.

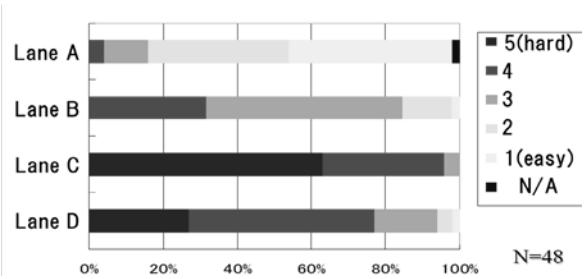

Figure 8 Difficult to Walk in Each Lanes

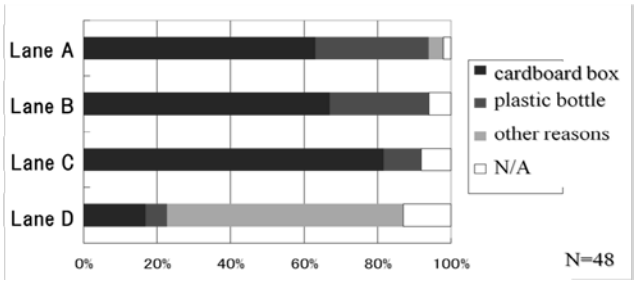

Figure 9 Obstacle have Some Influence on Walking

8	B	60%	0-1 Lux	Constant(half of emergency light)

Figure 11 Appearance of Conditions in the Experiments (1 Lux with emergency light)

Figure 12 Appearance of Conditions in the Experiments (0-1 Lux with half of emergency lights switched off)

3.2 Results on “speed”

Figure 13 indicates the results of the experiments for a single walking in each condition of lighting, in which the average walking speed and its band within±1σ(standard deviation) are shown.

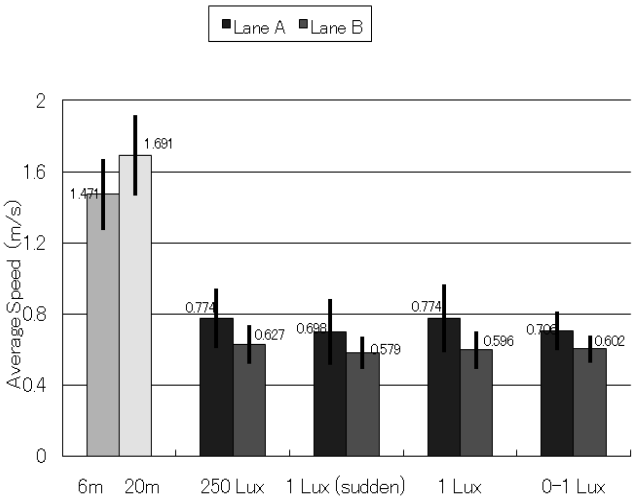

Figure 13 Average Waling Speed in Different Lighting Conditions

In reduced light, the walking speed decreases slightly but It is worth noting that the walking speed goes down by only 10% in case of emergency lighting with sudden switching off normal lighting. The effectiveness of emergency lighting was demonstrated in this experiment.

3.3 Results on "Questionnaire"

We questioned the participants in the experiments. In this questionnaire, we asked chiefly the following personal attributes and feelings.

- Age, Height, Clothes
- Feeling about Obstacles
- Fear in the Walking

If they felt fear in the walking, they answered "5"(most scary). In Figure 14, this ratio is shown.

Figure 15 show what they felt most nuisance. Switching off lighting has small influence on walking because there were still emergency lightings (1 Lux).

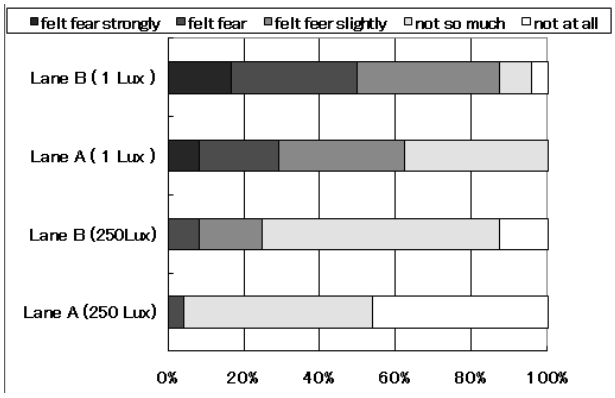

Figure 14 Fear at walking in each condition (N=24)

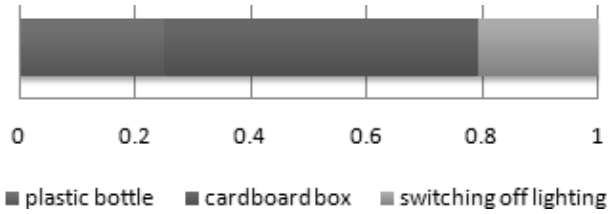

Figure 15 Obstacle at walking in each condition (N=24)

4. CONCLUSIONS

As the result of this experiment study, following points were found out.

1. As the goods scattered density increases, the walking speed decreases substantially. It is worth noting that the walking speed goes drastically down compare with the case of no obstacles. And, the walking speeds in the cases of larger density of scattered goods does not drop so much. The influence of broken glass is high.
2. The size of obstacle affects the walking speed. Small obstacle affects less.
3. In reduced light, the walking speed decreases slightly. The effectiveness of emergency lighting was demonstrated in this experiment.

CONSTRUCTIVE LOOP MODEL OF MANAGEMENT FOR PRE-QUAKE MITIGATION AND POST-QUAKE REHABILITATION

Haruyuki Fujii

Associate Professor, Department of Architecture, Tokyo Institute of Technology, Japan
hfujii@arch.titech.ac.jp

Abstract: Management for pre-quake mitigation and post-quake rehabilitation requires prompt decision-making and acts under such an uncertain situation that resources and information, which can be used for management, are limited and rapidly changing. To deal with the situation, a constructive model of management is proposed. The loop is composed of three major processes, i.e., generation, analysis, and focusing. It is important to repeat the loop effectively for management to accomplish the preferable goal.

1. INTRODUCTION

The final goal of this study is to construct a computational schema of pre-quake mitigation management as well as post-quake rehabilitation management. This paper abstracts the characteristics of these managements and proposes a constructive loop model that is expected to facilitate management dealing with the characteristics.

2. PRE AND POST QUAKE MANAGEMENT

Management is the act and art of judiciously using means to accomplish and maintain the designated situation, the target situation, in other words. Management is significant in the circumstance that the situation would become less preferable than the target situation if management were not properly done. The target situation is not fully or strictly designated in advance to allow flexible decision-making in unexpected or uncertain situations.

Two major characteristics of pre and post quake management in question, i.e., incompleteness and situatedness, are described.

2.1 Incompleteness

Both the management for pre-quake mitigation, or mitigation management, and management for post-quake rehabilitation, or rehabilitation management deal with a similar situation. It is uncertain where an earthquake comes, how strong the earthquake is, and what kind of damages does the earthquake brings about. Even though it is true that many means of predicting those things are being developed, it is not perfectly guaranteed that we never come across any situation beyond the predictions.

The mitigation management and the rehabilitation management are different from each other in the sense that the resources, such as time, information, etc., are less limited in mitigation management than rehabilitation management and that the situation faced is changing too fast to deliberate on what the best move is.

A process of management is situated. Decisions in management have to be made on the basis of incomplete information. The crucial nature of management is that the concrete means to accomplish the goal have to be constructed on the basis of the current situation and the assumptions. The assumptions complement incomplete information acquired so far. They are made before the concrete means are determined. During management, information is updated as a new situation is experienced and some of the assumptions are modified if they are not compatible with the current situation.

Decision is made to determine what should be done in order to select promising means towards a preferable situation. Decision under rapidly changing situations in rehabilitating process after an earthquake has to be made on the basis of incomplete or uncertain information. The situations often require prompt actions to change them into preferable ones or to avoid making them worse. The decisions on what to do in those situations cannot afford to be made after deliberation on the basis of complete and certain information even though it is ideal to make decision after deliberation. Even if decisions are made on the basis of incomplete or uncertain information, it is desirable that the decisions are made so as to increase the possibility of accomplishing the preferable situations.

In the case of emergency, some decision-making should be done timely even though the decision has to be made under incomplete and uncertain information. It is, of course, wise to wait for the result of analysis of the situation on the basis of enough information only when it is clear that the result waited is essential for adequate decision-making and is

clear what to do depending on the result. The worst thing is to just wait for the situation where information for decision-making is complete and certain without any plan to do with the information waited. Commitment to selected hypothesis and the flexible attitude that is not afraid of the replacement of the hypotheses are the keys to decision-making under rapidly changing situation.

2.2 Situatedness

Management deals with the proximal features as well as the distal features describing the things involved in management. A proximal feature is the feature that articulates a distal feature. A distal feature is the feature that emerges as an appearance of the unified totality of proximal features. The proximal features are recognized as the constituents of the distal feature, but the distal feature cannot be well-defined in terms of the proximal features. It depends on the level of the granularity, scale, and abstraction adopted for the observation of the thing if a feature is proximal or distal. The classification is relative since the level of the observation changes.

It is hard to consider every important feature to construct the concrete means in advance. Some features that have not been considered are found to be important in a certain situation. This means that management should be constructive and have dialectic nature and that decisions are made as drawing the trajectory towards the goal and adjusting it to the situations encountered during execution of the means.

Therefore, it is important for a management plan to afford situated decision-making and on-the-fly acts. A management plan should consist of a general schema with the framework that is not affected by measure of uncertainty and a flexible part that leaves the rooms for making decision in an actual situation.

A schema defines the framework of a management plan, from which the concrete means are embodied, and formulates the mechanism underlies emergence of the expected situations upon the management. A schema is individualized in the sense that it is formed so as to fulfill particular expectations in a certain context. Adding some features to the general schema in accordance with the context forms an individual schema. A schema is an abstraction of the means to accomplish the goal and is expressed in the form of a plan, an agenda, a manual, etc.

3. PREREQUISITE OF A TASK IN MANAGEMENT

Let T0 be one of the main tasks in management. Suppose that the objective of T0 is to accomplish the target situation S(t'). When T0 is successfully done, we become aware that the current situation S(t) changes into the target situation S(t'). T0 would also let us be aware of the unexpected situation Ss(t') brought about by the interaction between the task and the environment.

A task has to satisfy the prerequisites so as to be done successfully. The prerequisites of T0 are S(t), which is needless to say, and Sp(t"). It is necessary for the success of T0 that situation S(1) and situation Sp(t") are satisfied. The figure depicts that Sp(t") is decomposed into Sp1(t1) and Sp2(t2), where Sp1(t1) and Sp2(t2) are coupled by the diamond with label "&" linked to Sp(t"). This means that Sp(t") is satisfied if both Sp1(t1) and Sp2(t2) are satisfied. Therefore, it is required for the success of T0 that all of S(t), Sp1(t1), and Sp2(t2) are satisfied. The figure also depicts that situation Sp2(t2) is substituted by situation Sp2a(t2) or situation Sp2b(t2), where Sp2a(t2) and Sp2b(t2) are coupled by the diamond with label "or" linked to Sp2(t2). This means that either Sp2a(t2) or Sp2b(t2) satisfies Sp2(t"). Situation Sp1(t1), Ts2a(t2), and Ts2b(t2) are satisfied if task Ts1, Ts2a, and Ts2b are successful, respectively.

It becomes clear from above discussion that it is important for a task to be executed in the situation where the prerequisites of the task are satisfied. It is also important that subtasks should be done successfully in order to confirm that the prerequisites are satisfied. If we have enough resources so as to execute the tasks and the subtasks completely, we should do so. If the resources in rapidly changing situations were limited, the tasks and subtasks would have to be sorted out.

One of crucial task in management is to sort out the tasks and the subtasks. It is important to select the promising ones under the situation that the resources, i.e., time, budget, information, etc., for confirming that their prerequisites are satisfied or that it is possible to make the prerequisite satisfied by executing the subtasks.

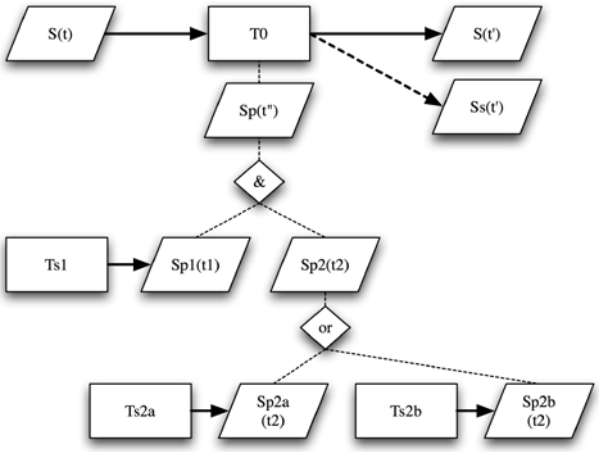

Figure 1. A Task and its Context

4. FEATURES INVOLVED IN MANAGEMENT

4.1 Feature Types

Things are differentiated from each other in terms of their features. A feature is expressed as a pair of a variable and its value. To define a feature is to select the variable and to determine the value among the alternatives. A process of management is formulated as a process where the features, which are designated to describe a preferable situation, are being acquired or maintained. The features are classified into five types with respect to the level of the accessibility and the level of granularity of the description of the things. Table below shows the classification.

Table 1. Classification of Features

	Proximal	*Distal*
Accessed	A-feature	-
Controlled	Dd-feature	-
Influenced	Di-feature	E-feature
Hardly Influenced	I-feature	I-feature

The level of accessibility is defined as follows. A feature is described as being accessed when the future is being specified by direct operation on it. A feature is described as being controlled when it cannot be accessed but is being indirectly but conclusively specified through the direct operation on one or more other features. A feature is described as being influenced when it cannot be controlled but is being affected as the consequence of the interaction between the result of the control of one or more other features and the environment. A feature is hardly influenced if it is not accessible, controlled, or influenced. The level of granularity of the description is defined by whether a feature is proximal or distal. This definition is relative since it depends on the abstraction level of observation whether a feature is proximal or distal. We assume that a feature can be directly determined or controlled if it is perceived as a proximal feature.

With respect to the levels, a feature is classified into on of an accessible feature, or A-feature, a directly deducible feature, or Dd-feature, an indirectly deducible feature, or Di-feature, an emergent feature, or E-feature, and an inaccessible feature, or I-feature, respectively. An E-feature is a distal feature whose proximal features are the A-features, D-features, and I-features. As it is relative to observation whether a feature is proximal or distal, a feature seen as an E-feature in an observation can be seen as another type of feature in another observation.

Table 2. Referents and Variable Type of Features

Features	*Referents*	*Variable Type*
A-feature	Structure	Design variable, Target Variable
Dd-feature	Behavior	Controlled variable, Target Variable
Di-feature	Behavior	Target variable
I-feature	Context	Context variable
E-feature	Function	Target variable

4.2 A Cycle in Management

Management is the combination of generation and analysis. The two parts are performed sequentially or synchronized with each other. In generation, a set of the means that is expected to have the potentiality to change the current situation into preferred one is formed. Generation produces a course of actions. In analysis, it is predicted what if the means are executed. The beliefs about causalities and information retrieved from the existing situations are used as grounds for the prediction. If it is convinced that the means have the expected potentiality on the basis of the consequence of prediction then a course of action to change the current situation into preferable one is determined. If not, the schema of the artifact and some beliefs are modified on the basis of the difference between the preferable situation and the predicted situation.

It is often the case that the significance of a thing being designed is described in terms of E-features promoted by the thing. In management, A-features are determined directly and D-features are controlled under the constraints described by I-features in the expectation that the E-features emerge upon the interaction among the features. An operation is specified in terms of A and Dd-features. The schema embodied by the artifact is described as the relation among A, Dd, Di, I, and E-features. Design explores the specific features towards the preferable situation as well as the relation among the features.

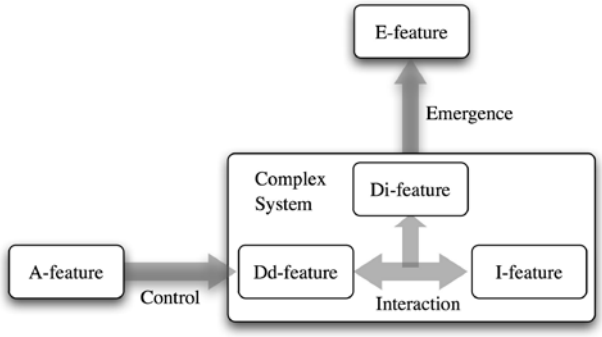

Figure 2. Relation among Features

1. To construct an image of a preferable situation expected to come true. The goal is described as the situation expected to be brought about.
2. To represent the preferable situation in terms of the features, to represent also the differences between the situation and the current situation and the things in common.
3. To assume the causalities associate the designable features with the target features, or to select or modify the causalities currently employed. The decisions are made on the basis of the decision-maker's beliefs about causalities related to the things in question and about the existing situations.
4. To set D-features to be expected to let the target features emerge.
5. To select or assume the mechanism expected to provide the D-features set above.
6. To determine A-features that embody the mechanism. It is desirable that decisions are made in the conviction that the expected phenomena will emerge with minimal unfavorable effects. If the effects are favorable then they may be expected explicitly in the succeeding decision-making. It is presupposed that an A-feature and a D-feature have a causal relation that an A-feature is the cause of a D-feature.
7. To produce actually or virtually the artifact that has the designable features set above.
8. To observe the interaction between the behaviors of the mechanism embodied and the environment. The secondary effects could be either favorable or unfavorable.
9. To evaluate whether the preferable situation emerges. If yes, then the process is done successfully, else, repeat from step 1.

4.3 Causalities Coupling Features

Management applies causalities to construct the schema as well as constructs causalities on the basis of the observation. The schema associating an artifact with the significance is formed with respect to causalities as well as causalities is modified constructively to understand the unexpected consequences of forming the schema.

Some A-features are determined on certain grounds. The relations among the features derived from causalities are consciously applied to form a schema with the conjecture that an artifact with the schema facilitates the expected features. It is essential for the success of schema forming to refer causalities that governs the features. It is important to do something with the consciousness and assumptions of existence of causalities. Causalities could be subjective, or private, in the sense that it represents personal understandings of the world formed through the experience. Even though it is subjective or private, it plays an important role to define the direction of design. To form a schema is to construct the hypothetical relations among the features.

Causalities are expressed in some ways.

(A) Some causality is expressed in the form of an equilibrium governing A-features, D-features, and I-features. The features must be in the same proximal level. A distal feature is not expressed in the equilibrium since a distal feature is defined as the feature that cannot be described by its proximal features completely.

(B) Some causality is expressed as qualitative or quantitative causalities between two things. A thing is expressed as the cause of the other thing, or a thing is expressed as the effect of the other thing. Procedural knowledge, which couples means and ends and is applied to plan a course of actions in generation, is expressed in this form. The relations between the emergent behavior of a system and the behavior of the constituents of the system are also expressed in this form.

At least one of the two things can be an action. When an action is the cause of the other thing, the thing is the result or consequence of the action. When an action is the effect of the other thing, the thing facilitates the action. Proximal features as well as distal features can characterize the things involved in this form of expression. The relations among the proximal features and the distal features are expressed by virtual causality. The notion of vertical causality refers to the causality among the features in the different conceptual level (Nakashima, Suwa, and Fujii 2007).

(C) The rest of causality is tacit and not expressed explicitly in the forms described above. It could be expressed implicitly in a narrative form. Intuitive beliefs about causalities, which determine which features should be focused in design, cannot be expressed in the form of either equilibrium or causality. The focused features are important to determine the direction of generation and analysis.

5. A CONSTRUCTIVE METHODOLOGY

Fujii, Nakashima, and Suwa have been constructing a model of a constructive methodology in design. In the broader sense, management is regarded as design since a promising course of means to accomplish the goal is designed and executed in management. The methodology enriches the process of problem solving so as to express the nature of the process of designing and to facilitate an innovative design. In innovative design, it is significant to find new design variables and to re-evaluate an evaluate function on-the-fly during design.

The core structure of the constructive methodology is composed of the cycles of three processes, i.e., generation, analysis, and focusing as shown in figure 1. Each of the processes traverses the layer of representation and that of entity or the current representation and the future representation. The current representation expresses the things currently recognized, while the future representation expresses the things expected to be realized.

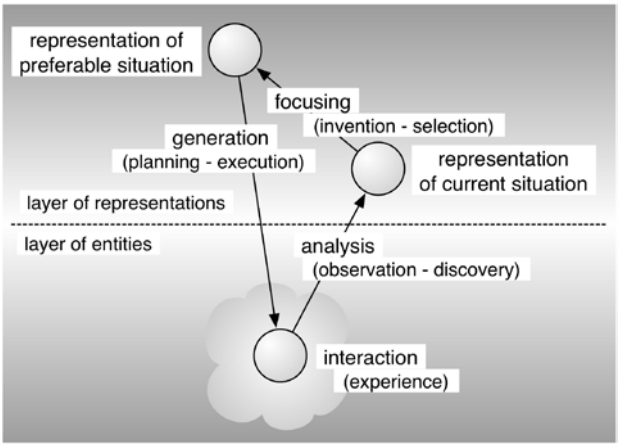

Figure 3. FNS loop.

The *generation* process is the process of embodying the future representation by synthesizing new formation of new and existing entities. The designer interacts with the environment by operating on the entities. The structure of the world changes as the result of the process and the expected phenomena depicted in the future representation and unexpected ones emerge as the consequence. This process has the intentionality of realizing the mechanism that is depicted in the future representation. It is intended to fabricate a situation that renders the future representation true. Operations towards the entity layer are executed with the expectation that the future representation. A process of generation in design is formulated as a process where relations among features are assumed and A-features are determined with respect to the relations.

The changes in the world structures are driven by the interaction between the direct operations in generation and the entities in the world. Since the entities constructs a complex system, it is theoretically impossible to foreseen the result and the consequence of generation completely. Therefore, interaction brings about unexpected changes in the layer of entities and provides an opportunity for a designer to find new design variables and to re-evaluate existing evaluation functions.

The designer predicts the conditional experiential consequences that would be logically or probably derived in accordance with certain inference rules if the selected hypothesis were true and the schema were embodied. Decision whether the schema should be embodied is made. If the decision is made, a course of actions to embody the schema is planned. Then, decision how the schema should be embodied is made.

The *analysis* process is the process of observing and depicting the result and consequence of the generation and the interaction. As the consequence of the process, the representation of the current formation of the entities and the emergent phenomena is made. The current representation is compared with the last future representation depicted just before this process. This process has the intentionality of understanding the current structure of the world. It is intended to narrate the experience in the current situation. The interpretation basically tends to remain the same as the interpretation in the previous cycle, but it is subject to change in focusing when unexpected things are observed and it is hard to express the things under the current interpretation. A process of analysis is formulated as a process where D-features are deduced from the A-features and it is predicted, on the basis of the assumptions, whether the expected E-features emerge upon the interaction among the A-features, the D-features, and the I-features or not.

The designer actually embodies the schema and verifies how far the predicted consequences are consistent with the experiential observations as estimating the proportion of truth of the hypothesis. Decisions whether the schema and the hypothesis are sensibly correct, or require some inessential modification to fulfills the intention, or must be rejected are made. If the second decision is made, then the direction of the modification is determined.

The *focusing* process is the process of depicting the next future representation of the mechanism on the basis of the current representation of mechanism acquired as and the differences between the current representation and the last future representation of the mechanism. Decisions on the acceptance of the assumptions and the adoption of the features are made. A course of actions in the next cycle is planned in this process. The direction of improving the designed artifact and the service given through the utilization of the artifact is decided. In an innovative design, new design parameters and the causalities coupling the entities and the parameters are constructed. It is intended to signify the current situation to construct the next cycle of generation, analysis, and focusing. Decisions on whether design has been completed, should be continued, or has to be stopped are made. The assumptions about the relations are modified to fill the gap between the prediction and the expectation in the succeeding generation process. The decisions on the direction of the modification are made. If the current representation is similar to the last future representation, it seems that the design is completed successfully.

The designer imagines, on the basis of the past and present experiences, how the situations will change if a certain schema is embodied. The designer invents some hypotheses that shall fulfills the will, and selects the one that seems promising. Decision which hypothesis should be the most promising and be adopted is made. A schema that is consistent with the hypothesis is formed. There is no logical way to invent or select the most plausible hypothesis and to design the consistent artifact. Even if we investigate the existing situations and correct a plenty of information on the current situation, we have to make decision with some intuition.

Either abduction or induction doesn't have logical inference rules that guarantee the truth of the consequences in spite that deduction does. Therefore, the success of design as well as scientific inquiry depends not only on the procedural schema like the rules of deductive reasoning but also on the heuristic capacities to be employed to select the most plausible hypothesis, to classify the empirical observations, and to imagine a course of action towards the goal.

6. CONCLUSIONS

A model of the constructive methodology of management for pre-quake mitigation and post-quake rehabilitation is proposed on the basis of two major nature of the management, i.e., incompleteness and situatedness.

Acknowledgment

Discussions given in this article are mostly the result of an on-going and long discussion with Hideyuki Nakashima (Future University – Hakodate) and Masaki Suwa (Keio University), and partially inspired by discussions with Yoshitsugu Aoki (Tokyo Institute of Technology).

HUMAN BEHAVIOR OF BUILDING RECONSTRUCTION AND FIREPROOFING OF CITIES

Toshihiro Osaragi[1] and Yumi Nakata[2]

1) Associate Professor, Graduate School of Information Science and Engineering, Tokyo Institute of Technology, Japan
2) Graduate Student, Graduate School of Information Science and Engineering, Tokyo Institute of Technology, Japan

Abstract: The fireproofing of building structures is one of the most important issues in the field of disaster prevention planning. In the Tokyo metropolitan area, improving fireproofing is of great concern, since a devastating earthquake and subsequent fires could cause the widespread damage. In this study, we construct a probabilistic model that describes the conversion process of building structures. Using this model, we estimate the time-series changes of the building structures in an established city area and extract hazardous areas from the viewpoint of disaster prevention. In these areas, we simulate time-series changes in the building structures by applying urban- and building-regulations and evaluate the effectiveness and efficiency of these regulations for promoting fireproofing in potentially dangerous areas.

1. INTRODUCTION

1.1 Background and objectives

One of the most urgent issues in regional disaster planning is how to make the densely built parts of a city more resistant to fires. Planners in Tokyo took the lesson of the 1995 South Hyogo Prefecture Earthquake (Kobe earthquake), and, in 1996, drew up plans for recreating Tokyo as a "fire-proof city", with the objectives of updating fire-fighting resources in the locations with the most densely clustered wooden buildings and promoting the clearing of firebreaks. The plan was revised in 2003; simultaneously, architectural safety ordinances (new fire safety regulations) were introduced that continued to allow quasi-fire-resistant structures in some districts but placed severe fire-prevention requirements on wooden structures. However, there are still many areas in Tokyo that are quite vulnerable to fires following an earthquake. As a result, there is widespread and intense interest in policies for efficiently and effectively promoting fireproof or fire-resistant construction.

This paper presents a quantitative assessment—from a "micro" perspective of fireproofing processes of individual buildings in Tokyo—of what kinds of regulations and policies promote efficient and effective change-over to fireproof or fire-resistant construction, in what places and to what extent. First, a stochastic model that describes the processes of replacing buildings was built. Factors affecting the promotion of fireproofing were identified. Next, this model was used to predict changes in building structures over a span of many years; this provides a "handle" on the current fireproofing remodeling situation and identifies districts in which this progress is slow.

1.2 Previous Research

One method for reducing the area burned in a fire is to divide a continuously built-up urban area into small subzones separated by fireproofed strips that function as firebreaks. This is anticipated to be vital in densely built-up cities, where fires cannot be expected to naturally "burn themselves out". Tsukakoshi et al. (1984) and Fujimoto et al. (1989) have assessed the effectiveness of firebreaks in models for simulating the spread of fire and explored what forms of firebreaks were the most effective. Itoigawa (2004) argued that fire spread models must be expanded in order to obtain valid assessments of how various factors, including building construction, affect the spread of urban fires. These reports resemble the present paper in their attempts to examine how rebuilding and structural changes contribute to fireproofing. Hirota et al. (1997) considered that rights-of-way such as roadways could function as firebreaks, and investigated the benefits of fire-resistant construction, limits on building floors and specifications for roadway widths. They suggested that main roads and cross streets could be modified to divide areas effectively into subzones. This paper presents a quantitative assessment of the above processes, with views of the current state of progress in the fireproofing of buildings along streets of different widths, and a review of the effectiveness of urban- and building-regulations and policies in areas where fireproofing has lagged behind.

The tragic history of urban fires makes plain to the importance of promoting the use of incombustible materials in densely built wooden residential areas. Not only is there a risk of spread once a fire breaks out, but narrow streets are all too easily blocked by burning rubble from the collapse of

buildings, trapping fleeing victims. Nevertheless, efforts to install incombustible materials and widen streets have not gone very far. Machida et al. (2006) and Katsumata et al. (2006) conducted surveys of residents of densely built wooden residential areas and local public organizations to investigate the causes of delays in the fireproofing of deteriorating wooden residences. While they found problems in citizens' attitudes, they also noted that conversion was hampered by the legal status of lots and other physical factors. This paper considers the physical factors contributing to the probability of building reconstruction and presents a quantitative analysis of how these factors hamper fireproofing.

2. A STOCHASTIC RECONSTRUCTION MODEL

2.1 Components of a stochastic reconstruction model

In a typical fireproofing modification, a fire-prone wooden structure is demolished and replaced with a completely new fire-resistant building. The rebuilding event is modeled in this paper in two stages: the demolishing process and the structural change process (Figure 1). The *demolition model* designates buildings to be demolished, and the *structural conversion model* predicts the changes made to the structure of new buildings. The combination of these two is referred to as the "*stochastic reconstruction model*".

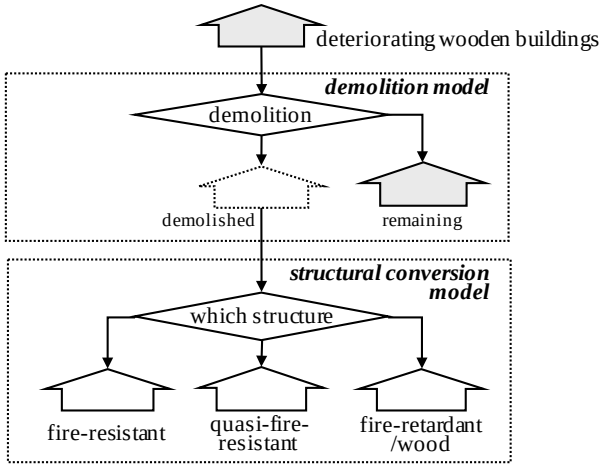

Figure 1 Stochastic reconstruction model

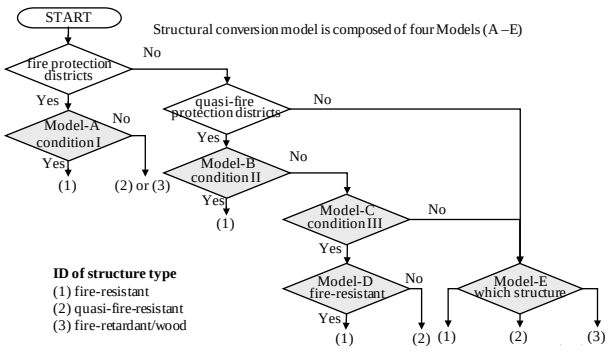
2.2 Demolition model and structural conversion model

The demolition model decides stochastically whether a building is to be dismantled at the following time step, depending on various factors (e.g., building attributes, the surroundings, urban- and building-regulations). The output takes a high value if there is a strong possibility that building j will be torn down by the next time point, and a low value if the building will probably be left as it is. u_j, the potential for building j to be demolished, is represented by the following linear model:

$$u_j = a_0 + \sum_k a_k x_{jk} \tag{1}$$

where x_{jk} is a variable expressing the attributes of building j, the surroundings, and regulations, and a_0 and a_k are unknown parameters. The probability p_j that building j will be demolished by the next time point is defined by the following binomial logit model:

$$p_j = \exp[u_j] \Big/ \left(1 + \exp[u_j]\right) \tag{2}$$



The structural conversion model is a stochastic model describing whether a newly constructed building will be fire-resistant, quasi-fire-resistant, or fire-retardant/wood construction, using nearly the same factors as above. When replacing buildings that meet conditions I - III in Figure 2 in fire-protection districts or quasi-fire-protection districts, however, the only permitted structural types are fire-resistant or quasi-fire-resistant. Thus, the model describes whether the conversion of a building that stands in a fire-protection district or quasi-fire-protection district meets conditions I - III.

The building is described by Models A - D in Figure 2, a diagram of the structural conversion model. In Equation (3), we define the fire-resistant potential v_j, whose value corresponds to the potential for building j to be rebuilt as a fire-resistant building:

$$v_j = b_0 + \sum_k b_k x_{jk} \tag{3}$$

where x_{jk} is a variable expressing the attributes of building j, the surroundings, and urban- and building-regulations, and b_0 and b_k are unknown parameters. The probability q_j that building j will become fire-resistant by the next time point is given, as above, by the binomial logit model as follows:

$$q_j = \exp[v_j] \Big/ \left(1 + \exp[v_j]\right) \tag{4}$$

Permission of structural types in fire-protection districts/ quasi-fire-protection districts

Regulations	Conditions	Size of building	Permitted structural types
Fire-protection districts	I	Number of floors ≧ 3 or Floor area>100㎡	(1)
	—	Others	(1) or (2)
Quasi-fire-protection districts	II	Number of floors ≧ 4 or Floor area>1500㎡	(1)
	III	Number of floors=3 or 500㎡<Floor area ≦ 1500㎡	(1) or (2)
	—	Others	(1) or (2) or (3)
No regulation	—		(1) or (2) or (3)

Figure 2 Structural conversion model

Model-E has three possible options for conversion — fire-resistant, quasi-fire-resistant or fire-retardant/ wood — and is constructed as follows. We insert the quasi-fire resistance potential w_j in addition to the fire resistance potential v_j. As in Equation (3), this model is linear and uses variables to express the attributes of building j, the surroundings, and urban- and building-regulations. The probability that building j will become fire-resistant and quasi-fire-resistant by the next time point is given by probabilities q_j and r_j respectively in the multinomial logit models:

$$q_j = \exp[v_j] \Big/ \left(1 + \exp[v_j] + \exp[w_j]\right), \qquad (5)$$

$$r_j = \exp[w_j] \Big/ \left(1 + \exp[v_j] + \exp[w_j]\right), \qquad (6)$$

$$where\ v_j = b_0 + \sum_k b_k x_{jk},\ w_j = c_0 + \sum_k c_k x_{jk}.$$

3. EXECUTING THE DEMOLITION MODEL AND THE STRUCTURAL CONVERSION MODEL

3.1 Study area and data for analysis

The region examined with these models was Setagaya Ward, Tokyo. Ward GIS data (1996; 2001) and applications for building plan approval were used. Since there were no direct connections between the building data and building plan approval data, these data were connected based on the spatial relationships of the same building-lot location. Information about building construction years is closely related to trends in the demolition of then-current structures. This is one of the integral factors in the remodeling process. The latter data set is incorporated in the construction year data. In addition, there is great potential for building reconstruction to occur simultaneously with divisions or consolidations of lots. A simulation of building renewals that includes lot division or consolidation may provide more useful information about these actions. A method proposed by Osaragi et al. (2005, 2006, 2007) was also used to compare lot shape changes between the two time points with GIS data in order to extract the lots that had been divided or consolidated.

3.2 Results of analysis by demolition model

Table 1 shows the results provided by the demolition model. The reader can see the following findings about the likelihood of a building to be demolished. (1) The most powerful of the many explanatory variables is the age of the building; the greater its age, the more likely a building is to be demolished. (2) The probability of demolition is increased when a lot is divided or combined with another. (3) The estimated value of [ratio of unused floor-area] is greater than 0, the greater the unused floor space, the more likely the building is to be demolished. (4) Since the estimated parameters of building area [0 - 50 m^2] is less than [50 - 150 m^2] and negative, the lower the area of a building, the less likely it is to be demolished. (5) The estimated parameters of lot area [100 - 200 m^2] is greater than 0, so buildings on smaller lots (about 100 m^2) are less likely to be demolished. (6) The estimated parameters of street frontage [0 - 2 m] is less than that of [2 - 6 m], so buildings on lots with bad connections to the adjoining street and illegal lots with insufficient frontage [0 - 2 m] tend not to be demolished. (7) The estimated parameters of street width [0 < 2 m] is less than 0, so buildings facing small streets in densely crowded neighborhoods have a low probability of being demolished. There is a common tendency for districts with the highest risk of fire spread to have the slowest progress in fireproofing.

3.3 Results of analysis by structural conversion model

Table 2 shows the results of running the structural conversion model. Model-A predicts that buildings will be at least three floors high or will have at least 100 m^2 of floor space (Condition I) when they are rebuilt in fire-protection districts. In the Setagaya Ward fire-protection district, a large majority (95.8%) of the replaced buildings from 1996 to 2001 met Condition I. Thus, it can be predicted that reconstructed buildings in a fire-protection district will be fire-resistant structure.

The next is Model-B, which predicts that a building replacing an old, demolished building in a quasi-fire -protection district will be at least four floors high or have more than 1500 m^2 of floor space (Condition II). From the estimated values of the parameters, the buildings most likely to meet this condition—i.e., become fire-resistant structure —replace large buildings, are on lots that have just been consolidated, are on lots with unused ground, or have some other condition favoring the construction of large buildings; these buildings might also have good street connections.

Under Model-C, when a building is replaced in a quasi-fire-protection district, it is predicted to be at least three floors high or have a floor area between 500 m^2 and 1500 m^2 (Condition III). From the estimated values of the parameters, the buildings most likely to meet this condition are in districts zoned for high-rises to use land more efficiently, when the building is shared residential and commercial, the street connections are good and the lot area is comparatively small.

Model-D predicts whether a building will be replaced in accordance with Condition III, which indicates in a fire-resistant or quasi-fire-resistant structure. From the estimated values of the parameters, reconstructed buildings tend to be fire-resistant when their predecessors were fire-resistant and when there are many fire-resistant buildings in the vicinity. Conversely, when a lot is small or has inconvenient connections to the adjoining street, it tends to be built with a quasi-fire-resistant structure when predecessors are residential- commercial use or residential-industrial use.

*regional variable observed in a town

Lastly, Model-E predicts whether a replacement building will have a fire-resistant, quasi-fire-resistant or fire-retardant/wooden structure when the original building is in a quasi-fire-protection district not in accordance with Conditions II and III or a district undesignated for fire-protection. From the estimated values of the parameters, when a building is fire-resistant or quasi-fire-resistant before demolition, it has a high probability of being rebuilt as fire-resistant or quasi-fire-resistant; however, when the lot is small, the building tends to be rebuilt with fire-retardant materials.

3.4 Compatibility of stochastic reconstruction model

The demolition model and structural conversion models were combined to create the stochastic reconstruction model and the compatibility of the combined model was validated. Here, the 1996 data were used as a base for predicting the demolitions, replacements and fireproofing upgrades from 1996 through 2001 to verify the accuracy of the model. The demolition model attempted to extract the buildings that were replaced and the stochastic reconstruction model attempted to predict the degree of fire-protection of their replacements. Because the results in Figure 3 combine multiple models, it is difficult to determine how accurate the predictions are for individual buildings. Nevertheless, if one examines the map by town (a subsection of a ward; there are 59 towns in Setagaya Ward), the model provides an accurate prediction of the number of demolished buildings. The prediction of structural conversions, however, was less accurate. One reason for this was that the errors in the estimates of the demolition model affected the structural conversion model.

At the same time, classification of zones by land use regulations, distance from main roads and railway stations, and width of the streets adjoining individual building lots and counting within the zones defined this way provided a more accurate count than estimates performed at each town.

Factors	Definition (Number of categories)
Land use regulation	low-rise/high-rise/residence/commercial or industry (4)
Distance from main roads (m)	0-10/-20/-30/-50/-100/-200/-300/ -400/-500/-600/-700/-800 (12)
Distance from stations (m)	0-100/-200/-300/-500/-800/ -1200/1200 or more (7)
Width of adjacent streets (m)	0-2/-4/-6/-8/-11/-16/16 ore more (7)

Figure 3 Fitness of stochastic reconstruction model

4. SIMULATION USING THE STOCHASTIC RECONSTRUCTION MODEL

4.1 Progress in fireproofing and extraction of most vulnerable areas

Figure 4 is a flow chart for the simulation. The stochastic reconstruction model was used to predict the replacement of buildings and changes in structure for a 30-year period beginning in 2001, assuming no control under urban- and building-regulations (the current regulations). The simulation results showed a predicted gradual rise in fire-resistant and quasi-fire-resistant buildings and a gradual decrease in fire-retardant/wooden structures.

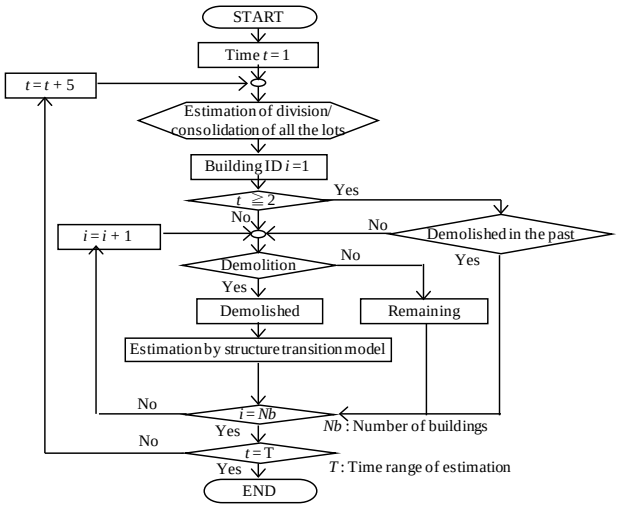

Figure 4. Flow chart of simulation

Next, districts were divided into several zones with respect to their distance from main roads, distance from railway stations, width of adjoining streets and land use regulations. Each zone was examined to find the rate of use of incombustible materials over the 30-year period and the mean rate of increase in use of incombustible materials. Figure 5 shows the results of that simulation. Over 70% of buildings were predicted to be fireproofed in the next 30 years in zones within 30 m of main roads excepting the low-, middle- and high-rise residential zones. In contrast, in the low-, middle- and high-rise residential zones, it was predicted to lag, with low rates of conversion. High rates of fire-resistant conversion were predicted for buildings within 30 m of main roads, but relatively low rates were expected beyond the 30 m line. Areas along main roads are expected to fulfill a role as firebreaks, so it will be important in low-, middle- and high-rise residential zones also to be adequately fireproofed.

Results of zones combining land use regulations and distance from railway stations showed increased levels of fireproofing in buildings closer to train stations. Again, however, in low-, middle- and high-rise-, residential zones were predicted to have low rates of fireproofing, even after 30 years. There are many transient occupants near railway stations, which makes safety that much more vital. Fireproofing should therefore be promoted in residential-use zones within 300 m of a station.

Factors of land use regulations and width of adjoining streets were also combined for simulation. A relatively large gain was predicted in fireproofing of buildings facing streets in the width range of 0 - 4 m, but the current rate of fireproofing among these buildings is so low that even after 30 years, the gain still resulted in a low overall level of fireproofing. Indeed, in low-rise residential zone, it showed only a small rise in fireproofing even when they were facing streets 6 m or more wide, with the same low rate of fireproofing after 30 years. From the viewpoint of preventing fire spread, it is essential to promote fireproofing of buildings near narrow streets. Since two functionalities are required—to serve as a firebreak and to serve as a route for evacuation of citizens—new policies are necessary to make aggressive improvements in the fire resistance of streets connecting to streets with widths of 6 - 8 m.

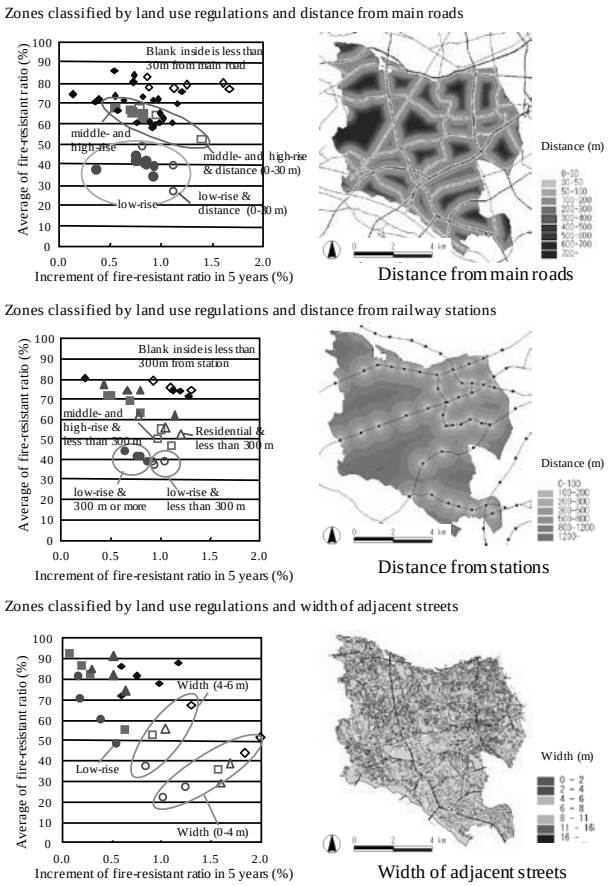

Figure 5. Average and increment of fire-resistant ratio in zones classified by factors

4.2 Assessment of influence of regulations and policies on fireproofing progress

Regulations and promotion policies that seem most effective for fireproofing of buildings were determined (26 total). They address (1) lot area; (2) lot connections to

adjoining street(s); (3) zoning; and (4) capacity factors. Next, the effects of each regulation and policy on the progress of fireproofing in the districts found in 4.1 to be the most vulnerable were predicted. These were compared with the consequences of not enforcing the regulations (the current situation) in order to observe which are most effective. Next, Fireproofing Promotion Plans were created using various combinations of the eight regulations found to be most effective; the benefits of each combination were assessed in terms of the "effect" and "efficiency".

It is more efficient to combine regulations and policies with special provisions for previously existing buildings that do not meet standards than to change zoning or capacity factors. This is because these buildings are then easier to replace under the special provisions of regulations and policies, and will then be replaced with fire-resistant or quasi-fire-resistant structures. If capacity factors are legally raised, there will be more fire-resistant buildings, but if capacity factors are loosened excessively, lot consolidation will be suppressed, promoting lot division; this would work against the final goal of increasing the number of fire-resistant buildings. Thus, planners must be cautious not to allow the outcome of deregulation to be the opposite of its desired effects.

Other effective policies apply minimum lot size regulations to entire districts to suppress lot divisions while promoting the construction of fire-resistant buildings. However, there are many cases in which lots are divided while wooden buildings are replaced; if minimum lot size regulations are enforced against small lots, lot division will be suppressed, potentially suppressing a large number of otherwise probable replacements of wooden buildings. Minimum lot size regulations are anticipated to be quite effective for forming favorable city lots, but caution must be exercised to promote the desirable replacement of deteriorating wooden buildings.

5. SUMMARY AND CONCLUSIONS

This paper presents a "micro" view of the process of fireproofing individual buildings in a city. A stochastic model was created to describe the process of building replacement in two parts: a demolition model and a structural conversion model. Real data were employed in model simulations, and the values of the estimated parameters revealed factors affecting the process of fireproofing of buildings.

Reconstruction simulations were carried out with data from existing city lots. These provided a view of progress in reconstruction of buildings assuming that current regulations and policies are continued without modification. Locations in particular need of faster reconstruction were identified.

Fireproofing promotion plans were created, combining a variety of different regulations and policies, and evaluated using the above model for effectiveness and efficiency. Regulations and policies resulting in the most effective increase in fireproofing were noted, as follows. (1) In order to promote more rapid building renewal, it is more efficient to enact regulations incorporating special, looser measures for existing buildings that do not meet current standards than simply to relax regulations on zoning or capacity factors. (2) Loosening restrictions on capacity factor generally encourages construction of fire-resistant structures, but it also suppresses the desirable consolidation of lots and promotes lot division. (3) Regulations on minimum lot size suppress lot division and promote construction of fire-resistant buildings, but also have the potential to suppress the replacement of wooden buildings that is likely to occur during lot division.

The results of the simulations with the stochastic reconstruction model created in this study demonstrated that fireproofing proceeds at different paces in different areas. Therefore, a key feature of these plans is to avoid uniform fireproofing policies affecting wide regions in favor of more localized approaches that are well tuned to each district's realities. The appropriate division and combination of lots will create a more safe and beautiful urban landscape.

STATIC AND DYNAMIC EMERGENCY EVACUATION GUIDANCE FOR COMPLEX BUILDING GEOMETRIES

Chih-Yuan Chu

Assistant Professor, Department of Civil Engineering, National Central University, Taiwan
jameschu@ncu.edu.tw

Abstract: The paper proposes a method for designing static and dynamic evacuation guidance in complex building spaces. A visibility graph is used to analyze the geometry of the building in a manner consistent with actual human behavior. The static evacuation sign installation locations and the associated evacuation direction information can then be found using the graph. However, the pre-determined, static emergency guidance does not respond to the real-time situations and may cause congestion in the event of evacuation. To address this problem, this paper further proposes a complementary method for planning dynamic emergency evacuation guidance using image process to support the static guidance system.

1. INTRODUCTION

The evacuation time of a building is one of the most critical measures of performance in its emergency design. In addition to building geometry, the design of the emergency guidance system is another key component that determines the time required for pedestrians to leave hazardous areas. The following sections introduce the proposed design methods for planning static and dynamic evacuation guidance.

2. STATIC EVACUATION GUIDANCE

Designing the static evacuation guidance is highly related to finding shortest paths in the presence of obstacles, which is a classic problem in computational geometry. The following theorem states the property of a shortest path from an origin to a destination in such space:

The shortest path from one point to another point among a set of disjoint polygonal obstacles is a polygonal path whose vertices (except for the origin and destination) are vertices of the obstacles.

The proof of the theorem can be found in de Berg et al. (2008). This theorem is very intuitive and can be illustrated with the following example. Consider a rope passing through two points with several obstacles between them. By assuming that the rope represents the correct path, the length of the path can be reduced by pulling on the rope from either end. When the rope cannot be pulled any further, the shortest path must be a polygonal line and its vertices are the vertices of the obstacles.

2.1 Visibility Graph and Shortest Path

A visibility graph is a network whose vertices are the vertices of obstacles and whose arcs connect all vertex pairs that are visible to each other. The rule for determining if two vertices are visible to each other is that a straight arc can be constructed between them without intersecting any obstacles. Based on the theorem, a visibility graph always contains the shortest paths from one vertex to another in complex building spaces. To find the shortest path between an origin–destination pair, new arcs are added to connect the origin and the vertices of the network visible to the origin. Similarly, new arcs are appended for the destination. When the graph is constructed, the shortest path between the origin and the destination can be found in the network using a shortest path algorithm such as Dijkstra's. See Ahuja et al. (1993) for examples of shortest path algorithms.

Figure 1 shows an example of a visibility graph. The black rectangles are the obstacles and the small squares are the candidate sign locations. The solid gray lines constitute the visibility graph and the green exit sign is the destination. The arcs are bidirectional except for arcs {e,b} and {g,d}. That is, corner b could be a candidate for sign installation from the location of corner e; however, e is not a candidate from the position of corner b because e is not on the shortest path from b to the exit or any other corner. The explanation for corners d and g is the same.

After the visibility graph is constructed, the next task is to find the shortest paths from all corners to the exit and the corresponding sign installation locations, which should be done with a many-to-one shortest path algorithm. Note that

the visibility is bidirectional; therefore, if one corner can be seen by another, the opposite is also true, and the distances for both directions would be identical. As a result, instead of running a many-to-one shortest path algorithm to find the shortest paths from all corners to the exit, a one-to-many shortest path algorithm is sufficient to find the shortest paths from the exit to all corners. The only required change is inverting the unidirectional arcs in the graph before running the shortest path algorithm and reversing the result of the shortest paths afterward. The shortest path from a corner to the exit can be easily traced.

2.2 Finding the Best Sign Location

Although signs could be installed at all vertices in the graph, only some of them would be useful for guiding pedestrians. We find the "best" corner for a pedestrian standing at a cell. The "best" corner and all the predecessor corners are marked until we reach the exit. The procedure is repeated for the complete building space. To simplify this step, the continuous space is discretized into 40 cm×40 cm cells, which is the average space a person occupies (Burstedde et al., 2001). After all cells are calculated, we remove all the corners that were never marked and their associated arcs. Finally, we install signs at all the remaining corners. To simplify the presentation, we assume that the range of visibility of a sign is unlimited. This assumption can easily be relaxed by adding relay signs between two distant signs. A detailed algorithm that determines which corners require sign installation can be found in Chu (2011).

In the procedure describe above, a "best" corner must be selected for the cell under consideration. It seems reasonable that pedestrians would select the signs closest to them. However, this criterion does not generate the shortest route to the exit. For example, in Figure 1, if pedestrians B and E start the evacuation by following the signs closest to them (b and f, respectively), they end up following paths b-a-exit and f-b-a-exit, respectively. On the other hand, pedestrians A, C, and D should not follow the signs that are closest to them. Instead, they should follow signs c, d, and b initially and evacuate via c-exit, d-c-exit, and b-a-exit for their shortest paths. Thus, the correct criterion for selecting the "best" corner for a sign is to find the corner such that the distance from the corner to the exit plus the distance between the cell and the corner the smallest. In the figure, these "best" corners selected for installing signs are colored red and their evacuation direction information is represented by the short blue arrows. In practice, this criterion does not cause too much confusion when there is only one exit because all the visible signs for a pedestrian should be pointing in the same direction and the pedestrian can determine the correct direction to move. For example, it should be evident for pedestrian D that b is the sign to follow because signs b, e, and f are all pointing to the left and, moreover, e and f both point to b. The remaining problem is how to ensure that pedestrians follow the "best" signs, which may not be as obvious as the closest ones to them. Additional information can be provided by measures such as text, color, and special signs visible only from a certain position. The appropriate equipment and technology to achieve this will be the subject of future research.

3. DYNAMIC EVACUATION GUIDANCE

The pre-determined, static emergency guidance introduced in Section 2 provides only static information of evacuation routes to exits and do not respond to the real-time situations. In the cases of large-scale evacuation, these evacuation routes are likely to be congested because a large number of pedestrians attempt to leave the hazardous areas at the same time. To address this problem, this paper further proposes a complementary method for planning dynamic emergency evacuation guidance to support the static guidance.

The technique of digital image processing is one of the key components in the identification of congestion in the event of evacuation. Because digital images are composed of pixels, it is required to convert the building under consideration into squares of equal-sized cells, which is identical to the discretization adopted in Section 2.2. Indeed, the model accuracy could be affected due to the discretization; it is emphasized that reducing the cell size is still possible if higher accuracy is required.

3.1 Identify congestion areas

Various studies have successfully adopted the techniques of image/video processing for pedestrian tracking and detection. For example, Hoogendoorn et al. (2003) and Helbing and Johansson (2007) are capable of detecting the positions of the pedestrians in a specific area. It follows that macroscopic measures such as density can also be calculated. They further combined various algorithms from different fields to extract the microscopic characteristics such as speed of each pedestrian over time. Therefore, the technologies of positioning the pedestrians in buildings are readily available and the spatial distribution of pedestrians that will be required in the follow procedures can be obtained through these techniques without difficulties.

The pedestrian simulation shown in Figure 2 is used to explain the problem of relying only on the static guidance in emergency evacuation. In the figure, the black areas represent the obstacles and the pedestrians are represented by gray areas. Stairways connecting to the ground floor are the exits and are marked with exit signs. To explain the methodology in detail, a 30 m×40 m space is selected in the lower right part of the figure and the following discussions will be focused on this area. As the selected area shows, the pedestrians are moving from north and west to leave the floor via the stairway following the static guidance. There are two sources of bottlenecks caused by the static guidance: pedestrians from north pass the same ticket gate to access the exit and all of those from west use the narrow space between the wall and a column. Because the

pedestrians follow the static guidance and all of them are taking the shortest paths, significant congestions are formed at the two bottlenecks. Without the dynamic guidance, the alternative routes are ignored and the evacuation process could be delayed.

The concept of the identification of congestion areas is treating the spatial distribution of the pedestrians as a binary image (i.e., black and white). Each pixel is equivalent to a small square of space, i.e. a cell, in the building. A congestion area implies a group of cells crowded with pedestrians and jamming and clogging are forming. Therefore, in terms of digital image processing, congestion can be identified by finding objects in a binary image converted from a pedestrian distribution. The standard procedure for identifying objects in image processing includes noise removal, erosion, and dilation.

When a pedestrian is moving without any pedestrians in the adjacent cells, it is clear that the pedestrian is able to walk freely and thus no congestion exists. In the sense of digital image processing, it is equivalent to a single dot in the image and can be seen as a noise. Because these scattered dots are not of interest for congestion identification, a noise removal algorithm can be used to eliminate them from the consideration. In this study, the commonly used *median filter* algorithm is adopted for this task. A median filter scans a neighborhood and uses the median value for all pixels in the neighborhood to replace the value of the pixel in the center of the neighborhood. This study selects a typical 5×5 neighborhood. Because the cell size chosen for this research is 40 cm×40 cm, the meaning of the selection is that if there are at least 13 persons in a 4 m^2 space (0.16 m^2× 25, equivalent to the density of 3.25 persons per m^2), the center cell of the space is considered congested. The threshold of 3.25 persons per m^2 is consistent with the jamming density reported in Jin (2002), which is 3.5 persons per m^2. Figure 3(a) and Figure 3(b) show the effect of a median filter. After the processing, pedestrians not in the congestion areas are removed from the image and only pedestrians in congestion areas remain. However, it can be seen from the figure that many small gaps and holes exist and theirs shapes are rather irregular. Because the planning of the guidance adopted in this paper depends on the polygonal obstacles and to avoid overly complicated dynamic guidance, it would be more effective if the identified areas have more regular shapes, preferably concave polygons; therefore, more processing is required.

After the step of noise removal, the next task is to search for major congestion areas with simple shapes in the facility. In the terminology of image processing, it is equivalent to finding objects of interest in an image, which can be done by smoothing out object outlines, filling small holes, and eliminating small projections in the image (Umbaugh, 2005). The common operations include erosion and dilation. Erosion shrinks objects by eroding their boundaries to simply their shapes in an image and dilation expands the objects for the loss of size in the step of erosion. By operating erosion and dilation in sequence, the objects with simpler shapes can be identified. When it is applied on the spatial distribution of pedestrians, the irregular shapes of small groups of pedestrians are smoothed out. Therefore, the planning of the adaptive guidance would not be affected by these relative small congestion areas. Figure 3(c) and Figure 3(d) show the effects of erosion and dilation respectively, and the results are the congestion areas that will be considered in the following procedure of adaptive guidance design. Finally, it should be emphasized that the parameters in the image processing algorithms determine the size and number of congestion areas. The appropriate parameters for different scenarios of emergency evacuation could be different and more research would be required for this topic.

3.2 Dynamic guidance

The main concept of the adaptive guidance is to consider the congestion areas identified above as virtual obstacles. A new static guidance considering both the original obstacles and the update-to-date congestion areas as obstacles is generated with the method proposed in Section 2. Due to the additional obstacles, the shortest paths to the exits and the optimal guidance would be different. By comparing the routes suggested by the original guidance system and the adaptive guidance, the required information to instruct the pedestrians to bypass the congestion areas can be determined. The procedure can be explained by Figure 3(a) and the congestion areas identified in Figure 3(d) are drawn in Figure 3(a) for comparison. As explained above, the pedestrians are moving toward to the exit from west and north. It can be seen from the pedestrian simulation shown in Figure 4 that the alternative guidance (arrows in the figure) instructs the pedestrians to bypass the congestion areas. One of the practical ways for implementing this adaptive guidance is to deploy staff members at appropriate locations and guide the pedestrians to use the less congested routes with vocal or gestural instruction. However, the mechanisms of providing the dynamic guidance is not specified in this study and still need more tests and experiments.

4. CONCLUSIONS

This paper has examined the design of the static and dynamic evacuation guidance system in complex building spaces. The static guidance designed with the proposed methodology has the following properties. First, at least one sign is visible from any point in the building; that is, all pedestrians are covered by the system. Second, each sign indicates the direction to the next sign via the shortest path to an exit. Most importantly, the system guides pedestrians to their closest exits via the shortest paths.

This paper further proposes a complementary method for planning dynamic emergency evacuation guidance to support the pre-determined, static guidance that does not respond to the real-time situations. Using the techniques of

digital image processing, the congestion areas in the building can be identified. By considering these areas as virtual obstacles, the dynamic guidance that instructs the pedestrians to take the alternative routes and bypass the congestion can be generated.

RESIDENTS ADAPTATION OF POST DISASTER HOUSING: THE ROLE OF PHYSICAL ENVIRONMENT FOR SOCIAL INTERACTION

Syam Rachma Marcillia

Graduate Student, Department of Built Environment, Tokyo Institute of Technology, Japan
syam.r.aa@m.titech.ac.jp

Abstract: In this paper, physical adjustment of Java 2006 post disaster housing is investigated to understand its influence to the social interaction by examining and analyzing residents` usage, adjustments and attitude toward the housing. Two case studies for self-built and donated post disaster housing were investigated. An intensive and comprehensive onsite fieldwork research was conducted not only by encompassing questionnaires and interviews but also observation of residents' activities as well as physical changes they made to the original donated dome houses and site plan. The results suggested that residents tends to built their self-built housing to satisfy their needs of social interaction with others in the house while still maintain their privacy. Even in a restricted dome donated housing, the residents have the ability to be adapted to the physical environment misfits by adjusting their physical and behavior aspects in order to accommodate and maintain their previous social lifestyle. However, flexibility and open ended design in physical built environment would give an advantage in their critical transition to the new environment.
.

1. INTRODUCTION

Housing reconstruction efforts were made by many parties, NGO, government, etc after tsunami (Aceh, 2004) and earthquake (Java, 2006) disasters. But large scale of emergency development in a short time without cultural sensitivity resulted in rejection of ill planned and designed settlement. On the other hand, some community based reconstruction housing get a good response because of its open ended design that facilitate the cultural needs. These highlight the importance of understanding cultural background in the design of a dwelling

Social behavior is one of the important cultural backgrounds in Indonesia dwellings and Java specifically. For Javanese, a house is living environment that represent the philosophical concept of the society itself.

In previous researches, traditional `margersari` housing and other public housing consist of so called `core house` , the room pattern is `guest room`, bedroom` and kitchen. (Ikaputra, 1992). Most of the `core housing` alteration start with the expansion of double/triple size of `guests room` which is a `social space` then bedroom.(Yoyok Subroto, 1993). Another finding is the phenomena of 'guest area` appearance in temporary tents and house right after Java 2006 earthquake (Fig. 1a and 1b. Even their needs of functional room (bedroom, kitchen, etc) is not yet fulfill, but the importance to facilitate social behavior to be a part of the society is express and actualize through the activity in `guest room`. These show the importance of social factors in the Javanese dwellings.

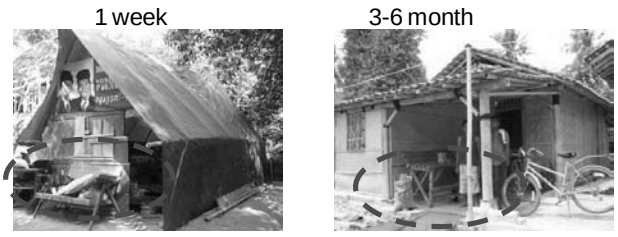

Figure 1: 1a and b Guest area appearances in temporary Java post disaster dwellings

There had been studies on how social behavior affect Indonesia domestic space (Java studies specifically). Some focused on how social interactions and its meaning influence the morphology of traditional dwellings (Tjahjono, 1989; Revianto, 1997) and others on its influence in the present non-traditional dwellings, such as public housing (Yoyok, 1993) or urban houses (Yulyta, 2008). Even though cultural changes in the society accompany the change in house, social behavior apparently still have influence in Indonesia dwellings. Correspondently, it is believed in this study also that the physical environment have influence to facilitate or inhibit certain social interaction that are necessary for the residents in Java 2006 post disaster housings.

In defining dwelling (housing), one can not only compare the physical artifacts encounters (Rapoport, 2005). Different culture had different perception and actualization of their dwelling. For most Javanese people, dwelling settings not only consist in the core house itself, but also the surrounding wells, streets, etc. as social space that accommodate various social behavior. In this study, data on physical setting as well as residents' behavior in self-built

and donated post disater housing are interpreted in the emphasis of the personal-social interaction activities to extract clearer basic relation between the social meanings, ideal, values with dwellings usage.

2. RESEARCH METHOD

Post disaster housing physical adjustments and residents' activities pattern was investigated as activities pattern can be 'the most useful entry point' for relating culture with the built environment (Rapoport, 1969). Two approaches were taken to analyze relationship between physical setting and social interaction behavior:

(A) The spatial development and adjustment for satisfying social interaction in constraint dwellings for both self-built and donated post disaster housing.

(B) The behavior adjustment and evaluation of mis-fit spaces in unchangeable dome donated post disaster housing.

2.1 Overview of Study Area

Two case studies were conducted according to the approaches above. First case is the Java earthquake 2006 self-built post disaster dwellings in three sub-villages of *Ketonggo, bawuran and Tegalrejo*、*Yogyakarta*. Two integrated surveys were taken within 2 years in order to see the development of temporary house to permanent house. In first survey, 39 respondents were chosen based on houses' condition after the earthquake where most houses destroyed and the permanent post disaster houses are rebuilt by themselves or based on their own design. Second survey targeted same respondents but only 33 respondents were re-surveyed.

Second case is donated dome post disaster housing in *New Ngelepen, Yogyakarta* . After Java earthquake May 27th 2006, in the original *Ngelepen* village, almost 50 houses were demolished by catastrophic landslide and the area declared as a geographically unbuildable land. As a result, the residents were relocated to *New Ngelepen* post disaster settlement, situated about 1,5km from the original village.

The *New Ngelepen* introduced house clusters site plan design where every 12 houses form a block that shared sanitation, electricity, public toilet/washing area and approach pathways. Dome monolithic with a hemispherical roof and a circular plan were introduced with concrete cast as a single and integral structure as the donated post disaster houses. The diameter of the house is 7 meters, two stories, with the total area about 38 square meters. The development of the houses began in October 10, 2006, and started to be occupied at the end of April 2007. These unique unchangeable dome house design and different settlement type from residents' original housing was investigated to understand its influence to residents' social interaction within the first 3 years occupancy. A total of 68% of the residents in 34 occupied dome houses were interviewed.

Both conditions are considered as 'constraint dwelling' because there is a change of situation from their previous 'preferred' living environment to their 'temporary' restricted condition. Table 1 shows the details of two case studies.

Table 1 Detail Description of Case Studies Areas

case	Java Post disaster dwellings		Dome Housing
Resident ethnic	Javanese 100%		Javanese 100%
Status	Owner 100%		House owner 100% Land borrower
Dwelling Design	Self-built post disaster temporary and permanent house build by self-design cognition		Donated dome housing with unchangeable limited size & differ design cognition with original house
Area type	Rural area, Yogyakarta, Java 3 sub villages (Ketonggo, Manggung and Tegalrejo). First survey obtained 39 data, only 33 data were re-attained.		Rural area, New Ngelepen, Yogyakarta, Java From total 71houses, only 51 lived in
Time survey	*First survey* in Nov.-Dec. 2006	*Second survey* in Nov.2008	August 2009

2.1 Data Questionnaires and Interview

Questionnaires, observation and in-depth interview with the residents were attained with the help of Gadjah Mada University volunteers. Each team consists of 2 people, one person was asked to sketch the house plan while the other interviews the resident. In Japan case, residents were interviewed and asked to draw their own house plan. Information acquired as follows:

a. Background
- Residents: age, sex, family, occupation, income, etc.
- House: structure, house age, land status, etc.

b. House plan: room space, size, etc

c. Space usage
- Personal activities in space which include: *personal biological needs* (eating, sleeping, etc), *entertainment* (watch TV, relaxing, etc), *work* (study, etc) and *household routines* (cooking, washing, etc).
- Interpersonal activities which include: location and behaviors in accepting different guest types in the house and interaction and frequency with neighbors.

d. Cognition of space on front/back, hidden/seen, public/private, flexibility, etc.

e. Evaluation of house, outdoor space and neighborhoods space (for dome housing)

3. RESEARCH RESULTS AND DISCUSSION

3.1 Importance of guest area and social interaction

From the survey in self-built post disaster housing 95% of the residents values traditional social behavior. Accepting guest activities in the house occurs 41% for everyday occasions and 90% residents involved in community gathering and accept large gathering guests in their house. Similar situations happen in dome post disaster housing. Approximately more than 95% for both heads of household and spouses said that they participate in community activities with their own willingness, while only less than 5% feel obligated to participate and null for no participation. High participation to community activities is supported by their perception on the importance of the value and existence

of community activities in their neighborhood. Approximately 65% head of household and 57% of spouses response is A "I feel that community activities are very important" and approximately only about 34% for both heads of household and spouses said that "they are neutral, don' t really have certain feeling". Unfortunately the incapability of dome house design to facilitates certain social interaction behavior results in the usage of outer space of the house and neighborhood as the `guest area` or `incidental social interaction space`

2.a Self-built housing

2.b dome housing

Fig.2 Accepting guest in Java 2006 post disaster housing

In self-built post disaster housing case where both temporary and permanent house is currently use by the residents, guest area is one of the earliest function that move to permanent house (Fig.3) . Expansion from temporary houses to permanent houses indicates the need of guest room increases by 5 times its original size and 3.6 times its original total room number (Fig. 4). Room modification also shows that it is important to have a separate formal guest area in the house (Fig.5). The expansion and separation tendency of guest area have relevant founding with public housing complex in Yogyakarta where most `core house` alteration cases started with the expansion of guest room to the front area and had doubled its original size (Yoyok, 1993). However, total room number and addition of bedroom modification is still the highest overall adjustments which also indicate a high need of private space although its average room size actually decreases (Fig.5).

3.2 Cognition of spaces in dwellings

Cognitions of space are much related with the arrangement and allocation of 'self'(personal) and 'other'(interpersonal) space. Space pattern development in self-built housing also showed the existence of private/public spaces in simplest condition (Fig 6). These related to findings in Java case where residents' cognition of front/back area is associated to hidden/shown area to other people (Fig.7). This supported by previous research on traditional dwellings where front of house is outwardly-oriented domain where domestic prestige displayed in form of status differences and formality in meeting others (Revianto, 1997).

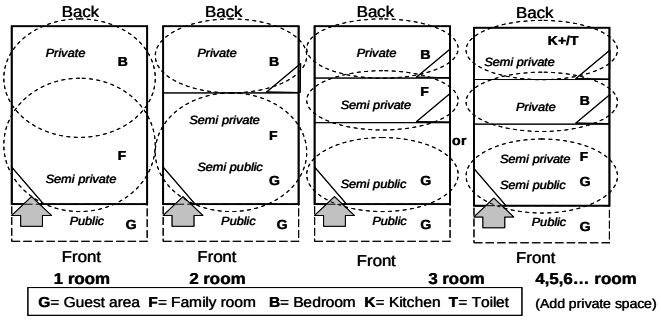

Figure 6 Development of private/public space pattern in self-built post disaster housing

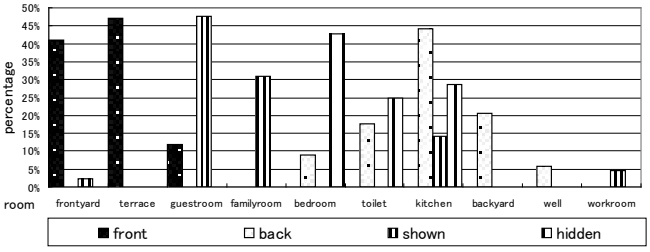

Figure 7 Spatial cognition and preferences in self built housing

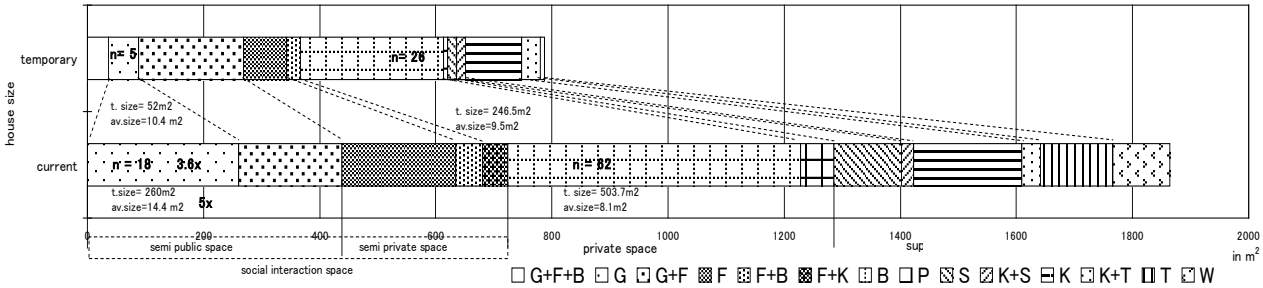

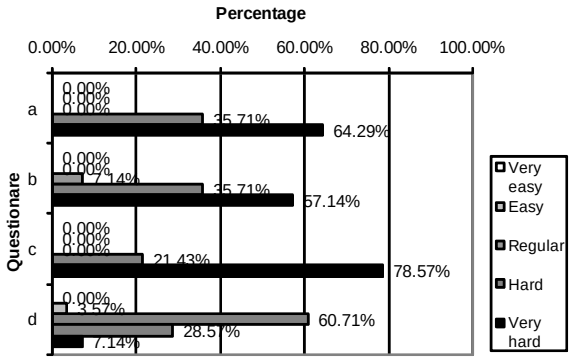

Figure 4 Size expansion from temporary to permanent in self-built houses

3.3 Misfit in Dome housing for Social Interaction.

From the residents‟ evaluation to their dome house design shows that "very hard" capability of residents to *"to change the order/function of the rooms"* (64%), *"to expand the room"*(57%), and *"to change the location of the doors or windows"* (76%). Only 61% for capability *"to give rooms addition"* shows *"regular"* capability (Figure 8). we can make a conclusion that flexibility in dome houses is one of the most complicated problems for the residents except for capability *"to give rooms addition"* although in reality it is also hard for the residents *"to make additional room that compatible with original donated house"*.

a. Easiness to change the order/function of the rooms.
b. Easiness to expand the original room
c. Easiness to change the location of the doors or windows.
d. Easiness to give rooms addition

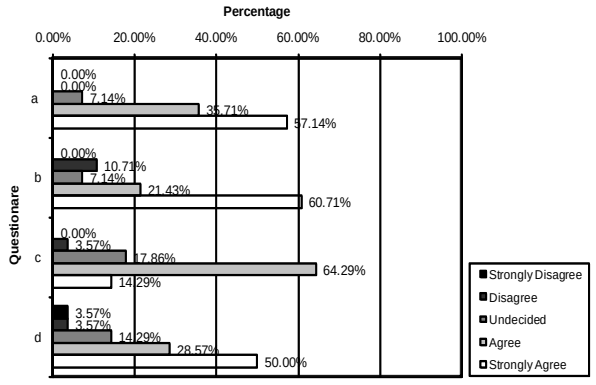

Figure 8 Residents' evaluation for dome house design flexibility

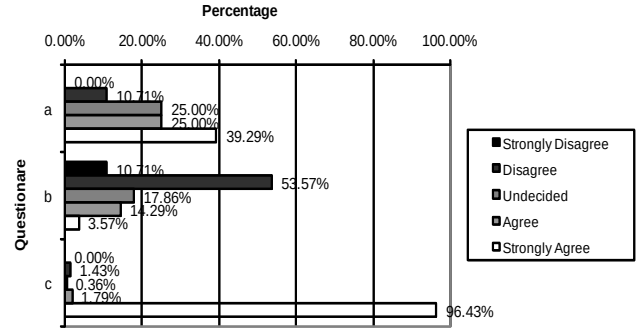
In Javanese traditional housing, a `guest room` hold an important role for social interaction within the house. The house contains both `self` and `others` domains that are interrelated (Revianto,1997). Inflexibility of the dome house design to provide enough social interaction space in the built-in less than 10m2 `guest area` had resulted in the usage of surrounding outer space or even the neighborhoods space.

Unfortunately, dome house outdoor site plan also have some misfit relating to its used as an extension space that facilitates the social interaction. Evaluation for house outdoor space shows *"very agree"* attitude toward statement *"it is better for each house to have private approach pathway"* (57%), *"there is not enough yard/room in the house to have social gathering"* (61%) and *"it is important to have a front terrace but the space available is not possible to made one"* (50%), while only 64% shows *"agree"* attitude toward statement *"each house should have own pathway from house to public toilet area"* (Figure 9).



From house outdoor evaluation showed that there is not enough space for need of front terrace not large gathering space. Moreover, house outdoor design elements such as pathways that were design to promote social interaction infact only intrude their privacy.

Evaluation for neighborhood streets shows that more than 96% of the residents are *"very agree"* to the statement *"the house front yard space should be larger instead of larger street for better social gathering space"*. However evaluation for statement *"streets inside the neighborhood should not be too large so that cars and motors not easily pass by" were "disagree"* by more than 53% (Figure 10).

a. It is better for each house to have private approach pathway.
b. There is not enough yard/room in the house to have social gathering.
c. Each house should have own pathway from house to public toilet/washing area

Figure 9 Residents' evaluation for dome house outdoor space

a. neighborhood streets are too dangerous to leave children play by themselves.
b. streets inside the neighborhood should not be too large so that cars and motors not easily pass by
c. The house front yard space should be larger instead of larger street for

Figure 10 Residents' evaluation for dome house neighborhood

From the residents‟ evaluation we can presume that house outdoor space hold an important role in their social interaction activities. Typical Javanese rural dwellings had large yard that function not only for planting and drying laundry but as drying harvest crops, burning garbage, drying the corkwood, etc. It also hold important role as a socialization space. In daily life, housewives like to chats with the neighbors while looking after their little children playing in the house yard. Occasionally large social gathering are also done in house yard area such as wedding, trah‟ gathering, etc.

In *New Ngelepen*, the limitation of house inner and outdoor space made the residents use neighborhood‟s streets for their social activities. From the interview and observation, during the day little children were playing freely on the streets, while housewives chat on side of the streets. The streets were also used as social gathering spaces. Near neighborhood entrance, main street was painted as badminton field where youths and man gather in the evening to play badminton or just to hang around. Social gathering

that used to be facilitated in original dwellings but not possible in dome houses, now performed on the streets such as ruwahan", etc. Even once the streets were closed for one of the resident' s wedding ceremony.

4. CONCLUSIONS

In java 2006 self-built post disaster dwellings, physical changes and development from temporary to permanent such as size and room number expansion, space modification, function changes, show that guest area is inevitably an important social interaction space to be provided in the house. On the other hand, total room number and addition of bedroom is still the highest overall adjustments which also indicate a high need of private space. These show that both needs of social interaction space and private space are simultaneous exist. The duality spheres in the house also actualize in their cognition of spaces.

Respondents' cognitions of space are much related with the arrangement and allocation of 'self'(personal) and other'(interpersonal) space and how it is interrelated in spatial arrangement of fixed and semi-fixed elements of the house.. Although self-built and dome housing cases are different in physical conditions but both residents` cognition of private/public have the same tendency and this also related to their front/back, hidden/shown spaces for interaction.

In mis-fit and unchangeable spaces, social interactions are still facilitated and preserved by the respondents although it means that private space is intruded. As consequences some behavior adjustments are needed to be taken such as appointment of time and preparing of incidental `guest area`. Since dome house design was misfit and unchangeable then house outdoor space facilitates some of its social function. In some cases where certain activities cannot be done inside and outside the house space then neighborhood spaces such as streets, etc. will bear bigger role in facilitating these social interaction needs.

This research has once again highlighted the importance of social behavior in Javanese dwelling even at its constraint situation. Meaning, values and ideals of social behavior are reflected on their cognition of spaces in the dwellings as well as their behavior adjustments. It is necessary that even in constraint dwelling such as post disaster housing need to consider social behavior importance as culturally sensitive design for reconstruction recovery. Flexibility and open ended design in physical built environment would give an advantage in their critical transition to the new environment

DEVELOPMENT OF A METHOD FOR DETECTING VULNERABLE AREA BY URBAN TEXTURE

Xue Ma[1] and Ryuzo Ohno[2]

1) Graduate student, Dept. of Build Environment, Tokyo Institute of Technology, Japan
2) Professor, Dept. of Build Environment, Tokyo Institute of Technology, Japan

Abstract: Accompanied by the high-speed urbanization, as a seismic active country, China has a great deal of requirements on disaster mitigation and prevention system. Especially after 2008 Wenchuan Earthquake, more and more attention has been attracting to this topic. Disaster mitigation parks as an essential part of the whole disaster mitigation system, which strengthen the capability of disaster prevention or mitigation measures such as evacuation, emergency action, urban safety, providing temporary home for victim of calamity. As an initial step in the development of disaster mitigation park system, to detect dangerous area and its vulnerability is the primal issue which can reflect the requirements for improving the areas in a city. The present research starts with learning the experiences of Japanese disaster mitigation parks system, and then compares the city conditions between Japan and China to discuss the necessity of development of a new system for Chinese city. In order to search those potential vulnerable urban areas of different type and to detect what might be their weaknesses under various damage situations, a measurement method of the "circulation spaces" is developed. Through a case study applied for the different areas in Tianjin city, this analysis method is proved to be useful for describing the vulnerability of each area.

1. INTRODUCTION

1-1 Background

China is a seismic active country. Since the beginning of the last century, China has had nearly 800 quakes with a magnitude of over 6 on the Richter scale. Especially after 1950, we experienced five very big earthquakes which caused big losses of life and property.

There are two features of damage caused by earthquakes in China. One is large number of fatalities caused by low building quality and low evacuation efficiency. The other is slow recovery after earthquake caused by the problems like no emergency responding system, the lack of rescue system and too long time taken in rebuilding.

This research focuses on developing a method for detecting dangerous area as an initial step towards establishing a planning method of disaster mitigation park system in China.

1-2 Definition of disaster mitigation park

The term of disaster mitigation parks was first used by Japanese. The original definition of disaster mitigation/prevention park is that those parks and sites which strengthen the ability of disaster prevention or mitigation when earthquake and secondary disasters happen, life and possessions are threaten. Here the ability of disaster prevention or mitigation means evacuation, emergency action, urban safety, temporary home for victim of calamity and homeless.

2. NECESSITY OF DEVELOPING DISASTER MITIGATION PARK SYSTEM IN CHINA

2-1 Japanese disaster mitigation system

Japan lies in one of the most seismically active areas of the world, and Japan already set up a serial of measures which consists of a comprehensive system facing to the earthquake. With relation to this research, the current disaster mitigation park system and vulnerability evaluation system in Japan could provide us useful suggestions.

The disaster mitigation park system as a part of the urban evacuation system basically built on the existing park system. It is classified as: 1) wide regional disaster mitigation center, 2) regional disaster mitigation center, 3) wide-regional evacuation site, 4) temporary evacuation site, 5) neighborhood evacuation site, and 6) evacuation path, green buffer from its function and scale.

The vulnerability evaluation system is applied for promoting preparations for earthquakes by enabling of the local government and the residents to understand the vulnerability of the community and providing basis for

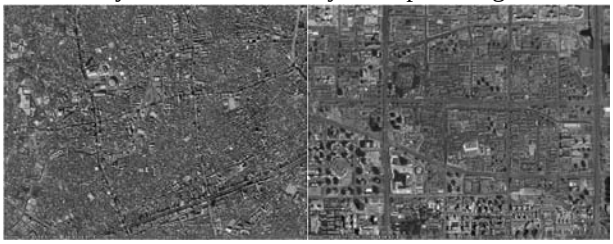

Figure 1 Typical urban texture in Japan and China

re-development under the aim of disaster-resistant city. This system in Tokyo, for instance, is applied to measure each district based on the basic information of building classification, aggregation and the type of ground structure. In accordance with the most threats in Tokyo, safety levels under dangers of building collapse and the spreading of fire are measured and ranked from low to high as level 1 to level 5. Finally, the integrated level of vulnerability is evaluated.

2-2 The disaster mitigation park system considering Chinese urban conditions

According to the physical and social conditions, different urban situation bring different demands and requirements on urban construction. Different cities may face with different potential dangers when earthquakes happen, consequently, the demands on disaster mitigation park spaces will be diverse also. When we consider setting up the disaster mitigation park system in Chinese city, it can't be simply copied from the Japanese system no matter how successful it performed when earthquake occurred in a Japanese city.

Compare with Japanese big cities, there are several significant differences in characters of Chinese cities which are shown in Table 1.

Table 1: Characteristics of urban areas in China and Japan

Characteristics	China	Japan
Building structure in vulnerable urban areas	Concrete/brick	Wooden-frame
Building type in vulnerable urban areas	6 floors/ high-rise (>18)	Low-rise (<10)
City Road pattern	Wide avenue divide urban area into superblock	Continuous pattern consist by dense and narrow street
Evacuation spaces system	Unplanned and inadequate	Planned
Concerned dangers	Building collapse Debris Safety during evacuation	Spreading of fire Building collapse

The network of road in Chinese city tends to use wide avenues as main road as contrasted with dense but narrow streets in Japan, which provides an easy identification of "super block" divided by it.

2-3 Process of developing disaster mitigation park system

Table 2: The green system in China is similar with one in Japan in terms of the system structure.

	CHINA	JAPAN		Area	Disaster Mitigation Park
Residential Pak	Group park	Block park (街区公園)	R=250 A=0.25	A>0.05	neighborhood evacuation site
	Street park	Neighbor park (近隣公園)	R=500 A=1-2	A>1	temporary evacuation site
	Zone park	Zone park (地区公園)	R=1000 A=4		
Urban Basic Pak	Urban park	Integrate park (総合公園)	A=10-50	A>10	wide-regional evacuation site
		Sport park (運動公園)	A=15-75	A>50	
Urban Extensive Park	Extensive park	Extensive park (広域公園)	A>50		regional disaster mitigation center
National Park	National Park	National Park (国営公園)	A>300(ha)		

There are two essential issues of developing a disaster mitigation park system: in one hand, the current green system and its relationship with disaster mitigation parks, from the comparison, connections can be made by its size and scale; And in the other hand, what is the demanding of disaster mitigation parks in target area?

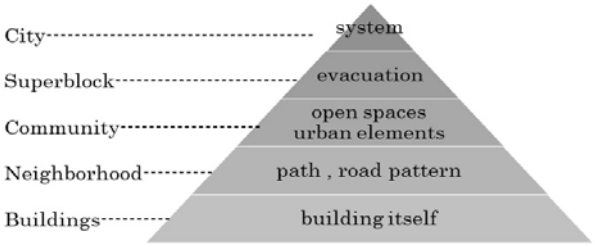

Figure 2 Urban elements and contents to be considered in different scales

We try to detect the dangerous area by examining urban elements in different scales. We classify the urban elements into 5 categories according to their scale: the buildings, the neighborhood, the community, the superblock, and city.

This research is basically concentrated on the scale of building and neighborhood. City has different sub-areas. In China the big avenues divides up the urban area into highly-recognizable sub-areas, the spaces inside one sub-area or between several areas usually show the similar road-pattern, building density and building size even height, thus show a curtain urban texture. We can recognize the difference in urban texture, and divide the urban area into sub-area, and based on each different features find out their potential dangers, and then we can propose a countermeasure by setting up the disaster mitigation parks system.

3. DEVELOPMENT OF A METHOD FOR EVALUATING CIRCULATION SPACE

3-1 Definition of circulation space

In this research, the state of circulation space is brought forward as criteria for evaluation of danger. It combines both outward and inward direction of movement, i.e. evacuation and access as well as usable spaces for staying. It means free movement or passage in a circuit inside particular area.

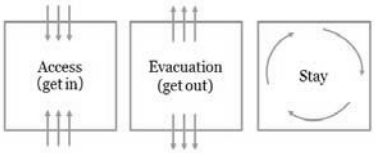

Figure 3 Three functions of circulation spaces

3-2 Measurement of space between buildings

After choosing target area, we draw network diagram

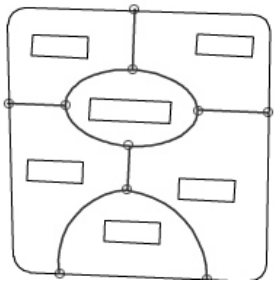

Figure 4 Network diagram

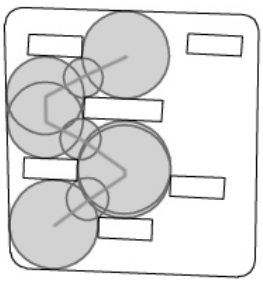

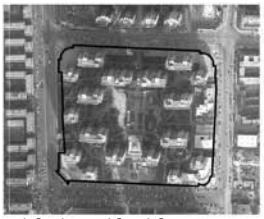

Figure 5 The circles drawn in the site plan

showing all possible circulation routes on the site plan in order to measure circulation spaces. Firstly, we identify the spaces where the junctions of network exist and draw circles of maximum size that fit into the identified spaces. Then the centre of circle is defined as a node of circulation route. Between two adjacent nodes, we draw circles of maximum size in the inflection point fit the spaces between buildings. With this method, we can describe the changing width of circulation spaces along the routes.

4. AN APPLICATION OF THE METHOD

4-1 Choosing target areas

A:High-rise residential area
Area: 8.37 ha/ Average height:60m/ Built year: after 1990/ Concrete

B:New low-rise residential area
Area: 8.16 ha/ Average height:15m/ Built year: after 1990/ Brick with shear wall

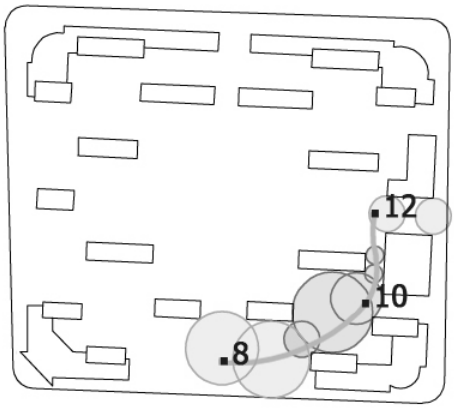
C:Old low-rise residential area
Area: 7.23 ha/ Average height:18m/ Built year: before 1990/ Concrete

D: Concession area
Area: 8.31 ha / Average height:10m/ Built year: after 1860/ Masonry

E: Traditional area
Area: 0.87 ha/ Average height:4m/ Built year: before 1990/ Masonry

Figure 6 Satellite image and circulation network

We choose the city of Tianjin, China as target city, which experienced the 1976 Tangshan earthquake with fatalities over 250,000. Five residential patterns are distinguished and picked out by different typical urban texture: high-rise building area (HB), new low-rise area (NL), old low-rise area (OL), historical concession (HC) area and old traditional (OT) area.



From each are, one residential site around 8ha in Chinese standard was chosen as a sample for applying the method.

4-2 Network in the target site

The outermost edge of buildings is connected to form the boundary of the chosen site. All the possible routes are marked including the city roads which pass through the site.

4-3 Measurement of circulation spaces

Category of width (radius) is set every 3 meter difference, the length of the route that belongs to each radius category are recorded.

	LL(total)	Radius
8	0	27.28
a1-f	26.04	12.86
10	29.01	28.42
a1-h	19.52	74.57
a1-i	21.06	95.63
A1-j	12.79	108.42
12	28.43	136.85

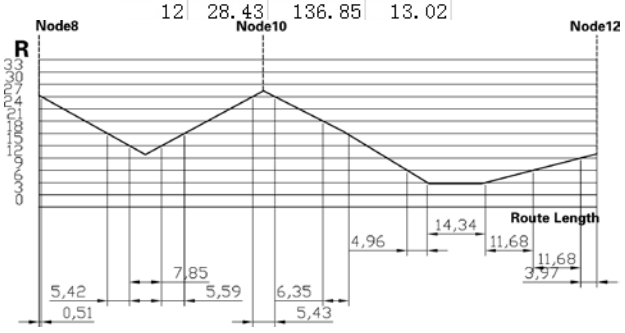


Figure 7 An example of measurement procedure of circulation spaces

from node 8 to 10 and 10 to 12 on the site A. At the node 8, the radius of the circle is 27m and towards node 10, it once reduce to 12m in the inflection point then increases up to 28m at the node 10.

Afterthen, the distribution frequency of the length that belongs to each category in all routes are collected as shown in Figure 8, the cumulative length of different radius is obtained in Figure 9.

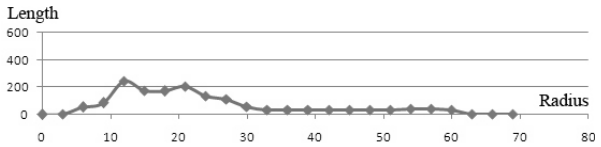

Figure 8: Analysis of circulation spaces on area A: Distribution frequency by radius

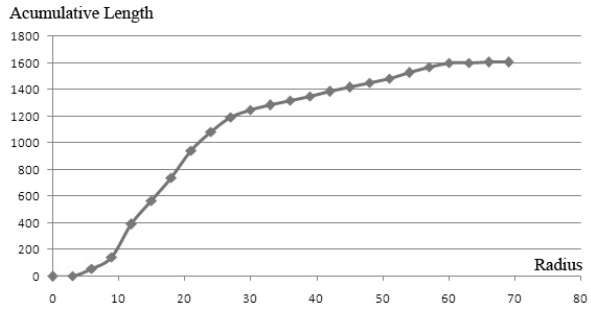

Figure 9: Analysis of circulation spaces on area A: Cumulative length by radius

4-4 Variation of circulation space under different building damage

We take the situation of surface damage and structure damage into consideration. Debris drop from the buildings have uncertain effecting area. Assuming that the width "W1"of surface damage effecting area is 10% of building's height, to judge if each circulation path still possible to be passed through. Once there is one point which radius is less the W1, then the whole route need to be removed. As Figure4-5 shows, there is one point with a radius 5.72m (<W1: 6m)on path 10-12, the circulation spaces locate on this path can't be taken into calculation.

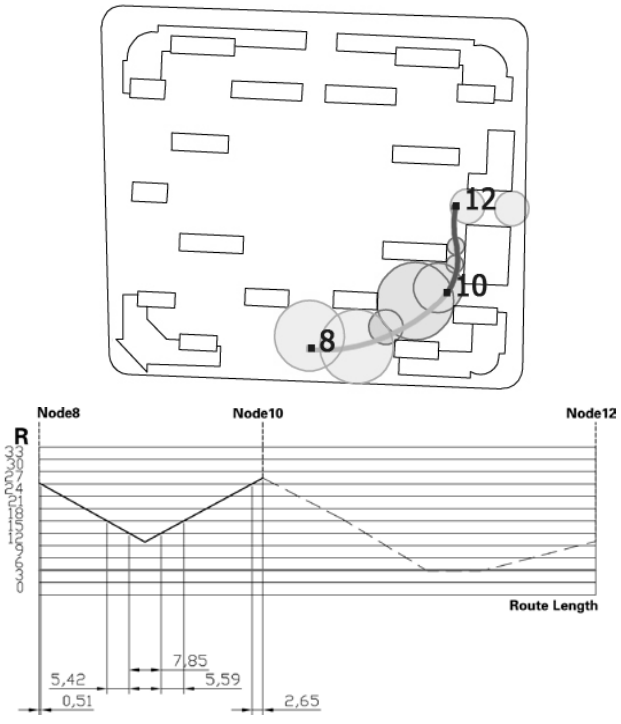

Figure 10: Analysis of circulation spaces of each path under damage situation under damage situation

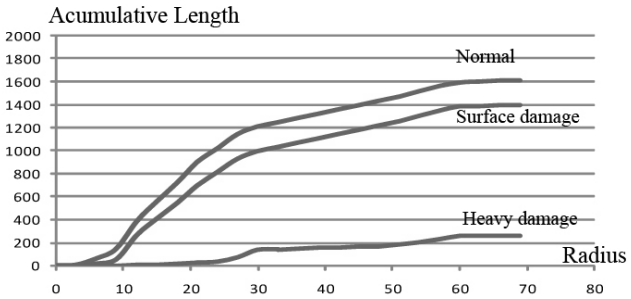

Figure 11: Analysis of circulation spaces of area A: Cumulative length of different radius

Using the same method, the situation of heavy damage takes width "W2" of effecting area which assumed as 30% of building's height. In the analysis of most areas, the surface damage just makes little influence but heavy damage triggers bigger influence.

4-5 Evaluation of circulation spaces for various usage

It is important that some circulation spaces over certain width can be used for temporary gathering for people or collecting or distributing emergency goods and materials. Besides, the situation on access of `fire engine also is can't be ignored. Even the fire is not easily to spread in Chinese city, fire engine is still significant towards the high risk of inside fire and rescue of trapped person. The same method can be used for measure those usable spaces. 4 meter (the minimal width for fire engine), 9 meter (two lanes for vehicle according to residential district index) and 18 meter are set separated as three standards.

4-6 Comparison of the target areas

Data under different damage situation of five areas are compared, showing the characters of each different type as Figure 12

Area (HB) possesses the widest circulation path. The total length is around 1600m. But it changes a lot when the heavy damage happen, only very limit but wide spaces in the center of the area are left.

Area (OL) performs best around in all the areas, the

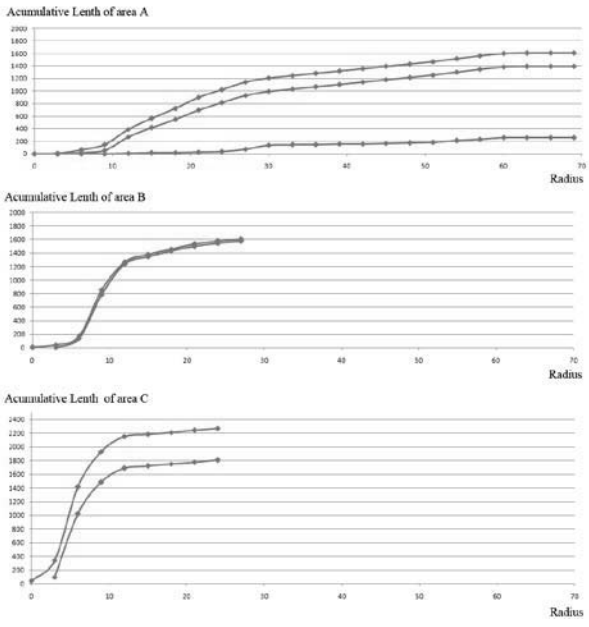

Figure 12: Analysis of circulation spaces on area A to area E: Cumulative length of different radius

circulation spaces are not affected when surface damage happen and just changes a little when heavy damage come. The total length is around 1600m.

The tendency of area (NL) is quite similar to area (OL) in the layout. But the influence of heavy damage present more distinct. However, its length exceeds almost 1/3 than area (OL) in the number of 2300m.

The (TC) area shows a dense pattern which is shown in the graph with a more than 2800m length. The width of circulation spaces is not more than 17m which changes a lot than those areas we mentioned above.

The (OT) area is quite special compare with all the other areas. It shows extremely dense and long circulation spaces. Several districts are picked up to make the analysis for it. Biggest radius is less than 5m while the total length reaches almost 5000m.

The comparison of usable circulation spaces under different damage level also shows a distinctive result in Figure13 .That blue express the normal situation, red shows the situation of surface damage as well as the green one

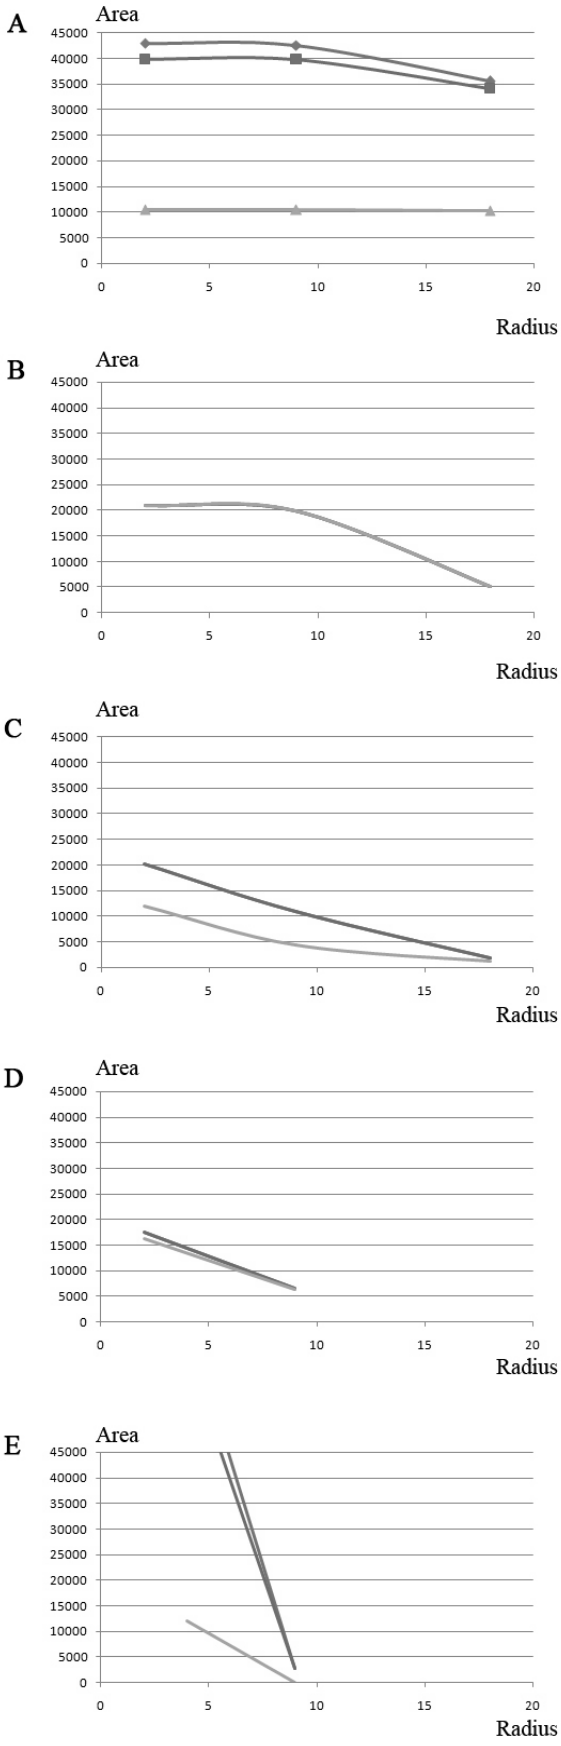

Figure 13: Analysis of usable spaces under different damage situation on area A to area E

shows the situation of heavy damage.

The horizontal axis indicates the certain width while the vertical axis states the area of usable circulation spaces.

Area (HB) has the biggest usable spaces on each certain width under normal state and surface damage. Area (NL) shows little changes under all situations. Although the usable spaces in area (OL) is not so abundant, but it suffers little decrease under damage. In area (OT), it doesn't look so good, Spaces wider than radius 4.5m is hard to be found and usable spaces over 4 meter declines to a great extent that means there is almost impossible for fire engine access when heavy damage happen.

5. CONCLUSION

This thesis is a part of the research that provides a basis for developing a planning method of disaster mitigation park system in China. The analysis result of measurement is expected to provide a numerical basis for the circulation spaces that is important criterion for judging the vulnerability in different areas.

Based on the result, suggestion and planning can be proposed directly towards the different urban areas. Later, the same method will be applied again to testify how the circulation spaces improve after the planning.

velasquezg@un.org

Abstract: The countries of the Association of Southeast Asian Nations (ASEAN), which comprises Brunei, Cambodia, Indonesia, Laos, Malaysia, Myanmar, Philippines, Singapore, Thailand, and Vietnam, are geographically located in one of the most disaster prone regions of the world. Often these disasters transcend national borders and overwhelm the capacities of individual countries to manage them. Most countries in the region have limited financial resources and physical resilience. Because of this high vulnerability and the relatively small size of most of the ASEAN countries, it will be more efficient and economically prudent for the countries to cooperate in the areas of civil protection, and disaster preparedness and prevention. A synthesis report on ASEAN member states disaster risks was developed at the country and regional levels. This review also analyses trans-boundary disaster risks and their effects; projected losses in the absence of mitigation measures (Average Annual Loss, AAL and economic losses for different probabilities of exceedance), climate change assessment, population growth, economic development, and urban expansion. Disaster Risk assessments for all the countries and the region have been prepared and the review concludes with recommendations on the way forward for ASEAN disaster risk reduction.

1. INTRODUCTION

The countries of the Association of Southeast Asian Nations (ASEAN), which comprises Brunei, Cambodia, Indonesia, Laos, Malaysia, Myanmar, Philippines, Singapore, Thailand, and Vietnam, is geographically located in one of the most disaster prone regions of the world. The ASEAN region sits between several tectonic plates causing earthquakes, volcanic eruptions and tsunamis. The region is also located in between two great oceans namely the Pacific and the Indian oceans causing seasonal typhoons and in some areas, tsunamis. The countries of the region have a history of devastating disasters that have caused economic and human losses across the region. Almost all types of natural hazards are present, including typhoons (strong tropical cyclones), floods, earthquakes, tsunamis, volcanic eruptions, landslides, forest-fires, and epidemics that threaten life and property, and droughts that leave serious lingering effects.

Typhoons are the most prevalent hazard in the region, causing destruction to human life, buildings, agriculture and infrastructure alike, while causing flooding and landslides/mudslides. The region provides compelling evidence of the destructive power of such disasters. For example, the recent tropical cyclone Nargis of May 2008 in Myanmar killed over 133 thousand people, affected over 2.4 million people and caused an estimated economic loss of over $ 4 billion. Over 600 thousand hectares of agriculture land was flooded, killing about 50 per cent of the draught animals. In the same year, on June 21, 2008, Typhoon Fenghsen in the Philippines killed 573 and affected at least 4 million people in just four hours. In October 2009, cyclone Pepang (Parma) in the Philippines killed 539 people, affected 4.5 million and caused an estimated economic loss of $592 million.

Some of the major disasters of recent times in the region are: the December 26, 2004 Indian Ocean tsunami, September 16, 1990 Luzon earthquake (Philippines), May 26, 2006 Yogyakarta earthquake (Indonesia), June 1991 volcanic eruption of Mount Pinatubo (Philippines), 2005 (Thailand), and 1997 (Vietnam) droughts, September 2009 cyclone Ketsana (known as Ondoy in the Philippines), catastrophic flood of October 2008, and January 2007 flood (Vietnam), September 1997 forest-fire (Indonesia) and many others. Climate change is expected to exacerbate disasters associated with hydro-meteorological hazards.

Often these disasters transcend national borders and overwhelm the capacities of individual countries to manage them. Most countries in the region have limited financial resources and physical resilience. Furthermore, the level of preparedness and prevention varies from country to country and regional cooperation does not exist to the extent necessary. Because of this high vulnerability and the relatively small size of most of the ASEAN countries, it will be more efficient and economically prudent for the countries to cooperate in the areas of civil protection, and disaster preparedness and prevention.

With the aim of reducing ASEAN's vulnerability to the risk of disasters, the World Bank, United Nations International Strategy for Disaster Reduction (UNISDR), through the Global Facility for Disaster Risk Reduction (GFDRR), and in collaboration with other international partners have started support for implementing the ASEAN Agreement for Disaster Management Emergency Response (AADMER) to promote sustainable development in ASEAN region. The AADMER is a regional legally binding agreement that binds ASEAN Member States together to promote regional cooperation and collaboration in reducing disaster losses and intensifying joint emergency response to disasters in the ASEAN region. AADMER is also ASEAN's affirmation of its commitment to the Hyogo Framework for Action 2005-2015 (HFA). The HFA, endorsed by 168 countries, is coordinated by UNISDR to provide nations and communities the roadmap to disaster-proof the significant development gains.

To support ASEAN, the World Bank, UNISDR and ASEAN secretariat signed a tripartite Memorandum of Cooperation (MoC) on disaster risk reduction (DRR) in 2009. The MoC lays a framework for technical support from the World Bank and UNISDR to help the ASEAN secretariat formulate and implement strategies and action plans for disaster risk reduction and management. The objectives of this program include (i) building ASEAN's capacity in the areas of disaster risk reduction and climate change adaptation; (ii) mobilizing resources for the implementation of DRR initiatives in ASEAN; and (iii) helping ASEAN policy-makers gain knowledge of effective and practical ways to reduce disaster risks.

As part of the work of the tripartite MoC, the objective of this assignment is to develop a synthesis report on ASEAN member states' disaster risks by carrying out a desk review of already available reports, studies, maps, analyses and assessments regarding disaster risks at the country and regional levels. This 'desk review' also analyses trans-boundary disaster risks and their effects; projected losses in the absence of mitigation measures (Average Annual Loss, AAL and economic losses for different probabilities of exceedance), climate change assessment, population growth, economic development, and urban expansion. Disaster Risk assessments for all the countries and the region have been prepared and the review concludes with recommendations on the way forward for ASEAN disaster risk reduction.

2. METHODOLOGY

This synthesis report on ASEAN disaster risks has been prepared by carrying out a desk review of already available reports, studies, maps, analyses and assessments regarding disaster risks at the country and regional levels within the scope of the tripartite Memorandum of Cooperation (MoC) on Disaster Risk Reduction (DRR), between ASEAN Secretariat, the UNISDR and the World Bank. The MoC on DRR is a part of ASEAN Agreement for Disaster Management Emergency Response (AADMER), which is in line with the Hyogo Framework for Action 2005 – 2015 (HFA). The objective of this synthesis report is to carry a simplified quantitative risk assessment to determine the social and economic loss potentials and the likelihood of occurrence of different hazards at country and regional levels.

The review analyses and assesses disaster risk at country and regional levels, focusing on natural hazards such as earthquakes, tropical cyclonic storms (typhoons), floods, landslides, tsunamis, droughts, and forest fires. It analyses trans-boundary disaster risks (common risks) and their effects, and projected losses in the absence of mitigation measures (Average Annual Loss, AAL and economic losses for different probabilities of exceedance). The review also analyses climate change assessment, economic developments, and urban expansion and rural development in ASEAN countries.

ASEAN consists of the ten following countries - Brunei, Cambodia, Indonesia, Lao PDR, Malaysia, Myanmar, Philippines, Singapore, Thailand, and Vietnam. It covers a total land area of 4.48 million sq km and has a population of 593 million (2009). The People's Republic of China borders the region to the north, the Pacific Ocean and Papua New Guinea to the east, Australia to the southeast, the Indian Ocean to the south, Bay of Bengal and Andaman-Nicobar Islands (India) to the west and India and Bangladesh to the northwest.

The ASEAN region is geographically diverse and includes high hills and rugged mountains, elevated plateaus, highlands, floodplains, coastal plains and deltas. It is home to large river systems such as the Mekong and Ayeyarwady, and major water bodies such as the Tonle Sap and Lake Toba, the latter being the largest volcanic lake in ASEAN region. Most part of ASEAN has hot and humid tropical climate, an exception being the mountainous areas in the Indochina Peninsula that experience a milder temperature and drier landscape.

A major part of the population in the region lives in riverine plains, delta and coastal plains. Hence, the most populous areas are subjected to periodic and extensive hazards such as flood, tsunami, and cyclone. Moreover, the unique geographic and climatic conditions make ASEAN one of the world's most vulnerable regions to disasters caused by natural hazards as well as climate change impact. Almost every year, powerful typhoons that cause flooding and landslides batter the region. In addition, the region faces risk from earthquakes, volcanic eruptions, tsunamis, and forest fires that threaten life and property, and drought that leaves serious lingering effects.

A review of the existing hazard, vulnerability and economic loss data at country level was performed. The

main data sources consulted include the CRED EM-DAT, ADRC, NGDC, GSHAP, MRC, WAMIS, DWR, Munich Re, World Bank, UNISDR, GAR, InTerragate, IFNet, and CCFSC, DESINVENTAR, country specific reports and research papers were also reviewed.

The socio-economic data was analyzed along with the mortality risk for various hazards to quantify the vulnerability (ISDR, 2009). As most of the data available in the public domain are related to disasters rather than hazard risk, this study relied on the Global Assessment Report (GAR) preview platform database (GAR, 2009) for mortality risk for various hazards such as earthquake, flood, landslide, cyclone and drought; GSHAP hazard data for earthquake and NGI hazard data for landslide. The GAR preview platform (http://preview.grid.unep.ch) has created spatial data for the entire world using simplified modeling techniques. The hazard risk data for the region was extracted from this global data and graded into four/five categories of very high, high, medium and low/very low for earthquake, flood, landslide, drought, cyclonic storm, and multi-hazards. The hazard risk data were analyzed along with grid based population data to assess the population exposed to various hazard risks.

To analyze risk profiles at country and regional levels, reported economic disaster data (1970-2009) have been used. However, for earthquake and tsunami (1900-2009), a longer duration of disaster data have been used. Analyses of projected losses in the absence of mitigation measures expressed in the form of average annual loss (AAL) and economic loss potential for selected probabilities of exceedance have been carried out.

3. KEY FINDINGS

3.1 Disasters

The disasters risk assessment analyses show that in terms of human casualties, cyclonic storms are the dominant disaster risk in ASEAN followed by earthquakes, tsunamis, floods, epidemics, landslides, droughts, volcanic eruptions and forest-fires. During the last 40 years (1970-2009), 1,211 reported disasters have caused over 414,900 deaths. Out of the reported disasters, 36 per cent were floods, 32 per cent were cyclonic storms, 9 per cent were earthquakes, 8 per cent were epidemics, and 7 per cent were landslides. Cyclones (storms) caused the maximum number of deaths: over 184,000, followed by earthquakes (114,000) and tsunamis (83,600).

3.2 Vulnerability

The social vulnerability (SV) ranking of each country was estimated based on the average number of people killed per year per million (relative social vulnerability). The analysis of disaster data for the period 1970-2009 shows that the average number of people killed per year per million for ASEAN region is 17.5. In Myanmar, the relative SV is more than 3.5 times that of Indonesia (the second highest). In terms of relative SV ranking, Myanmar has the highest ranking followed by Indonesia, Philippines, Thailand, Vietnam, Lao PDR, Cambodia, and Malaysia. Due to paucity of disaster loss data, the SV ranking could not be carried out for Brunei and Singapore. The quantitative risk assessment performed in this study confirms the following risk patterns for the ASEAN countries:

- Cambodia: floods represent the dominant risk followed by droughts
- Indonesia: forest (wild) fires, earthquakes and tsunamis, and floods represent the dominant risks followed by volcanoes, droughts, and landslides
- Lao PDR: cyclonic storms, and floods are the dominant risks followed by droughts
- Malaysia: floods are the dominant risks followed by forest fires, tsunamis, and cyclonic storms
- Myanmar: cyclonic storms are the dominant risk followed by tsunamis, floods and forest-fires
- Philippines: typhoons (cyclonic storms) are the dominant risk followed by floods, earthquakes; volcanoes, droughts, and landslides
- Thailand: floods are the dominant risk followed by tsunamis, cyclonic storms, and droughts
- Vietnam: cyclonic storms, and floods are the dominant risk followed by droughts, and landslides
- Brunei and Singapore: no disaster data is available

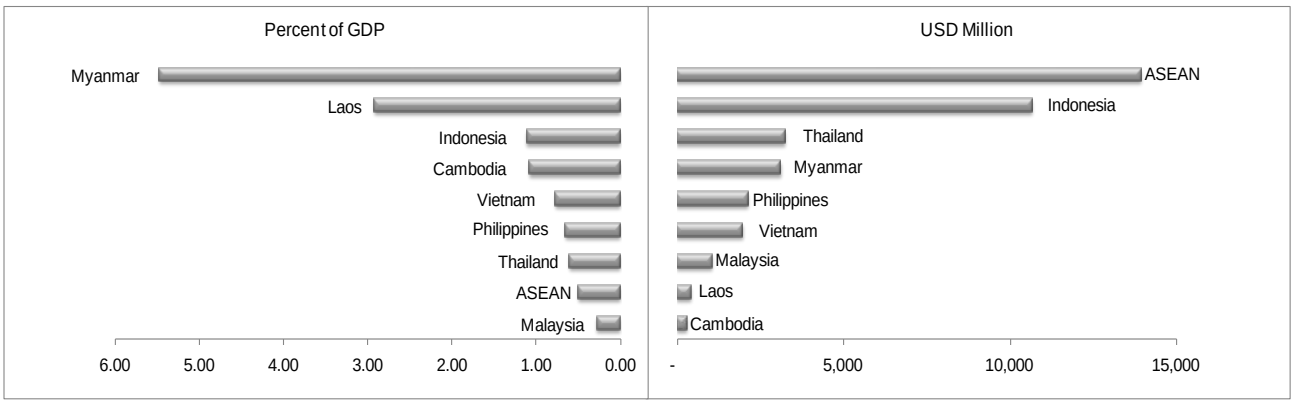

Figure A: Economic Loss Potential for annual probability of exceedance of 0.5 per cent

Disasters can have enormous economic consequences. The quantitative risk assessment performed in this study confirms that a catastrophic event with a 200-year return period (0.5 per cent annual probability of exceedance) would have a major impact on ASEAN countries' economies, some of which are already fragile. To gauge the potential economic impact, the economic vulnerability (EV) ranking of each country has been estimated in terms of likely economic losses that an event with a 200-year return period would cause as a percentage of that country's Gross Domestic Product (GDP PPP) (Figure A). According to this categorization, Myanmar has the highest EV ranking in the region, followed in descending order by Laos, Indonesia, Cambodia, Vietnam, Philippines, Thailand, and Malaysia.

Due to paucity of economic loss disaster data, the Average Annual Loss (AAL) and economic loss analysis for different probabilities of exceedance could not be carried out for Brunei and Singapore.

Urban areas are especially vulnerable to the adverse impact of disasters. Capital cities: Manila, Jakarta, Bangkok, Ha Noi, and Singapore are amongst the most populated cities in the ASEAN region and all are undergoing intense economic transformation. In terms of earthquake risk, Manila is at highest risk followed by Jakarta and Bangkok. In terms of flood risk, Manila is also at highest risk followed by Jakarta, Bangkok, and Ha Noi. In terms of tropical cyclonic risk, Manila is also at highest risk followed by Ha Noi, and Jakarta. In terms of overall risks from these hazards, Manila is at highest risk, followed by Jakarta, Bangkok, Ha Noi, Singapore, Kuala Lumpur, Naypyidaw, Phnom Penh, Vientiane, and Bandar Seri Begawan.

3.3 Climate Change Impacts

Climate change is considered as one of the most significant developmental challenges confronting ASEAN nations in the 21st century. According to the Intergovernmental Panel on Climate Change (IPCC, 2007) reports, the mean surface air temperature in Southeast Asia increased at the rate of 0.1 – 0.3°C per decade between 1951 and 2000. Following the global trend, the mean sea level is projected to rise by 40 cm on average by 2100 in comparison to 1990. Moreover, the region experiences decreasing rainfall and increasing sea levels (1–3 mm per year). The frequencies of extreme weather events like heat waves, heavy precipitation, and tropical cyclones have been increasing considerably. These climatic changes have brought massive flooding, landslides, and droughts in different regions and have caused extensive damage to property, assets, and human life. High concentration of population and intense economic activities in coastal areas, and a high dependence on agriculture and forestry in many countries of the region are making the situation more complex and may hinder the regions sustainable development.

Global Circulation Models addressing climate change do not present a uniform view of the impact of climate change on ASEAN as they have limited capabilities to forecast the present meteorological patterns. A high-resolution climate change model of the region appears to be more stable and predicts a temperature increase of 3 to 4 0C over the next 80 years.

Developing countries are especially vulnerable to climate change because of their geographic exposure, low incomes, and greater reliance on climate sensitive sectors such as agriculture. The cost of climate change in ASEAN could be as high as a 6-7 per cent loss in GDP by 2100 compared to what could have been achieved in a world without climate change.

4. WAY FORWARD

Based on the analyses, the review makes the following recommendations to reduce disaster risk in ASEAN:

4.1 Additional Analyses

Three levels of analyses are envisioned to refine the results presented in this report. These analyses should emphasize more on floods, typhoons (tropical cyclonic storms), and earthquakes and tsunamis, as they are the most damaging quick-onset disasters.

- Level 1: An analysis similar to this one based only on historical records should be repeated at a higher level of resolution. Instead of limiting the resolution of the analysis at the country level, a high-resolution grid (for example a 100-km grid) should be considered. Risk aggregation by hazard type and area would provide, at low cost, a much more refined picture of the risk than is offered by the present analysis.
- Level 2: On a second level, using the same methodology, worst-case scenarios should be considered for the highly populated cities. This analysis would provide a reasonable quantification of loss, given the occurrence of a particular disaster scenario. The uncertainty around the risk could then be bracketed by scientifically estimating the range of probability of occurrence of such scenarios. Such worst-case scenario studies can be used in preparation of city specific Disaster Management Plans (DMP).
- Level 3: On a third level, fully probabilistic analysis containing all the elements of standard risk analysis should be performed for the hazards and regions identified as high risk in levels 1 and 2.

Drought hazard should be addressed in the context of climate change and long-term adaptation strategies should be considered. Climate risk assessments study should merge traditional risk assessments with climate change assessments.

Use of Open Source Risk Models is recommended, in which probabilistic techniques are applied to the analysis of various natural hazards. At this level of analysis, hazard information is combined with exposure and vulnerability data allowing the user to determine the risk simultaneously on an inter-related multi-hazard basis. In recent years, several open source GIS-based multi-hazard risk platform has/are being developed. HAZUS-MH is a powerful risk assessment platform for analyzing potential losses from earthquakes, floods, and winds. CAPRA- Central American Probabilistic Risk Assessment is another GIS-based platform for risk analysis of earthquakes, tsunamis, tropical cyclones, floods, landslides, forest-fires, and volcanoes. HazSana'a and HazYemen are other two such open source GIS-based multi-hazard risk platform being developed for Sana'a city and Yemen country, respectively. These open source platform should build upon existing initiatives, with the objective of consolidating methodologies for hazard, exposure, and risk assessment, and raising risk management awareness in the region.

Abstract: Natural disasters occur all over the world, regardless of the geographical region. A sustainable development of the built infrastructure of Romania needs a strategy of mitigating the natural disaster effects at country and region level, as stated in 2009 in a published report of United Nations Organization. This paper is presenting a risk evaluation methodology for the Iasi Municipality, a city of North Eastern Romania, characterized by an existing crowded infrastructure. The first step of research methodology is the F.E. analysis of specific classes of residential buildings widely used in Romanian cities. The structural models were subjected to Romanian earthquake scenarios, for monitoring their behavior for different degrees of degradation developed during their life span. The second stage of research is based on the evaluation of the structural vulnerability using the seismic risk index. The visualization of the specific risk of each structure in a selected urban sample is achieved by using NetSET software, a Geographic Information System, GIS, developed for Iasi municipality built infrastructure. The final results along with research study conclusions are useful to fully comprehend seismic vulnerability of the existing city building stock. This enables mapping the vulnerable areas affected by past earthquakes and also forecasting seismic risk, important features for decision makers.

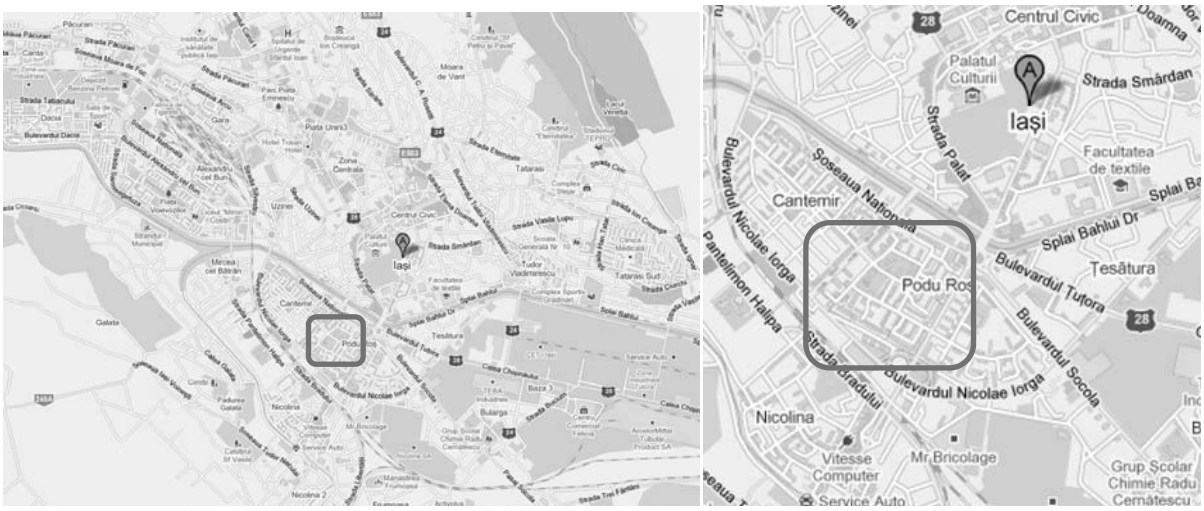
1. INTRODUCTION

In order to help and support a community in managing an incoming disaster, it is necessary to understand and evaluate the risk that the potential danger holds. The process of risk assessment involves hazard assessment and vulnerability analysis. In the case of earthquakes, the seismic vulnerability represents the evaluation of the consequences that an earthquake has upon a community and the environment together with the time of response and recovery from the disaster (Wood et al. 2002).

This paper is presenting a risk evaluation methodology for the Iasi Municipality, a city of North Eastern Romania, characterized by an existing crowded infrastructure.

For the first step of the research methodology, the Finite Element Analysis of two specific classes of residential buildings was considered. The first type of structure is a four stories Load Bearing Masonry condominium (P+4 LBM) and the second one is a four stories building made of Precast Concrete Panels (P+4 PCP), as shown in Figure 1.

The second step of the research consists in evaluating the seismic vulnerability of the city building stock, based on



a) 4 stories Load Bearing Masonry condominium

b) 4 stories Precast Concrete Panel

Figure 1 Examples of structures frequently met in the urban areas in Romania, Iasi

a) General view of Iasi city, Romania b) Considered area sample

Figure 2 Selected urban sample for the city of Iasi, Romania, (www.maps.google.com)

the seismic risk index. For this purpose, the numerical models are subjected to different levels of degradations and their behavior to earthquake actions was closely monitored.

The visualization of specific risk of each structure in a selected urban sample, shown in Figure 2, is achieved by using a Geographic Information System (GIS) software. A GIS is an organized collection of hardware, software geographic data and personnel designed to efficiently capture, store, update, manipulate, analyze and display all forms of geographically referenced information (Lavakare and Krovvidi 2001). This methodology enables mapping the vulnerable areas affected by past earthquakes and forecasting the seismic risk, all important features for decision makers in case of disasters.

2. FINITE ELEMENT ANALYSIS

2.1 The Finite Element Models

The conventional design methods used in civil engineering are considered to be deterministic approaches. There is a wide range of applications of the deterministic method not only in civil engineering (Joshi and Mohan 2008) but also in weather forecasting and hurricane risk assessment (Emanuel et al. 2006). The deterministic approach of the evaluation is based on the modelling and numerical simulations using SAP2000 software, (Computers and Structures Inc. 2005).

In the case of the P+4 PCP, the materials used were C16/20 (NE 012-99) for the exterior walls and floors, C12/15 (NE 012-99) for the interior walls. The considered reinforcement was smooth stirrups made of OB37 steel (STAS 438/1-89) and ribbed bars for the tensile reinforcement made of PC60 steel (STAS 438/1-89).

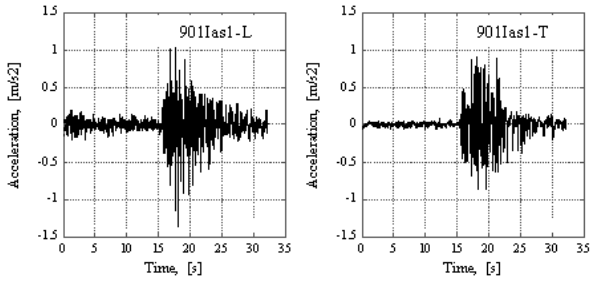
In the case of P+4LBM, the material properties of the masonry are presented in Table 1. The values are in accordance with the Romanian design code CR 6-2006.

Shell elements were used to model the walls, floors and stair cases for both numerical models (Toma and Atanasiu 2010).

2.2 Analysis Cases

The analysis of the structures was made by subjecting the models to three types of actions: dead load, live loads and repetitive seismic loads. The loading cases were defined in accordance with Romanian standards, in agreement with Eurocode 0 (UTCB 2006).

The seismic actions have been introduced in the program in the form of time-history functions in terms of accelerations. The accelerograms chosen at this stage of the research were those corresponding to Vrancea earthquakes in Romania. A summary of the information with respect to the considered earthquakes is shown in Table 2 (Borcia 2007).



The earthquakes were chosen due to the fact that the considered types of structures were built starting from 1960 and are representative for the building stock for Romanian urban areas, as Iasi municipality.

Table 3 Classification of the structures based on the coefficient of degradation

Degradation state	Reference interval, δ_M
Minor degradations	0.0 – 0.2
Capital repairs needed	0.2 – 0.5
Irreparable	0.5 – 1
Total collapse	> 1.0

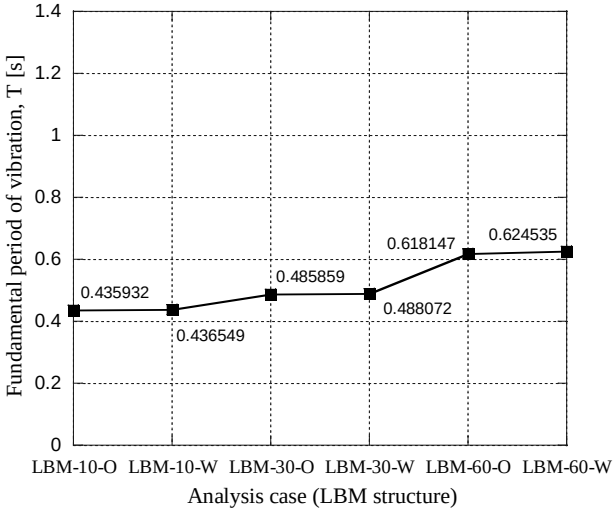

Figure 4 Variation of the fundamental period of vibration for the PCP model structure

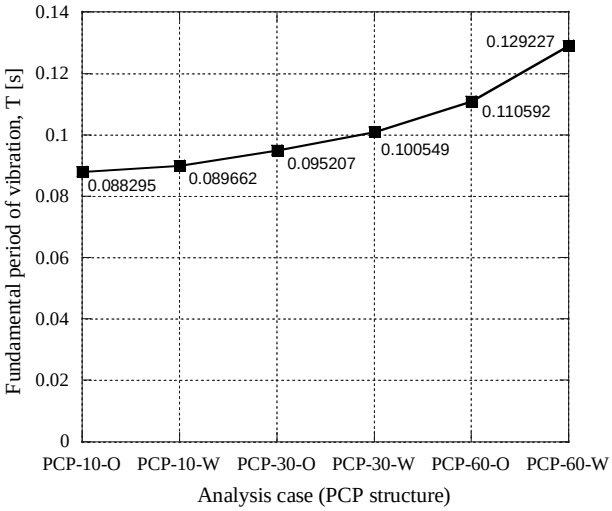

Figure 5 Variation of the fundamental period of vibration for the LBM model structure

An example of the longitudinal and transversal components of the time history graphs for a Vrancea earthquake, denoted as 901 (Table 2), is represented in Figure 3. The finite element program superposes the two components of the earthquake for a better representation of the real natural event.

The notations of the analysis cases are explained below for an easier understanding of the upcoming results. Each case has been denoted in the form: type of structure followed by a number and by a letter. The two types of structures considered in the analysis were LBM, load bearing masonry, and PCP, precast concrete panel, structures. The number following in the name of the analysis case indicate the percentage of damage considered for each case. Finally, the letter at the end of the analysis case name shows the location of the considered degradations: "O" for walls with openings (windows and doors) and "W" for all walls. For example, the analysis case denoted LBM-10-O refers to a load bearing masonry structure having 10% degradation in the walls with openings.

The main parameters of the present paper were the seismic loading scenarios, different degradation percentages applied to the structure as well as their assumed distribution in the numerical models. The considered degradation percentages were 10%, 30% and 60%. The behaviour of the structures under seismic excitations was investigated for two possible distributions scenarios of the degradations: the first scenario assumed that only the walls with openings were affected by degradations and the second scenario assumed that all the walls were affected by degradations. These degradations were introduced into the numerical models by means of stiffness modifiers (SAP 2000).

3. RESULTS AND DISCUSSIONS

3.1 Degradation Coefficient

The coefficient of degradation, equation 1, as defined by DiPasquale and Cakmak (1990), depends of the natural periods of vibration of the structure. The classification of the structures depending on the coefficient of degradation has been made according to the reference intervals shown in Table 3 (Patras and Patras 2002).

$$\delta_M = 1 - \frac{T_0}{T_{degr}} \quad (1)$$

where:

T_0 is the natural period of vibration of the structure in its initial state;

T_{degr} is the natural period of vibration of the structure in its degraded state.

The fundamental period of vibration for the LBM and PCP structures were 0.417 seconds and 0.085 seconds, respectively.

Table 4 Classification of the models from the first case study based on the degradation coefficient

Case study	δ_M	Degradation state
LBM-10-O	0.045	Minor degradations
LBM-10-W	0.046	
LBM-30-O	0.143	
LBM-30-W	0.147	
LBM-60-O	0.326	Capital repairs needed
LBM-60-W	0.333	

Table 5 Classification of the models from the second case study based on the degradation coefficient

Case study	δ_M	Degradation state
PCP-10-O	0.032	Minor degradations
PCP -10-W	0.047	
PCP -30-O	0.103	
PCP -30-W	0.151	
PCP -60-O	0.227	Capital repairs needed
PCP -60-W	0.339	

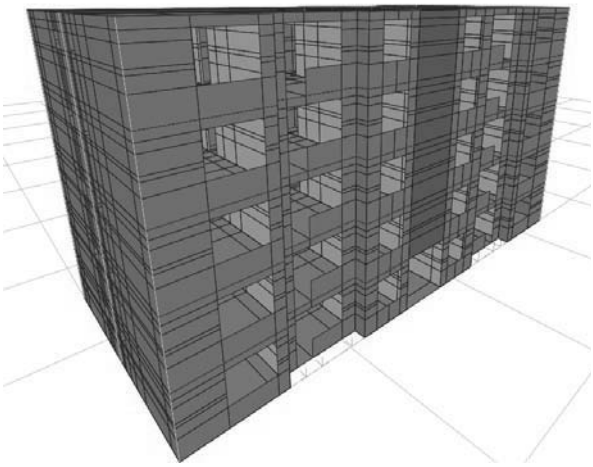

Figure 6 Finite element model for the LBM structure (SAP2000)

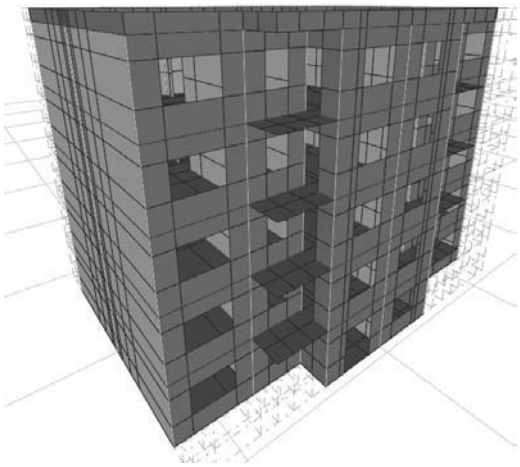

Figure 7 Finite element model for the PCP structure (SAP2000)

Figure 4 and Figure 5 show the variation of the fundamental period of vibration for the two structural models when all degradation percentages were considered for both distribution scenarios. It can be observed that the fundamental period of vibration increases for both types of structures with the increase of the degradation percentage. This can be explained by the decreased stiffness of the structure affected by degradations. Furthermore, a wider spread of the damage, from wall with openings only to all structural walls, causes further decrease in the overall stiffness of the structures.

The difference between the fundamental periods of vibrations for the two damage distribution scenarios increases with the increase in the considered amount of degradations. It ranges from 1.5% to 16.85% for the PCP case and from 0.1% to 1% for the LBM case.

The analysis cases can be classified to a degradation state by applying equation (1). The results are summarized in Table 4, for the LBM structure, and in Table 5, for the PCP structure. It can be observed that even though the classification of the analysis cases is similar for both scenarios, the LBM structure has slightly higher degradation coefficients especially for the more extended damage scenarios.

3.2 Peak Displacements

Figures 6 and 7 show the F.E. models considered in this paper. The structures were subjected to earthquake loads that occurred during their lifespan.

For each type of structure and for each damage percentage and damage distribution investigated in this research the peak displacements at the top were recorded during each earthquake excitation. The values are summarized in Table 6 for the LBM structure and in Table 7 for the PCP structure. Due to the limit space available, only the 30% damage analysis cases, with two distribution patterns of the degradations, are presented here. However, similar trends of the recorded data were observed for all other analysis cases.

From the analysis of the data presented in Tables 6 and 7, it can be concluded that the highest values of the peak displacements were obtained for the 1977 Vrancea earthquake (Table 2). At the same time, higher values for the peak displacements were obtained for the LBM structure compared with the PCP structure.

This can be explained by an increased stiffness of the PCP structure. An increased stiffness would result in a lower fundamental period of vibration, as presented in section 3.1.

Figures 8 and 9 show the variation of peak displacements for the LBM and PCP structures, respectively. The displayed results are for the undamaged state of the buildings. In both cases, it can be observed that the peak displacements in Y direction are larger than the ones in X direction. The Y direction is set along the shorter side of each structure (Figure 6 and 7, respectively). Therefore, a lower stiffness is expected with respect to Y axis. The analysis results confirm this assumption, as it can be observed from the data summarized in Tables 6 and 7. A similar trend was observed for the other analysis cases, as well.

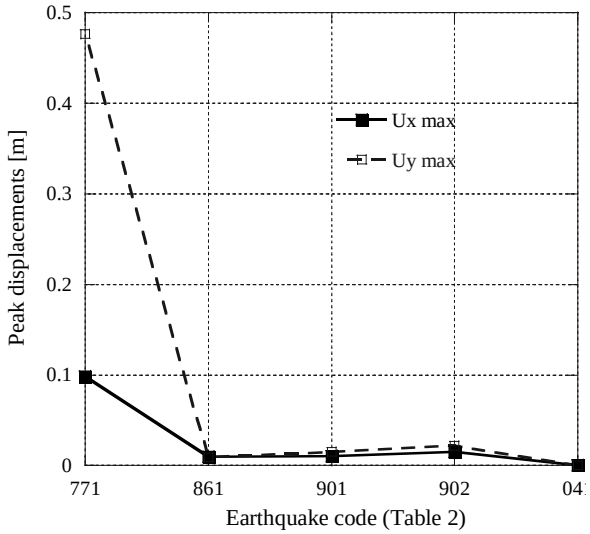

Figure 8 Peak displacements for LBM-0 analysis case

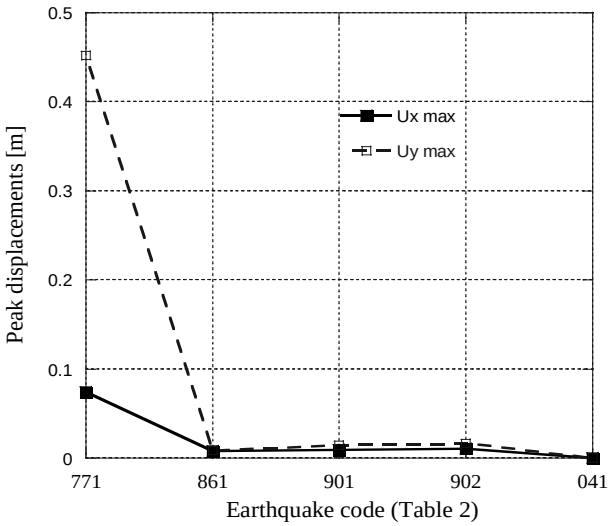

Figure 9 Peak displacements for PCP-0 analysis case

Table 6 Maximum displacements measured for the Load Bearing Masonry structure

Earthquake Code	LBM-0		LBM-30-O		LBM-30-W	
	Ux max [m]	Uy max [m]	Ux max [m]	Uy max [m]	Ux max [m]	Uy max [m]
771	0.098	0.477	0.098	0.470	0.100	0.471
861	0.0099	0.0092	0.0097	0.0098	0.0097	0.0094
901	0.0102	0.0151	0.0103	0.0158	0.0104	0.0159
902	0.0148	0.0221	0.0161	0.0189	0.0164	0.0195
041	0.00026	0.00029	0.00019	0.00023	0.000208	0.00021

Table **7** Maximum displacement measured for the Precast Concrete Panel structure

Earthquake Code	PCP-0		PCP-30-O		PCP-30-W	
	Ux max [m]	Uy max [m]	Ux max [m]	Uy max [m]	Ux max [m]	Uy max [m]
771	0.0746	0.452	0.0747	0.452	0.0747	0.452
861	0.008	0.0088	0.0083	0.0091	0.008	0.0088
901	0.0098	0.0145	0.0098	0.0145	0.0098	0.0144
902	0.0108	0.0168	0.0108	0.0168	0.0110	0.0168
041	0.00008	0.00009	0.00016	0.00011	0.00011	0.00012

A closer look at the values of displacements for the cases when a 30% damage was considered shows the fact that the peak values are almost the same, despite a different distribution of the degradations. It is the belief of the authors that this matter should be further investigated in more detail.

4. VISUALIZATION OF THE RESULTS IN A GIS ENVIRONMENT

The vulnerability of buildings, structures and population is dependent on their exposure to the hazard, which varies from location to location. The spatial characteristics of hazard and vulnerability justify the application of mapping and spatial technologies, such as Geographical Information Systems (GIS), remote sensing and photogrammetry in the risk assessment process (Lavakare and Krovvidi 2001).

In order to visualize the damaged structures from the considered urban sample, it is necessary to use a mapping Geographic Information System (GIS). GIS represents a system that joins two data bases. One data base operates with geometrical spatial objects and the second data base with the attributes of the information contained in the first one (Dimitriu 2001; Toma 2010). The main purpose of this system is analyzing and studying the information that is stored in its data bases. It can be a very powerful tool in complex decisions making.

4.1 NetSET Description

NetSET (**Net**work **S**patial **E**diting **T**ool) is a software package designed by a Romanian company from Iasi

(Ciobanu et al. 2005). It is a GIS application designed to solve important problems for the local public administration and economic agencies.

The software application is based on the widely used shape file format (.shp), compatible with any other GIS solutions on the market that are using the same format for storing vectorial map elements. NetSET package can perform various types of analyses based on implemented or user defined subroutines and has been successfully applied for viewing and analyzing risk data using the map of Iași city (Leon and Atanasiu 2007; Atanasiu et al. 2008; Atanasiu and Toma 2010).

4.2 Evaluation of Seismic Risk of the Iasi Urban Area using NetSET Map

In order to evaluate the seismic risk in a certain urban region, one should have data about the existing building stock, the earthquakes that have been registered in that area and the routes that firemen and medical teams must take in case of a disaster.

For the city of Iasi, building data came from experts' reports, field investigations and computer simulations (Toma and Atanasiu 2010; Atanasiu and Toma 2010). Inserting all the data in NetSET, a very clear picture of the seismic risk in the considered area can be obtained. For the first step, the user has to define the urban infrastructure, introducing for each building from the map the following data: the complete address, the structural type and height, type of foundation soil, the functional of the building and the year of construction, a.s.o. The buildings are then classified into four groups, depending on their degree of risk in case of an earthquake (Vișan and Hapurne 2008).

Figure 10 shows the urban sample area chosen for this research. The buildings in the area are colour coded depending on their structural type: precast concrete panels (light blue), load bearing masonry (red), frames (dark blue) and frames with shear walls (purple).

The degradation coefficient, (equation 1) obtained from numerical simulations or field survey to assess the damage of a structure can be also inserted into the program (Figure 11). Following the pre-programmed functions, the program can show the buildings depending on the degradation coefficient. The user can select to view only the buildings with a certain level of damage. Moreover, the program can display all the buildings for which a degradation coefficient is computed and display them with different colours depending on the values of the coefficient, as shown in Figure 12.

Also, with the help of this software, one can visualize the route that firemen or medical teams could take in case of an emergency situation, only by introducing the address of the place in need (Figure 13).

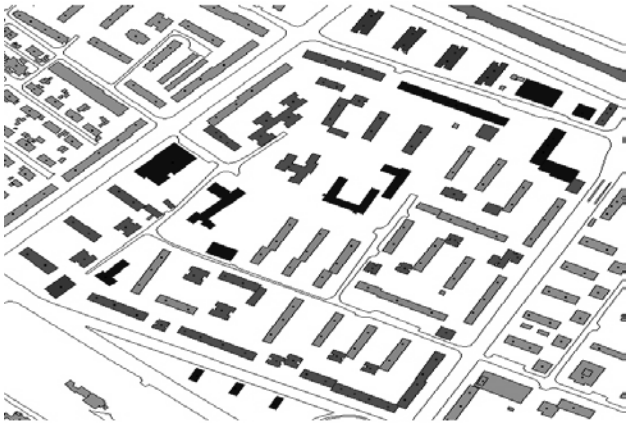

Figure 10 The chosen urban area sample

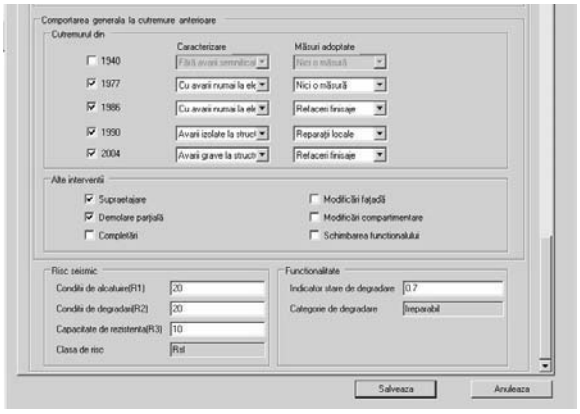

Figure 11 Type of data related to the degree of damage of a structure

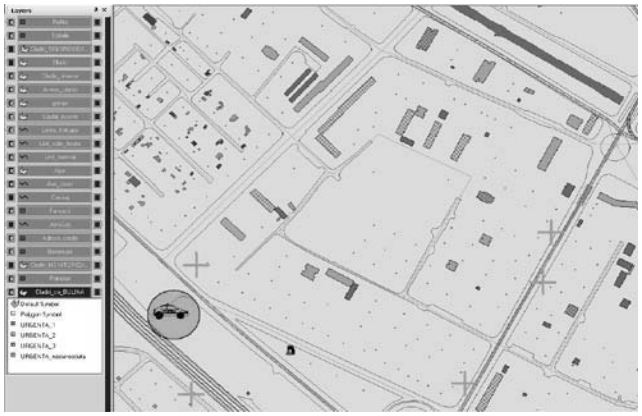

Figure 12 The chosen urban area sample

Figure 13 Sample of route displaying for fire fighters

5. CONCLUSIONS

The seismic vulnerability represents the evaluation of the consequences that an earthquake has upon a community and the environment together with the time of response and recovery from the disaster. In order to assess the vulnerability of a community it is necessary to visualize the damaged areas from the urban sample. For this purpose it is necessary to use a mapping Geographic Information System (GIS).

The deterministic approach of the seismic risk evaluation is based on the modelling and numerical simulations using SAP2000 software. This evaluation is conducted on two classes of building structures from Romanian building stock, subjected to seismic loads. The first construction class consists of a P+4 residential building made of precast concrete panels, while the second class is represented by a P+4 load bearing masonry structures. The degradation coefficient is computed based on the data obtained from the numerical simulation of the two models subjected to different earthquake loads, degrees of degradation and distribution of the damage throughout the structure.

Even though the obtained results are similar to those from field surveys, it is the belief of the authors that further improvements should be made to this approach. Currently, nonlinear numerical simulations are conducted for each type of structure in the chosen urban area sample. The analysis consists of nonlinear time history cases representing all the earthquakes that took place during the lifetime of the considered structure.

The results of the research are used for classifying the building structures based on their seismic risk index and the degree of degradations in order to fully comprehend and investigate the seismic vulnerability of the existing building stock. NetSET mapping system is used to visualise the present damaged areas. The results of this research work are used to improve the prediction functions of the software and make it become a powerful complex tool to help the society in case of future earthquakes. With its help, many scenarios can be simulated and, as a result, a better time response and management of situations in case of disasters will be provided.

STRATEGIC FIREFIGHTING OPERATION TO MITIGATE FIRE DAMAGE RISK IN A NEAR-FIELD EARTHQUAKE IN THE METROPOLIS OF TOKYO –ANALYSIS OF THE RELATIONSHIP BETWEEN THE TIMING OF THE SWITCH TO FIREFIGHTING OPERATION AND DAMAGE REDUCTION–

Eiichi Itoigawa

Graduate School of Systems and Information Engineering, University of Tsukuba

Abstract: In response to fears that a near-field earthquake might occur in Tokyo, the Tokyo metropolitan government recently published the report, "Damage Estimates of an Earthquake with an Epicenter in the Tokyo Metropolitan Area." The report states that one of the main dangers is the extensive damage from fires that will result from such an earthquake. This study focuses on the timing of the switch from a local firefighting operation to a more wide-area firefighting operation, in which the limited available firefighting resources are used to deal with simultaneous outbreaks of fires in different locations. We discuss the relationship between the timing of the operation switch and the effect of the fire damage reduction quantitatively via simulation experiments under various conditions.

1. BACKGROUND AND PURPOSE OF THE STUDY

(1) Background of the Study

In response to fears regarding the impending risk that a near-field earthquake might occur in Tokyo, the Tokyo metropolitan government published in 2006 the report "Damage Estimates of an Earthquake with an Epicenter in the Tokyo Metropolitan Area."[1)]. According to this report, if an earthquake of a magnitude 7.3 were to occur at 18:00 on a winter day with an epicenter in the northern part of Tokyo Bay, which is considered to be highly probable and to cause extensive damage, the result could be more than 5,600 deaths, the complete collapse of 127,000 buildings, and other extensive damage.

One of the main factors causing such extensive damage is fire; among the various causes of damage resulting from large earthquakes, fire takes a significant toll regarding both human casualties and damage to buildings.

Whether or not fires resulting from a large earthquake spread through a city largely depends on initial countermeasures as well as town and city redevelopment for disaster prevention on ordinary days. Suppressing fires as quickly as possible is the most important measure for preventing catastrophic fires, and rapidly detecting a fire and extinguishing it immediately is the most important principle in fire prevention activities in an earthquake disaster. For this reason, bringing local firefighting resources to bear immediately at the initial stage of a large earthquake (each fire station handles local fires within its area with its own fire brigades) is considered to have considerable advantages; for example, each fire station can establish bases for receiving disaster reports and information collection at the initial stage of an earthquake disaster, when collection of detailed disaster outbreak information is assumed to be difficult due to congestion and disruption etc. of emergency service telephone lines (119 in Japan), making it easier to conduct flexible firefighting operations appropriate for the scale and conditions of the disaster.

On the other hand, in order to alleviate fire disasters across the entire Metropolis of Tokyo, it is necessary to deploy unified operations of all firefighting forces with a broader perspective in accordance with actual disaster conditions so as to promptly eliminate differences in fire fighting capabilities among regions due to various local characteristics, and operate all the currently available fire fighting forces efficiently.

From the above viewpoints, at a time of a large earthquake, it is thought to be advantageous to switch from operation of local firefighting units to a wider-area firefighting operation at a certain time in order to efficiently alleviate damage from spreading fires. However, switching too early, before a sufficient amount of detailed disaster information has been acquired, could result in biased allocation of the available fire brigades to fires breaking out immediately after the earthquake. Such a bias would likely lead to reduced operation efficiency due to concentration on already-detected fires, which delays handling undetected fires and fires breaking out later in areas with high risk of fire spreading; this has the risk of aggravating overall fire damage. Therefore, in order to operate the firefighting services efficiently, the relationship between the timing of the switch from local firefighting operations to more

wide-area firefighting operations and damage reduction must be quantified.

(2) Purpose of the Study

Against this background, this study focuses on the simultaneous outbreak of many fires, a significant cause of severe damage during a earthquake disaster, and it considers fire district units as wide-area operation units of firefighting services. On this basis, we clarify the relationship between the timing of the switch from local firefighting operations undertaken immediately after the occurrence of an earthquake to a district-wide firefighting operation effort, and the effect in alleviating fire damage. Thereby, this study aims to contribute to the examination of strategic firefighting operations to alleviate damage caused by the simultaneous outbreak of many fires in a near field earthquake in the Metropolis of Tokyo. Note that a fire district headquarters (hereinafter referred to as "district headquarters") analyzes the conditions of fires and fire brigade operation within its area based on reports from each fire station. However, it is expected that it will be increasingly difficult for the district headquarters to manage the operation of all fire brigades within its district in the most efficient manner as the number of fires increases, and such operation is thus not assumed under the current operations of firefighting services in an earthquake disaster. On the contrary, considering the purpose above, this study assumes that a district headquarters makes judgments on how to operate all fire brigades against fires occurring within its district and verifies the effects. We then verify the existence of more-effective approaches than the current fire fighting operation method, and attempt to obtain basic data that can be reflected on the future firefighting operations against earthquake disasters.

(3) Method of the Study

In this study, we will construct a simulation model that allows simulating the outbreak and spread of fires during an earthquake disaster, taking both local and district-wide firefighting operations into consideration. Furthermore, we will run simulation experiments in which we vary the timing of the switch from local firefighting operations to district operations under various conditions in order to analyze the relationship between the timing of the operation switch and the effect on the fire damage reduction.

2. CONSTRUCTION OF SIMULATION MODELS

(1) Overview of Simulation Models

In this study, we construct the simulation model shown in Figure 1 using a mesh model that expresses the conditions of the urban area (hereinafter referred to as the "mesh") in square zone units measuring 250m on a side, from a macroscopic viewpoint. Note that the data of the urban area conditions investigation by the Tokyo Fire Department[2] is used for all mesh unit data.

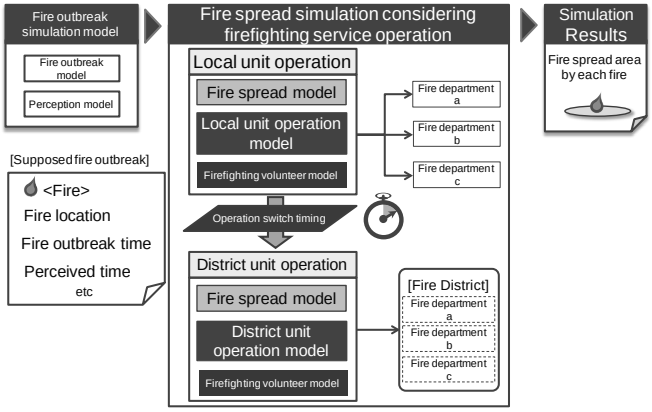

Figure 1 Overview of Simulation Models

The fire outbreak simulation model comprises a fire outbreak model and a perception model. In the fire outbreak model, locations of fires are assigned to the mesh units by probability based on the expected number of fires resulting from an earthquake[3] and, further, the starting time of each fire is assigned to each fire by probability based on the prediction function[4] derived from past earthquake fire cases. The perception model indicates the probable time required to detect each fire using the prediction function[4] obtained from the method and time of perception in past earthquakes.

The spreading fire simulation model, taking fire control services into consideration, comprises a spreading fire model and a fire brigade operation model (comprised of local unit operation model, district unit operation model, and firefighting volunteer model). The spreading fire model extracts the building-to-land ratio, ratio of roads, ratio of open space, etc. to building structures (wooden structures, fire-resistant structures, quasi-fireproof structures, and fireproof structures) for each mesh unit, and calculates the area of fire spreading for each fire, taking into consideration the speed of spread calculated using the rate of spreading equation (Tokyo Fire Defense Board equation 2001 (macro equation))[5] and fire spread prevention activities by fire brigades. The fire brigade operation model is to compute the dynamic state of fire brigades (including firefighting volunteers) in local firefighting operations and district operations. The timing of the switch from local firefighting operations to district operations can be set arbitrarily.

(2) Local Firefighting Operation Model

a) Number of Participating Fire Brigades

Past studies[4] indicate that, in local firefighting operations during the early stages of an earthquake disaster, specification of the number of participating brigades according to a ranking of the fire-spreading risk where the fire is breaking out[6] is effective in reducing the area of fire spreading. Based on this research result, the number of participating brigades per fire is determined by the ranking of the fire spreading risk, at the location of the fire, as shown in Table 1, and specified in advance.

Table 1 Number of Participating Brigades by Risk Rank of Fire Spread

Risk of fire spreading risk	Specified number of participating brigades
7 or more	3
5 or 6	2
4 or 3	1
2 or less	0 (no mobilization)

b) Priority of Mobilization at Fire

A fire brigade headquarters must decide "how many fire brigades in total should be sent to which fire from what district" in case of detected fires for which the specified number of brigades has not been committed yet (hereinafter called "fires requiring judgment") if it has standby teams or teams available to take on another fire after a fire has been extinguished (hereinafter, such teams are referred to as "mobilizable teams"). If there are multiple fires requiring judgment, fire brigades are committed to fires with higher rank of fire spreading risk first. If there are several fires requiring judgment with the same the rank of fire spreading risk, fire brigades are committed to fires detected earlier first.

c) Determination of Mobilized Fire Brigades

The fire brigades to be mobilized are selected among fire brigades belonging to the fire station that is in charge of the location of fire outbreak, in order of teams that can be mobilized closer to the fire in question. Fire brigades in the middle of firefighting shall not be moved to another fire location.

d) Mobilization Judgment Speed

So far, no existing studies have fully investigated the time required for mobilization judgment. In this model, therefore, we allowed setting the time required for one mobilization judgment Δt [min] as well as the number of fires for which mobilization judgment can be made simultaneously Np (hereinafter referred to as "number of fires for which mobilization judgment can be made"), to arbitrary values. With these two variables, we defined the speed of mobilization judgment as follows:

$$s_f = \frac{N_p}{\Delta t} \quad \text{[fires/min]} \qquad \cdots[5]$$

Note that it is reasonable to expect that the greater the number of fires requiring judgment, the longer the time required for mobilization judgment. Therefore, the time required for one mobilization judgment is set to be determined by the number of fires requiring judgment. In addition, if a new fire is detected while making mobilization judgment, the detected fire in question shall not be included in the currently performed mobilization judgment, but included in the subsequent fires requiring judgment.

e) Formation of Emergency Fire Brigades

There are two types of emergency fire brigades formed and mobilized to deal with fires at earthquake disasters (hereinafter referred to as "emergency fire brigade"): emergency pump teams and portable pump teams. Emergency pump teams and portable pump teams are organized around reserve fire engines equipped with pumps and portable pumps of each fire station and firefighters gathering at each fire station. The time required for firefighters to gather at each fire station is calculated by the assembly ratio curve for each fire station based on data from assembly trainings conducted assuming earthquake disasters; one emergency fire brigade can be formed with every 5 fire fighters that are gathered.

f) Settings of Fire Brigade Moving Speed etc.

When a fire brigade is dispatched to a fire, it immediately starts moving toward the location of the fire outbreak. The speed of the fire brigade etc. is set based on past studies[4), 7)], which closely examined traffic obstructions etc. experienced by fire brigades due to blocked roads, which posed an impediment to firefighting during the Great Hanshin-Awaji Earthquake Disaster.

(3) District Operation Model

a) Fire Brigade Operation Method in District Operation

Each time a mobilization judgment is made, fire brigades are dispatched to all detected fires in order to minimize the fire spreading.

b) Judgment of the Number of Mobilized Fire Brigades and Order of Mobilization Priority Order

The district headquarters makes mobilization judgment when there are detected fires that are spreading within the district and teams that can be mobilized are available. The algorithm used for the judgment is as follows.

If the un-besieged perimeter length of fire i is $L_i(t)$ at time t and the length $E_i(t)$ ($L_i(t) \geq E_i(t)$) is to be besieged for each fire, the enlarged fire spread area for all detected fires from time t to t+1 is expressed as follows:

$$\Delta S = \sum_{i=1}^{K(t)} ds_i = \sum_{i=1}^{K(t)} \frac{\{L_i(t) - E_i(t)\}}{2 \cdot r_i(t)} \{r_i(t+1)^2 - r_i(t)^2\} \qquad \cdots[6]$$

Here, $s_i(t)$ is the fire spread area at time t [m^2]
$L(t)$ is the un-besieged fire perimeter length at time t [m], $E(t)$ is the besieged perimeter length at time t [m]
$r(t)$ is the maximum radius of fire at time t [m], and
$K(t)$ is the number of already detected fires at time t [m]

At this point, define:

$$\frac{r_i^2(t+1) - r_i^2(t)}{r_i(t)} = U_i(t) \qquad \cdots[7]$$

Then, the objective function to minimize ΔS *is*:

$$\Delta S = \frac{1}{2}\sum_i U_i(t) \cdot L_i(t) - \frac{1}{2}\sum U_i(t) \cdot E_i(t) \to \min \qquad \cdots[8]$$

$$\Leftrightarrow \sum_i U_i(t) \cdot E_i(t) \to \max \qquad \cdots[9]$$

That is, in order to minimize the total growing area of the spreading fire, it is necessary to mobilize fire

brigades to fires with large U first. Note that, from equation [7], it can be confirmed that the greater the increase of fire spreading area per unit of time and the smaller the maximum radius of a fire, the greater the value of U becomes. This means that mobilizing fire brigades to fires with greater U first is equivalent to mobilizing fire brigades to "fires that spread quickly and are easy to besiege (greater siege perimeter length per brigade relative to fire perimeter length) preferentially," which is considered to be a reasonable judgment.

(4) Firefighting Volunteer Model

a) Operation of Firefighting Volunteers

In the firefighting volunteer model we construct in this study, firefighting squads organized by volunteer firefighters gathered after the occurrence of an earthquake are considered to be the smallest units available for firefighting. Firefighting squads are committed by the firefighting volunteer commander based on the instruction of the fire brigade headquarters. Based on past studies[4), 7)], the general properties of fire teams, such as settings of mobility etc., are set to be the same as for portable pump teams. Moreover, in view of the basic principle of firefighting volunteers that "our own town must be protected by ourselves," it is not considered appropriate to assume that such firefighting squads will be operated in wider areas. They are thus operated as in local firefighting operations (activities in a squad's own area of jurisdiction) even after the switching of the operation.

b) Time Required to Organize Firefighting Squads

Volunteer firefighters in wards of the Metropolis of Tokyo (hereinafter referred to as "branch firefighting volunteers") are classified into service-area volunteers and resident-area volunteers. Since an earthquake is assumed to break out at 18:00 in this study, we assume that only resident-area volunteers have time to gather.

The time for a firefighting squad to be formed is calculated and set based on the lead-time for branch firefighting volunteers to start gathering after an earthquake and the transportation time required for gathering.

The lead-time required for branch firefighting volunteers to confirm the safety of family members etc. and start gathering is assumed to be 15 minutes. This value is found from statistical analysis of questionnaire surveys targeting branch firefighting team commanders in wards of the Metropolis of Tokyo; 15 minutes corresponds to the median of the cumulative response ratio of time required for gathering at earthquake disaster stated by the branch firefighting squad commanders.

c) Transportation Time Required for Gathering

The area that branch firefighting team D_i is in charge of is defined as a circle having the equivalent area as the actual branch firefighting team zone (radius R_im) and the branch firefighting team headquarters is assumed to be located at the center. The firefighting squad members (total number of members m_i) that are able to gather at the fire station are assumed to be uniformly distributed within the branch firefighting team zone; immediately after the earthquake, they start to move toward the headquarters. The time required for the xth firefighting squad member to reach the headquarters, $t_{i,x(move)}$ min, is calculated as follows [14)]:

$$t_{i,x(move)} = \sqrt{\frac{x}{Dm_i}} \cdot \left(\frac{1.3R_i}{v_w} \right) \quad \cdots[14]$$

Where v_w is the assembling speed (set to 100 [m/min] on foot)

One firefighting squad is organized with every five firefighting volunteers that are gathered.

3. SIMULATION EXPERIMENTS

(1) Selection of Case Study Areas

For the simulated fire district, we will choose a fire district closest to the average in terms of density of fire occurrences assumed at the earthquake disaster scene and the ratio of fire brigade to the assumed number of fires within the jurisdiction of each local fire station among the eight fire districts having jurisdiction over the wards of the Metropolis of Tokyo. And Fire District "F" is chosen as the case study area in this study. (Figure 3)

(2) Parameter Settings

The time required for making a judgment at the local firefighting operation and at the district operation is presumed as shown in Table 2. We then conducted experiments in which we changed certain key parameters shown in Table 3 in order to understand the factors affecting the time for switching the method of operation and the effect on damage reduction. Note that the underlined values in Table 3 indicate the reference value of each parameter.

Table 2 Time Required for Mobilization Judgment

Number of fires requiring judgment	At local firefighting operation (min.)	At district operation (min.)
1 to 5	1	1
6 to 10	2	2
1 to 15	—	3
15 or more	—	4

Table 3 Parameter Settings

Factor	Parameter	Set value
Number of fires	Coefficient of expected number of fires	0.5 , <u>1.0</u>, 1.5
Speed of mobilization judgment	Number of fires for which mobilization judgment can be made	1 , <u>2</u> , 3
Operation of firefighting volunteer	Operation of firefighting volunteers	Yes, <u>No</u>

*Coefficient of expected number of fires: a coefficient by which the expected number of fires per mesh unit is multiplied in order to change the assumed number of fires.

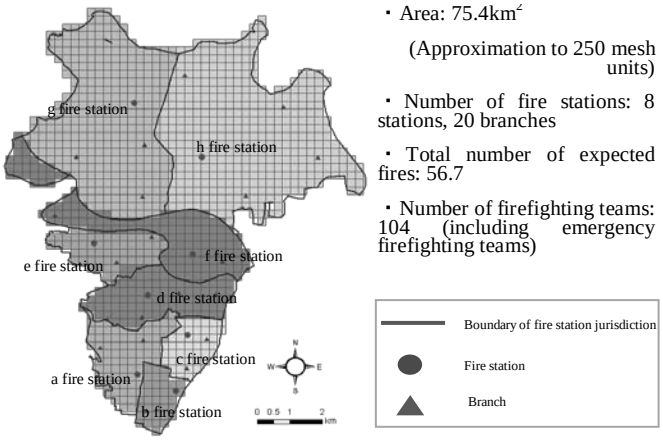

Figure 3 Map of Fire District "*F*"

4. RESULTS OF EXPERIMENTS AND ANALYSIS

(1) Basic Experiments

In order to first understand the trends of each evaluation index at each operation switch time, we conducted experiments based on the default scenario using the underlined values in Table 3 (Experiment 1).

Figure 4 shows the numbers of fires and detected fires by time of occurrence in the basic experiments. The result shows that approximately half of the fires start within five minutes after the occurrence of the earthquake, and the majority of fires are detected within 5 to 20 minutes after the occurrence of the earthquake. In addition, Figure 5 shows the relationship between the operation switching time following the earthquake and the area that fire spreads to within the district. The result shows that the fire spread area within the district is minimized when the operation is switched 25 minutes after the occurrence of the earthquake; if the switch takes place either earlier or later, the fire spread area would be greater.

a) Operation Switch Timing and Effect on Damage Reduction Seen from Entire District

Figure 6 shows the relationship between the fire spread area within the district and the ratio of extinguished fires within the district (ratio of fires extinguished by fire brigades relative to the number of fires breaking out within 180 minutes after the outbreak of the earthquake) when the operation switch timing is changed. The ratio of extinguished fires is higher and the fire spread area is smaller in the upper left part of the graph, which is more favorable.

Figure 6 indicates a strong negative correlation between the fire spread area and the ratio of extinguished fires in the district. From this result, in order to mitigate the fire spread area, it is considered important to operate firefighting services according to the principle of firefighting at an earthquake disaster called "early extinguishing of fires." That is, mobilizing fire brigades in more wide-area fire operations to deal with local fires with inferior firefighting services in early stages is considered effective in minimizing the fire spread area. With this measure, it becomes possible for a small number of fire brigades to extinguish fires quickly and be moved to other fires. Thus, the effect of preventing fire spreading per fire brigade can be increased to achieve more efficient firefighting operation.

However, if the operation is switched too early, the fire spread area in the district overall becomes greater and both the ratio of extinguished fires and the area where fire spreading is prevented per fire brigade become smaller. Here, comparing Figure 4 and Figure 5 for confirmation, it can be seen that the optimal time to switch operation seen from the entire district is slightly after the time when the number of detected fires by time within the district becomes the maximum. From this result, it is thought that if the operation is switched too early, the judgment about the operation of fire brigades cannot catch up with the fire detection, leading to delays in mobilization commands to the fire brigades. Thus, it becomes difficult to extinguish fires in the early stage and, as a result, the fire spread area will increase. On the other hand, if the operation switch is too late, taking actions against fires where firefighting services are insufficient is delayed, allowing the fire spread area to expand in the region in question and making early fire extinguishing difficult, and the fire spread area will increase.

From these considerations, we can say that local firefighting operations are effective in the period when a rush of reports and detections of fires come in after the outbreak of an earthquake. Then, when a certain period has elapsed after the occurrence of the earthquake and the peak of fire detections has passed, all firefighting services should be mobilized to switch to wider area operations as early as possible. Thereby, it is possible to extinguish fires in the early stage and mitigate damage caused by fire spreading.

b) Time of Operation Switch and Effect on Damage Reduction Seen by Jurisdiction of Fire Station

Figure 7 shows changes in the fire spread area by fire station jurisdiction when the operation method is switched 25 minutes after the outbreak of the earthquake as compared to no operation switching. The fire spread area was reduced in nearly all fire station jurisdictions, but the area increased in fire station jurisdiction b only, by approximately 27 percent. This result suggests that operation method switching can reduce the overall damage in a district, but it is accompanied by the risk of increased local damage.

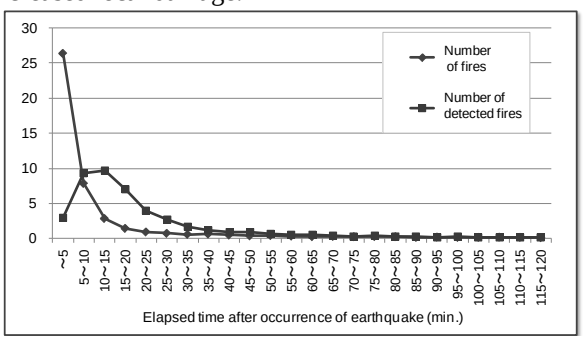

Figure 4 Number of Fires/Number of Detected Fires by Time (experiment 1)

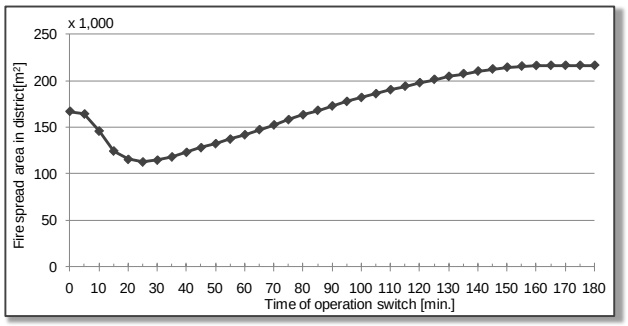

Figure 5 Operation Switch Time－Fire Spread Area in District (Experiment 1)

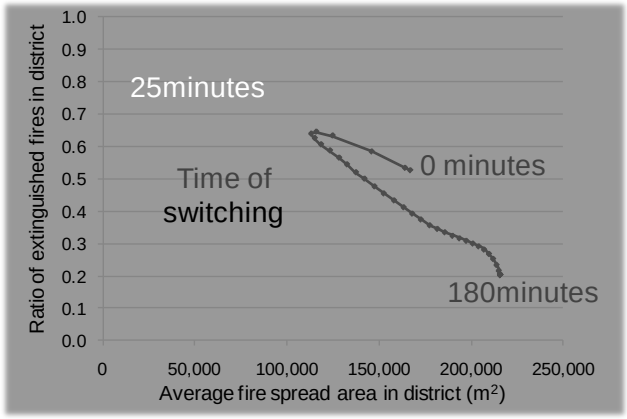

Figure 6 Average Fire spread area within District－Average Ratio of Fire Extinction

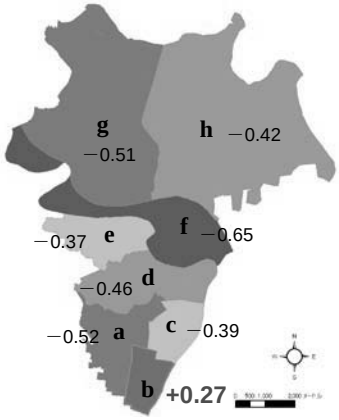

Figure 7 Rate of Change of Fire Spread Area due to Operation Switching (25 minutes)

The reasons why the fire spread area increased in fire station jurisdiction b only are thought to be found in the local characteristics of the jurisdiction and the district operation policy. Comparing the expected number of fires within the district on a five-point scale, fire station jurisdiction b is considered to have a relatively high risk of fires compared to other jurisdictions within the district, while the risk of fire spreading is low. In this study, we employed the district operation policy to "prioritize fires that spread quickly." For this reason, the risk of multiple fires is high in fire station jurisdiction b, but the priority on fires within the jurisdiction is lowered after switching the operation because the speed of fire spreading is relatively slow in this jurisdiction, which inhibited sending a large number of fire brigades, resulting in increased area of fire spreading. This result suggests the risk of allowing local fires to spread based on characteristics different from local characteristics such as speed of fire spreading, depending on the local characteristics and operation policy. It is thus considered important to identify areas with a high risk of fire spreading and the damage increase trend in such areas, when judging the timing of switching firefighting operations.

(2) Understanding the Influence of Mobilization Judgment

a) Speed of Mobilization Judgment in Local Firefighting Operations

In order to understand the impact of speed of mobilization judgment in local firefighting operations on the relationship between the operation switch timing and the effect on damage reduction, we conducted experiments with the same fire assumptions as in the default scenario, but we changed the number of fires for which mobilization judgment can be made during local firefighting operation. Even if the operation judgment speed of the local firefighting operation is changed, scarcely any difference could be recognized in the relationship between the operation switch timing and the fire spread area in the district.

b) Speed of Mobilization Judgment in District Operations

In order to understand the impact of speed of mobilization judgment in district operations on the relationship between the operation switch timing and damage reduction, we conducted experiments under the same fire assumptions as in the default scenario, but we changed the number of fires for which mobilization judgment can be made at district operation as shown in Table 4.

Figure 8 shows the relationship between the operation switch timing after the occurrence of the earthquake and the fire spread area in the district. It is seen that if the operation judgment speed in district operations becomes faster, the operation switch timing that minimizes the fire spread area in the district becomes earlier, and the risk of increased fire spread area if the judgment to switch operation is made too early also drops. The possible reason is that damage is reduced due to an earlier switch to district operation, because operation judgment can also be made relatively efficiently in the early period of earthquake disaster when fire detections peak. On the other hand, if number of fires for mobilization judgment is fewer, the efficiency of mobilization judgment is greatly affected by the number of detected fires. In particular, if the operation is switched too early during the initial period of an earthquake disaster, the efficiency of fire brigade operation judgment drops dramatically due to the high concentration of fire detections, manifesting itself directly in a higher amount of damage.

Table 4 Experimental Conditions (Experiments 4 and 5)

Experiment number	Coefficient of expected number of fires	Number of fires for which mobilization judgment can be made		Operation of firefighting volunteer
		Local firefighting operation	District operation	
4	1.0	2	1	None
5			3	

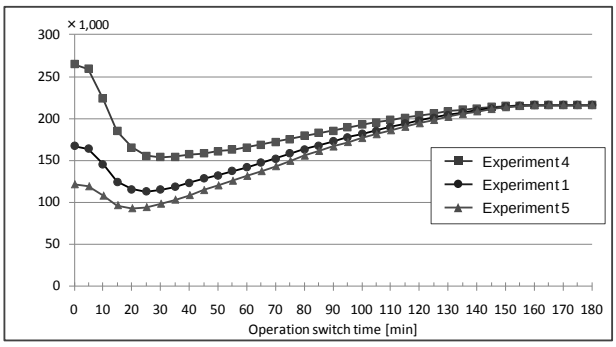

Figure 8 Operation Switch Timing －Average Fire spread area within District

(3) Understanding Influence of Number of Fires

In order to understand the influence of the number of fires on the relationship between the operation switch timing and the damage reduction, we conducted experiments under the some conditions changing the coefficient of expected number of fires.

From the results, it indicates that the operation switch timing that minimizes the fire spread area within the district does not change greatly in line with the number of fires. Moreover, when the number of fires is high, the difference in the area flame propagation due to the operation switch timing in the early period of the earthquake disaster becomes larger. The reason for this may be that if the number of fires is large, many fires break out before emergency fire brigades are formed and firefighting services become insufficient in some areas in the early stage after the occurrence of the earthquake, manifesting the effect of an early operation switch. If, however, the number of fires is large, the number of fire detections concentrated at the early stage of the earthquake disaster naturally also becomes large. For this reason, if the operation switch is performed too early, operation judgment made by the district headquarters will not catch up with the number of detected fires and the efficiency of mobilization becomes lower compared to local firefighting operation, which thus resulted in aggravating fire damage just as well.

(4) Influence of Operation of Firefighting Volunteers

In order to see the influence of the operation of firefighting volunteers on the operation switch timing and reduction of damage, we conducted experiments under the same fire assumptions as in the default scenario by operating firefighting volunteers, and compared the results. Table 5 shows the experimental conditions.

Looking at the area of fire spreading in the entire district, it is possible to reduce the fire spread area by approximately 40 to 50 percent, by means of firefighting volunteers, which confirms the considerable effect of these volunteers (See Figure 9). In particular, if the operation switch timing is earlier, the effect of the operation of firefighting volunteers to reduce the fire spread area becomes large. Moreover, if firefighting volunteers are used, the operation switch timing that minimizes the fire spread area takes place earlier and the difference in fire spread area due to the operation switch timing lessens in the early stage of an earthquake disaster. The reason for this is that, even if the operation method is switched at the early period of earthquake disaster when fire detections peak, if firefighting volunteers are mobilized, they are mobilized to nearby fires immediately after formation and prevent the spread of fire, compensating for the tentative drop of efficiency of mobilization judgment by the local firefighting department. This also has an advantage that required number of fire brigades can be sent out.

Moreover, it is possible to compensate for the disadvantages of switching the operation too early, causing a lack of firefighting services in certain areas in the district and focusing fire brigades on fires that broke out relatively early, for the same reasons as mentioned above. We thus consider that the spreading of fire will be suppressed even if the operation switch is made too early as well.

Table 5 Experimental Conditions (Experiment 8)

Experiment number	Coefficient of expected number of fires	Number of fires for which mobilization judgment can be made		Operation of firefighting volunteer
		Local firefighting operation	District operation	
8	1.0	2	2	Yes

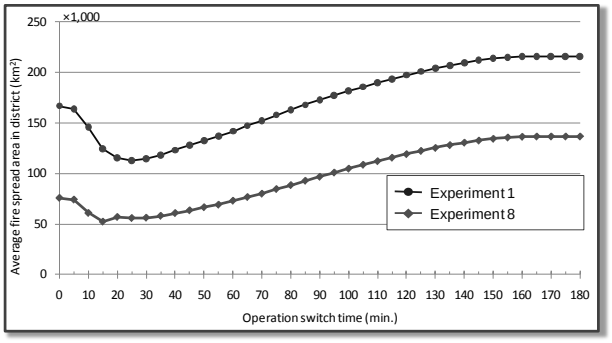

Figure 9 Number of Fires/Number of Detected Fires by Hour

5 CONCLUSION AND FUTURE ISSUES

(1) Conclusion

The conclusion drawn from this study is as follows.

a)Operation Switch Timing where an Effect on Damage Reduction Can Be Expected

Utilizing local firefighting operations in the initial phase of an earthquake disaster when reports (detections)

of many simultaneous fires peak, and switching to district operation as soon as possible after the peak of fire detections subsides some time after the outbreak of the earthquake, is effective to minimize fire damage. However, depending on the distribution of dangers of fires within a district, distribution of dangers of spreading of fires, or operation policies at district operation and the timing of operation switch, switching from local to district operation in an early stage involves a certain risk of increased local damages even though it reduces overall damages in the entire district. For this reason, it is necessary to identify areas with high risks of damage increase due to operation switching and the trends of damage increase in such areas in advance.

b) Influence of Speed of Mobilization Judgment

If the operation method is to be switched in the early stage after the outbreak of an earthquake, the judgment speed of mobilizing fire brigades by the district headquarters has a strong impact on the reduction of damages.

Thus, establishment of operation framework of fire brigades by the district headquarters in an early stage and repletion of command functions of the headquarters are effective.

c) Influence of Number of Fires

From a standpoint of wider area operation, the number of fires has little impact on the operation switch timing that minimizes the area of fire spreading. However, if the number of fires is great, the differences in the areas where fire is spreading become greater if the operation framework is switched during the initial stage of an earthquake disaster. If the operation framework is switched extremely early, in particular, there is a risk of significantly increasing fire damage. Moreover, if the number of fires is small, the later the operation is switched, the more difficult it becomes to conduct efficient firefighting operations; thus the effect on fire damage reduction is substantially reduced. Therefore, when the number of fires is anticipated to be small during the initial phase of an earthquake disaster, early operation switching should be examined in a proactive manner, and if the number of fires is projected to be great, careful judgment is required to switch operation at an early time.

d) Effect of Operation of Firefighting Volunteers

When wide-area fire brigades operate in combination with community-based firefighting activities by firefighting volunteers, a significant reduction of fire damage can be expected. Moreover, if firefighting activities by firefighting volunteers are conducted effectively, the risk of an increase in fire damage at the time of the operation switch to fire brigades in the initial phase of an earthquake disaster can be reduced.

(2) Future Issues

The future issues of this study are as follows.

a) Trials and Analyses in Multiple Fire Districts

The numeric values of effective operation switch timing shown in this study are applicable only when the operation method assumed in this paper is applied in a specified district. The same results are not assured if urban area conditions, firefighting service conditions, or disaster conditions are changed. This means that it is necessary to see how the relationship between the operation switch timing and damage reduction changes due to local characteristics of other fire districts, as well as understand the optimum operation switch timing for each district and risks involved in operation switching in the future.

b) Trials of Combinations of Various Operation Methods

This study examined the effects of combinations of a certain strategy (how to maneuver fire brigades), but diverse combinations of strategies at each operation are conceivable. From here on, it is necessary to model realistic operation strategies in touch with damage conditions at each operation and understand the relationship between the operation switch timing and damage reduction in these various combinations.

c) Consideration of Damage other than from Fires

During an earthquake disaster, all kinds of destruction is assumed to occur in addition to that caused by fires. When such things other than fires are included in the simulation models, it is necessary to take into account the possibility of fire brigades being unable to engage in firefighting or unable to start firefighting immediately, through evaluation of risks of outbreak of each type of disaster in chronological order.

d) Improvement of Simulation Model Accuracy

From now on, in order to improve the accuracy of the simulation models, it is required to closely examine impediments to firefighting, time required for making judgments on operation of fire brigades and so on, taking water supply and uncertainty into consideration, and to reflect the results in the simulation models.

Abstract: Managing circulation of trains, including regular inspection, car cleaning times and turning back operations, has become important due to the scarcity of railway company resources. The Taiwan High-Speed Railway (THSR) already has cyclic patterns of daily train circulation, but these patterns have not been modeled yet. Moreover, based on a review of the literature, researchers in the railway field have never considered train circulation, especially in HSR systems, even though it is important. This research proposes a scheduling optimization model that has the capability to accommodate not only basic requirements such as railway topology, traffic rules, and user requirements, but also train circulation as well. Mixed integer and dynamic programming have been chosen to solve the model under CPLEX. In addition, railway systems are often characterized by high traffic density that is sensitive to disturbances; thus, rescheduling activity for updating an existing schedule in response to disruptions is needed. This research has presented the mathematical model to reschedule the timetable. Assumptions as well as input and output values are configured by using real data from THSR, which used two lines, 128 services, 29 trains, and eight stations. The model has obtained a timetable result as good as the real timetable in two hours (that is, 7442.51 second). Rescheduling results could determine the new timetable for calamity. Therefore, it could be a good simulation analysis for predicting the effect of disruptions on the timetable without doing real experiments such as trains being disordered and overtaken.

1. INTRODUCTION

Railway transportation plays an important role in the passenger and freight transportation market. The railway has grown by over 40% in both freight and passenger sectors over the past 10 years. All railway companies try to provide good services in order to satisfy their customers. One way to realize this is by improving the quality of the train control process or scheduling so that the railway company could optimize these services as well. In addition, the train timetable is the basis for performing the train operations. It contains information regarding the topology of the railway, train number and classification, arrival and departure times of trains at each station, arrival and departure paths, etc. More formally, the train scheduling problem is to find an optimal train timetable, subject to a number of operational and safety requirements. Due to the limited resources of railway companies, managing circulation of trains becomes important, including turning back operations, regular inspection and car cleaning times. Any solution that ignores train circulation requirements is unreasonable to train companies. The Taiwan High-Speed Railway System already has cyclic patterns of daily train circulation, but these patterns have not been modeled yet. Furthermore, based on the data in the contingency timetable, THSR prefers to cancel many trains and operates only two trains per hour in many cases of disturbances. On the other hand, creating an optimal timetable, which means optimal journey time, is important since the THSR Company has to preserve the maximal profit during disturbances. In addition, in order to mitigate the impact of disturbances instead of cancelling many trains on their system, THSR needs a method for analyzing how disturbances propagate within the original timetable and which actions to decide. In the end, the train operator could predict the effects of disruptions on the timetable without doing real experiments.

Train scheduling problems have been studied by researchers over the years. They have been formulated using operation research (OR)-based techniques including mixed integer programming and network optimization models. Among the solution techniques developed to solve the problems were branch and bound, heuristics, and Lagrangian relaxation. In addition, researchers have proposed some methods to solve scheduling problems as the Job-Shop problem, program evaluation and review technique, and satisfaction constraint.

The strengths and weaknesses of each method depend on research objectives. Many researchers prefer to use a heuristic method to speed up the computation time and direct the search towards a feasible solution, but a heuristic needs more evaluation in practice due to the optimality issue of the results. There is no guarantee that the heuristic will generate an optimal solution in every test case (Chiu et al. 2002). The scheduling and rescheduling problem in this research is formulated as mixed-integer-programming (MIP), in which some of the variables are real-valued and some are integer-valued. There are two ways to solve MIP: exact solution, including branch and bound, and dynamic programming and approximation, including heuristic and lagrangian relaxation techniques (Yan and Shih 2009). The most widely used method for solving MIP for exact solution is branch and bound, and no researchers have used dynamic programming as a solution technique, although it could obtain the optimal solution as well. Therefore, this research proposes the exact-solution algorithm, which is dynamic programming, to solve train-scheduling problems and get the optimal solution exactly.

2. FORMAT REQUIREMENTS

Suppose a railway system with r station, n trains going down and m trains going up. Minimizing the operation times for all trains means minimizing the journey times (arrival and departure times) for all trains going-down, initialized as i (1 to n) plus the journey time of trains going-up as j (1 to m) in every station (1 to r). Thus, the mathematical constraint for representing the objective function in this research is presented as Eq. (1) below:
Minimized total operation time

$$\sum_{i=1}^{i=n}\left(T_i A_r - T_i D_1\right) + \sum_{j=1}^{j=m}\left(T_j A_1 - T_j D_r\right) \qquad (1)$$

The variables of this research are journey time, arrival and departure time of all trains with travel time, station time, headway, car cleaning time, regular inspection time and turning back operation, as parameters. Travel time constraints restrict minimum time to travel between two contiguous stations (k to k+1) for all trains going up initialized as i (1 to n) and trains going down initialized as j (1 to m).

$$T_i A_{k+1} - T_i D_k \geq time\ i_{k\to(k+1)} \qquad (2)$$

As represented by Eq. (2), the arrival time for train i in the station k+1 minus departure time in the station k (origin station) should be greater or equal to the needed time for trains i to travel between two contiguous stations (k to k+1).

$$T_j A_k - T_j D_{k+1} \geq time\ j_{(k+1)\to k} \qquad (3)$$

The arrival time for train j in the station k minus departure time in station k+1 should be greater or equal to the needed time for trains j to travel between two contiguous stations (k+1 to k). This research uses minimum travel time between two contiguous stations, because different types of trains have different speeds and travel time would automatically differ. As explained before, running time is calculated from departure times in the timetable minus dwell times. Therefore, station time for each train i and j at station k (1 to r) should be greater than departure time minus arrival time, as shown in Eq. (4) and (5). This condition represents that the model uses maximum station time at each station, because not all trains will stop at every station.

$$T_i D_k - T_i A_k \leq TS_{i_k} + CS_{i_k} \qquad (4)$$

$$T_j D_k - T_j A_k \leq TS_{j_k} + CS_{j_k} \qquad (5)$$

Headway constraint restricts to the departure times differences between two consecutive trains in the same station. The headway time in this research is fixed to one value because we want to keep the time spacing between two trains exactly.

$$T_{t'} D_k - T_t D_k + INF \times Y_{t-t';k->(k+1)} \leq INF - headway \qquad (6)$$

$$T_{t'} D_k - T_t D_k + INF \times Y_{t-t';k->(k+1)} \geq headway \qquad (7)$$

$$T_{t'} A_{k+1} - T_t A_{k+1} + INF \times Y_{t-t';k->(k+1)} \leq INF - headway \qquad (8)$$

$$T_{i'} A_{k+1} - T_i A_{k+1} + INF \times Y_{t-t';k->(k+1)} \geq headway \qquad (9)$$

As represented by Eq. (6)-(9), $Y_{t\text{-}t';k->(k+1)}$ is the decision variable for the availability of track in one segment. The value is 1 if there is a track available between station k to k+1 and 0 otherwise. Travel time in line determines the total travel time for one train to travel through a line southbound

and northbound plus allowed time margin. Travel time in line determines the total travel time for one train to travel through a line southbound and northbound plus allowed time margin. Maximum travel time has been applied in the model; thus, the difference between arrival and departure time for one train in the same station should be less or equal to this travel time, as formulated in Eq. (10) and (11) below:

$$T_i A_r - T_i D_1 \le \left(1 + \partial/100\right) \times time\ i_{1 \to r} \quad (10)$$

$$T_j A_1 - T_j D_r \le \left(1 + \partial/100\right) \times time\ j_{r \to 1} \quad (11)$$

In the THSR system, allowed time margin was set to different numbers for different types of train. Therefore, this parameter would be a good input in sensitivity analysis to reveal the effects of changes in this parameter on objective value. Like many railway companies, THSR has a cyclic timetable in order to manage the resources comprising its infrastructure. In this research, it is assumed that the cycle time is 120 minutes (maximum travel time). Thus, if the headway time is set to 12 minutes, it means there are ten trains in the first cycle, and the next train (11th train) would be the same train as number one. It means the timetable at every two hours is the same pattern; the daily timetable is obtained by carrying out this pattern repeatedly. A train circulation model is needed to deal with these requirements. In the THSR system, train circulation takes 30 minutes maximum time, including car cleaning, regular car inspection, and turning back operations. Consequently, departure time for another train which will use the same track as those operations should be greater or equal to arrival time plus train circulation times as formulated in Eq. (12) and (13) below:

$$T_{i\left(j + \frac{traveltime}{headway}\right)} D_r \ge T_j A_1 + (InsT_1 + ClT_1 + TB_1) \quad (12)$$

$$T_{j\left(i + \frac{traveltime}{headway}\right)} D_r \ge T_i A_r + (InsT_r + ClT_r + TB_r) \quad (13)$$

If there were an event that required long travel times and headway between two contiguous trains, then the train circulation pattern would change as well.

3. RESULT

After the mathematical model for scheduling problem was formulated, a collection of data regarding scheduling requirements from the THSR Company began. Primary data was collected from interviews with senior engineers in the THSR Company, and secondary data was gathered from THSR documents including the Equipment and Facilities Operations Manual, and existing timetables from THSR. Mixed integer programming (MIP) methods and dynamic programming solution techniques have been used to solve the models with the CPLEX solver tool. The tests were operated in an Intel Core 2 Duo CPU 2Ghz with 2GB RAM.

The results showed 0% gap during the process, and the algorithm defined the results by cutting off the model. It means that the nodes were being solved during the branch and cut search. This value is typically computed by exceeding the cutoff value, and then the node can be pruned without the need to solve the node to optimality. Therefore, the computation time to solve the model is (7442.51 seconds) and performance time is 6,780 minutes as the optimal result of minimum total operation time in the THSR system. Compared to a real timetable, THSR has 6,420 minutes operation time in their system, thus the gap between these two timetables is 360 minutes or a 2.72% gap. It is caused by the difference in assumptions between the model and the real problem. In the THSR system, every type of train has its own speed to run among stations, whereas in the model this is not the case. The timetable diagram contains information regarding departure and arrival times of trains at each station. From the output departure and arrival times for each train at stations, we developed the timetable diagram in Figure 1. The new timetable for rescheduling is shown by Figure 2, that is a calamity in station 3 at time is 100.

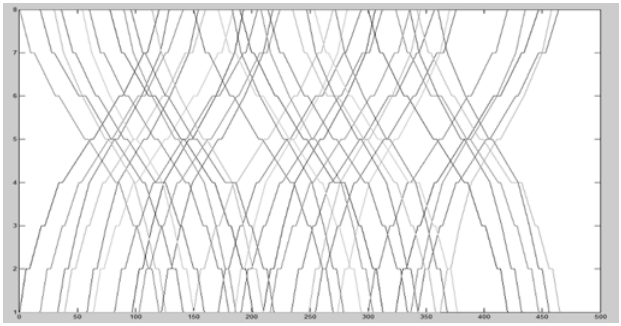

Figure 1 Timetable diagram for general event

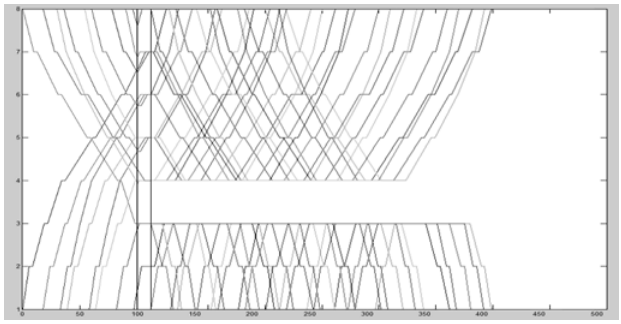

Figure 2 Timetable diagram of rescheduling for disaster

In the Figure 3, the train 1 and train 2 for southbound are not cross at all station. If the train 1 at station 2 delay 10 minutes, the timetable is shown in Figure 4, that bring the train 1 and train 2 occur the cross event at station 7.

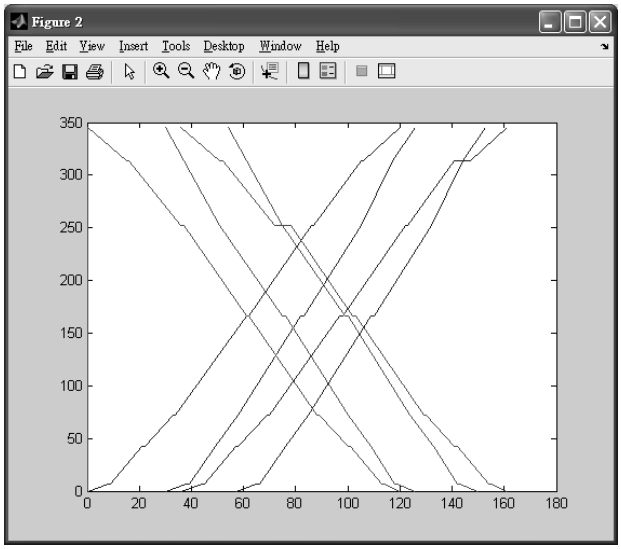

Figure 3 Timetable with no delay time event

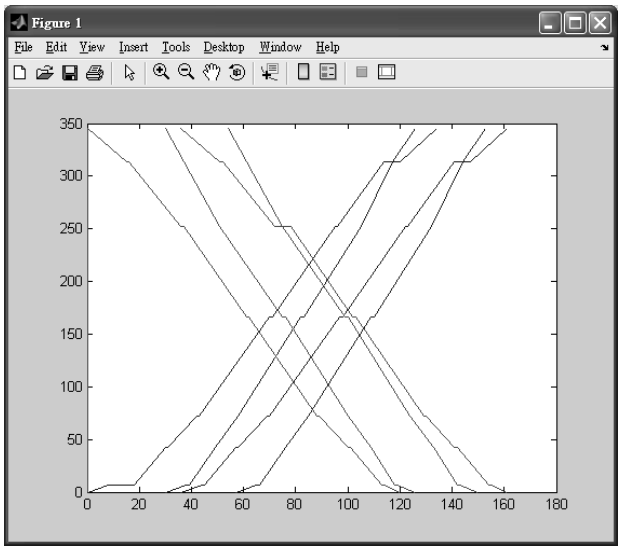

Figure 4 Timetable with delay 10 minutes on station 2 for train 1

We use the input and output patterns from mathematical model to build a decision tree using the J48 algorithm. The attributes of the decision tree as shown in Table 1. The TYPE represents the type of train with southbound and northbound, TNO represents the train number with 1 to 4, STATION represents the station number with 1 to 8, STOPT represents the delay time (minute) for a train stop at the station, and CLASS is the class of the decision tree. In the CLASS attribute, the ORG means the timetable for rescheduling is same with original timetable, T(t, t')NC means the train t and train t' are not occurring the cross event, and T(t, t')C(s) means the train t and train t' are occurring the cross event at after s stations. The decision tree algorithm selected with J48 algorithm, the result is shown in Table 2. Table 2 shown that is a very high accuracy for any number of stations and any number of trains, it can be explain that the proposed decision tree model can find the relation between the delay time and cross event.

Table 1 The attributes of tree model

Attribute	Range
TYPE	SB, NB
TNO	1, 2, 3, 4
STATION	1, 2, 3, 4, 5, 6, 7, 8
STOPT	+0, +1, +2, …, +10
CLASS	ORG, T(t, t')NC, T(t, t')C(s)

Table 2 The result of decision tree with J48 algorithm

Number of Station	Number of Train	Accuracy
8	4	85.22 %
8	8	87.09 %
10	8	70.31 %
10	4	76.22 %

4. CONCLUSIONS

This research developed an optimization model for designing timetables in high-speed railway systems that considers basic requirements as well as special requirements regarding train circulation, including car cleaning, regular inspection, and train turning back operations. The model could generate a good timetable result as good as a real timetable in two hours (7442.51 seconds). Furthermore, the model could generate train circulation patterns as illustrated in the timetable diagram results. The proposed decision

tree model can find the relation between the delay time and cross event. The rescheduling could be a good simulation analysis for predicting the effects of disruptions on the timetable without conducting real experiments.

Study of Self-risk Management of Local Residents for Earthquake Disaster

Masami Kobayashi

Professor, Graduate School of Global Environmental Studies, Kyoto University, Japan
mkoba@archi.kyoto-u.ac.jp

Abstract: Impending Nankeen Earthquake is published to be expected magnitude 8.4, event probability 60% in 30 years, by the Central Disaster Prevention Council. It is also announced that the forecasting of the event is difficult. Therefore the residents in affected areas have to be in safe places beforehand. Setting the research field on Saijyo-city, Ehime prefecture, which is designated as the Tonankai Nankai Earthquake Disaster Prevention Promote Area, we examined two topics. Topic 1 refers whether or not residents could know their personal damage risk of Nankai Earthquake from officially disclosed earthquake damage estimations (EDEs), examining the risk factors considered. Topic 2 refers the possible measures for residents to reduce their risk. Firstly, as a measure promoted by government, seismic retrofitting of wooden houses with official support is examined. Then, using questionnaire and governmental ledger, we investigated the households in which 'people vulnerable to disaster' are living in 'ineligible wooden housing'. Analyzing their situations of life risk at earthquake and their self-risk management, possible practical measures to reduce human damage are discussed.

1. INTRODUCTION

In Japan, government has taken measures with escape plan for residents based on 'earthquake damage estimation (EDE)', setting 'the Local Disaster Prevention Planning' which is obligation of local government by 'the Basic Law of the Natural Disasters'. But central government announced that forecast of impending of 'Nankai earthquake', which is published to be expected magnitude 8.4, event probability 50% in 30 years[1)], is difficult[2)]. As the residents in affected area could not escape just before the event, there are no ways of disaster prevention for residents but to be in safe place before the event. This is the reason why residents have to know their personal damage risk in order to take appropriate measures for their safety. This paper deals with two topics. The first topic refers whether or not residents could know their personal damage risk of Nankai earthquake from disclosed EDEs, by examining how risk factors are considered in EDEs. The second topic refers the possible measures for their self-risk management, by examining the measures promoted by government with official support. Setting research field on Saijo-city*, Ehime-prefecture in Japan, which is designated as the Tonankai & Nankai Earthquake Disaster Prevention Promotion Area (2003) by the central government, we investigated their EDEs and preparedness of the residents. In Saijo-city there are 2 EDEs disclosed in public by governments. They are Saijyo-city Disaster Prevention Planning (2006) based on Ehime-prefecture EDE (2002) obtained via Saijo-city official homepage and Central Government EDE (2003) via the central government official homepage. As for the residents, Ehime-prefecture the Basic Ordinance of the Disaster Prevention (2006)" is stating that 'measures taken by residents' selves are important' in the preceding sentence[3)]

*Saijo-city: Population 115,651, household 46,977, area 509.04km^2(2007.10)

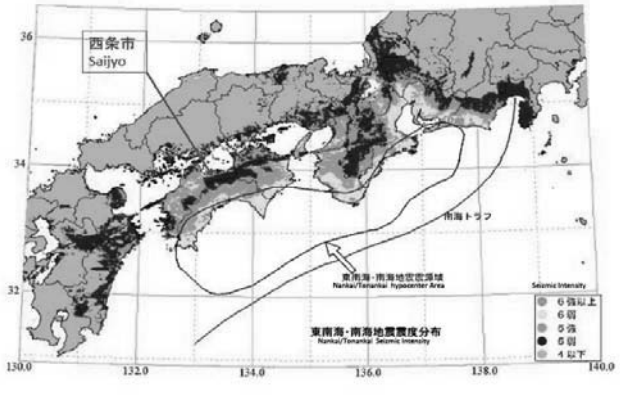

Fig.1 Location of Saijyo-City

2. TOPIC 1: To know personal damage risk of Nankai earthquake

Is it possible for each resident to know his/her personal damage risk from EDE (earthquake damage estimation) disclosed by government? It is examined how EDE is calculated, made outcome and described to public, what information is informed to residents, considering risk factor with each residents.

2.1 Major risk factors of human damage in earthquake disaster

From the tendency of recent earthquake hazard[4)5)], high-risk conditions are 1)big shake place, 2) old wooden building' and 3)escape difficulties such as the old or disabled people who stay inside for long time and are struck by building destruction. That is, major risk factors of earthquake damage are 'address', 'structure and age of housing' and 'existence or nonexistence of escape difficulties in housing', which are all personal information and each resident must have known his/her rate of each risk factor.

2.2 Informed content to residents

About the described way of Ehime-prefecture EDE, there are "estimated outcome" and "brief explanations of calculation way": but the detailed content of calculation way is not shown, and so residents couldn't calculate by themselves. The way of description of outcome is like this. Ground motion is expressed as distribution of classification of intensity on Ehime-prefecture map (scale about 1:700,000, 500m-mesh). Building damage is expressed as severe damage building–count, severe & moderate damage building-count, and the ratio of severe damage building and so on. Saijo-city is composed of 4 areas and building-count is shown as area total. The ratio is shown as the distribution of number per mesh on the map. The percentage is average in mesh nevertheless each house has different risk factor. Human damage is expressed as death people-count, which is shown as area total. Building damage and human damage are shown as total number of wide area or average of mesh area and they don't describe personal damage risk.

2.3 Calculation way

Ehime-prefecture EDE is calculated in 500m-mesh using 'governmental ledger (Fixed Asset Tax Rolls)' and 'prediction formula' developed from the Great Hanshin-Awaji Earthquake in 1995, in this case. The calculation has 4 steps: [1]Setting of expected Nankai earthquake→[2]Ground motion→[3]Building damage→ [4]Human damage. About building damage, 'the ratio of severe damage building' is determined by PGV (peak ground velocity) and 'structure and age of building'; PGV (peak ground velocity) is calculated by the mesh, building is counted by mesh with 'structure has 5 sections (Wood, Light-gauge Steel, Steel, RC/SRC, others)', 'age of buildings has 5 sections (-1951, 1952-1961, 1962-1972-1981, 1982-)'. Risk factor of building is considered at calculation level, but it is not at public description level; shown as average of mesh area. About human damage, it is calculated from risk factor of place and building, which is 'the ratio of severe damage building' and 'structure of housing (wood or the other'. It is not considering the risk factor of humans, just in a single uniform way, which does not have make sense.

2.4 Informed outcome

Central government EDE shows that about 5,000-6,400 severe damage of buildings, about 80-100 death of people in Ehime-prefecture, while Ehime-prefecture EDE shows 210,958 severe damage of buildings, and 2,556 death people. For example, used prediction formula 'correlation equation of ground motion & building damage' is different, that of Ehime-prefecture EDE[6)] is 'intensity & the ratio of the severe damage building', and that of Central Government EDE[7)] is 'peak ground velocity & the ratio of the severe damage building'.

2.5 Conclusion of Topic 1

Residents could not know personal damage risk from EDE disclosed by government. There are problems on the way of description to public and the way of calculation, and so, the informed contents are different. Personal damage risk is calculated by personal information (risk factor of building) and official information (prediction formula, ground motion and so on) which residents do not know. Personal information is used so the way of disclosing in public becomes 'obscure'. EDE should be disclosed so that each resident could know his/her personal damage risk and its calculation way. The future tasks are (1) development of tool for informing (e.g. inputting personal information on Web service, damage risk is calculated automatically), and (2) confirmation or unification of calculation way (Prediction formula is made from unitary event, and outcome is different by each prefecture).

3. TOPIC 2: Possible measures for self-risk management

Topic 2 refers to "What are possible measures for resident to practice their self-risk management".

Fig.3 Survey Area

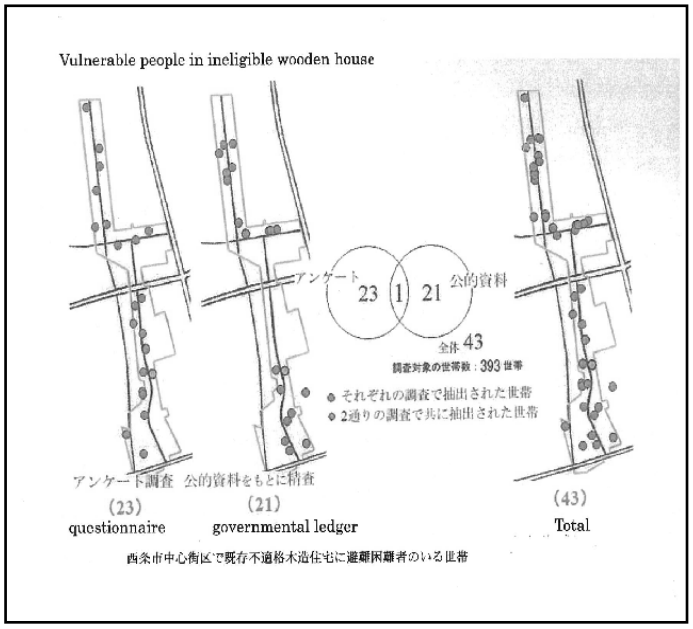

Fig.4 Vulnerable people in Ineligible Wooden House

3-1 Legally safe standard

In recent earthquake hazard, human damage has concentrated on old people living in old wooden building[4)5)]. (See Fig.2 and Table1) The building with pre code-revision (before 1981) is existing ineligible, which is often luck of seismic performance. Such housings are about 10,000,000 in Japan[8)]. Government has taken measures to especially 'ineligible wooden housing'. While, residents who are in difficulties to escape at disasters by themselves were defined as 'people vulnerable to disaster' by Central Government Guideline (2005), and government recognized necessity of support of their escape. This study investigated the number of households that are *'people vulnerable to disaster' living in 'ineligible wooden housing'*, in the central district of Saijyo-city on Sep. 2007. The research area (See Fig.3) has 1,538 people and 693 households are crowded with old wooden houses. The research way was with ① questionnaire to ask existence of 'people vulnerable to disaster', which is conformable to Central government guideline, and to check the same issues by ② the governmental ledger. We asked 11 neighborhood councils in the area to distribute the questionnaire sheets and 228 households (62.6%) have answered them. The outcome is ①23,②21,①∩②1,①∪②43, total is 1 in 14 households (43/228), not a few residents.(See Fig.4)

3-2 Official support

After the Great Hanshin-Awaji Earthquake, local government has taken measures for 'ineligible wooden housing' with official support about seismic retrofitting: subsidy for seismic diagnosis and seismic retrofitting. While, local government has taken measures for 'people vulnerable to disaster' with 'Escape Support Plan' which sets the way of rescue or leading to evacuation center for each of them immediately. But it is 'after the event (earthquake)', in case of surviving. After the event, there are 'Escape Support Plan', provision of temporary housing, reconstruction money and condolence money for bereaved families and so on, which are for residents with building or human damage. While before the event, official support is only about seismic retrofitting.

3-3 Measures promoted by government

Measure promoted by government is only 'seismic retrofitting' which can prevent unpredictable earthquake disaster. But it is unpopular to residents, there are mainly 4 reasons: (1) residents' economical burden, (2) botheration in regular life and deterioration of habitability (by decrease of open mouth and increase of wall), (3) trustless to effect, and (4) lack of information[9)]. Economical reason is big. The subsidy is often given only for the case to over the structural-overall score 1.0 (1.0 is standard of the Building Code), which needs structural calculation and adequate construction work by licensed person. And the government has taken stance of not using official money for contribution to personal property, so subsidy to housing is limited.

We also asked 228 households in the survey area with questionnaire 'Why don't you do seismic retrofitting?' The major reasons (multiple selections) are 1st: 'Non-dweller after several years' 49(21.5%) and 2nd: 'Economical burden' 40(17.5%). Among 21 households with 'people vulnerable to disaster' living in 'ineligible wooden housing', 20 households answered the reasons for not doing seismic retrofitting. Their major reasons are 'No dweller after several years' 7(35%), and 'economic burden' 7(35%). The average cost of seismic retrofitting for old wooden houses is reported as 1.76 million yen[3)].

Informed the brief explanation of Ehime-prefecture EDE within the questionnaire, 37 households hoped to consult about seismic retrofitting, so it was explained about official support to them with city officer, but only 1 household used seismic diagnosis and no household did seismic retrofitting.

3-4 Possible measures for self-risk management

Even if it is impossible to prevent earthquake disaster, it is possible to reduce human damage risk. The concept is to save human life. There are some possible measures for self-risk-management. Mitigation way is to make a space residents spend most of their time not to be destroyed severely, and also not to stay long time at high-risk space. Some examples are like these.

a) Simple seismic retrofitting**:** (e.g. Sumida, Tokyo) Official support could be applied to the case that seismic performance improved before, even if overall score doesn't over 1.0. It also could be applied to only bedrooms or living rooms.

b) Self-build or self order**:** These are based on each resident's judgment, so repair way or the contractor is chosen by themselves. These might not be taken place strictly following with legal standard.

c) Cooperation of each resident**:** For example, cooperative reconstruction by neighborhood. If residents unfulfilled with legal safety standard cooperate and build as 'community shelter' for pre-escape, there might be possibility of official support in future.

d) Application of seismic diagnosis**:** By seismic diagnosis, resident could know high-risk rooms so they could choose where to be in a day and sleeping time.

e) Application of public resources**:** To shorten time to

stay at high-risk housing, there is possibility by application of public resources (e.g. café, spa, community bus…etc.) available in regular life in neighborhood. The public buildings have seismic performance. Enriching public service and infrastructure to access, it is promoted to be out of high-risk space.

3-5 Conclusion of Topic 2

The measure promoted by government is about 'seismic retrofitting', which is exactly a way for disaster prevention. If the residents are living in 'ineligible wooden housing', they can receive official support, but it is unpopular though there are not a few 'people vulnerable to disaster' are living in 'ineligible wooden housing'. The main reason of unpopularity is economical burden (including 'non-dweller after several years), which is the outcome of Benefit/Cost (B/C) of the residents. Housing is personal property and so, measures shall be done by self-help, which is governmental consensus. However, considering with the concept to reduce personal risk of human damage, there are possible measures implemented by self-risk management. And measures which enable residents to choose could be increased if social and public resources are used for their safe places before the event. Future task is (1) sharing the same information of damage risk between government and the residents: presence of residents with high-risk, presence of old wooden houses unfulfilled with legal safety standard, and the rate of damage risk caused by the coupling of the two factors, (2) affordable activities for mitigation conducted by residents and government with official support. That is if the resident could check and obtain the rate of personal life risk in their houses at the coming earthquake by the disclosed EDEs which are personally accessed through internet at the governmental websites, for instance, it is possible for the residents to choose to judge their accessible safe place before the earthquake as well as 'acceptable size and expense for house retrofitting', considering their span of life expectancy.

LONG-RUN EFFECTS OF A DISASTER: MEASURING THE ECONOMIC IMPACTS OF THE KOBE EARTHQUAKE

Yasuhide Okuyama

Center for Urban Earthquake Engineering, Tokyo Institute of Technology, and University of Kitakyushu, Japan
okuyama.y.ac@m.titech.ac.jp

Abstract: In 1995, the Great Hanshin-Awaji Earthquake, a.k.a. Kobe Earthquake, occurred in the second largest economic region of Japan, and its economic damages were accounted around 10 trillion yen (Okuyama et al., 1999). A catastrophic event in this magnitude would have surely created some long-run impacts on the regional economy as well as on the surrounding regions. In addition, the recovery and reconstruction activities would have affected the economic structure of the region and interdependencies between regions. While these long-run economic impacts are considered to be sizable, few studies have conducted to empirically measure or estimate such impacts, due to the significant noises in economic data disturbed by macroeconomic fluctuations and to the lack of detailed economic data on the damages and losses caused by the earthquake. At the same time, several cross-country and/or cross-hazard studies, for example Skidmore and Toya (2002) and Cuaresma et al. (2008), have been carried out to analyze whether or not long-run economic implications of disasters actually materialize, while their results are somewhat mixed. This paper presents an empirical investigation of long-run economic impacts of the Kobe earthquake, using econometric models.

1. INTRODUCTION

While significant progress has been made in recent years for the economic analysis of disasters, especially in the field of economic modeling for disaster impact (for example, Okuyama and Chang, 2004; and an excellent compilation of related papers by Kunreuther and Rose, 2004). Since the pioneering work by Dacy and Kunreuther (1969), a generalized framework for the economic analysis of natural disasters had been proposed (for example, Sorkin, 1982; and Albala-Bertrand, 1993). The recent advancements have been more toward empirical analysis and toward strategies for modeling extensions and modifications to fit them to disaster situations. This trend is due to improved data availability of disaster damages and losses and to increased multidisciplinary research activities about disasters, including sociology, economics, and psychology. At the same time, the uniqueness of each hazard and of its damages and impacts presents enormous challenges in economic modeling for disaster impact estimates; many issues remain unsolved to this date. In particular, while the domination of flow analysis models employed in the recent research indicates that the impacts of a catastrophic disaster spread over to other regions or nations through expanded trades between regions (Okuyama et al., 1999) and/or sometimes between nations (Okuyama, 2010), some other researchers claimed that the the impact estimation of even a large disaster ends up "insignificant total impacts." (Albala-Bertrand, 1993)

These arguments should have entertained the measurement of empirically observed disaster impacts; however, few studies, if non-existent, have done such study. Most of those studies estimating the impacts of a particular disaster after its occurrence only assessed the impacts based on the available input data and some economic models, like input-output models and so on. It appears considerably entangled to literary measure disaster impacts based on empirically available macroeconomic data, partly because the disaster statistics are not standardized even among developed countries and are even "somewhat crude measures," (Skidmore and Toya, 2002) and also because in usual macroeconomic indicators, such as gross domestic products or gross regional products, economic impacts of a particular disaster may be potentially hidden within macroeconomic fluctuations and may be more likely cancelled out between negative impacts from damages and positive impacts of recovery and reconstruction activities. At the same time, empirical measurement of disaster impacts is necessary and critical to improve the accuracy of and assure those impact estimates derived based on economic model, and to understand how a disaster affect economies in terms of readily available data and indices.

In this paper, the economic impacts of the Hanshin-Awaji Earthquake occurred in 1995 are measured empirically using the time-series data and econometric models. Next section briefly summarized the previous studies and findings related to economic impacts of natural disasters. Section 3 presents the econometric models for measurement and sets time frame for the case study. The results of model estimation and the discussions are presented

in Section 4. Section 5 concludes this paper with the discussion of findings and some remarks.

2. ECONOMIC IMPACTS OF NATURAL DISASTERS

Natural disasters can cause physical destructions to built-environment and networks, such as transportation and lifelines, and can also cause casualties and injuries to human lives. These damages are often called damages, and are by economics' definition the damages on stocks, which include physical and human capitals. Then, these damages lead to the interruptions of economic activities, such as production and/or consumption, and the losses from business interruptions are called the (first-order) losses of a disaster. At the same time, there is another term called higher-order effects, which take into account the system-wide impact of flow losses through interindustry relationships. (Rose, 2004). And, total impacts are the total of flow impacts, adding (first-order) losses and higher-order effects (Okuyama and Sahin, 2009). While some researchers critique that the higher-order effects of disaster are "more a possibility than a reality" (Albala-Bertrand, 1993, p. 104), the estimation of indirect effects has been attempted to "gauge individual and community vulnerability, evaluate the worthiness of mitigation, determine the appropriate level of disaster assistance, improve recovery decisions, and inform insurers of their potential liability" (Rose, 2004, p. 13).

The economic impacts of natural disasters have been studies in various contexts and with a range of time frames. Ex-ante analysis of a hypothetical and/or potential hazard occurrence is often done for the decision-making of preparedness and mitigation strategies; and ex-post analysis of actual hazards and disasters is usually carried out to investigate how the event affected the economy and to examine to what extent the relief efforts by various levels of public sector and by other institutions are needed. The impact studies of natural disasters can be also categorized between short-run impact analysis and long-run impact analysis. Short-run analysis of disaster impact studies intends to estimate the total (flow) impacts of a hazard, defined above, for the period of a few years, and usually employs input-output model, social accounting matrix, or computable general equilibrium model of a particular region, regions, or nation. By its nature, short-run analysis measures only flow changes and can distinguish between the negative impacts based on loss data and the positive impacts from recovery and reconstruction activities, which serve as intense demand injections to the region. Several shor-run analyses of disasters were compiled in Okuyama and Chang (2004) and the methodologies are summarized in Okuyama (2007). On the other hand, long-run analysis of disaster studies aims to measure the effects of damages on stock, which may affect the long-run growth path of the damaged region, resulted from the changes in physical and human capital accumulation level and technology replacement (Okuyama, 2003). The long-run analysis of disasters usually employs econometric models with time series data; and because of it, they cannot distinguish between negative and positive impacts of a disaster and can only derive net impacts. Notable studies in this line include Skidmore and Toya (2002), Rasmussen (2004), and Cuaresma et al. (2008). Comparing to short-run analysis, long-run analyses of natural disasters have been limited, due mainly to the significant noises in macroeconomic data and also to the difference in details and extent of damage data gathered over time.

3. EMPIRICAL MODELS FOR STATISTICAL TESTS AND MEASUREMENT OF THE IMPACT OF AN EARTHQUAKE

We employ the Hanshin-Awaji Great Earthquake (hereafter Kobe Earthquake),which occurred in 1995 at Kobe, Japan, as the case study for empirically measuring the trends of the total impact over time. In doing so, we construct time-series models for City of Kobe and Hyogo Prefecture that includes Kobe.

3.1 Recap of Kobe Earthquake

On January 17, 1995, the worst disaster in the postwar Japan struck the second largest region of Japan—the Kinki region. The City of Kobe and surrounding municipalities experienced massive destruction of houses, buildings, roads, rails, and infrastructure. The magnitude of this event can be shown with the following facts: according to the Hyogo Prefecture Government (2010), the number of casualties was 6,434; the number of injuries was 43,792; the number of evacuees was 316,678 (at its peak); and the number of damaged houses was about 640,000. The direct damages from this Kobe Earthquake were estimated at about 10 trillion yen (US$ 100 billion, as $1=100 yen), equivalent to about 2.1% of Japan's GDP and 11% of Kinki's GRP (Gross Regional Product) at that time. These direct damages were concentrated in the destruction of buildings (including houses and production facilities), transportation facilities, and utilities. Although the damaged area was geographically only 4% of Kinki, it included 15% of the Kinki's population. The damages to capital stocks were estimated about 0.8% of Japan's total (Okuyama et al., 1999).

3.2 Time-Series Models

In order to statistically analyze the total impact of the Kobe Earthquake using the empirical time-series data, a series of time-series models is constructed. The functional form of these models employs an autoregressive-distributed lag model (Hendry, 1995). This is because we are interested in the total impact of an exogenous shock (earthquake) on gross regional product (GRP), a flow measure of the economy, and also because we measure the total impact as departures from the long-run growth path of an economy. The general form of the linear autoregressive-distributed lag model can be written as follows:

$$y_t = \beta_1 z_t + \beta_2 y_{t-1} + \beta_3 z_{t-1} + \varepsilon_t$$

where y_t is the dependent variable, z_t is the independent variable. In this formulation, z_t can be used to control exogenous factors influencing the growth path of y_t. Any miscellaneous influences to y_t will be captured by ε_t, residuals.

Base on this formulation, three models are constructed to statistically measure and test the total impact of the Kobe Earthquake. The first model is for the City of Kobe where the earthquake struck and damaged most severely:

$$KOBE_t = \beta_0 + \beta_1 JPN_t + \beta_2 JPN_{t-1} + \beta_3 KOBE_{t-1} + \varepsilon_t \quad (1)$$

where $KOBE_t$ is the logarithm of GRP per capita for the City of Kobe at t, JPN_t is the logarithm of GDP for Japan at t. JPN_t and its lagged variable intend to control the macroeconomic trends, such as changes in inflation, interest rate, currency exchange rate, economic booms (bubble economy of mid and late 80's) and slumps (after early 90's), etc., of Japan. The second model is for the Hyogo Prefecture, which includes the City of Kobe and other cities and municipalities hit by the earthquake:

$$HYOGO_t = \beta_0 + \beta_1 JPN_t + \beta_2 JPN_{t-1} + \beta_3 HYOGO_{t-1} + \varepsilon_t \quad (2)$$

where $HYOGO_t$ is the logarithm of GRP per capita for the Hyogo Prefecture at t. As seen above, the basic structure of equation (2) is exactly the same as the one of equation (1). One of the assumptions here to use JPN_t and its lagged variable in the right hand side of equations (1) and (2) is that the earthquake did not impact on the Japan's GDP per capita. If it did, the inclusion of JPN_t in the right hand side may lead to the violation of residual distribution assumptions, and the models require some countermeasures, like instrumental variable or others, for estimation. In order for testing whether or not the earthquake impacted on Japan's GDP, the third model is constructed:

$$JPN_t = \beta_0 + \beta_1 JPN_{t-1} + \varepsilon_t \quad (3)$$

This form constitutes a univariate time-series model, a variant of the above linear auto-regressive lag model.

In order to test the hypothesis that the earthquake has some impact on the respective long-run growth path, dummy variables for the year when the earthquake occurred and subsequent years are added to each model.

3.3 Data and Period

The time series data used for the analysis was extracted from the Cabinet Office of Japan's web site.[1] The data are "National Accounts" for GDP, and "Prefectural Accounts" for GRPs. Since the Japanese government started collecting and releasing these statistics using the Systems of National Accounts (SNA) from 1975, the consistent time series data are also from 1975. Thus, the period of analysis for this study becomes during 1975 and 2006, which is the latest data point. Note that all the data that the Japanese government publishes are fiscal year base, and the Japanese fiscal year starts from April and ends at March of the next year. This implies that while the Kobe earthquake occurred in January, 1995, it is within the fiscal year 1994.

All the data are converted to the 2000 constant price. An overview of the trends of three variables, *JPN*, *HYOGO*, and *KOBE* are shown in Figure 1. The Japan's GDP per capita had steadily increased throughout the period, while the rate of growth had slowed down a bit after 1990, when the bubble economy bursted, and has regained some speed after 2002. Hyogo's GRP per capita is mostly lower than Japan's, and the rate of growth appears to parallel to the Japan's till 1993. The fiscal year 1994, when the Kobe earthquake occurred, shows a small dent, whereas 1995 and 1996 show sharp increases. At the same time, after 1997, the Hyogo's trend looks downward, until it turned to upward after 2004. The Kobe's growth path mirrors the Hyogo's, but the values are generally larger than not only Hyogo's but also Japan's. The dent of 1994 for Kobe is much larger than the Hyogo's, and the increase in 1995 is also higher. Unlike Hyogo's, however, Kobe seems not to turn the trend upward until 2006. This may be resulted partly from population changes in the City of Kobe after the earthquake.

Figure 1. Trends of per capita GDP and GRPs

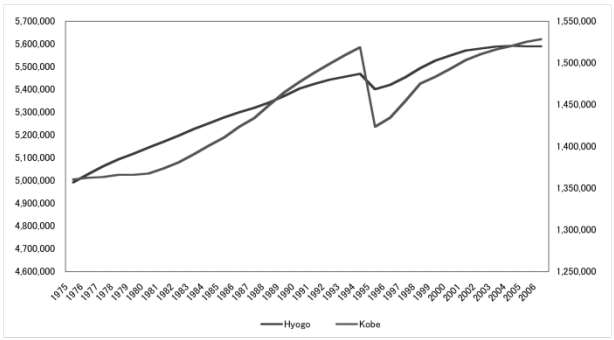

Figure 2. Trends of Population for Hyogo Prefecture and City of Kobe
(right vertical axis for Kobe and left vertical axis for Hyogo)

As displayed in Figure 2, after the sharp decline of its population in 1994, Kobe had struggled to regain its population to the pre-earthquake level until 2002, and the population increase has continued afterwards. On the other hand, the Hyogo Prefecture, including the City of Kobe, also lost their population in 1994, but it was not as sever as Kobe did in terms of the rate of change. Hyogo returned to its previous population level in 1998, and after 2003 their population trends appear flat. With these casual

[1] http://www.esri.cao.go.jp/jp/sna/toukei.html#kenmin (in Japanese)

observations, the effects of the Kobe Earthquake are apparent: a sharp negative impact in 1994, positive ones in the following few years, and some slumps afterwards until picking up the paces in the mid 2000s. We estimate these trends statistically in the following section to see whether or not this observation is supported statistically.

4. HYPOTHESIS TESTS AND ANALYSIS

In this section, a series of hypothesis tests are carried out to investigate whether or not the Kobe earthquake's total impact made statistically significant influence on the respective economy's long-run growth path. In addition, with the estimated long-run growth model, the earthquake's total impacts are measured for the period after the occurrence.

4.1 Hypothesis Tests

First, we test the hypothesis whether or not the earthquake had any statistical impact on the long-run growth path of Japanese's economy. Equation (3) above was estimated using the Japan's GDP data during 1976 and 2006[2]. Dummy variables for each year after fiscal year 1994 are included to see their statistical significance. The estimation results are shown in Table 1 below.

Table 1. Significance of the earthquake on GDP (JPN as dependent variable)

Variables	Model 3-1	Model 3-2	Model 3-3	Model 3-4	Model 3-5
Dependent variable	JPN	JPN	JPN	JPN	JPN
Constant	1.073*		1.165*	1.194*	1.307**
	(0.566)		(0.582)	(0.585)	(0.602)
JPN (t-1)	0.897***	1.002***	0.888***	0.885***	0.873***
	(0.056)	(0.002)	(0.057)	(0.058)	(0.059)

			(0.120)		(0.121)
D95				0.106	0.116
				(0.121)	(0.122)
Number of observations	31	31	31	31	31
R-squared	0.90	0.90	0.90	0.90	0.90
BIC	-20.70	-20.61	-19.32	-19.40	-18.11

Standard error in parentheses.
* Significant at the 10% level.
** Significant at the 5% level.
*** Significant ar the 1% level.

Models 3-1 and 3-2 do not include any time dummy variables. Model 3-1 includes the constant term, β_0 in the above equation (3), and it is barely significant at 10% revel. While R-squared for both models are about the same, the value of BIC for Model 3-1 is slightly better than 3-2's, the models with time dummy variables include the constant, indicating a moving average process. Models 3-3, 3-4, and 3-5 include time dummy variables in different ways[3]. As seen above, however, these time dummy variables for the fiscal years 1994, when the earthquake occurred, and 1995, when the reconstruction activities were at their full swing, are not statistically significant in any of three models. Also, the inclusion of these dummy variables either does not improve the values of R-squared and of BIC. This is an indication that the Kobe earthquake did not influence and did not have any impacts on the long-run growth path of Japan. This also implies that the use of Japan's GDP as an independent variable to control macroeconomic influences in equations (1) and (2) can be rationalized, and does not cause the endogeneity problem.

Secondly, we estimate equation (2) to test the statistical significance of the earthquake impact on the Hyogo's economy. The results are shown in Table 2.

Table 2. Significance of the earthquake on GRP (HYOGO as dependent variable)

Variables	Model 2-1	Model 2-2	Model 2-3	Model 2-4	Model 2-5
Dependent variable	HYOGO	HYOGO	HYOGO	HYOGO	HYOGO
Constant	0.065				
	(0.044)

				(0.030)	
D96					0.057*
					(0.030)
Number of observations	31	31	31	31	31
R-squared	0.97	0.97	0.97	0.98	0.98
BIC	-60.59	-61.13	-60.21	-60.80	-61.40

Standard error in parentheses.
* Significant at the 10% level.
** Significant at the 5% level.
*** Significant ar the 1% level.

The results of Models 2-1 and 2-2 illustrate no statistical significance of constant term; thus the following estimations with time variables do not include the constant term in their models. The estimation with time dummy variables displays the mixed results. The dummy variables for the fiscal year 1994 when the earthquake occurred and the following fiscal year, 1995, are not statistically significant with large margins, while the dummy variable for the fiscal year, almost two years after the earthquake is statistically significant at 10% level with a small and positive coefficient value. The value of BIC with the 1996 dummy variable is marginally better than the model without time dummy variables. The interpretation of these results requires some caution. This anomaly of the fiscal year 1996 may or may not be caused by the earthquake, since we cannot distinguish between the impact from the earthquake and related activities, such as recovery and reconstruction activities, and the other influence specific to the Hyogo Prefecture in the current model structure. The coefficient for the 1996 dummy variable is positive and relatively small.

[2] 1975 data was lost due to the lag structure of the model. Thus, the number of sample for this and subsequent models becomes 31.

[3] Time dummy variables after the fiscal year 1996 were also implemented and estimated, but they appeared not statistically significant at all, either included separately or all together. Thus, the results for these cases are not included in this table. This tendency also found in the following HYOGO and KOBE cases; therefore, the tables below do not include those results, either.

This means the slight increase in the Hyogo's GRP, departing from the long-run growth path. If it were resulted from the earthquake related activities, however, this result implicates that the influence from such activities would have required some time, in this case around two years, to materialize in a larger region, the Hyogo Prefecture. Or, maybe, the total impact from the earthquake would have absorbed in a larger economy, canceling out between the negative impact from destructions and damages and the positive impact of demand injections through recovery and reconstruction activities for the fiscal years 1994 and 1995. Again, it is difficult to conclude how this positive departure in the fiscal year 1996 emerged.

Finally, the results of Kobe's model (1) are summarized in Table 3. Based on the Models 1-1 and 1-2, the constant term is not included in the following analysis, since the constant term in Model 1-1 is not significant and the model without constant term, Model 1-2, has the better BIC. Models 1-3 and 1-4 reveal that the fiscal years 1994 and 1995 are statistically different from the long-run growth model[4]. The coefficients are negative for 1994, when the earthquake occurred, and positive for 1995. These signs are consistent with the trend observation above and with disaster theory that the destructions by earthquake lead to the negative impacts on the economy, while the demand injection of recovery and reconstruction activities can create some positive impacts later on.

Standard error in parentheses.
* Significant at the 10% level.
** Significant at the 5% level.
*** Significant ar the 1% level.

We also tested the Model 1-5, which includes both the dummy variables of 1994 and 1995. The result indicates a better BIC value and the largest R-squared among the models we estimated. All the coefficients become statistically significant at 1% level, and the sign and size of them are consistent with the previous models. Unlike the Hyogo's case, it is less ambiguous that why 1994 and 1995 are dissociated with the Kobe's long-run growth path; these negative and positive departures are considered as the result from the occurrence of the Kobe Earthquake. However, if this is the case, we may encounter two potential problems: 1) the size of negative impact in 1994 is about a half of the 1995's positive impact, implying that the earthquake created net positive impact, i.e. net gain, in Kobe; and 2) the impacts of the earthquake and of the recovery and reconstruction activities appear lasted only two years. These problems are investigated in the following sub-section by measuring the total impacts of the earthquake using the time-series model.

4.2 Measuring the Impacts of the Kobe Earthquake

The total impact of the Kobe Earthquake is measured based on the model estimated above. Since Model 1-5 in Table 3 has the highest R-squared and the best BIC value, it is employed for this task as follows:

$$KOBE_t^{est} = b_1 JPN_t + b_2 JPN_{t-1} + b_3 KOBE_{t-1} + b_4 D_{94} + b_5 D_{95} \quad (4)$$

In order to measure the earthquake's impacts, it is often suggested to compare between the values with the earthquake, i.e. the actual GRP, and the projected values as if the earthquake never occurred; then, the differences between them become the changes made by the event. In this context, we can just compare the actual values with the fitted values based on equation (4) excluding two dummy variables, D_{94} and D_{95}, to calculate the impacts, as follows:

$$KOBE_t^{est} = b_1 JPN_t + b_2 JPN_{t-1} + b_3 KOBE_{t-1} \quad (5)$$

However, the equation (5) includes a lagged variable, $KOBE_{t-1}$, which represents the actual Kobe's GRP values containing the earthquake's influences after its occurrence. This may create a causality problem--for example, the projected 95 value is derived based on equation (5) using the actual 1994 GRP value, $KOBE_{94}$, including the earthquake's influence. Therefore, the projected 1995 GRP for KOBE without earthquake influences should not adopt the actual 1994 GRP value; rather, it should employ the estimated 1994 GRP, $KOBE_{94}^{est}$, in equation (5). This modifies the equation (5) to become as follows after 1995:

$$\left.\begin{aligned} KOBE_t^{est} &= b_1 JPN_t + b_2 JPN_{t-1} + b_3 KOBE_{t-1} \quad until\ 1994 \\ KOBE_t^{est} &= b_1 JPN_t + b_2 JPN_{t-1} + b_3 KOBE_{t-1}^{est} \quad after\ 1995 \end{aligned}\right\} \quad (6)$$

In this way, the impacts of earthquake are excluded in the projected values after 1994. The projected 'no-earthquake' values are compared with the fitted values derived using equation (4). This is because the residuals of Model 1-5, difference between actual and fitted values, include some other unknown disturbances specific to the City of Kobe than macroeconomic influences controlled by the Japan's GDP and its lagged term and the impacts of the earthquake controlled by dummy variables. Hence, the comparison between the fitted values and the projected 'no earthquake' values counts out those unknown disturbances.

The trends of actual (in blue), fitted (in red), and projected 'no-earthquake' cases (in yellow) are shown in

[4] Dummy variables for all other years after 1996 are not statistically significant.

Figure 3. The yellow trend line of no earthquake case departs from the red line of the fitted trends at 1994, when the earthquake occurred. The earthquake impact of 1994 is negative, as indicated with the dummy variable for 1994, D94 in equation (4). In the mean time, from 1995, the fitted values are greater than the no-earthquake ones till 2003, indicating the positive impacts, potentially from the demand injections of recovery and reconstruction activities within the City of Kobe. These positive impacts appear larger during 1995 and 1996 and gradually declining afterwards. After 2004, however, the difference becomes negative, implying the Kobe's economy is not performing well as the long-run growth path predicted. These last three years' negative impacts might be seen as a realization of the long-run effects caused by the earthquake, by which the Kobe's economy has become slump after the completion of reconstructions exogenously boosting the economy. These observations have to be investigated more closely and carefully with the empirical events and activities to make more insightful analysis.

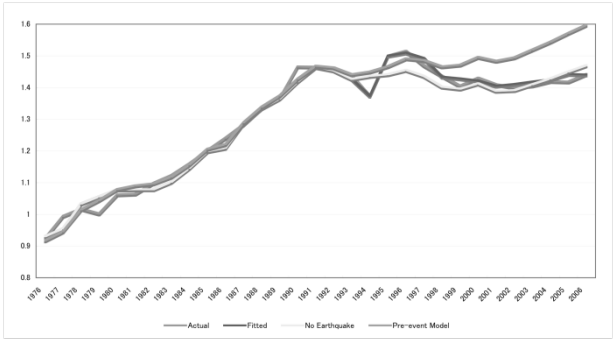

Figure 3. Comparison of Trends with and without the Kobe Earthquake
(logarithm of per capita GRP; 2000 constant price)

Figure 3 also accompanies another trend line in green. This trend is derived based on the estimated equation (1) but using only the time series data during 1975 and 1993. This projection is made because a usual way for the comparison between trends before and after an event or policy is to compare the projected trend based on the trends before the event with the actual trends after it, in order not to take into account the structural change caused potentially by the event. The estimation results of equation (1) with 1975-1993 data are displayed in Table 4 below. The constant term is again not statistically significant as in Model 1-6, so the final model (Model 1-7) does not include it. The sign of three coefficients in Model 1-7 are the same as ones in 1-5, while the size of them is smaller in Model 1-7 than ones in 1-5, indicating a relatively smooth trend. In fact, the trends of the Kobe's GRP per capita during 1975 and 1993 seem to have lesser fluctuations except the ones after 1990, when the bubble economy collapsed.

The projected trend based on Model 1-7 uses the similar data conversion after 1995 to the above case in equation (6), in order for counting out the earthquake's influences. The differences between the projected trends in green and the actual values after 1994 present quite large and increasing gaps. The initial impacts are negative one in 1994, like the previous result, and positive ones for a few years after 1995, while the positive impacts are short lived and the gap becomes negative and larger as time passes by. The projected trend line based on the pre-earthquake trend becomes upward after 2002, reflecting the trend of Japan's GDP included in the right hand side of Model 1-7.

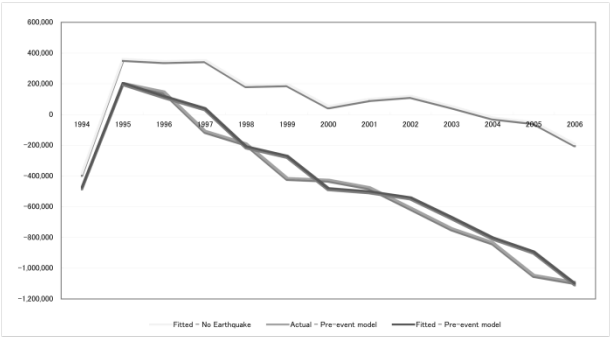

Figure 4. Comparison of Calculated Impacts
(difference in GRP; million yen in 2000 constant price)

These estimation results manifest considerable discrepancies in the measurement of the earthquake's total impacts, shown in Figure 4. The results based on Model 1-5 show the extended period, around nine years, of positive gains caused by recovery and reconstruction activities; on the other hand, the results based on Model 1-7, estimated using only the pre-earthquake period, present a short period of relatively small positive gains and the steady downward trends afterwards. The comparison of the estimated earthquake impacts over time is summarized in Table 5. The sum of estimated impacts, total net impact, during 1994 and 2006 becomes positive with Model 1-5, around 1 trillion yen, while it becomes negative with Model 1-7, about 6 trillion yen. With closer observations, both models derive the similar initial negative impact in 1994, around 400 to

470 million yen; the following positive gains from demand injections are quite diverse, ranging from about 1.8 trillion yen by Model 1-5 to around 360 million yen by Model 1-7--5 times difference; similarly, the long-run effects (losses) look contradictory, between 260 million yen loss by Model 1-5 and almost 6 trillion yen loss by Model 1-7--23 times separation.

Table 5. Comparison of Estimated Earthquake Impacts (million yen in 2000 constant price)

	Fitted - No Earthquake Model 1-5	Actual - Pre-event model Model 1-7	Fitted - Pre-event model Model 1-7
1994	-386,832	-474,010	-474,010
1995	361,370	204,745	204,745
1996	347,230	150,160	119,333
1997	353,664	-105,790	40,724
1998	191,053	-187,848	-206,814
1999	197,620	-412,783	-269,595
2000	52,479	-423,285	-479,035
2001	100,185	-472,264	-499,138
2002	120,476	-605,282	-540,081
2003	53,229	-740,395	-666,972
2004	-19,407	-831,489	-799,394
2005	-49,729	-1,043,062	-891,542
2006	-194,001	-1,089,740	-1,098,206
Total	1,127,336	-6,031,042	-5,559,985
Initial Impact	-386,832	-474,010	-474,010
Positive Gains	1,777,305	354,906	364,801
Long-run Losses	-263,137	-5,911,938	-5,450,777

How are these discrepancies caused? One potential explanation is that Model 1-5 includes the post-earthquake data of Kobe (1994-2006) for the coefficients estimation of long-run growth path, while Model 1-7 does not. This implies if any structural change specific to the Kobe economy arose after the earthquake, Model 1-7 cannot take into account, whereas Model 1-5 can. It has been reported that the earthquake's catastrophic destructions resulted some companies' bankrupt, some other companies' moving away from the Kobe area, other companies' changing the business practices, or some new companies' replacing the old and damaged ones, etc. These restructuring of the Kobe economy surely caused the structural change and interindustry relationships. In addition, when companies restore their old and damaged equipments and facilities, they might have replaced the damaged ones with newer and more sophisticated ones, causing technology update (Okuyama, 2003). The technology update alters productivity, influencing the production function of the Kobe economy. These changes are certainly economic consequences of the Kobe earthquake and specific to the Kobe economy. Therefore, while the estimates based on Model 1-5 sound more plausible, and appear consistent with the empirical observations and other studies (for example, Okuyama et al., 1999), it may be superficial not taking to account the long-run effects. If the estimate based on Model 1-7 is the case, the total impacts and long-run effects of the Kobe earthquake may be much larger and severer than what we derived previously with short-run models.

5. CONCLUSIONS

This study aimed to measure the total impacts of the Kobe Earthquake using the empirical time series data. Based on the econometric analyses, the estimated impacts have the negative initial impact in the year the earthquake occurred, followed by the positive gains resulted from the demand injections for recovery and reconstruction activities, and leading to the negative long-run effects due to the changes in economic structure of Kobe. In addition, the results appear consistent with the conventional disaster theory and other studies. Particularly, the estimation results of equations (1), (2), and (3) in Tables 1, 2, and 3 may potentially prove the Albala-Bertrand's (2007) claim that the economic impact of a disaster may not affect negatively the macro-economy in both short-term and long-term, and rather may concentrate on the local economy. Our results clearly show that earthquake's impacts on the long-run growth path are statistically significant only for Kobe, and not significant with Hyogo or Japan, larger economies.

These results are contradictory to the findings in other studies that analyze interregional impacts of disasters (for example, Okuyama et al., 1999 and Okuyama, 2010), suggesting that sizable impacts spill over to other regions through interregional and interindustry relationships. It turns out that this is exactly the evidence that the measurement of impacts using macroeconomic indicator, i.e. GDP or GRP, can derive only the net impacts, the sum of negative and positive impacts. The larger the economy becomes, the more these negative and positive impacts may offset each other and may become insignificant. For the further and more detailed analysis of the aftermath and how a disaster affects economy, net impact needs to be disaggregated to negative and positive impacts separately. This is because negative impact and positive gain affect the economy in many different ways, and because the extent of their effects may differ by its significance and over space. Careful examinations of these disaggregated impacts will provide important and useful information for decision making on preparedness and mitigation strategies for the future catastrophes and on recovery and reconstruction strategies of the next calamity.

This disaggregation of total impacts to negative and positive ones requires also to consolidate this line of empirical study for the bench mark with other economic evaluation models, such as input-output (I-O) model and computable general equilibrium (CGE) model and the standardized database of damages and losses caused by an earthquake and recovery and reconstruction activities. These evaluation models can estimate negative and positive impacts separately (or all together), and can disaggregate the impacts also over space and/or by income group, for example. At the same time, the accuracy of estimation by these evaluation models depends essentially on the accuracy of the input data--data of damages, losses, and recovery and reconstruction activities. As discussed above, in disaster research community, even the definition of damages and losses are vague. We need a standardized definition and

framework to collect the damage and loss data consistently, so that comparative study of disaster impact can be carried out and the historical data can be accumulated. In addition, as Greenberg et al. (2007) suggested, the standardization of evaluation models is also an urgent task. Of course, empirical measurement of economic impacts like this study should be also carried out for major disasters to investigate the long-run effects, which may be quite different from the short-run impact estimation.

EARTHQUAKE PREPAREDNESS AND BCM IN JAPAN

Shinichi Okabe

Management Science and Technology, Graduate School of Engineering, Tohoku University
shinichi.okabe@tokiorisk.co.jp

Abstract: According to the Japanese Government Cabinet Office Survey 2010 on Disaster Management and BCM, among companies affected by any disasters, 60 % of them have been affected by earthquake, followed by 30% by flood. For last 70 years Japanese Government and private companies have been tackling natural disasters as high priority. In contrast, other country, like UK shows a very different picture. The UK Government's National Risk Register 2010 shows that attacks on transportation and crowed places, pandemic human disease, and severe whether come high in their frequency and impact assessment of the risks for the country. Those differences are reflected in BCM approaches in two countries. In Japan, companies tend to consider BCP for large disaster measures. Many companies approach BCM along pre-disaster measures for the facilities. On the other hand, the UK approach seems to focus more on ordinary business disruption incidents. This paper reviews Japan BCM approaches and earthquake preparedness. If a severe earthquake totally destroys key facilities, reasonably quick resumption of business would not be possible. Pre-earthquake measures are critical to minimize losses to the extent that BCM strategies would be effective to resume operation at the expected time frame.

1. INTRODUCTION

The Cabinet Office of Japanese Government has been conducting the surveys on Business Continuity Management(BCM) and Disaster Management(DM) in the private sector since 2008. About 1000 to 1500 companies from wide rage of industries have participated in the surveys. These reports show the current status of implementation of BCM and DM in Japan. This 2010 report tells 19% of the companies had been affected by disasters in the past. The ratios vary by company size as large company group (large G) 35%, middle company group (middle G) 19%, small company group (small G) 14%. Among those, 60% has been affected by earthquake, 33% by flood and 10% by fire. It is also noted that large G is more affected than other two groups, large: 78%, middle: 68%, small: 43%).

2. DISASTER MANAGEMENT PLAN AND BUSINESS CONTINUITY PLAN

Japan is a disaster prone country. Private companies have been spending resources to enhance resiliency for natural disasters and accidents. The 2010 survey report shows 54% (*)of companies have implemented Disaster Management Plan (DMP). There is a large difference by company sizes. 80% of large G have implemented DRP but only half of companies in middle G and small G. (* This ratio includes companies which are preparing DRP.)

The implementation of Business Continuity Plan (BCP) ratios(*) also vary by company size groups; large G: 58%, middle G: 27%, small G 22%. Between 2008 and 2010, DMP rations have not much changed but BCP ratios have increased in large G by 23%, middle G by 11%, small G by 10%. This indicates that companies which have already implemented DMP have been proceeding into BCP implementation. The companies which have not implemented DMP have not much changed.

The top disasters which those companies have prepared for by DRP are earthquake (88%), fire (78%), and flood (31%). The top disasters which are prepared for by BCP are earthquake (57%), fire (42%), and flood (20%). This clearly shows earthquake is the top concern

There are large differences in implementation of DMP and BCP in the main industries. Figure 1 shows DMP and BCP ratios of eight industries. There is correlation between implementation of DRP and BCP. Electricity and Gas come top by far and IT/Communication and Financial / Insurance follow. Retail is the lowest among those eight industries.

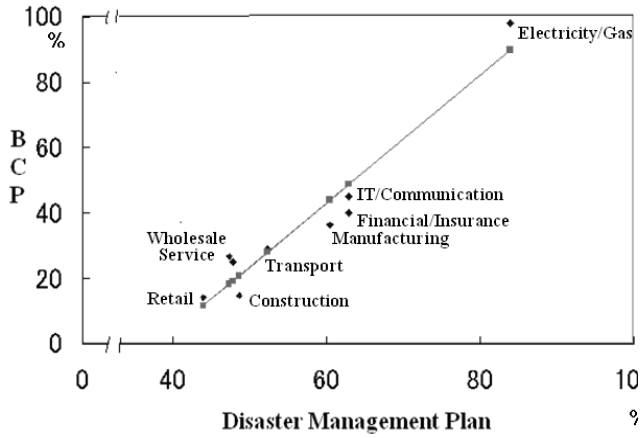

Figure 1 DRP and BCP implementation

The Cabinet Office 2008 survey shows high ratio of the companies throughout the industry which do not know BCP. The Figure 2 shows reverse correlation between DRP implementation and BCP recognition. Retail show lowest DRP implementation ratio and it show highest ratio of "Do not know BCP" The higher is the DMP implementation ratio, the lower the 'Don't know BCP" ratio. This indicates introducing DMP leads to knowledge of BCP. In other words DMP can be regarded as the grounding for BCP implementation.

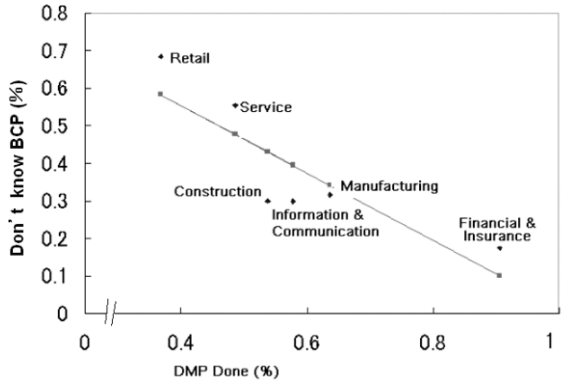

Figure2 DRP and BCP implementation

3. BCP IMPLEMENTATION STAGES OF MUNUFACTURING INDUSTRY

Based on the survey questions, BCP implementation processes are categorized in four stages; 1st: DRP done, 2nd: BCP Recognized, 3rd: BCP done and 4th: BCP done with BIA. This categorization assumes the implementation process that companies which implemented DRP would move to BCP recognition, BCP implementation and to BCP with BIA. BIA stands for Business Impact Analysis which is one of important key process during BCP planning in order to analyze potential impact to organization by disaster and identify the critical functions which should be resumed at highest priority to survive disasters.

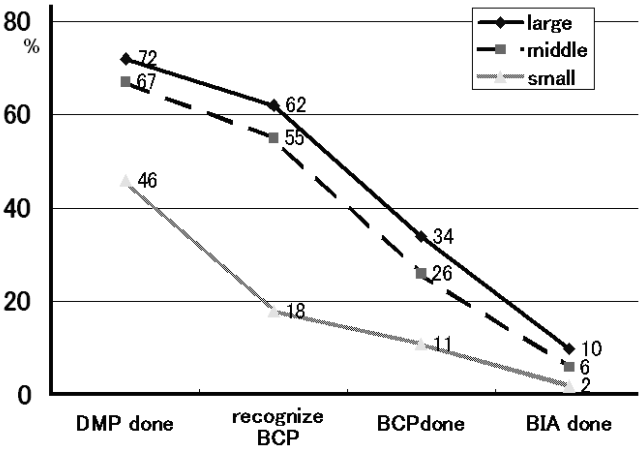

Figure 3 BCP implementation stages

The Figure 3 shows implementation ratios in the above 1st to 4th stages of manufacturing companies. It shows trends by the three company groups. The two graph lines of large and middle Gs show very similar trends but the small G's line is apart down and from the above two.

DRP is implemented by 72% of large G, 67% of middle G but only by 46% of small G. The 2nd / recognized BCP ratio is down from 1st / DRP done by about 10 points in large and middle G, but only 1/3 of small G. The 2nd /BCP implementation ratios from 3rd /BCP done of large G and middle G go down to half but to 1/4 in small G.

In order to promote BCP introduction, further analysis is needed to review the causes why there are such large gaps between ratios of 2nd / recognized BCP and 3rd / BCP done in all three groups.

Further more, among companies which answered that they have done BCP, only 1/3 of large G (10%), 1/4 of middle G (6%) and 1/5 of small G (2%) conducted BIA. BIA is a fundamental and required process during BCP planning. In other words, the companies which have not conducted BIA are not considered to have implemented BCP in the strict sense from BCP guidelines published by Cabinet Office of Japanese Government or major foreign BCM standards.

4. ANTI-EARTUQUAKE MEASURES AND BCP

The surveys ask questions on what kinds of earthquake damage mitigation measures are done, such as tip resistant measures for office equipment, anti-earthquake machinery/equipment fixation, anti-seismic reinforcement, compliance with seismic building code, relocation to seismic resistant building.

Those anti-earthquake measures have been done

traditionally through DRP. The Figure 4 shows implementation ratios of those anti-earthquake measures in five DPR and BCP implementation stages. In Figure 4, one stage before DRP done is added as no DRP which means DRP is not implemented.

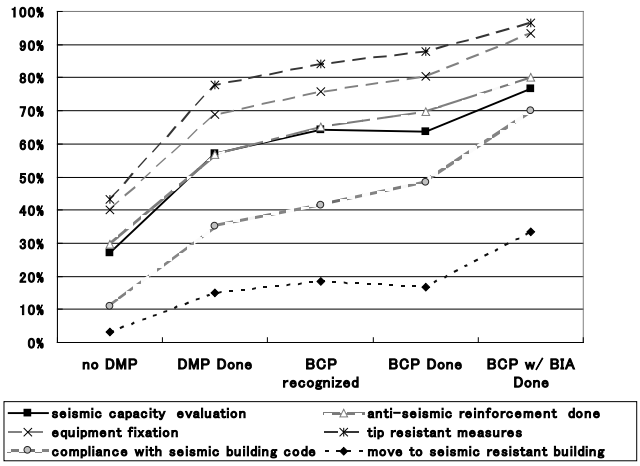

Figure 4 Anti-earthquake measures and BCP stages

The six graph lines of anti-earthquake measures show very similar trends. The implementation ratios of those measures become larger along the BCP stages advance. It is noted that the order of ratios is the same in six stages and it is considered that this would be an order of easier feasibility of those six measures. The companies start with implementing economically easier measures such as fixation of office equipment or machinery. The anti-seismic reinforcement measures of the buildings or complying with seismic building code are effective but require funds and time.

There are larger increases noted between stages between no DRP and DRP done and stages between BCP done and BCP with BIA than other two stages. In the last stage of BCP with BIA, 70% of companies have complied with new building code, which is a very significant measure for earthquake preparedness.

5. CASE STUDIES

Based upon the current status of DRP and BCP, are companies able to survive major earthquake or other natural disasters if they have implemented DMP and BCP? My answer would be "Maybe yes, if they are lucky"

The writer interviewed small to middle size companies which were damaged by earthquakes occurred in Niigata Pref. in 2004 and 2007. There are two successful recovery cases, one is Japanese sake (rice wine) brewery and another is a regional general hospital.

5.1 Japanese sake brewery

This company was severely damages as 70% of their buildings were totally collapsed and about 10,000 sake bottles waiting for shipment were broken. Fortunately, the earthquake hit on holiday and there were no injuries because nobody was working in the brewery. Top executive said that employees would have been dead or injured by collapsed buildings if the earthquake had hit during working hours. The building of bottling lines which was built in compliance with new building code withstood the earthquake without major damage.

The key infrastructure has been restored within shorter period of time than other affected area hit by the same earthquake. The company did not have alternate option for water supply but it was recovered within 20 days. The company was able to resume partial (less than 20%) production within a month.

The executive who was interviewed emphasized, from his learned lessons, that the critical process should be protected to be able to recover even if entire earthquake reinforcement measures are not financially feasible to the company.

5.2 A regional general hospital

In a regional hospital case, the main buildings (except one old one) were complied with seismic building code and not severely damaged. But walls fell, pipes above ceilings were broken and upper floors were flooded. Medical equipment fell and tipped over. The emergency generator which was supposed to run for two days with stored oil supply stopped after having operated for only 40 minutes. It was because that cooling water supply was cut off by breakage of pipes from the water tank. This unexpected electricity failure forced hospital staffs to manually support breathing of patients on a respirator.

But there were fortunate factors; the earthquake hit in the early evening on Saturday when there were not any scheduled operation and dialysis. And there were more staffs at the shift change from day to night shift. More than 200 hospitalized patients were safely transferred to lower levels by the trained hospital staffs. They had to temporarily rest on the floor until they were transferred to other hospitals. The hospital successfully managed keeping safety of patients and providing increasing out patients injured by the earthquake under such a severely disaster emergency situation.

From reviewing its recovery process, the hospital financially suffered substantial revenue reduction in addition to the heavy burden of restoration costs. The buildings were not severely damaged but the damage to equipment and rooms are substantial and hospital was not usable until repaired.

After nine day, outpatient treatment and dialysis were resumed. After 11day, half of hospitalized patients came back. But it took almost one month to resume operation because of the delayed oxygen equipment restoration. The operation is one of important revenue source for the hospital.

In addition, the hospital owns an adjacent nursing facility, which was a building with the foundation installed with seismic isolation rubber. It was proved very effective in this earthquake that this building was not damaged and internal equipment did not fall.

6. CONCLUSIONS

6.1 Disaster Management Plan

As shown in the above two case studies, the current status of DRP and BCP do not seem to sufficient for survival for middle to small companies. The traditionally disaster management measures are linked to premises and facilities (or mainly tangible properties such as building and equipment) As the above two cases show, critical operation should be protected or its expected damage should be reduced to the extent that resumption should be feasible within reasonable short time or acceptable period to the bottom line of the company. Therefore anti-earthquake measures such as compliance with anti-earthquake building codes are very critical. Such measures are absolutely necessary and without those measures, survival cannot be expected. For middle to small companies, such anti-earthquake measures are very costly and many companies cannot afford them. As long as such risk remains, the company has to make necessary measures through mid to long term plans.

6.2 Business Continuity Plan

The traditional Disaster Management Plan focuses on safety of human being and protection of assets. Even such measures can protect people and assets, they are not sufficient to protect business operations. The critical factors to protect and to resume business operations are not only tangible but also intangible and not only internal assets but also external services such as infrastructure and key parts/ material supplies. The current BCP which have been implemented by Japanese companies tend to be carried out in extension of DRP which have been closely tied with premises and locations. BCP requires out of location measures if there are no viable alternative options for business recovery within own premises.

BCP aims to protect business operation by implementing business continuity measures. Such measures are not limited to own properties. There are various key factors of critical functions depend. For example, among important infrastructure services, electricity is normally restored sooner than other services. But water supply needs longer period to restore water piping repair. The above sake maker case shows water supply was their bottle neck for recovery as the company did not have alternative source of water supply. But they were fortunate that water recovered to be able to resume partial operation within a month. Another food maker which was severely affected by the earthquake drilled a well for back up water supply within its premise.

In the hospital case, an emergency generator unexpectedly stopped due to lack of cooling water supply only after it ran for only 40 minutes. But the emergency generator system including cooling water supply pipes were damaged by earthquake. This was a blind spot. Even back up systems are installed, it is necessary to evaluate if such systems would survive disaster and could operate at disasters. And oxygen supply was critical to operations at hospital. The oxygen restoration substantially affected hospital financial bottom line.

In both cases, the recovery works by top managements and employees at the time of emergency deserve the praised for their efforts. But those two organizations did not implement BCP and did not have pre-measures which enabled to shorten the recovery time. As preparedness for disasters, DRP and BCP have common and overlapping factors. And if both DRP and BCP are coordinated for under the common goals, more effective measures would be feasible to minimize losses and damages.

QUANTITATIVE RISK ANALYSIS APPROACH FOR BCP (BUSINESS CONTINUITY PLANNING) DECISION MAKING AGAINST EARTHQUAKES

Satoru Nishikawa

Director of Regional Planning, Ministry of Land Infrastructure Transport and Tourism, Japan
nishikawa-s2iv@mlit.go.jp

Abstract: Business continuity is now being regarded as an important factor in management of enterprises. In order to draw BCP (Business Continuity Plan) for enterprises, and for the top executives to decide on necessary measures and investments, there is a need for a quantitative risk analysis method to evaluate their risk. Most of the enterprises are not stand-alone; they depend on Supply Chain (SC), for their operations. The business interruption time is a crucial factor in terms of economic loss. Two model enterprises each with three factories connected through series and parallel supply chain patterns are applied in comparing and analyzing the risk. The annual exceedance probability of business interruption time of these enterprises are calculated and compared. The business interruption time risk of series supply chain is greater than the parallel. Three alternative options, by provision of redundant nodes, for decreasing the risk are proposed. The annual exceedance probability of business interruption time of these location and supply chain types are calculated and compared. The options are examined from the viewpoint of BC Planning. This risk analysis method is proven to be realistic and functional. Through combining these factors a realistic risk analysis method for evaluating business interruption is proposed and is proven to be functional. This method may be applied for strategic location planning of supply chain dependent enterprises who wish to minimize their risk and to justify the necessary investments.

1. INTRODUCTION

Japan is facing imminent threats of possible large scale earthquakes such as the Tokai, the Tonankai & Nankai, the Japan Trench & Kuril Trench Type and the Tokyo Metropolitan Area Direct Beneath Earthquakes. All of these earthquakes are foreseen to occur within the next thirty years' time span and the economic damages from these earthquakes are feared to be gigantic. The economic damage by the 1995 Hanshin-Awaji (Kobe) Earthquake was estimated as 2% of the GDP of Japan, which did not seriously affect the Japanese economy and it was capable of providing sufficient capital for the recovery and reconstruction of Kobe. Whereas the economic damage by the Tokyo Metropolitan Area Direct Beneath Earthquake is estimated to claim approximately 1/5 to 1/4 of GDP, which may degrade the Japanese economy and bring socio-economic stagnation. How to minimize this economic damage by preventive measures? This is the challenge that we face and it is the race against time.

In April 2006, the Central Disaster Management Council chaired by the Prime Minister decided the Earthquake Disaster Reduction Strategy where it aims to halve the estimated human and economic damage within the next 10 years. One of the main pillars for reduction of economic damage is the adoption of Business Continuity Plans (BCP) by enterprises. The strategy calls for all of the large scale enterprises and half of the medium scale enterprises to adopt BCP. There have been many efforts paid to propagate BCP. The Cabinet Office issued the BCP guideline in 2005 and formed committees to encourage trade unions to formulate their own BCP guidelines to meet their characteristics. The Development Bank of Japan started a new low interest loan to encourage enterprises to adopt BCP in 2006. A non-profit organization BCAO was newly established in 2006 as a forum to promote BCP in Japan. Five years have passed; there is a big gap between the strategy and the reality regarding the adoption of BCP.

How can this gap be filled? One solution may be to clearly indicate the benefit of adopting BCP in quantitative terms so that the entrepreneurs who are skeptics may understand the value of BCP and agree to invest for preventive measures for business continuation. This paper focuses on the business interruption time (BIT) as an important factor in decreasing the economic damage from earthquakes and proposes quantitative analysis methods to assist decision making to introduce necessary measures to shorten BIT in case of earthquakes.

2. QUANTITATIVE RISK ANALYSIS METHOD to EVALUATE BIT of SUPPLY CHAIN DEPENDENT ENTERPRISE

2.1 Risks Facing Supply Chain (SC) Dependent Enterprises

Most of the modern enterprises are not stand-alone; they depend on supply chains (SC), for their operations. In

many of the competitive manufacturing industries, the management, for the sake of decreasing the cost of stockpiling and also to respond quickly to changing market demands, is shifting to the "Just in Time" procurement and manufacturing system. This system is based on the assumption that the SC to their factory functions without interruption. Therefore, once the SC is interrupted, they face the immediate risk of halt of operations. On the other hand, business continuity is now being regarded as an important factor in risk management of enterprises.

In the case of the Niigata-Chuetsu-Oki Earthquake on 16 July 2007 in Japan, an automobile engine piston ring manufacturer suffered serious damage. Since this manufacturer had a dominant share, most of the major automobile companies in Japan had to halt their assembly lines for one week, due to the fact that they did not have extra stock of piston rings in their hands. Since it was difficult to identify an alternate supplier for the sophisticated piston rings in a short period, the automobile companies sent their own engineers to this piston ring manufacturer to assist the quick restoration of the piston ring manufacturing lines. This is a typical example of a local disaster affecting production in other locations since they are SC connected. This incident demonstrated the need to consider the supply chain as an important factor in drawing BCP in such enterprises. Similar cases were seen in the October 2004 Niigata-Chuetsu Earthquake and in the 1995 Hanshin-Awaji Earthquake, where the direct damage to the factories hit by the earthquake spread to the enterprises located outside the affected area through the halt of the supply chain of parts and materials.

2.2 Necessity to Evaluate BIT of Supply Chain (SC) Dependent Enterprise

These cases call for the need to develop an earthquake risk evaluation method for business continuity planning of SC dependent enterprise. For such evaluation, multiple locations of the nodes of the SC system and the individual risks of the buildings on these locations need to be combined and considered. Not only the direct material damage by the earthquake to the nodes, but moreover the Business Interruption Time (BIT) of the enterprise is a crucial factor for the survival of the enterprise in the competitive market. The BIT is a crucial factor in terms of economic loss. If an enterprise halts its supply of products over a consumer acceptable timeframe, the consumer will be quickly taken over by rival enterprises and if the business resumption time exceeds a certain limit, the enterprise will no longer be able to return to the previous market. Therefore a method to quantify the BIT of the SC dependent system and to evaluate options to decrease the BIT is needed (Nishikawa et al. 2007).

This paper, proposes a quantitative risk evaluation method of BIT of SC dependent enterprise, and applies to model enterprises based in the Greater Tokyo Metropolitan Area. Also several alternative options to decrease the BIT is proposed and evaluated.

3. STRUCTURE of the RISK EVALUATION METHOD of BIT

There has been previous proposal and study on a method to evaluate earthquake damage risk of an enterprise who possesses a portfolio of multiple building assets in various locations (Fukushima et al. 2002). This method, by generating numerous possible scenario earthquakes (hereinafter earthquake events), estimates possible damage to the individual buildings and by summation of these damages calculates the damage risk of the portfolio. By expanding this methodology, 1) BIT of individual nodes of a SC is calculated according to each earthquake event and 2) by combining the results of BIT of individual nodes according to the supply chain pattern, thus generating event trees, the BIT of the SC dependent enterprise will be obtained.

3.1 Business Interruption Time of Individual Node

BIT of individual node *j* by earthquake event *i* shall be represented as $t_j(i)$ and is defined by equation (1) as follows.

$$t_j(i) = \sum_{k=0}^{4} [\, p_{j,k}(i) \cdot t_{j,k}(i)] \qquad (1)$$

k is the variable representing levels of damage as follows, *k*=0: no damage, *k*=1: slight damage, *k*=2: moderate damage, *k*=3: severe damage, *k*=4: collapse.

$t_{j,k}(i)$ represents BIT of node *j* by event *i* according to level of damage *k*.

$p_{j,k}(i)$ represents conditional probability of $t_{j,k}(i)$.

$p_{j,k}(i)$ is drawn from the fragility curve of individual node *j*.

3.2 Business Interruption Time of Supply Chain

BIT of SC by earthquake event *i* shall be represented as $t_{SC}(i)$ and is defined by equation (2) as follows.

$$t_{SC}(i) = \sum_{l=1}^{N} f[\mathbf{p}_l(i)] \cdot g[\mathbf{t}_l(i)] \qquad (2)$$

l is the variable representing individual end-branches of event trees.

N is the total number of end-branches.

$\mathbf{t}_l(i)$ represents the vector composed from $t_{j,k}(i)$ for end-branch case *l*.

$\mathbf{p}_l(i)$ represents the vector of conditional probability corresponding to $\mathbf{t}_l(i)$.

$f[\cdot]$ represents the conditional probability of occurrence of end-branch case *l* and is defined by equation (3) as a function of $\mathbf{p}_l(i)$.

$$f[\mathbf{p}_l(i)] = p_{1,k1} \times p_{2,k2} \times \cdots \times p_{n,kn} \qquad (3)$$

n represent the number of nodes composing the SC.

$g[\cdot]$ represents the BIT of SC for each end-branch and is a function of $\mathbf{t}_l(i)$. This function is determined by the connection pattern of the nodes of the SC. For a series SC the maximum, for a parallel SC the minimum, is chosen.

Fig.1 shows the outline of evaluation of BIT for each earthquake event. Fig.2 shows the procedure of the proposed BIT risk evaluation method. In order to consider the uncertainties, a Monte-Carlo simulation with ground motion strength and building strength as stochastic variables is applied.

4. APPLICATION to MODEL SUPPLY CHAIN

4.1 Setting of Model Supply Chain

Three nodes located in the Greater Tokyo Metropolitan Area were set as examples. The nodes are, Saitama, Chiba and Yokohama as shown in Fig.3. Based on the previous findings in (Fukushima et al. 2002) and (Sakamoto et al. 2006), the seismic strength of each nodes and BIT by damage level were set as shown in Table 1. Fig.4 shows the two connection patterns of the three nodes, series and parallel, as model SCs.

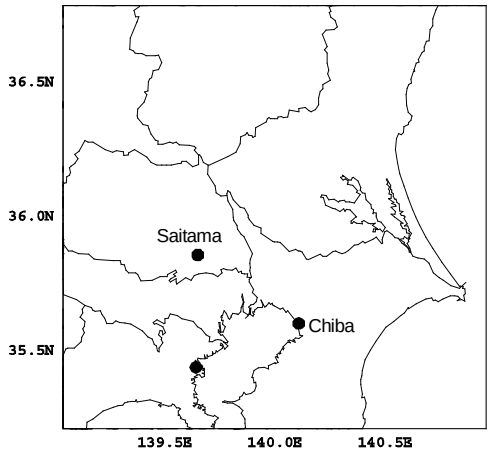

Fig.3 Location of Nodes of SC

Table 1 Fragility Curve and BIT by Level of Destruction

Damage Level	Characteristic Values of Fragility		BIT (day)
	Median (cm/s/s)	Log-normal Std. Deviation	
Slight	200	0.4	3
Moderate	600	0.4	15
Severe	1000	0.4	60
Collapse	1400	0.4	180

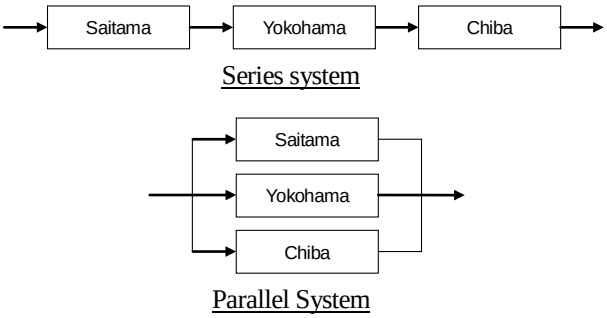

Fig.4 Supply Chain Models

4.2 Setting of Seismic Activity Model

Seismic activity zone model was set according to (Architectural Institute of Japan, 2004). Fig.5 shows the location of seismic sources and the seismic parameters are shown in Table 2. With reference to (Annaka & Yashiro 1998) attenuation relation of ground motion was calculated following the Annaka Model as shown in equation (4).

$$\log a = 0.61M + 0.00501h - 2.203\log d + 1.377 \quad (4)$$
$$d = \sqrt{\Delta^2 + 0.45h^2} + 0.22\exp(0.699M)$$

a stands for maximum ground acceleration, Δ for distance from the epicenter,

h for depth of seismic source, M for magnitude of the earthquake event.

Logarithmic standard deviation representing the variability of the range attenuation was set at natural logarithm 0.5.

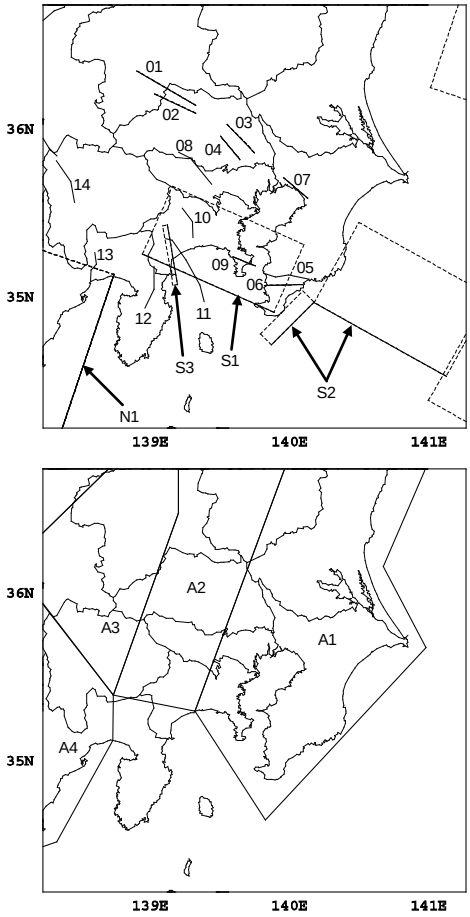

Fig.5 Location of Seismic Sources

Table 2 Parameters of Seismic Sources

Source Number	*Range of M*	Return Period (yr.)	Source Number	*Range of M*	Return Period (yr.)
01	7.0-7.6	1182	02	6.9-7.3	5212

A1	5.0-7.0	2.344	A2	5.0-7.0	4.235
A3	5.0-7.0	1.645	A4	5.0-7.0	2.344

b-Value in G-R equation for sources A1, A2, A3 and A4 is set 0.9.

5. BIT RISK CURVE of MODEL SUPPLY CHAIN

Risk Curve of BIT for the Parallel Model Supply Chain is shown in Fig.6. Risk Curve of BIT for the Series Model Supply Chain is shown in Fig.7. In these figures, the horizontal axis shows the 90 percentile exceedance of BIT(days), the vertical axis shows the annual exceedance probability. The bold line shows the risk curve of the SC, the thin lines show the risk curve of the different nodes.

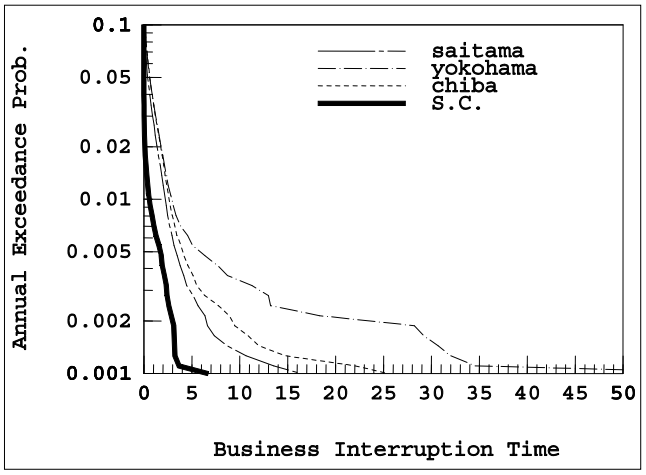

Fig.6 Risk Curve of Parallel SC

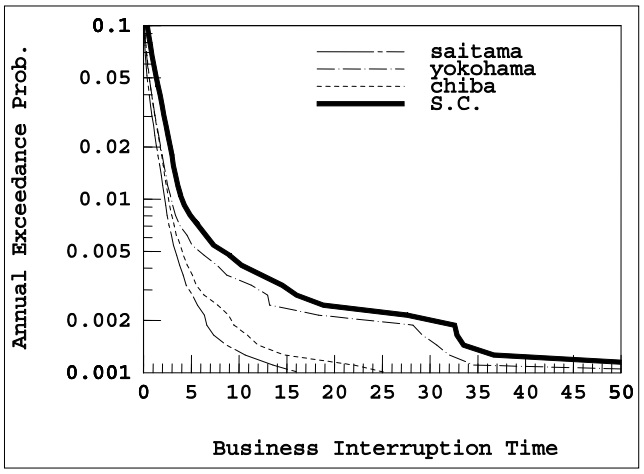

Fig.7 Risk Curve of Series SC

In Parallel SC, the SC halts only when all three nodes suffer damage at the same earthquake event. Therefore, as shown in Fig.6, the risk curve of the SC is smaller than any of the individual risk curve of the different nodes. In Series SC, if one or more of the three nodes suffers damage, the SC halts. Therefore, as shown in Fig.7, the risk curve of the SC is larger than any of the nodes and is strongly affected by node Yokohama which has the largest risk curve of the three.

Through the comparison of the two SC models, in order to decrease the BIT risk of a series supply chain, making the nodes parallel, in other words, providing alternates to the nodes would be effective. Since node Yokohama has the highest probability of

earthquake occurrence out of the three nodes, countermeasures to decrease the risk by node Yokohama need to be identified.

6. REDUCTION of BIT RISK by PROVISION of ALTERNATIVE NODES

6.1 Setting Alternatives of Nodes for Risk Reduction

In order to identify effective countermeasures to reduce the BIT risk of a series SC, three modified models are proposed, as shown in Fig.8. In Modification *A* an alternative node with same seismic strength for node Saitama is provided on the same location of the original node. In Modification *B* an alternative for node Yokohama is provided. In Modification *C* alternatives for all three nodes are provided.

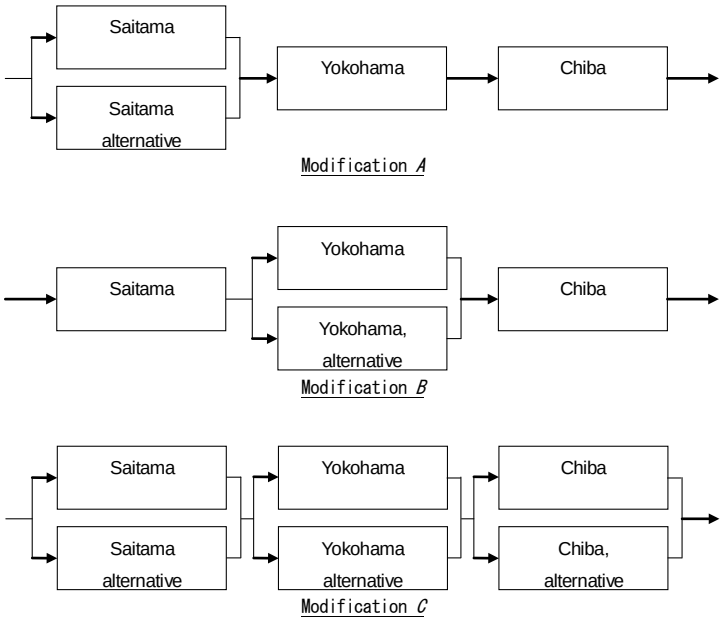

Fig.8 Modified Series SC by Provision of Alternative Nodes

6.2 Risk Curve of BIT of Series SC with Alternatives

Risk curve of BIT for modified series SC is shown on Fig.9, Fig.10 and Fig.11. By provision of alternative nodes, in all of the modified SC their risk curves are smaller than the original series SC. The probability of the two nodes on the same location suffering exactly the same level of damage is smaller than the probability of single node suffering the same level of damage. Therefore the provision of alternative node contributes to risk reduction of SC.

Fig.10 shows that provision of alternative node for Yokohama, which has the highest probability of earthquake occurrence, is effective for decreasing the risk curve. Fig.9 shows that provision of alternative node for Saitama, which has the lowest probability of earthquake occurrence, has limited effect for decreasing the risk curve. Fig.11 shows that provision of alternative nodes for all three locations gives the lowest risk curve of the three cases.

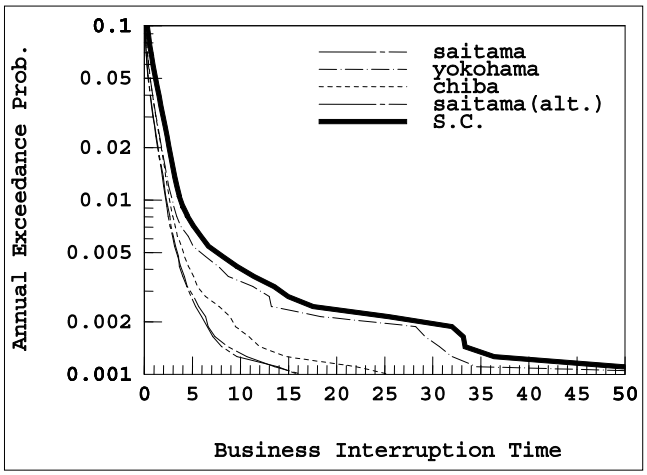

Fig.9 Risk Curve of Modification *A*

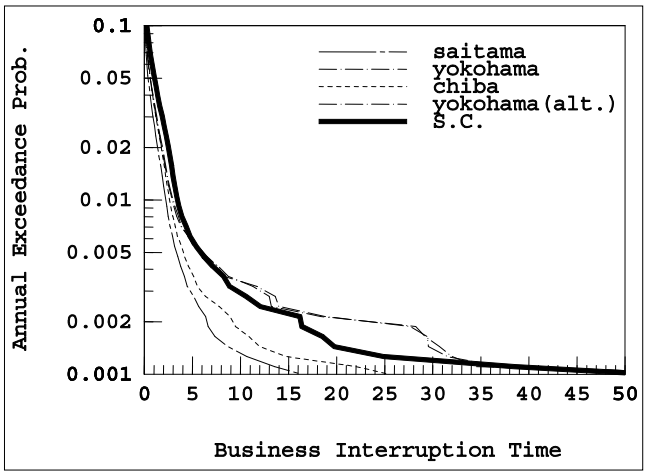

Fig.10 Risk Curve of Modification *B*

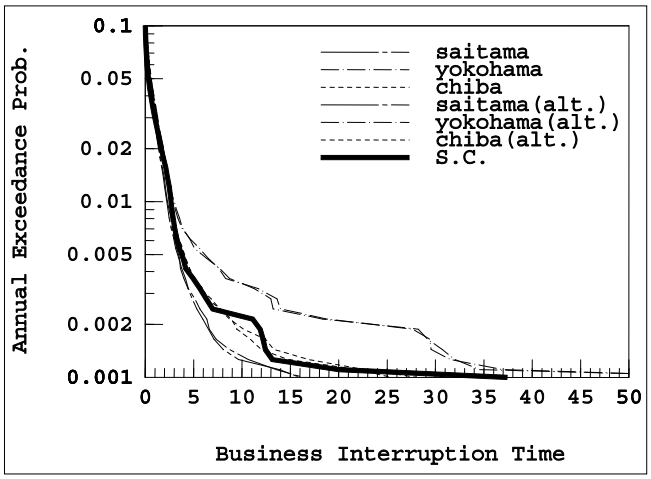

Fig.11 Risk Curve of Modification *C*

6.3 Effect of Provision of Alternative Nodes and Reflections for BCP

Fig.12 shows the comparison of the modified SC's BIT with the original series SC. The vertical axis is the annual exceedance probability, the horizontal axis is the ratio of BIT (modified SC's BIT divided by the original series SC's BIT).

For the domain where the annual exceedance probability is greater than 0.01, Modification *A* and Modification *B* do not demonstrate significant decrease of BIT risk. In this domain, high frequency & small scale earthquakes are dominant, thus provision of alternative for one location does not effectively decrease the BIT of the SC, since the remaining two locations will be frequently affected. Modification *C* demonstrates significant decrease of BIT risk since all three nodes are doubled.

For the domain where the annual exceedance probability is smaller than 0.005, Modification *B* demonstrates significant decrease of BIT risk. In this domain, low frequency & large scale earthquakes similar to the 1923 Great Kanto Earthquake are dominant. Yokohama has the high probability of being affected by such earthquake compared with Saitama and Chiba. Therefore provision of alternate node for Yokohama effectively decrease BIT risk. Whereas, Saitama has relatively low probability of being affected by such earthquake. Therefore provision of alternate node for Saitama (Modification *A*) does not effectively decrease BIT risk. Modification *C* decreases BIT risk, however, if the cost of providing alternative node is same in three locations, compared with Modification *B*, the benefit is relatively low in consideration of the necessary cost. If an enterprise with series SC with nodes in these three locations is to draw BCP to decrease it's BIT risk, the best option would be Modification *B*.

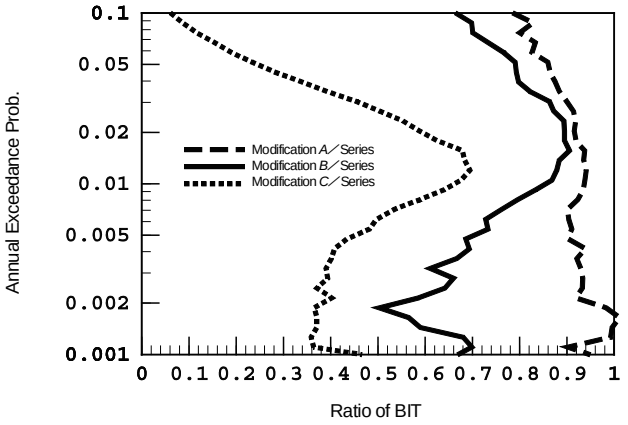

Fig.12 BIT Risk Reduction by Provision of Alternative Nodes

7. APPLICATION for STRATEGIC BUSINESS CONTINUITY PLANNING and DECISION MAKING

There are two main objectives for enterprises to draw BCP (Fig.13). First, to avoid the total halt of operations, even in case of disasters and maintain the minimal level of operations for business continuity. Second, to resume the operations to pre-disaster level within an acceptable timeframe from the viewpoint of corporate management in the competitive market.

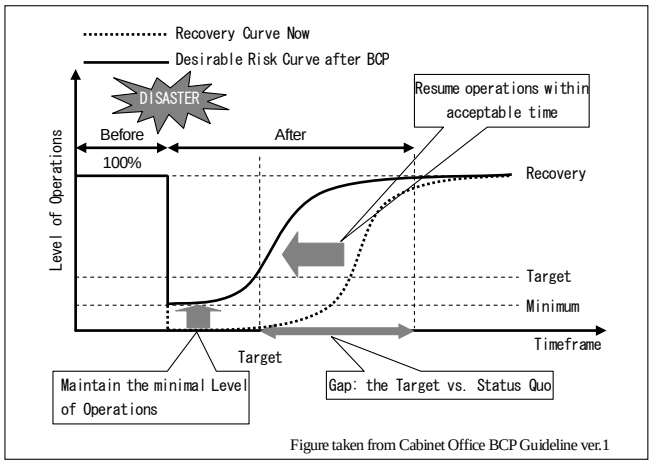

Fig.13 The Overall Concept of BCP

Let us suppose that a factory was hit by an earthquake. For the user of the product of the factory, his biggest interest would be when the factory would resume supply to him. If he sees that he cannot expect the supply within the timeframe he can wait, he will search for an alternative product or manufacturer. If the user decides that he cannot wait anymore, the factory will lose the user. Even if the factory resumes production afterwards, since the previous user is already taken by other manufacturer, the enterprise that runs the factory will have to pay marketing efforts to regain the user or to find new customers, which will require additional marketing costs. The longer the BIT, the marketing cost necessary will augment. If the BIT of the factory is further prolonged, the enterprise may no longer be able to return to the market. Thus BIT is an important factor for business continuity of an enterprise.

It might look like ideal to minimize BIT even in case of severe earthquakes. However it would require various investments to secure business continuation; seismic reinforcement or base isolation of buildings, stockpiling of abundant materials and parts, backup generators and fuel, additional water tanks, provisional contracts for backup offices, all of which might be just a burden for enterprises if they do not appreciate the value of BIT reduction. Enterprises need to identify the time limits for their customers to "wait" and plan to meet this time limit by choosing the good alternative for themselves.

The proposed method for evaluation of business interruption time for supply chain dependent enterprises will enable corporate executives to quantitatively appreciate the risks they face, support their decision making for countermeasures and justify the costs to reduce the risk. The proposed method is flexible to be adapted to various types of supply chain patterns. Furthermore, by decomposing the elements of the individual nodes of the supply chains, it can be further adapted to reflect the different types of operations by industry. Also by considering the connection routes between the nodes as one of the nodes, this method can be further fine-tuned.

The proposed method for analysis of alternatives for BIT risk reduction will enable corporate executives to compare options for reducing the risk and to draw strategies to fit their needs. Each enterprise has their own "limits" for BIT according to their type of business and their relation with the customers. Through comparison of the expected rate of reduction of probabilities to exceed their "limits" for BIT, the enterprises will be able to choose the best alternative to reduce their risk in balance with the costs incurred.

8. CONCLUSIONS

A quantitative risk evaluation method of BIT of SC dependent enterprise is proposed, and applied to model enterprises based in the Greater Tokyo Metropolitan Area. The risk curves of BIT for series and parallel supply chain are calculated and examined. Three alternative options to decrease the BIT risk of series SC are proposed and evaluated.

This method enables enterprises to quantitatively compare their options for decreasing their BIT risks. Taking into consideration the costs for these options, this method will be an effective tool for BC planning of supply chain dependent enterprise.

Through the application of this method, it is expected to decrease the possible business interruption time in future disasters and thus reduce the economic damage. The author hopes that these methods to be put into practice in the near future and contribute to the reduction of economic damage.

"DISASTER PREVENTION" AND BUSINESS CONTINUITY: LINGUISTIC AND CULTURAL PITFALLS FOR IMPLEMENTING EFFECTIVE BCM IN JAPAN

Nathan Lee Rhoden[1)] and Shinji Hosotsubo[2)]

1) Director, Crisis Management & Preparedness Organization, Japan
2) Chairman, Crisis Management Education & Exercise Center, Japan

Abstract: Earthquakes loom large as a major hazard that must be taken into consideration when implementing Business Continuity Management (BCM) in Japan, yet earthquakes and other natural disasters are not the only issues which need to be addressed by Japanese organizations seeking viable continuity. Historically, Japan has fostered a sophisticated culture of Bosai (防災) or "Disaster Prevention," but the authors' research indicates that effective BCM can be hampered by this deeply ingrained cultural mindset. Part of the difficulty stems from the fact that the concept of "Disaster" has been translated into Japanese as Saigai (災害) which traditionally implies only natural disasters, whereas the English term, especially as defined within the BCM community, has a far broader meaning.

1. INTRODUCTION

Spurred by the need for improved Crisis Management in the wake of the 1995 Great Hanshin-Awaji Earthquake, the authors of this paper were among the earliest proponents of Business Continuity Management (BCM) in Japan. During that period, the phrase "Business Continuity" was still virtually unknown in Japan, and much of the early efforts to raise awareness and promote the concepts of BCM fell on deaf ears. Since that time there has been a kind of great-awakening, and BCM has even become a kind of buzzword among organizations in Japan.

Beginning in 2005, several official guidelines were issued by the Japanese government, including the "Business Continuity Guidelines" by Cabinet Office, and the "Guidelines to Formulate and Operate BCP for Small and Medium Enterprise" by the Small and Medium Enterprise Agency. In addition, in 2006, the Koizumi Administration announced targeted goals, stating that within 10 years it wanted "almost all large corporations, and more than half of medium-size firms" to have implemented BCM.[1]

Such government announcements carry considerable weight in Japan, so these events have caused a tremendous increase in interest about BCM. And, to satisfy this interest, a great many educational and instructional books have been published to supplement and provide commentary on the various official government guidelines.

Despite this new found interest in BCM, the authors' empirical research indicates that the vast majority of organizations attempting to implement BCM in Japan are not realizing its full benefits. In fact, top management at many organizations have come to perceive BCM as some kind of expensive boondoggle that they can ill afford in view of today's difficult economic climate.

This situation is quite regrettable, since at its effective best, BCM is a proven management methodology which can greatly aid top management in all times of crisis, including a poor economy. But, so far, fundamental misconceptions about the nature and purpose of BCM have generally limited its introduction to only relatively low management levels. Most of the top management in Japan remain unaware of its potential benefits, and therefore extremely few organizations have actually implemented effective BCM.

This paper attempts to explain some of the linguistic and cultural pitfalls that appear to be hampering the implementation of effective BCM in Japan, establish some of the key similarities between BCM and traditional Strategic Management, and point out why BCM can be especially useful in times of rapid change.

2. LINGUISTIC AND CULTURAL ISSUES

2.1 The Definition of Disaster

The word "disaster" has typically been translated into the Japanese term Saigai (災害), a term that is generally applied only to natural disasters.

Japan has long history of Bosai (防災) or "Disaster Prevention," and this concept is deeply ingrained into the Japanese culture. Business Continuity Management (BCM) shares its origins with a related discipline called "Disaster Recovery," and English language treatises on BCM frequently employ the word "disaster." Since this word is invariably translated as Saigai, many Japanese readers have been led to the misconception that BCM is just another (albeit potentially advanced) form of Bosai of "Disaster Prevention," and that BCM is also focused primarily on earthquakes and other natural disasters.

To the contrary, the BCM discipline has never been

particularly focused only on natural disasters per se, and its methodology is now increasingly being applied to completely non-physical events.[2]

Even in colloquial English the word "disaster" has a far broader meaning than natural disaster (e.g., "That meeting was a disaster." or "My party was a disaster."), and it is defined within much of the BCM community as:

"A sudden, unplanned catastrophic event causing unacceptable damage or loss. 1) An event that compromises an organization's ability to provide critical functions, processes, or services for some unacceptable period of time 2) An event where an organization's management invokes their recovery plans."[3]

The significance of this difference between the Japanese and English definitions lies in the fact that Japanese organizations typically have an existing Bosai or "Disaster Prevention" function which is usually positioned within their Soumu-Bu (総務部) or "General Affairs Department." And, this Bosai function is indeed focused almost entirely on preventing or mitigating the effects of natural disasters and fires. Therefore, when BCM is misperceived as also being primarily about natural disasters, it too is usually relegated to the "General Affairs Department."

According to the authors' extensive experience, positioning of the BCM function at this level within the hierarchical structure of a Japanese organization rarely results in effective BCM.

2.2 Risk Management vs. Crisis Management

Another related linguistic issue is how the Japanese term Kiki-Kanri (危機管理) has also been translated into English. While every Japanese-English dictionary translates the first portion of the term, Kiki (危機), as "Crisis," and the second portion of the term, Kanri (管理), as "Management," the complete term Kiki-Kanri has often been translated as "Risk Management."

As it happens, there is no obvious way to succinctly translate the word "Risk" into Japanese, making simple translation of the phrase "Risk Management" difficult, except by phonetic method. So, when the concepts of Risk Management were being introduced into Japan, it is likely that the well known (though often poorly understood) Japanese term Kiki-Kanri may have presented itself as a simple solution to this translation issue. And, it is even possible that the English words for "Risk" and "Crisis" were poorly understood and somehow equated. In any case, the authors' believe this additional bit of linguistic confusion has also hampered the implementation of effective BCM in Japan.

Risk Management and Crisis Management are not always well defined even within the English speaking world, and a detailed examination of the two concepts is beyond the scope of this paper. However, suffice it so say that the two disciplines are quite different, and in the authors' view, most Japanese possess a cultural propensity for Bosai or "Disaster Prevention" which makes them far more comfortable with the concepts found in Risk Management, and relatively uncomfortable with many of those in Crisis Management.

Risk Management tends to be a statistically driven discipline largely focused on known risks (whether natural or otherwise) and as such, tends to fit well with the Bosai cultural mindset which has, as its "core nature" the desire to, if possible, prevent natural disasters, even earthquakes. Bosai recognizes, of course, that where prevention is not yet possible, mitigation must be applied. However, the ultimate goal of the Bosai mindset is prevention.

On the other hand, to be at all effective, Business Continuity Management (BCM) must fully and unequivocally accept the concept of truly unknown risks, which are therefore inherently unpreventable.

The fact is that "disasters" (i.e. Events that compromise an organization's ability to provide critical functions, processes, or services.) will always occur. So, while cost effective prevention and/or mitigation efforts can play a significant role in BCM, there is a particular kind of high-level strategic planning found in effective BCM that is intended to counter even heretofore unknown risks, and has propelled towards the realm of Crisis Management.

2.3 Danger vs. Opportunity

The linguistic and cultural issues described above have had the unfortunate tendency to limit the implementation of BCM in such a way that its full benefits cannot be completely actualized in Japan due to inadequate top management understanding and participation.

BCM has, as its "core nature," the desire to successfully continue an organization's operations, under any and all circumstances. And presumably, the top management of any organization will share such a desire. Because of its highly strategic "core nature," effective BCM can serve a dual purpose. The fundamental principles embodied in effective BCM can be applied equally well to capitalizing on opportunities and growing an organization, as they can to "preventing disaster." Once fully empowered by top management, the BCM methodology becomes extremely useful to the day-to-day organization, whether or not it ever actually faces disaster. Effective BCM can enhance both the agility and the resiliency of the organization.

Perhaps such duality was understood by the ancients who developed the ideogram for Kiki (危機) or "Crisis." The first character (危) denotes the concept of danger, since it is also used as the first character of term Kiken (危険) or "Danger." Similarly, the second character (機) is used as the first character of the term Kikai (機会) which means "Opportunity" or "Chance," as in a chance meeting. Thus to the Japanese eye, their ideogram for crisis appears to embody a dual nature of both danger and opportunity.

3. STRATEGIC MANAGEMENT & BCM

3.1 "Full Scope" BCM

Lehman Brothers Holdings Inc. was founded in 1850 and stood for over 158 years. But, their sudden bankruptcy on September 15, 2008, led to a global business calamity that is referred to in Japan as the "Lehman Shock."

Within the international BCM community, the

Lehman's bankruptcy stands out, not as a failure of BCM, but as a highly visible example of the risk associated with having too limited a scope when applying the principles of BCM within an organization. Thus, the "Lehman Shock" can be said to officially mark the beginning of an already existing trend towards "Full Scope" (or "All-Risk") BCM.

Traditionally, even sophisticated practitioners of BCM, such as Lehman Brothers, have tended to limit the scope of their BCM to operational threats, since financial threats (such as the unprecedented tightening of short-term credit which led to the demise of Lehman Brothers), typically fell within the scope of their Risk Management Department.

Unfortunately, the discipline of Risk Management is singularly unsuited to the task of evaluating "unprecedented" risks, so the "Lehman Shock" has further accelerated the movement of effective BCM towards the realm of Crisis Management, or perhaps more precisely, towards the realm of Japanese Kiki-Kanri which has always tended to have a broad scope that encompasses all threats to an organization.

3.2 Strategic Management

The discipline of Strategic Management has never been in danger of being mistaken by Japanese top management as a form of Bosai, or "Disaster Prevention," yet it shares many important attributes with effective BCM.

Strategic Management asks and answers questions like "Which business should we be in?" and "How does being in this business add value to our customers?" Such questions and their answers are also crucial to effective BCM.

Strategic Management also provides direction to corporate values, corporate culture, corporate goals, and corporate missions, and these too are also crucial to effective BCM.

3.3 Corporate Strategy

Strategic Management can be illustrated as a pyramid with four levels of strategy as shown in Figure 1.

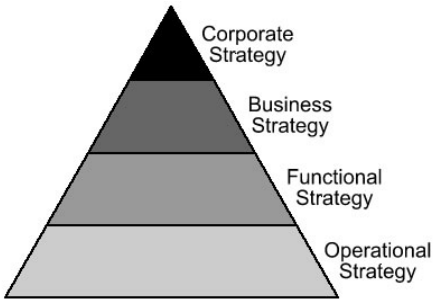

Figure 1 Strategic Pyramid with Corporate Strategy at its apex.

Like Strategic Management, which has Corporate Strategy at its apex, BCM has, at its highest level, the logical equivalent.

Just as Corporate Strategy is determined by corporate values, corporate culture, corporate goals, and corporate missions; these same values, culture, goals, and missions must determine the overall Business Continuity Strategy. Therefore, given this transitive relationship, Business Continuity Strategy (BCS) and Corporate Strategy must be essentially equivalent.

The establishment of an overall Business Continuity Strategy (BCS) by top management is essential to effective BCM. Just as Corporate Strategy drives all the lower levels of strategy within the pyramid of Strategic Management, it is the overall BCS which must drive all the lower levels of business continuity, functional recovery and operational recovery in BCM. Without a coherent BCS established with the full commitment of top management, all BCM efforts will likely be doomed to failure, or at best, be limited and ineffective.

The traditional pyramid of strategic hierarchy with Corporate Strategy at its apex may not be the best way to illustrate this point. Perhaps it is more useful to reconstruct the pyramid as shown in Figure 2. This figure better illustrates how Corporate Strategy (and BCS) must be established at the very foundation of the organization, and how it is upon this foundation that both Business Strategy and Business Continuity must be built.

Figure 2 Strategic Pyramid with Corporate Strategy as its foundation.

Given the strong foundation of a solid Corporate Strategy it is possible to establish successful business, functional, and operational strategies, but without a solid Corporate Strategy, all the other dependent strategies will collapse into rubble. Likewise, without the strong foundation of a solid BCS, it is impossible to establish effective (and cost effective) BCM.

The authors' empirical research indicates that in Japan the previously mentioned linguistic and cultural issues work together to limit top management understanding and involvement, which in turn weakens the foundation and limits effective BCM.

3.4 Structure Follows Strategy

Alfred Chandler, one of the pioneers of Strategic Management, emphasized the importance of a central strategy by stating quite succinctly that "Structure follows Strategy."[4]

Over the years, successful practitioners of BCM have arrived at this same conclusion, although perhaps from a different route. But, whatever the routes, the disciplines of BCM and Strategic Management have come to share many key principles and concepts in common.

3.5 Process Reengineering

Jay Barney conceived of strategy, within the context of Strategic Management, as assembling an optimum mix of resources (financial assets, human assets, technological assets) and configuring them in sustainable ways.[5] And, Michael Hammer and James Champy suggested that these resources should be restructured, so that an organization's assets are organized around whole processes rather than individual tasks. They named this concept Process Reengineering.[6]

The similarity to BCM methodology is striking. The Business Impact Analysis (BIA) is central to BCM methodology, and much of the initial analysis undertaken during a BIA involves thoroughly understanding an organization's processes, how those processes are developed from tasks, and how the various processes and tasks interrelate and sustain each other.

3.6 Core Competencies

Gary Hamel and C. K. Prahalad's best known contribution to the Strategic Management discipline is their concept of core competency, and they emphasize just how important it is to know the one or two key things that your organization does better than the competition.[7] And, John Kay further states that the role of Strategic Management is to identify core competencies, and then assemble a collection of assets that will increase value added and provide a competitive advantage.[8]

Again, these key concepts of Strategic Management parallel those of BCM. In addition to understanding the organization's processes as mentioned above, the Business Impact Analysis (BIA) also entails judicious prioritization of core competencies based on quantitative and qualitative analysis of just how those core competencies add value to stakeholders.

The BIA is essential to effective BCM because it allows for detailed strategic planning well in advance of a crisis, whether that crisis be a danger or an opportunity.

3.7 Core Values

Another key element of BCM involves establishing clear social, socioeconomic and ethical values that are well understood throughout the organization, and can provide vital guidance during times of crisis. How an organization comports itself under stress is an excellent indicator as to the depth and strength of its core values.

James Collins and Jerry Porras spent years conducting empirical research on successful organizations in hopes of determining just what makes a great organization "great." And, they finally uncovered one key underlying principle: "great organizations encourage and preserve a core ideology that sustains the organization." Strategy may change, and tactics will certainly change, but great organizations manage to maintain a constant set of core values.[9]

3.8 What is BCM?

Despite the misconceptions common in Japan, effective BCM is not about planning in advance for an earthquake, or some other kind of disaster that would have a negative impact on the organization, should it occur.

Effective BCM is about establishing and preserving core values that can endure the test of time, thoroughly understanding both the strengths and weaknesses of the organization's processes, and fully recognizing just how, and to whom, those processes can add the most value.

Ironically, once this kind of BCM has been established at the top management level, earthquake mitigation is often achieved by the organization as a kind of "free bonus." This is because effective BCM is indeed uniquely capable of minimizing, or possibly even preventing, impacts from all manner of disruptive events, including earthquakes.

But it is important to note that this kind of "free bonus" can only be received from one direction: top down, not bottom up. When implemented from the bottom up, for the purposes of earthquake mitigation, BCM rarely rises to the level where it can be perceived as a useful management methodology by top management.

Not only that, when implemented from the bottom up, BCM also commonly fails at even its stated goal of earthquake mitigation because it quickly reaches an impasse with top management over costs. Since bottom up BCM does not incorporate the true strategic thinking of top management, the earthquake mitigation "strategies" (more often tactics) proposed from the bottom up are typically deemed to be too expensive and unrealistic to be approved by top management.

This impasse is commonly overcome by compromising on lower cost earthquake mitigation tactics that are not only ineffective against all but nominal earthquake scenarios; they are usually completely useless against other threats such as pandemic. This is not effective BCM.

3.9 Positioning the BCM Department

In "Crisis Leadership," Ian Mitroff describes how and why Alfred P. Sloan changed the GM organizational structure by adding a new and previously unknown department at its top.[10]

When Sloan took over as CEO, GM was experiencing a crisis: it had no idea how many cars it was selling. The organization had grown so huge that it had lost control over its inventory, it couldn't get accurate and timely sales data from its dealers, and it had trouble getting the various car divisions to share their revenues with the central parent corporation.

Sloan solved this crisis through the creation of a Finance Department at the very top of the company. Today many might assume that Finance Departments have always been a part of corporate structures, but in actuality, Sloan established the world's first Finance Department less than a hundred years ago.

Similarly, if today's organizations are to survive their current crisis of a rapidly changing environment, they would be well served to establish a BCM Department at the highest level of their organizational structure.

Just as past leaders required financial savvy, today's leaders will require BCM savvy.

4. STRATEGIC CHANGE & BCM

4.1 The Age of Discontinuity

The phrase "Age of Discontinuity" was coined by Peter Drucker to describe how change disrupts the continuity of our society.[11] In periods of continuity, extrapolating from the past provides a reasonably useful and relatively accurate method for predicting the future. But in an Age of Discontinuity, extrapolating from the past is completely ineffective. Trends that exist today cannot be assumed to continue into the future.

Alvin Toffler is well known for predicting a trend towards accelerating rates of change.[12] In his popular books, Toffler describes how social and technological norms have increasingly shorter life spans, and he predicts society's increasing inability to cope with such constant change. He sees relentless change as the defining feature of our current civilization.[13]

Richard Pascale wrote that constant change requires that businesses continuously reinvent themselves.[14] He is famous for stating that "Nothing fails like success," meaning that yesterday's strengths become today's weaknesses.

Effective BCM can be highly useful in managing strategic change. Unlike Risk Management which tends to utilize relatively passive methods of prevention or mitigation, BCM incorporates proactive principles of Crisis Management that require rapid decision-making in times of rapid change, and rapid decision-making even when all the information desired for decision-making is not available.

The concept of "continuous reinvention" also has a strong correlation with BCM. A continuous improvement cycle is a fundamental part of the BCM methodology, and effective BCM can readily drive continuous reinvention as it constantly reevaluates the strengths and weaknesses of an organization's processes, and how, and to whom, those processes are adding value.

4.2 Scenario Planning

BCM methodology also employs scenario planning in a number of ways. The Business Impact Analysis (BIA) process utilizes multiple scenarios where impacts from the complete disruption of each discrete function or task that makes up of each of the organization's processes are evaluated individually, but on a non-threat-specific basis.

Threat-specific scenario planning is also used to evaluate the likely effectiveness of proposed, and often highly creative, Business Continuity Strategies (BCS). It is this kind of scenario planning found in BCM that can encourage the spirit of inquiry, the constructive conflict, and the healthy debate that is necessary for organizations to survive in an environment of constant change.

As Peter Schwartz put it, strategic outcomes can no longer be known in advance, so the sources of competitive advantage cannot be predetermined.[15] The rapid pace of change in the current environment makes the sustainability of competitive advantage too uncertain. But, scenario planning allows multiple outcomes to be explored, and their implications assessed.

According to Pierre Wack, scenario planning is about insight, complexity, and subtlety, not about formal analysis and numbers.[16] Effective BCM also shares these qualities, and in fact, strategic creativity is frequently the most important factor in achieving viable continuity

5. CONCLUSIONS

Far from being an expensive boondoggle, once understood and fully implemented by top management, effective Business Continuity Management (BCM) can actually be highly profitable, and help promote the growth of an organization, not just its continuity.

While BCM is not primarily about natural disasters, once it is incorporated into an organization's overall management strategy, it is uniquely effective in reducing, or even eliminating, the impacts from any business interruption.

Due to its effectiveness in times of rapid change, BCM has become an increasingly important methodology in the management of modern organizations.

Once BCM is better recognized by Japanese top management as the Strategic Management methodology that it is, Japanese organizations will also be able to implement BCM that is more strategically aligned with their business goals and thus begin to reap its true benefits.

TOKYO INLAND EARTHQUAKES AND BUSINESS CONTINUITY OF COMPANIES/ORGANIZATION

Hiroaki Maruya

Professor, Center for Urban Earthquake Engineering, Tokyo Institute of Technology, Japan,
Research Fellow, Research Institute of Construction and Economy, Japan,
Board Chairman, Business Continuity Advancement Organization, Japan
h-maruya@tiara.ocn.ne.jp

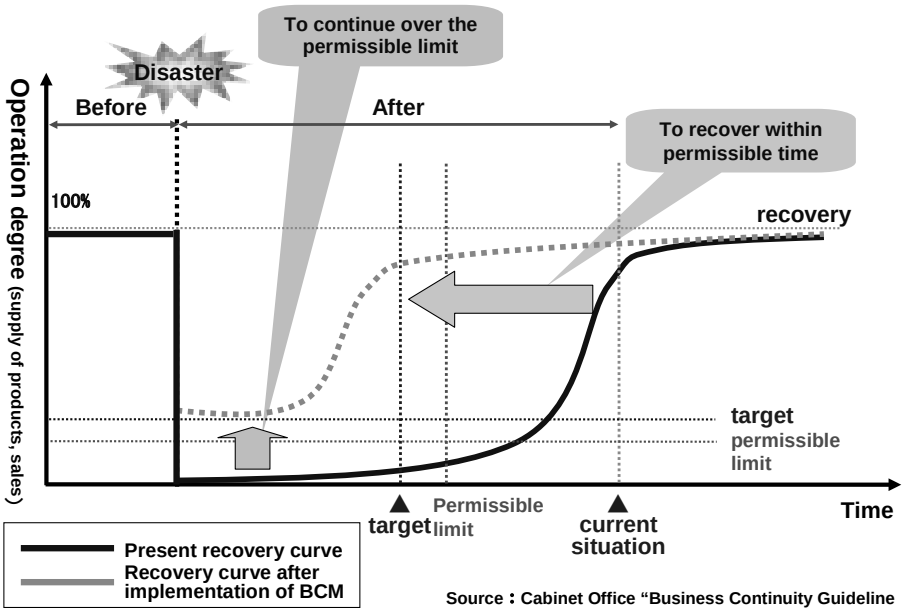
Abstract: Facing the threats of Tokyo Inland Earthquakes, both government and private organizations are required to equip their BCP (Business Continuity Plan). Even if the core government organizations were forced to move out of the central districts of Tokyo by their damage, they would stay in cities within the greater Tokyo region, such as Tachikawa, Yokohama, Saitama, etc. to preside over the recovery and reconstruction activities that should be their top priorities. Some private enterprises who think it is more advantageous to keep their headquarters in the greater Tokyo region would stay just like the core government organizations. On the other hand, many other enterprises would move their head office functions to major branches in cities such as Osaka and Nagoya, considering the constraining factors of securing houses for their workers, their commuting difficulty and so on. Therefore, it is meaningful for major cities outside of capital region including Osaka and Nagoya to make preparations to accept a part of private enterprises' core functions.

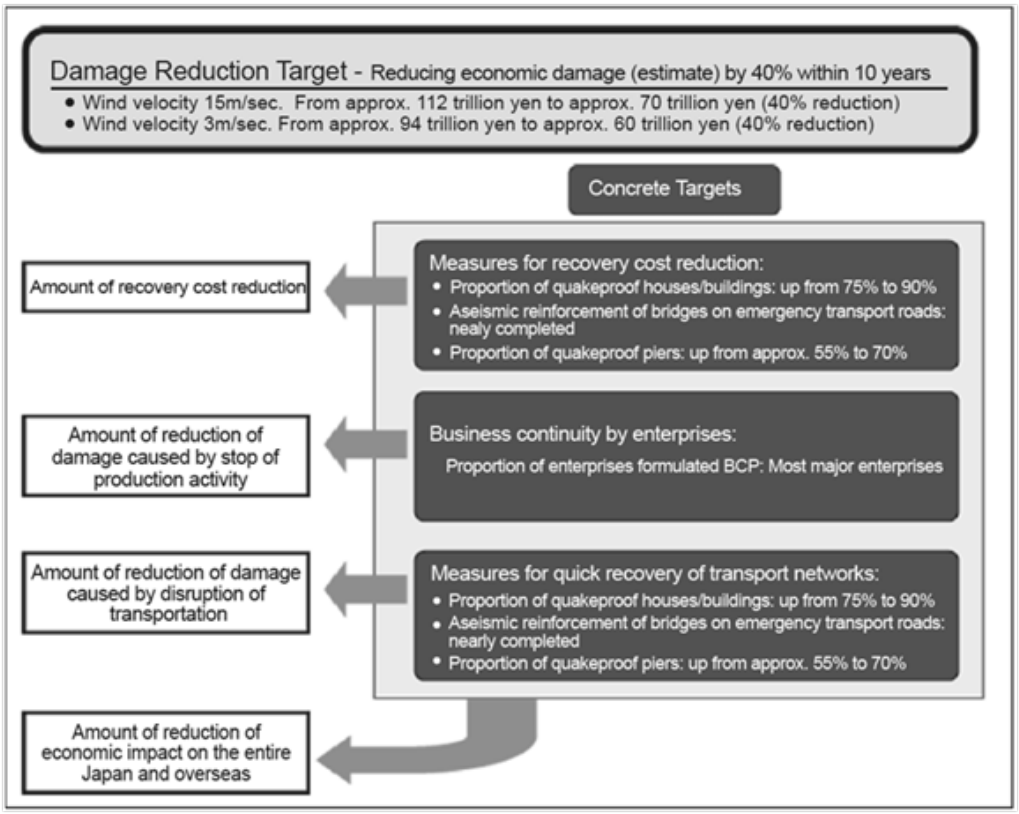
1. INTRODUCTION

Today the Japanese capital's core functions face threats such as Tokyo Inland Earthquakes, pandemic influenza and large-scale terrorism. To protect the national capital functions, there are some opinions that Tokyo's core functions should be dispersed into other areas of the country. The Japanese government is discussing continuously the dispersal of the Parliament House and other important government organizations out of Tokyo. However, no detail plan has been decided for capital function dispersal.

On the other hand, as countermeasures against these threats, both the government and private businesses in Tokyo are required to formulate BCP (Business Continuity Plan) to keep continuity of important activities in a time of disaster. The concept of Business Continuity is shown in Figure1.

The method of BCP includes selecting important operations, estimating damage to resources of organizations such as people, goods, money, information and systems that are essential to continue important operations, as well as securing alternative resources and/or reinforcing resources to reduce damage.





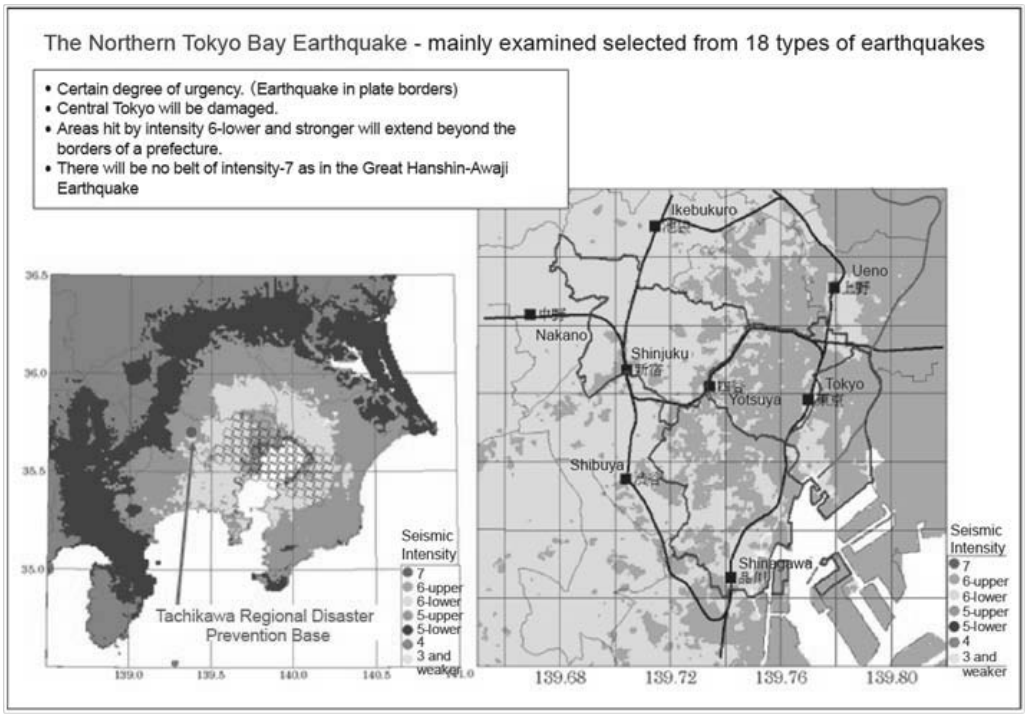


Figure 1 Concept of Business Continuity

Material of the Cabinet Office (Disaster Prevention)

Figure 2　Earthquake Disaster Prevention Strategy in Case of Tokyo Inland Earthquakes（Economic Damage）

Material of the Cabinet Office (Disaster Prevention)

Figure 3　Distribution of Seismic Intensity during the Northern Tokyo Bay Earthquake (7.3-magunitude)

2. Damages of Tokyo Inland Earthquakes

2.1 The Expected Worst Type

It is scientifically understood that in the greater Tokyo capital area, massive trench-type earthquakes with a magnitude of 8 or greater, like the Great Kanto Earthquake (1923), occur at intervals of 200-300 years. Additionally, it is estimated that smaller several types of Tokyo Inland Earthquakes (magnitude 7 (M7) class) occur before a M8 scale earthquake.

Japanese government published the estimation that a M7 class will occur in the probability of 70% in next 30 years.[1] The Central Disaster Management Council of Japanese government has carried out damage estimations for 18 types of Tokyo Inland Earthquakes (M7 class). The type whose epidemic center is at northern part of Tokyo Bay (assumed scale of M7.3 at 6pm in winter) is estimated to cause most serious damage. It would include a death toll of approximately 11,000 people, total collapse of 85,000 buildings and a maximum economic loss of 112 trillion yen. To reduce the economic loss, introduction of BCP to public and private organizations is positioned as one of the main countermeasures (Figure 2).

2.2 Distribution of a Seismic Intensity

Figure 3 shows maps of the seismic intensity distribution of the expected Tokyo Inland Earthquake whose epidemic center is at northern part of Tokyo Bay. On this earthquake, most places in east half of the central districts of Tokyo is predicted to experience a seismic intensity[2] 6-upper. The standard damages by the intensity 6-upper earthquakes are defined by Japan Meteorological Agency as in Table 1[3].

Table 1 The Standard Damage of Earthquakes of a Intensity 6-Upper

- One cannot stand. One cannot move unless crawling.
- A lot of the furniture moves unless it is not fixed, and Some of them fall down.
- Of many buildings, tiles on walls and windowpanes are damaged and drop.
- Most of fences made of blocks which are not reinforced are fall down.
- Some wooden houses with high quake resistance have crazing and cracks on walls.
- Many of wooden houses with low quake resistance have crazing and cracks on walls. A considerable number of those incline or fall down.
- Some steel reinforced concrete buildings with high quake resistance have crazing and cracks on walls, beams, pillars etc.
- Some steel reinforced concrete building with low quake resistance have diagonal or X-shaped crazing and cracks on walls, beams, pillars, etc. Of these, there are buildings that collapse caused by breaking down of pillars of the first floor or intermediate floors.

3. Substitution Places for the Central Districts of Tokyo

3.1 Business/ Operational Nucleus Cities

To de-centralize excessive “capital core functions” of the central districts of Tokyo, the concept of the “Business/Operational Nucleus Cities (BNCs)” have been introduced based on the “Act for the Promotion of Multipolar Pattern National Land Formation” in 1988. The act stipulates to choose BNCs from the area except the 23 wards area which are including the central districts of Tokyo.[4] At the time of a large-scaled disaster in Tokyo, BNCs are expected to play important role as substitute places for the organizations and enterprises located at the central districts of Tokyo.

Government has supported to develop and facilitate BNCs by systematic and financial methods. Among these, most effective method seems to be the transfer of ministries’ branch offices for Kanto region (i.e. several prefectures around Tokyo) from the central districts of Tokyo to some of BNCs such as Saitama City (north from Tokyo) and Yokohama City (southwest from Tokyo). Another BNC is Tachikawa (west from the central districts of Tokyo) where the alternative base of the Cabinet of Japanese government is prepared for the time of disaster. Others are Chiba City (east from Tokyo) and so on.

The distance from the center of Tokyo to each BNC which is scattered in Tokyo metropolitan area and three prefectures neighboring Tokyo (hereafter “the greater capital area”) is more than 30 kilo-meters. We can expect that for any type of Tokyo Inland Earthquake whose epidemic center is in the greater capital area, one or more BNCs would be safe without serious damage. In other words, it is not predicted that all of BNCs are simultaneously hit by seismic shaking of intensity 6-lower (the minimum seismic intensity to cause considerable damage) or over.

3.2 Substitute Headquarters for Government Organization

Presently, important buildings and facilities of the Japanese central government are mostly earthquake-resistant. On this reason, the present BCPs of the ministries’ head offices prepared against Tokyo Inland Earthquakes assumed that the ministries would be able to use their headquarter buildings with high probability.

However, we have to consider that the ministries may not be able to use their headquarters because of unexpected damage of building structure, outbreak of fire, troubles of electric power supply and telecommunication service breakage of sewage pipes, workers’ commuting problems and so on. Japanese BCP guidelines for central ministries[5] recommended that a substitute office is specified in each ministry’s BCP. For example, the substitute offices for Ministry of Land, Infrastructure, Transport and Tourism (MLIT) which is the first ministry to formulate BCP in Japan, are as follows; 1) Kanto Regional Survey Department, Geospatial Information Authority of Japan (Chiyoda Ward, Tokyo), 2) College of Land, Infrastructure, Transport and Tourism (Kodaira City, west from the central districts of Tokyo) . This college is near to the Tachikawa Regional

Disaster-prevention Base where the Cabinet would evacuate as mentioned above. Substitute offices of ministries of Japanese government are shown in Table 2.

Table 2 Substitute Offices for Ministries

Name of Ministry	Substitute Offices
Ministry of Land, Infrastructure, Transport and Tourism (MLIT)	1) Kanto Regional Survey Department, Geospatial Information Authority of Japan (Chiyoda Ward, Tokyo), 2) College of Land, Infrastructure, Transport and Tourism (Kodaira City, Tokyo)
Ministry of Internal Affairs and Communications	Local Autonomy College (Tachikawa City, Tokyo), Institute for Information and Communications Policy (Kokubunji City, Tokyo)
Ministry of Economy, Industry and Trade	Japan Patent Office (Chiyoda Ward, Tokyo)
Ministry of Agriculture, Forestry and Fisheries	Sanbancho Branch Government Office (Chiyoda Ward, Tokyo)
Ministry of the Environment	1) Chidorigafuchi National Cemetery Administration Office (Chiyoda Ward, Tokyo) 2) Kokyogaien National Garden Office (Chiyoda Ward, Tokyo) 3) Shinjuku Gyoen National Garden Office (Shinjuku Ward, Tokyo) 4) The National Environmental Research and Training Institute (Tokorozawa City, Saitama Prefecture)
Consumer Affairs Agency	Specific place is not published
Japan Coast Guard	Coast Guard Research Center (Tachikawa City, Tokyo) Yokohama Maritime Disaster Prevention Base (Yokohama City, Kanagawa Prefecture)
Japan Meteorological Agency	Secured in nearby (Chiyoda Ward, Tokyo)
Ministry of Education, Culture, Sports, Science and Technology	Considering Continuously
Ministry of Finance	To consider in future
Financial Service Agency	To consider in future
Ministry of Justice	Not referred
Ministry of Defense	Not referred
National Police Agency	Not referred
Japan Fair Trade Commission	Not referred

When a severe natural disaster hits Tokyo, it should be a top priority for most ministries to preside over the recovery and reconstruction activities in capital area. Although most of ministries do not specify the substitute offices outside of the 23 ward area of Tokyo in their present BCPs, the author expects that their branch offices for Kanto region in Saitama City or Yokohama City would be good candidates for the substitute offices. Small number of ministries might move their headquarters to some big cities such as Osaka, Nagoya, or Kobe, but they would secure their second headquarters in BCMs or other cities in the greater capital area.

However, above-mentioned story seems to be not applicable if the Diet decides to move to any cities outside of greater capital region. Some ministries would decide the place of substitute head office in the same cities which the Diets move to. Others would set up second headquarters in the same cities. As the BCP of the Diet has not been published yet, we cannot deny the probability of these, but the Diet member would prefer, in the author's anticipation, to stay nearby where the Cabinet is working for the reconstruction works.

3.3 Substitute Worksites for Large Enterprises

A portion of large enterprises acting nationwide in Japan would stay in the great capital region when they cannot use their headquarters and think it is more advantageous to keep their headquarters in the region. Examples of these companies are those whose business activities are deeply related to recovery and reconstruction projects in Tokyo. However, this expectation does not mean that most of the workers of these companies would necessarily keep staying in and around Tokyo. This point will be discussed in Chapter 4.

Other enterprises would move their head offices to other branches or factories in the cities outside of the greater Tokyo region such as Osaka, Nagoya and so on, if they feel difficult to operate as usual in the region. However parts of their operational functions would stay in BNCs or other cities in greater Tokyo region for the business activities in and around Tokyo.

4. Evacuation from Tokyo for Business Continuity Purpose

4.1 Necessity of Evacuation of People

For the business/operational continuity, it is not enough for each organization to secure their operations carried out by restricted members of emergency response team. It is also indispensable to recover all critical operations as soon as possible which are carried out by many other ordinal workers/officials. In initial several days after the quake, emergency response activities are very important, but after this period, each organization has to restart more important operations.

According to Damage Estimation by Tokyo Metropolitan Government, Tokyo Inland Earthquake at northern part of Tokyo Bay (scale of M7.3) would cause major damage on railways at 28 places[6]. The major damage needs civil engineering works to recover, and it ordinary takes at least several weeks. BCP of MLIT uses assumptions as follows: "In the area suffered from a seismic intensity 5-upper and more, rail way service would stop for 3 days, then, gradually recover. All railway service would recover in 30 days." Therefore, commuting problems of officials would be very serious for about a month or more in Tokyo area.

In addition, Government published the estimation of serious shortfalls of tentative housing.[7] In the worst case of Tokyo Inland Earthquakes (scale of M7.3, at northern part of Tokyo Bay at 6pm, in winter), the needs of tentative housing is expected to 1.62 million units of emergency dwelling in Tokyo metropolitan and three neighboring prefectures. However, by one month after the earthquake, supply would be only 1.26 million housing units including vacant private rental houses in Tokyo, its three neighboring prefectures and other prefectures nearby. This number apparently cannot meet the needs. Even by six months later, supply of 120 thousand emergency temporary houses, 310 thousand units of emergency repair of sufferers' houses and two thousand public rental housing are expected. Only if we include vacant private rental houses in Tokyo and above mentioned prefectures, we can finally fulfill the needs.

Considering these problems, evacuations of people living in the great capital area are very useful. Furthermore it would be necessary for large companies to transfer their workers/officials and their family to other business site outside of Tokyo as quickly as possible in order to retain business continuity.

4.2 Important Meaning of the Evacuation

Most of government officials and workers of enterprises in charge of recovery works would not be able to depart from Tokyo. In addition, workers in small and medium scaled companies which do not have substitute sites outside of Tokyo would be very difficult to go away from Tokyo. Therefore, the author thinks that larger companies having other business sites outside of Tokyo are requested to evacuate workers and their family from Tokyo to these sites. Important social effect of this evacuation is to make ease of shortfall of housing, commuting troubles, commodity supply restriction, etc. This evacuation seems to relate directly to social contribution and corporate social responsibility.

One of critical requirements for this evacuation is quickness and smoothness. To realize in very short period, Osaka, Nagoya, and other major cities in Japan would have important roles as recipients of evacuation. These cities are requested to supply sufficient workspace, business facilities, housing, school, nursery service and so on. Preparation in advance of these recipient cities seems to be highly desirable for the business continuity of companies based in Tokyo. For this preparation, the author would like to proposes a questionnaire survey to major companies in Tokyo to find out to which city and how much workers they expect to evacuate at the time of Tokyo Inland Earthquakes.

However, we should be careful that these sudden needs of work place, facilities, housing and so on in recipient cities would arise very fast after a Tokyo Inland Earthquake occurs, but in addition, the needs will start to decline as early as in several months or in several years at the longest. Therefore construction investment of additional offices and housing in the recipient cities may not cost-effective for the preparation of the evacuation. If the preparation activities cause major development projects in recipient cities, it would be, of course, welcomed by business associations in these cities. This may be one of the most difficult discussion points.

5. Conclusion

From the perspective of crisis management for natural disasters and other threats, it is apparently better that the nation's political and economic core functions do not concentrate in one place. However, in present-day Japan, both governmental and business functions are concentrated in Tokyo and the greater Tokyo region. Full-scale dispersion of those functions, if we could, would require a vast amount of money and time. Therefore, we must devise business and operational continuity methods based on present conditions in preparation for a crisis that may occur even in this year.

As mentioned above, all government organizations and private companies that have headquarters in central districts of Tokyo should secure substitute offices/sites as soon as possible. They should carefully study and decide the locations of substitute offices/sites. Their first option would be the places nearby in the central districts of Tokyo, since it is convenient for them to transfer from their headquarters to their substitute offices/sites. However, they should also secure the second substitute offices/sites in the places where one and the same disaster does not causes severe damage to both of their headquarter and substitute offices/sites simultaneously. Most of government organizations seem to select the places in the greater capital area, for example in BNCs. Private companies are expected to choose their substitute offices/sites in the greater capital region or out of this region based on the character of their business.

In addition, regardless of the place of substitute site, many of large companies in Tokyo are requested to consider quick evacuation of workers and their family from Tokyo to their substitute sites/office in other city far from Tokyo to avoid troubles caused by the quake until the recovery progresses sufficiently. Preparation for this evacuation in recipient cities are desirable.

Abstract: This paper introduces a case study of the university BCP for the early recovery of its education and research activities, which has been conducted on Suzukakedai Campus, Tokyo Institute of Technology, in 2009. The paper first discusses the reasons why the university needs BCP, mainly focusing on its social role and responsibility, with the aim of clarifying theoretical background for setting the major goals of the university BCP. The paper then proposes a method of identifying the priority activities which are essential for early recovery, and applies to the education and research activities of the Campus. On a base of the analysis, the earthquake warning system and the isolation tables for the priority equipment have been installed as practical measure in this case. Regarding with emergency responses, the paper examines the current guideline of Tokyo-Tech in terms of early recovery in emergency cases, and points out substantial defects disturbing early recovery of the university activities, which must be common with every university. The paper, thus, proposes a methodological guidance for university BCP which can be applied to universities in general.

1. INTRODUCTION

Most of universities in Japan are located in earthquake prone areas. Thus, once an earthquake occurs, the education and research activities of the universities will be interrupted, resulting in the delay of student's graduation and the severe setback on the advanced researches.

Needless-to-say, these negative effects may be enlarged as the interruption period becomes longer, and on the contrary, they can be minimized by early resumption. The concept of Business Continuity Planning (abbreviated by BCP hereafter) advocated by USA, aims at pursuing the minimum consequential loss of businesses after unexpected emergencies, such as natural disasters, terrorisms, contagion, and so on. The idea has been introduced to Japan since 2004 [*](Ministry of Cabinet Affairs 2005). The authors try to apply this concept to university activities taking the Suzukakedai Campus, Tokyo Institute of Technology, as a case study.

Suzukakedai Campus locates in the Tokyo Metropolitan region, where tectonic earthquakes occur around every 200 to 250 years and two to three active fault earthquakes underneath the area give sever damage to the region in this interval. Since the region has not suffered from any earthquake for the past 87 years since the last tectonic Kanto Earthquake in 1923, seismologists thus anticipate the occurrence of earthquakes by the active faults located underneath the area in very near future. In addition, the location of the Campus is also in the influential territory of Tokai earthquake.

The Campus is not particularly more earthquake-prone than other universities in Japan but rather it is a common fate with Japanese universities, and therefore the methodology applied in this paper may contribute to Japanese universities in general, which confront same problems.

2. WHY DO UNIVERSITIES NEED BCP?

The universities have similar characteristics with business enterprises in a sense that they are competitive each other for both student enrolment and advanced researches. In case of a university, however, some other reasons why it needs BCP may be argued from the view points of its fundamental function that is totally different from private businesses seeking their profit. The paper thus tries to take

[*] This paper was originally prepared to the 3rd Asia Conference on Earthquake Engineering, held in Bangkok, Thailand, 1-3, Dec., 2010, and has been revised based on the discussions and comments raised to the presentation there.

up the following five points for discussion.

The first argument is on the fulfillment of a contract with students. The primary function of a university is to provide educational services to students and to issue a certificate of graduation to those who have completed the given courses within scheduled period. These services are performed under the contract with students who may collaterally pay tuition fee to the university. The interruption of its services or a delay of given schedule is not only non-fulfillment of a contract but also causes severe disadvantages to the students, because the certificate issued by the university has a great social value as a guarantee of quality of the said student. It is also serious fault of the university which may lead to lose its social credit, resulting in severe influence on competitive student enrolment in future.

Secondly, the university has social responsibility to a nation and region for supplying human resources which the society requires. The interruption of university activities implies, in other words, a disorder of this supply system and may cause confusion to the governments or enterprises which regularly expect new human resources.

Thirdly, the university also bears responsibility for keeping its operation to those high school students who are preparing for an entrance examination. It is because, in recent society, the cultural structure in which people evaluate each other based on the certificate of graduation from the university as guarantee of individual quality is popularly established. Thus, the university education is regarded as a mean of individual career development rather than of pursuing scientific truth. In this sense, the university is already a part of social system in which it is expected to pursue its business. This relationship between the university and the society is a kind of a tacit understanding and thus the students preparing for the entrance examination have a tacit right under this understanding. It could therefore be said that the university should not be interrupted unilaterally at its own convenience.

Fourthly, more substantial argument may be drawn from the fundamental function of the university. The raison d'être of the university is no other than to provide higher and qualified education to the nation. The long term interruption of university businesses may cause deterioration of its academic performance in both education and researches, resulting in depreciation of quality of human resources on a country. It may sometimes lead to a national crisis when the said university is the leading academic center in teams of national policy of the country. In this sense, the promotion of the university BCP can be regarded as a part of the national strategy.

Finally, the university BCP is related to employment management, which is common with the enterprise BCP. The long term interruption of the university businesses may cause financial deterioration, resulting in dismissal of its employees, particularly in case of private universities.

As far as employment management, there is some other argument for supporting the importance of BCP. In general, the interruption of businesses of big companies may give the great influences on neighborhood market in the sense that demand for their sales might drastically decline and thus may cause bankruptcies of neighboring businesses leading to dismissal of their employments. However, here in this paper, the authors place it beyond discussion.

3. GOALS OF UNIVERSITY BCP

The goals of the university BCP can naturally be drawn from the above arguments. The pioneering attempt at a university BCP was the one of the "Business Resumption Planning at the University of California, Berkeley" (Sarah K. Nathe, 2005), which was adopted in late 2001 and practically commenced in 2006. The planning goal is to have the university open for business within 30 days of a major earthquake on the Hayward fault. The guidelines are in place to coordinate recovery efforts in four areas of university "business":

1) Inspecting, cleaning & repairing, and reoccupying buildings;
2) Roles and responsibilities of university employees during the recovery effort;
3) Resumption of instruction and research in departments; and
4) Recovery of information and communications systems.

Taking account of this example, the authors have identified the following five goals of the BCP for earthquake disaster at the Suzukakedai Campus on the base of arguments mentioned earlier:

[Goal 1] To secure students, faculty members, and other employees against earthquake disasters;

This goal is primarily for damage mitigation's sake, but the highest priority can also be placed on BCP. It is not only because rescue operations of human life overcome business continuity when human damage is severe, but also because the particular educational programs cannot be continued when the affected professors are not replaceable. Thus, the human resources are regarded as the most fundamental property in BCP.

[Goal 2] To graduate students as scheduled;

As argued earlier, it is a contract with students for a university to graduate them. And the university has social responsibility to a nation and region for supplying human resources which the society requires. In order for the university to perform this duty, particular businesses such as securing regular class hours, authorizing credits, acknowledging graduation, and so on should be continued without delay. Some supplemental businesses such as the issue of certificates, writing of recommendation letters, and assistance of job hunting should be accompanied as well.

[Goal 3] To enroll new students as scheduled;

Regular execution of entrance examination by the university implies to maintain the social system in which the university education is established as a mean of individual career development and its certificate of graduation is regarded as a guarantee of individual quality. The businesses directly

related to it include series of works on application for admission, execution of examination, marking, announcement of successful applicants, and so on. Some supplementary activities such as public guidance of university, distribution of application forms, and preparation of exam questions may also be performed.

[Goal 4] To ensure highly qualified education and researches;

All professors and researchers involve in very advanced and challenging researches, which are highly time competitive in a sense that new academic results can belong to the paper publisher based on the first come and first serve principle. Therefore, even a short interruption of performance may bring the severe setback in their respective academic fields. Needless-to-say, these setback may be enlarged as a resumption time becomes longer, and on the contrary, they can be caught up with easily by reducing recovery time.

[Goal 5] To ensure employment status of faculty members and other employees;

As an employer, the university supports the family lives of its employees. To secure their lives is basic responsibility for the organization. In particular, it would be vital for the university to protect from a brain drain of qualified resource persons.

4. PLANNING CONDITION

4.1 Possible Earthquakes

The first step of BCP is to clarify the possible earthquakes, which may cause damage to the Campus. In 2004, the Disaster Mitigation Division of Cabinet Office, Government of Japan, conducted overall earthquake damage estimate on the faults located in Metropolitan region. According to the result, the four events by the fault shown in table 1 and figure 1 possibly cause severe damage to the Campus. Among them, it is anticipated that Tachikawa fault may cause most severe damage to the Campus (figure 2).

Table 1 Possible earthquakes

Earthquake	Magnitude
1.Kanagawa east EQ (underneath Yokohama city)	M6.9
2. EQ underneath Kawasaki city	M6.9
3. EQ by Tachikawa fault	M7.3
4. EQ by Miura faults	M7.2

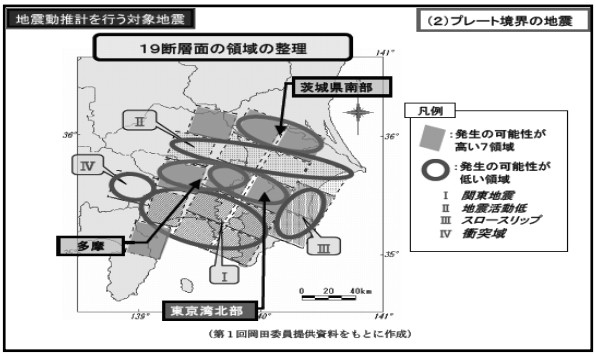

Figure 1 Location of faults

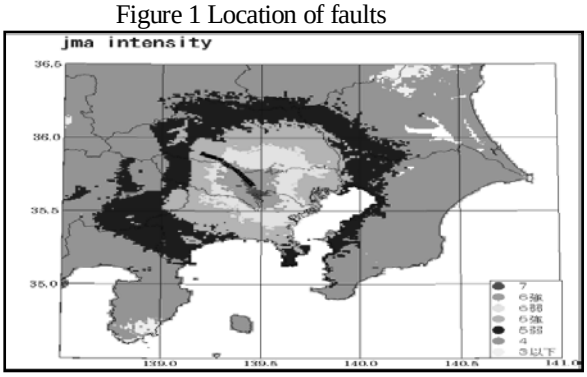

Figure2. Grand motion by Tachikawa fault

4.4 Target Resumption Date

The target resumption date of businesses is, in other words, the acceptable interruption period. But by whom is it acceptable? The argument made in the section 2 suggests variety of the stakeholders such as; by students, by society, by examinees, by a nation, and by its employees. Theoretically speaking, the interruption period has to be determined by all of them, but it would be hard enough.

Moreover situation is more complicate, because the acceptable period depends on the time when the event occurs and on the affected area and severity of damage. In fact, more time may be available when it occurs before a summer vacation, while time may be limited before the graduation season. The society may accept the delay of resumption when the affected area is extremely vast, and damage is so severe, while it does not tolerate long interruption in case of limited damage.

In summary, there is not clear criterion to determine a proper resumption date, and rather it may vary from a case to another. In order to formulate the BCP, however, the date has to be set up. So, after the example of University of California, Berkeley, the planning goal is determined to have the university open for business within 30 days after any possible earthquakes.

4.3 Educational Program at Suzukakedai Campus

The Suzukakedai campus of Tokyo Institute of technology consists of one undergraduate school and two graduate schools, with 2350 students in total.

As to the undergraduate school, the 3rd and 4th grade students of about 350 persons study in the two Departments of School of Bioscience and Biotechnology for their graduation thesis works.

One of two graduate schools is Graduate School of Bioscience and Biotechnology, which consists of five courses (departments) such as Life Science, Biological Sciences, Biological Information, Bioengineering, and Bimolecular Engineering, and about 450 students join in master and doctoral program. Another graduate school is Interdisciplinary Graduate School of Science and Engineering, which consists of 11 courses (departments) such as Innovative and Engineered Materials, Electronic

chemistry, Materials Science and Engineering, Environmental Science and Technology, Built Environment, Energy Science, Environmental Chemistry and Engineering, Electronics and Applied Physics, Mechano-Micro Engineering, Computational Intelligence and Systems Science, and Information Processing and about 1600 master and doctoral students are working.

4.4 Research Activities at Suzukakedai Campus

In the Suzukakedai campus, about 500 employees are working. Out of them, 400 persons are researchers such as professor, associate professor, lecturer, and research associate, and others are engineers and administrators. In addition, some more part time stuff joins. Most of researchers perform their research works under the above mentioned departments integrating with educational activities. Apart from these educational organizations, however, six research laboratories are in operation at the campus. They are; Chemical Resources Laboratory, Precision and Intelligence Laboratory, Materials and Structures Laboratory, Imaging Science and Engineering Laboratory, Frontier Research Center, and Center for Biological Resources and Informatics.

5. EXISTING GUIDELINE TO EMERGENCY RESPONSE AT TOKYO TECH

In order to resume the educational and research activities as quick as possible, protective measures avoiding fatal loss leading to a severe delay of recovery is vital. In this respect, the structure of university buildings has to be resistant to a earthquake and office furniture have to be fixed. As to the Suzukakedai Campus, retrofit of all buildings has been completed, and the fix of the office furniture is proceeding.

Such earthquake measures are also a part of BCP in broader sense. In other words, however, it is a common field with a traditional earthquake measurement. More substantial problems in terms of BCP rather lie in the guideline to emergency response, which is commonly prepared at any university.

5.1 Emergency Response System to Earthquake

One of the difficulties for establishing the emergency response system at university, the command system of the emergency operation has to be designed based on physical location or individual building where every damage event occurs. It must be, however, normally observed that research and educational activities of one department are scattered about several buildings in the Campus and to the contrary, there is a case where couples of departments share one building. It means that the regular administrative organization cannot be applied to the command system of emergency operation.

In case of the Suzukakedai Campus, the situation is not exceptional, and the guideline of emergency responses involves substantial faults, which must be common with other universities. As mentioned earlier, there are two undergraduate departments and sixteen graduate courses (departments) at Suzukakedai Campus. However, the numbers of research and educational buildings are thirty-one. Thus, the guideline of emergency responses at Tokyo Tech set “Self Defense Corps for Disaster (SDCD)” for individual building. These thirty-one SDCDs are placed under the command of the Emergency Headquarter (EH) which is supposed to be established just after the event by the ten members of the head of the schools, the research laboratories, and administration office. The problems identified through the careful examination of existing SDCD operations on the emergency case are as follows;

- Although emergency response operation will depend on the extent of damage, no clear criteria is described in the guideline for setting-up and operation procedure of an EH,
- The member of EH serves concurrently as a chief of two to four SDCDs. Though this arrangement aims to gather all information to the EH, the SDCD at the scene has to work without leader,
- There is no clear procedure for collecting damage information on the affected buildings, where dangerous experimental materials are normally dealt with, and most severely,
- No duty is given to SDCD to assure itself that the building in charge is safe for the building residents to reoccupy their respective office or laboratory and to resume their education and research activities. This point is vital for early recovery and resumption.

5.2 Amendment to the Guideline for BCP

On the basis of the existing guideline, an amendment to the guideline has been proposed from the view point of BCP as follows;

- To clarify the trigger criteria for setting-up an EH and for starting SDCD operation,
- To prepare the operation manuals at the different level of damage,
- To establish an independent operation system of SDCD at the affected scene under the command of the respective team leader at the early stage of the event,
- The EH to dispatch special team to investigate the leakage of dangerous materials on the base of the request made by the respective SDCD, and
- To formulate the clear procedure for the building residents to reoccupy their respective office or laboratory and to resume their education and research activities.

6. BCP FOR EDUCATION

As mentioned above, the guideline of emergency responses of Tokyo Tech regulates to form a special command system at the occurrence of an earthquake and all faculty members have to behave under the system. The guideline, however, does not cover measures for the educational program of the respective department such as resumption of the classes, authorization of credits for

graduation, or indispensable exceptional rules. Thus, each department has to set its own rules and emergency responses action plan of the following items.

(1) Commencement of emergency operation at the department
- To urgently hold the faculty meeting of the department,
- To make a rule on who calls the meeting since the chairman is not always available,
- To clarify beforehand the trigger event for holding the meeting, and
- To make a decision criterion which is different from normal majority rule, as only limited faculty members can attend.

(2) Inspection of damage and student life

(3) Resumption program of classes
- To reform the curriculum based on available faculty members,
- To establish information transmission system with the students, and
- To make a rotation program of faculty members including replacement with the injured.

(4) Execution of graduation and entrance examination
- To provides a particular works for fulfilling conditions for required educational period, and
- To apply the exceptional rule to authorization of credits with given criteria

(5) Recovery of experimental laboratories

(6) Public relations

7. BCP FOR RESEARCH ACTIVITIES

7.1 Survey of Current Activities and Damage Estimate

Whatever earthquake resistant measures are taken, physical damage to a set of experimental equipment in every laboratory cannot be avoidable to a certain extent once an earthquake occurs, as no perfect protective measure to keep all the equipment safely to the events exists. In order to clarify the current activities and working environment of the research laboratories, and also to estimate their loss and damage caused by an earthquake, the investigation of the following contents through a questionnaire survey and direct interview survey to research stuff is required.
- What kind of research works or experiments are in operation?
- What kinds of equipment and dangerous materials are used under what conditions?
- How much energy is normally in use?
- How far the researches would be influenced through one month interruption by earthquake?
- How long does it take for the researches to be resumed when major equipment is collapsed?

In this paper, “Frontier Research Center” where the five laboratories are currently performing their research works is taken as a case study.

7.2 Priority Preparatory Measures for Early Recovery

One of the principal ideas of BCP is to clarify the target resumption date, or acceptable period of interruption. In order to keep it, however, the function of some basic experimental equipment or law materials should be kept safely without collapse or deterioration by an earthquake. It is thus essential for BCP to identify the most fundamental function and to give priority investments beforehand to avoid fatal loss leading to a severe delay of recovery. In this paper, two criteria have been applied to identify such priority investment as follows:

Influence of Business Interruption
= (Acceptable period of interruption: 5 ranks)
× (Intent of influence: 5 ranks) (1)

Acceptable period of interruption:
Rank 1 – more than 30 days
Rank 2 – less than 3 weeks
Rank 3 – less than 2 weeks
Rank 4 – less than 1 week
Rank 5 – within 1 day

Intent of influence:
Rank 1 – no influence
Rank 2 – small influence
Rank 3 – certain influence
Rank 4 – large influence
Rank 5 – severe influence

Difficulty of Resumption
= (Acceptable time for repair: 5 ranks)
× (Possibility of repair: 3ranks) (2)

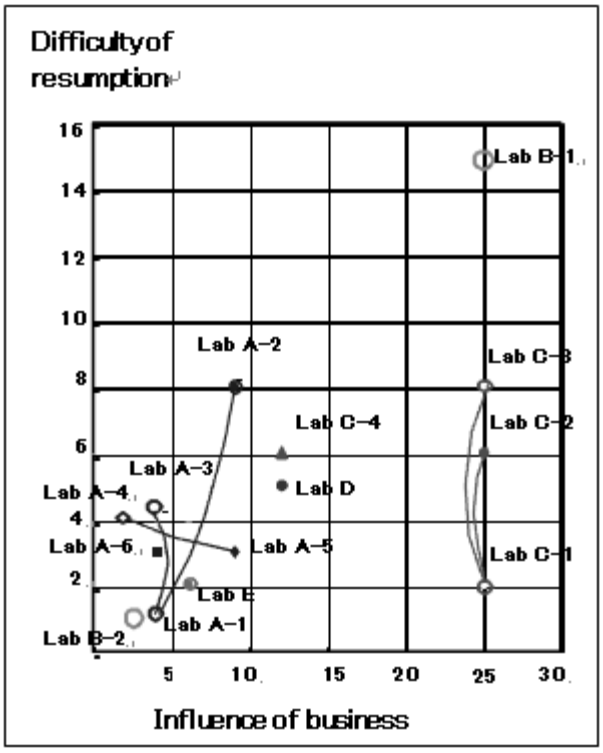
Acceptable time for repair:
Rank 1 – about 1 month
Rank 2 – about 3 months
Rank 3 – about 5 months
Rank 4 – about 6 months
Rank 5 – about 1year or more

Possibility of repair:
Rank 1 – possible
Rank 2 – hard to repair
Rank 3 – impossible

The result is shown in figure 3. Since Lab B-1 has been identified as the highest priority research program in a sense that both the difficulty of resumption and the influence of interruption are greatest, the recommendation of special investment to secure the research program has been proposed.

In addition to it, the following arrangements to be prepared beforehand have been recommended.
- To identify all resources that are required to achieve this target, including human resources, working space, experimental equipment and materials, energy, water and so on so force,
- To reserve spare parts or preferably a spare set of equipment,

- To establish priority repair agreement with a manufacturer,
- To reserve experimental materials, or to establish a purchase channel on them,
- To coordinate with electric company for priority energy supply,
- To coordinate with water supply agency for priority water supply, and
- To prioritize recovery order with emergency funding arrangement



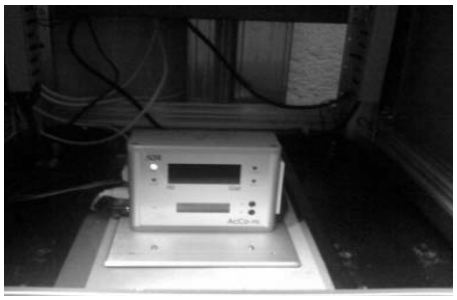


Figure 3 Laboratories on two criteria

7.3 Practical Measures

As to the first step of practical implementation of the BCP for the Campus, the isolation tables were installed to the instruments to which protective measures should be given as the top priority on the bases of the analysis in the previous section (Picture 1), and the special treatment to fix fundamental experiment instruments on the floor or to side wall. To be particularly highlighted, the Earthquake Early Warning System (EEWS) has been installed at the "Frontier Research Center" building (Picture 2, 3). The system is expected to catch P-wave and to give a warning of the occurrence of an earthquake 15 to 25 second before the reach of S-wave that causes major ground motion.

Picture1. Isolation table

Picture2. Seismogram

Picture3. Information board

8. CONCLUSIONS

In order for the BCP to be implemented effectively, the intensive involvement of the all stakeholders is vital. Therefore, some continuous program for promoting people's awareness must be provided in daily life. In addition, the activities of respective laboratories are not stable but are changing with some research cycles. It means that the BCP has to be up-dated on regular bases in order to catch up with these changes and to reflect new situations.

Lastly but not the least, the university also must need to prepare for accepting refugees who are escaping from neighboring calamity. It must definitely be a part of social responsibility of the university.

SEISMIC RISK AND DAMAGE COST ANALYSIS OF MID-RISE BASE ISOLATED BUILDINGS IN PERU

Luis A. Bedrinana[1)] and Taiki Saito[2)]

luisbedrim@gmail.com, tsaito@kenken.go.jp

Abstract: The principal objective of this study is to evaluate the cost-effectiveness as well as the seismic safety of a base isolated building located in Peru. A methodology to evaluate quantitatively the seismic risk and the cost-effectiveness of a base isolated building during its lifetime is presented. The process starts with the hazard analysis and the earthquake ground motion generation in the studied area. Lima area is considered in this study. Series of artificial earthquake ground motions are generated by a stochastic method in the studied area. Then a preliminary seismic design of the target building is carried out, by using the Peruvian seismic code. To get the response distribution of the target building, several dynamic nonlinear analyses are performed by using the generated artificial motions as input waves. By assuming a structural response distribution, the seismic risk analysis is performed in terms of three structural parameters such as: interstory drift ratio (*IDR*), floor acceleration (*FA*) and the structural damage index (*DI*). The damage of the target building is evaluated by using a damage index. Finally, the cost-effectiveness of using base isolation system is examined, by comparing the exceedance probability of repair cost in the target building with and without base isolation during a given time period.

1. INTRODUCTION

Peru is an earthquake prone country, which has experienced many severe earthquakes in its history. Most of those severe earthquakes have been a big disaster, producing huge losses and fatalities. Most important problems noticed in buildings during these events, are: low resistance, high level of damage, and no protection of contents. To increase resistance in buildings several improvements have been made in the seismic code; however, there is no any regulation about damage limit levels in buildings in current codes. Moreover, current provisions do not provide any protection to nonstructural components, equipment and contents of buildings.

One of the best alternatives to reduce the damage and to provide protection of contents in buildings is the use of base isolation. Base isolation has proved to be a reliable technology to prevent damage in buildings and to increase the seismic performance; however current seismic provisions do not provide information of the real safety of base isolated buildings. Furthermore, in developing countries the use of base isolation is not wide due to the high construction cost of isolation system. So, a methodology to evaluate the real seismic safety and cost-effectiveness of the base isolation system is needed to meet current performance requirements in buildings. This methodology has to provide a rational basis and clear procedures to achieve the target in order to be used normally.

2. SEISMIC HAZARD AND EARTHQUAKE GROUND MOTION MODELING

Seismic hazard of studied area is determined using past earthquake data. The historical data of past earthquakes (Figure 1) from the Peruvian seismic catalog (Tavera et al. 2007) are used to model the earthquake occurrence of magnitude (*M*) and hypocentral distance (*R*) around Lima area.

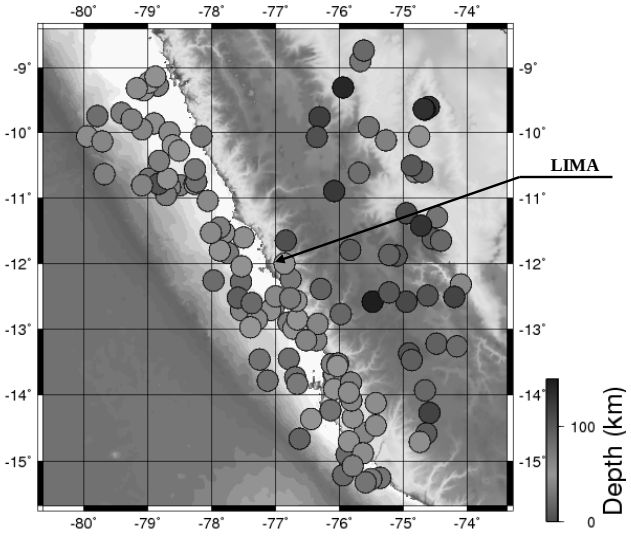

Figure 1 Distribution of earthquake epicenters around Lima from 1963 to 2005.

The earthquake occurrence of magnitude and hypocentral distance is modeled by a truncated G-R formula and the Beta probability function respectively as is shown in Figure 2. To generate the artificial ground motions, several sets of *M* and *R* are randomly generated according to their probability distributions by standard procedures. Then, each set of values of *M* and *R* is related to ground motions by means of an attenuation formula in terms of spectral acceleration for Peru subduction earthquakes. In this study the attenuation relationship for spectral acceleration in Peru is used (Chavez 2006), which was proposed for different soil conditions of the Peruvian coastal area.

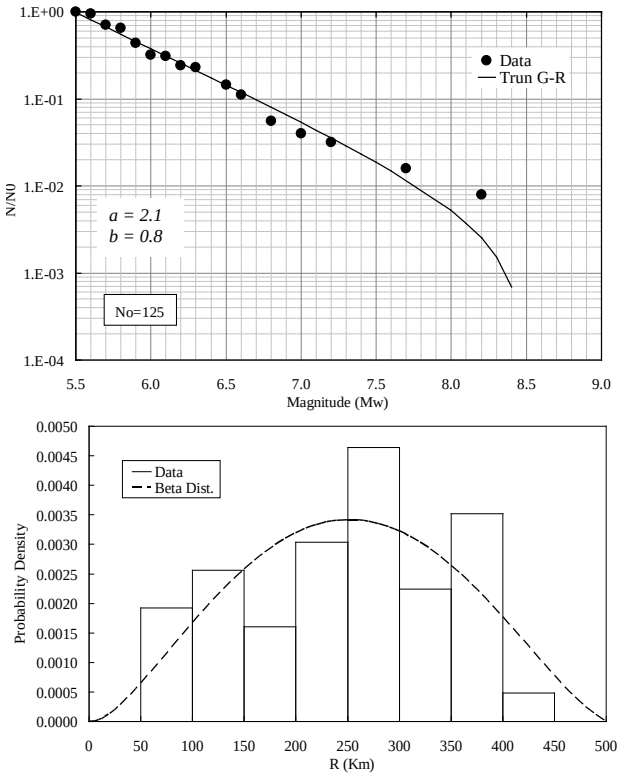

Figure 2 Earthquake occurrence of magnitude *M* and hypocentral distance *R* (1963 to 2005).

The artificial earthquake ground motions are generated as a nonstationary stochastic process compatible with the response spectrum calculated previously with the attenuation formula. By using the random vibration theory, a simple model of earthquake ground motion *A(t)* is expressed as a product of a wave *x(t)* from a stationary random process, with a power spectral density *PS(ω)*, and an intensity envelope function *E(t)* (Shibata 2010) as follows

$$A_{(t)} = E_{(t)}.x_{(t)} \tag{1}$$

In this study, the Jennings's intensity envelope function *E(t)* is used (Jennings et al. 1969). This function takes into account the transient effects in time of earthquake ground motions. The sample wave *x(t)* is generated by a combination of harmonic functions, with a given power spectral density *PS(ω)* (Gasparini et al. 1976). This power spectral density *PS(ω)* represents the importance of the harmonic function, in some specified band frequencies, and it matches the target spectrum defined previously. A total number of 800 artificial earthquake ground motions are generated for the studied area. Figure 3 shows the response spectrum of a sample generated wave (Sample 128) *RSX* which is compared with the target response spectrum *RST*.

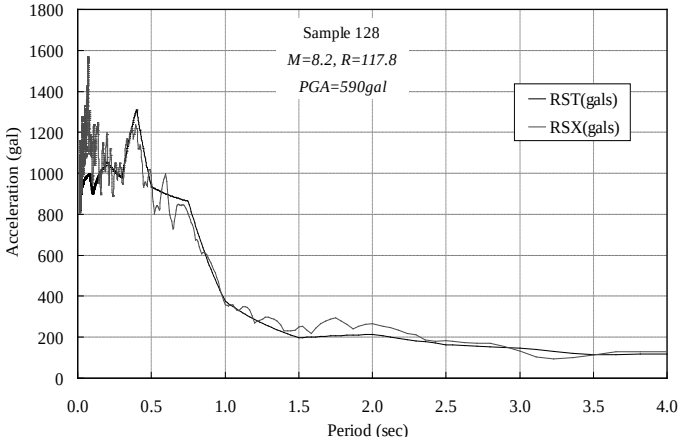

Figure 3 Comparison between target response spectrum and response spectrum of generated sample wave.

3. STRUCTURAL AND DAMAGE ANALYSIS

3.1 Target building

The target building for this study is an RC office building with 8 stories as is shown in Figure 4. This building is assumed to be located in Lima downtown and it is a representative mid-rise building. The concrete used in this building has a nominal strength of *f'c=21MPa*, and the nominal strength of steel is *fy=412MPa*. The total weight of the structure is around *46174kN*, and the fundamental period is 0.65s in X direction and 0.54s in Y direction. The target building is designed according to the Peruvian seismic code. The design base shear coefficient is 0.08 in X direction and 0.09 in Y direction.

3.2 Design of base isolation system

In this study, the equivalent SDOF method (Okamoto et al. 2002) is used to design the base isolation system in the target building. This method considers an isolated building as a rigid body moving with hysteretic properties of isolation devices, with a bilinear model. The lead rubber bearing LRB is used as isolation devices in this study. The total design yield force of the isolation system is set to 4% of the total weight and the design limit displacement is 300mm. Moreover, the design target period of the isolation system is 2.24s. Table 1 shows the dimensions of isolation devices.

3.3 Dynamic Analysis

To obtain structural response of the target building a series of nonlinear dynamic analyses are carried out, using artificial ground motions generated previously as input motions. These artificial ground motions represent future

earthquakes that would occur in the life cycle of the building. In this study structural uncertainty is assumed to be small compared with uncertainties of ground motions, and structural uncertainty is not taken into account. The nonlinear dynamic analyses are carried out in the building with conventional design as well as with base isolation.

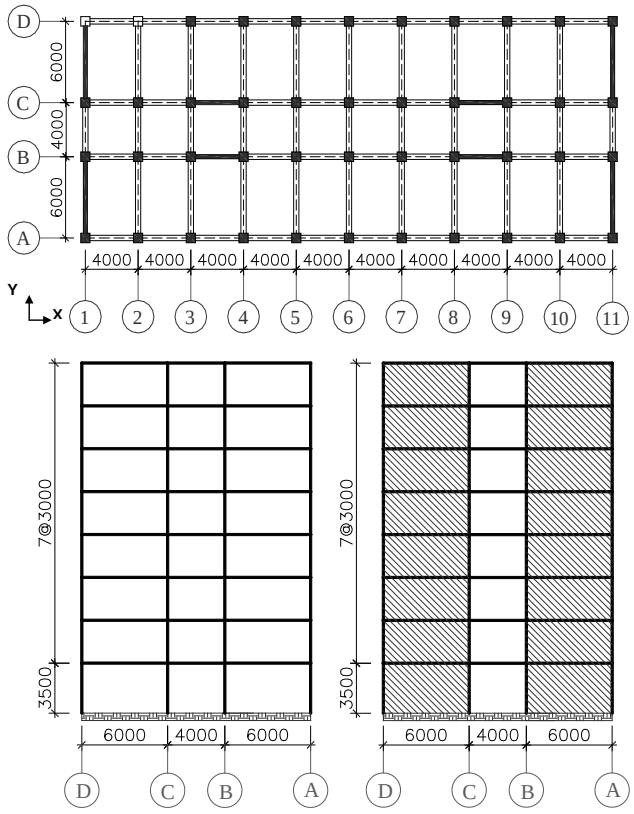

Figure 4 Plan and elevation view of the target building.

Table 1 Dimensions of isolation devices.

	LRB-600	LRB-500
Shear Modulus (N/mm2)	0.39	0.39
Shear Modulus lead (N/mm2)	0.59	0.59
Exterior Diameter (mm)	600	500
Interior Diameter (mm)	100	100
Thickness of rubber layer (mm)	4	3.5
Total rubber thickness (mm)	144 4 x 36	123 3.5 x 35
Steel layer thickness (mm)	2.5	2.5
Primary Shape Factor S1	37.5	35.7
Secondary Shape Factor S2	4.2	4.1
Number of Bearings	36	8

3.4 Damage Analysis

Additionally to the structural response in terms of *IDR* and *FA*, the structural damage in the target building is evaluated. To correlate the values of *IDR* with damage, the Park-Ang's damage index (1985) is used. This damage index considers earthquake damage in RC members is composed of the damage caused by the maximum displacement and the absorbed hysteretic energy. The damage index *DI* is expressed by.

$$DI = \frac{\delta_m}{\delta_u} + \beta_c \frac{Eh}{Q_y \delta_u} \tag{2}$$

Where Q_y the yield strength, Eh is the total hysteretic energy dissipated during earthquake, δ_m is the maximum drift during earthquake, δ_u is the ultimate drift under monotonic loads, and β_c is a constant.

Moreover, the overall damage of entire buildings is checked by means of the total damage index DI_T, (Park et al. 1985) as follows

$$DI_T = \sum \lambda_i DI_i \qquad \lambda_i = \frac{Eh_i}{\sum Eh_i} \tag{3}$$

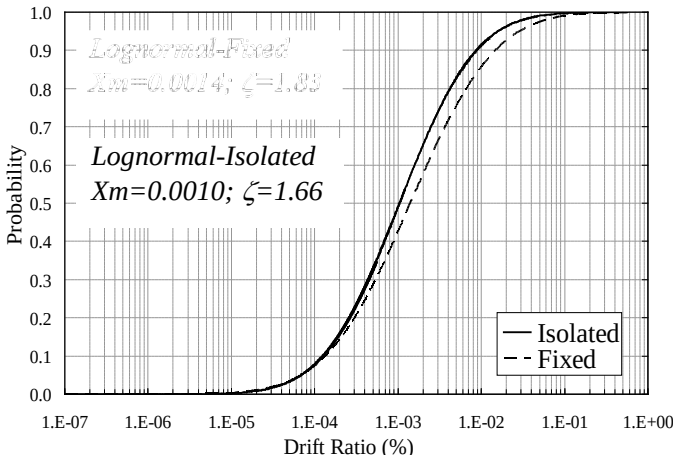

Figure 5 Lognormal distribution of *IDR* in 1st story.

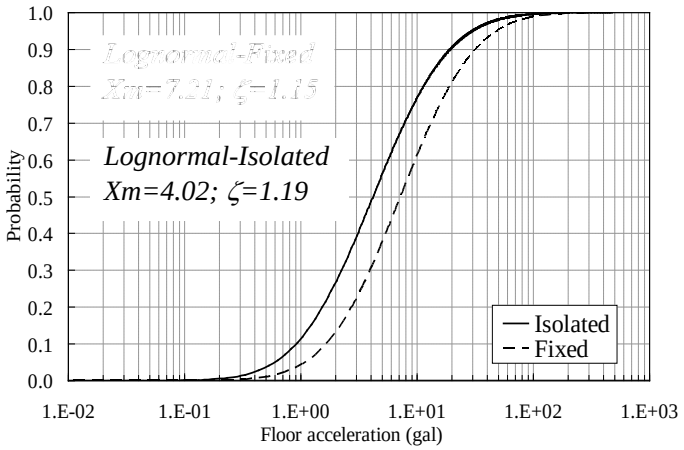

Figure 6 Lognormal distribution of *FA* in 1st story.

4. STRUCTURAL RESPONSE DISTRIBUTION

A total of 800 nonlinear dynamic analyses are carried out in the target building, with and without base isolation, by using artificial earthquake ground motions previously generated. With information of structural maximum response in each analysis, the probability distribution of the interstory drift ratio (*IDR*) and peak floor acceleration (*FA*) is obtained. The structural response is modeled by a lognormal distribution in this study and Figure 5 and Figure 6 show the distribution of *IDR* and *FA* respectively in the first story of the target building.

Based on the 800 values of maximum *IDR* showed previously, the damage index is calculated for each and every case. Park and Ang (1985) determined that the damage index is reasonably lognormal distributed. Figure 7 shows the lognormal probability distribution of total damage (DI_T) in the target building. It can be seen from this plot that structural damage in isolated building is considerably reduced. Additionally, the median value and the standard deviation of damage distribution of isolated building are lower than conventional one.

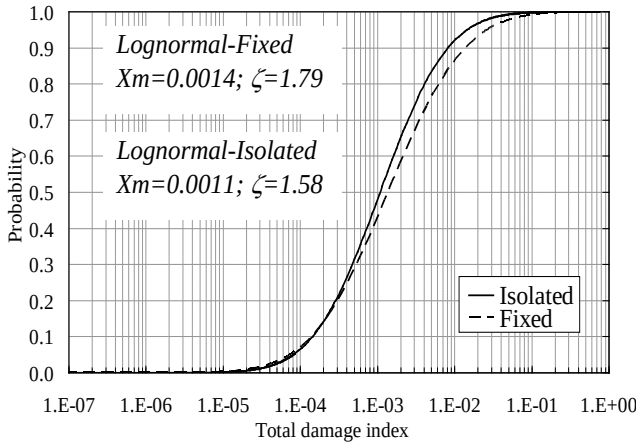

Figure 7 Probability distribution of DI_T.

5. SEISMIC RISK ANALYSIS

The seismic safety of a building can be quantified in terms of the exceedance probability of the structural response. To evaluate the exceedance probability of a random variable *X*, which represents structural response, the Poisson process model is used as is shown in Figure 8. If *X* is the random variable evaluated, $F_{(X)}$ is the cumulative distribution of *X*, and ν is the annual occurrence of the event; the exceedance probability that $X>X_m$ in t years is given as follows (Saito and Wen 1994)

$$p_f = P\left(X > X_m \middle| [0,t]\right) = 1 - \exp\left[-\nu t(1 - F(X_m)\right] \quad (4)$$

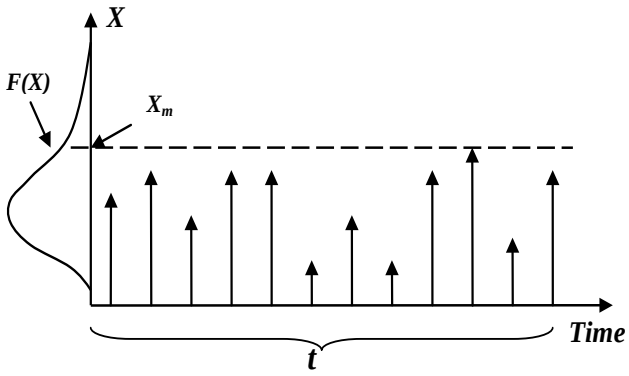

Figure 8 Exceedance probability of random variable based on the Poisson process.

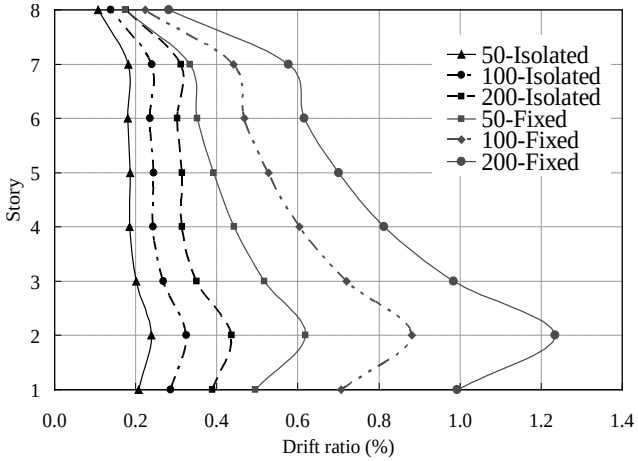

Figure 9 Values of *IDR* with 10% of exceedance probability in 50, 100 and 200 years.

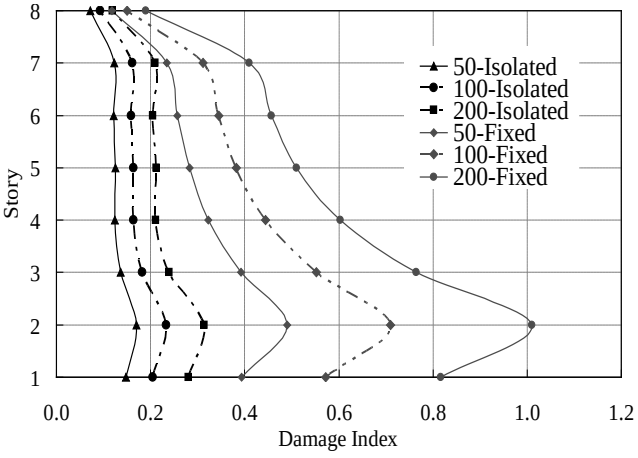

Figure 10 Values of *DI* with 10% of exceedance probability in 50, 100 and 200 years.

The seismic risk of the structure can be quantified in terms of exceedance probability of the structural response. To estimate the probability that the *IDR* will exceed some threshold value, the Poisson process model is assumed for the earthquake occurrence. The annual earthquake occurrence is $\nu=2.98$ in this study. Figure 9, shows the

values of *IDR* for the target building with 10% of exceedance probability. The values of *IDR* for isolated building are much lower than values for conventional building. So, it can be said that isolated building has better seismic safety than conventional building.

The seismic risk of the structure can be also quantified in terms of exceedance probability of damage index. The Poisson process model for earthquake occurrence is also used to obtain the probability that *DI* will exceed some threshold value. Figure 10 shows the values of *DI* with 10% of exceedance probability. It is observed that conventional building suffer large damage for long time periods and after 100 years there is a 10% exceedance probability to have a value of *DI* equal or more than 0.60. Damage in main structure is reduced by using the base isolation system, so the probabilities to have severe damage are significantly lower than the case of conventional building.

6. COST-EFFECTIVENESS ANALYSIS

In addition to the seismic risk analysis, the cost-effectiveness analysis of the target building, with and without base isolation, is carried out. In this study just the structural cost is taken into account, principally due to the lack of reliable data of nonstructural components, contents and maintenance of buildings in Peru. The cost-effectiveness is evaluated by a model which correlates damage index into structural repair cost of each story, so the total cost is the sum of repair cost in each story. In this study the model to correlate damage and repair cost is based on the proposal of Takahashi and Shiohara (1987). The repair cost is defined by the structural repair cost ratio R_S, which is the normalized repair cost by the cost of total replacing with new one. The repair cost ratio R_S is defined by

$$R_S = \begin{cases} 0.0; & DI < Dc \\ \dfrac{DI - Dc}{1 - Dc}; & Dc \le DI < 1 \\ 1.0; & DI \ge 1 \end{cases} \quad (5)$$

Where *Dc* is the minimum damage index in which repair work is necessary and a value of 0.01 is taken.

Results obtained in damage analysis are related to repair cost by the cost ratio. Using values of damage index with 10% of exceedance probability, the structural cost repair ratio can be obtained in every case. It is noticed from these tables that conventional building has large values of R_S; especially in long time intervals, it is observed that some stories need to be almost totally repaired. If the life time were 100 years; it would be expected a value of 37.1% for total cost ratio in the conventional building, which is about 4.7 times larger than value of isolated building.

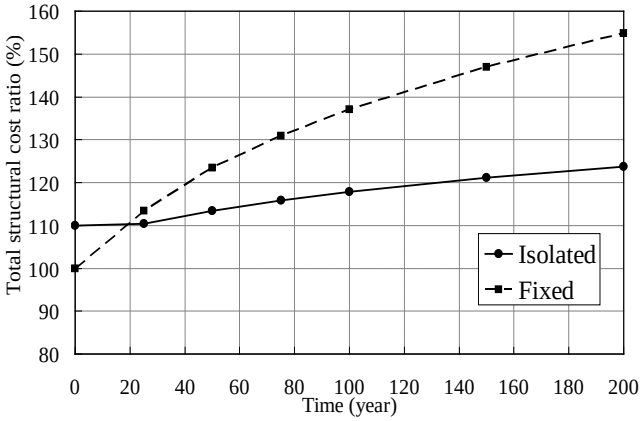

Figure 11 Expected values of total structural cost with 10% of exceedance probability in the lifetime of the building.

7. CONCLUSIONS

The methodology presented here is a useful tool to quantify the seismic risk and the cost effectiveness of base isolated buildings. Additionally this procedure could be extended to any kind of building structure.

The total damage in conventional building is considerably larger than isolated building. The expected value of the total damage index in 50 years, with 10% of exceedance probability, for the fixed building has a value of about 2.47 times larger than isolated one.

Although the initial total structural cost in the isolated building is larger than in fixed one, the total structural cost in isolated building is much smaller for long time interval. So, base isolated building is cheaper than fixed building during the lifetime of the target building.

It can be concluded that the seismic risk is much lower in isolated building; moreover, the cost-effectiveness in isolated building is better than fixed building, during lifetime period when large damage is expected.

An upgrade in seismic codes is needed in order to include probabilistic methodologies to evaluate the seismic risk of buildings.

Abstract: NEES Integrated Seismic Risk Assessment Framework (NISRAF) combines several components in order to obtain the most reliable earthquake impact assessment results possible. The components are: hybrid simulation, free-field and structural sensor measurement, hazard characterization, system identification-based model updating technology, hybrid fragility analysis, and impact assessment packages. A software tool has been built and verified, concurrently, via application to an actual test bed in California. Impact assessment results using the generated hazard map and fragility curves correlated with field reports of the Northridge earthquake 1994. The novelty of the developed system is primarily the integration of components of earthquake impact assessment—most of which have not been deployed in such an environment before.

1. INTRODUCTION

The objective of research in earthquake engineering is to improve seismic loss estimation which aids in emergency planning, mitigation, response and recovery. Through field investigations after damaging earthquakes, along with theoretical and experimental studies, practitioners and researchers have substantially improved their understanding of the effects of earthquakes in the recent decades. Individual sub-disciplines have been focused on specific problems within the broad field of earthquake engineering. Examples of disciplinary developments are strong-motion measurements, system identification, model updating, structural performance evaluation through experimental and analytical simulations, fragility derivation, and the development of consequence estimation software.

The above component-specific studies allow researchers to focus on a particular problem at a fundamental level. Even though these specific studies have progressed considerably and produced mature research results, uncertainties remain in their outcomes not only because of their inherent characteristics, but also because of the interactions between them. For example, the derivation of fragility curves requires that a large amount of simulations be performed. It is essential to have an accurate structural model which closely represents the response of the real structure. In most fragility simulations, however, either a very simplified structural model is used or a complicated numerical model is used without being calibrated to measured response. Such methods, therefore, introduce significant and by-and-large unquantifiable uncertainties in the derived fragility curves. Moreover, the fragility curves heavily depend on input ground motions, particularly when the fragility curves are defined in terms of peak ground acceleration (PGA) (Kwon and Elnashai 2006). The ground motion is in turn influenced by source, path, and site characterization, each of which is a formidable challenge in its own right. The realism of both model and input is therefore essential to the accuracy and applicability of the ensuing fragility relationships.

Hazard, fragility, and inventory are the three major components of earthquake impact assessment. Among these, the inventory can be improved through the development and application of survey methods and technologies. This renders the accuracy of the assessment dependent on the reliability of the fragility curves and hazard characterization. Unquantifiable uncertainty and inaccuracies in the latter two components of hazard and fragility lead to earthquake impact assessments—that are unreliable and that do not form a viable basis for societal readiness.

2. METHODOLOGY

To reduce the above-mentioned uncertainties and unreliability in impact assessment, an integrated framework is proposed, developed, and verified via application to an actual test bed. Figure 1 illustrates the proposed framework and how its components are combined to achieve the main goal of this research. As can be seen, the proposed framework, referred to as NEES Integrated Seismic Risk Assessment Framework (NISRAF), integrates hybrid simulation with free-field and structure sensor measurements, hazard characterization analysis, system identification-based model updating technology, hybrid fragility analysis, and

earthquake impact assessment tools. The procedure is specifically proposed and programmed for ease of use.

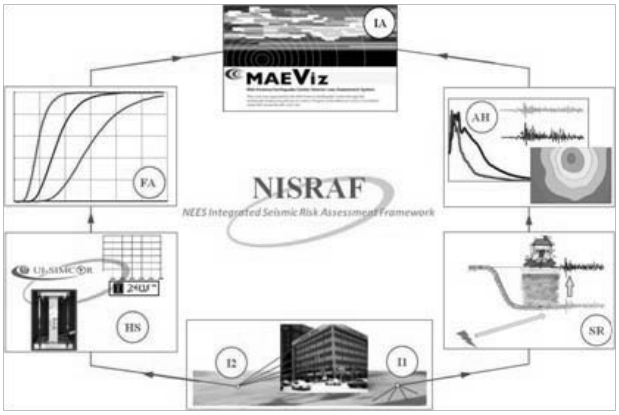

Figure 1 Schematic of the proposed integrated framework

In the schematic representation of the integrated framework given in Figure 1, free-field measurements (**I1**) along with nonlinear site response analysis (**SR**) are used to generate the advanced hazard map and ground motion records (**AH**). The measured and synthetic records are then used as seismic inputs in hybrid simulation and fragility analysis. Meanwhile, the structural model is calibrated with the measured structural response (**I2**). Next, hybrid simulations (**HS**) are performed with the most critical component of the structural system tested in the laboratory and the remainder of the structure simulated analytically. These simulations are conducted to derive the mean seismic intensity value (PGA, for example) of the corresponding performance limit state. The fragility curves (**FA**) of the structure are then generated using the hybrid simulation data and the dispersions from the literature. Finally, the derived fragility curves and the calibrated hazard map are fed into the impact assessment tools, such as MAEviz (MAE Center 2007) (**IA**) to evaluate the seismic losses.

The integration feature provides a chance to bring together all the sub-disciplines, capitalizing on the respective advances of each sub-discipline. This method of integration is not only intended to provide a tool, but it is also intended to stimulate the sub-communities of researchers to investigate the problems at the interfaces between them. Through this systematic and transparent framework, uncertainties from each sub-discipline can be managed more effectively and the use of the instrumentation will increase. For example, the reliability of probabilistic seismic hazard can be significantly improved through the use of free-field strong-motion measurements. Analytical and hybrid (analytical-experimental) simulations can be realistic due to calibration with system identification results from sensor measurements. The uncertainties resulting from deriving fragility relationships can be greatly reduced through the use of more reliable representation of hazard and more accurate structural models. Confidently, with seismic hazard from field measurements and fragility curves from more accurate models, NISRAF can significantly improve upon earthquake impact assessment results with higher reliability.

In the subsequent sections, the methodologies and techniques utilized in each component are discussed and then followed by application examples of the integrated framework.

3. ADVANCED METHODS UTILIZED IN NISRAF

To achieve a seamless integration and to arrive at an operational and verified system, several components were used innovatively, tailored to perform the role required by NISRAF.

3.1 Advanced Hazard Analysis Method

Owing to uncertainties from seismo-tectonic, earthquake energy attenuation and site conditions, it is difficult to describe accurately the hazard characterization. Many tools for seismic hazard analysis have been developed over the past decades. Among them, Deterministic Seismic Hazard Analysis (DSHA) and Probabilistic Seismic Hazard Analysis (PSHA) are the most commonly used methods, and both are generally implemented within the earthquake impact assessment packages. Due to the probabilistic nature and the simplified assumption for the local site effect, such as the use of site coefficients *Fa* and *Fv* (FEMA 2009), uncertainties remain in the procedure and outcome. To reduce these uncertainties, an advanced hazard characterization analysis approach, including site response analysis, is proposed.

As shown in Figure 2, this approach is composed of (i) seismic hazard analysis, (ii) synthetic ground motion generation, (iii) site response analysis and (iv) hazard map generation. First of all, the natural records are directly investigated to evaluate the hazard characterization. Synthetic records of different hazard levels are then generated for further use in hybrid simulation and fragility curve derivation. Subsequently, both the natural and synthetic records are ready to be modified to reflect the local site condition. DEEPSOIL (Hashash et al. 2009)—a 1-D site response analysis program—is implemented in NISRAF to conduct this analysis.

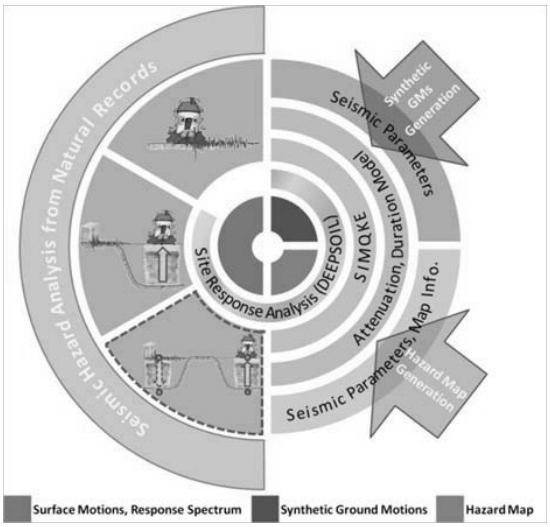

Figure 2 Methodology and procedure of the advanced hazard characterization analysis method

In addition to the seismic hazard analysis, synthetic ground motion generation and site response analysis, this advanced hazard analysis method also provides a function to generate hazard map, which is the exposure of the impact assessment.

3.2 Efficient Model Calibration Method

Finite element model simulation provides a powerful way to understand the response of structures. Unfortunately, even well constructed models may produce significant differences in some dynamic response predictions, in particular when the structure behaves nonlinearly. The difference is from the uncertainties of the material, boundary conditions and the contribution of the non-structural elements in the real structures. In order to overcome this drawback, a model calibration method based on the experimental or real response—which is composed of system identification and model updating techniques—is proposed. The following sections give an overview of these two techniques.

Among the many state-space based system identification methods, the Eigensystem Realization Algorithm (ERA) (Juang and Pappa 1985) is implemented in NISRAF due to its wide application and good performance in multi-input multi-output (MIMO) problems. Moreover, in order to filter out computational or noise modes, a two-step strategy is applied. Since more singular values are retained, more potentially genuine modes can be identified. In NISRAF, the dimension of the realized system N is increased until an adequate number of modes are included. For each particular order of a system, three commonly used mode accuracy indicators, namely, Modal Amplitude Coherence (MAC) (Juang and Pappa 1985), Extended Modal Amplitude Coherence (EMAC) and Modal Phase Colinearity (MPC) (Pappa and Elliott 1993) are used to filter out the computational or noise modes. The retained modes are then deemed trustable and a stabilization diagram is plotted for further confirmation.

Model updating aims to minimize the discrepancies between the numerical and real model by adjusting the stiffness and mass matrices. The objective function is formed as a linear combination of the natural frequency residuals and mode shape residuals, with different weighting factors for each residual.

$$F(x) = w_f \sum_{k=1}^{N_f} \left(\frac{f_{ak} - f_{ek}}{f_{ek}} \right)^2 + w_m \sum_{k=1}^{N_m} \frac{cos^{-1}(\sqrt{MAC_k})}{(\pi/2)} \quad (1)$$

f_{ak} and f_{ek} denote the analytical and experimental natural frequencies; w_f and w_m are weighting factors applied to the frequency residuals and mode shape residuals, respectively. *MAC* (Modal Assurance Criteria) is a measurement of mode shape discrepancy and is defined as (Allemang and Brown 1982):

$$MAC_i = \frac{(\emptyset_{ai}^T \emptyset_{ei})^2}{(\emptyset_{ai}^T \emptyset_{ai})(\emptyset_{ei}^T \emptyset_{ei})} \quad (2)$$

$\emptyset_{ai}$ and $\emptyset_{ei}$ are analytical and experimental mode shapes, respectively. *MAC* = 1 means $\emptyset_{ai}$ and $\emptyset_{ei}$ are perfectly matched; *MAC* = 0 means they are orthogonal. It is known that *MAC* is rather insensitive to the change of mode shape. It is also noted that the *MAC* is actually the square of the inner product between the two mode shape vectors. Therefore, the objective function for the mode shape residual is formed as the normalized angle between the two mode shape vectors, which are much more sensitive to the changes in the mode shape.

3.3 Advanced Hybrid Fragility Analysis Method

Fragility, or vulnerability, presents the probability of reaching or exceeding a specific performance level under a specific seismic hazard. Fragility curves relate the effects of seismic hazard to the damage of the structures. Through the application of fragility curves, losses from earthquake hazard can be estimated.

Generally, fragility curves are sub-divided into four categories based on data sources, namely, empirical, judgmental, analytical, and hybrid fragility curves (Rossetto and Elnashai 2003). Empirical fragility curves are developed through field investigations after earthquakes—are the most realistic. However, this observation data is scarce and clustered in the low damaged range. Judgmental fragility curves are based on expert opinion, and are therefore subjective. Unlike the empirical and judgmental fragility curves, analytical fragility curves are more general, curves are allowed to be generated for different limit states and different structural types, although at a higher computation cost. Due to this limitation, most analytical fragility curves are generated either by simplified models or by complicated models without calibration to the real structural response, which can result in uncertainties in these curves.

To reduce the uncertainties, an advanced hybrid fragility analysis method is proposed, as shown in Figure 3. In this hybrid approach, hybrid simulation, with critical element tested in the laboratory and the rest simulated in the calibrated finite element model, is conducted to evaluate the structural response. By scaling ground motions, several hybrid tests are performed to reach the target structural response. The PGA value of the scaled ground motion is then assigned as the mean PGA value for the current limit state. Here, the target structural response is defined for different limit states, such as interstory drift angle of 0.7% for immediate occupancy limit state for steel moment frame building. Finally, with the mean PGA values and the dispersions from similar structures found in the literature, the fragility curves are generated based on the lognormal distribution assumption.

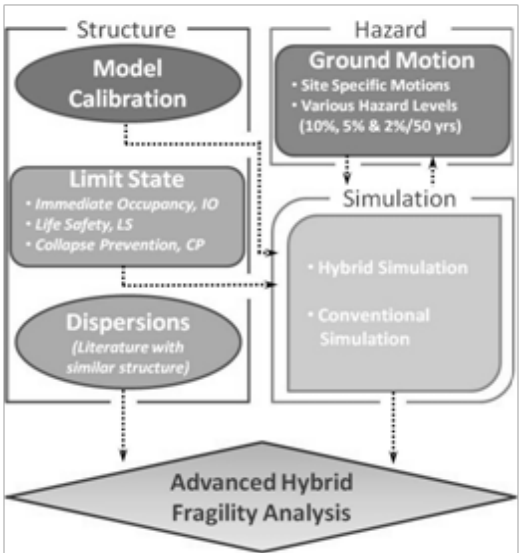

Figure 3 Methodology and procedure of the advanced hybrid fragility analysis method

4. NEES INTEGRATED SEISMIC RISK ASSESSMENT FRAMEWORK

NISRAF, a software platform with a graphical user interface (GUI) under the MATLAB environment, has been developed for the purpose of making impact assessment more efficient and more reliable. Several components—instrumentation, advanced hazard characterization, system identification, model updating, hybrid simulation, advanced hybrid fragility analysis and impact assessment tools—have been implemented and tailored with novel methods to build the seamless, transparent and extensible framework. Figure 4 presents several components with GUI implemented in NISRAF.

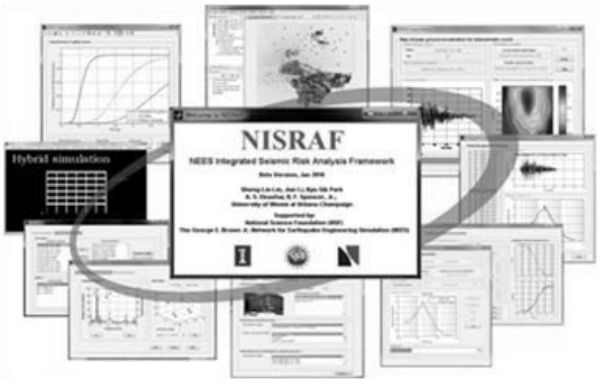

Figure 4 Components with GUI in NISRAF

There are several advanced features contained in this integrated framework. Among those features are:

- *Open source software with friendly GUI:* This software, as well as the source code, will be open to the public. The open source feature will allow NISRAF to be utilized efficiently, as well as improve its integrity and robustness.
- *Extensible and accessible:* In NISRAF, each component is developed separately (modularized), which facilitates understanding and maintenance. Most importantly, it is extensible and accessible to any latest research findings and program techniques.
- *Efficient and reliable impact assessment:* This is the first time that all the components for impact assessment are integrated and work seamlessly in just one software platform. Concurrently, the integrated feature brings the most advanced tools in order to obtain the most reliable earthquake impact assessment results possible. Surely, with these seamlessly-integrated and advanced technologies, which provide a more accurate hazard and structural model and hence generate superb fragility curves, the assessment of earthquake impact will be more efficient and more reliable than ever.

5. CASE STUDY

A six-story instrumented building in Burbank, California was selected to demonstrate NISRAF. This selected building is a steel moment resisting frame structure, in which the perimeter frames are the primary lateral load resisting system and the internal frames only resist the gravity load. Reference was made to Anderson and Bertero (1991) and Fumal et al. (1979) for more detailed information about this building and site condition, respectively. The building was instrumented by the California Strong Motion Instrumentation Program (CSMIP) in 1980 with 13 sensor channels. Several significant earthquakes were captured, including the 1987 Whittier earthquake, the 1991 Sierra Madre earthquake and the 1994 Northridge earthquake.

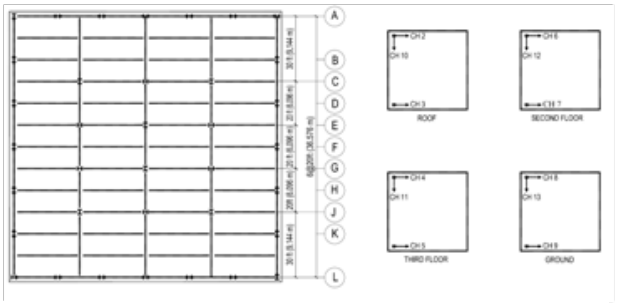

Figure 5 Plan view of Burbank building and sensors

The finite element model was built in ZEUS-NL platform (Elnashai et al. 2004). Due to the fact that only the perimeter frames are part of the lateral load resisting system, a 2-D frame was built to represent the entire structure. Section dimensions and material properties for each beam and column were based on design documents. Lumped masses were used and applied at the beam-column connections. Concrete slabs were modeled and connected to the steel girders using rigid elements to account for their contribution to stiffness.

5.1 Instrumentation

Many database centers archive tens of thousands of strong-motion records and structural sensor histories. To increase the utilization of this data, an interface with linkage

to several web databases, such as ANSS, Advanced National Seismic System; COSMOS, the Consortium of Organizations for Strong Motion Observation Systems; CESMD, Center for Engineering Strong Motion Data; and PEER, the Pacific Earthquake Engineering Research Center, was developed, which allows users to easily access to the database and to download any records of interest. Moreover, NISRAF allows users to create a project folder to archive the downloaded records and some basic information about this project. Figure 6 is an example, which shows the basic information of the Burbank building and the already-downloaded records.

Figure 6 Basic information of Burbank building archived in NISRAF

5.2 Hazard Characterization Analysis

Secondly, the hazard characterization at the Burbank site was performed by using both the downloaded free-field station records and the generated synthetic ground motion records. To generate the synthetic records for different hazard levels (e.g. 10%, 5%, and 2% probability of exceedance in 50 years), the deaggregation results were fed into the attenuation model to produce the response spectra and duration for SIMQKE (Gasparini and Vanmarcke 1976) to generate synthetic ground motions. Subsequently, DEEPSOIL was used to generate site specific ground motions. Figure 7 is the GUI, which shows the generated site specific ground motion as well as the hazard map in NISRAF.

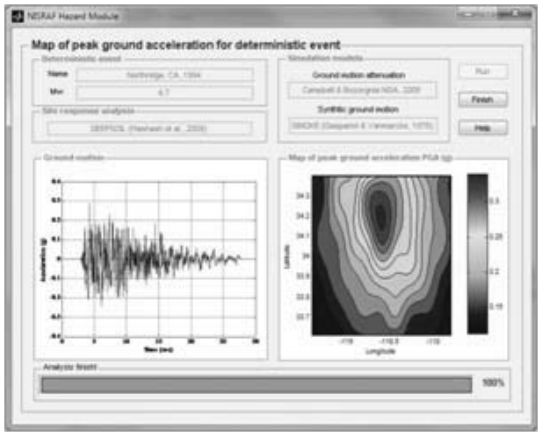

Figure 7 Site specific ground motions and hazard map generation in NISRAF

5.3 Model Calibration

The ERA method was performed on the Northridge earthquake records in order to identify the frequency of this building. At the beginning of the process, small values of EMAC and MPC were recommended since they are more sensitive to the noise modes compared to the MAC. Some genuine modes may be filtered out due to too large EMAC or MPC values. Hence, the information in the stabilization diagram was too limited to identify the natural frequencies. The values were then adjusted for multiple running of ERA to get a reasonable stabilization diagram. Eventually, the first and second bending modes were identified as 0.72 Hz and 2.14 Hz, respectively. The corresponding damping ratios were 3.37% and 6.71%.

Based on the identified information, model updating was performed. Young's modulus of steel (*Es*), lumped mass and effective width of concrete slab were selected as candidate parameters based on the sensitivity analysis. The optimization problem defined previously was solved by the Nelder-Mead method (Nelder and Mead 1965). Table 1 tabulates the structural frequencies of the identified, original and updated model. As can be seen, the errors between the identified and updated model reduced to 1% and 5.78% for the first and second natural frequency, respectively. With this refined finite element model, hybrid simulation was then conducted to yield a seismic response prediction with higher accuracy.

Table 1 Identify, original and updated models

Mode	ERA	Original FE		Updated FE	
	Freq. (Hz)	Freq. (Hz)	Error (%)	Freq. (Hz)	Error (%)
1	0.719	0.688	-4.31	0.712	-1.00
2	2.144	1.956	-8.77	2.020	-5.78

5.4 Hybrid Simulation

The calibrated building model along with ground motions from hazard characterization analysis were used to verify the integration of the hybrid simulation in NISRAF. The tuned 2-D structure was divided into two sub-structures, namely, the column (the lower part of the left exterior column at the first floor) and the frame (the remaining structure). The frame module was simulated in ZEUS-NL platform, while the column module—replaced by a small scale aluminum specimen—was tested in the laboratory using the NEES@UIUC (MUST-SIM) facility (Figure 8). Testing at small scale is acceptable here because the objective is to demonstrate the integration of hybrid simulation in NISRAF. Hybrid simulation, coordinated by UI-SIMCOR (Kwon et al. 2007) under the 1994 Northridge earthquake, was first conducted as the proof test prior to the generation of the hybrid fragility curves. Good agreement was found between the measured response during the Northridge earthquake and the responses from the hybrid simulation test, as shown in Figure 9.

Figure 8 Hybrid simulation setup using NEES facilities

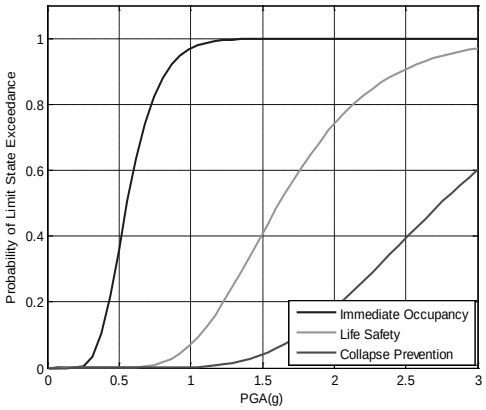

Figure 10 Fragility curves generated by NISRAF

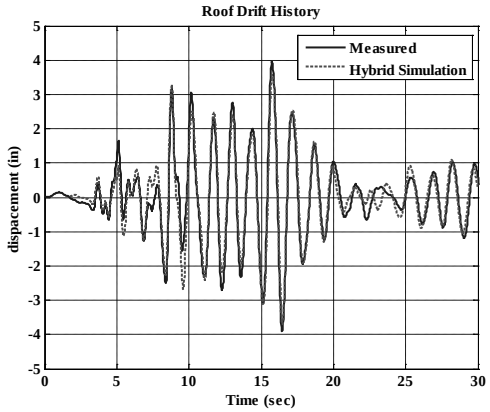

Figure 9 Comparison of the roof drift history between the measured and the hybrid simulation result

5.5 Hybrid Fragility Analysis

Hybrid simulation results under different synthetic ground motions (10%, 5% and 2% probability of exceedance in 50 years for immediate occupancy, life safety and collapse prevention performance level, respectively) were used to derive the mean PGA value for each performance level. Using these mean values, along with dispersions from previous studies with similar structures (Table 2), fragility curves were generated based on lognormal distribution assumption (Figure 10).

Table 2 Interstory drift angle, dispersion and mean PGA of different performance levels

Performance Level	Immediate Occupancy	Life Safety	Collapse Prevention
ISDA (%)*	0.7	2.5	5.0
Dispersion**	0.311	0.328	0.346
Mean PGA (g)***	0.545	1.627	2.777

**FEMA 2000b*

***FEMA 2000a, Cornell et al. 2002*

****Hybrid simulation results*

5.6 Impact Assessment

Finally, with the generated compatible hazard map and fragility curves, MAEviz under NISRAF was conducted to calculate earthquake impact losses. Table 3 lists the probabilities of exceeding limit states. As shown, only 15% probability for damage occurred in the immediate occupancy limit state. The results correlated with the post-earthquake report made by Applied Technology Council (ATC 2001), which reported slight damage observed to this building from the Northridge earthquake of 17 January 1994.

Table 3 NISRAF impact assessment results

Probability of exceeding limit state		
Immediate Occupancy	Life Safety	Collapse Prevention
0.15	0.00	0.00

6. APPLICATIONS OF REGIONAL IMPACT ASSESSMENT

The actual test bed in Burbank, California, the 6-story steel building was carried out to verify the framework as well as its components. This building example demonstrated not only the seamlessly-integrated, extensible and transparent framework, but it also showed that all the elements required for an accurate impact assessment can be performed under just one software platform. Consequently, the impact assessment result, which showed good agreement with the post-earthquake report, confirmed one of the advanced features of NISRAF—efficient and reliable impact assessment. Meanwhile, it also established that the proposed advanced methods—the hazard characterization analysis, the model calibration and the hybrid fragility analysis—were reliable. As a result of demonstration of this impact assessment on one individual building, the same procedures can be applied to other different building types, seismic code levels and construction materials, to perform regional impact assessment. Figure 11 is an example, which shows the regional impact assessment in Los Angeles area using NISRAF.

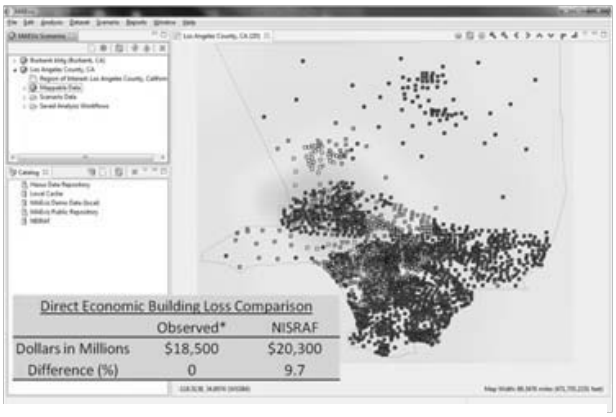

Figure 11 Regional impact assessment

7. CONCLUSIONS

NISRAF serves as a user-friendly software platform through which impact assessment can be efficiently and reliably performed by combining hazard (exposure) and fragility (sensitivity), to provide assessment of impact on the built environment at the regional scale. Concurrently, it extends the state-of-the-art hybrid simulation approach to fragility analysis, and proposes novel method for hazard characterization and model calibration. The successful completion of the development of the framework and verification of its components not only demonstrates that these objectives have been achieved, but also showcases the power and advantages offered by the George E. Brown, Jr. Network for Earthquake Engineering Simulation (NEES). For example, the hybrid simulation technique enables NISRAF to integrate testing capabilities at multiple NEES sites. The assessment thereby employs the strength of existing computational models and the expertise of individual research groups to explore previously unapproachable problems. Finally, the application of NISRAF will be a stimulus not only for geotechnical and structural earthquake engineers and impact assessment experts, but also for seismologists and structural control researchers improving their algorithms in order to pursue the ultimate goal of NEES under NEHRP: the assessment and mitigation of earthquake losses.

Abstract: Istanbul, which is one of the World Heritage Sites, has been repeatedly struck by destructive earthquakes. This paper examines local site effects on damage of historical monuments in Istanbul during the 1894 Marmara Sea Earthquake. In order to understand local site conditions in Istanbul, microtremore measurements were conducted at 64 sites near monuments, which were damaged by 1894 Earthquake. By taking forms of H/V spectral ratio of microtremor and boring logs into consideration, 64 sites are classified into six groups. Then, a relation between damage of historical monuments and local site condition by a proposed site classification is examined. The result shows that damage degree of historical monuments is better correlated with the site class proposed in this study than the site class by IMM (2007).

1. INTRODUCTION

Istanbul, which is one of the mega cities in the world, has been repeatedly struck by destructive earthquakes because it is located at the west end of the North Anatolian Fault Zone. At the same time, Istanbul itself is designated a World Heritage Site because of many historical monuments and its cityscape. Therefore it is important for the earthquake disaster prevention of human lives and those monuments to investigate building damage caused by past earthquakes. Findings obtained from such historical facts and lessons are contributory to establish a better disaster protection and reduction system. From this view point, the main objectives in this paper are historical monuments in Istanbul damaged during the 1894 Marmara Sea Earthquake (Ms=7.3), which is the latest earthquake causing severe damage to Istanbul, as a case study.

Concerning to casualties and building damage, books and articles are published by several researchers (Ambraseys 2001, Ürekli 1999, Çalık 2003). These articles summarized damage of historical monuments with collecting records from many newspapers and journals of the day. Ansal *et al*. (1990) examined the distribution of building damage and the influence of local soil condition. However, the damage distribution was grossly compiled, and the discussion was limited to the damage of several important monuments. In the previous paper (Morita *et al*. 2010), damage of historical monuments and its distribution caused by 1894 Earthquake, which were obtained from the records of the day (Öztin 1994), were compared with the geology and site class in Istanbul (JICA *et al*. 2000, IMM 2007). As the result, a certain correlation between damage degrees and soil conditions was found.

In order to examine local site effects on damage of historical monuments in detail, microtremor measurements were conducted at total 64 sites near historical monuments in Istanbul, which were damaged by 1894 Earthquake. First, local site conditions based on the result of microtremor measurements in Istanbul are considered. Next, a new site class is proposed based on forms of H/V spectral ratios by microtremor and boring logs. After that, a relation between damage of historical monuments and local site conditions in accordance with a proposed site class is examined.

2. OUTLINE OF DAMAGE ON HISTORICAL MONUMENTS CAUSED BY 1894 EARTHQUAKE

The report by Öztin (1994) contains records of building damage in the area corresponding to Istanbul province at present. In cases that damaged parts of historical monuments such as a dome or walls were clearly written and damage degrees were described, it is possible to estimate their damage degrees. As referring to the damage criteria for masonry buildings by EMS-98 (ESC 1998) too, damage degrees of historical monuments are classified into four levels according to the criteria based on the damage description as shown in Table 1. DL4, DL3 and DL2 indicate totally collapsed, half collapsed or heavy damage, and partly collapsed or light damage respectively (Fig. 1). DL1 indicates that damage levels are not determined because of no detailed description about a damage degree.

As for eight important historical monument types such as mosque, minaret, church, Muslim seminary (*medrese*), school (*mekteb*), large commercial building (*han*), public bath (*hamam*) and mausoleum (*Türbe*), the locations of damaged historical monuments are identified. Figure 2 shows the distribution of all damaged historical monuments with damage levels on the site class map by Istanbul Metropolitan Municipality (IMM 2007). In this figure, locations of historical monuments, whose damage were not recorded, are also indicated as N/A for considering overall distribution of historical monuments in Istanbul at that time. The site class by IMM is determined by a combination of standard penetration test, relative density, S-wave velocity and thickness of topmost soil in accordance with the Turkish Regulation (Ministry of Public Works and Settlement 1997). In this criterion, Z1 means the hardest soil, Z4 means the softest soil and AF/O means artificial soil or other soils not defined by the regulation.

Damaged historical monuments mostly stood from the eastern to northwestern part of the city except at the middle of the northern coastal area. Along the southwestern coastal area, somewhat concentration of damaged historical monuments is also identified. With respect to damage degree, heavy damage occurred in the middle of southern

Table 1 Criteria for Damage Level of Historical Monument

Damage Degree		Descrieption of Damage	EMS98
Unknown	DL1	Described with only words yıkırmıştır (broken, fell down) çatlamiştır (cracked)	
Partly Collapsed (Light Damage)	DL2	bazı yerleri ... (some part ...) kısımen ... (a part ...) biraz ... (a little ...)	Grade 2 Grade 3
Half Collapsed (Heavy Damage)	DL3	haylice ... (a large part ...) ekser yerleri ... (most par t...) yarısı ... (half)	Grade 4
Totally Collapsed	DL4	harap olmuş (ruined) çökmüştır (collpsed all) tümüyle ... (totally ...)	Grade 5

Grand Bazaar (DL4) Amcazade Hüseyin Paşa Medrese (DL3)

Figure 1 Photos of Damaged Historical Monuments by 1894 Earthquake

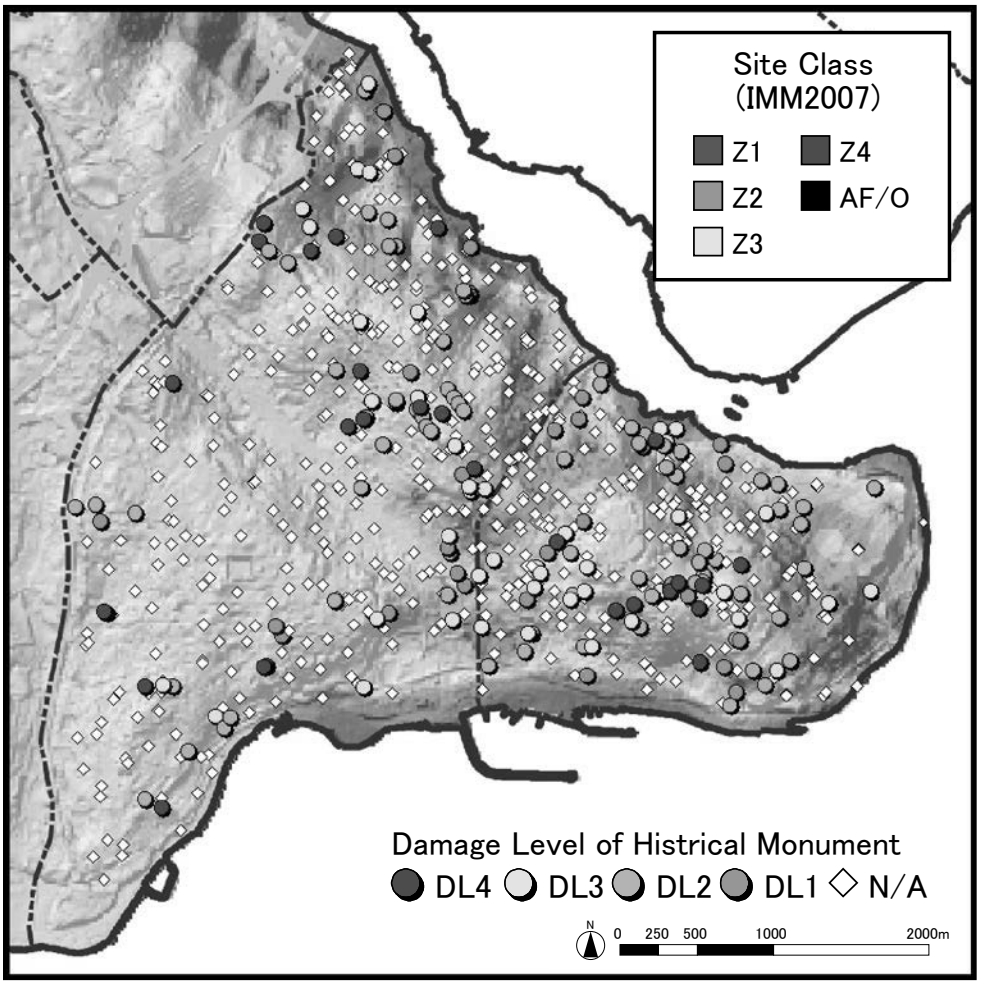

Figure 2 Distribution of All Damaged Historical Monuments with Damage Level on the Site Class Map (IMM 2007)

part of Istanbul. Figure 3 shows the ratio of all damaged historical monuments together with damage degrees and the classification criteria. The ratios of DL4 increase from Z1 to Z4 as 1.0%, 2.7%, 3.5% and 4.9% in order, and there is no historical monument which was totally collapsed in AF/O. Though the ratios of D3 also tend to increase from Z1 to AF/O as 3.5%, 5.4%, 4.0%, 7.3% and 15.4% in order, the ratio in Z3, which is the softer site class than Z2, decrease. In regard to total of damaged historical monuments, the ratio in Z1 is about 10%, the ratios in Z2 and Z4 are over 20% but the ratio of Z3 is less than 20 %. The ratio in AF/O exceeds 30%. Therefore, the ratio of heavily damaged historical monuments becomes high as soils become soft in general. However, in Z2 and Z3, opposite tendencies are appeared partly. It is suggested by this result that the site class by IMM doesn't indicate good correlation with damage levels of historical monuments.

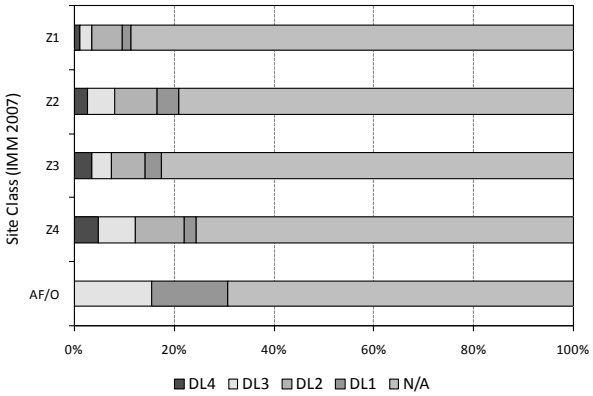

Figure 3 Ratio of All Damaged Historical Monuments in accordance with the Site Class (IMM2007)

3. OUTLINE OF MICROTREMOR MEASUREMENT IN ISTANBUL

In order to understand local site conditions of Istanbul in detail, microtremor measurements in Istanbul were carried out at total 64 points on March and October 2010. Measurement points for microtremor were selected close to historical monuments which were damaged by the 1894 Earthquake (Fig. 4). A high sensitive velocity seismometer was used for measurements. The microtremor instrument has 3 components that X directs to North-South, Y directs to East-West and Z directs to Up-Down component. At every measurement point, microtremor was usually recorded at least 4 times with 1/100 second sampling rate and 42.0 second data length. Fourier spectra of each component are calculated from records of microtremors.

For calculation, a unit of 20.48 seconds at each record was picked up by judging from waveform in the time domain in order to avoid noise parts. A Parzen window of 0.2-Hz bandwidth is adopted to obtain smooth spectra. After calculating Fourier spectra of each component, H/V spectral ratio of each record and average H/V spectral ratio were calculated at each measurement point. Figure 5 shows the results of H/V spectral ratios at several measurement points. From the average H/V spectral ratio in each measurement point, a predominant period and a peak value of H/V spectral ratio are obtained. Table 2 shows types of historical monuments, damage levels, predominant periods and peak values of H/V spectral ratios at each measurement point. Figure 6 shows the measurement points with predominant periods.

4. LOCAL SITE CONDITION BASED ON MICRO-TREMOR MEASURMENT

Predominant periods at all of measurement points range 0.1 to 1.1 second (Table 2). As shown in Figure 5 and Figure 6, in the northwestern and eastern part of Istanbul,

peaks of H/V spectral ratios at measurement points near the seashore (No. M1-10) are not clear and predominant periods of those points are short. At measurement points with increasing distance from the seashore (No. 8 and 1), peaks of H/V spectral ratios become clear and predominant periods become long. In southwestern part, peaks of H/V spectral ratios are very clear (No. M2-9) and predominant periods are over 1.0 second.

When predominant periods are compared with the site class by IMM, some measurement points where short predominant periods are obtained (No.M1-1, M1-4, 10, 18 and 22) are located on, or close to Z4 which is the softest soil. Around the seashore including these points, the site classes change from AF/O to Z2 rapidly within a short distance from the seashore line. In addition, Istanbul has a terrain with its many uphills and downhills. Especially, in the area around No.10, steep slopes run from the seashore. Judging from these topographical characteristics, it is presumed that subsurface structures in these areas are complex, and there is a possibility that a classification of sites was not performed correctly. Therefore, short predominant periods are obtained at points which are even close to Z4. Moreover, there are some points located on Z3, whose predominant periods are shorter than 0.5 second, in the eastern part of Istanbul. On the contrary, predominant periods and peak values of H/V spectral ratios at several points in the western part of Istanbul differ considerably with location though all of those sites are classified into Z3. That is, it is needed that Z3 occupying a great part of Istanbul should be considered in detail more.

Figure 7 shows the relation between damage levels of historical monuments and predominant periods at each point.

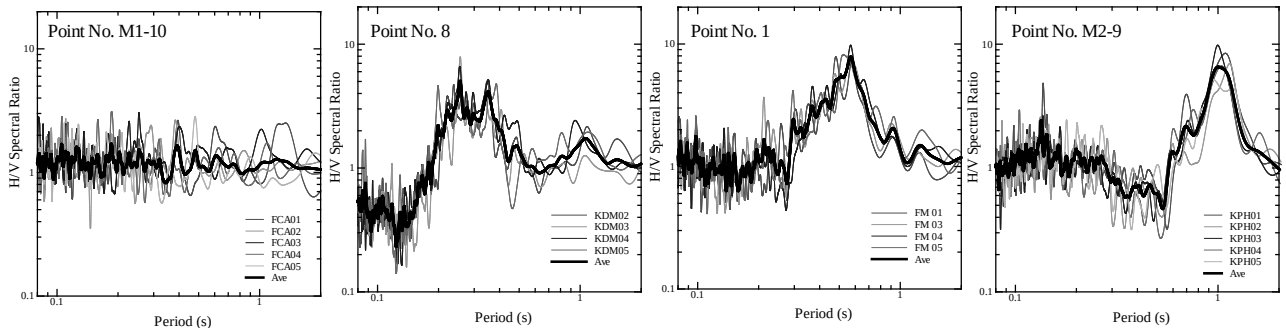

Figure 5 Examples of H/V Spectral Ratio

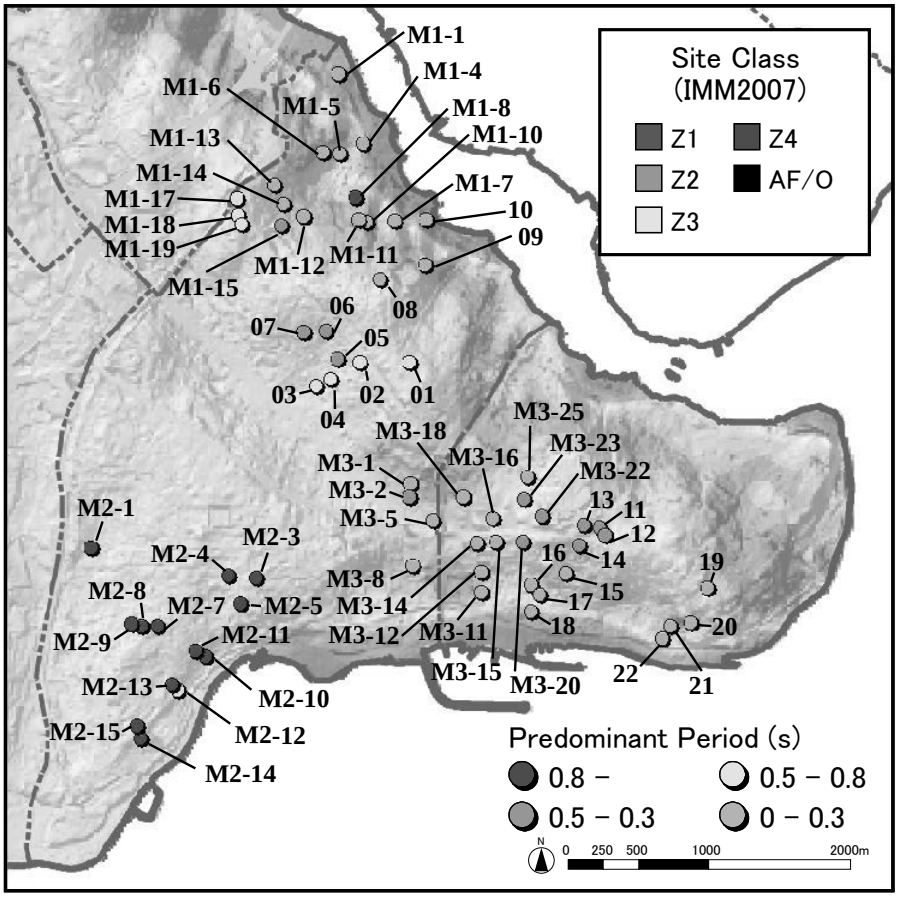

Figure 6 Measurement Point with Predominant Period

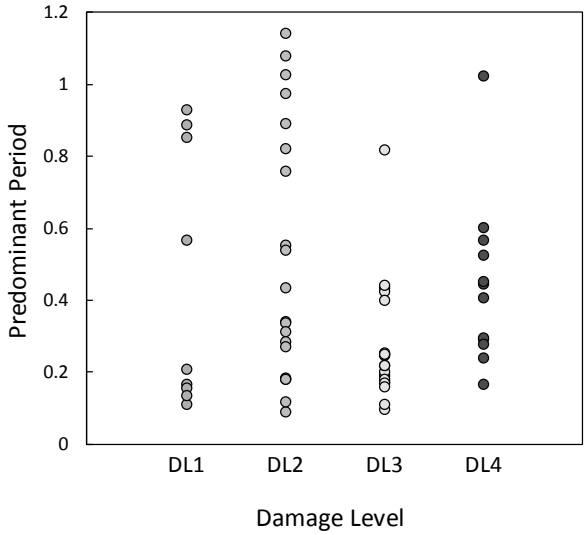

Figure 7 Relation between Damage Level of Historical Monument and Predominant Period

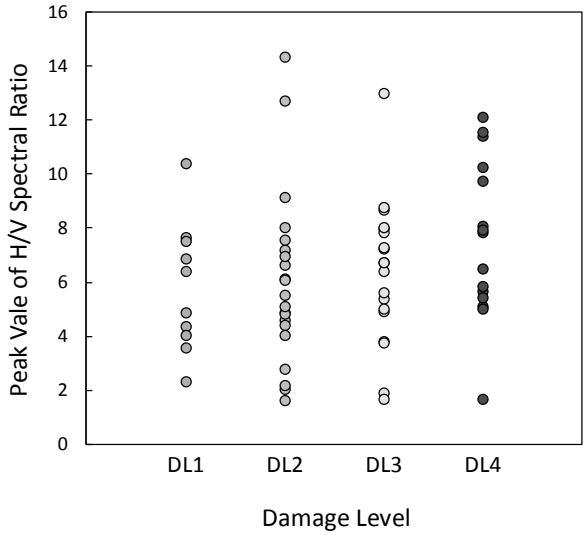

Figure 8 Relation between Damage Level of Historical Monument and Peak Value of H/V Spectral Ratio

Predominant periods range from 0.11 to 0.93 second in DL1, from 0.09 to 1.14 second in DL2, from 0.10 to 0.82 second in DL3 and from 0.17 to 1.02 second in DL 4. In addition, the longest predominant period is appeared in DL2. Therefore, damage levels of historical monuments don't tend to become heavy as predominant periods become long. This tendency applies to the relation between damage levels of historical monuments and peak values of H/V spectral ratios at each point as shown in Figure 8. From these results, it is needed that causes of damage should be considered with not only the result of microtremor measurements but also with more detailed information concerning to soils.

5. RELATION BETWEEN DAMAGE OF HISTORICAL MONUMENTS AND LOCAL SITE CONDITION

5.1 Re-Classification of Site based on Form Patterns of H/V Spectral Ratios and Boring Logs

In Istanbul, the boring investigation to a depth of 30 meters had been carried out at approximately 250-meter intervals. By using the result of microtremor measurement and the boring logs, site conditions of 17 measurement points, which are within 100 m from boring points, are re-classified. According to a similarity of form patterns of H/V spectral ratios basically, 17 selected points are classified into six groups. Figure 9 shows the result of classification and boring logs obtained from the nearest boring points at each selected point. Here, Trakya Formation of Lower Carboniferous age is composed of sandstone and siltstone. Bakırköy and Güngören Formations of Upper Miocene are mainly composed of loose clay and sand.

Group A: H/V spectral ratios don't have clear peaks. Around these points, Trakya Formation is deposited thickly under thin artificial fills. Therefore, Group A can be classified as the hardset soil group among six groups.

Group B: H/V spectral ratios are smooth mountainious forms with having a peak at short period side. Subsurface structures around these poins are mainly composed of artificial fills and Traky Formation with thin Güngören Formation between them. Looking at Point 19, Güngören Formation is deposited thickly at the nearest boring ponit. However, No. 19 is 72.0 m away from the boring point toward Z2 side (Fig. 4). Therefore, it is possible to think that the actual thickness of Güngören Formation at No. 19 is a little thiner.

Group C: H/V spectral ratios have two sharp peaks at short period side. Subsurface structures include alluvion in only this group. Looking at No. M1-4、alluvion is deposited thickly at the nearest boring point. However, No. M1-4 is 78.6 m away from the boring point in fact, and subsurface structures aroud No. M1-4 change rapidly (Fig. 4). Taking this situation into consideration, it is possible to think that the actual thickness of alluvion at No. M1-4 is a little thiner. Therefore, it is predictable that subsarface sturctures are composed of artificial fills and Trakya Formation with thin soft layer between them and tend to have distinct contrast of soil hardness at shallow depth whrere such a H/V spectral ratio is obtaied.

Group D: Thoguh predominant periods range from 0.2 to 0.6 second, peaks of H/V spectral ratios are not sharp. As for subsurface structures around these points, Güngören Formation are deposited thickly under thin artificial fills.

Group E: Though predominat preiods range from 0.2 to 0.6 second like Group D, peaks of H/V spectral ratios are very sharp. As for subsurface structures around these point, compositions of formations and their thickness are almost same as one in GroupD. Therefore, it is hard to distingish Group E from Group D by only boring logs.

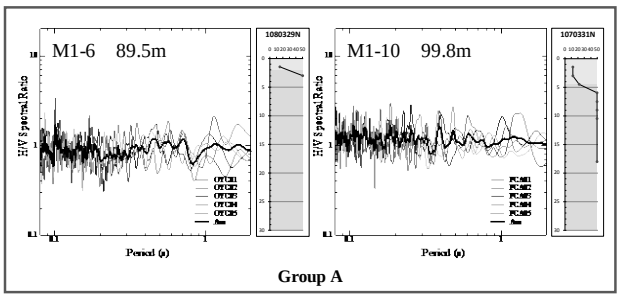

Figure 9 Grouping of 17 selected points

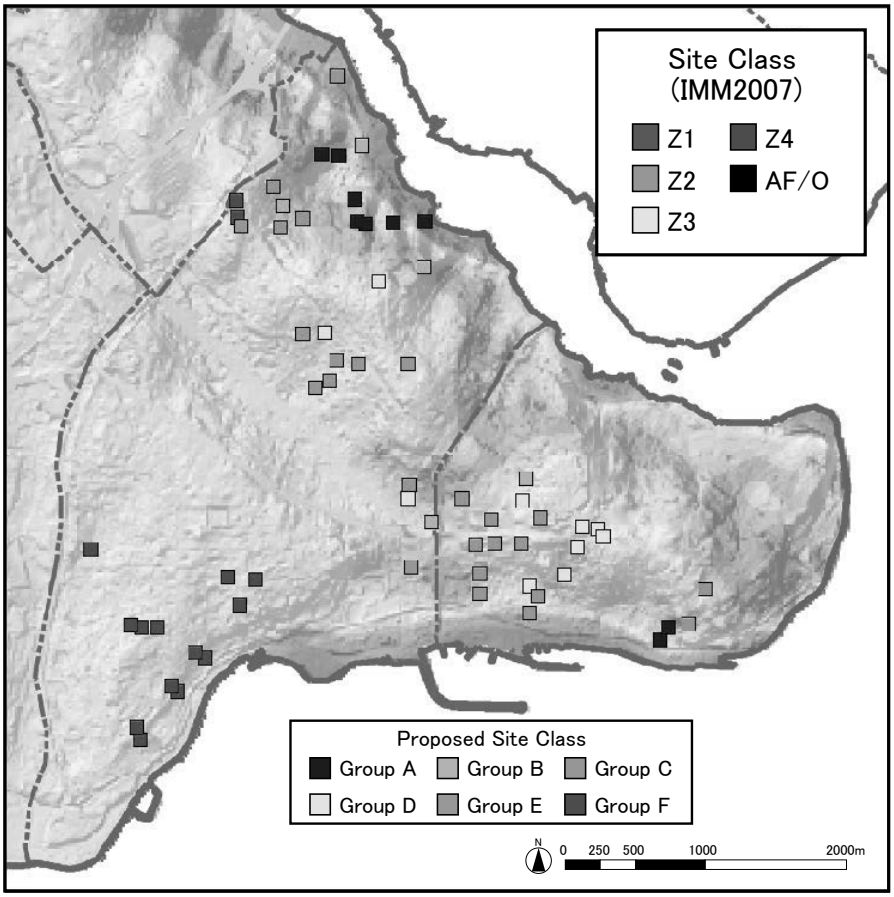

Figure 10 Proposed Site Class at Microtremor Measurement Point

Group F: Predominant periods range from 0.6 to 1.0 second, and peaks of H/V spectral ratios are very sharp. Subsurface structures aroud these points are composed of artifisial fills, Bakırköy Formation and Güngören Formation without Trakya Formation. Therefore, Group F can be classified as the softest soil group among six groups.

5.2 Comparison of Damage Degree of Historical Monuments with Site Class

Figure 10 shows the result that other 47 points were classified into the six groups which were obtained in the previous section. Points located on Z1 and Z2 in the northwestern part of Istanbul were classfied into GroupA and GroupB, which indicate hard soils amoung the six groups. Points in the eastern part were classified into 4 groups. It corresponeds to complicated soil conditions as shown by the site clss of IMM. Points located on Z3 in the wester part could be classfied into Group D, Group E and Group F. That is, the proposed site class in Istanbul are classified finely as the result of re-calssification is harmonized with the site class by IMM

As for the historical monuments closed to which microtemor measurements were conducted, the ratios of damaged historical monuments together with the damage degrees and the proposed site classification criteria is shown in Figure 11. The ratios over DL3 are about 30.0%, 57.1%, 55.6%, 45.5%, 68.8% and 57.9% in Group A to Group F respectively. The ratios of DL4 are about 10.0%, 7.1%, 22.2%, 27.3%, 25.0% and 42.1% in Group A to Group F respectively. It is clearly shown that damage degrees become heavy when soils are soft. Figure 12 shows the ratios of damaged historical monuments together with the damage degrees and the classification criteria by IMM. In Z4, there is no damaged historical monument, whose damage level is DL4. In Z2, the ratio of DL3 is the highest. Comparing to the site class by IMM, a correlation between damage of historical monuments and the proposed site class becomes better.

6. CONCLUDING REMARKS

This paper examines local site effects on damage of historical monuments in Istanbul during the 1894 Marmara Sea Earthquake. Microtremore measurements were conducted at 64 sites closed to historical monuments, which were damaged by 1894 Earthquake. According to forms of H/V spectral ratios of microtremor and boring logs, re-classification of sites in Istanbul was performed. Then, damage degrees of historical monuments were compared with the proposed site class in this study. As the result, the proposed site class shows a better correlation with damage degree of historical monuments than the site class by IMM.

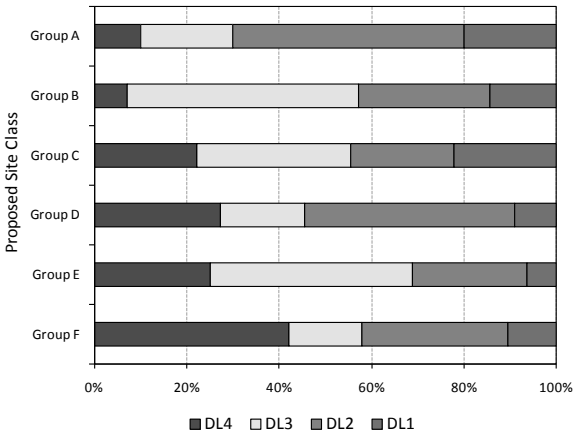

Figure 11 Ratio of Damaged Historical Monuments in accordance with the Proposed Site Class

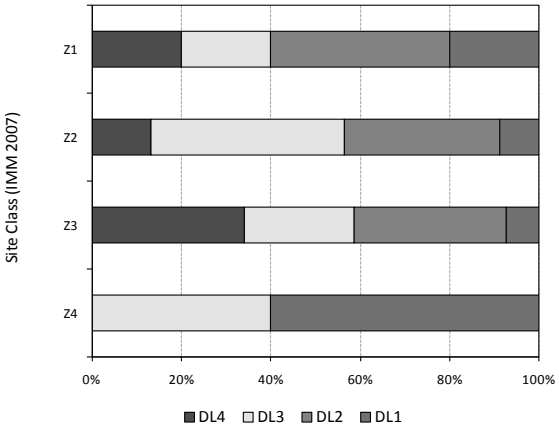

Figure 12 Ratio of Damaged Historical Monuments in accordance with the Site Class (IMM2007)

It is suggested by this result that there is a possibility to estimate building damage in accordance with a site class based on microtremor with relatively-accuracy even where boring logs are unavailable.

Abstract: The Japan Meteorological Agency (JMA) was started the public service of earthquake early warning (EEW) since October 1st, 2007. The 2008 Iwate-Miyagi Inland Earthquake on June 14, 2008 was the first case that EEW could be successfully broadcasted before the arrival of strong tremors. However, the warning could not be provided before strong tremors to some areas near the hypocenters. The number of earthquakes that EEW was announced since October, 2007 is too limited to evaluate the effectiveness of EEW properly. Therefore, in this research, using the data of the past earthquakes' occurred from 1923 to 2007, expected lead times before S-waves were analyzed based on the assumption that EEW system had been operated before those earthquakes. In addition, the effect of increasing seismometers in the future was also simulated. Based on the results obtained in both current and future cases, regional characteristics of expected lead times of EEW and their damage mitigation effect in each region were revealed, and future strategies for making the best use of EEW were discussed.

1. INTRODUCTION

It is said that seismic activity around Japan is increasing. Japan has a high probability of big earthquakes such as Tokyo Metropolitan Inland Earthquake with magnitude around 7, Tokai, Tonankai, and Nankai Earthquakes with magnitude 8 or more in the near future. The Japan Meteorological Agency (JMA) has launched earthquake early warning (EEW) system for the public since Oct. 1st, 2007. This is a new system that quickly analyses seismic wave data observed by seismometers near an epicenter and provides prompt alerts which may reach people before the arrival of strong tremors (S-waves).

The 2008 Iwate-Miyagi Inland Earthquake on June 14, 2008 was the first case since October 2007 that EEW could be successfully broadcasted before the arrival of S-waves. The warning was widely provided by television, the radio and mobile phones. At the earthquake, however, the warning could not reach before S-waves in some areas near the epicenters. This situation was regarded as a failure of EEW among the general public although it was due to technological limitation of EEW methods in case of inland earthquakes. After the earthquake, some mass media questioned the meanings of EEW and unfortunately, this led to negative understanding on effectiveness of EEW among some of the general public.

According to JMA, EEW had announced to the public 17 times. The number of EEWs which were succeeded in being available before strong tremor is limited. In addition, EEW for advanced users had announced 111 earthquakes until Octber 2010 since it started. These numbers are statistically too limited to decide the effectiveness of EEW. It is important to provide quantitative data about expected lead time that EEW could provide before future earthquakes in order to promote proper understanding on its merits and limitations.

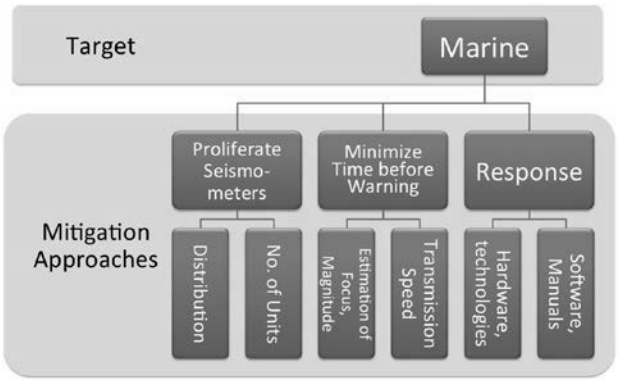

Figure 1 Target and Mitigation Approaches Considered in This Study

Technologies for announcing EEW are still renovating (Meguro, 2007). Figure 1 illustrates three approaches for making better use of EEW. The first approach is proliferation of seismometers, such as increasing the number of seismometers and densifing their network, which leads to

the prompt detection of an earthquake. The second is minimization of time before the warning, such as data transmissions and determination of a focus and magnitude of an earthquake. The last approach is response; in other words, how people can prepare for a strong tremor during lead times. Software approaches such as preparing manuals, are one part of the response. On the other hand, hardware approaches such as automatic response systems, play the other part.

In this study, using the past earthquakes occurred during 1923 to 2007, expected lead times before S-waves were analyzed on the assumption that the current EEW system had been operated before those earthquakes. According to the results, regional characteristics of expected lead times of EEW and their damage mitigation effect were revealed. In addition, the effect of increasing seismometers such as Ocean-bottom seismometers or Hi-Net by National Research Institute for Earth Science and Disaster Prevention (NIED) in the future was also simulated. Considering the results obtained in both current and future cases, future strategies for making the best use of EEW were discussed.

2. METHOD FOR CALCULATION

2.1 Data of Earthquakes Used

In this rstudy, data of 62,127 earthquakes with magnitude 4 or more occurred during 1927 to 2007 listed in "Report on Earthquakes and Volcanoes (Catalog)" by JMA was used. The number of earthquakes that EEW was announced since October, 2007 is too limited to evaluate the effectiveness of EEW properly. Then, the data of the past earthquakes was used in order to understand expected lead times that could be provided by EEW in future earthquakes.

Table 1 The Number of Earthquakes for Calculation

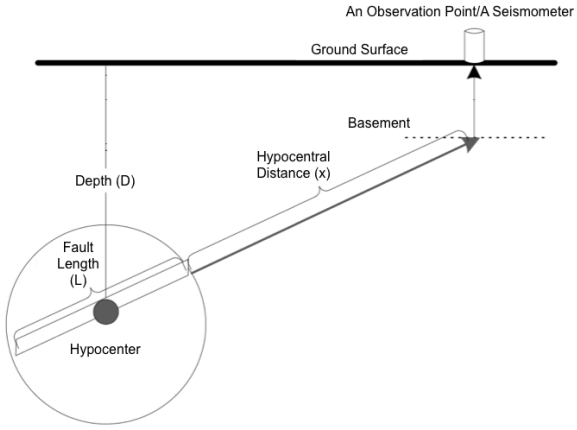
Year	M4	M5	M6	M7	M8	Total
1923–1966	6,505	2,673	620	348	7	10,153
1967–1980	4,637	1,496	287	83	5	6,508
1981–1990	5,911	3,607	459	12	0	9,989
1991–2000	13,660	6,772	657	22	1	21,112
2001–2007	9,074	4,799	482	28	2	14,385
Total	39,787	19,347	2,505	493	15	62,147

2.2 Locations of Seismometers

JMA uses 205 seismometers for providing initial alert of EEW as of November 2010. According to JMA, 774 seismometers of Hi-Net by National Research Institute for Earth Science and Disaster Prevention (NIED) are currently used only to double-check the location of the estimated hypocenter and the magnitude of a coming earthquake. Figure 2 shows the distribution of 205 JMA seismometers, and Fig. 3 shows that of Hi-Net. In the chapter 3, locations of JMA seismometers were used. The fourth chapter simulated the effect of increasing seismometers and 774 seismometers of Hi-Net were used for the calculation.

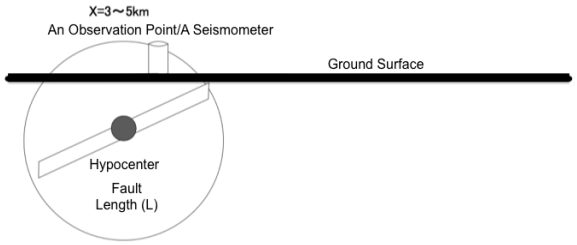
Figure 2 Distribution of JMA Seismometers

Figure 3 Distribution of Hi-Net Seismometers



2.3 Method for Estimating Lead Time and Seismic Intensity

Japan has 47 prefectures and totally 1955 local municipalities under prefectures. This research estimated lead times and expected seismic intensities of the 62,147 past earthquakes at 1,955 local municipality offices all over Japan based on the assumption that EEW had been operated before those earthquakes. We regard the locations of 1955 local municipality as observation points. The procedure for estimation is same as the method currently used by JMA (2010).



When an earthquake occurs, seismometers near its hypocenter detect ground vibration, and the location of hypocenter is estimated by using the data observed by these seismometers. Figure 4 illustrates a model of obtaining the distance between a hypocenter and the nearest seismometer or an observation point. The distance was calculated using equations, eqs. (1) to (9). Here, all the seismometers were assumed to be located at the ground surface because their depth was negligible for obtaining the distance to the hypocenter. Hypocenters were treated as fault planes as shown in Fig. 4 (a). In case that half of the fault length was longer than the distance between the hypocenter and an observation point / the nearest station, the distances were set

to be 3km as shown in Fig. 4 (b).

Next, expected times for P-wave to travel to the nearest seismometer and for S-wave to strike each observation point were calculated. Based on these time differences, lead time provided by EEW before the arrival of S-wave at the observation point was obtained. In the real procedure for announcing EEW, analysis for estimating the hypocenter takes several seconds, but this time lag was not considered in this paper in order to estimate the maximum effectiveness of EEW. The velocities of P-wave and S-wave varying according to depth level were used following the table by JMA.

(a) Case Where Distance Between An Observation Point / A Seismometer Is Smaller Than A Half of Fault Length

(b) Case Where Distance Between An Observation Point / A Seismometer Is Bigger Than A Half of Fault Length

Figure 4 Calculation Model for Deciding The Distance Between A Hypocenter and An Observation Point / The Nearest Station

$$a = \cos\phi \cdot \cos\theta \quad (1)$$

$$b = \cos\phi \cdot \sin\theta \quad (2)$$

$$c = \sin\phi \quad (3)$$

$$d = \cos\phi' \cdot \cos\theta' \quad (4)$$

$$e = \cos\phi' \cdot \sin\theta' \quad (5)$$

$$f = \sin\phi' \quad (6)$$

$$x = \sqrt{\{R \cdot \arccos(a \cdot d + b \cdot f + c \cdot e)\}^2 + D^2} - L/2 \quad (0 \le x) \quad (7)$$

$$x = 3 \quad (x < 0) \quad (8)$$

$$\log L = 0.5M - 1.85 \text{ (Utsu: 1977)} \quad (9)$$

θ, ϕ: Latitude, Longitude (rad), D: Depth(km), R: Radius (km), x: Minimum distance to fault(km), L: Length of fault

Then, expected seismic intensities at 1955 local municipality in case of the 62147 past earthquakes were calculated using equations of eqs. (10) to (13).

$$M_w = M_{JMA} - 0.171 \quad (10)$$

$$\log(PGV_{600}) = 0.58M_w + 0.0038D - 1.29 - \log(x + 0.028 \cdot 10^{0.50M_w}) - 0.002x \quad (11)$$

$$PGV = ARV_i \cdot PGV_i (= ARV_i \cdot 0.90 \cdot PGV_{600}) \quad (12)$$

$$I_{INSTRA} = 2.68 + 1.72\log(PGV) \pm 0.21 \quad (4 < I_{INSTRA} < 7) \quad (13)$$

M_w: Moment magnitude, M_{jma}: JMA magnitude, PGV_{600}: Maximum velocity at engineering bedrock (S-wave velocity is 600 m/s), PGV_i: Maximum velocity at land surface, ARV_i: Amplification factor between land surface and 30m depths

2.4 Method for Evaluating Damage Mitigation Effects

In Japan, earthquakes are categorized to 2 types; inland and marine earthquakes according their location of epicenters as described in Fig.1. As for increase of inland earthquakes, lead times are generally small because time lags between S-wave and P-wave are expected to be short. On the other hand, lead times of marine earthquakes whose epicenters are in the ocean might be much longer. Therefore, this research treats these two earthquake types separately.

This research estimated lead times and expected seismic intensities of the 62,147 past earthquakes with magnitude 4 or more at 1,955 local municipality offices in Japan. These results were summarized to the number of earthquakes in each prefecture according to the expected lead times and seismic intensities. The past earthquakes included both marine and inland earthquakes. The trends of expected lead time in both marine and inland earthquake types in each prefecture were analyzed. Moreover, regional characteristics of expected lead times of EEW and their damage mitigation effect were evaluated in each prefecture.

As mentioned in the chapter 1, proliferation of seismometers is vital for EEW improvement. Since only 205 seismometers are currently used for the initial alert of EEW, the distance between a hypocenter and a seismometer might be long in some area. This possibly causes a late detection of a future earthquake. If seismometers are proliferated, lead time generally increases because of the minimization of the distance. This research clarified the effectiveness of the proliferation of seismometers. The cases,

in which the number of seismometers was increased and their network was densified, were simulated. Comparing the results of these cases with the current situation, the effectiveness of lead times was evaluated.

3. ANALYSIS OF EXPECTED LEAD TIME OF EEW AT PAST EARTHQUAKES

In this chapter, lead times for the past earthquakes during 1923-2007 were analyzed based on the assumption that EEW had been operated before those earthquakes.

3.1 Expected Lead Time Distribution of EEW in Each Prefecture

The lead times and seismic intensities of EEW at the past earthquakes were calculated at 1,955 local municipality offices as explained in the chapter 2. Outcomes of calculations for municipalities in one prefecture were added up to be data of one prefecture. When several municipalities in one prefecture record shaking at an earthquake, the largest seismic intensity among the municipalities and its corresponding lead times were plotted on the figure. Figure 5 shows the distribution of the expected lead times in Kanagawa Prefecture. The horizontal axis means lead time, and the vertical axis shows the cumulative numbers of earthquakes whose lead times are more than the value on the horizontal axis. Cumulative curves for expected lead times were plotted according estimated seismic intensities from 4 to 7. The negative value of the horizontal axis infers that S-wave strikes before an EEW announcement. The seismic intensity 4(a) means the curve for EEW whose seismic intensity is simply estimated 4. The seismic intensity 4(b) means the curve whose maximum intensity outside the prefecture is 5- or more although the intensity inside that prefecture is 4.

3.3 Analysis on Regional Characteristics of Expected Lead Time of EEW

Japan is surrounded by 4 plates. Distances from ocean trenches could affect regional characteristics of the expected lead times in each prefecture differently. According to the expected lead times in each prefectures, 47 prefectures were classified into four typical types; Kanagawa, Iwate, Nagano, and Hokkaido's types.

First, Kanagawa type has relatively long lead times among all the prefectures. The cumulative number of earthquakes moderately decreased according to the length of lead time as shown in Fig.5 because the effect of marine earthquakes with long lead times was more strongly

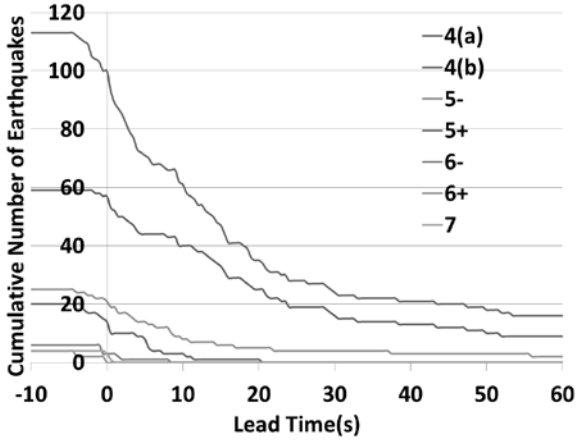


Figure 5 Expected Distribution of Lead Times in Kanagawa Prefecture

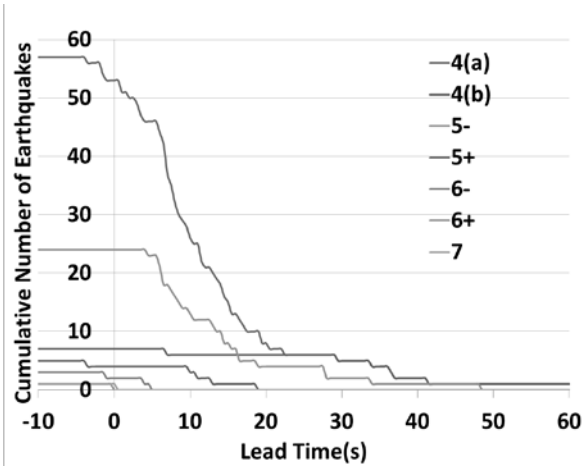

Figure 6 Expected Lead Times of EEW in Iwate Prefecture

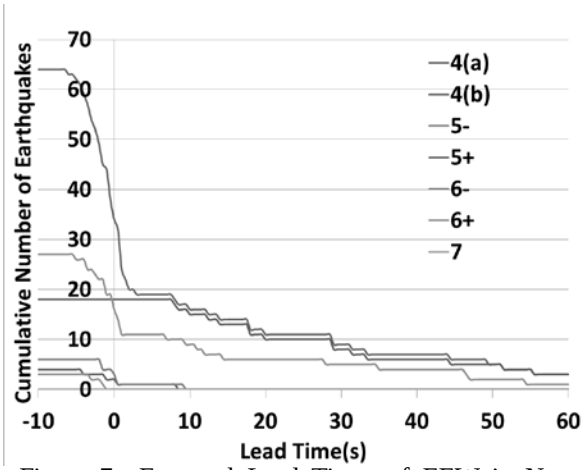

Figure 7 Expected Lead Times of EEW in Nagano Prefecture

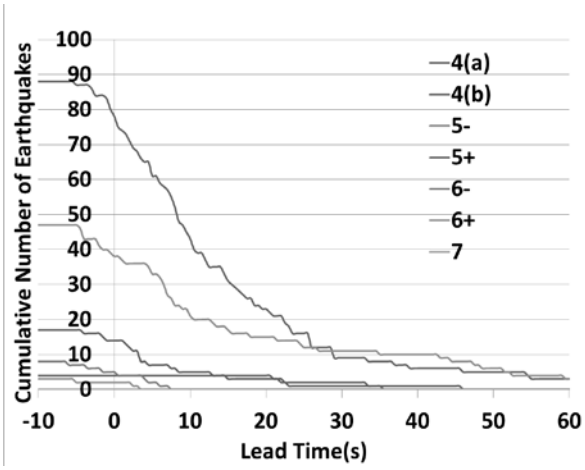

Figure 8 Expected Lead Times of EEW in Hokkaido Prefecture

reflected than that of inland earthquakes. Yamanashi, Osaka, Mie and Tokushima Prefectures were similar to this type. Osaka had longer lead times in case of inland earthquakes because of soft surface soils below Osaka area led to big seismic intensity at remote earthquakes with big magnitude. In this case, much longer lead time could be provided to respond against the coming shaking.

Second is Iwate type. Its expected lead times are not as long as Kanagawa type because Iwate prefecture is located near trenches. As shown in Fig.6, the cumulative number of earthquakes rapidly decreased as lead time was between 0 to 10 seconds. Fukushima Prefecture was also classified in the same type because curves of the lead time less than 20 seconds were especially similar to Iwate type. In prefectures with these characteristics, damage mitigation approaches within 10 seconds should be arranged.

Third is Nagano type. In this case, long lead time can not be expected as shown in Fig.7 because of frequent occurrence of inland earthquakes. In fact, 90 were inland earthquakes while the total number of earthquakes affecting Nagano Prefecture was 104; about 87% of the earthquakes with seismic intensities 4 or more were inland types in this area. Therefore, the curves dropped drastically around lead time 0 second because hypocenters were too close to the observation points. Consequently, damage mitigation approaches including automatic response systems, which are possibly applicable with in seconds, are extremely necessary to cope with these inland earthquakes. On the other hand, the gently decreasing line after that drop indicates this type also has long lead times in case of large earthquakes which occurred far away.

Finally, fourth is Hokkaido type. Because there is enough distance from trenches and troughs to obtain long lead time of EEW, the curves of this type moderately decreased from the top at lead time 0 second as shown in Fig.8. 113 of total 163 earthquakes which recorded seismic intensities 4 or more, occurred in ocean area, and the most of them had long lead times such as 30 seconds or more. All of the earthquakes with seismic intensities 5- were located at the boundary between North America plate and Eurasian plate. This characteristics show the effectiveness of damage mitigation approaches taking 10 seconds or more.

4 EVALUATION OF EFFECT OF USE OF MORE SEISMOMETERS FOR EEW

4.1 Effect of Use of Ocean-Bottom Seismometers

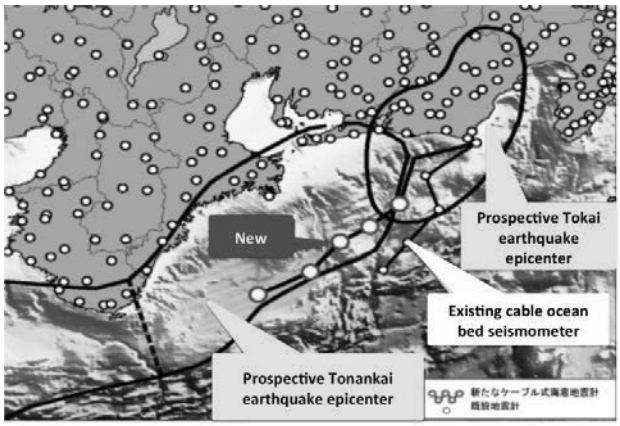

Table 3 Locations of Ocean-Bottom Seismometers

Seismometers Name	North Latitude	East Longitude	Altitude
TT1OBS	33.62	136.78	−2068m
TT2OBS	33.73	137.03	−2100m
TT3OBS	33.86	137.40	−1000m
TT4OBS	34.01	137.54	−1836m
TT5OBS	34.25	137.72	−1019m

In October 2008, JMA started to operate extra 5 ocean-bottom cable seismometers in Tokai and Tonankai area. In this section, the effect of using new 5 ocean-bottom seismometers in addition to the existing 205 seismometers was evaluated. Table 3 and Figure 9 show the locations of new ocean-bottom seismometers reported by JMA (2008).

Installing ocean-bottom seismometers aimed to increase lead times of EEW at the future earthquakes. In order to evaluate these effects, an index "E" was proposed to quantify the increase of lead time by using new ocean-bottom seismometers. It corresponds to the difference of the total area of lead time curves with/without ocean-bottom seismometer. Here, curves $f(t)$ of lead times in expected lead times figures were used.

Figure 9 Locations of Ocean-Bottom Seismometers

$$E = A - A_0 \tag{14}$$

$$A = \int f(t)dt \tag{15}$$

A_0: Area of lead time curves with the current systems without ocean-bottom seismometer, A: Area of lead time curves with ocean-bottom seismometers.

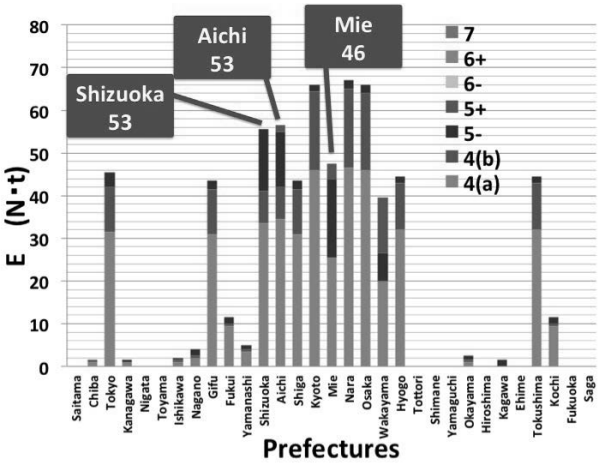

Figure 10 E Value in Each Prefecture with Ocean-Bottom Seismometers

Figure10 shows the value of index E for each prefecture in case that the ocean-bottom seismometers were used in addition to the current JMA ones. In the prefectures

near by Nankai Trough such as Shizuoka, Aichi, and Mie, the values of E were big especially with the seismic intensity 5- or more. Since these prefectures have shorter distance from the trough than the other prefectures, installing ocean-bottom seismometers is expected to have positive effect against strong earthquakes. Figure 11 shows the relationship between expected seismic intensities and the growth of the lead time that were achieved at the earthquakes by using ocean-bottom seismometers in Shizuoka Prefecture. In Fig.11, the total number of earthquakes with intensity 5- is 13, which is almost same as the other prefectures whose values of E were high. The highest growth of lead times by installing ocean-bottom seismometers was over ten seconds at the earthquake whose expected intensity in Shizuoka was 5-. Compared to the lead time growth in Mie as shown in Fig.12, most dots only slide to the right because of the distance decay with seismic intensities. Both prefectures are suffered from the 1944 Tonankai earthquake and the 1946 Nankai earthquake. These earthquakes were magnitude 7.9 and 8.0. However, both figures do not show the lead time growth in these earthquakes because added ocean-bottom seismometers are not so critically near by the epicenters of these two earthquakes.

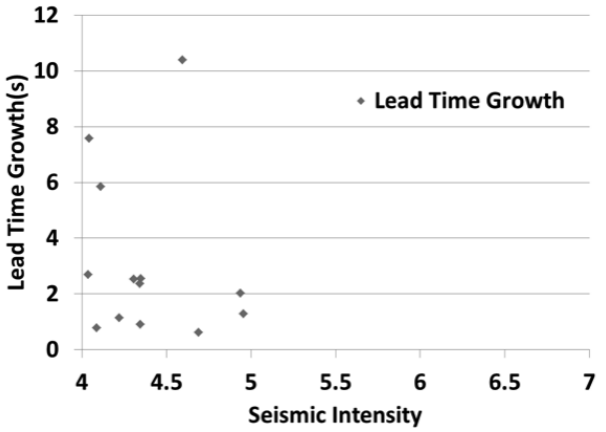

Figure 11 Lead Time Growth in Shizuoka

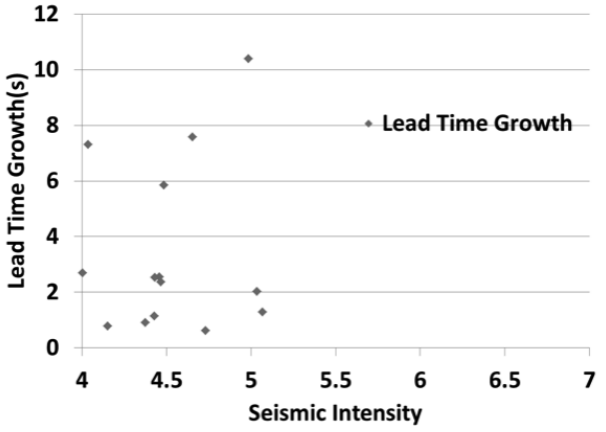

Figure 12 Lead Time Growth in Mie

4.2 Effect of Using Hi-Net

In this section, the effect of use of Hi-net was evaluated. Hi-Net has 774 seismometers operated by NIED. Index E for each prefecture was calculated by eqs.(14) and (15) in case that Hi-Net was used in addition to 210 seismometers including JMA and ocean-bottom seismometers.

Proper response to EEW is different according to the lead times available. If lead time before S-wave is few seconds, only automatic response systems could reduce the damage due to a coming earthquake. For example, automatic system for protecting important facilities, shutting down gas supply, stopping transportation systems, etc. could be effective. If about 10 seconds is provided as lead time, there is possibility for people to take some actions to protect themselves. As the lead time increase to be more than 10 seconds, more complicated actions for protecting properties and people become possible. Installing more seismometers aims to increase lead time at the future earthquakes. Increasing short lead time might have more impact than increasing long lead time; for example, growth of lead time from 0 to 5 seconds could be more meaningful than that of lead time from 30 to 35 seconds. It implies that the meaning of index E could be different according to the lead time. Then, three types of index E were proposed to understand the detail impact by installing new seismometers. They are $E_{0\text{-}5}$ that corresponds to the change of lead time curve during 0-5 seconds, $E_{0\text{-}10}$ during 0-10 seconds, and $E_{10\text{-}}$ during the lead time more than 10 seconds. The lead time is more demanded than the one of longer lead time.

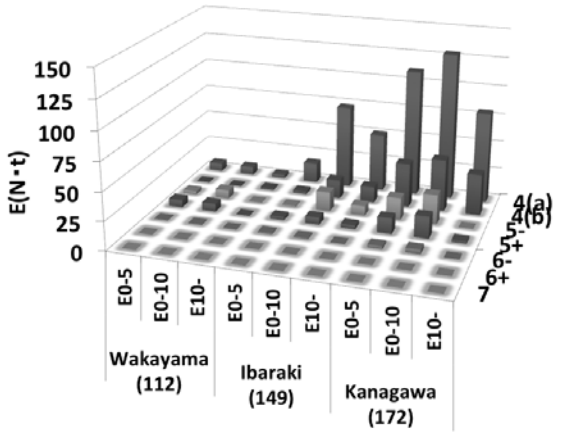

Figure 13 E Value in Wakayama, Ibaraki, Kanagawa with Hi-Net

Index $E_{0\text{-}5}$, $E_{0\text{-}10}$, and $E_{10\text{-}}$ for each prefecture were calculated in case that Hi-Net was used in addition to 210 seismometers including JMA and ocean-bottom seismometers. As a result, three typical types were observed; Kanagawa, Ibaraki, and Saitama types. Figure 13 shows the value of Index $E_{0\text{-}5}$, $E_{0\text{-}10}$, and $E_{10\text{-}}$ of three prefectures according to the seismic intensity. The numbers of total earthquakes in each prefecture are shown in the parentheses under prefecture names.

First, the Kanagawa type shows high $E_{0\text{-}5}$ and $E_{0\text{-}10}$; especially, $E_{0\text{-}5}$ was high enough to dominate the high percentage of $E_{0\text{-}10}$. It is said that use of Hi-Net will provide more opportunities whose lead times are 0 to 5 seconds.

These trends were observed not only for the earthquakes with intensity 4 but also for the earthquakes with seismic intensity 5- or more. In Kanagawa Prefecture, adding Hi-Net to the current EEW network was considered highly beneficial because it could totally achieve big growth of indexes E. Considering future use of Hi-Net, implementation of automatic response system had better be promoted in order to make better use of expected lead time.

Second, Ibaragi type shows the characteristics that $E_{0\text{-}10}$ and $E_{10\text{-}}$ are high instead of $E_{0\text{-}5}$. Use of Hi-Net will provide more opportunities whose lead times are more than 5 seconds. In order to use the benefit of Hi-Net, software approaches including human response might be effective as well as hardware approaches.

Third, Wakayama type has low value in each indexes E. The result shows that Hi-Net does not generally affect the lead time 0 to 60 even though the total number of earthquakes is 62. Therefore, the proliferation of seismometers needs more investigation on where to install, otherwise damage mitigation approaches can not improve.

In this chapter, index E evaluated the effect of increasing the lead time by using ocean-bottom seismometers or Hi-Net. In order to understand the effect of proliferations of seismometers, referring to both the expected lead time distribution and the value of index E is necessary. Based on the effect of installing Hi-Net on EEW damage mitigation approaches suitable for each prefectures were proposed in this section.

5. CONCLUSIONS

In this study, expected lead times of EEW were analyzed using the past earthquakes during 1923 to 2007 based on the assumption that EEW had been operated before those earthquakes. Based on the results obtained in the study, regional characteristics of expected lead times and their damage mitigation effects were revealed.

In addition, method for evaluating the effect of use of more seismometers was proposed defining three kinds of indexes E. Not only the currently-used 205 JMA seismometers, but also 5ocean-bottom seismometers and Hi-Net ones were taken into account for estimation. Finally, approaches to make suitable strategies for each area reflecting the characteristics of expected lead times were proposed.

At first, there are mainly four types in expected lead times with the current 205 JMA seismometers. Kanagawa and Hokkaido types expectedly have long lead times and are able to plan damage mitigation approaches sparing long time. However, in a hand, Kanagawa type does not suffer from earthquakes with intensity 5- or more. On the other hand, Hokkaido type has many 5+ earthquakes. On the contrary, both Iwate and Nagano types show shorter lead times even if each of them suffers from each type of earthquakes; inland and marine. In prefectures with these characteristics, damage mitigation approaches which are applicable within seconds should be considered.

Second, the effectiveness of ocean-bottom seismometers was analyzed using index E. Prefectures near by Nankai trough benefitted from these additional seismometers. Especially Shizuoka, Mie, and Aichi were so affected by these seismometers that they could maintain 10 seconds or more lead time growth.

Third, the effect of Hi-Net installing to EEW were studied. In this case, index E are taken apart to three; $E_{0\text{-}5}$, $E_{0\text{-}10}$, $E_{10\text{-}}$. Depending on the amount of indexes E, the effectiveness on expected lead times in the future was analyzes, and strategies considering this prospect were mentioned in this study.

Abstract: Earthquakes are one of the most unpredictable natural hazards but recently short-lead-time Earthquake Early Warning Systems (EEWS) have become practical with a system operating in Japan and another planned for operation in California in the next year or two. A few seconds to a minute or so of early warning is achievable. For example, if appropriate, an early warning can be broadcast to enhance the effectiveness of evacuations, water and gas supplies can be temporarily cut off, and other more advanced engineering applications may also be developed. Due to the limited warning time and the uncertainty of the information from an EEWS, applications that require real-time human decision-making are not practical. This motivates recent research to develop a robust automated rapid decision-making procedure for mitigation actions. A rational procedure is to initiate a potential loss-reduction action if, based on the incoming information from an EEWS, the expected loss from taking no action is greater than the expected loss from taking the mitigation action. To estimate the expected loss of a predicted event, it is proposed to use the recently developed PEER performance-based earthquake engineering methodology.

1. INTRODUCTION

Due to the high uncertainty of the stress and strength distributions within the tectonic plates on Earth, earthquakes are one of the most unpredictable natural hazards. Accurate prediction of when an earthquake will happen is still not possible, but the concept of earthquake early warning can be achieved because of the rapid development of computing power and network communication. *Earthquake Early Warning Systems* (EEWS) have been operating in several different regions. Japan has a long history of earthquake monitoring: Urgent Earthquake Detection and Alarm System (UrEDAS) of the Japan Railway Group is one of the first applications of EEWS and now most regions in Japan are covered by a public warning broadcast network operated by the Japan Meteorological Agency (JMA) (Allen et al. 2009b, Doi 2000, Yamazaki and Meguro and Noda 1998). In Mexico, warnings are issued to the general public as well. In Taiwan, Istanbul and Bucharest, warnings are released to one or more users outside the research community (Allen et al. 2009b). Currently, an EEWS, called the California Integrated Seismic Network (CISN) ShakeAlert System, is also under testing in California, USA.

Early warning systems are usually based on P-wave detection that exploits the slower transmission velocity of S-waves, the main destructive wave, relative to electronic signals and P-waves. Comparing to other natural hazard early warning systems, the main challenge of EEWS is the extremely short *lead time*, defined as the time elapsing between the moment when the occurrence of a catastrophic shaking event at a given location is known to be reasonably certain to occur and the moment it actually occurs (Gasparini et al. 2007). Therefore, it is necessary to develop an *Automated Decision-making System* (ADS), which can make fast rational decisions based on the information from an EEWS. Here, we use expected economic loss as a basis for rational decision-making, and the *Pacific Earthquake Engineering Research Center* (PEER) *Performance-Based Earthquake Engineering* (PBEE) methodology (Porter 2003) is used for seismic loss estimation during the decision process. However, due to the complexity of the methodology, such a decision process suffers from long computation times. In order to obtain a fast ADS framework, the concept of *Action Function* and *Surrogate Model* are utilized in this paper. Combining all these ideas, a complete ADS framework is presented.

2. BACKGROUND

2.1 Brief Overview of EEWS in California, USA

The CISN ShakeAlert System, as currently planned, combines the outputs of three early warning systems each based on a different theory: τ_c-P_d on-site algorithm, Earthquake Alarms Systems (ElarmS), and Virtual Seismologist (V-S) (see Fig.1). The τ_c-P_d on-site algorithm is based on observations from a single sensor with two key parameters: period parameter τ_c and high-pass filtered

displacement amplitude P_d. Vertical components of velocity and/or displacement data within the first three seconds window of P-waveforms is used to determine both parameters (Bose et al. 2009). On the other hand, ElarmS and V-S are regional network-based EEWS. ElarmS's earthquake location estimation is mainly based on a grid search to minimize arrival time residuals when there are more than 2 sensors triggered in the network. Its magnitude estimation relies on the amplitude and frequency content of the detected P-wave. Acceleration, velocity, displacement and predominant period (Allen and Kanamori 2003) are continuously determined from the vertical component of P-waves from all stations (Allen et al. 2009a). The V-S algorithm is based on a Bayesian method, which combines prior information with a likelihood function to narrow down the uncertainties. The V-S location estimation uses Voronoi Cells with a probabilistic approach. Its magnitude estimation relies on an attenuation model that is based on P-wave and S-wave envelopes (Cua and Heaton 2007). The likelihood function is formulated in terms of the attenuation model, while prior information, such as network topology, station health status, regional hazard maps, earthquake forecasts, etc., may be utilized to construct the prior probability density function (PDF). The PDF for the earthquake magnitude is then found by combining both likelihood function and prior PDF using Bayes' Theorem (Cua et al. 2009).

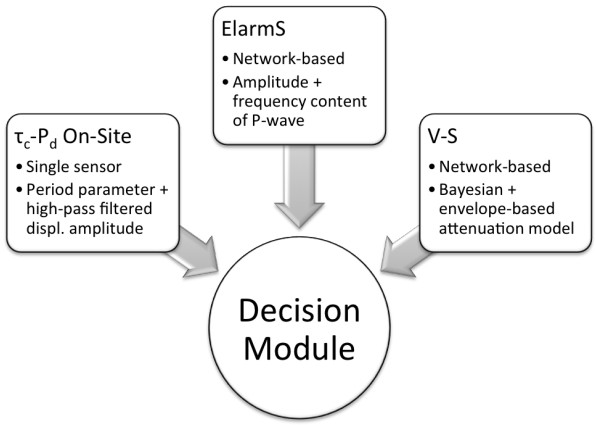

Figure 1 Structure of CISN Shake Alert System

All three systems receive data from the same CISN seismic network. Once a station is triggered within the network, each system will run its own algorithm to produce PDFs of earthquake magnitude and location estimation based on the received data signals. Then, all results will be integrated in a centralized module, called the Decision Module (Fig.1), which will produce a PDF for earthquake magnitude and location estimates based on the PDFs from all three systems.

2.2 Importance of ADS for Applications of EEWS

A few seconds to a minute of early warning can provide significant benefits to society. For example, through broadcasting an early warning of an earthquake, the efficiency of evacuation of at-risk structures or hazardous locations can be enhanced. Also, an automated action can be taken to mitigate the impending earthquake's impact on society, such as temporarily cutting off water and gas supplies. However, we believe that the true power of EEWS will only be achieved through more sophisticated engineering applications, which in many cases will involve mitigation actions that have significant resulting costs, including significant downtime losses caused by interference with normal operations. The decision of whether to activate such a mitigation action is a complicated tradeoff problem which, if time allowed, would best be done by human decision-making. Unfortunately, due to the limited warning time and the uncertainty in the predictions from EEWS, applications that involve human decision-making are not practical. Therefore, it is important to develop a decision-making system that can make rational decisions given uncertain predictions, as well as to make fast enough decisions in order to maximize available lead time for responding to the warning from the EEWS. This motivates the research presented here to develop a general framework of ADS. By using ADS, the utility of EEWS may be extended to cover a broader range of engineering applications. Hence, the impact of future large-scale earthquakes to society can be mitigated.

3. ADS FRAMEWORK

A decision is usually made between available choices by balancing different tradeoffs from the consequences of the choices. For EEWS applications, the automated system must choose whether to take mitigation actions or not based on a pre-determined criterion. In the simplest situation, the alternatives are **To Take Action** or **Not To Take Action**. Taking an action often leads to some kind of interruption to the operation of the facility, business or society, while not taking an action induces a risk of hazardous losses. To compare possibly disparate consequences, they need to be converted into a single metric, called here a *Decision Variable* (DV). Once we have a consistent metric for tradeoff comparisons, a rational decision-making procedure can be based on comparing the expected values of the DV, conditional on the EEWS data, for the two cases: action taken and action not taken. The decision criterion can be specified mathematically:

If smaller values of the chosen metric DV are preferred (i.e. it measures a negative/harmful event, such as economic loss or structural damage):

$$Take\ Action\ if\quad E_{\overline{A}}[DV|D(t)] \geq E_A[DV|D(t)] \quad (1)$$

If larger values of the chosen metric DV are preferred (i.e. it measures a positive/beneficial event, such as economic savings or structural damage avoidances):

$$Take\ Action\ if\quad E_{\overline{A}}[DV|D(t)] \leq E_A[DV|D(t)] \quad (2)$$

where:

$E_a[X|Y]$: $Expected\ value\ of\ X\ given\ Y\ for\ case$ "a"

$D(t)$: $Data\ from\ EEWS\ as\ a\ function\ of\ time\ (t)$

a: $\overline{A}\ or\ A$; $\overline{A}$: $Action\ not\ taken$; A: $Action\ taken$

3.1 Calculation of the Expected Values

Depending on the complexity of the mitigation actions in an EEWS application, the calculation of expected DV values may be difficult. In order to illustrate the complexity of the problem, a commonly used DV, economic loss, is chosen. Economic loss is a very suitable metric in many cases because it is able to quantify different types of losses. It is also the DV in the PEER PBEE methodology, as shown in Fig.2.

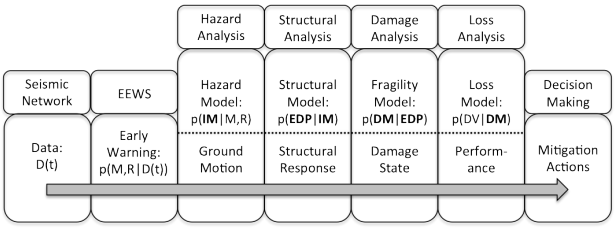

Figure 2 Information flow of PBEE-based EEWS (Grasso, Beck and Manfredi 2007)

In this figure, M and R are the magnitude and site-to-event distance of the incipient earthquake; **IM** is the ground shaking intensity measure; **EDP** is a vector of engineering demand parameters, and **DM** is a damage state measure for all the vulnerable components in the structure. Typical probability models for each analysis stage can be found, for example, in Goulet et al. (2007).

Using the PBEE methodology, the expected economic loss (denoted as DV in the following) can be calculated with the integral form as shown below (Goulet et al. 2007):

$$E_a[DV|D(t)] = \int DV\, p_a(DV|\boldsymbol{DM})\, p_a(\boldsymbol{DM}|\boldsymbol{EDP}) \ldots p_a(\boldsymbol{EDP}|\boldsymbol{IM}) p(\boldsymbol{IM}|M,R) p\big(M,R\big|D(t)\big) \ldots dDV d\boldsymbol{DM} d\boldsymbol{EDP} d\boldsymbol{IM} dM dR \quad (3)$$

Here, $p_a(x|y)$ denotes the PDF of x given y for case "a". Once all the PDFs are obtained from the models shown in Fig.2, the expected loss for both cases $\overline{A}$ and A are found. Then, a decision can be made based on (1) or (2).

Even though there is an explicit expression for calculating $E_a[DV|D(t)]$, there remains an important challenge for practical usage. Since it is not possible to analytically evaluate the integral for most practical applications, a numerical integration scheme that may require heavy computing power is necessary. As a result, the real-time decision-making process may not be fast enough for EEWS purpose. To solve this problem, the concepts of *Action Function* (AF) and *Surrogate Model* are introduced.

3.2 Action Function and Surrogate Model

In order to shorten the computational time for real-time decision-making, most parts of the expected loss calculation may be pre-calculated and stored in a computationally efficient form. This can be done by introducing the Action Function and a surrogate model. Let us first re-write (3) in a more compact form:

$$E_a[DV|D(t)] = \int E_a[DV|M,R]\, p(M,R|D(t)) dM dR$$

where

$$E_a[DV|M,R] = \int DV\, p_a(DV|\boldsymbol{DM})\, p_a(\boldsymbol{DM}|\boldsymbol{EDP}) \ldots p_a(\boldsymbol{EDP}|\boldsymbol{IM}) p(\boldsymbol{IM}|M,R) dDV d\boldsymbol{DM} d\boldsymbol{EDP} d\boldsymbol{IM}$$

is to be pre-computed. Define the Action Function (AF) by:

$$AF = E_{\overline{A}}[DV|M,R] - E_A[DV|M,R] \quad (4)$$

then from (1) and (2), the new form of the decision criterion becomes:

If smaller values of the chosen metric DV are preferred:

$$\text{Take Action if and only if} \quad E[AF|D(t)] \geq 0 \quad (5)$$

If larger values of the chosen metric DV are preferred:

$$\text{Take Action if and only if} \quad E[AF|D(t)] \leq 0 \quad (6)$$

where $E[AF|D(t)] = \int AF(M,R) p\big(M,R\big|D(t)\big) dM dR$

Note that AF in (4) can be pre-determined from the four probability models shown in Fig.2 because it is not related to real-time information from the EEWS. Therefore, all of the integrals giving AF can be pre-calculated so that AF(M,R) can be approximated by a surrogate model, thereby increasing the efficiency of calculating E[AF|D(t)]. It is expected that the EEWS in California will quantify the uncertainty in the predicted magnitude and location estimates by a Gaussian PDF p(M,R|D(t)), so we have chosen to use Gaussian radial kernel functions as a basis for a surrogate model for AF. Since both AF(M,R) and p(M,R|D(t)) have a Gaussian form, their product also has a Gaussian form and thus its integral can be written in an analytical form. The surrogate model regression scheme is chosen to be the relevance vector machine (RVM) because of its ability to provide a sparse and accurate regression model (Tipping 2001 and 2004, Tipping and Faul 2003, Bishop 2006). As a result, an efficient analytical form for E[AF|D(t)] can be obtained that significantly speeds up the real-time decision-making process.

3.3 ADS Framework Summary

Let us consider a simple EEWS application that contains only one mitigation action on a target structure/system. First, based on the PEER PBEE methodology, the Action Function is pre-calculated and approximated by the RVM using a Gaussian radial kernel basis. Next, as the EEWS starts to feed in earthquake estimates to ADS, E[AF|D(t)] is rapidly calculated as described above. An automated decision is then made based on (5) or (6) depending on the chosen DV, as well as the action time constraint:

Take back-up action or no action when $t_{left} < 0$

where $t_{left} = t_{EEWS} - t_{ADS} - t_{Act}$

t_{EEWS} = *remaining lead time from EEWS*

t_{ADS} = *average decision-making time delay*

t_{Act} = *time required to complete action*

The above time constraint checks if the remaining time is enough for completing the target mitigation action. If not,

then either no action is taken or, if there exists one, the back-up action is taken which is not as effective as the principal mitigation action but that can be implemented in sufficient time. Fig.3 shows a summary of the structure of the ADS framework. For more complicated applications, such as multiple mitigation actions, this framework can be extended.

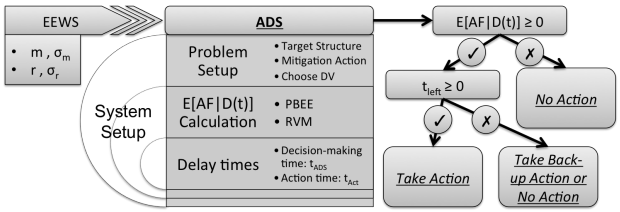

Figure 3 Structure of the ADS framework: m and r are the means of M and R; σ_m and σ_r are the standard deviations of M and R

4. CONCLUSION AND FUTURE WORK

The benefits and feasibility of EEWS is getting better appreciated throughout the world. It is expected that there will be one operating in California in a year or two. In order to maximize the benefits of EEWS, a fast ADS is essential to tackle the very short lead times. However, the whole process of rational decision-making requires a complicated model analysis and long computational times in general. Therefore, the only way to make it practical is to break up the computations so that many can be done prior to implementing ADS at a structure or facility. From the moment that EEWS releases warning information, the three main steps to achieve are performing the ground motion prediction at a chosen site, the response prediction for the target structure/system, and the loss/damage prediction. Since all three steps do not involve information from the EEWS, these can be done ahead of time and then approximated with a robust Bayesian surrogate model using the RVM. Combining the concepts of Action Function and the surrogate model, we can develop a fast ADS framework. The next step in our research is to investigate the framework for various case studies using past-earthquake data. We are currently doing so, but there remain some key challenges to apply the ADS framework. One of them is that it is difficult to quantify the benefit of a mitigation action. Over-estimating the benefit will increase the probability of taking a mitigation action when it should not have been done, while under-estimating will increase the probability of not acting when it is appropriate to do so. More research will be done on these kind of practical issues.
